Pneumatic conveyors are suitable for materials which are granular and free-flowing when dispersed in the gas stream, so they do not stick on the conveyor walls or agglomerate. Sticky materials such as filter cakes may be dispersed and partially dried by an air-swept disintegrator in many cases. Otherwise, dry product may be recycled and mixed with fresh feed, and then the two dispersed together in a disintegrator. Coarse material containing internal moisture may be subjected to fine grinding in a hammer mill. The main requirement in all applications is that the operation be instantaneously completed; internal diffusion of moisture must not be limiting in drying operations, and particle sizes must be small enough that the thermal conductivity of the solids does not control during heating and cooling operations. Pneumatic conveyors are rarely suitable for abrasive solids. Pneumatic conveying can result in significant particle size reduction, particularly when crystalline or other friable materials are being handled. This may or may not be desirable but must be recognized if the system is selected. The action is similar to that of a fluid-energy grinder.

Pneumatic conveyors may be single-stage or multistage. The former is employed for evaporation of small quantities of surface moisture. Multistage installations are used for difficult drying processes, e.g., drying heat-sensitive products containing large quantities of moisture and drying materials initially containing internal as well as surface moisture.

Typical single- and two-stage drying systems are illustrated in Figs. 12-100, 12-101, and 12-102. Figure 12-100 illustrates the flow diagram of a single-stage dryer with a paddle mixer, a screw conveyor followed by a rotary disperser for introduction of the feed into the airstream at the throat of a venturi section. The drying takes place in the drying column after which the dry product is collected in a cyclone. A diverter introduces the option of recycling part of the product into the mixer in order to handle somewhat sticky products. The environmental requirements are met with a wet scrubber in the exhaust stream.

Figure 12-101 illustrates a two-stage dryer where the initial feed material is dried in a flash dryer by using the spent drying air from the second stage. This semidried product is then introduced into the second-stage flash dryer for contact with the hottest air. This concept is in use in the pulp and paper industry. Its use is limited to materials that are dry enough on the surface after the first-stage to avoid plugging of the first-stage cyclone. The main advantage of the two-stage concept is the heat economy which is improved considerably over that of the single-stage concept.

Figure 12-102 is an elevation view of an actual single-stage dryer, employing an integral coarse-fraction classifier, used to separate undried particles for recycle.

Several typical products dried in pneumatic conveyors are described in Table 12-44.

*Design methods for pneumatic conveyor dryers* Depending upon the temperature sensitivity of the product, inlet air temperatures between 125 and 750°C are employed. With a heat-sensitive solid, a high initial moisture content should permit use of a high inlet air temperature. Evaporation of surface moisture takes place at essentially the wet-bulb air temperature. Until this has been completed, by which time the air will have cooled significantly, the surface-moisture film prevents the solids temperature from exceeding the wet-bulb temperature of the air. Pneumatic conveyors are used for solids having initial moisture contents ranging from 3 to 90 percent, wet basis. The air quantity required and solids-to-gas loading are fixed by the moisture load, the inlet air temperature, and, frequently, the exit air humidity. If the last is too great to permit complete drying, i.e., if the

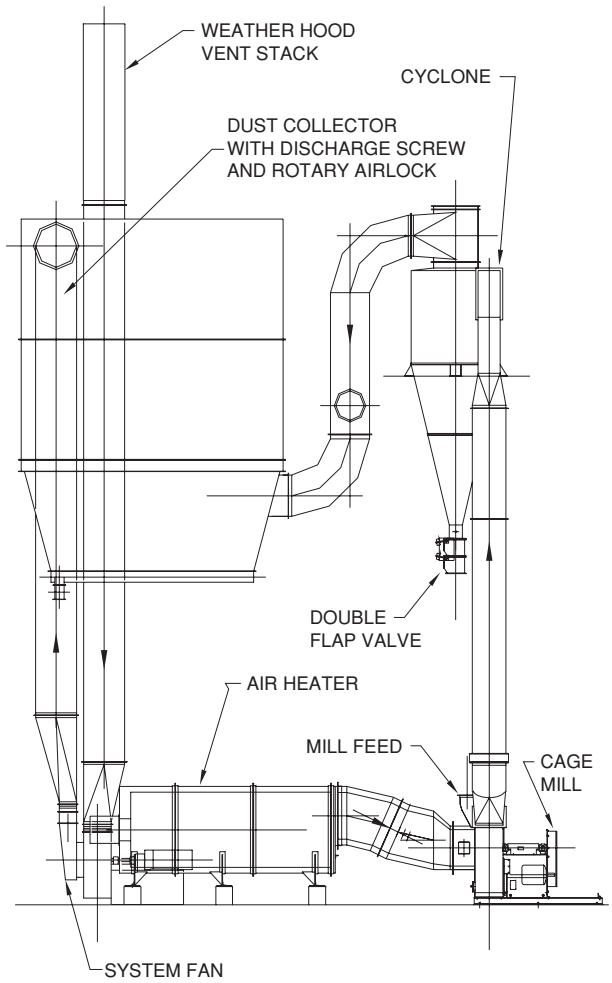

**FIG. 12-100** Flow diagram of single-stage flash dryer. (*Air Preheater Company, Raymond® & Bartlett Snow™ Products.*)

exit air humidity is above that in equilibrium with the product at required dryness, then the solids/gas ratio must be reduced together with the inlet air temperature.

The gas velocity in the conveying duct must be sufficient to convey the largest particle. This may be calculated accurately by methods given in Sec. 17, "Gas-Solids Operations and Equipment." For estimating purposes, a velocity of 25 m/s, calculated at the exit air temperature, is frequently employed. If mainly surface moisture is present, the temperature driving force for drying will approach the log mean of the inlet and exit gas wet-bulb depressions. (The exit solids temperature will approach the exit gas dry-bulb temperature.)

Observation of operating conveyors indicates that the solids are rarely uniformly dispersed in the gas phase. With infrequent exceptions, the particles move in a streaklike pattern, following a streamline along the duct wall where the flow velocity is at a minimum. Complete or even partial diffusion in the gas phase is rarely experienced even with low-specific-gravity particles. Air velocities may approach 20 to 30 m/s. It is doubtful, however, that even finer and lighter materials reach more than 80 percent of this speed, while heavier and larger fractions may travel at much slower rates [Fischer, *Mech. Eng.*, **81**(11): 67–69 (1959)]. Very little information and few operating data on pneumatic conveyor dryers which would permit a true theoretical basis for design have been published.

Therefore, firm design always requires pilot tests. It is believed, however, that the significant velocity effect in a pneumatic conveyor is the difference in velocities between gas and solids, which is strongly linked to heat- and mass-transfer coefficients and is the reason why a major part of the total drying actually occurs in the feed input section.

For estimating purposes, the conveyor cross-section is fixed by the assumed air velocity and quantity. The standard scoping design method is used, obtaining the required gas flow rate from a heat and mass balance, and the duct cross-sectional area and diameter from the gas velocity (if unknown, a typical value is 20 m/s). An incremental mode may be used to predict drying conditions along the duct. However, several parameters are hard to obtain, and conditions change rapidly near the feed point. Hence, for reliable estimates of drying time and duct length, pilot-plant tests should always be used. A conveyor length larger than 50 diameters is rarely required. The length of the full-scale dryer should always be somewhat larger than required in pilot-plant tests, because wall effects are higher in small-diameter ducts. This gives greater relative velocity (and thus higher heat transfer) and lower particle velocity in the pilot-plant dryer, both effects giving a shorter length than the full-scale dryer for a given amount of drying. If desired, the length difference on scale-up can be predicted by using the incremental model and using the pilot-plant data to backcalculate the uncertain parameters; see Kemp, *Drying Technol.* **12**(1&2):279 (1994) and Kemp and Oakley (2002).

An alternative method of estimating dryer size very roughly is to estimate a volumetric heat-transfer coefficient [typical values are around 2000 $J/(m^3 \cdot s \cdot K)$] and thus calculate dryer volume.

Pressure drop in the system may be computed by methods described in Sec. 6, "Fluid and Particle Dynamics." To prevent excessive leakage into or out of the system, which may have a total pressure drop of 2000 to 4000 Pa, rotary air locks or screw feeders are employed at the solids inlet and discharge.

The conveyor and collector parts are thoroughly insulated to reduce heat losses in drying and other heating operations. Operating control is maintained usually by control of the exit gas temperature, with the inlet gas temperature varied to compensate for changing feed conditions. A constant solids feed rate must be maintained.

***Ring Dryers*** The ring dryer is a development of flash, or pneumatic conveyor, drying technology, designed to increase the versatility of application of this technology and overcome many of its limitations.

One of the great advantages of flash drying is the very short retention time, typically no more than a few seconds. However, in a conventional flash dryer, residence time is fixed, and this limits its application to materials in which the drying mechanism is not diffusion-controlled and where a range of moisture within the final product is acceptable. The ring dryer offers two advantages over the flash dryer. First, residence time is controlled by the use of an adjustable internal classifier that allows fine particles, which dry quickly, to leave while larger particles, which dry slowly, have an extended residence time within the system. Second, the combination of the classifier with an internal mill can allow simultaneous grinding and drying with control of product particle size and moisture. Available with a range of different feed systems to handle a variety of applications, the ring dryer provides wide versatility.

The essential difference between a conventional flash dryer and the ring dryer is the manifold centrifugal classifier. The manifold provides classification of the product about to leave the dryer by using differential centrifugal force. The manifold, as shown in Fig. 12-103, uses the centrifugal effect of an airstream passing around the curve to concentrate the product into a moving layer, with the dense material on the outside and the light material on the inside.

This enables the adjustable splitter blades within the manifold classifier to segregate the denser, wetter material and return it for a further circuit of drying. Fine, dried material is allowed to leave the dryer with the exhaust air and to pass to the product collection system. This selective extension of residence time ensures a more evenly dried material than is possible from a conventional flash

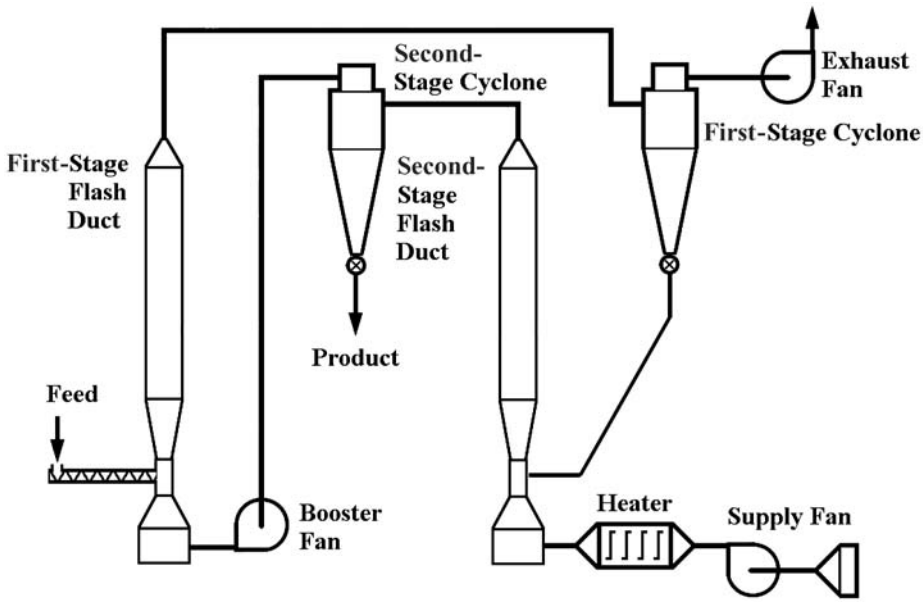

**FIG. 12-101** Flow diagram of countercurrent two-stage flash dryer. (*Niro.*)

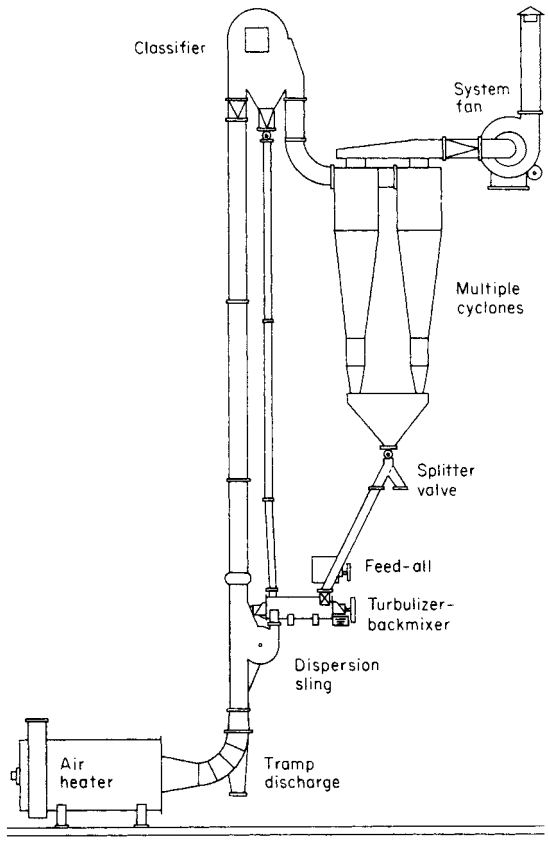

**FIG. 12-102** Flow diagram of Strong Scott flash dryer with integral coarse-fraction classifier. (*Bepex Corp.*)

dryer. Many materials that have traditionally been regarded as difficult to dry can be processed to the required moisture content in a ring dryer. The recycle requirements of products in different applications can vary substantially depending upon the scale of operation, ease of drying, and finished-product specification. The location of reintroduction of undried material back into the drying medium has a significant impact upon the dryer performance and final-product characteristics.

Three configurations of the ring dryer have been developed to offer flexibility in design and optimal performance:

1. *Single-stage manifold-vertical configuration* The feed ring dryer (see Fig. 12-104) is similar to a flash dryer but incorporates a single-stage classifier, which diverts 40 to 60 percent of the product back to the feed point. The feed ring dryer is ideally suited for materials which neither are heat-sensitive nor require a high degree of classification. An advantage of this configuration is that it can be manufactured to very large sizes to achieve high evaporative capacities.

2. *Full manifold-horizontal configuration* The full ring dryer (see Fig. 12-105) incorporates a multistage classifier which allows much higher recycle rates than the single-stage manifold. This configuration usually incorporates a disintegrator which provides adjustable amounts of product grinding depending upon the speed and manifold setting. For sensitive or fine materials, the disintegrator can be omitted. Alternative feed locations are available to suit the material sensitivity and the final-product requirements. The full ring configuration gives a very high degree of control of both residence time and particle size, and is used for a wide variety of applications from small production rates of pharmaceutical and fine chemicals to large production rates of food products, bulk chemicals, and minerals. This is the most versatile configuration of the ring dryer.

3. *P-type manifold-vertical configuration* The P-type ring dryer (see Fig. 12-106) incorporates a single-stage classifier and was developed specifically for use with heat-sensitive materials. The undried material is reintroduced into a cool part of the dryer in which it recirculates until it is dry enough to leave the circuit.

An important element in optimizing the performance of a flash or ring dryer is the degree of dispersion at the feed point. Maximizing the product surface area in this region of highest evaporative

**TABLE 12-44 Typical Products Dried in Pneumatic Conveyor Dryers (Barr-Rosin)**

| Material | Initial moisture, wet basis, % | Final moisture, wet basis, % | Plant configuration |
|---|---|---|---|
| Expandable polystyrene beads | 3 | 0.1 | Single-stage flash |
| Coal fines | 23 | 1.0 | Single-stage flash |
| Polycarbonate resin | 25 | 10 | Single-stage flash |
| Potato starch | 42 | 20 | Single-stage flash |
| Aspirin | 22 | 0.1 | Single-stage flash |
| Melamine | 20 | 0.05 | Single-stage flash |
| Com gluten meal | 60 | 10 | Feed-type ring dryer |
| Maize fiber | 60 | 18 | Feed-type ring dryer |
| Distillers dried grains (DDGs) | 65 | 10 | Feed type ring dryer |
| Vital wheat gluten | 70 | 7 | Full-ring dryer |
| Casein | 50 | 10 | Full-ring dryer |
| Tricalcium phosphate | 30 | 0.5 | Full-ring dryer |
| Zeolite | 45 | 20 | Full-ring dryer |
| Orange peels | 82 | 10 | Full-ring dryer |
| Modified com starch | 40 | 10 | P-type ring dryer |
| Methylcellulose | 45 | 25 | P-type ring dryer |

driving force is a key objective in the design of this type of dryer. Ring dryers are fed using similar equipment to conventional flash dryers. Ring dryers with vertical configuration are normally fed by a flooded screw and a disperser which propels the wet feed into a high-velocity venturi, in which the bulk of the evaporation takes place. The full ring dryer normally employs an air-swept disperser or mill within the drying circuit to provide screenless grinding when required. Together with the manifold classifier this ensures a product with a uniform particle size. For liquid, slurry, or pasty feed materials, backmixing of the feed with a portion of the dry product will be carried out to produce a conditioned friable material. This further increases the versatility of the ring dryer, allowing it to handle sludge and slurry feeds with ease.

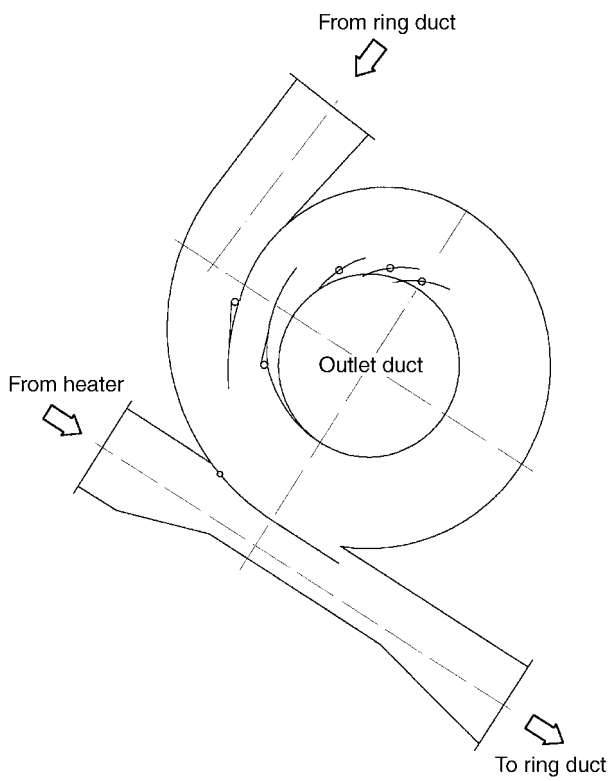

**FIG. 12-103** Full manifold classifier for ring dryer. (*Barr-Rosin.*)

Dried product is collected in either cyclones or bag filters depending upon the product-particle properties. When primary collection is carried out in cyclones, secondary collection in a bag filter or scrubber is usually necessary to comply with environmental regulations. A rotary valve is used to provide an air lock at the discharge point. Screws are utilized to combine product from multiple cyclones or large bag filters. If required, a portion of the dried product is separated from the main stream and returned to the feed system for use as backmix.

*Design methods for ring dryers* Depending on the temperature sensitivity of the material to be processed, air inlet temperatures as high as 750°C can be utilized. Even with heat-sensitive solids, high feed moisture content may permit the use of high air inlet temperature since evaporation of surface moisture takes place at the wet-bulb air temperature. Until the surface moisture has been removed, it will prevent the solids temperature from exceeding the air wet-bulb temperature, by which time the air will generally have cooled significantly. Ring dryers have been used to process materials with feed moisture contents between 2 and 95 percent, weight fraction. The product moisture content has been controlled to values from 20 percent down to less than 1 percent.

The air velocity required and air/solids ratio are determined by the evaporative load, the air inlet temperature, and the exhaust air humidity. Too high an exhaust air humidity would prevent complete drying, so then a lower air inlet temperature and air/solids ratio would be required. The air velocity within the dryer must be sufficient to convey the largest particle, or agglomerate. The air/solids ratio must be high enough to convey both the product and backmix, together with internal recycle from the manifold. For estimating purposes a velocity of 25 m/s, calculated at dryer exhaust conditions, is appropriate both for pneumatic conveyor and ring dryers.

***Agitated Flash Dryers*** Agitated flash dryers produce fine powders from feeds with high solids contents, in the form of filter cakes, pastes, or thick, viscous liquids. Many continuous dryers are unable to dry highly viscous feeds. Spray dryers require a pumpable feed. Conventional flash dryers often require backmixing of dry product to the feed in order to fluidize. Other drying methods for viscous pastes and filter cakes are well known, such as contact, drum, band, and tray dryers. They all require long processing time, large floor space, high maintenance, and aftertreatment such as milling.

The agitated flash dryer offers a number of process advantages, such as ability to dry pastes, sludges, and filter cakes to a homogeneous, fine powder in a single-unit operation; continuous operation; compact layout; effective heat- and mass-transfer short drying times; negligible heat loss and high thermal efficiency; and easy access and cleanability.

The agitated flash dryer (Fig. 12-107) consists of four major components: feed system, drying chamber, heater, and exhaust air system. Wet feed enters the feed tank, which has a slow-rotating impeller to break up large particles. The level in the feed tank is maintained by a

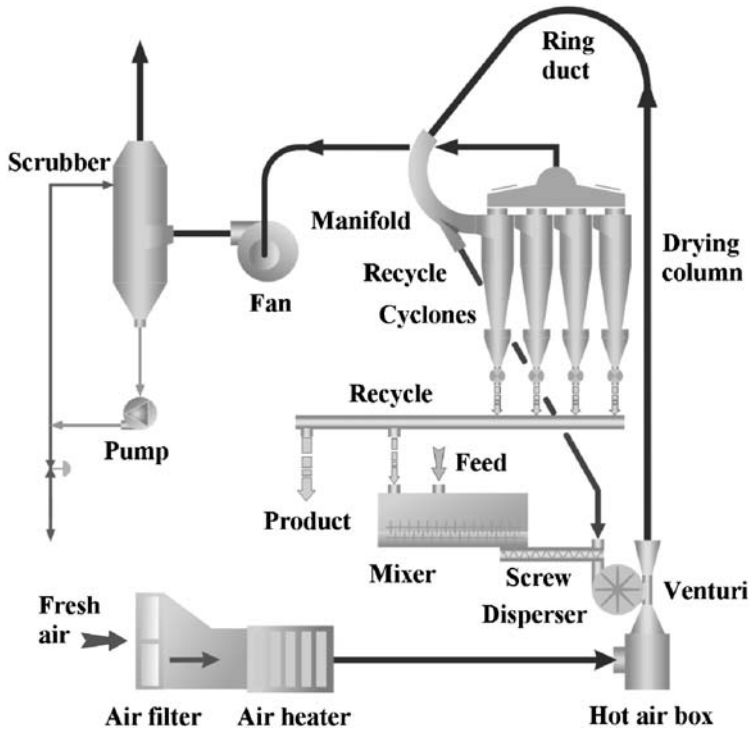

**FIG. 12-104** Flow diagram of feed-type ring dryer. (*Barr-Rosin.*)

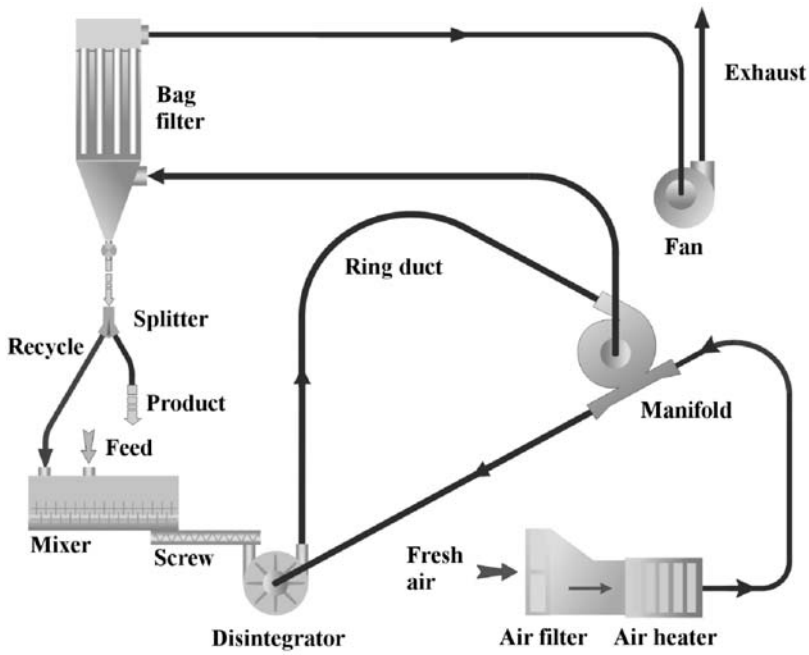

**FIG. 12-105** Flow diagram of full manifold-type ring dryer. (*Barr-Rosin.*)

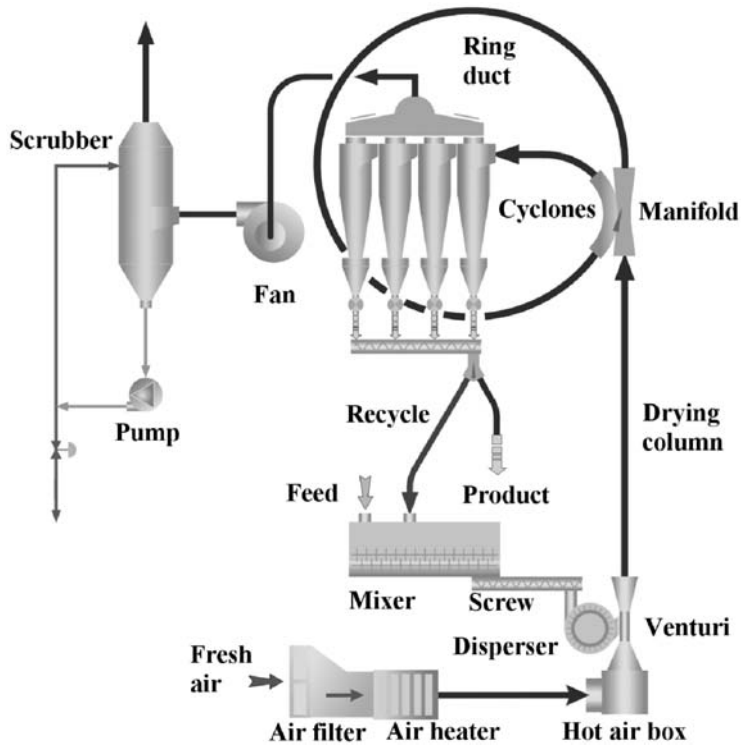

**FIG. 12-106** Flow diagram of P-type ring dryer. (*Barr-Rosin.*)

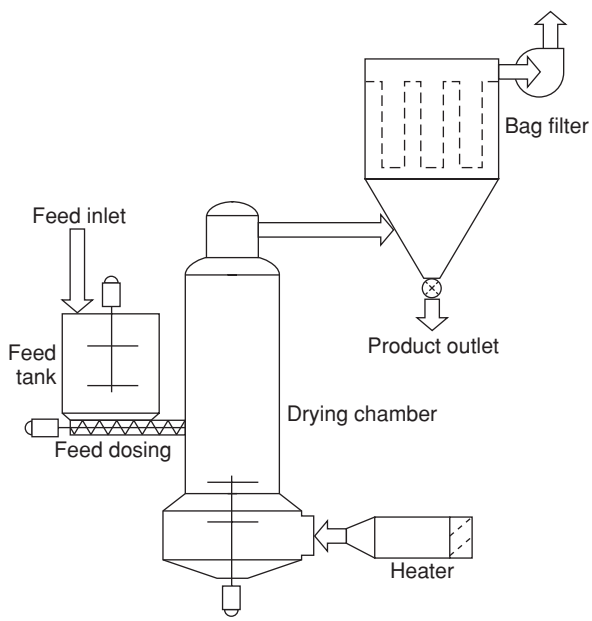

**FIG. 12-107** Agitated flash dryer with open cycle. (*Niro, Inc.*)

level controller. The feed is metered at a constant rate into the drying chamber via a screw conveyor mounted under the feed tank. If the feed is shear thinning and can be pumped, the screw feeder can be replaced by a positive displacement pump.

The drying chamber is the heart of the system consisting of three important components: air disperser, rotating disintegrator, and drying section. Hot, drying air enters the air disperser tangentially and is introduced into the drying chamber as a swirling airflow. The swirling airflow is established by a guide-vane arrangement. The rotating disintegrator is mounted at the base of the drying chamber. The feed, exposed to the hot, swirling airflow and the agitation of the rotating disintegrator, is broken up and dried. The fine dry particles exit with the exhaust air and are collected in the bag filter. The speed of the rotating disintegrator controls the particle size. The outlet air temperature controls the product moisture content.

The drying air is heated either directly or indirectly, depending upon the feed material, powder properties, and available fuel source. The heat sensitivity of the product determines the drying air temperature. The highest possible value is used to optimize thermal efficiency. A bag filter is usually recommended for collecting the fine particles produced. The exhaust fan maintains a slight vacuum in the dryer, to prevent powder leakage into the surroundings. The appropriate process system is selected according to the feed and powder characteristics, available heating source, energy utilization, and operational health and safety requirements.

Open systems use atmospheric air for drying. In cases where products pose a potential for dust explosion, plants are provided with pressure relief or suppression systems. For recycle systems, the drying system medium is recycled, and the evaporated solvent recovered as condensate. There are two alternative designs. In the self-inertizing mode, oxygen content is held below 5 percent by combustion control at the heater. This is recommended for products with serious dust

explosion hazards. In the inert mode, nitrogen is the drying gas. This is used when an organic solvent is evaporated or product oxidation during drying must be prevented.

*Design methods* The size of the agitated flash dryer is based on the evaporation rate required. The operating temperatures are product-specific. Once established, they determine the airflow requirements. The drying chamber is designed based on air velocity (approximately 3 to 4 m/s) and residence time (product-specific).

### Other Dryer Types

***Freeze Dryer*** Industrial freeze drying is carried out in two steps:

1. Freezing of the food or beverage product
2. Freeze drying, i.e., sublimation drying of the ice content and desorption drying of the bound or crystal water content

Freeze drying differs from conventional drying in that when ice is sublimated, only water vapor is transported within the product, causing no displacement of soluble substances such as sugars, salts, and acids. In all conventional drying systems in which water is dried, the water containing the soluble substances is transported to the product surface by capillary action. The water will evaporate from the surface, leaving the soluble substances displaced on the product surface. The major advantages of freeze drying are therefore

- Preservation of original flavor, aroma, color, shape, and texture
- Very little shrinkage, resulting in excellent and instant rehydration characteristics
- Negligible product loss
- Minimal risk of cross-contamination

The freeze drying process is today used widely for a number of products including vegetables, fruits, meat, fish, and beverage products, such as

- Instant coffee for which excellent flavor and aroma retention are of special importance
- Strawberries for which excellent color preservation is of special importance
- Chives for which shape preservation is of special importance

*Freezing* The freezing methods applied for solid products are all conventional freezing methods such as blast freezing, individual quick freezing (IQF), or similar.

The products maintain their natural cell structure, and the aim is to freeze the free water to pure ice crystals, leaving the soluble substances as high concentrates or even crystallized. To ensure good stability of the product during storage, a product temperature of –20 to –30°C should be achieved to ensure that more than 95 percent of the free water is frozen.

Liquid products have no cell structure, thus the structure of the freeze dried products is formed by the freezing process. The intercrystalline matrix of the concentrated product giving the structure of the freeze dried product is formed around the ice crystals. The size of the ice crystals is a function of the freezing time. Quick freezing results in small ice crystals, slow freezing in large ice crystals. The structure of the matrix determines the freeze drying performance as well as the appearance, mechanical strength, and solubility rate. Small ice crystals lead to light color (high surface reflection of light), diffusion restrictions for vapor transport inside the product, and a good mechanical strength of the freeze dried product. Large ice crystals lead to the opposite results.

Thus the freezing method must be carefully adapted to the quality criteria of the finished product. The preferred methods are

- Drum freezing, by which a thin slab of 1.5 to 3 mm is frozen within 1.5 to 3 min
- Belt freezing, by which a slab of 6 to10 mm passing through different freezing zones is frozen during 10 to 20 min
- Foaming, used to influence the structure and mainly to control the density of the freeze dried product

*Freeze drying* Freeze drying of foods takes place in a freeze dryer at vacuum levels of 0.4 to 1.3 mbar absolute, corresponding to sublimation temperatures from –30 to –17°C depending on the product requirements. The main components of the freeze dryer are

- The vacuum chamber, heating plates, and vapor traps, all built into the freeze dryer

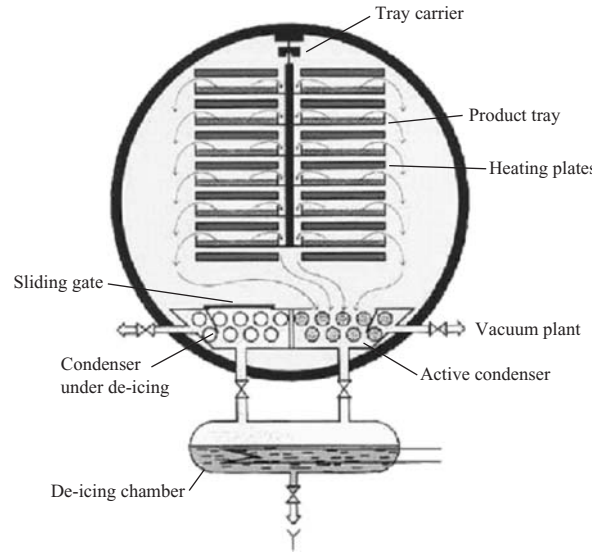

**FIG. 12-108** Cross-section of RAY™ batch freeze dryer. (*Niro A/S.*)

- The external systems, such as the transport system for the product trays, the deicing system, and the support systems for supply of heat, vacuum, and refrigeration

*Batch freeze drying* The frozen product is carried in trays, and the trays are carried in tray trollies suspended in an overhead rail system for easy transport and quick loading and unloading. The freeze dryer as illustrated in Fig. 12-108 is charged with 3 to 6 trolley loads depending on the size of the freeze dryer. The trollies place the trays between the heating plates for radiation heat transfer. Radiation is preferred to ensure an even heat transfer over the large heating surface, typically 2× (70 to 140 $m^2$). The distribution of the heating medium (water or thermal oil) to the heating plates and the flow rate inside the plates are very important factors. To avoid uneven drying, the surface temperature difference of the heating plates should not exceed 2 to 3°C at maximum load.

When the loading is completed, the freeze dryer is closed and vacuum applied.

The operation vacuum should be reached quickly (within 10 min) to avoid the risk of product melting. For the same reason, the heating plates are cooled to approximately 25°C. When the operation vacuum is achieved, the heating plate temperature is raised quickly to the maximum drying temperature restricted by the capacity of the vapor traps, to perform the sublimation drying as quickly as possible for capacity reasons. During this period, the product is kept cool by the sublimation, and approximately 75 to 80 percent of the free water is sublimated.

The capability of the freeze drying plant to perform during this period is vital for efficient operation. To maintain the required sublimation temperature, the surface temperature of the ice layer on the vapor trap condenser must compensate for the pressure loss of the vapor flow from the sublimation front to the condenser.

The evaporation temperature of the refrigerant must further compensate for the temperature difference through the ice layer to the evaporating refrigerant.

With the flow rate at 1 mbar of approximately 1 $m^3/(s \cdot m^2$ of tray area), the thermodynamic design of the vapor trap is the main issue for a well-designed freeze dryer.

A built-in vapor trap allowing a large opening for the vapor flow to the condenser and a continuous deicing (CDI) system, reducing the ice layer on the condenser to a maximum of 6 to 8 mm, are important features of a modern freeze drying plant. Approximately 75 percent of the energy costs relate to the refrigeration plant, and if the requirement

**TABLE 12-45 Freeze Dryer, Performance Data, Niro RAY™ and CONRAD™ Types**

| | Tray area, $m^2$ | Typical sublimation capacity | | Electricity consumption, kWh/kg, sublimated | Steam consumption, kg/kg sublimated |
|---|---|---|---|---|---|

°Other sizes available.

of the evaporation temperature is 10°C lower than optimum, the energy consumption of the refrigeration plant will increase by approximately 50 percent.

At the end of the sublimation drying, the product surface temperature reaches the maximum allowable product temperature, requiring that the temperature of the heating plates be lowered gradually, and the drying will change to desorption drying. The temperature will finally be kept constant at the level of the maximum allowable product temperature until the residual moisture has been reduced to 2 to 3 percent, which is a typical level for a freeze dried product.

*Continuous freeze drying* From the description of batch freeze drying, it can be seen that the utility requirements vary considerably. During sublimation drying the requirements are 2 to 2.5 times the average requirement. To overcome this peak load and to meet the market request for high unit capacities, continuous freeze dryer designs have been developed. The special features are twofold:

- The tray transport system is a closed-loop system in which the trays pass one by one under the tray filler, where frozen product is automatically filled into the trays at a preset weight. The full tray is charged to the vacuum lock which is then evacuated to the drier vacuum level. Then the tray is pushed into the dryer and grabbed by an elevator which is filled stepwise with a stack of trays. Next a full stack of trays is pushed into the drying area whereby each of the stacks inside the drying area will move one step forward. Thus the last stack containing the finished, freeze dried product will be pushed out of the drying area to an outlet elevator which will be emptied stepwise by discharge of the trays through the outlet vacuum lock. From the outlet vacuum lock the trays are pushed to the emptying station for emptying and then returned to the tray filler.
- As the tray stacks are pushed forward through the freeze dryer, they pass through various temperature zones. The temperature zones form the heating profile, high temperatures during the sublimation drying, medium temperatures during the transition period toward desorption drying, and low temperatures during the final desorption drying. The temperature profile is selected so that overheating of the dry surface is avoided.

*Design methods* The size of the freeze drying plant is based on the average sublimation capacity required as well as on the product type and form. The external systems for batch plants must be designed for a peak load of 2 to 2.5 times the average capacity in the case of a single plant. Further, a batch plant is not available for drying all the time. A modern batch freeze dryer with the CDI system loses approximately 30 min per batch. Typically, 2 to 3 batches will be freeze dried per day. The evaporation temperature of the refrigeration plant depends on the required vacuum. At 1 mbar it will be –35 to –40°C depending on the vapor trap performance. Sample data are shown in Table 12-45.

### Field Effects Drying—Drying with Infrared, Radio-Frequency, and Microwave Methods

***Dielectric Methods (Radio-Frequency and Microwave)*** Schiffmann (1995) defines dielectric (radio-frequency) frequencies as covering the range of 1 to 100 MHz, while microwave frequencies range from 300 MHz to 300 GHz. The devices used for generating microwaves are called magnetrons and klystrons.

Water molecules are dipolar (i.e., they have an asymmetric charge center), and they are normally randomly oriented. The rapidly changing polarity of a microwave or radio-frequency field attempts to pull these dipoles into alignment with the field. As the field changes polarity, the dipoles return to a random orientation before being pulled the other way. This buildup and decay of the field, and the resulting stress on the molecules, causes a conversion of electric field energy to stored potential energy, then to random kinetic or thermal energy. Hence dipolar molecules such as water absorb energy in these frequency ranges. The power developed per unit volume $P_v$ by this mechanism is

$$P_v = kE^2 f\varepsilon' \tan \delta = kE^2 f\varepsilon'' \qquad (12\text{-}117)$$

where $k$ is a dielectric constant, depending on the units of measurement, $E$ is the electric field strength (V/m), $f$ is the frequency, $\varepsilon'$ is the relative dielectric constant or relative permeability, tan $\delta$ is the loss tangent or dissipation factor, and $\varepsilon''$ is the loss factor.

The field strength and the frequency are dependent on the equipment, while the dielectric constant, dissipation factor, and loss factor are material-dependent. The electric field strength is also dependent on the location of the material within the microwave/radio-frequency cavity (Turner and Ferguson, 1995), which is one reason why domestic microwave ovens have rotating turntables (so that the food is exposed to a range of microwave intensities). This mechanism is the major one for the generation of heat within materials by these electromagnetic fields.

There is also a heating effect due to ionic conduction, since the ions (sodium, chloride, and hydroxyl) in the water inside materials are accelerated and decelerated by the changing electric field. The collisions which occur as a result of the rapid accelerations and decelerations lead to an increase in the random kinetic (thermal) energy of the material. This type of heating is not significantly dependent on either temperature or frequency, and the power developed per unit volume $P_v$ from this mechanism is

$$P_v = E^2 qn\mu \qquad (12\text{-}118)$$

where $q$ is the amount of electric charge on each of the ions, $n$ is the charge density (ions/m), and $\mu$ is the level of mobility of the ions.

Schiffmann (1995) indicates that the dielectric constant of water is over an order of magnitude higher than that of most underlying materials, and the overall dielectric constant of most materials is usually nearly proportional to moisture content up to a critical moisture content, often around 20 to 30 percent. Hence microwave and radio-frequency methods preferentially heat and dry wetter areas in most materials, a process which tends to give more uniform final moisture contents. The dielectric constant of air is very low compared with that of water, so lower density usually means lower heating rates. For water and other small molecules, the effect of increasing temperature is to decrease the heating rate slightly, hence leading to a self-limiting effect.

Other effects (frequency, conductivity, specific heat capacity, etc.) are discussed by Schiffmann (1995), but are less relevant because the range of available frequencies (which do not interfere with radio transmissions) is small (2.45 GHz, 910 MHz). Lower frequencies lead

to greater penetration depths into material than higher frequencies, with 2.45-GHz frequencies sometimes having penetration depths as low as 1 in. For in-depth heating ("volumetric heating"), radio frequencies, with lower frequencies and longer wavelengths, are often used.

***Infrared Methods*** Infrared radiation is commonly used in the dehydration of coated films and to even out the moisture content profiles in the drying of paper and boards. The mode of heating is essentially on the material surface, and IR sources are relatively inexpensive compared with dielectric sources.

The heat flux obtainable from an IR source is given by

$$q = F\alpha\varepsilon\,(T^4_{\text{source}} - T^4_{\text{drying material}}) \qquad (12\text{-}119)$$

where $q$ = heat flux, W/m$^2$; $\alpha$ = Stefan-Boltzmann constant = $5.67 \times 10^{-8}$ W/(m$^2 \cdot$ K$^4$); $\varepsilon$ = emissivity; $F$ = view factor; and $T$ = absolute temperature of the source or drying material.

The emissivity is a property of the material. The limiting value is 1 (blackbody); shiny surfaces have a low value of emissivity. The view factor is a fractional value that depends on the geometric orientation of the source with respect to the heating object.

It is very important to recognize the $T^4$ dependence on the heat flux. IR sources need to be very hot to give appreciable heat fluxes. Therefore, IR sources should not be used with flammable materials. Improperly designed IR systems can also overheat materials and equipment.

## OPERATION AND TROUBLESHOOTING

**Troubleshooting** Dryer troubleshooting is not extensively covered in the literature, but a systematic approach has been proposed by Kemp and Gardiner (2001). The main steps of the algorithm are as follows:

- *Problem definition*—definition of the dryer problem to be solved.
- *Data gathering*—collection of relevant information, e.g., plant operating data
- *Data analysis*—e.g., heat and mass balance—and *identification of the cause of the problem*
- *Conclusions and actions*—selection and implementation of a solution in terms of changes to process conditions, equipment, or operating procedures
- *Performance auditing*—monitoring to ensure that the problem was permanently solved

There is often a danger in practice that the pressure to get the plant back into production as soon as possible may lead to some of these stages being omitted. Even if a short-term fix has been found, it is highly desirable to make sure what the problem really was, to see whether there are better ways of solving it in the long term, and to check that the problem really has been solved (sometimes it reappears later, e.g., when a temporarily cleaned heat exchanger becomes fouled again, or climatic conditions return to previous values).

The algorithm might also be considered as a "plant doctor." The doctor collects data, or symptoms, and makes a diagnosis of the cause or causes of the problem. Then alternative solutions, or treatments, are considered and a suitable choice is made. The results of the treatment are reviewed (i.e., the process is monitored) to ensure that the "patient" has returned to full health. See Fig. 12-109.

The algorithm is an excellent example of the "divergent-convergent" (brainstorming) method of problem solving. It is important to list all possible causes and solutions, no matter how ridiculous they may initially seem; there may actually be some truth in them, or they may lead to a new and better idea.

***Problem Categorization*** In the problem definition stage, it is extremely useful to categorize the problem, as the different broad groups require different types of solution. Five main categories of dryer problems can be identified:

1. Drying performance (outlet moisture content too high, throughput too low)
2. Materials handling (dried material too sticky to get out of dryer, causing blockage)
3. Product quality (too many fines in product or bulk density too low)

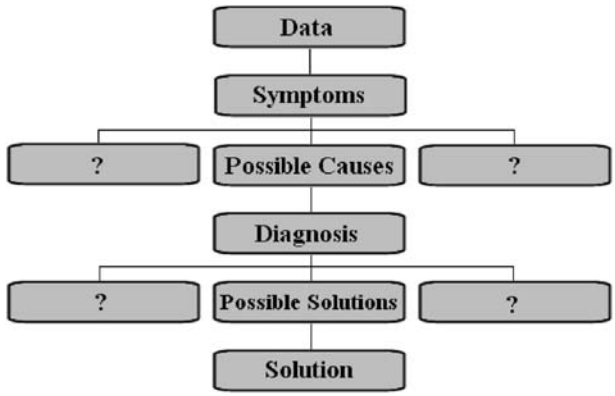

**FIG. 12-109** Schematic diagram of algorithm for dryer troubleshooting.

4. Mechanical breakdown (catastrophic sudden failure)
5. Safety, health, and environmental (SHE) issues

Experience suggests that the majority of problems are of the first three types, and these are about equally split over a range of industries and dryer types. Ideally, unforeseen SHE problems will be rare, as these will have been identified in the safety case before the dryer is installed or during commissioning. Likewise, major breakdowns should be largely avoided by a planned maintenance program.

***Drying Performance Problems*** Performance problems can be further categorized as

1. Heat and mass balance deficiencies (not enough heat input to do the evaporation)
2. Drying kinetics (drying too slowly, or solids residence time in dryer too short)
3. Equilibrium moisture limitations (reaching a limiting value, or regaining moisture in storage)

For the heat and mass balance, the main factors are

- Solids throughput
- Inlet and outlet moisture content
- Temperatures and heat supply rate
- Leaks and heat losses

As well as problem-solving, these techniques can be used for performance improvement and debottlenecking.

Drying kinetics, which are affected by temperature, particle size, and structure, are limited by external heat and mass transfer to and from the particle surface in the early stages, but internal moisture transport is the main parameter at lower moisture.

Equilibrium moisture content increases with higher relative humidity, or with lower temperature. Problems that depend on the season of the year, or vary between day and night (both suggesting a dependence on ambient temperature and humidity), are often related to equilibrium moisture content.

***Materials Handling Problems*** The vast majority of handling problems in a dryer concern sticky feedstocks. Blockages can be worse than performance problems as they can close down a plant completely, without warning. Most stickiness, adhesion, caking, and agglomeration problems are due to *mobile liquid bridges* (surface moisture holding particles together). These are extensively described in particle technology textbooks. Unfortunately, these forces tend to be at a maximum when the solid forms the continuous phases and surface moisture is present, which is the situation for most filter and centrifuge cakes at discharge. By comparison, slurries (where the liquid forms the continuous phase) and dry solids (where all surface moisture has been eliminated) are relatively free-flowing and give fewer problems.

Other sources of problems include electrostatics (most marked with fine and dry powders) and *immobile liquid bridges*, the so-called sticky-point phenomenon. This latter is sharply temperature-dependent, with only a weak dependence on moisture content, in contrast to mobile

liquid bridges. It occurs for only a small proportion of materials, but is particularly noticeable in amorphous powders and foods and is often linked to the glass transition temperature.

***Product Quality Problems*** (These do not include moisture level of the main solvent.) Many dryer problems either concern product quality or cannot be solved without considering the effect of any changes on product quality. Thus it is a primary consideration in most troubleshooting, although product quality measurements are specific to the particular product, and it is difficult to generalize. However, typical properties may include color, taste (not easily quantifiable), bulk density, viscosity of a paste or dispersion, dispersibility, or rate of solution. Others are more concerned with particle size, size distribution (e.g., coarse or fine fraction), or powder handling properties such as rate of flow through a standard orifice. These property measurements are nearly always made off-line, either by the operator or by the laboratory, and many are very difficult to characterize in a rigorous quantitative manner. (See also "Fundamentals" Section.)

Storage problems, very common in industry, result if the product from a dryer is free-flowing when packaged, but has caked and formed solid lumps when received by the customer. Sometimes, the entire internal contents of a bag or drum have welded together into a huge lump, making it impossible to discharge.

Depending on the situation, there are at least three different possible causes:

1. *Equilibrium moisture content*—hygroscopic material is absorbing moisture from the air on cooling.
2. *Incomplete drying*—product is continuing to lose moisture in storage.
3. *Psychrometry*—humid air is cooling and reaching its dew point.

The three types of problem have some similarities and common features, but the solution to each one is different. Therefore, it is essential to understand which mechanism is actually occurring.

*Option 1:* The material is hygroscopic and is absorbing moisture back from the air in storage, where the cool air has a higher relative humidity than the hot dryer exhaust. *Solution:* Pack and seal the solids immediately on discharge in tough impermeable bags (usually double- or triple-lined to reduce the possibility of tear and pinholes), and minimize the ullage (airspace above the solids in the bags) so that the amount of moisture that can be absorbed is too low to cause any significant problem. Dehumidifying the air to the storage area is also possible, but often very expensive.

*Option 2:* The particles are emerging with some residual moisture, and continue to dry after being stored or bagged. As the air and solids cool down, the moisture in the air comes out as dew and condenses on the surface of the solids, causing caking by mobile liquid bridges. *Solution:* If the material is meeting its moisture content specification, cool the product more effectively before storage, to stop the drying process. If the outlet material is wetter than specification, alter dryer operating conditions or install a postdryer.

*Option 3:* Warm, wet air is getting into the storage area or the bags, either because the atmosphere is warm with a high relative humidity (especially in the tropics) or because dryer exhaust air has been allowed to enter. As in option 2, when the temperature falls, the air goes below its dew point and condensation occurs on the walls of the storage area or inside the bags, or on the surface of the solids, leading to caking. *Solution:* Avoid high-humidity air in the storage area. Ensure the dryer exhaust is discharged a long way away. If the ambient air humidity is high, consider cooling the air supply to storage to bring it below its dew point and reduce its absolute humidity.

See Kemp and Gardiner, "An Outline Method for Troubleshooting and Problem-Solving in Dryers," *Drying Technol.* **19**(8):1875–1890 (2001).

**Dryer Operation**

***Start-up Considerations*** It is important to start up the heating system before introducing product into the dryer. This will minimize condensation and subsequent product buildup on dryer walls. It is also important to minimize off-quality production by not overdrying or underdrying during the start-up period. Proper control system design can aid in this regard. The dryer turndown ratio is also an important consideration during start-up. Normally the dryer is started up at the lowest end of the turndown ratio, and it is necessary to match heat input with capacity load.

***Shutdown Considerations*** The sequence for dryer shutdown is also very important and depends on the type of dryer. The sequence must be thoroughly thought through to prevent significant off-quality product or a safety hazard. The outlet temperature during shutdown is a key operating variable to follow.

***Energy Considerations*** The first consideration is to minimize moisture content of the dryer feed, e.g., with dewatering equipment, and to establish as high an outlet product moisture target as possible. Other energy considerations vary widely by dryer type. In general, heating with gas, fuel oil, and steam is significantly more economical than heating with electricity. Hence RF, microwave, and infrared drying is energy-intensive. Direct heating is more efficient than indirect in most situations. Sometimes air recycle (direct or indirect) can be effective to reduce energy consumption. And generally operating at high inlet temperatures is more economical.

***Recycle*** In almost all situations, the process system must be able to accommodate product recycle. The question is, How to handle it most effectively, considering product quality, equipment size, and energy?

***Improvement Considerations*** The first consideration is to evaluate mass and energy balances to identify problem areas. This will identify air leaks and excessive equipment heat losses and will enable determination of overall energy efficiency.

A simplified heat balance will show what might need to be done to debottleneck a convective (hot gas) dryer, i.e., increase its production rate $F$.

$$F(X_I - X_O)\lambda_{ev} \approx GC_{PG}(T_{GI} - T_{GO}) - Q_{wl}$$

Before proceeding along this line, however, it is necessary to establish that the dryer is genuinely heat and mass balance limited. If the system is controlled by kinetics or equilibria, changing the parameters may have undesirable side effects, e.g., increasing the product moisture content.

The major alternatives are then as follows (assuming gas specific heat capacity $C_{PG}$ and latent heat of evaporation $\lambda_{ev}$ are fixed):

1. Increase gas flow rate $G$—usually increases pressure drop, so new fans and gas cleaning equipment may be required.
2. Increase inlet gas temperature $T_{GI}$—usually limited by risk of thermal damage to product.
3. Decrease outlet gas temperature $T_{GO}$—but note that this increases NTUs, outlet humidity, and relative humidity, and reduces both temperature and humidity driving forces. Hence it may require a longer drying time and a larger dryer, and may also increase equilibrium and outlet moistures $X_E$ and $X_O$.
4. Reduce inlet moisture content $X_I$, say, by dewatering by gas blowing, centrifuging, vacuum or pressure filtration, or a predryer.
5. Reduce heat losses $Q_{Wl}$ by insulation, removing leaks, etc.

**Dryer Safety** This section discusses some of the key considerations in dryer safety. General safety considerations are discussed in Sec. 23, "Safety and Handling of Hazardous Materials," and should be referred to for additional guidance.

Fires, explosions, and, to a lesser extent, runaway decompositions are the primary hazards associated with drying operations. The outbreak of fire is a result of ignition which may or may not be followed by an explosion. A hazardous situation is possible if

1. The product is combustible
2. The product is wetted by a flammable solvent
3. The dryer is direct-fired

An explosion can be caused by dust or flammable vapors, both of which are fires that rapidly propagate, causing a pressure rise in a confined space.

***Dust Explosions*** Dispersion dryers can be more hazardous than layer-type dryers if we are drying a solid combustible material which is then dispersed in air, particularly if the product is a fine particle size. If this finely dispersed product is then exposed to an ignition source, an explosion can result. The following conditions (van't Land, *Industrial Drying Equipment,* Marcel Dekker, New York, 1991) will be conducive to fire and explosion hazard:

1. Small particle sizes, generally less than 75 μm, which are capable of propagating a flame
2. Dust concentrations within explosive limits, generally 10 to 60 g/m$^3$
3. Ignition source energy of 10 to 1000 mJ or as low as 5 mJ for highly explosive dust sources
4. Atmosphere supporting combustion

Since most product and hence dust compositions vary widely, it is generally necessary to do quantitative testing in approved test equipment.

***Flammable Vapor Explosions*** This can be a problem for products wetted by flammable solvents if the solvent concentration exceeds 0.2% v/v in the vapor phase. The ignition energy of vapor-air mixtures is lower (< 1 mJ) than that of dust-air suspensions. Many of these values are available in the literature, but testing may sometimes be required.

***Ignition Sources*** There are many possible sources of an ignition, and they need to be identified and addressed by both designers and operators. A few of the most common ignition sources are

1. Spontaneous combustion
2. Electrostatic discharge
3. Electric or frictional sparks
4. Incandescent solid particles from heating system

Safety hazards must be addressed with proper dryer design specifications. The following are a few key considerations in dryer design.

*Inert system design* The dryer atmosphere is commonly inerted with nitrogen, but superheated steam or self-inertized systems are also possible. Self-inertized systems are not feasible for flammable solvent systems. These systems must be operated with a small overpressure to ensure no oxygen ingress. And continuous on-line oxygen concentration monitoring is required to ensure that oxygen levels remain well below the explosion hazard limit.

*Relief venting* Relief vents that are properly sized relieve and direct dryer explosions to protect the dryer and personnel if an explosion does occur. Normally they are simple pop-out panels with a minimum length of ducting to direct the explosion away from personnel or other equipment.

*Suppression systems* Suppression systems typically use an inert gas such as carbon dioxide to minimize the explosive peak pressure rise and fire damage. Dryer operating pressure must be properly monitored to detect the initial pressure rise followed by shutdown of the dryer operating systems and activation of the suppression system.

*Clean design* Care should be taken in the design of both the dryer and dryer ancillary (cyclones, filters, etc.) equipment to eliminate ledges, crevices, and other obstructions which can lead to dust and product buildup. Smooth drying equipment walls will minimize deposits. This can go a long way in prevention. No system is perfect, of course, and a routine cleaning schedule is also recommended.

*Start-up and shutdown* Start-up and shutdown situations must be carefully considered when designing a dryer system. These situations can create higher than normal dust and solvent concentrations. This coupled with elevated temperatures can create a hazard well beyond normal continuous operation.

**Environmental Considerations** Environmental considerations are continuing to be an increasingly important aspect of dryer design and operation as environmental regulations are tightened. The primary environmental problems associated with drying are particulate and volatile organic compound (VOC) emissions. Noise can be an issue with certain dryer types.

***Environmental Regulations*** These vary by country, and it is necessary to know the specific regulations in the country in which the dryer will be installed. It is also useful to have some knowledge of the direction of regulations so that the environmental control system is not obsolete by the time it becomes operational.

Particulate emission problems can span a wide range of hazards. Generally there are limits on both toxic and nontoxic particles in terms of annual and peak emissions limits. Particles can present toxic, bacterial, viral, and other hazards to human, animal, and plant life.

Likewise, VOC emissions can span a wide range of hazards and issues from toxic gases to smelly gases.

***Environmental Control Systems*** We should consider environmental hazards before the drying operation is even considered. The focus should be on minimizing the hazards created in the upstream processing operations. After potential emissions are minimized, these hazards must be dealt with during dryer system design and then subsequently with proper operational and maintenance procedures.

***Particle Emission Control Equipment*** The four most common methods of particulate emissions control are as follows:

1. *Cyclone separators* The advantage of cyclones is they have relatively low capital and operating costs. The primary disadvantage is that they become increasingly ineffective as the particle size decreases. As a general rule of thumb, we can say that they are 100 percent efficient with particles larger than 20 μm and 0 percent efficient with particles smaller than 1 μm. Cyclones can also be effective precleaning devices to reduce the load on downstream bag filters.
2. *Scrubbers* The more general classification is wet dedusters, the most common of which is the wet scrubber. The advantage of wet scrubbers is that they can remove fine particles that the cyclone does not collect. The disadvantages are they are more costly than cyclones and they can turn air contamination into water contamination, which may then require additional cleanup before the cleaning water is put to the sewer.
3. *Bag filters* The advantages of filters are that they can remove very fine particles and bag technologies continue to improve and enable ever-smaller particles to be removed without excessive pressure drops or buildup. The primary disadvantages are higher cost relative to cyclones and greater maintenance costs, especially if frequent bag replacement is necessary.
4. *Electrostatic precipitators* The capital cost of these systems is relatively high, and maintenance is critical to effective operation.

***VOC Control Equipment*** The four most prevalent equipment controls are

1. *Scrubbers* Similar considerations as above apply.
2. *Absorbers* These systems use a high-surface-area absorbent, such as activated carbon, to remove the VOC absorbate.
3. *Condensers* These systems are generally only feasible for recovering solvents from nonaqueous wetted products.
4. *Thermal and catalytic incinerators* These can be quite effective and are generally a low capital and operating cost solution, except in countries with high energy costs.

***Noise*** Noise analysis and abatement is a very specialized area. Generally, the issue with dryers is associated with the fans, particularly for systems requiring fans that develop very high pressures. Noise is a very big issue that needs to be addressed with pulse combustion dryers and can be an issue with very large dryers such as rotary dryers and kilns.

Additional considerations regarding environmental control and waste management can be found in Secs. 22, "Waste Management," and 23, "Process Safety."

**Control and Instrumentation** The purpose of the control and instrumentation system is to provide a system that enables the process to produce the product at the desired moisture target and that meets other quality control targets discussed earlier (density, particle size, color, solubility, etc.). This segment discusses key considerations for dryer control and instrumentation. Additional more detailed information can be found in Sec. 8, "Process Control."

Proper control of product quality starts with the dryer selection and design. Sometimes two-stage or multistage systems are required to meet product quality targets. Multistage systems enable us to better control temperature and moisture profiles during drying. Assuming the proper dryer design has been selected, we must then design the control and instrumentation system to ensure we meet all product quality targets.

***Manual versus Automatic Control*** Dryers can be controlled either manually or automatically. Generally lab-, pilot-, and small-scale production units are controlled manually. These operations are usually batch systems, and manual operation provides lower cost and greater flexibility. The preferred mode for large-scale, continuous dryers is automatic.

***Key Control Variables*** Product moisture and product temperature are key control variables. Ideally both moisture and temperature measurement are done on-line, but frequently moisture measurement is done off-line and temperature (or exhaust air temperature) becomes the primary control variable. And generally, inlet temperature

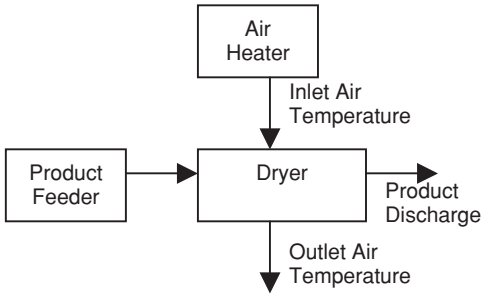

**FIG. 12-110** Typical dryer system.

will control the rate of production and outlet temperature will control the product moisture and other product quality targets.

***Common Control Schemes*** Two relatively simple, but common control schemes in many dryer systems (Fig. 12-110) are as follows:

1. Outlet air temperature is controlled by feed rate regulation with inlet temperature controlled by gas heater regulation.
2. Outlet air temperature is controlled by heater regulation with feed rate held constant.

Alternatively, product temperatures can replace air temperatures with the advantage of better control and the disadvantage of greater maintenance of the product temperature sensors.

***Other Instrumentation and Control***

*Pressure* Pressure and equipment pressure drops are important to proper dryer operation. Most dryers are operated under vacuum. This prevents dusting to the environment, but excess leakage in decreases dryer efficiency. Pressure drops are especially important for stable fluid-bed operation.

*Air (gas) flow rate* Obviously gas flows are another important parameter for proper dryer operation. Pitot tubes are useful when a system has no permanent gas flow sensors. Averaging pitot tubes work well in permanent installations. The devices work best in straight sections of ductwork which are sometimes difficult to find and make accurate measurement a challenge.

*Product feed rate* It's important to know that product feed rates and feed rate changes are sometimes used to control finished product moistures. Weigh belts are common for powdered products, and there is a wide variety of equipment available for liquid feeds. Momentum devices are inexpensive but less accurate.

*Humidity* The simplest method is sometimes the best. Wet- and dry-bulb temperature measurement to get air humidity is simple and works well for the occasional gas humidity measurement. The problem with permanent humidity measurement equipment is the difficulty of getting sensors robust enough to cope with a hot, humid, and sometimes dusty environment.

***Interlocks*** Interlocks are another important feature of a well-designed control and instrumentation system. Interlocks are intended to prevent damage to the dryer system or to personnel, especially during the critical periods of start-up and shutdown. The following are a few key interlocks to consider in a typical dryer system.

*Drying chamber damage* This type of damage can occur when the chamber is subjected to significant vacuum when the exhaust fans are started up before the supply fans.

*Personnel injury* This interlock is to prevent injury due to entering the dryer during operation, but more typically to prevent dryer start-up with personnel in the main chamber or inlet or exhaust air ductwork on large dryers. This typically involves microswitches on access doors coupled with proper door lock devices and tags.

*Assurance of proper startup and shutdown* These interlocks ensure, e.g., that the hot air system is started up before the product feed system and that the feed system is shut down before the hot air system.

*Heater system* There are a host of important heater system interlocks to prevent major damage to the entire drying system. Additional details can be found in Sec. 23, "Process Safety."

**Drying Software** Several software programs for psychrometric charts and calculations are available and are described in the "Psychrometry" section.

Dryers are included as modules in standard process simulators such as Aspen Plus and HYSYS (Aspen Technology), Pro/II (Simsci/Invensys) and Unisim (Honeywell), and the prototype Solidsim solids process simulator. These are confined (as of 2006) to heat and mass balances or, at most, simple scoping design.

Many higher-level dryer models have been produced by researchers and universities, but they are not commercially available. Windows-based drying programs are available in the Process Tools (Aspen Technology), including a psychrometric chart, dryer selection expert system, dryer scoping design, and fluid-bed dryer simulation. Some CFD programs (e.g., Fluent, CFX) include a module for spray dryers.

In addition to textbooks, a detailed online knowledge base, the Process Manual, is available from Aspen Technology (see www.processmanual.com). This covers equipment, scientific background, design, and operation for drying and 10 other technical areas in solids and separation processes. Company and university licenses are available.

Detailed reviews of drying software packages given by Menshutina and Kudra, *Drying Technol.* **19**(8):1825–1850 (2001); and by Kemp, Chap. 7 in *Modern Drying Technology*, vol. 1, Wiley–VCH (2007), and *Drying Technol.* **25** (2007).

# INTRODUCTION TO DISTILLATION OPERATIONS

## GENERAL PRINCIPLES

Separation operations achieve their objective by the creation of two or more coexisting zones which differ in temperature, pressure, composition, and/or phase state. Each molecular species in the mixture to be separated responds in a unique way to differing environments offered by these zones. Consequently, as the system moves toward equilibrium, each species establishes a different concentration in each zone, and this results in a separation between the species.

The separation operation called *distillation* utilizes vapor and liquid phases at essentially the same temperature and pressure for the coexisting zones. Various kinds of devices such as *random* or *structured packings* and *plates* or *trays* are used to bring the two phases into intimate contact. Trays are stacked one above the other and enclosed in a cylindrical shell to form a *column.* Packings are also generally contained in a cylindrical shell between hold-down and support plates. The column may be operated continuously or in batch mode depending on a number of factors such as scale and flexibility of operations and solids content of feed. A typical tray-type continuous distillation column plus major external accessories is shown schematically in Fig. 13-1.

The *feed* material, which is to be separated into fractions, is introduced at one or more points along the column shell. Because of the difference in density between vapor and liquid phases, liquid runs down the column, cascading from tray to tray, while vapor flows up the column, contacting liquid at each tray.

Liquid reaching the bottom of the column is partially vaporized in a heated *reboiler* to provide *boil-up,* which is sent back up the column. The remainder of the bottom liquid is withdrawn as *bottoms,* or bottom product. Vapor reaching the top of the column is cooled and condensed to liquid in the *overhead condenser.* Part of this liquid is returned to the column as *reflux* to provide liquid overflow. The remainder of the overhead stream is withdrawn as *distillate,* or overhead product. In some cases only part of the vapor is condensed so that a vapor distillate can be withdrawn.

This overall flow pattern in a distillation column provides countercurrent contacting of vapor and liquid streams on all the trays through the column. Vapor and liquid phases on a given tray approach thermal, pressure, and composition equilibria to an extent dependent upon the efficiency of the contacting tray.

The *lighter* (lower-boiling temperature) components tend to concentrate in the vapor phase, while the *heavier* (higher-boiling temperature) components concentrate in the liquid phase. The result is a vapor phase that becomes richer in light components as it passes up the column and a liquid phase that becomes richer in heavy components as it cascades downward. The overall separation achieved between the distillate and the bottoms depends primarily on the *relative volatilities* of the components, the number of contacting trays in each column section, and the ratio of the liquid-phase flow rate to the vapor-phase flow rate in each section.

If the feed is introduced at one point along the column shell, the column is divided into an upper section, which is often called the *rectifying* section, and a lower section, which is often referred to as the *stripping* section. In *multiple-feed* columns and in columns from which a liquid or vapor *sidestream* is withdrawn, there are more than two column sections between the two end-product streams. The notion of a column section is a useful concept for finding alternative *systems* (or *sequences*) of columns for separating multicomponent mixtures, as described below in the subsection Distillation Systems.

All separation operations require energy input in the form of heat or work. In the conventional distillation operation, as typified in Fig. 13-1, energy required to separate the species is added in the form of heat to the reboiler at the bottom of the column, where the temperature is highest. Also heat is removed from a condenser at the top of the column, where the temperature is lowest. This frequently results in a

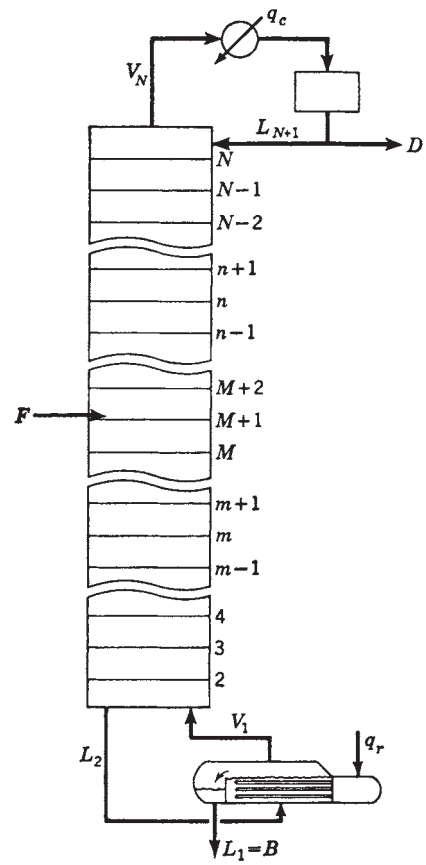

**FIG. 13-1** Schematic diagram and nomenclature for a simple continuous distillation column with one feed, a total overhead condenser, and a partial reboiler.

large energy-input requirement and low overall thermodynamic efficiency, especially if the heat removed in the condenser is wasted. Complex distillation operations that offer higher thermodynamic efficiency and lower energy-input requirements have been developed and are also discussed below in the subsection Distillation Systems.

Batch distillation is preferred for small feed flows or seasonal production which is carried out intermittently in "batch campaigns." In this mode the feed is charged to a still which provides vapor to a column where the separation occurs. Vapor leaving the top of the column is condensed to provide liquid reflux back to the column as well as a distillate stream containing the product. Under normal operation, this is the only stream leaving the device. In addition to the batch rectifier just described, other batch configurations are possible as discussed in the subsection Batch Distillation. Many of the concepts and methods discussed for continuous distillation are useful for developing models and design methods for batch distillation.

## EQUILIBRIUM AND NONEQUILIBRIUM-STAGE CONCEPTS

The transfer processes taking place in an actual distillation column are a complicated interplay between the thermodynamic phase equilibrium properties of the mixture, rates of intra- and interphase mass and energy transport, and multiphase flows. Simplifications are necessary to develop tractable models. The landmark concept of the *equilibrium-stage model* was developed by Sorel in 1893, in which the liquid in each stage is considered to be well mixed and such that the vapor and liquid streams leaving the stage are in thermodynamic equilibrium with each other. This is needed so that thermodynamic phase equilibrium relations can be used to determine the temperature and composition of the equilibrium streams at a given pressure. A hypothetical column composed of equilibrium stages (instead of actual contact trays) is designed to accomplish the separation specified for the actual column. The number of hypothetical equilibrium stages required is then converted to a number of actual trays by means of *tray efficiencies*, which describe the extent to which the performance of an actual contact tray duplicates the performance of an equilibrium stage. Alternatively and preferably, tray inefficiencies can be accounted for by using rate-based models that are described below.

Use of the equilibrium-stage concept separates the design of a distillation column into three major steps: (1) Thermodynamic data and methods needed to predict equilibrium-phase compositions are assembled. (2) The number of equilibrium stages and the energy input required to accomplish a specified separation, or the separation that will be accomplished in a given number of equilibrium stages for a given energy input, are calculated. (3) The number of equilibrium stages is converted to an equivalent number of actual contact trays or height of packing, and the column diameter is determined. Much of the third step is eliminated if a rate-based model is used. This section deals primarily with equilibrium and rate-based models of distillation. Section 4 covers the first step, but a summary of methods and some useful data are included in this section. Section 14 covers equipment design.

## RELATED SEPARATION OPERATIONS

The simple and complex distillation operations just described all have two things in common: (1) Both rectifying and stripping sections are provided so that a separation can be achieved between two components that are adjacent in volatility; and (2) the separation is effected only by the addition and removal of energy and not by the addition of any mass separating agent (MSA) such as in liquid-liquid extraction.

Sometimes, alternative single- or multiple-stage vapor-liquid separation operations, of the types shown in Fig. 13-2, may be more suitable than distillation for the specified task.

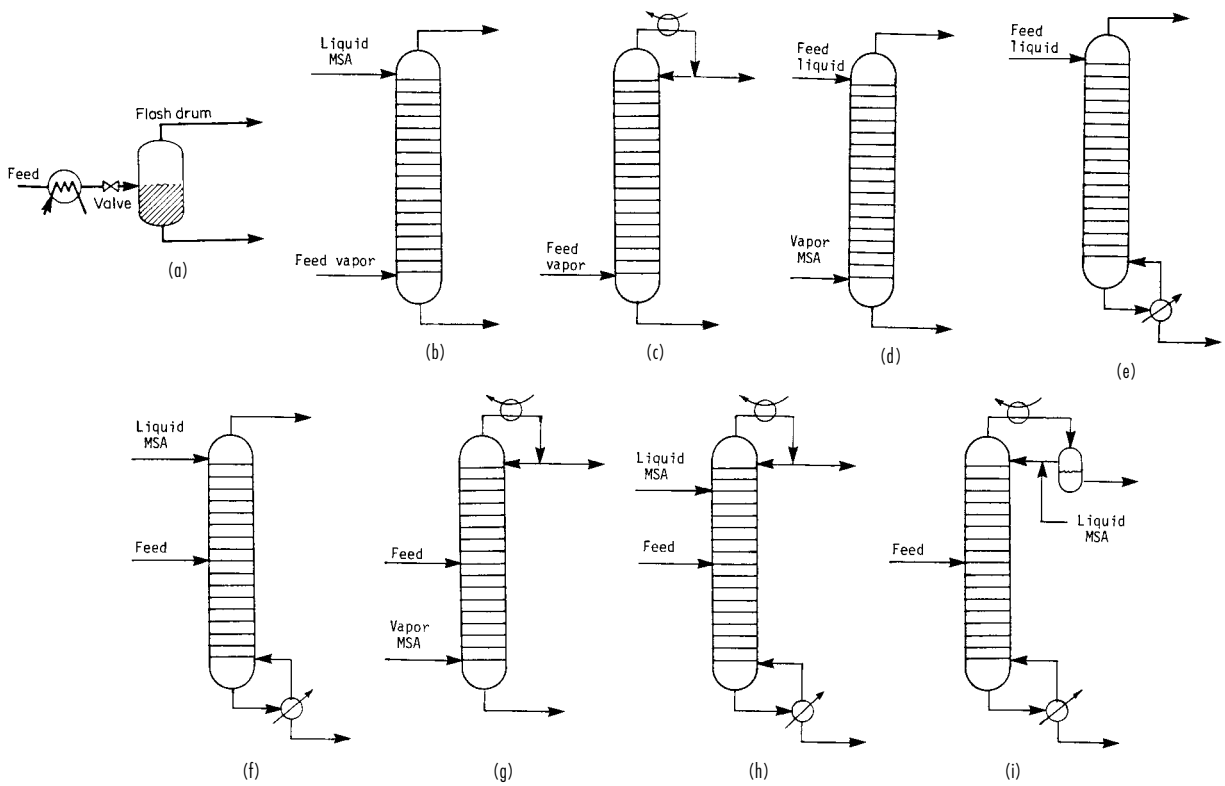

**FIG. 13-2** Separation operations related to distillation. (*a*) Flash vaporization or partial condensation. (*b*) Absorption. (*c*) Rectifier. (*d*) Stripping. (*e*) Reboiled stripping. (*f*) Reboiled absorption. (*g*) Refluxed stripping. (*h*) Extractive distillation. (*i*) Azeotropic distillation.

A single-stage flash, as shown in Fig. 13-2*a,* may be appropriate if (1) the relative volatility between the two components to be separated is very large; (2) the recovery of only one component in one of the two product streams is to be achieved, without regard to the separation of the other components; or (3) only a partial separation is to be made. A common example is the separation of light gases such as hydrogen and methane from aromatics. The desired temperature and pressure of a flash may be established by the use of heat exchangers, a valve, a compressor, and/or a pump upstream of the vessel, used to separate the product vapor and liquid phases. Depending on the original condition of the feed, it may be partially condensed or partially vaporized in a so-called flash operation.

If the recovery of only one component is required rather than a sharp separation between two components of adjacent volatility, their absorption or stripping in a single section of stages may be sufficient. If the feed is vapor at separation conditions, absorption is used either with a liquid MSA absorbent of relatively low volatility, as in Fig. 13-2*b,* or with reflux produced by an overhead partial condenser, as in Fig. 13-2*c.* The choice usually depends on the ease of partially condensing the overhead vapor or of recovering and recycling the absorbent. If the feed is liquid at separation conditions, stripping is used, either with an externally supplied vapor stripping agent of relatively high volatility, as shown in Fig. 13-2*d,* or with boil-up produced by a partial reboiler, as in Fig. 13-2*e.* The choice depends on the ease of partially reboiling the bottoms or of recovering and recycling the stripping agent.

If a relatively sharp separation is required between two components of adjacent volatility, but either an undesirably low temperature is required to produce reflux at the column operating pressure or an undesirably high temperature is required to produce boil-up, then refluxed stripping, as shown in Fig. 13-2*g,* or reboiled absorption, as shown in Fig. 13-2*f,* may be used. In either case, the choice of MSA follows the same consideration given for simple absorption and stripping.

When the volatility difference between the two components to be separated is so small that a very large number of stages would be required, then extractive distillation, as shown in Fig. 13-2*h,* should be considered. Here, an MSA is selected that increases the volatility difference sufficiently to reduce the stage requirement to a reasonable number. Usually, the MSA is a polar compound of low volatility that leaves in the bottoms, from which it is recovered and recycled. It is introduced in an appreciable amount near the top stage of the column so as to affect the volatility difference over most of the stages. Some reflux to the top stage is used to minimize the MSA content in the distillate. An alternative to extractive distillation is azeotropic distillation, which is shown in Fig. 13-2*i* in just one of its many modes. In a common mode, an MSA that forms a heterogeneous minimum-boiling azeotrope with one or more components of the feed is used. The azeotrope is taken overhead, and the MSA-rich phase is decanted and returned to the top of the column as reflux.

Numerous other multistaged configurations are possible. One important variation of a stripper, shown in Fig. 13-2*d,* is a refluxed stripper, in which an overhead condenser is added. Such a configuration is sometimes used to steam-strip sour water containing $NH_3$, $H_2O$, phenol, and HCN.

All the separation operations shown in Fig. 13-2, as well as the simple and complex distillation operations described earlier, are referred to here as distillation-type separations because they have much in common with respect to calculations of (1) thermodynamic properties, (2) vapor-liquid equilibrium stages, and (3) column sizing. In fact, as will be evident from the remaining treatment of this section, the trend is toward single generalized digital computer program packages that compute many or all distillation-type separation operations.

This section also includes a treatment of distillation-type separations from a rate-based point of view that uses principles of mass- and heat-transfer rates. Section 14 also presents details of that subject as applied to absorption and stripping.

## THERMODYNAMIC DATA AND MODELS

Reliable thermodynamic data are essential for the accurate design or analysis of distillation columns. Failure of equipment to perform at specified levels is often attributable, at least in part, to the lack of such data.

This subsection summarizes and presents examples of phase equilibrium data currently available to the designer. The thermodynamic concepts used are presented in the subsection Thermodynamics of Sec. 4.

### PHASE EQUILIBRIUM DATA

For a binary mixture, pressure and temperature fix the equilibrium vapor and liquid compositions. Thus, experimental data are frequently presented in the form of tables of vapor mole fraction $y$ and liquid mole fraction $x$ for one constituent over a range of temperature $T$ for a fixed pressure $P$ or over a range of pressure for a fixed temperature. A small selection of such data, at a pressure of 101.3 kPa (1 atm, 1.013 bar), for four nonideal binary systems is given in Table 13-1. More extensive presentations and bibliographies of such data may be found in Hala, Wichterle, Polak, and Boublik (*Vapour-Liquid Equilibrium Data at Normal Pressures,* Pergamon, Oxford, 1968); Hirata, Ohe, and Nagahama (*Computer Aided Data Book of Vapor-Liquid Equilibria,* Elsevier, Amsterdam, 1975); Wichterle, Linek, and Hala (*Vapor-Liquid Equilibrium Data Bibliography,* Elsevier, Amsterdam, 1973, Supplement I, 1976, Supplement II, 1979); Ohe (*Vapor-Liquid Equilibrium Data,* Elsevier, Amsterdam, 1989); Ohe (*Vapor-Liquid Equilibrium Data at High Pressure,* Elsevier, Amsterdam, 1990); Walas (*Phase Equilibria in Chemical Engineering,* Butterworth, Boston, 1985); and, particularly, Gmehling and Onken [*Vapor-Liquid Equilibrium Data Collection,* DECHEMA Chemistry Data ser., vol. 1 (parts 1–10), Frankfurt, 1977]. Extensive databases of phase equilibrium measurements are readily available in most process simulators together with models for correlating, interpolating, and extrapolating (care is needed here) the data. Many of these simulators also provide graphical display of the data for easy visualization and interpretation.

For application to distillation (a nearly isobaric process) binary-mixture data are frequently plotted, for a fixed pressure, as $y$ versus $x$, with a line of 45° slope included for reference, and as $T$ versus $y$ and $x$, as shown in Figs. 13-3 to 13-8. In some binary systems, one of the components is more volatile than the other over the entire composition range. This is the case in Figs. 13-3 and 13-4 for the benzene-toluene system at pressures of both 101.3 and 202.6 kPa (1 and 2 atm), where benzene is more volatile than toluene.

For other binary systems, one of the components is more volatile over only a part of the composition range. Two systems of this type, ethyl acetate–ethanol and chloroform-acetone, are shown in Figs. 13-5 to 13-7. Figure 13-5 shows that chloroform is less volatile than acetone below a concentration of 66 mol % chloroform and that ethyl acetate is more volatile than ethanol below a concentration of 53 mol % ethyl acetate. Above these concentrations, volatility is reversed. Such mixtures are known as azeotropic mixtures, and the composition in which the reversal occurs, which is the composition in which vapor and liquid compositions are equal, is the azeotropic composition, or azeotrope. The azeotropic liquid may be homogeneous or heterogeneous (two immiscible liquid phases). Two of the binary mixtures of Table 13-1 form homogeneous azeotropes. Non-azeotrope-forming mixtures such as benzene and toluene in Figs. 13-3 and 13-4 can be separated by simple distillation into two essentially pure products. By contrast, simple distillation of azeotropic mixtures will at best yield the azeotrope and one essentially pure species. The distillate and bottoms products obtained depend upon the feed composition and whether a minimum-boiling azeotrope is formed as with the ethyl acetate–ethanol mixture in Fig. 13-6 or a maximum-boiling azeotrope is formed as with the chloroform-acetone mixture in Fig. 13-7. For example, if a mixture of 30 mol % chloroform and 70 mol % acetone is fed to a simple distillation column, such as that

shown in Fig. 13-1, operating at 101.3 kPa (1 atm), the distillate could approach pure acetone and the bottoms could approach the maximum-boiling azeotrope.

An example of heterogeneous-azeotrope formation is shown in Fig. 13-8 for the water–normal butanol system at 101.3 kPa. At liquid compositions between 0 and 3 mol % butanol and between 40 and 100 mol % butanol, the liquid phase is homogeneous. Phase splitting into two separate liquid phases (one with 3 mol % butanol and the other with 40 mol % butanol) occurs for any overall liquid composition between 3 and 40 mol % butanol. A minimum-boiling heterogeneous azeotrope occurs at 92°C (198°F) when the vapor composition and the overall composition of the two liquid phases are 25 mol % butanol.

For mixtures containing more than two species, an additional degree of freedom is available for each additional component. Thus, for a four-component system, the equilibrium vapor and liquid compositions are fixed only if the pressure, temperature, and mole fractions of two components are set. Representation of multicomponent vapor-liquid equilibrium data in tabular or graphical form of the type shown earlier for binary systems is either difficult or impossible. Instead, such data, as well as binary-system data, are commonly represented in terms of $K$ values (vapor-liquid equilibrium ratios), which are defined by

$$K_i = \frac{y_i}{x_i} \tag{13-1}$$

and are correlated empirically or theoretically in terms of temperature, pressure, and phase compositions in the form of tables, graphs, and equations. The $K$ values are widely used in multicomponent distillation calculations, and the ratio of the $K$ values of two species, called the relative volatility,

$$\alpha_{ij} = \frac{K_i}{K_j} \tag{13-2}$$

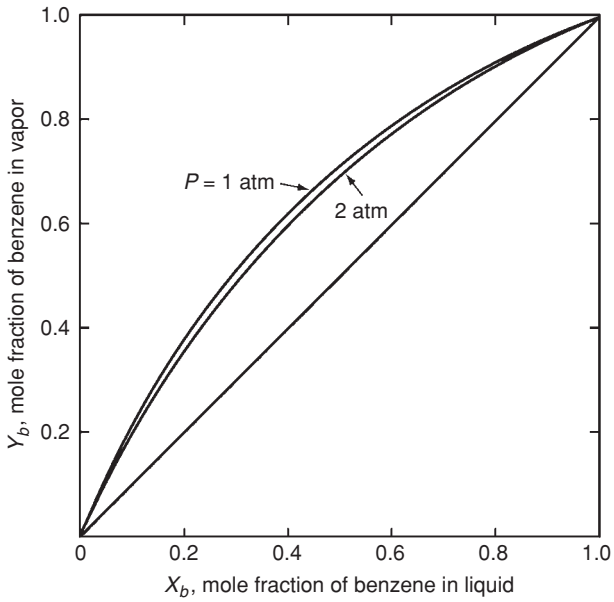

**FIG. 13-3** Isobaric *y-x* curves for benzene-toluene. (*Brian,* Staged Cascades in Chemical Processing, *Prentice-Hall, Englewood Cliffs, N.J., 1972.*)

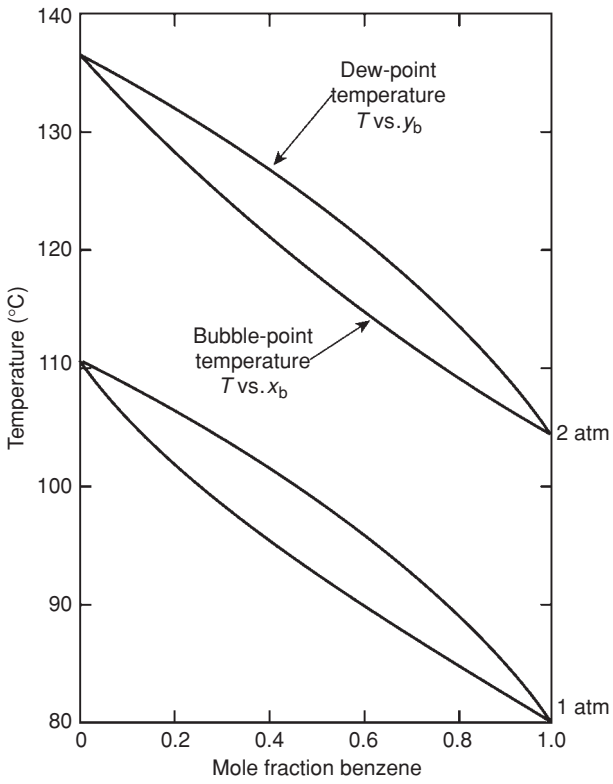

**FIG. 13-4** Isobaric vapor-liquid equilibrium curves for benzene-toluene. (*Brian,* Staged Cascades in Chemical Processing, *Prentice-Hall, Englewood Cliffs, N.J., 1972.*)

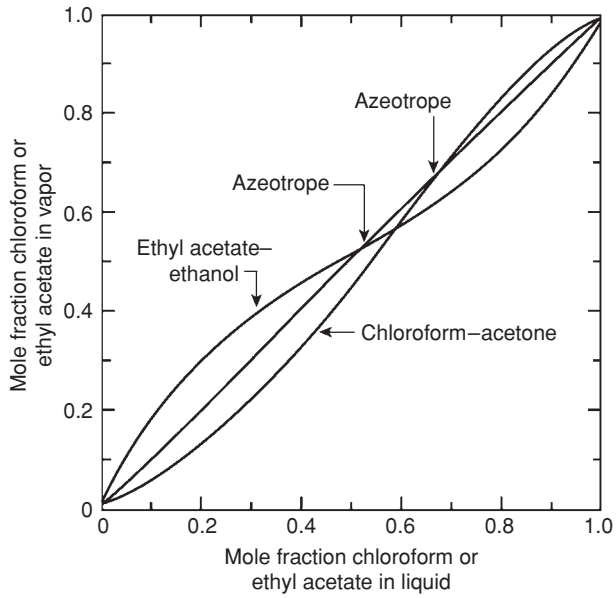

**FIG. 13-5** Vapor-liquid equilibria for the ethyl acetate–ethanol and chloroform-acetone systems at 101.3 kPa (1 atm).

is a convenient index of the relative ease or difficulty of separating components *i* and *j* by distillation. Rarely is distillation used on a large scale if the relative volatility is less than 1.05, with *i* more volatile than *j*.

## GRAPHICAL *K* VALUE CORRELATIONS

As discussed in Sec. 4, the *K* value of a species is a complex function of temperature, pressure, and equilibrium vapor- and liquid-phase compositions. However, for mixtures of compounds of similar molecular structure and size, the *K* value depends mainly on temperature and pressure. For example, several major graphical *K* value correlations are available for light-hydrocarbon systems. The easiest to use are the DePriester charts [*Chem. Eng. Prog. Symp. Ser.* 7, **49,** 1 (1953)],

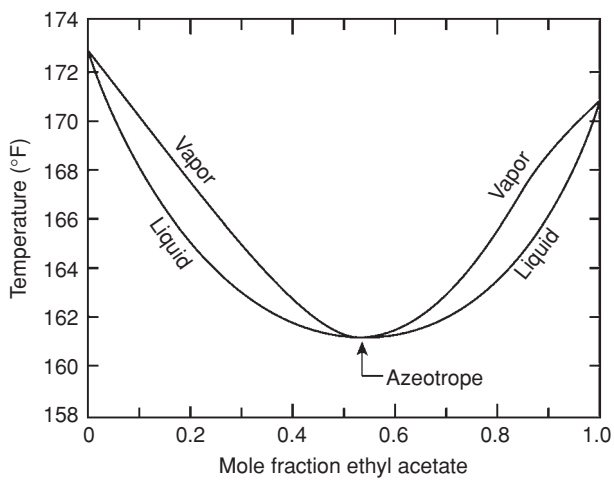

**FIG. 13-6** Liquid boiling points and vapor condensation temperatures for minimum-boiling azeotrope mixtures of ethyl acetate and ethanol at 101.3-kPa (1-atm) total pressure.

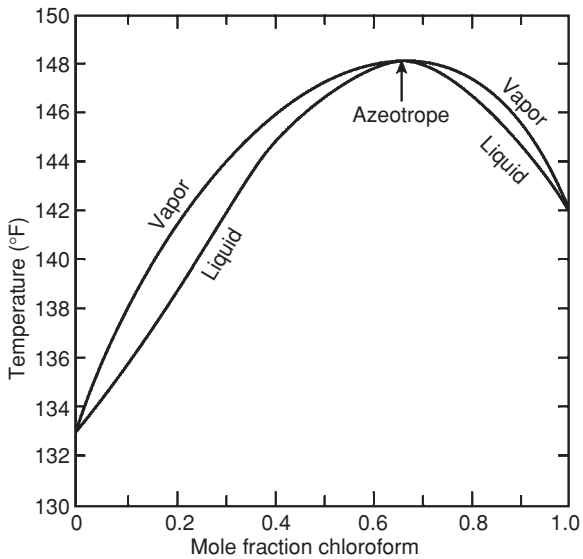

**FIG. 13-7** Liquid boiling points and vapor condensation temperatures for maximum-boiling azeotrope mixtures of chloroform and acetone at 101.3-kPa (1-atm) total pressure.

which cover 12 hydrocarbons (methane, ethylene, ethane, propylene, propane, isobutane, isobutylene, *n*-butane, isopentane, *n*-pentane, *n*-hexane, and *n*-heptane). These charts are a simplification of the Kellogg charts (*Liquid-Vapor Equilibria in Mixtures of Light Hydrocarbons, MWK Equilibrium Constants, Polyco Data,* 1950) and include additional experimental data. The Kellogg charts, and hence the DePriester charts, are based primarily on the Benedict-Webb-Rubin equation of state [*Chem. Eng. Prog.,* **47,** 419 (1951); **47,** 449 (1951)], which can represent both the liquid and the vapor phases and can predict *K* values quite accurately when the equation constants are available for the components in question.

A trial-and-error procedure is required with any *K* value correlation that takes into account the effect of composition. One cannot calculate *K* values until phase compositions are known, and those cannot be known until the *K* values are available to calculate them. For *K* as a function of *T* and *P* only, the DePriester charts provide good starting values for the iteration. These nomographs are shown in Fig. 13-9*a* and *b.* SI versions of these charts have been developed by Dadyburjor [*Chem. Eng. Prog.,* **74**(4), 85 (1978)].

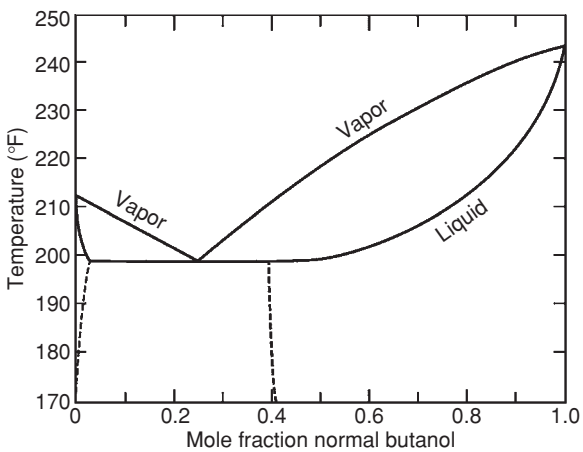

**FIG. 13-8** Vapor-liquid equilibrium data for an *n*-butanol–water system at 101.3 kPa (1 atm); phase splitting and heterogeneous-azeotrope formation.

The Kellogg and DePriester charts and their subsequent extensions and generalizations use the molar average boiling points of the liquid and vapor phases to represent the composition effect. An alternative measure of composition is the convergence pressure of the system, which is defined as that pressure at which the *K* values for all the components in an isothermal mixture converge to unity. It is analogous to the critical point for a pure component in the sense that the two phases become indistinguishable. The behavior of a complex mixture of hydrocarbons for a convergence pressure of 34.5 MPa (5000 psia) is illustrated in Fig. 13-10.

Two major graphical correlations based on convergence pressure as the third parameter (besides temperature and pressure) are the charts published by the Gas Processors Association (GPA, *Engineering Data Book,* 9th ed., Tulsa, 1981) and the charts of the American Petroleum Institute (API, *Technical Data Book—Petroleum Refining,* New York, 1966) based on the procedures from Hadden and Grayson [*Hydrocarbon Process., Pet. Refiner,* **40**(9), 207 (1961)]. The former uses the method proposed by Hadden [*Chem. Eng. Prog. Symp. Ser. 7,* **49,** 53 (1953)] for the prediction of convergence pressure as a function of composition. The basis for Hadden's method is illustrated in Fig. 13-11, where it is shown that the critical loci for various mixtures of methane-propane-pentane fall within the area circumscribed by the three binary loci. (This behavior is not always typical of more nonideal systems.) The critical loci for the ternary mixtures vary linearly, at constant temperature, with weight percent propane on a methane-free basis. The essential point is that critical loci for mixtures are independent of the concentration of the lightest component in a mixture. This permits representation of a multicomponent mixture as a pseudobinary. The light component in this pseudobinary is the lightest species present (to a reasonable extent) in the multicomponent mixture. The heavy component is a pseudosubstance whose critical temperature is an average of all other components in the multicomponent mixture. This pseudocritical point can then be located on a *P-T* diagram containing the critical points for all compounds covered by the charts, and a critical locus can be drawn for the pseudobinary by interpolation between various real binary curves. Convergence pressure for the mixture at the desired temperature is read from the assumed loci at the desired system temperature. This method is illustrated in the left half of Fig. 13-12 for the methane-propane-pentane ternary. Associated *K* values for pentane at 104°C (220°F) are shown to the right as a function of mixture composition (or convergence pressure).

The GPA convergence pressure charts are primarily for alkane and alkene systems but do include charts for nitrogen, carbon dioxide, and hydrogen sulfide. The charts may not be valid when appreciable amounts of naphthenes or aromatics are present; the API charts use special procedures for such cases. Useful extensions of the convergence pressure concept to more varied mixtures include the nomographs of Winn [*Chem. Eng. Prog. Symp. Ser. 2,* **48,** 121 (1952)], Hadden and Grayson (op. cit.), and Cajander, Hipkin, and Lenoir [*J. Chem. Eng. Data,* **5,** 251 (1960)].

## ANALYTICAL *K* VALUE CORRELATIONS

The widespread availability and use of digital computers for distillation calculations have given impetus to the development of analytical expressions for *K* values. McWilliams [*Chem. Eng.,* **80**(25), 138 (1973)] presents a regression equation and accompanying regression coefficients that represent the DePriester charts of Fig. 13-9. Regression equations and coefficients for various versions of the GPA convergence pressure charts are available from the GPA.

Preferred analytical correlations are less empirical and most often are theoretically based on one of two exact thermodynamic formulations, as derived in Sec. 4. When a single pressure-volume-temperature *(P-V-T)* equation of state is applicable to both vapor and liquid phases, the formulation used is

$$K_i = \frac{\hat{\Phi}_i^L}{\hat{\Phi}_i^V} \tag{13-3}$$

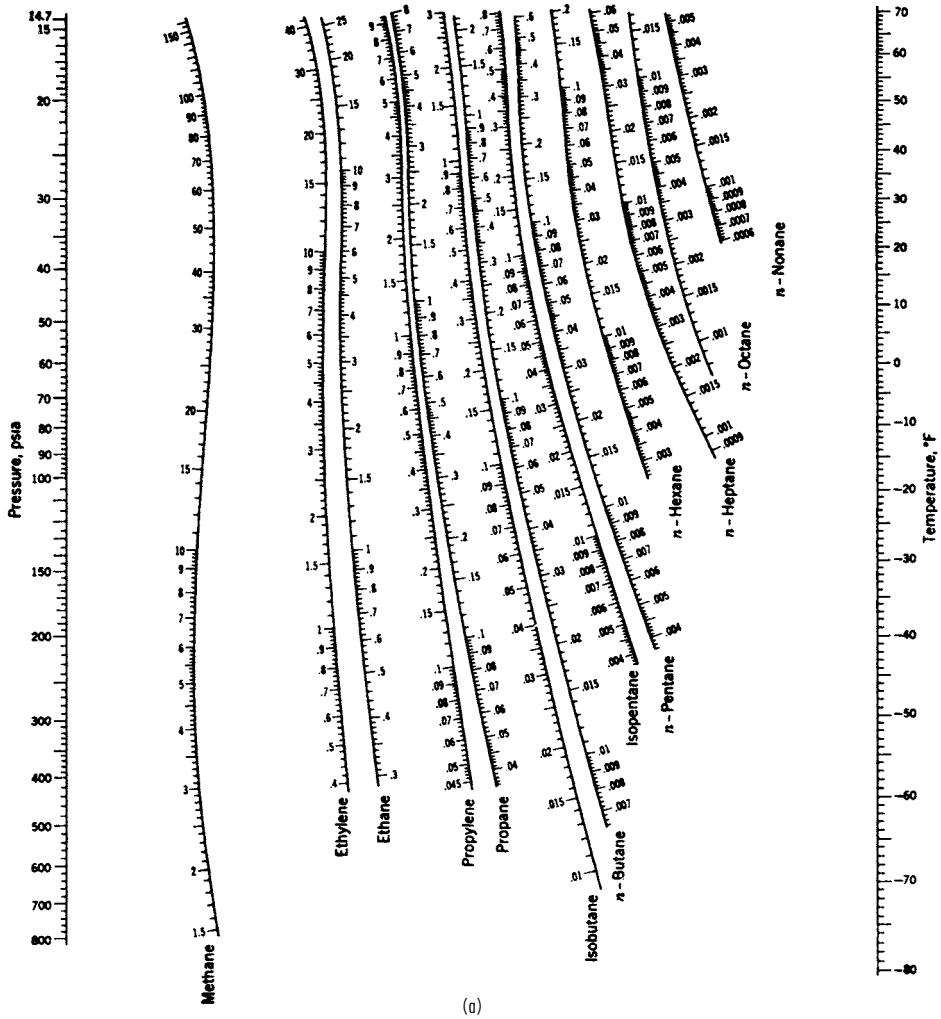

**FIG. 13-9** The $K$ values ($K = y/x$) in light-hydrocarbon systems. (*a*) Low-temperature range. (*b*) High-temperature range. [*DePriester*, Chem. Eng. Prog. Symp., *Ser. 7,* ***49****, 1 (1953).*]

where the mixture fugacity coefficients $\hat{\Phi}_i^L$ for the liquid and $\hat{\Phi}_i^V$ for the vapor are derived by classical thermodynamics from the *P-V-T* expression. Consistent equations for enthalpy can be similarly derived.

Until recently, equations of state that have been successfully applied to Eq. (13-3) have been restricted to mixtures of nonpolar compounds, namely, hydrocarbons and light gases. These equations include those of Benedict-Webb-Rubin (BWR), Soave (SRK) [*Chem. Eng. Sci.,* **27,** 1197 (1972)], who extended the remarkable Redlich-Kwong equation, and Peng-Robinson (PR) [*Ind. Eng. Chem. Fundam.,* **15,** 59 (1976)]. The SRK and PR equations belong to a family of so-called cubic equations of state. The Starling extension of the BWR equation (*Fluid Thermodynamic Properties for Light Petroleum Systems,* Gulf, Houston, 1973) predicts $K$ values and enthalpies of the normal paraffins up through *n*-octane, as well as isobutane, isopentane, ethylene, propylene, nitrogen, carbon dioxide, and hydrogen sulfide, including the cryogenic region. Computer programs for $K$ values derived from the SRK, PR, and other equations of state are widely available in all computer-aided process design and simulation programs. The ability of the SRK correlation to predict $K$ values even when the pressure approaches the convergence pressure is shown for a multicomponent system in Fig. 13-13. Similar results are achieved with the PR correlation. The Wong-Sandler mixing rules for cubic equations of state now permit such equations to be extended to mixtures of organic chemicals, as shown in a reformulated version by Orbey and Sandler [*AIChE J.,* **41,** 683 (1995)].

An alternative $K$ value formulation that has received wide application to mixtures containing polar and/or nonpolar compounds is

$$K_i = \frac{\gamma_i^L \Phi_i^L}{\hat{\Phi}_i^V} \tag{13-4}$$

where different equations of state may be used to predict the pure-component liquid fugacity coefficient $\Phi_i^L$ and the vapor-mixture fugacity coefficient, and any one of a number of mixture free-energy models may be used to obtain the liquid activity coefficient $\gamma_i^L$. At low to moderate pressures, accurate prediction of the latter is crucial to the application of Eq. (13-4).

When either Eq. (13-3) or Eq. (13-4) can be applied, the former is generally preferred because it involves only a single equation of state applicable to both phases and thus would seem to offer greater consistency. In addition, the quantity $\Phi_i^L$ in Eq. (13-4) is hypothetical for any components that are supercritical. In that case, a modification of Eq. (13-4) that uses Henry's law is sometimes applied.

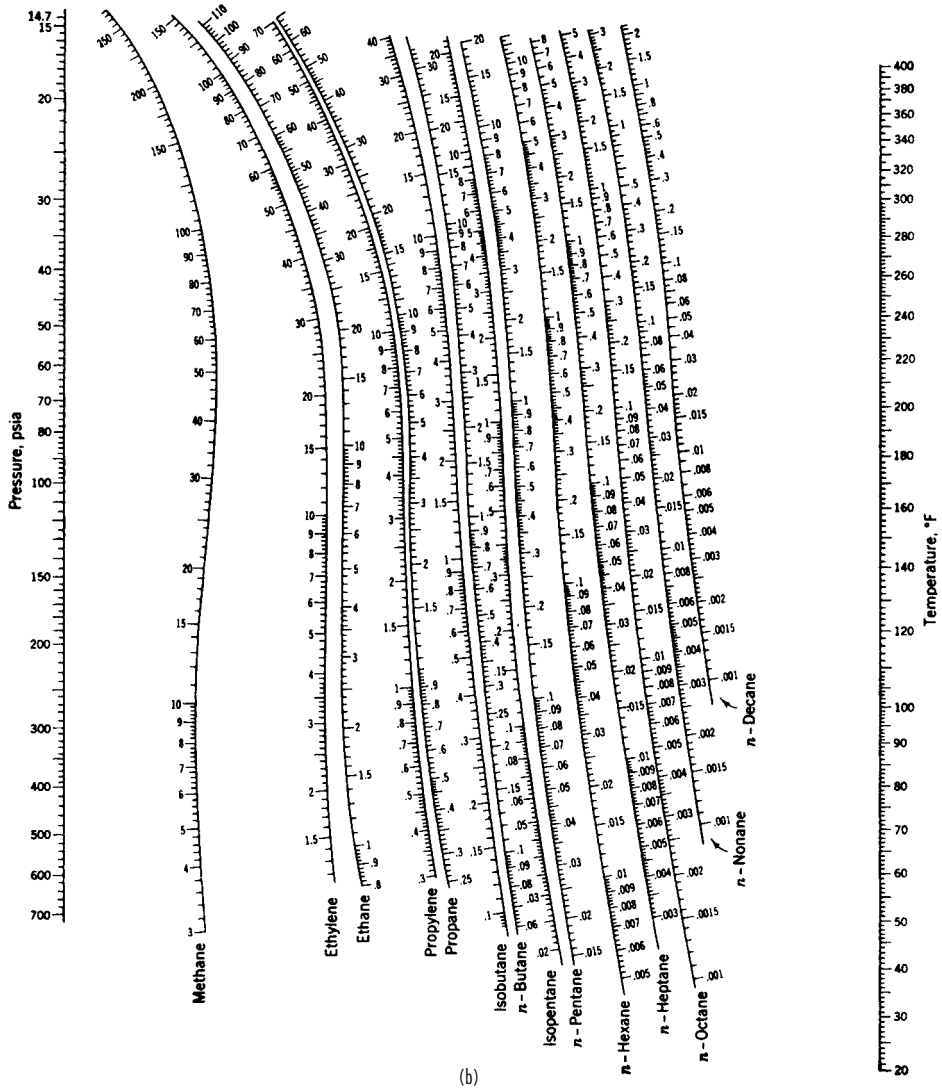

**FIG. 13-9** (*Continued*)

For mixtures of hydrocarbons and light gases, Chao and Seader (CS) [*AIChE J.*, **7,** 598 (1961)] applied Eq. (13-4) by using an empirical expression for $\Phi_i^L$ based on the generalized corresponding-states *P-V-T* correlation of Pitzer et al., the Redlich-Kwong equation of state for $\hat{\Phi}_i^V$, and the regular solution theory of Scatchard and Hildebrand for $\gamma_i^L$. The predictive ability of the last-named theory is exhibited in Fig. 13-14 for the heptane-toluene system at 101.3 kPa (1 atm). Five pure-component constants for each species ($T_v$, $P_v$, $\omega$, $\delta$, and $v^L$) are required to use the CS method which, when applied within the restrictions discussed by Lenoir and Koppany [*Hydrocarbon Process.*, **46**(11), 249 (1967)], gives good results. Revised coefficients of Grayson and Streed (GS) (Paper 20-P07, Sixth World Pet. Conf. Frankfurt, June, 1963) for the $\Phi_i^L$ expression permit application of the CS correlation to higher temperatures and pressures and give improved predictions for hydrogen. Jin, Greenkorn, and Chao [*AIChE J*, **41,** 1602 (1995)] present a revised correlation for the standard-state liquid fugacity of hydrogen, applicable from 200 to 730 K.

For mixtures containing polar substances, more complex predictive equations for $\gamma_i^L$ that involve binary-interaction parameters for each pair of components in the mixture are required for use in Eq. (13-4), as discussed in Sec. 4. Six popular expressions are the Margules, van Laar, Wilson, NRTL, UNIFAC, and UNIQUAC equations. The preferred expressions for representing activity coefficients are the NRTL and UNIQUAC equations. Extensive listings of binary-interaction parameters for use in all but the UNIFAC equation are given by Gmehling and Onken (op. cit.). They obtained the parameters for binary systems at 101.3 kPa (1 atm) from best fits of the experimental *T-y-x* equilibrium data by setting $\Phi_i^V$ and $\Phi_i^L$ to their ideal-gas, ideal-solution limits of 1.0 and $P^{sat}/P$, respectively, with the vapor pressure $P^{sat}$ given by a three-constant Antonie equation, whose values they tabulate. Table 13-2 lists their parameters for selected binary systems based on the binary system activity coefficient equation forms given in Table 13-3.

Consistent Antoine vapor pressure constants and liquid molar volumes are listed in Table 13-4. The Wilson equation is particularly useful for systems that are highly nonideal but do not undergo phase splitting, as exemplified by the ethanol-hexane system, whose activity coefficients are shown in Fig. 13-15. For systems such as this, in which activity coefficients in dilute regions may exceed values of

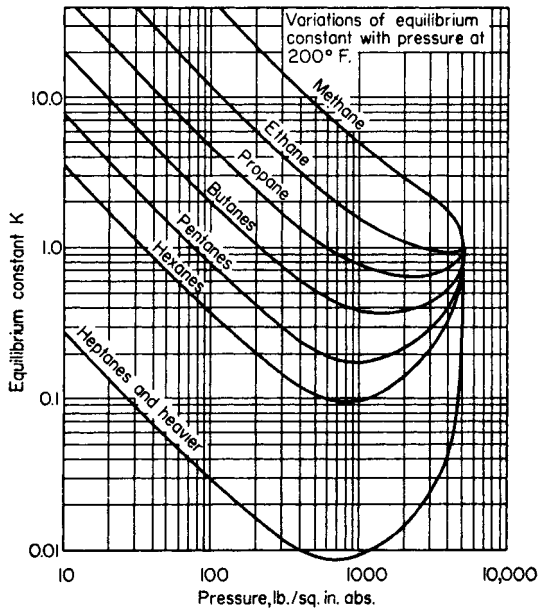

**FIG. 13-10** Typical variation of $K$ values with total pressure at constant temperature for a complex mixture. Light hydrocarbons in admixture with crude oil. [*Katz and Hachmuth*, Ind. Eng. Chem., **29,** *1072 (1937).*]

approximately 7.5, the van Laar equation erroneously predicts phase splitting.

Tables 13-2 and 13-4 include data on formic acid and acetic acid, two substances that tend to dimerize in the vapor phase according to the chemical equilibrium expression

$$K_D = \frac{P_D}{P_M^2} = 10^{A+B/T} \tag{13-5}$$

where $K_D$ is the chemical equilibrium constant for dimerization, $P_D$ and $P_M$ are partial pressures of dimer and monomer, respectively, in torr,

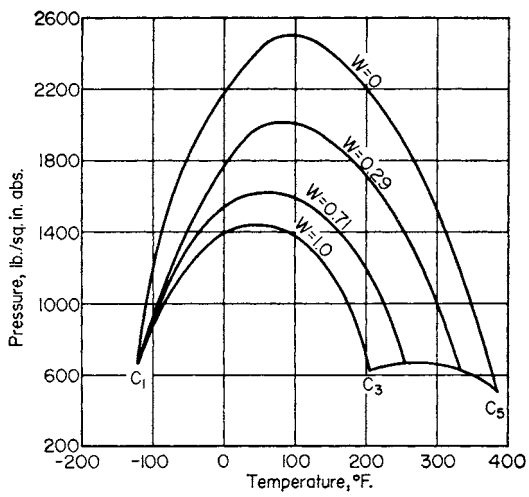

**FIG. 13-11** Critical loci for a methane-propane-pentane system according to Hadden [Chem. Eng. Prog. Symp. Sec. 7, **49,** *53 (1953)*]. Parameter $W$ is weight fraction propane on a methane-free basis.

and $T$ is in kelvins. Values of $A$ and $B$ for the first four normal aliphatic acids are

| | $A$ | $B$ |
|---|---|---|
| Formic acid | –10.743 | 3083 |
| Acetic acid | –10.421 | 3166 |
| *n*-Propionic acid | –10.843 | 3316 |
| *n*-Butyric acid | –10.100 | 3040 |

As shown by Marek and Standart [*Collect. Czech. Chem. Commun.,* **19,** 1074 (1954)], it is preferable to correlate and use liquid-phase activity coefficients for the dimerizing component by considering separately the partial pressures of the monomer and dimer. For example, for a binary system of components 1 and 2, when only compound 1 dimerizes in the vapor phase, the following equations apply if an ideal gas is assumed:

$$P_1 = P_D + P_M \tag{13-6}$$

$$y_1 = \frac{P_M + 2P_D}{P} \tag{13-7}$$

These equations when combined with Eq. (13-5) lead to the following equations for liquid-phase activity coefficients in terms of measurable quantities:

$$\gamma_1 = \frac{Py_1}{P_1^{\text{sat}}x_1}\left\{\frac{1+(1+4K_DP_1^{\text{sat}})^{0.5}}{1+[1+4K_DPy_1(2-y_1)]^{0.5}}\right\} \tag{13-8}$$

$$\gamma_2 = \frac{Py_1}{P_2^{\text{sat}}x_2}\left(\frac{2(1-y_1+[1+4K_DPy_1(2-y_1)]^{0.5}}{(2-y_1)\{1+[1+4K_DPy_1(2-y_1)]^{0.5}\}}\right) \tag{13-9}$$

Detailed procedures, including computer programs for evaluating binary-interaction parameters from experimental data and then using these parameters to predict $K$ values and phase equilibria, are given in terms of the UNIQUAC equation by Prausnitz et al. (*Computer Calculations for Multicomponent Vapor-Liquid and Liquid-Liquid Equilibria,* Prentice-Hall, Englewood Cliffs, N.J., 1980) and in terms of the UNIFAC group contribution method by Fredenslund, Gmehling, and Rasmussen (*Vapor-Liquid Equilibria Using UNIFAC,* Elsevier, Amsterdam, 1980). Both use the method of Hayden and O'Connell [*Ind. Eng. Chem. Process Des. Dev.,* **14,** 209 (1975)] to compute $\hat{\Phi}_i^V$ in Eq. (13-4). When the system temperature is greater than the critical

*Abstracted from Gmehling and Onken, *Vapor-Liquid Equilibrium Data Collection,* DECHEMA Chemistry Data ser., vol. 1 (parts 1–10), Frankfurt, 1977.

†Antoine equation is $\log P^{sat} = A - B/(T + C)$ with $P^{sat}$ in torr and $T$ in °C.

NOTE: To convert degrees Celsius to degrees Fahrenheit, °F = 1.8°C + 32. To convert cubic centimeters per gram-mole to cubic feet per pound-mole, multiply by 0.016.

temperature of one or more components in the mixture, Prausnitz et al. use a Henry's law constant $H_{i,M}$ in place of the product $\gamma_i^L \Phi_i^L$ in Eq. (13-4). Otherwise $\Phi_i^L$ is evaluated from vapor pressure data with a Poynting saturated-vapor fugacity correction. When the total pressure is less than about 202.6 kPa (2 atm) and all components in the mixture have a critical temperature that is greater than the system temperature, then $\Phi_i^L = P_i^{sat}/P$ and $\Phi_i^V = 1.0$. Equation (13-4) then reduces to

$$K_i = \frac{\gamma_i^L P_i^{sat}}{P} \tag{13-10}$$

which is referred to as a modified Raoult's law $K$ value. If, furthermore, the liquid phase is ideal, then $\gamma_i^L = 1.0$ and

$$K_i = \frac{P_i^{sat}}{P} \tag{13-11}$$

which is referred to as a Raoult's law $K$ value that is dependent solely on the vapor pressure $P_i^{sat}$ of the component in the mixture. The UNIFAC method is being periodically updated with new group contributions; e.g., see Hansen et al. [*Ind. Eng. Chem. Res.*, **30,** 2352 (1991)].

# SINGLE-STAGE EQUILIBRIUM FLASH CALCULATIONS

The simplest continuous distillation process is the adiabatic single-stage equilibrium flash process pictured in Fig. 13-16. Feed temperature and the pressure drop across the valve are adjusted to vaporize the feed to the desired extent, while the drum provides disengaging space to allow the vapor to separate from the liquid. The expansion across the valve is at constant enthalpy, and this fact can be used to calculate $T_2$ (or $T_1$ to give a desired $T_2$).

A degrees-of-freedom analysis indicates that the variables subject to the designer's control are $C + 3$ in number. The most common way to use these is to specify the feed rate, composition, and pressure ($C + 1$ variables) plus the drum temperature $T_2$ and pressure $P_2$. This operation will give one point on the *equilibrium flash curve* shown in Fig. 13-17. This curve shows the relation at constant pressure between the fraction $V/F$ of the feed flashed and the drum temperature. The temperature at $V/F = 0.0$ when the first bubble of vapor is about to form (saturated liquid) is the *bubble point* temperature of the feed mixture, and the value at $V/F = 1.0$ when the first droplet of liquid is about to form (saturated vapor) is the *dew point* temperature.

## BUBBLE POINT AND DEW POINT

For a given drum pressure and feed composition, the bubble and dew point temperatures bracket the temperature range of the equilibrium flash. At the bubble point temperature, the total vapor pressure exerted by the mixture becomes equal to the confining drum pressure, and it follows that $\sum y_i = 1.0$ in the bubble formed. Since $y_i = K_i x_i$ and since the $x_i$'s still equal the feed compositions (denoted by $z_i$), calculation of the bubble point temperature involves a trial-and-error search for the temperature which, at the specified pressure, makes $\sum K_i z_i = 1.0$. If instead the temperature is specified, one can find the bubble point pressure that satisfies this relationship.

At the dew point temperature $y_i$ still equals $z_i$ and the relationship $\sum x_i = \sum z_i/K_i = 1.0$ must be satisfied. As in the case of the bubble point, a trial-and-error search for the dew point temperature at a specified pressure is involved. Or, if the temperature is specified, the dew point pressure can be calculated.

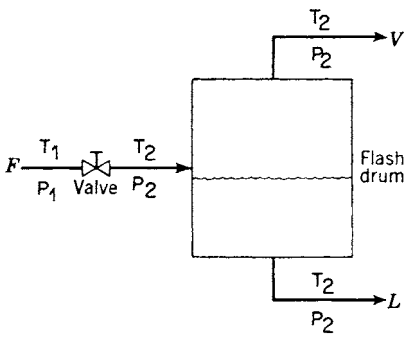

**FIG. 13-16** Equilibrium flash separator.

## ISOTHERMAL FLASH

The calculation for a point on the flash curve that is intermediate between the bubble point and the dew point is referred to as an isothermal flash calculation because $T_2$ is specified. Except for an ideal binary mixture, procedures for calculating an isothermal flash are iterative. A popular and recommended method is the following, due to Rachford and Rice [*J. Pet. Technol.*, **4**(10), sec. 1, p. 19, and sec. 2, p. 3 (October 1952)]. The component mole balance ($Fz_i = Vy_i + Lx_i$), phase distribution relation ($K_i = y_i/x_i$), and total mole balance ($F = V + L$) can be combined to give

$$x_i = \frac{z_i}{1 + (V/F)(K_i - 1)} \tag{13-12}$$

$$y_i = \frac{K_i z_i}{1 + (V/F)(K_i - 1)} \tag{13-13}$$

Since $\sum x_i - \sum y_i = 0$,

$$f\left(\frac{V}{F}\right) = \sum_i \frac{z_i(1 - K_i)}{1 + (V/F)(K_i - 1)} = 0 \tag{13-14}$$

Equation (13-14) is solved iteratively for $V/F$, followed by the calculation of values of $x_i$ and $y_i$ from Eqs. (13-12) and (13-13) and $L$ from the total mole balance. Any one of a number of numerical root-finding procedures such as the Newton-Raphson, secant, false-position, or bisection method can be used to solve Eq. (13-14). Values of $K_i$ are constants if they are independent of liquid and vapor compositions. Then the resulting calculations are straightforward. Otherwise, the $K_i$ values must be periodically updated for composition effects, perhaps

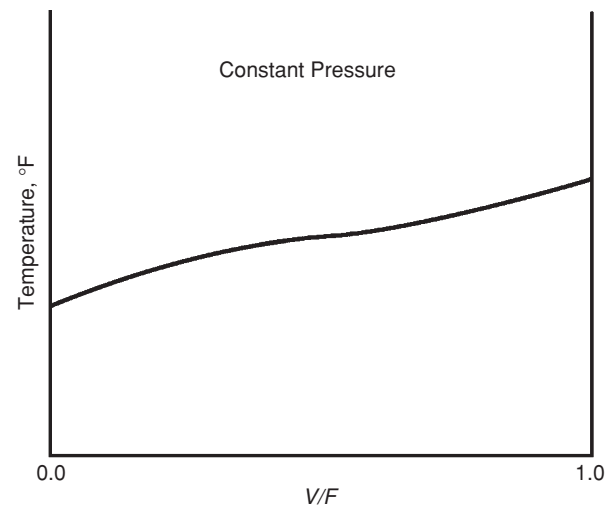

**FIG. 13-17** Equilibrium flash curve.

after each iteration, using prorated values of $x_i$ and $y_i$ from Eqs. (13-12) and (13-13). Generally the iterations are continued until the change in the absolute value of $V/F$ is sufficiently small and until the absolute value of the residual $f(V/F)$ is close to zero. When converged, $\sum x_i$ and $\sum y_i$ will each be very close to a value of 1, and, if desired, $T_1$ can be computed from an energy balance around the valve if no heat exchanger is used. Alternatively, if $T_1$ is fixed, as mentioned earlier, a heat exchanger must be added before, after, or in place of the valve with the required heat duty being calculated from an energy balance. The limits of applicability of Eqs. (13-12) to (13-14) are the bubble point, at which $V = 0$ and $x_i = z_i$, and the dew point, at which $L = 0$ and $y_i = z_i$. At these limits Eq. (13-14) reduces to the bubble point equation

$$\sum_i K_i x_i = 1 \tag{13-15}$$

and the dew point equation, respectively,

$$\sum_i \frac{y_i}{K_i} = 1 \tag{13-16}$$

For a *binary feed,* specification of the flash drum temperature and pressure fixes the equilibrium-phase compositions, which are related to the $K$ values by

$$x_1 = \frac{1 - K_2}{K_1 - K_2} \quad \text{and} \quad y_1 = \frac{K_1 K_2 - K_1}{K_2 - K_1}$$

The mole balance can be rearranged to

$$\frac{V}{F} = \frac{z_1(K_1 - K_2)/(1 - K_2) - 1}{K_1 - 1}$$

If $K_1$ and $K_2$ are functions of temperature and pressure only (ideal solutions), the flash curve can be calculated directly without iteration.

## ADIABATIC FLASH

In Fig. 13-16, if $P_2$ and the feed-stream conditions (that is, $F$, $z_i$, $T_1$, $P_1$) are known, then the calculation of $T_2$, $V$, $L$, $y_i$, and $x_i$ is referred to as an adiabatic flash. In addition to Eqs. (13-12) to (13-14) and the total mole balance, the following energy balance around both the valve and the flash drum combined must be included:

$$H^F F = H^V V + H^L L \tag{13-17}$$

By taking a basis of $F = 1.0$ mol and eliminating $L$ with the total mole balance, Eq. (13-17) becomes

$$f_2\{V, T_2\} = H^F - V(H^V - H^L) - H^L = 0 \tag{13-18}$$

With $T_2$ now unknown, Eq. (13-14) becomes

$$f_1\{V, T_2\} = \sum_i \frac{z_i(1 - K_i)}{1 + V(K_i - 1)} = 0 \tag{13-19}$$

A number of iterative procedures have been developed for solving Eqs. (13-18) and (13-19) simultaneously for $V$ and $T_2$. Frequently, and especially if the feed contains components of a narrow range of volatility, convergence is rapid for a tearing method in which a value of $T_2$ is assumed, Eq. (13-19) is solved iteratively by the isothermal flash procedure, and, using that value of $V$, Eq. (13-18) is solved iteratively for a new approximation of $T_2$, which is then used to initiate the next cycle until $T_2$ and $V$ converge. However, if the feed contains components of a wide range of volatility, it may be best to invert the sequence and assume a value for $V$, solve Eq. (13-19) for $T_2$, solve Eq. (13-18) for $V$, and then repeat the cycle. If the $K$ values and/or enthalpies are sensitive to the unknown phase compositions, it may be necessary to solve Eqs. (13-18) and (13-19) simultaneously by a Newton or other suitable iterative technique. Alternatively, the two-tier method of Boston and Britt [*Comput. Chem. Eng.,* **2,** 109 (1978)], which is also suitable for difficult isothermal flash calculations, may be applied.

## OTHER FLASH SPECIFICATIONS

Flash drum specifications in addition to ($P_2$, $T_2$) and ($P_2$, adiabatic) are possible but must be applied with care, as discussed by Michelsen [*Comp. Chem. Engng.,* **17,** 431 (1993)]. Most computer-aided process design and simulation programs permit a wide variety of flash specifications.

## THREE-PHASE FLASH

Single-stage equilibrium flash calculations become considerably more complex when an additional liquid phase can form, as in mixtures of water with hydrocarbons, water with ethers, and water with higher alcohols (containing four or more carbon atoms). Procedures for computing such situations are referred to as three-phase flash methods, which are given for the general case by Henley and Rosen (*Material and Energy Balance Computations,* Wiley, New York, 1968, chap. 8). When the two liquid phases are almost mutually insoluble, they can be considered separately and relatively simple procedures apply, as discussed by Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1963). Condensation of such mixtures may result in one liquid phase being formed before the other. Computer-aided process design and simulation programs all contain a Gibbs free-energy routine that can compute a three-phase flash by minimization of the Gibbs free energy. Many important and subtle aspects of three-phase flash calculations are discussed by Michelsen [*Fluid Phase Equil.,* **9,** 1, 21 (1982)], McDonald and Floudas [*AIChE J.*, **41,** 1798 (1995)], and Wasylkiewicz et al. [*Ind. Eng. Chem. Research*, **35,** 1395 (1996)].

## COMPLEX MIXTURES

Feed analyses in terms of component compositions are usually not available for complex hydrocarbon mixtures with a final normal boiling point above about 38°C (100°F) (*n*-pentane). One method of handling such a feed is to break it down into pseudocomponents (narrow-boiling fractions) and then estimate the mole fraction and $K$ value for each such component. Edmister [*Ind. Eng. Chem.*, **47,** 1685 (1955)] and Maxwell (*Data Book on Hydrocarbons,* Van Nostrand, Princeton, N.J., 1958) give charts that are useful for this estimation. Once $K$ values are available, the calculation proceeds as described above for multicomponent mixtures. Another approach to complex mixtures is to obtain an American Society for Testing and Materials (ASTM) or true-boiling point (TBP) curve for the mixture and then use empirical correlations to construct the atmospheric-pressure equilibrium flash vaporization (EFV) curve, which can then be corrected to the desired operating pressure. A discussion of this method and the necessary charts is presented in a later subsection Petroleum and Complex-Mixture Distillation.

# GRAPHICAL METHODS FOR BINARY DISTILLATION

Multistage distillation under continuous, steady-state operating conditions is widely used in practice to separate a variety of mixtures. Table 13-5, taken from the study of Mix, Dweck, Weinberg, and Armstrong [*AIChE Symp. Ser.* **76,** 192, 10 (1980)] lists key components along with typical stage requirements to perform the separation for 27 industrial distillation processes. The design of multistage columns can be accomplished by graphical techniques when the feed mixture contains only two components. The *x-y* diagram method developed by McCabe and Thiele [*Ind. Eng. Chem.,* **17,** 605 (1925)] uses only phase equilibrium and mole balance relationships. The method assumes an adiabatic column (no heat losses through the column walls) and constant latent heat for the binary mixture at all compositions (which requires, among other things, equal latent heat for both components). The method is exact only for those systems in which energy effects on vapor and liquid rates leaving the stages are negligible. However, the approach is simple and gives a useful first estimate of the column design which can be refined by using the enthalpy composition diagram method of Ponchon [*Tech. Mod.,* **13,**

**TABLE 13-5 Key Components and Typical Number of (Real) Stages Required to Perform the Separation for Distillation Processes of Industrial Importance**

| Key components | Typical number of trays |
|---|---|
| Hydrocarbon systems | |
| Ethylene-ethane | 73 |
| Propylene-propane | 138 |
| Propyne–1–3-butadiene | 40 |
| 1–3 Butadiene-vinyl acetylene | 130 |
| Benzene-toluene | 34, 53 |
| Benzene-ethyl benzene | 20 |
| Benzene–diethyl benzene | 50 |
| Toluene–ethyl benzene | 28 |
| Toluene-xylenes | 45 |
| Ethyl benzene–styrene | 34 |
| *o*-Xylene-*m*-xylene | 130 |
| Organic systems | |
| Methonol-formaldehyde | 23 |
| Dichloroethane-trichloroethane | 30 |
| Acetic acid–acetic anhydride | 50 |
| Acetic anhydride–ethylene diacetate | 32 |
| Vinyl acetate–ethyl acetate | 90 |
| Ethylene glycol–diethylene glycol | 16 |
| Cumene-phenol | 38 |
| Phenol-acetophenone | 39, 54 |
| Aqueous systems | |
| HCN-water | 15 |
| Acetic acid–water | 40 |
| Methanol-water | 60 |
| Ethanol-water | 60 |
| Isopropanol-water | 12 |
| Vinyl acetate–water | 35 |
| Ethylene oxide–water | 50 |
| Ethylene glycol–water | 16 |

20, 55 (1921)] and Savarit [*Arts Metiers,* **65,** 142, 178, 241, 266, 307 (1922)]. This approach uses the energy balance in addition to mole balance and phase equilibrium relationships and is rigorous when enough calorimetric data are available to construct the diagram without assumptions.

With the widespread availability of computers, the preferred approach to design is equation-based since it provides answers rapidly and repeatedly without the tedium of redrawing graphs. Such an approach is especially useful for sensitivity analysis, which gives insight into how a design changes under variations or uncertainty in design parameters such as thermodynamic properties; feed flow rate, composition, temperature, and pressure; and desired product compositions. Nevertheless, diagrams are useful for quick approximations, for interpreting the results of equation-based methods, and for demonstrating the effect of various design variables. The *x-y* diagram is the most convenient for these purposes, and its use is developed in detail here. The use of the enthalpy composition diagram is given by Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1963) and Henley and Seader (*Equilibrium-Stage Separation Operations in Chemical Engineering,* Wiley, New York, 1981). An approximate equation-based approach based on the enthalpy composition diagram was proposed by Peters [*Ind. Eng. Chem.,* **14,** 476 (1922)] with additional aspects developed later by others. Doherty and Malone (*Conceptual Design of Distillation Systems*, McGraw-Hill, 2001, app. A) describe this method for binary mixtures and extend it to multicomponent systems. The approach is exact when the enthalpy composition surfaces are linear.

## PHASE EQUILIBRIUM DIAGRAMS

Three types of binary phase equilibrium curves are shown in Fig. 13-18. The *y-x* diagram is almost always plotted for the component that is the more volatile (denoted by the subscript 1) in the region where distillation is to take place. Curve *A* shows the common case in which component 1 remains more volatile over the entire composition range. Curve *B* is typical of many systems (e.g., ethanol-water) in which the

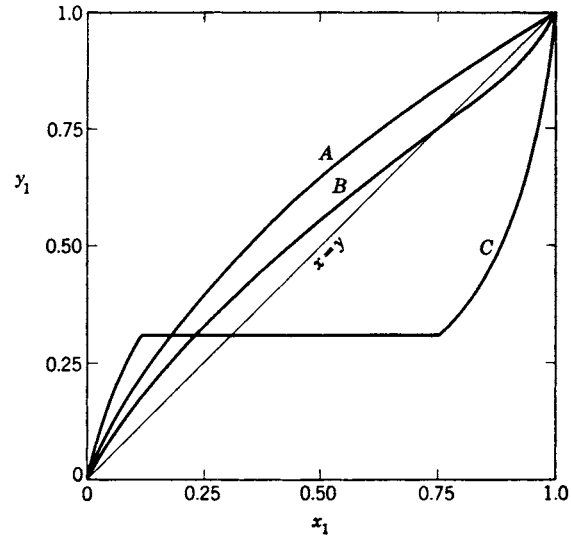

**FIG. 13-18** Typical binary equilibrium curves. Curve *A,* system with normal volatility. Curve *B,* system with homogeneous azeotrope (one liquid phase). Curve *C,* system with heterogeneous azeotrope (two liquid phases in equilibrium with one vapor phase).

component that is more volatile at low values of $x_1$ becomes less volatile than the other component at high values of $x_1$. The vapor and liquid compositions are identical for the homogeneous azeotrope where curve *B* crosses the 45° diagonal (that is, $x_1 = y_1$). A heterogeneous azeotrope is formed by curve *C,* in which there are two equilibrium liquid phases and one equilibrium vapor phase.

An azeotrope limits the separation that can be obtained between components by simple distillation. For the system described by curve *B,* the maximum overhead-product concentration that could be obtained from a feed with $z_1 = 0.25$ is the azeotropic composition. Similarly, a feed with $x_1 = 0.9$ could produce a bottom-product composition no lower than the azeotrope.

The phase rule permits only two variables to be specified arbitrarily in a binary two-phase mixture at equilibrium. Consequently, the curves in Fig. 13-18 can be plotted at either constant temperature or constant pressure but not both. The latter is more common, and data in Table 13-1 correspond to that case. The *y-x* diagram can be plotted in mole, weight, or volume fractions. The units used later for the phase flow rates must, of course, agree with those used for the equilibrium data. Mole fractions, which are almost always used, are applied here.

It is sometimes permissible to assume constant *relative volatility* to approximate the equilibrium curve quickly. Then by applying Eq. (13-2) to components 1 and 2,

$$\alpha = \frac{K_1}{K_2} = \frac{y_1 x_2}{x_1 y_2}$$

which can be rewritten as (using $x_2 = 1 - x_1$ and $y_2 = 1 - y_1$)

$$y_1 = \frac{x_1 \alpha}{1 + (\alpha - 1) x_1} \tag{13-20}$$

With a constant value for $\alpha$ this equation provides a simple, approximate expression for representing the equilibrium $y = x$ diagram. Doherty and Malone (*Conceptual Design of Distillation Systems,* McGraw-Hill, 2001, sec. 2.3) discuss this approximation in greater detail and give a selection of binary mixtures for which the approximation is reasonable. At a constant pressure of 1 atm these include benzene + toluene, $\alpha = 2.34$; benzene + *p*-xylene, $\alpha = 4.82$; and hexane + *p*-xylene, $\alpha = 7.00$.

## McCABE-THIELE METHOD

**Operating Lines** The McCabe-Thiele method is based upon representation of the material balance equations as operating lines on the *y-x* diagram. The lines are made straight by the assumption of *constant molar overflow*, which eliminates the need for an energy balance. The liquid-phase flow rate is assumed to be constant from tray to tray in each section of the column between addition (feed) and withdrawal (product) points. If the liquid rate is constant, the vapor rate must also be constant.

The constant-molar-overflow assumption rests on several underlying thermodynamic assumptions. The most important one is equal molar heats of vaporization for the two components. The other assumptions are adiabatic operation (no heat leaks) and no heat of mixing or sensible heat effects. These assumptions are most closely approximated for close-boiling isomers. The result of these assumptions on the calculation method can be illustrated with Fig. 13-19, which shows two material balance envelopes cutting through the top section (above the top feed stream or sidestream) of the column. If the liquid flow rate $L_{n+1}$ is assumed to be identical to $L_{n-1}$, then $V_n = V_{n-2}$ and the component material balance for both envelopes 1 and 2 can be represented by

$$y_n = \left(\frac{L}{V}\right)x_{n+1} + \frac{Dx_D}{V} \tag{13-21}$$

where $y$ and $x$ have a stage subscript $n$ or $n+1$, but $L$ and $V$ need be identified only with the section of the column to which they apply. Equation (13-21) has the analytical form of a straight line where $L/V$ is the slope and $Dx_D/V$ is the $y$ intercept at $x = 0$.

The effect of a sidestream withdrawal point is illustrated by Fig. 13-20. The material balance equation for the column section below the sidestream is

$$y_n = \frac{L'}{V'}x_{n+1} + \frac{Dx_D + Sx_S}{V'} \tag{13-22}$$

where the primes designate the $L$ and $V$ below the sidestream. Since the sidestream must be a saturated phase, $V = V'$ if a liquid sidestream is withdrawn and $L = L'$ if it is a vapor.

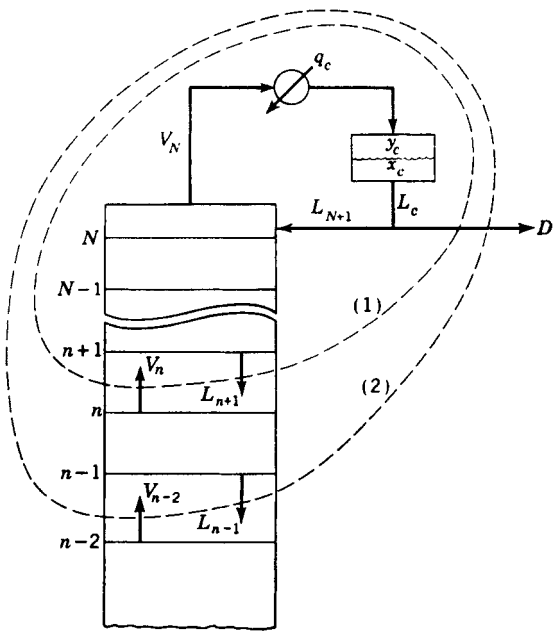

**FIG. 13-19** Two material balance envelopes in the top section of a distillation column.

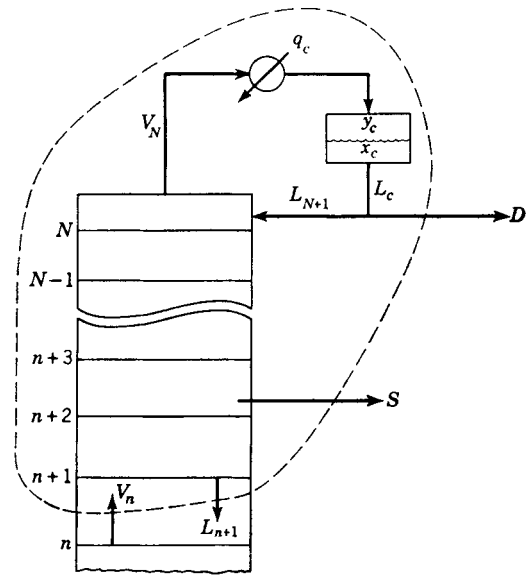

**FIG. 13-20** Material balance envelope which contains two external streams $D$ and $S$, where $S$ represents a sidestream product withdrawn above the feed plate.

If the sidestream in Fig. 13-20 is a feed (not necessarily a saturated liquid or vapor), the balance for the section below the feed becomes

$$y_n = \frac{L'}{V'}x_{n+1} + \frac{Dx_D - Fz_F}{V'} \tag{13-23}$$

Similar equations can be written for the bottom section of the column. For the envelope shown in Fig. 13-21,

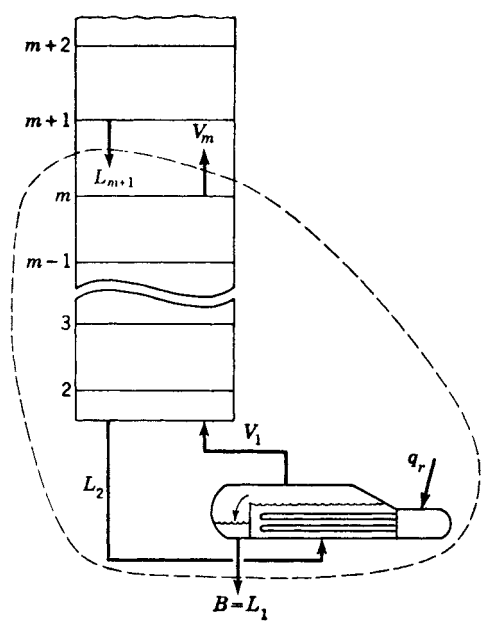

**FIG. 13-21** Material balance envelope around the bottom end of the column. The partial reboiler is equilibrium stage 1.

$$y_m = \frac{L'}{V'} x_{m+1} - \frac{Bx_B}{V'} \tag{13-24}$$

where the subscript $m$ is used to identify the stage number in the bottom section.

Equations such as (13-21) through (13-24), when plotted on the $y$-$x$ diagram, furnish a set of *operating lines.* A point on an operating line represents two *passing streams,* and the operating line itself is the locus of all possible pairs of passing streams within the column section to which the line applies.

An operating line can be located on the $y$-$x$ diagram if (1) two points on the line are known or (2) one point and the slope are known. The known points on an operating line are usually its intersection with the $y$-$x$ diagonal and/or its intersection with another operating line.

The slope $L/V$ of the operating line is termed the *internal reflux ratio.* This ratio in the operating line equation for the top section of the column [see Eq. (13-21)] is related to the *external reflux ratio* $R = L_{N+1}/D$ by

$$\frac{L}{V} = \frac{L_{N+1}}{V_N} = \frac{RD}{(1+R)D} = \frac{R}{1+R} \tag{13-25}$$

when the reflux stream $L_{N+1}$ is a saturated liquid.

**Thermal Condition of the Feed** The slope of the operating line changes whenever a feed stream or a sidestream is passed. To calculate this change, it is convenient to introduce a quantity $q$ which is defined by the following equations for a feed stream $F$:

$$L' = L + qF \tag{13-26}$$

$$V = V' + (1-q)F \tag{13-27}$$

The primes denote the streams below the stage to which the feed is introduced. The value of $q$ is a measure of the thermal condition of the feed and represents the moles of saturated liquid formed in the feed stage per mole of feed. The value of $q$ for a particular feed can be estimated from

$$q = \frac{\text{energy to convert 1 mol of feed to saturated vapor}}{\text{molar heat of vaporization}}$$

It takes on the following values for various thermal conditions of the feed:

| | |
|---|---|
| Subcooled liquid feed: | $q > 1$ |
| Saturated liquid feed: | $q = 1$ |
| Partially flashed feed: | $0 < q < 1$ |
| Saturated vapor feed: | $q = 0$ |
| Superheated vapor feed: | $q < 0$ |

Equations analogous to (13-26) and (13-27) can be written for a sidestream, but the value of $q$ will be either 1 or 0 depending upon whether the sidestream is taken from the liquid or the vapor stream.

The quantity $q$ can be used to derive the "$q$ line equation" for a feed stream or a sidestream. The $q$ line is the locus of all points of intersection of the two operating lines, which meet at the feed stream or sidestream stage. This intersection must occur along that section of the $q$ line between the equilibrium curve and the $y = x$ diagonal. At the point of intersection, the same $y, x$ point must satisfy both the operating line equation above the feed stream (or sidestream) stage and the one below the feed stream (or sidestream) stage. Subtracting one equation from the other gives for a feed stage

$$(V - V')y = (L - L')x + Fz_F$$

which, when combined with Eqs. (13-26) and (13-27), gives the $q$ line equation

$$y = \frac{q}{q-1} x - \frac{z_F}{q-1} \tag{13-28}$$

A $q$ line construction for a partially flashed feed is given in Fig. 13-22. It is easily shown that the $q$ line must intersect the diagonal at $z_F$.

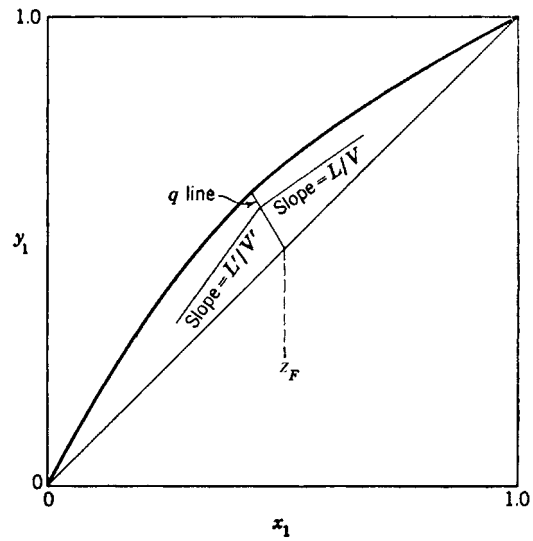

**FIG. 13-22** Typical intersection of the two operating lines at the $q$ line for a feed stage. The $q$ line shown is for a partially flashed feed.

The slope of the $q$ line is $q/(q-1)$. All five $q$ line cases are shown in Fig. 13-23. Note that when $q = 1$, the $q$ line has infinite slope and is vertical.

The derivation of Eq. (13-28) assumes a single-feed column and no sidestream. However, the same result is obtained for other column configurations. Typical $q$ line constructions for sidestream stages are shown in Fig. 13-24. Note that the $q$ line for a sidestream must always intersect the diagonal at the composition ($y_S$ or $x_S$) of the sidestream. Figure 13-24 also shows the intersections of the operating lines with the diagonal construction line. The top operating line must always intersect the diagonal at the overhead-product composition $x_D$. This can be shown by substituting $y = x$ in Eq. (13-21) and using $V - L = D$ to reduce the resulting equation to $x = x_D$. Similarly (except for columns in which open steam is introduced at the bottom), the bottom operating line must always intersect the diagonal at the bottom-product composition $x_B$.

**Equilibrium-Stage Construction** Use of the equilibrium curve and the operating lines to "step off" equilibrium stages is illustrated in Fig. 13-25. The plotted portions of the equilibrium curve (curved) and the operating line (straight) cover the composition range existing in the column section shown in the lower right-hand corner of the figure. If $y_n$ and $x_n$ represent the compositions (in terms of the more volatile

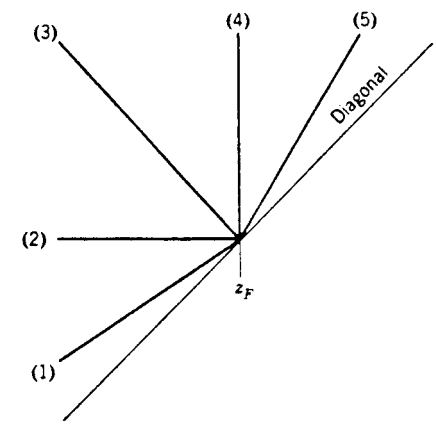

**FIG. 13-23** All five cases of $q$ lines: (1) superheated vapor feed, (2) saturated vapor feed, (3) partially vaporized feed, (4) saturated liquid feed, and (5) subcooled liquid feed. Slope of $q$ line is $q/(q-1)$.

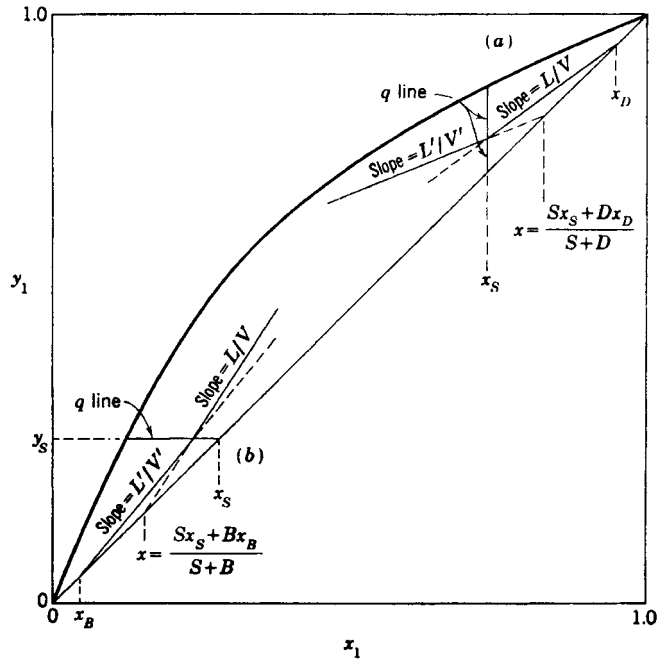

**FIG. 13-24** Typical construction for a sidestream showing the intersection of the two operating lines with the $q$ line and with the $x$-$y$ diagonal. (*a*) Liquid sidestream near the top of the column. (*b*) Vapor sidestream near the bottom of the column.

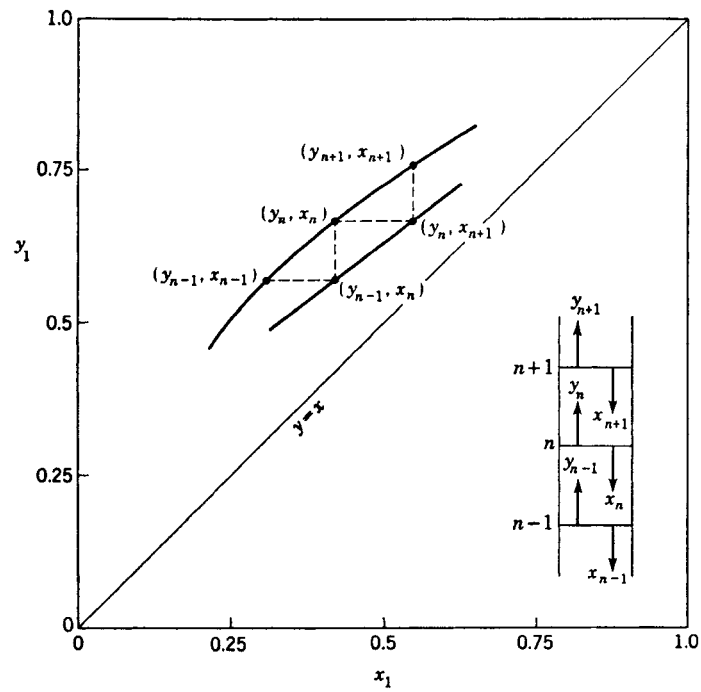

**FIG. 13-25** Illustration of how equilibrium stages can be located on the $x$-$y$ diagram through the alternating use of the equilibrium curve and the operating line.

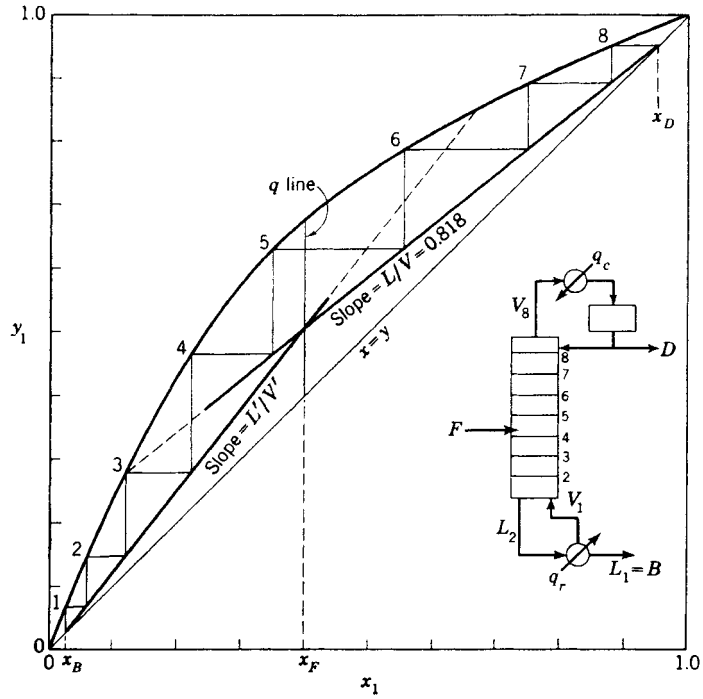

**FIG. 13-26** Construction for a column with a bubble point feed, a total condenser, and a partial reboiler.

component) of the equilibrium vapor and liquid leaving stage $n$, then point $(y_n, x_n)$ on the equilibrium curve must represent the equilibrium stage $n$. The operating line is the locus for compositions of all possible pairs of passing streams within the section, and therefore a horizontal line (dashed) at $y_n$ must pass through the point $(y_n, x_{n+1})$ on the operating line since $y_n$ and $x_{n+1}$ represent passing streams. Likewise, a vertical line (dashed) at $x_n$ must intersect the operating line at point $(y_{n-1}, x_n)$. The equilibrium stages above and below stage $n$ can be located by a vertical line through $(y_n, x_{n+1})$ to find $(y_{n+1}, x_{n+1})$ and a horizontal line through $(y_{n-1}, x_n)$ to find $(y_{n-1}, x_{n-1})$. This procedure can be repeated by alternating the use of equilibrium and operating lines upward or downward through the column to find the total number of equilibrium stages.

**Total Column Construction** The graphical construction for an entire column is shown in Fig. 13-26. The process, pictured in the lower right-hand corner of the diagram, is an existing column with a number of actual trays equivalent to eight equilibrium stages. A partial reboiler (equivalent to an equilibrium stage) and a total condenser are used. This column configuration has $C + 2N + 9$ design variables (degrees of freedom) which must be specified to define one unique operation [see subsection Degrees of Freedom and Design Variables, especially Fig. 13-62 and Eq. (13-111)]. These may be used as follows as the basis for a graphical solution:

| Specifications | Degrees of freedom |
|---|---|
| Stage pressures (including reboiler) | $N$ |
| Condenser pressure | 1 |
| Stage heat leaks (except reboiler) | $N - 1$ |
| Pressure and heat leak in reflux divider | 2 |
| Feed stream | $C + 2$ |
| Feed-stage location | 1 |
| Total number of stages $N$ | 1 |
| One overhead purity | 1 |
| Reflux temperature | 1 |
| Eternal reflux ratio | 1 |
| | $C + 2N + 9$ |

Pressures can be specified at any level below the safe working pressure of the column. The condenser pressure will be set at 275.8 kPa (40 psia), and all pressure drops within the column will be neglected. The equilibrium curve in Fig. 13-26 represents data at that pressure. All heat leaks will be assumed to be zero. The feed composition is 40 mol % of the more volatile component 1, and the feed rate is 0.126 kg·mol/s (1000 lb·mol/h) of saturated liquid ($q = 1$). The feed-stage location is fixed at stage 4 and the total number of stages at eight.

The overhead purity is specified as $x_D = 0.95$. The reflux temperature is the bubble point temperature (saturated reflux), and the external reflux ratio is set at $R = 4.5$.

Answers are desired to the following two questions. First, what bottom-product composition $x_B$ will the column produce under these specifications? Second, what is the value of the top vapor rate $V_N$ in this operation, and will it exceed the maximum vapor rate capacity for this column, which is assumed to be 0.252 kg·mol/s (2000 lb·mol/h) at the top-tray conditions?

The solution is started by using Eq. (13-25) to convert the external reflux ratio of 4.5 to an internal reflux ratio of $L/V = 0.818$. The distillate composition $x_D = 0.95$ is then located on the diagonal, and the upper operating line is drawn as shown in Fig. 13-26.

If the $x_B$ value were known, the bottom operating line could be immediately drawn from the $x_B$ value on the diagonal up to its required intersection point with the upper operating line on the feed $q$ line. In this problem, since the number of stages is fixed, the value of $x_B$ which gives a lower operating line that will require exactly eight stages must be found by trial and error. An $x_B$ value is assumed, and the resulting lower operating line is drawn. The stages can be stepped off by starting from either $x_B$ or $x_D$; $x_B$ was used in this case.

Note that the lower operating line is used until the fourth stage is passed, at which time the construction switches to the upper operating line. This is necessary because the vapor and liquid streams passing each other between the fourth and fifth stages must fall on the upper line.

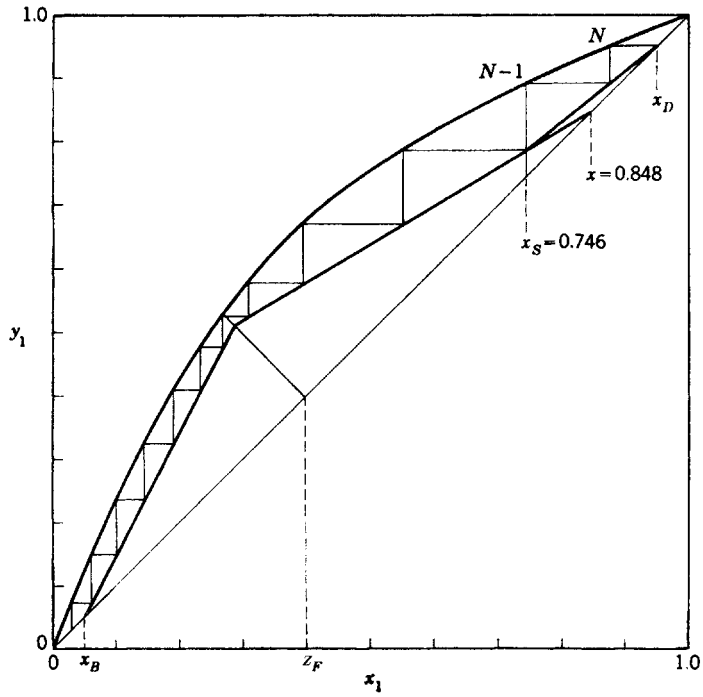

**FIG. 13-27** Graphical solution for a column with a partially flashed feed, a liquid sidestream, and a total condenser.

The $x_B$ that requires exactly eight equilibrium stages is $x_B = 0.026$. An overall component balance gives $D = 0.051$ kg·mol/s (405 lb·mol/h). Then

$$V_N = V_B = L_{N+1} + D = D(R + 1) = 0.051(4.5 + 1.0)$$

$$= 0.280 \text{ kg·mol/s (2230 lb·mol/h)}$$

which exceeds the column capacity of 0.252 kg·mol/s (2007 lb·mol/h). This means that the column cannot provide an overhead-product yield of 40.5 percent at 95 percent purity. Either the purity specification must be reduced, or we must be satisfied with a lower yield. If the distillate specification ($x_D = 0.95$) is retained, the reflux rate must be reduced. This will cause the upper operating line to pivot upward around its fixed point of $x_D = 0.95$ on the diagonal. The new intersection of the upper line with the $q$ line will lie closer to the equilibrium curve. The $x_B$ value must then move upward along the diagonal because the eight stages will not "reach" as far as before. The higher $x_B$ composition will reduce the recovery of component 1 in the 95 percent overhead product.

Another entire column with a partially vaporized feed, a liquid sidestream rate equal to $D$ withdrawn from the second stage from the top, and a total condenser is shown in Fig. 13-27. The specified compositions are $z_F = 0.40$, $x_B = 0.05$, and $x_D = 0.95$. The specified $L/V$ ratio in the top section is 0.818. These specifications permit the top operating line to be located and the two top stages stepped off to determine the liquid sidestream composition $x_s = 0.746$. The operating line below the sidestream must intersect the diagonal at the "blend" of the sidestream and the overhead stream. Since $S$ was specified to be equal to $D$ in rate, the intersection point is

$$x = \frac{(1.0)(0.746) + (1.0)(0.95)}{1.0 + 1.0} = 0.848$$

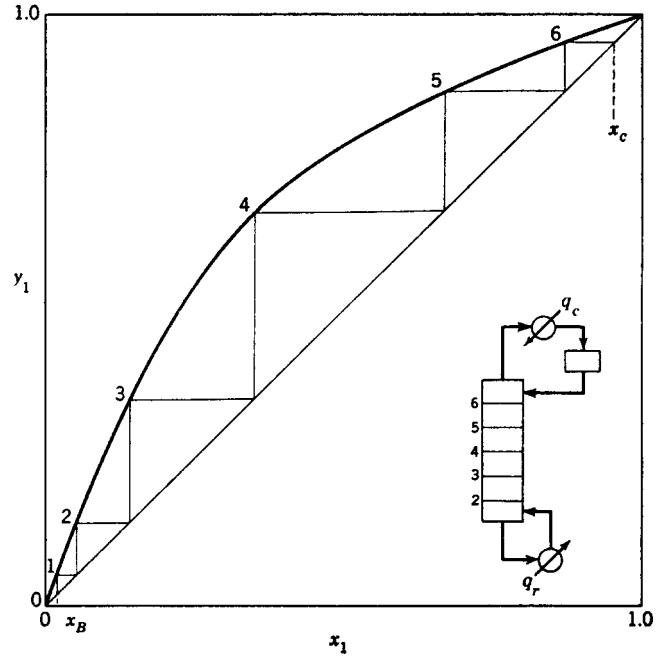
This point plus the point of intersection of the two operating lines on the sidestream $q$ line (vertical at $x_s = 0.746$) permits the location of the middle operating line. (The slope of the middle operating line could also have been used.) The lower operating line must run from the specified $x_B$ value on the diagonal to the required point of intersection on the feed $q$ line. The stages are stepped off from the top down in this case. The sixth stage from the top is the feed stage, and a total of about 11.4 stages are required to reach the specified $x_B = 0.05$.

Fractional equilibrium stages have meaning. The 11.4 will be divided by a tray efficiency, and the rounding up to an integral number of actual trays should be done after that division. For example, if the average tray efficiency for the process modeled in Fig. 13-27 is 80 percent, then the number of actual trays required is 11.4/0.8 = 14.3, which is rounded up to 15.

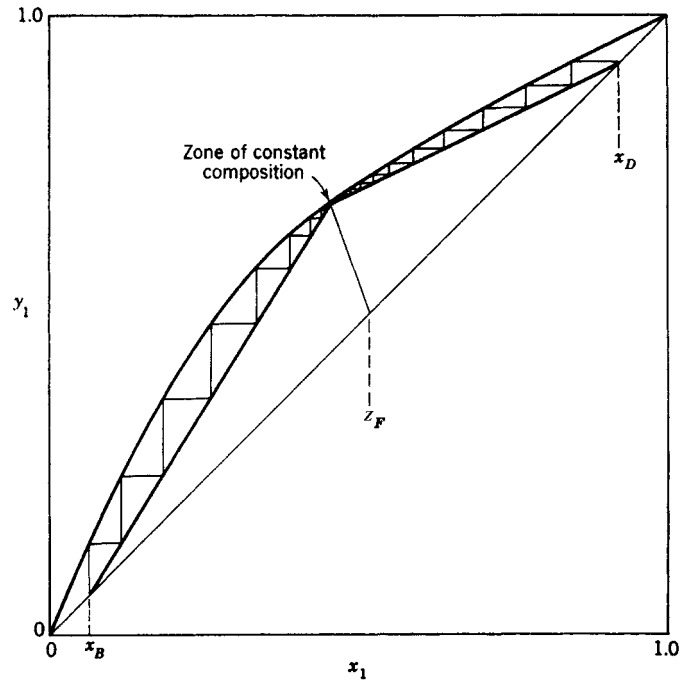
**Feed-Stage Location** The *optimum* feed-stage location is that location which, with a given set of other operating specifications, will result in the widest separation between $x_D$ and $x_B$ for a given number of stages. Or, if the number of stages is not specified, the optimum feed location is the one that requires the lowest number of stages to accomplish a specified separation between $x_D$ and $x_B$. Either of these criteria will always be satisfied if the operating line farthest from the equilibrium curve is used in each step, as in Fig. 13-26.

It can be seen from Fig. 13-26 that the optimum feed location would have been the fifth tray for that operation. If a new column were being designed, that should be the designer's choice. However, when an existing column is being modeled, the feed stage on the diagram should correspond as closely as possible to the actual feed tray in the column. It can be seen that a badly mislocated feed (a feed that requires one to remain with an operating line until it closely approaches the equilibrium curve) can be very wasteful insofar as the effectiveness of the stages is concerned.

**Minimum Stages** A column operating at total reflux is represented in Fig. 13-28*a*. Enough material has been charged to the column to fill the reboiler, the trays, and the overhead condensate drum to their working levels. The column is then operated with no feed and with all the condensed overhead stream returned as reflux ($L_{N+1} = V_N$ and $D = 0$). Also all the liquid reaching the reboiler is



(a)



(b)

**FIG. 13-28** McCabe-Thiele diagrams for limiting cases. (*a*) Minimum stages for a column operating at total reflux with no feeds or products. (*b*) Minimum reflux for a binary system of normal volatility.

vaporized and returned to the column as vapor. Since $F$, $D$, and $B$ are all zero, $L_{n+1} = V_n$ at all points in the column. With a slope of unity ($L/V = 1.0$), the operating line must coincide with the diagonal throughout the column. Total reflux operation gives the minimum number of stages required to effect a specified separation between $x_B$ and $x_D$.

**Minimum Reflux** The minimum reflux ratio is defined as that ratio which if decreased by an infinitesimal amount would require an infinite number of stages to accomplish a specified separation between two components. The concept has meaning only if a separation between two components is specified and the number of stages is not specified. Figure 13-28*b* illustrates the minimum reflux condition. As the reflux ratio is reduced, the two operating lines swing upward, pivoting around the specified $x_B$ and $x_D$ values, until one or both touch the equilibrium curve. For equilibrium curves shaped like the one shown, the contact occurs at the feed $q$ line, resulting in a *feed pinch point*. Often an equilibrium curve will dip down closer to the diagonal at higher compositions. In such cases, the upper operating line may make contact before its intersection point on the $q$ line reaches the equilibrium curve, resulting in a *tangent pinch point*. Wherever the contact appears, the intersection of the operating line with the equilibrium curve produces a pinch point which contains a very large number of stages, and a zone of constant composition is formed (see Doherty and Malone, 2001, chap. 3 and sec. 4.6 for additional information).

**Intermediate Reboilers and Condensers** When a large temperature difference exists between the ends of the column due to a wide boiling point difference between the components, intermediate reboilers and/or condensers may be used to add heat at a lower temperature, or remove heat at a higher temperature, respectively. [A distillation column of this type is shown in *Perry's Chemical Engineers' Handbook*, 7th ed. (1986), Fig. 13-2*a*.] A column operating with an intermediate reboiler and an intermediate condenser in addition to a regular reboiler and a condenser is illustrated with the solid lines in Fig. 13-29. The dashed lines correspond to simple distillation with only a bottoms reboiler and an overhead condenser. Total boiling and condensing heat loads are the same for both columns. As shown by Kayihan [*AIChE Symp. Ser.* **76,** 192, 1 (1980)], the addition of intermediate reboilers and intermediate condensers increases thermodynamic efficiency but requires additional stages, as is clear from the positions of the operating lines in Fig. 13-29.

**Optimum Reflux Ratio** The general effect of the operating reflux ratio on fixed costs, operating costs, and the sum of these is shown in Fig. 13-30. In ordinary situations, the minimum on the total cost curve will generally occur at an operating reflux ratio in the interval 1.1 to 2 times the minimum value. Generally, the total cost curve rises slowly from its minimum value as the operating reflux ratio increases, and very steeply as the operating reflux ratio decreases. In the absence of a detailed cost analysis for the specific separation of interest, it is recommended to select operating reflux ratios closer to 1.5 to 2.0 times the minimum value (see Doherty and Malone, 2001, chap. 6 for additional discussion).

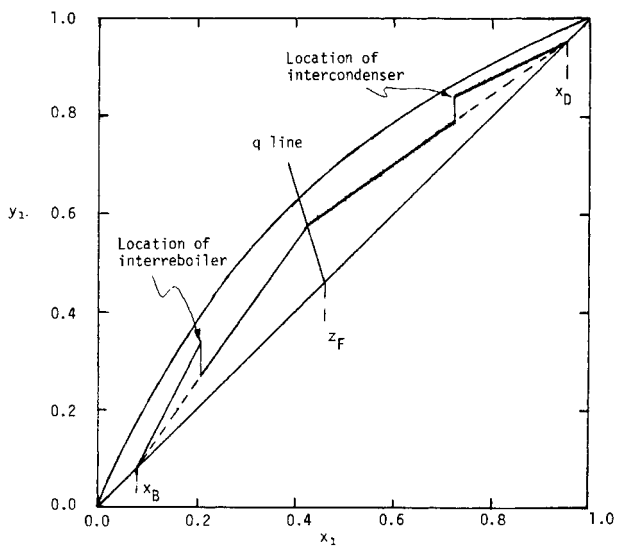


**FIG. 13-29** McCabe-Thiele diagram for columns with and without an intermediate reboiler and an intermediate condenser.

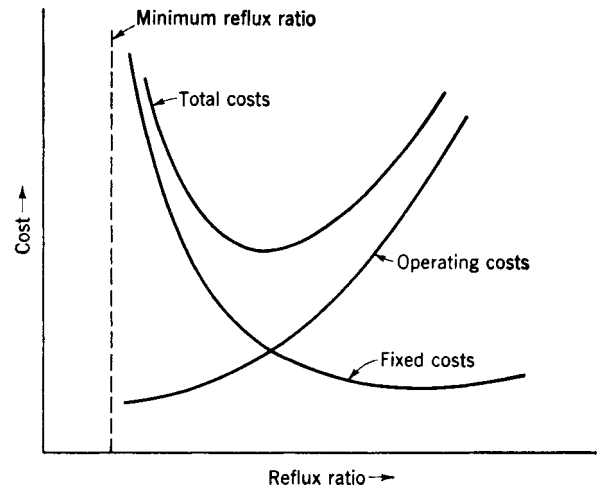

**FIG. 13-30** Location of the optimum reflux for a given feed and specified separation.

**Difficult Separations** Some binary separations may pose special problems because of extreme purity requirements for one or both

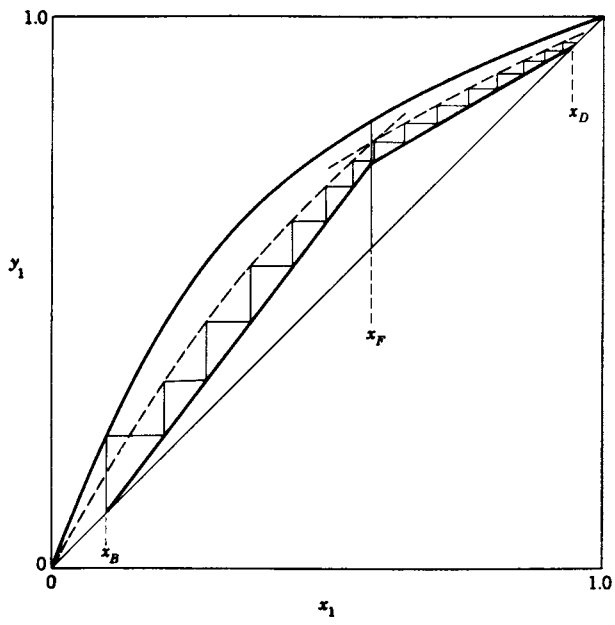

**FIG. 13-31** Application of a 50 percent Murphree vapor-phase efficiency to each stage (excluding the reboiler) in the column. Each step in the diagram corresponds to an actual stage.

products or because of a relative volatility close to 1. The $y$-$x$ diagram is convenient for stepping off stages at extreme purities if it is plotted on log-log paper. However, such cases are best treated by equation-based design methods.

**Equation-Based Design Methods** Exact design equations have been developed for mixtures with constant relative volatility. Minimum stages can be computed with the Fenske equation, minimum reflux from the Underwood equation, and the total number of stages in each section of the column from either the Smoker equation (*Trans. Am. Inst. Chem. Eng.,* **34,** 165 (1938); the derivation of the equation is shown, and its use is illustrated by Smith, op. cit.), or Underwood's method. A detailed treatment of these approaches is given in Doherty and Malone (op. cit., chap. 3). Equation-based methods have also been developed for nonconstant relative volatility mixtures (including nonideal and azeotropic mixtures) by Julka and Doherty [*Chem. Eng. Sci.*, **45,** 1801 (1990); *Chem. Eng. Sci.*, **48,** 1367 (1993)], and Fidkowski et al. [*AIChE J.*, **37,** 1761 (1991)]. Also see Doherty and Malone (op. cit., chap. 4).

**Stage Efficiency** The use of the *Murphree plate efficiency* is particularly convenient on $y$-$x$ diagrams. The Murphree efficiency is defined for the vapor phase as

$$E^{MV} = \frac{y_n - y_{n-1}}{y_n^* - y_{n-1}} \tag{13-29}$$

where $y_n^*$ is the composition of the vapor that would be in equilibrium with the liquid leaving stage $n$ and is the value read from the equilibrium curve. The $y_{n-1}$ and $y_n$ are the actual (nonequilibrium) values for vapor streams leaving the $n-1$ and $n$ stages, respectively. Note that for the $y_{n-1}$ and $y_n$ values we assume that the vapor streams are completely mixed and uniform in composition. An analogous efficiency can be defined for the liquid phase.

The application of a 50 percent Murphree vapor-phase efficiency on a $y$-$x$ diagram is illustrated in Fig. 13-31. A pseudoequilibrium curve is drawn halfway (on a vertical line) between the operating lines and the true equilibrium curve. The true equilibrium curve is used for the first stage (the partial reboiler is assumed to be an equilibrium stage), but for all other stages the vapor leaving each stage is assumed to approach the equilibrium value $y_n^*$ only 50 percent of the way. Consequently, the steps in Fig. 13-31 represent actual trays.

In general, application of a constant efficiency to each stage as in Fig. 13-31 will not give the same answer as obtained when the number of equilibrium stages (obtained by using the true equilibrium curve) is divided by the same efficiency factor.

The prediction and use of stage efficiencies are described in detail in Sec. 14. Alternative approaches based on mass-transfer rates are preferred, as described in the subsection below, Nonequilibrium Modeling.

**Miscellaneous Operations** The $y$-$x$ diagrams for several other column configurations have not been presented here. The omitted items are *partial condensers, rectifying columns* (feed introduced to the bottom stage), *stripping columns* (feed introduced to the top stage), total reflux in the top section but not in the bottom section, multiple feeds, and introduction of *open steam* to the bottom stage to eliminate the reboiler. These configurations are discussed in Smith (op. cit.) and Henley and Seader (op. cit.), who also describe the more rigorous Ponchon-Savarit method, which is not covered here.

# APPROXIMATE MULTICOMPONENT DISTILLATION METHODS

Some approximate calculation methods for the solution of multicomponent, multistage separation problems continue to serve useful purposes even though computers are available to provide more rigorous solutions. The available phase equilibrium and enthalpy data may not be accurate enough to justify the longer rigorous methods. Or in extensive design and optimization studies, a large number of cases can be worked quickly and cheaply by an approximate method to define roughly the optimum specifications, which can then be investigated more exactly with a rigorous method.

Two approximate multicomponent shortcut methods for simple distillation are the Smith-Brinkley (SB) method, which is based on an analytical solution of the finite-difference equations that can be written for staged separation processes when stages and interstage flow rates are known or assumed, and the Fenske-Underwood-Gilliland (FUG) method, which combines Fenske's total reflux equation and Underwood's minimum reflux equation with a graphical correlation by Gilliland that relates actual column performance to total and minimum reflux conditions for a specified separation between two key components. Thus, the SB and FUG methods are rating and design methods, respectively. Both methods work best when mixtures are nearly ideal.

The SB method is not presented here, but is presented in detail in the 6th edition of *Perry's Chemical Engineers' Handbook.* Extensions of the SB method to nonideal mixtures and complex configurations are developed by Eckert and Hlavacek [*Chem. Eng. Sci.,* **33,** 77 (1978)] and Eckert [*Chem. Eng. Sci.,* **37,** 425 (1982)], respectively, but are not discussed here. However, the approximate and very useful method of Kremser [*Nat. Pet. News,* **22**(21), 43 (May 21, 1930)] for application to absorbers and strippers is discussed at the end of this subsection.

## FENSKE-UNDERWOOD-GILLILAND (FUG) SHORTCUT METHOD

In this approach, Fenske's equation [*Ind. Eng. Chem.,* **24,** 482 (1932)] is used to calculate $N_{min}$, which is the number of plates required to make a specified separation at total reflux, i.e., the minimum value of $N$. Underwood's equations [*J. Inst. Pet.,* **31,** 111 (1945); **32,** 598 (1946); **32,** 614 (1946); and *Chem. Eng. Prog.,* **44,** 603 (1948)] are used to estimate the minimum reflux ratio $R_{min}$. The empirical correlation of Gilliland [*Ind. Eng. Chem.,* **32,** 1220 (1940)] shown in Fig. 13-32 then uses these values to give $N$ for any specified $R$, or $R$ for any specified $N$. Limitations of the Gilliland correlation are discussed by Henley and Seader (*Equilibrium-Stage Separation Operations in Chemical Engineering,* Wiley, New York, 1981). The following equation, developed by Molokanov et al. [*Int. Chem. Eng.,* **12**(2), 209 (1972)], satisfies the endpoints and fits the Gilliland curve reasonably well:

$$\frac{N - N_{min}}{N+1} = 1 - \exp\left(\frac{1 + 54.4\Psi}{11 + 117.2\Psi} \times \frac{\Psi - 1}{\Psi^{0.5}}\right) \tag{13-30}$$

where $\Psi = (R - R_{min})/(R+1)$.

The Fenske total reflux equation can be written as

$$\left(\frac{x_i}{x_r}\right)_D = (\alpha_i)^{N_{min}}\left(\frac{x_i}{x_r}\right)_B \tag{13-31}$$

or as

$$N_{min} = \frac{\log[(Dx_D/Bx_B)_i(Bx_B/Dx_D)_r]}{\log \alpha_i} \tag{13-32}$$

where $i$ is any component and $r$ is an arbitrarily selected reference component in the definition of relative volatilities

$$\alpha_i = \frac{K_i}{K_r} = \frac{y_i x_r}{y_r x_i} \tag{13-33}$$

The particular value of $\alpha_i$ used in Eqs. (13-31) and (13-32) is the effective value calculated from Eq. (13-34) defined in terms of values for each stage in the column by

$$\alpha^N = \alpha_N \alpha_{N-1} \cdots \alpha_2 \alpha_1 \tag{13-34}$$

Equations (13-31) and (13-32) are exact relationships between the splits obtained for components $i$ and $r$ in a column at total reflux.

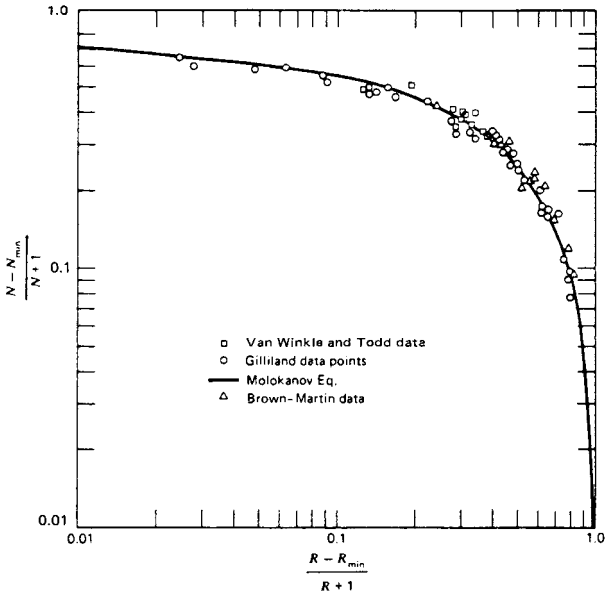

**FIG. 13-32** Comparison of rigorous calculations with Gilliland correlation. [*Henley and Seader,* Equilibrium-Stage Separation Operations in Chemical Engineering, *Wiley, New York, 1981; data of Van Winkle and Todd,* Chem. Eng., **78**(*21*), *136 (Sept. 20, 1971); data of Gilliland,* Elements of Fractional Distillation, *4th ed., McGraw-Hill, New York, 1950; data of Brown and Martin,* Trans. Am. Inst. Chem. Eng., **35,** *679 (1939).*]

However, the value of $\alpha_i$ must always be estimated, and this is where the approximation enters. It is usually estimated from

$$\alpha = (\alpha_{top}\alpha_{bottom})^{1/2} \tag{13-35}$$

or

$$\alpha = (\alpha_{top}\alpha_{middle}\alpha_{bottom})^{1/3} \tag{13-36}$$

As a side note, the separation that will be accomplished in a column with a known number of equilibrium stages can often be reasonably well estimated by specifying the split of one component (designated as the reference component $r$), setting $N_{min}$ equal to 40 to 60 percent of the number of equilibrium stages (not actual trays), and then using Eq. (13-32) to estimate the splits of all the other components. This is an iterative calculation because the component splits must first be arbitrarily assumed to give end compositions that can be used to give initial end-temperature estimates. The $\alpha_{top}$ and $\alpha_{bottom}$ values corresponding to these end temperatures are used in Eq. (13-5) to give $\alpha_i$ values for each component. The iteration is continued until the $\alpha_i$ values do not change from trial to trial.

The Underwood minimum reflux equations of main interest are those that apply when some of the components do not appear in either the distillate or the bottom products at minimum reflux. These equations are

$$\sum_i \frac{\alpha_i (x_{iD})_{min}}{\alpha_i - \Theta} = R_{min} + 1 \tag{13-37}$$

and

$$\sum_i \frac{\alpha_i z_{iF}}{\alpha_i - \Theta} = 1 - q \tag{13-38}$$

The relative volatilities $\alpha_i$ are defined by Eq. (13-33), $R_{min}$ is the minimum reflux ratio, and $q$ describes the thermal condition of the feed (1 for a saturated liquid feed and 0 for a saturated vapor feed). The $z_{i,F}$ values are available from the given feed composition. The $\Theta$ is the common root for the top section equations and the bottom section equations developed by Underwood for a column at minimum reflux with separate zones of constant composition in each section. The common root value must fall between $\alpha_{hk}$ and $\alpha_{lk}$, where *hk* and *lk* stand for *heavy key* and *light key,* respectively. The *key components* are the ones the designer wants to separate. In the butane-pentane splitter problem in Example 1, the light key is $n$-$C_4$ and the heavy key is $i$-$C_5$.

The $\alpha_i$ values in Eqs. (13-37) and (13-38) are effective values obtained from Eq. (13-35) or Eq. (13-36). Once these values are available, $\Theta$ can be calculated in a straightforward iteration from Eq. (13-38). Since the $\alpha$-$\Theta$ difference can be small, $\Theta$ should be determined to four decimal places to avoid numerical difficulties.

The $(x_{iD})_{min}$ values in Eq. (13-37) are minimum reflux values, i.e., the overhead composition that would be produced by the column operating at the minimum reflux with an infinite number of stages. When the light key and the heavy key are adjacent in relative volatility and the specified split between them is sharp or the relative volatilities of the other components are not close to those of the two keys, only the two keys will distribute at minimum reflux and the $(x_{iD})_{min}$ values are easily determined. This is often the case and is the only one considered here. Other cases in which some of or all the nonkey components distribute between distillate and bottom products are discussed in detail by Henley and Seader (op. cit.).

The FUG method is convenient for new column design with the following specifications:

1. A value for $R/R_{min}$
2. Desired split on the reference component (usually chosen as the heavy key)
3. Desired split on one other component (usually the light key)

However, the total number of equilibrium stages $N$, $N/N_{min}$, or the external reflux ratio can be substituted for one of these three specifications. Note that the feed location is automatically specified as the optimum one; this is assumed in the Underwood equations. The assumption of saturated liquid reflux is also inherent in the Fenske and Underwood equations (i.e., the reflux is *not* subcooled). An important limitation on the Underwood equations is the assumption of constant molar overflow. As discussed by Henley and Seader (op. cit.), this assumption can lead to a prediction of the minimum reflux that is considerably lower than the actual value. No such assumption is inherent in the Fenske equation. An exact calculation technique for minimum reflux is given by Tavana and Hansen [*Ind. Eng. Chem. Process Des. Dev.*, **18,** 154 (1979)]. Approximate explicit expressions for minimum reflux for various types of splits in three- and four-component mixtures were developed by Glinos and Malone [*Ind. Eng. Chem. Process Des. Dev.*, **23,** 764 (1984)] as well as lumping rules for applying their expressions to mixtures containing more than four components. These expressions are fairly accurate (usually within 5 percent of the exact value for $R_{min}$) and are extremely convenient for using in the FUG method since they remove the tedious calculation of $R_{min}$ via the Underwood equations. A computer program for the FUG method is given by Chang [*Hydrocarbon Process.*, **60**(8), 79 (1980)]. The method is best applied to mixtures that form ideal or nearly ideal solutions, and should not be used for strongly nonideal or azeotropic mixtures.

***Example 1: Application of FUG Method*** A large butane-pentane splitter is to be shut down for repairs. Some of its feed will be diverted temporarily to an available smaller column, which has only 11 trays plus a partial reboiler. The feed enters on the middle tray. Past experience with similar feeds indicates that the 11 trays plus the reboiler are roughly equivalent to 10 equilibrium stages and that the column has a maximum top vapor capacity of 1.75 times the feed rate on a mole basis. The column will operate at a condenser pressure of 827.4 kPa (120 psia). The feed will be at its bubble point ($q = 1.0$) at the feed tray conditions and has the following composition on the basis of 0.0126 kg·mol/s (100 lb·mol/h):

| Component | $Fx_{iF}$ |
|---|---|
| $C_3$ | 5 |
| $i$-$C_4$ | 15 |
| $n$-$C_4$ | 25 |
| $i$-$C_5$ | 20 |
| $n$-$C_5$ | 35 |
| | 100 |

The original column normally has less than 7 mol % $i$-$C_5$ in the overhead and less than 3 mol % $n$-$C_4$ in the bottom product when operating at a distillate rate of $D/F = 0.489$. Can these product purities be produced on the smaller column at $D/F = 0.489$?

Pressure drops in the column will be neglected, and the $K$ values will be read at 827 kPa (120 psia) in both column sections from the DePriester nomograph in Fig. 13-9*b*. When constant molar overflow is assumed in each section, the rates in pound moles per hour in the upper and lower sections are as follows:

| Top section | Bottom section |
|---|---|
| $D = (0.489)(100) = 48.9$ | $B = 100 - 48.9 = 51.1$ |
| $V = (1.75)(100) = 175$ | $V' = V = 175$ |
| $L = 175 - 48.9 = 126.1$ | $L' = L + F = 226.1$ |
| $\frac{V}{L} = 1.388$ | $\frac{V'}{L'} = 0.7739$ |

$$\frac{L}{L'} = \frac{126.1}{226.1} = 0.5577$$

$$R = \frac{126.1}{48.9} = 2.579$$

NOTE: To convert pound-moles per hour to kilogram-moles per second, multiply by $1.26 \times 10^{-4}$.

Application of the FUG method is demonstrated on the splitter. Specifications necessary to model the existing column include these:

1. $N = 10$, total number of equilibrium stages
2. Optimum feed location (which may or may not reflect the actual location)
3. Maximum $V/F$ at the top tray of 1.75
4. Split on one component given in the following paragraphs

The solution starts with an assumed arbitrary split of all the components to give estimates of top and bottom compositions that can be used to get initial end temperatures. The $\alpha_i$'s evaluated at these temperatures are averaged with the $\alpha$ at the feed-stage temperature (assumed to be the bubble point of the feed) by using Eq. (13-36). The initial assumption for the split on $i$-$C_5$ is $Dx_D/Bx_B = 3.15/16.85$. As mentioned earlier, $N_{min}$ usually ranges from $0.4N$ to $0.6N$, and the initial $N_{min}$ value assumed here will be $(0.6)(10) = 6.0$. Equation (13-32) can be rewritten as

$$\left(\frac{Dx_D}{Fx_F - Dx_D}\right)_i = \alpha_i^{6.0}\left(\frac{3.15}{16.85}\right) = \alpha_i^{6.0}(0.1869)$$

or

$$Dx_{iD} = \frac{0.1869\alpha_i^{6.0}}{1 + 0.1869\alpha_i^{6.0}} Fx_{iF}$$

The evaluation of this equation for each component is as follows:

| Component | $\alpha_i$ | $\alpha_i^{6.0}$ | $0.1869\alpha_i^{6.0}$ | $Fx_{iF}$ | $Dx_{iD}$ | $Bx_{iB}$ |
|---|---|---|---|---|---|---|
| $C_3$ | 5.00 | | | 5 | 5.0 | 0.0 |
| $i$-$C_4$ | 2.63 | 330 | 61.7 | 15 | 14.8 | 0.2 |
| $n$-$C_4$ | 2.01 | 66 | 12.3 | 25 | 25.1 | 1.9 |
| $i$-$C_5$ | 1.00 | 1.00 | 0.187 | 20 | 3.15 | 16.85 |
| $n$-$C_5$ | 0.843 | 0.36 | 0.0672 | 35 | 2.20 | 32.80 |
| | | | | 100 | 48.25 | 51.75 |

The end temperatures corresponding to these product compositions are 344 K (159°F) and 386 K (236°F). These temperatures plus the feed bubble point temperature of 358 K (185°F) provide a new set of $\alpha_i$'s which vary only slightly from those used earlier. Consequently, the $D = 48.25$ value is not expected to vary greatly and will be used to estimate a new $i$-$C_5$ split. The desired distillate composition for $i$-$C_5$ is 7 percent; so it will be assumed that $Dx_D = (0.07)(48.25) = 3.4$ for $i$-$C_5$ and that the split on that component will be 3.4/16.6. The results obtained with the new $\alpha_i$'s and the new $i$-$C_5$ split are as follows:

| Component | $\alpha_i^{6.0}$ | $0.2048\alpha_i^{6.0}$ | $Fx_{iF}$ | $Dx_{iD}$ | $Bx_{iB}$ | $x_{iD}$ | $x_{iB}$ |
|---|---|---|---|---|---|---|---|
| $C_3$ | | | 5 | 5.0 | 0.0 | 0.102 | 0.000 |
| $i$-$C_4$ | 322 | 65.9 | 15 | 14.8 | 0.2 | 0.301 | 0.004 |
| $n$-$C_4$ | 68 | 13.9 | 25 | 23.3 | 1.7 | 0.473 | 0.033 |
| $i$-$C_5$ | 1.00 | 0.205 | 20 | 3.4 | 16.6 | 0.069 | 0.327 |
| $n$-$C_5$ | 0.415 | 0.085 | 35 | 2.7 | 32.3 | 0.055 | 0.636 |
| | | | 100 | 49.2 | 50.8 | 1.000 | 1.000 |

The calculated $i$-$C_5$ composition in the overhead stream is 6.9 percent, which is close enough to the target value of 7.0 for now.

Table 13-6 shows subsequent calculations using the Underwood minimum reflux equations. The $\alpha$ and $x_D$ values in Table 13-6 are those from the Fenske total reflux calculation. As noted earlier, the $x_D$ values should be those at minimum reflux. This inconsistency may reduce the accuracy of the Underwood method; but to be useful, a shortcut method must be fast, and it has not been shown that a more rigorous estimation of $x_D$ values results in an overall improvement in accuracy. The calculated $R_{min}$ is 0.9426. The actual reflux assumed is obtained from the specified maximum top vapor rate of 0.022 kg·mol/s [175 lb·(mol/h)] and the calculated $D$ of 49.2 (from the Fenske equation).

$$L_{N+1} = V_N - D$$

$$R = \frac{V_N}{D} - 1 = \frac{175}{49.2} - 1 = 2.557$$

The values of $R_{min} = 0.9426$, $R = 2.557$, and $N = 10$ are now used with the Gilliland correlation in Fig. 13-32 or Eq. (13-30) to check the initially assumed value of 6.0 for $N_{min}$. Equation (13-30) gives $N_{min} = 6.95$, which differs from the assumed value.

Repetition of the calculations with $N_{min} = 7$ gives $R = 2.519$, $R_{min} = 0.9782$, and a calculated check value of $N_{min} = 6.85$, which is close enough. The final product compositions and the $\alpha$ values used are as follows:

| Component | $\alpha_i$ | $Dx_{iD}$ | $Bx_{iB}$ | $x_{iD}$ | $x_{iB}$ |
|---|---|---|---|---|---|
| $C_3$ | 4.98 | 5.00 | 0 | 0.1004 | 0.0 |
| $i$-$C_4$ | 2.61 | 14.91 | 0.09 | 0.2996 | 0.0017 |
| $n$-$C_4$ | 2.02 | 24.16 | 0.84 | 0.4852 | 0.0168 |
| $i$-$C_5$ | 1.00 | 3.48 | 16.52 | 0.0700 | 0.3283 |
| $n$-$C_5$ | 0.851 | 2.23 | 32.87 | 0.0448 | 0.6532 |
| | | 49.78 | 50.32 | 1.0000 | 1.0000 |

These results indicate that the 7 percent composition of $i$-$C_5$ in $D$ and the 3 percent composition of $i$-$C_4$ in $B$ obtained in the original column can also be obtained with the smaller column. These results disagree somewhat with the answers obtained from a rigorous computer solution, as shown in the following comparison. However, given the approximations that went into the FUG method, the agreement is good.

| | $x_{iD}$ | | $x_{iB}$ | |
|---|---|---|---|---|
| Component | Rigorous | FUG | Rigorous | FUG |
| $C_3$ | 0.102 | 0.100 | 0.0 | 0.0 |
| $i$-$C_4$ | 0.299 | 0.300 | 0.006 | 0.002 |
| $n$-$C_4$ | 0.473 | 0.485 | 0.037 | 0.017 |
| $i$-$C_5$ | 0.073 | 0.070 | 0.322 | 0.328 |
| $n$-$C_5$ | 0.053 | 0.045 | 0.635 | 0.653 |
| | 1.000 | 1.000 | 1.000 | 1.000 |

**TABLE 13-6 Application of Underwood Equations**

| Component | $x_F$ | $\alpha$ | $\alpha x_F$ | $\theta = 1.36$ | | $\theta = 1.365$ | | $x_D$ | $\alpha x_D$ | $\alpha - \theta$ | $\frac{\alpha x_D}{\alpha - \theta}$ |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | $\alpha - \theta$ | $\frac{\alpha x_F}{\alpha - \theta}$ | $\alpha - \theta$ | $\frac{\alpha x_F}{\alpha - \theta}$ | | | | |
| $C_3$ | 0.05 | 4.99 | 0.2495 | 3.63 | 0.0687 | 3.625 | 0.0688 | 0.102 | 0.5090 | 3.6253 | 0.1404 |
| $i$-$C_4$ | 0.15 | 2.62 | 0.3930 | 1.26 | 0.3119 | 1.255 | 0.3131 | 0.301 | 0.7886 | 1.2553 | 0.6282 |
| $n$-$C_4$ | 0.25 | 2.02 | 0.5050 | 0.66 | 0.7651 | 0.655 | 0.7710 | 0.473 | 0.9555 | 0.6553 | 1.4581 |
| $i$-$C_5$ | 0.20 | 1.00 | 0.2000 | −0.36 | −0.5556 | −0.365 | −0.5479 | 0.069 | 0.0690 | −0.3647 | −0.1892 |
| $n$-$C_5$ | 0.35 | 0.864 | 0.3024 | −0.496 | −0.6097 | −0.501 | −0.6036 | 0.055 | 0.0475 | −0.5007 | −0.0949 |
| | 1.00 | | | | −0.0196 | | +0.0014 | 1.000 | | | $1.9426 = R_m + 1$ |

Interpolation gives $\theta = 1.3647$.

## KREMSER EQUATION

Starting with the classical method of Kremser (op. cit.), approximate methods of increasing complexity have been developed to calculate the behavior of groups of equilibrium stages for a countercurrent cascade, such as is used in simple absorbers and strippers of the type shown in Fig. 13-2*b* and *d*. However, none of these methods can adequately account for stage temperatures that are considerably higher or lower than the two entering stream temperatures for absorption and stripping, respectively, when appreciable composition changes occur. Therefore, only the simplest form of the Kremser method is presented here. Fortunately, rigorous computer methods described later can be applied when accurate results are required. The Kremser method is most useful for making preliminary estimates of absorbent and stripping agent flow rates or equilibrium-stage requirements. The method can also be used to extrapolate quickly results of a rigorous solution to a different number of equilibrium stages.

Consider the general adiabatic countercurrent cascade of Fig. 13-33 where $v$ and $\ell$ are molar component flow rates. Regardless of whether the cascade is an absorber or a stripper, components in the entering vapor will tend to be absorbed and components in the entering liquid will tend to be stripped. If more moles are stripped than absorbed, the cascade is a stripper; otherwise, the cascade is an absorber. The Kremser method is general and applies to either case. Application of component material balance and phase equilibrium equations successively to stages 1 through $N-1$, 1 through $N-2$, etc., as shown by Henley and Seader (op. cit.), leads to the following equations originally derived by Kremser. For each component $i$,

$$(v_i)_N = (v_i)_0(\Phi_i)_A = (l_i)_{N+1}[1 - (\Phi_i)_s] \tag{13-39}$$

where

$$(\Phi_i)_A = \frac{(A_i)_c - 1}{(A_i)_c^{N+1} - 1} \tag{13-40}$$

is the fraction of component $i$ in the entering vapor that is not absorbed,

$$(\Phi_i)_s = \frac{(S_i)_c - 1}{(S_i)_c^{N+1} - 1} \tag{13-41}$$

is the fraction of component $i$ in the entering liquid that is not stripped,

$$(A_i)_e = \left(\frac{L}{K_i V}\right)_e \tag{13-42}$$

is the effective or average absorption factor for component $i$, and

$$(S_i)_e = \frac{1}{(A_i)_e} \tag{13-43}$$

is the effective or average stripping factor for component $i$. When the entering streams are at the same temperature and pressure and negligible absorption and stripping occur, effective component absorption and stripping factors are determined simply by entering stream conditions. Thus, if $K$ values are composition-independent, then

$$(A_i)_e = \frac{1}{(S_i)_e} = \frac{L_{N+1}}{K_i(T_{N+1}, P_{N+1})V_0} \tag{13-44}$$

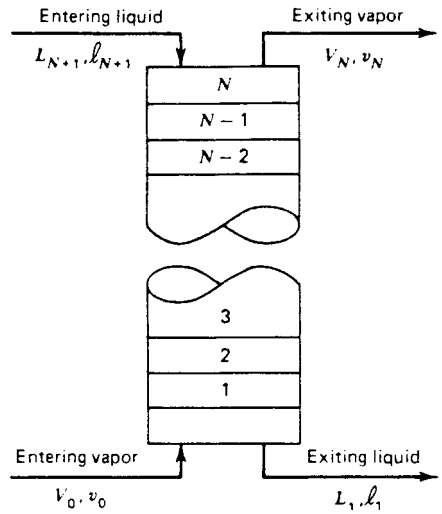

**FIG. 13-33** General adiabatic countercurrent cascade for simple absorption or stripping.

When entering stream temperatures differ and/or moderate to appreciable absorption and/or stripping occurs, values of $A_i$ and $S_i$ should be based on effective average values of $L$, $V$, and $K_i$ in the cascade. However, even then Eq. (13-44) with $T_{N+1}$ replaced by $(T_{N+1} + T_0)/2$ may be able to give a first-order approximation of $(A_i)_e$. In the case of an absorber, $L_{N+1} < L_e$ and $V_0 > V_e$ will be compensated to some extent by $K_i\{(T_{N+1} + T_0)/2,\ P)\} < K_i\{T_e,\ P\}$. A similar compensation, but in opposite directions, will occur in the case of a stripper. Equations (13-40) and (13-41) are plotted in Fig. 13-34. Components having large values of $A_e$ or $S_e$ absorb or strip, respectively, to a large extent. Corresponding values of $\Phi_A$ and $\Phi_S$ approach a value of 1 and are almost independent of the number of equilibrium stages.

An estimate of the minimum absorbent flow rate for a specified amount of absorption from the entering gas of some key component $K$ for a cascade with an infinite number of equilibrium stages is obtained from Eq. (13-40) as

$$(L_{N+1})_{\min} = K_K V_0[1 - (\Phi_K)_A] \tag{13-45}$$

The corresponding estimate of minimum stripping agent flow rate for a stripper is obtained as

$$(V_0)_{\min} = \frac{L_{N+1}[1 - (\Phi_K)_s]}{K_K} \tag{13-46}$$

***Example 2: Calculation of Kremser Method*** For the simple absorber specified in Fig. 13-35, a rigorous calculation procedure as described below gives the results in Table 13-7. Values of $\Phi$ were computed from component

**TABLE 13-7 Results of Calculations for Simple Absorber of Fig. 13-35**

NOTE: To convert pound-moles per hour to kilogram-moles per hour, multiply by 0.454.

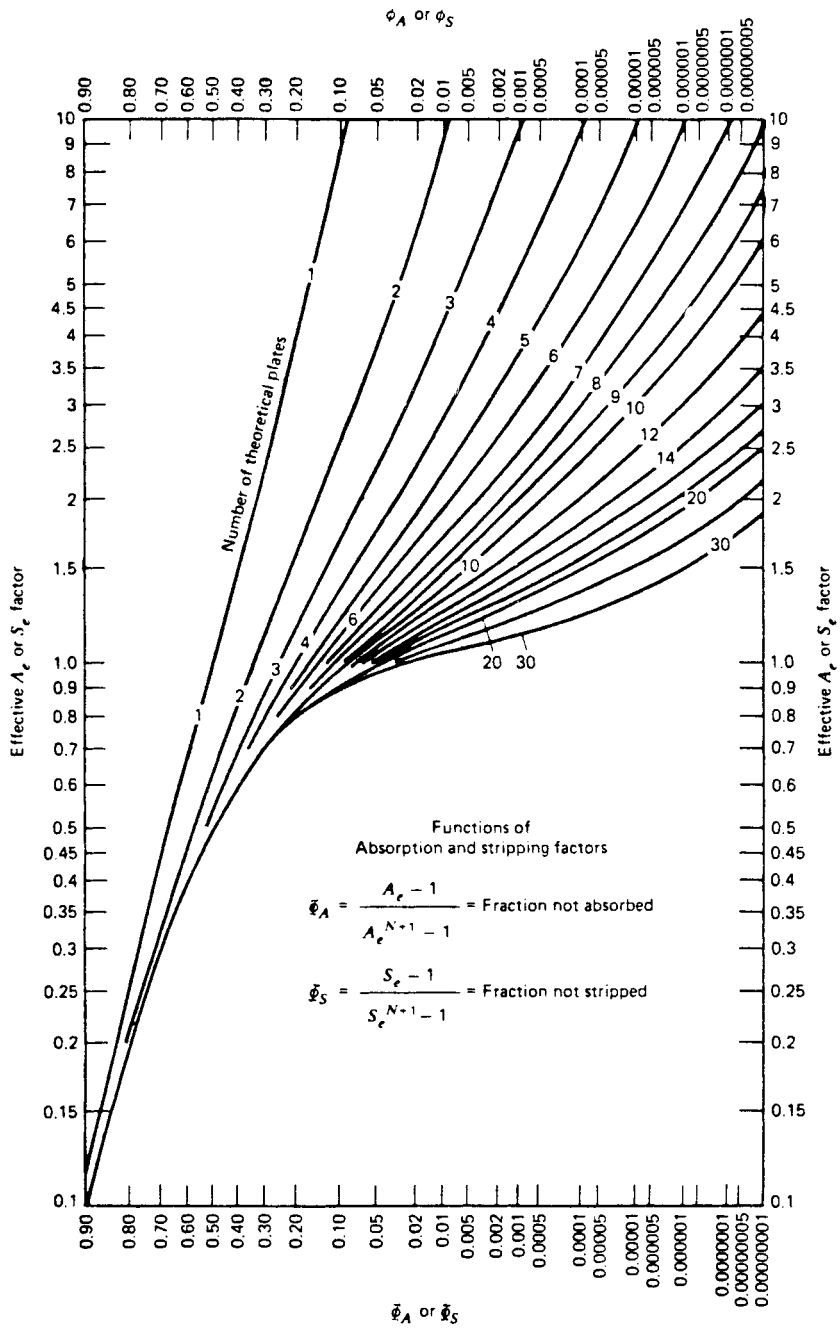

**FIG. 13-34** Absorption and stripping factors. [*W. C. Edmister,* AIChE J., **3,** *165–171 (1957).*]

product flow rates, and corresponding effective absorption and stripping factors were obtained by iterative calculations in using Eqs. (13-40) and (13-41) with $N = 6$. Use the Kremser method to estimate component product rates if $N$ is doubled to a value of 12.

Assume that values of $A_e$ and $S_e$ will not change with a change in $N$. Application of Eqs. (13-40), (13-41), and (13-39) gives the results in the last four columns of Table 13-7. Because of its small value of $A_e$, the extent of absorption of $C_1$ is unchanged. For the other components, somewhat increased amounts of absorption occur. The degree of stripping of the absorber oil is essentially unchanged. Overall, only an additional 0.5 percent of absorption occurs. The greatest increase in absorption occurs for $n$-$C_4$, to the extent of about 4 percent.

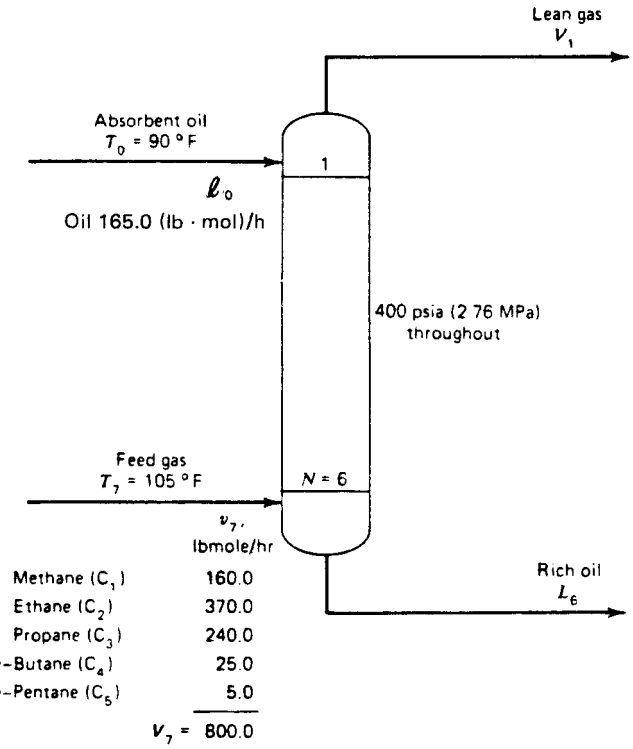

**FIG. 13-35** Specifications for the absorber example.

## SIMULATION OF DISTILLATION PROCESSES

Chemical engineers have been solving distillation problems by using the *equilibrium-stage model* since 1893 when Sorel outlined the concept to describe the distillation of alcohol. Since that time, it has been used to model a wide variety of distillation-like processes, including simple distillation (single-feed, two-product columns), complex distillation (multiple-feed, multiple-product columns), extractive and azeotropic distillation, petroleum distillation, absorption, liquid-liquid extraction, stripping, and supercritical extraction.

Real distillation processes, however, nearly always operate away from equilibrium. In recent years it has become possible to simulate distillation and absorption as the mass-transfer rate-based operations that they really are, using what have become known as *nonequilibrium* (NEQ) or *rate-based* models [Taylor et al., *CEP* (July 28, 2003)].

The computer simulation of distillation processes, whether done using equilibrium or nonequilibrium models, requires us to address the following topics:

- Formulation of the model equations
- Physical property data and calculations (see Sec. 4 of this handbook)
- Degrees-of-freedom analysis
- Solution of large linear and strongly nonlinear systems of equations

These are the topics we consider in what follows. We also discuss the use of simulation tools in the modeling of real distillation columns.

### EQUILIBRIUM-STAGE MODELING

A schematic diagram of an equilibrium stage is shown in Fig. 13-36*a*. Vapor from the stage below and liquid from a stage above are brought into contact on the stage together with any fresh or recycle feeds. The vapor and liquid streams leaving the stage are assumed to be in equilibrium with each other. A complete separation process is modeled as a sequence of these *equilibrium stages,* as shown in Fig. 13-36*b*.

**The MESH Equations (the 2*c* + 3 Formulation)** The equations that model equilibrium stages often are referred to as the MESH equations. The M equations are the material balance equations, E stands for equilibrium equations, S stands for mole fraction summation equations, and H refers to the heat or enthalpy balance equations.

There are two types of material balance: the total material balance

$$V_{j+1} + L_{j-1} + F_j - (1 + r_j^V)V_j - (1 + r_j^L)L_j = 0 \qquad (13\text{-}47)$$

and the component material balance

$$V_{j+1}y_{i,j+1} + L_{j-1}x_{i,j-1} + F_j z_{i,j} - (1 + r_j^V)V_j y_{i,j} - (1 + r_j^L)L_j x_{i,j} = 0 \qquad (13\text{-}48)$$

In the material balance equations given above, $r_j$ is the ratio of sidestream flow to interstage flow:

$$r_j^V = \frac{U_j}{V_j} \quad r_j^L = \frac{W_j}{L_j} \qquad (13\text{-}49)$$

Mole fractions must be forced to sum to unity, thus

$$\sum_{i=1}^{c} x_{i,j} = 1 \quad \sum_{i=1}^{c} y_{i,j} = 1 \quad \sum_{i=1}^{c} z_{i,j} = 1 \qquad (13\text{-}50)$$

The enthalpy balance is given by

$$V_{j+1}H_{j+1}^V + L_{j-1}H_{j-1}^L + F_j H_j^F - (1 + r_j^V)V_j H_j^V - (1 + r_j^L)L_j H_j^L - Q_j = 0 \qquad (13\text{-}51)$$

The superscripted $H$'s are the enthalpies of the appropriate phase.

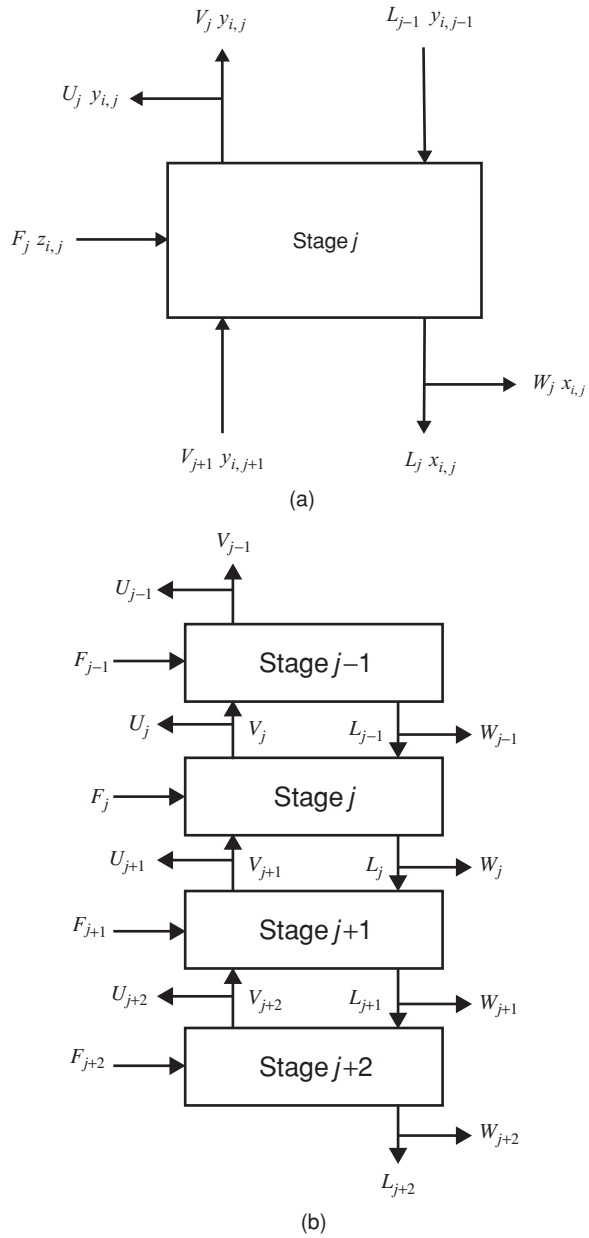

**FIG. 13-36** (*a*) The equilibrium stage. (*b*) Multistage column.

To complete the model, it is usual to add equations that relate the compositions of the two streams leaving the stage. In the standard model of a distillation column, we assume that these two streams are in equilibrium with each other. Thus, the mole fractions in the exiting streams are related by the familiar equations of phase equilibrium:

$$y_{i,j} = K_{i,j} x_{i,j} \tag{13-52}$$

The $K_{i,j}$ are the equilibrium ratios or $K$ values for species $i$ on stage $j$.

**Degrees-of-Freedom Analysis and Problem Formulation** Table 13-8 summarizes the equations for a single equilibrium stage (in a sequence of stages). There are $2c + 4$ equations per stage, of which only $2c + 3$ are independent. Thus, one of these equations must be ignored in a (computer-based) method to solve the equations. In some methods we disregard the total material balance; an alternative is to combine the vapor and liquid mole fraction summation equations (as was done for flash calculations by Rachford and Rice, op. cit.). Note that the mole fraction summation equations for the feed are omitted here, as are the mole fraction summation equations for interstage vapor and liquid traffic; the latter "belong" to the equation set for adjacent stages (see, however, the subsection Degrees of Freedom below in which this topic is revisited in greater detail).

**TABLE 13-8 Equations for an Equilibrium Stage**

| Equation | Equation no. | Number |
|---|---|---|
| Total mass balance | (13-47) | 1 |
| Component mass balances | (13-48) | $c$ |
| Total energy balance | (13-51) | 1 |
| Mole fraction summation equations | (13-50) | 2 |
| Equilibrium equations | (13-52) | $c$ |
| | | $2c + 4$ |

The quantities for stage $j$ that appear in these equations are summarized in Table 13-9. The total number of variables appearing in these equations is $3c + 10$. Note that the $K$ values and enthalpies that also appear in the MESH equations are not included in the table of variables, nor are equations for their estimation included in the list of equations. Thermodynamic properties are functions of temperature, pressure, and composition, quantities that do appear in the table of variables.

The $2c + 3$ unknown variables normally determined by solving the MESH equations are the $c$ vapor mole fractions $y_{i,j}$; the $c$ liquid mole fractions $x_{i,j}$; the stage temperature $T_j$; and the vapor and liquid flow $V_j$ and $L_j$. The remaining variables, $c + 7$ in number (the difference between the number of variables and the number of independent equations), that need to be specified are the stage pressure $P_j$, the feed flow rate, $c - 1$ mole fractions in the feed (the last is then computed directly from the feed mole fraction summation equation, which was not included in the equations for stage $j$ in Table 13-8), temperature and pressure of the feed, the stage heat duty $Q_j$, and the sidestream flows $U_j$ and $W_j$. It is important to recognize that the other flows and composition variables appearing in the MESH equations are associated with the equivalent equations for adjacent stages.

For a column of $N$ stages, we must solve $N(2c + 3)$ equations. The table below shows how we may need to solve hundreds or even thousands of equations.

| $c$ | $N$ | $N(2c + 3)$ |
|---|---|---|
| 2 | 10 | 70 |
| 3 | 20 | 180 |
| 5 | 50 | 650 |
| 10 | 30 | 690 |
| 40 | 100 | 8300 |

**TABLE 13-9 Variables for an Equilibrium Stage**

| Variable | Symbol | Number |
|---|---|---|
| Vapor flow rate | $V_j$ | 1 |
| Liquid flow rate | $L_j$ | 1 |
| Feed flow rate | $F_j$ | 1 |
| Vapor sidestream flow | $W_j$ | 1 |
| Liquid sidestream flow | $U_j$ | 1 |
| Vapor-phase mole fractions | $y_{i,j}$ | $c$ |
| Liquid-phase mole fractions | $x_{i,j}$ | $c$ |
| Feed composition | $z_{i,j}$ | $c$ |
| Stage temperature | $T_j$ | 1 |
| Stage pressure | $P_j$ | 1 |
| Feed temperature | | 1 |
| Feed pressure | | 1 |
| Stage heat duty | $Q_j$ | 1 |
| | | $3c + 10$ |

**The $2c + 1$ Formulation** An alternative form of the MESH equations is used in many algorithms. In this variation, we make use of the component flow defined by

$$v_{ij} = V_j y_{ij} \quad l_{ij} = L_j x_{ij} \quad f_{ij} = F_j z_{ij} \tag{13-53}$$

In terms of the component flow, the component material balance becomes

$$v_{i,j+1} + l_{i,j-1} + f_{i,j} - (1 + r_j^V) v_{i,j} - (1 + r_j^L) l_{i,j} = 0 \tag{13-54}$$

Since the total vapor and liquid flow rates are, by definition, the sum of the component flow rates of the respective phases, the summation equations and total mass balance equation are satisfied automatically. Thus, the number of equations and variables per stage has been reduced by 2 to $2c + 1$.

**The $c + 3$ Formulation** The number of unknown variables per stage can be reduced to only $c + 3$ if we use the equilibrium relations to eliminate the vapor-phase mole fractions from the component mass balances

$$V_{j+1} K_{i,j+1} x_{i,j+1} + L_{j-1} x_{i,j-1} + F_j z_{i,j} - (1 + r_j^V) V_j K_{i,j} x_{i,j} - (1 + r_j^L) L_j x_{i,j} = 0 \tag{13-55}$$

and from the summation equation

$$\sum_{i=1}^{c} K_{i,j} x_{i,j} = 1 \tag{13-56}$$

This equation is familiar to us from bubble point calculations. In this formulation of the MESH equations, the vapor-phase mole fractions no longer are independent variables but are defined by Eq. (13-52). This formulation of the MESH equations has been used in quite a number of algorithms. It is less useful if vapor-phase nonideality is important (and, therefore, the $K$ values depend on the vapor-phase composition).

**Condenser and Reboiler** The MESH equations given above apply to all the interior stages of a column. In addition, any reboiler and condenser must be considered. On an actual plant, a total condenser may be followed by a reflux accumulator and a stream divider. The accumulator does not add any equations to a steady-state model (but it is important to consider in an un-steady-state model), but the stream splitter is a separate unit with its own temperature, pressure, and heat loss, and modeled by the appropriate balance equations (see the section below on Degrees of Freedom where we address this topic in greater detail). In practice the condenser and reflux splitter often are modeled as a single combined unit, and the MESH equations described above may be used to model these stages with only some minor modifications. For example, for a total condenser *and* the reflux stream splitter at the top of a distillation column, the liquid distillate is $U_1$ and the reflux ratio $R = 1/r_1^L$. For a partial condenser (with no stream splitter needed) the vapor product is $V_1$ and the reflux ratio $R = L_1/V_1$. A condenser/splitter device unit that provides both vapor and liquid products is given by a combination of these two units. Finally, for a partial reboiler at the base of a column, the bottoms flow rate is $L_N$. Note that an equilibrium stage with a sidestream is considered here to be a single unit in essentially the same way.

In computer-based methods for solving the MESH equations, it is common to replace the energy balance of the condenser (with or without the associated stream splitter) and reboiler with a specification equation. Possible specifications include

- The flow rate of the distillate/bottoms product stream
- The mole fraction of a component in either the distillate or bottoms product stream
- Component flow rate in either the distillate or bottoms product stream
- A reflux/reboil ratio or rate
- The temperature of the condenser or reboiler
- The heat duty to the condenser or reboiler

If the condenser and/or reboiler heat duties are not specified, it is possible to calculate them from the energy balances after all the other model equations have been solved.

For a total condenser, the vapor composition used in the equilibrium relations is that determined during a bubble point calculation based on the actual pressure and liquid compositions found in the condenser. These vapor mole fractions are not used in the component mass balances since there is no vapor stream from a total condenser. It often happens that the temperature of the reflux stream is below the bubble point temperature of the condensed liquid (subcooled condenser). In such cases it is necessary to specify either the actual temperature of the reflux stream or the difference in temperature between the reflux stream and the bubble point of the condensate.

**Solution of the MESH Equations** We may identify several classes of methods of solving the *equilibrium*-stage model equations:

- *Graphical methods.* These methods were developed before modern computer methods became widely adopted. Some graphical methods retain their value for a variety of reasons and were discussed at length in a prior subsection.
- *Approximate methods.* In these a great many simplifying assumptions are made to obtain solutions of the model equations. These methods were the subject of the immediately preceding subsection.
- *Computer-based methods.* Indeed, from the late 1950s to the early 1990s hardly a year passed without the publication of at least one (and usually many more than one) new algorithm for solving these equations (Seader, op. cit.). It is possible to make the case that it was the equilibrium model that brought computing into chemical engineering in the first place! One of the incentives for this activity has always been a desire to solve problems with which existing methods have trouble. The evolution of algorithms for solving the stage model equations has been influenced by, among other things, the availability (or lack) of sufficient computer storage and speed, the development of mathematical techniques that can be exploited, the complexity of physical property ($K$ value and enthalpy) correlations, and the form of the model equations being solved. We continue with a brief discussion of computer-based methods. Readers interested in complete details of the methods discussed should consult the references cited below. In addition, many computer-based methods are discussed at length in a number of textbooks [see, e.g., Holland, op. cit.; King, op. cit.; Seader and Henley, op. cit.; Haas (in Kister op. cit. 1992)]. Seader (op. cit.) has written an interesting history of equilibrium-stage simulation.

The MESH equations form a set of nonlinear, algebraic equations (in the sense that no derivatives or integrals are involved) and must, therefore, be solved by some iterative process. There are two key steps in the development of an algorithm for solving systems of nonlinear equations:

- The selection of particular numerical methods
- The selection of the order in which the equations are to be solved

We may identify several classes of methods for numerically solving the MESH equations:

1. Tearing methods in which the equations are divided into groups and each group is solved separately
2. Inside-out (IO) methods
3. Simultaneous convergence (SC) methods in which all the equations are solved at the same time simultaneously by using Newton's method (or a variant thereof)
4. Relaxation methods in which the MESH equations are cast in unsteady-state form and integrated numerically until the steady-state solution has been found
5. Continuation methods
6. Collocation methods
7. Optimization methods

The methods for solving the MESH equations that are used most widely fall into categories 1 through 3 and 5—tearing methods, inside-out methods, simultaneous convergence methods, and continuation method. Following the sections on each of these three classes of method, we discuss homotopy continuation methods. For many years the older tearing methods formed the backbone of sequential modular flow sheet simulation programs; such methods have largely been replaced by the inside-out methods that now are standard in all major (and many less widely used) flow sheet simulation programs. Simultaneous convergence methods also now are available in many of these systems. Even homotopy methods (sometimes considered to belong

to the domain of specialists) are finding increasing use in commercial software.

**Tearing Methods** Equation tearing involves breaking a system of nonlinear equations into small groups and solving each group of equations in turn. In solving any subset of the complete set of equations, only a corresponding number of variables, the "tear" variables, can be determined. To start the calculations, therefore, it is necessary to assume values for the remaining variables. The "torn" set of equations is then solved for the "tear" variables, assuming that the values assigned to all other variables are correct. Successive groups of equations and variables are *torn* or *decoupled* from the full set of equations and variables until all the variables have been updated. At this point, the process starts over and is repeated until all the equations are satisfied simultaneously.

A great many tearing methods for solving the MESH equations have been proposed. According to Friday and Smith (1964), tearing methods may be analyzed in the following terms:

- The order in which the equations are grouped
- The order in which each group of equations is solved
- The selection of which variables are to be computed from which equation

Subsequent issues are

- The method(s) used to solve the M and E equations
- The method of calculating the new stage temperatures
- The method of calculating the new flow rates $V_j$ and $L_j$

Most tearing methods are based on keeping all the equations of a given type together, e.g., the M equations or the H equations, for all the stages at once.

The classic papers by Lewis and Matheson [*Ind. Eng. Chem.,* **24,** 496 (1932)] and Thiele and Geddes [*Ind. Eng. Chem.,* **25,** 290 (1933)] represent the first attempts at solving the MESH equations for multicomponent systems numerically (the graphical methods for binary systems discussed earlier had already been developed by Ponchon, by Savarit, and by McCabe and Thiele). At that time the computer had yet to be invented, and since modeling a column could require hundreds, possibly thousands, of equations, it was necessary to divide the MESH equations into smaller subsets if hand calculations were to be feasible. Despite their essential simplicity and appeal, stage-to-stage calculation procedures are not used now as often as they used to be.

Matrix techniques were first used in separation process calculations by Amundson and Pontinen [*Ind. Eng. Chem.,* **50,** 730 (1958)] who demonstrated that the combined M + E equations (the $c + 3$ formulation) could be conveniently written in tridiagonal matrix form.

Three quite different approaches to the problem of computing the flow rates and temperatures have evolved:

1. In the bubble point (BP) method, the S + E equations are used to determine the stage temperatures from a bubble point calculation. The vapor and liquid flow rates are computed from the energy balances and total material balances. The BP method was introduced by Amundson and Pontinen (op. cit.) who used matrix inversion to solve equations. A significant improvement in the BP method was introduced by Wang and Henke [*Hydrocarbon Process.,* **45**(8), 155 (1966)] who used a form of Gaussian elimination known as the Thomas algorithm that can be used to solve a tridiagonal system very efficiently. Holland and coworkers (Holland, op. cit.) have combined some of these ideas with the "theta method" of convergence acceleration.

2. In the sum rates (SR) method, the vapor and liquid flow rates are computed directly from the summation equations and the stage temperatures determined from the energy balances. The SR algorithm was due originally to Sujuta [*Hydrocarbon Process.,* **40**(12), 137 (1961)] and Friday and Smith (op. cit.). Sujuta used the $2c + 1$ version of the MESH equations in his work and the tridiagonal system of combined M + E equations was written in terms of the component flow rates in the liquid phase. Burningham and Otto [*Hydrocarbon Process.,* **46**(10), 163 (1967)] incorporated the Thomas algorithm in their implementation of the SR method. Sridhar and Lucia [*Comput. Chem. Eng.* **14,** 901 (1990)] developed a modified SR method that is capable of solving problems involving narrow, intermediate, and wide-boiling mixtures alike.

3. In the Newton-Raphson methods, the bubble point equations and energy balances are solved simultaneously for the stage temperatures and vapor flow rates; the liquid flow rates follow from the total material balances [Tierney and coworkers, *AIChE J.,* **13,** 556 (1967); **15,** 897 (1969); Billingsley and Boynton, *AIChE J.,* **17,** 65 (1971)]. Similar methods are described by Holland (op. cit.) and by Tomich [*AIChE J.,* **16,** 229 (1970)].

**Inside-Out Methods** First proposed by Boston and Sullivan [*Can. J. Chem. Engr.,* **52,** 52 (1974)] and further developed by Boston and coworkers [*Comput. Chem. Engng.,* **2,** 109 (1978); *ACS Symp. Ser.* No. 124, 135 (1980); *Comput. Chem. Engng.,* **8,** 105 (1984); and *Chem. Eng. Prog.,* **86** (8), 45–54 (1990)], Jelinek [*Comput. Chem. Engng.,* **12,** 195 (1988)], and Simandl and Svrcek [*Comput. Chem. Engng.,* **15,** 337 (1991)], inside-out methods really belong in the group of tearing methods; however, their very widespread use in many commercial simulation programs demands that they be granted a category all to themselves. In these methods, complicated equilibrium and enthalpy expressions are replaced by simple models, and the iteration variables $T$, $V$, $x$, $y$ are replaced by variables within the simple models that are relatively free of interactions with each other. Seader and Henley (op. cit.) provide complete details of the somewhat lengthy algorithm. Inside-out methods have replaced many of the older algorithms in commercial simulation programs, the modified version of Russell [*Chem. Eng.,* **90,** (20), 53 (1983)] being the basis for some of them.

**Simultaneous Convergence Methods** One drawback of some tearing methods is their relatively limited range of application. For example, the BP methods are more successful for distillation, and the SR-type methods are considered better for mixtures that exhibit a wide range of (pure-component) boiling points (see, however, our remarks above on modified BP and SR methods). Other possible drawbacks (at least in some cases) include the number of times physical properties must be evaluated (several times per outer loop iteration) if temperature- and composition-dependent physical properties are used. It is the physical properties calculations that generally dominate the computational cost of chemical process simulation problems. Other problems can arise if any of the iteration loops are hard to converge.

The development of methods for solving all the equations at the same time was tackled independently by a number of investigators. Simultaneous solution of all the MESH equations was suggested as a method of last resort by Friday and Smith (op. cit.) in a classic paper analyzing the reasons why other algorithms fail. They did not, however, implement such a technique. The two best-known papers are those of Goldstein and Stanfield [*Ind. Eng. Chem. Process Des. Dev.,* **9,** 78 (1970)] and Naphtali and Sandholm [*AIChE J.,* **17,** 148 (1971)], the latter providing more details of an application of Newton's method described by Naphtali at an AIChE meeting in May 1965. A method to solve all the MESH equations for all stages at once by using Newton's method was implemented by Whitehouse [Ph.D. Thesis, University of Manchester Institute of Science and Technology (1964)] (see Stainthorp and Whitehouse [*I. Chem. E. Symp. Series*, **23,** 181 (1967)]). Among other things, Whitehouse's code allowed for specifications of purity, $T$, $V$, $L$, or $Q$ on any stage. Interlinked systems of columns and nonideal solutions could be dealt with even though no examples of the latter type were solved by Whitehouse.

Many others have since employed Newton's method or a related method to solve the MESH equations. Such methods have become standard in commercial process simulation programs, most often for simulating systems for which tearing and inside-out methods are less successful (typically those that involve strongly nonideal mixtures). Simultaneous convergence procedures have shown themselves to be generally fast and reliable, having a locally quadratic convergence rate in the case of Newton's method, and these methods are much less sensitive to difficulties associated with nonideal solutions than are tearing methods. Seader (Sec. 13, *Perry's Chemical Engineers' Handbook,* 7th ed., 1986) discusses the design of simultaneous convergence methods.

**Continuation Methods (for Really Difficult Problems)** For those problems that other methods fail to solve, we may use continuation

methods. These methods begin with a known solution of a companion set of equations and follow a path to the desired solution of the set of equations to be solved. In most cases, the path exists and can be followed. We can identify the following categories of continuation method that have been used for solving the equilibrium-stage MESH equations:

1. Mathematical methods which place the MESH equations into a homotopy equation of purely mathematical origin
2. Physical continuation methods in which the nature of the equations being solved is exploited in some way

The first to use the Newton homotopy for separation process problems were Hlavacek and coworkers [*Chem. Eng. Sci.*, **36,** 1599 (1981); *Chem. Eng. Commun.*, **28,** 165 (1984)]. In papers of considerable significance Wayburn and Seader [*Comput. Chem. Engng.,* **11,** 7–25 (1987); *Proc. Second Intern. Conf. Foundations of Computer-Aided Process Design,* CACHE, Austin, Tex., 765–862 (1984); *AIChE Monograph Series,* AIChE, New York, **81,** No. 15 (1985)] used the Newton homotopy in their solution of the MESH equations for interlinked distillation columns. Kovach and Seider [*Comput. Chem. Engng.,* **11,** 593 (1987)] used the Newton homotopy for solving distillation problems involving highly nonideal mixtures.

In the category of physical continuation methods are the thermodynamic homotopies of Vickery and Taylor [*AIChE J.*, **32**, 547 (1986)] and a related method due to Frantz and Van Brunt (AIChE National Meeting, Miami Beach, 1986). Thermodynamic continuation has also been used to find azeotropes in multicomponent systems by Fidkowski et al. [*Comput. Chem. Engng.,* **17,** 1141 (1993)]. Parametric continuation methods may be considered to be physical continuation methods. The reflux ratio or bottoms flow rate has been used in parametric solutions of the MESH equations [Jelinek et al., *Chem. Eng. Sci.*, **28,** 1555 (1973)].

Bryne and Baird [*Comput. Chem. Engng.,* **9,** 593 (1985)] describe the use of proprietary continuation methods. Woodman (Ph.D. thesis, University of Cambridge, 1989) has combined several continuation methods to solve problems that involved nonstandard specifications and multiple liquid phases.

For detailed descriptions of homotopy methods in chemical engineering, see Seader [*Computer Modeling of Chemical Processes*, AIChE Monograph Series 15, **81,** (1985)].

**Other Methods** *Relaxation techniques* differ from both tearing algorithms and simultaneous convergence methods in that the relaxation techniques do not solve steady-state problems. Rather, at least one set of the MESH equations is cast in an unsteady-state form. The equations are then integrated from some initial state (guess) until successive values of the variables do not change. The appeal of the relaxation methods lies in their extreme stability. A drawback is that convergence is generally a very slow process, slowing even more as the solution is approached. For this reason, the method is used (only) for problems which are very difficult to converge or for situations in which a knowledge of how the steady state is achieved is important. Key papers are by Rose, Sweeney, and Schrodt [*Ind. Eng. Chem.*, **50,** 737 (1958)]; Ball (AIChE National Meeting, New Orleans, 1961); Verneuil and Oleson (ACS National Mtg., Los Angeles, 1971); and Ketchum [*Chem. Eng. Sci.*, **34,** 387 (1979)].

*Collocation methods* are widely used for solving systems of partial differential equations. Despite their considerable potential for certain types of equilibrium-stage simulation problems, collocation methods have not become part of the mainstream of equilibrium-stage simulation. Key papers are by Stewart et al. [*Chem. Eng. Sci.*, **40,** 409 (1985)], Swartz and Stewart [*AIChE J.*, **32,** 1832 (1986)], Cho and Joseph [*AIChE J.*, **29,** 261, 270 (1983); *Comput. Chem. Engng.*, **8,** 81 (1984)], and Seferlis and Hrymak [*Chem. Eng. Sci.*, **49,** 1369 (1994); *AIChE J.*, **40,** 813 (1994)].

Methods that have been developed for finding the optimal solution(s) to engineering models have also been used to solve difficult equilibrium-stage separation process problems. An example of a method in this category is that of Lucia and Wang [*Comput. Chem. Engng.,* **28,** 2541 (2004)].

**Examples** In what follows we illustrate possible column specifications by considering four examples from Seader (*Perry's Chemical Engineers' Handbook,* 7th ed., 1997). They are a simple distillation column, a more complicated distillation column, an absorber, and a reboiled stripper. A simultaneous convergence method was used for the calculations reported below. The computer program that was used for these exercises automatically generated initial estimates of all the unknown variables (flows, temperatures, and mole fractions). In most cases the results here differ only very slightly from those obtained by Seader (almost certainly due to small differences in physical property constants).

***Example 3: Simple Distillation Column*** Compute stage temperatures, interstage vapor and liquid flow rates and compositions, and reboiler and condenser duties for the butane-pentane splitter studied in Example 1. The specifications for this problem are summarized below and in Fig. 13-37.

The specifications made in this case are summarized below:

| Variable | Number | Value |
|---|---|---|
| Number of stages | 1 | 11 |
| Feed stage location | 1 | 6 |
| Component flows in feed | $c = 5$ | 5, 15, 25, 20, 35 lb·mol/h |
| Feed pressure | 1 | 120 psia |
| Feed vapor fraction | 1 | 0 |
| Pressure on each stage including condenser and reboiler | $N = 11$ | $P_j = 120$ psia |
| Heat duty on each stage except reboilers and condensers | $N - 2 = 9$ | $Q_j = 0$ |
| Vapor flow to condenser (replaces heat duty of reboiler) | 1 | $V_2 = 175$ lb·mol/h |
| Distillate flow rate (replaces heat duty of condenser) | 1 | $D = 48.9$ lb·mol/h |
| Total | 31 | |

In addition, we have assumed that the pressure of the reflux divider is the same as the pressure of the condenser, the heat loss from the reflux divider is zero, and the reflux temperature is the boiling point of the condensed overhead vapor.

The Peng-Robinson equation of state was used to estimate $K$ values and enthalpy departures [as opposed to the De Priester charts used in Example 1 and by Seader (ibid.) who solved this problem by using the Thiele-Geddes (op. cit.) method].

With 11 stages and 5 components the equilibrium-stage model has 143 equations to be solved for 143 variables (the unknown flow rates, temperatures, and mole fractions). Convergence of the computer algorithm was obtained in just four iterations. Computed product flows are shown in Fig. 13-37.

A pseudobinary McCabe-Thiele diagram for this multicomponent system is shown in Fig. 13-38. For systems with more than two components, these diagrams can only be computed from the results of a computer simulation. The axes are defined by the relative mole fractions:

$$X = \frac{x_{lk}}{x_{lk} + x_{hk}} \qquad Y = \frac{y_{lk}}{y_{lk} + y_{hk}}$$

where the subscripts *lk* and *hk* refer to light and heavy key, respectively. The lines in the diagram have similar significance as would be expected from our knowledge of McCabe-Thiele diagrams for binary systems discussed earlier in this section; the triangles correspond to equilibrium stages. The operating lines are not straight because of heat effects and because the feed is not in the best location.

The fact that the staircase of triangles visible in Fig. 13-38 fails to come close to the corners of the diagram where $X = Y = 1$ and $X = Y = 0$ shows that the separation is not especially sharp. It is worth asking what can be done to improve the separation obtained with this column. The parameters that have a significant effect on the separation are the numbers of stages in the sections above and below the feed, the reflux ratio, and a product flow rate (or reflux flow). Figure 13-39 shows how the mole fraction of *i*-pentane in the overhead and of *n*-butane in the bottom product changes with the reflux ratio. For the base case considered above, the reflux ratio is 2.58 (calculated from the results of the simulation). It is clear that increasing the reflux ratio has the desired effect of improving product purity. This improvement in purity is, however, accompanied by an increase in both the operating cost, indicated in Fig. 13-39 by the increase in reboiler duty, and capital cost, because a larger column would be needed to accommodate the increased internal flow. Note, however, that the curves that represent the mole fractions of the keys in the overhead and bottoms appear to flatten, showing that product purity will not increase indefinitely as the reflux ratio increases. Further improvement in product purity can best be made by changing a different specification.

Figure 13-40 shows the tradeoff in product purities when we change the specified distillate flow rate, maintaining all other specifications at the values

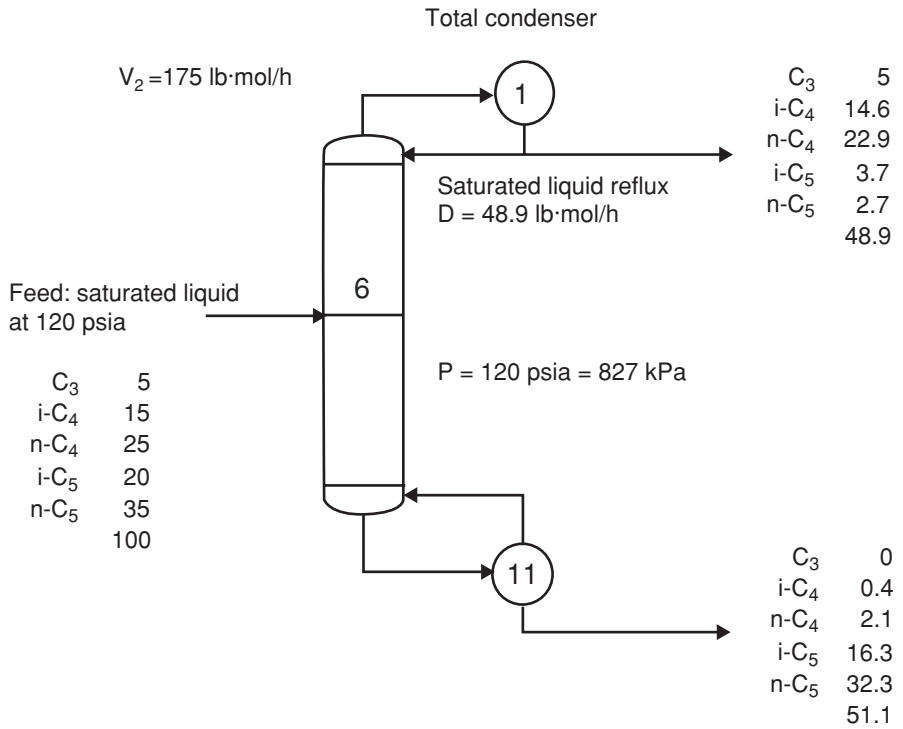

**FIG. 13-37** Specifications and calculated product stream flows for butane-pentane splitter. Flows are in pound-moles per hour.

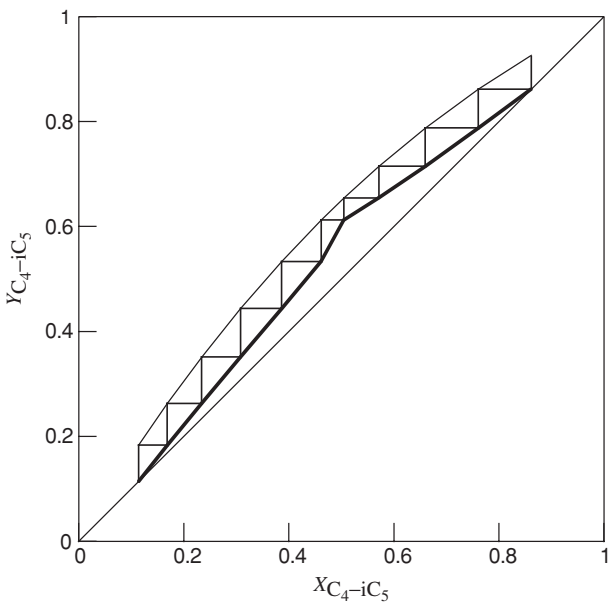

**FIG. 13-38** Multicomponent McCabe-Thiele diagram for butane-pentane splitter in Fig. 13-37.

specified in the base case. At lower distillate flow rates the mole fraction of heavy key (*i*-$C_5$) in the distillate is small, and at higher distillate flow rates the mole fraction of light key (*n*-$C_4$) in the bottoms is small. Both cannot be small simultaneously. From this result we see that the "best" overall product purities are obtained when the distillate rate is in the vicinity of 45 lb·mol/h. On reflection this should not come as a surprise; the flow rate of the light key (*n*-butane) and all components with a higher volatility is 45 lb·mol/h. However, even with the distillate flow rate set to 45 lb·mol/h there remains room for improvement in the separation.

The other key design specifications here are the total number of stages and the location of the feed stage. In most cases, increasing the number of stages will improve the separation. On increasing the number of stages to 26, with the feed to stage 12, increasing the overhead vapor flow to 195 lb·mol/h, and decreasing the distillate rate to 45 lb· mol/h, we obtain the following products:

| Mole flows, lb·mol/h | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 5.00 | 5.00 | 0.00 |
| Isobutane | 15.00 | 15.00 | 0.00 |
| *N*-Butane | 25.00 | 24.81 | 0.19 |
| Isopentane | 20.00 | 0.16 | 19.84 |
| *N*-Pentane | 35.00 | 0.03 | 34.97 |
| Total | 100.00 | 45.00 | 55.00 |

The McCabe-Thiele diagram for this configuration, shown in Fig. 13-41, shows that the product purities have improved significantly.

The temperature and liquid phase composition profiles for this final case are shown in Fig. 13-42. The temperature increases from top to bottom of the column. This is normally the case in distillation columns (exceptions may occur with cold feeds or feeds with boiling points significantly lower than that of the mixture on stages above the feed stage). The composition profiles also are as expected. The components more volatile than the light key (*n*-butane) are

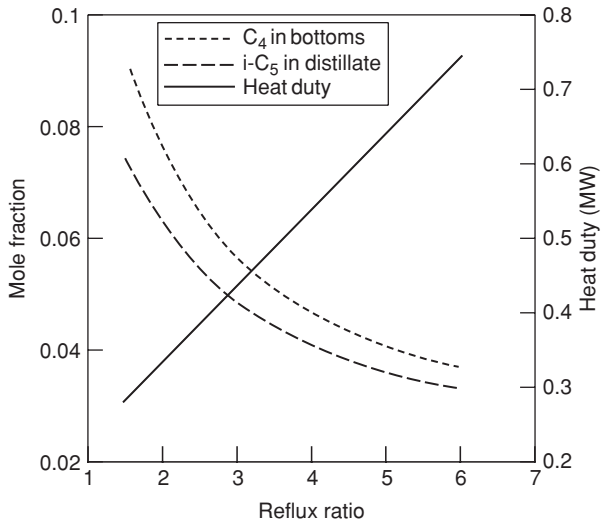

**FIG. 13-39** Product mole fractions and reboiler heat duty as a function of the reflux ratio for butane-pentane splitter in Fig. 13-37.

concentrated above the feed; those compounds less volatile than the heavy key (*i*-pentane) are concentrated below the feed. The mole fractions of the two keys exhibit maxima, the light key above the feed stage and the heavy key below the feed stage. The decrease in the mole fraction of light key over the top few stages is necessary to accommodate the increase in the composition of the lighter compounds. Similar arguments pertain to the decrease in the mole fraction of the heavy key over the stages toward the bottom of the column.

Flow profiles are shown in Fig. 13-42*c*. Note the step change in the liquid flow rate around the feed stage. Had the feed been partially vaporized, we would have observed changes in both vapor and liquid flows around the feed stage, and a saturated vapor feed would significantly change only the vapor flow

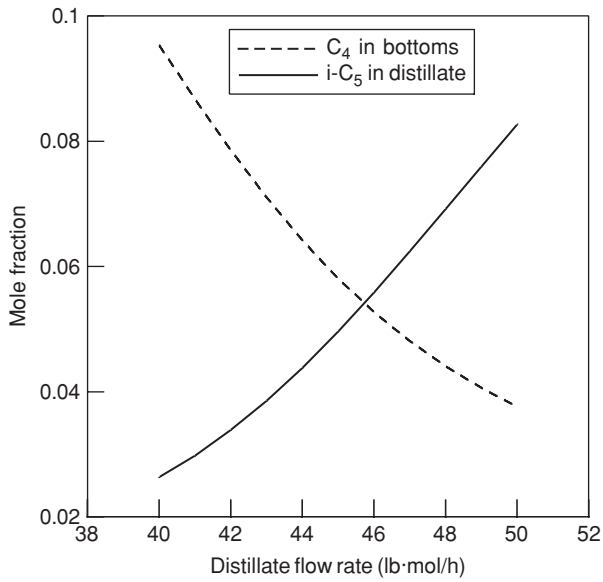

**FIG. 13-40** Product mole fraction duty as a function of the distillate rate for butane-pentane splitter in Fig. 13-37.

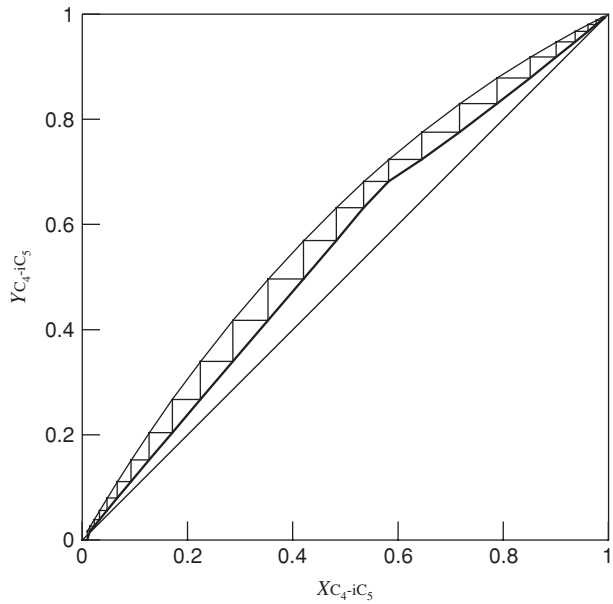

**FIG. 13-41** Multicomponent McCabe-Thiele diagram for butane-pentane splitter after optimization to improve product purities.

profile. The slight (in this case) curvature in the flow profiles is due to enthalpy changes.

***Example 4: Light Hydrocarbon Distillation*** Compute stage temperatures, interstage vapor and liquid flow rates and compositions, and reboiler and condenser duties for the light hydrocarbon distillation column shown in Fig. 13-43. How might the separation be improved?

This more complicated example features a partial condenser (with vapor product) and a vapor sidestream withdrawn from the 13th stage. The SRK equation of state may be used for estimating the *K* values and enthalpy departures for thermodynamic properties.

The specifications made in this case are summarized below:

| Variable | Number | Value |
|---|---|---|
| Number of stages | 1 | 17 |
| Feed stage location | 1 | 9 |
| Component flows in feed | $c = 5$ | 3, 20, 37, 35, 5 lb·mol/h |
| Feed pressure | 1 | 260 psia |
| Feed vapor fraction | 1 | 0 |
| Pressure on each stage including condenser and reboiler | $N = 17$ | $P_j = 250$ psia |
| Heat duty on each stage except reboilers and condensers | $N - 2 = 15$ | $Q_j = 0$ |
| Reflux rate (replaces heat duty of reboiler) | 1 | $L_1 = 150$ lb·mol/h |
| Distillate flow rate (replaces heat duty of condenser) | 1 | $D = 23$ lb·mol/h |
| Sidestream stage | 1 | 13 |
| Sidestream flow rate and phase | 2 | 37 lb·mol/h vapor |
| Total | 46 | |

As in Example 3, we have assumed that the pressure of the reflux divider is the same as the pressure of the condenser, the heat loss from the reflux divider is zero, and the reflux temperature is the boiling point of the condensed overhead vapor.

The specifications were selected to obtain three products: a vapor distillate rich in $C_2$ and $C_3$, a vapor sidestream rich in *n*-$C_4$, and a bottoms rich in *n*-$C_5$ and *n*-$C_6$, as summarized in the table below.

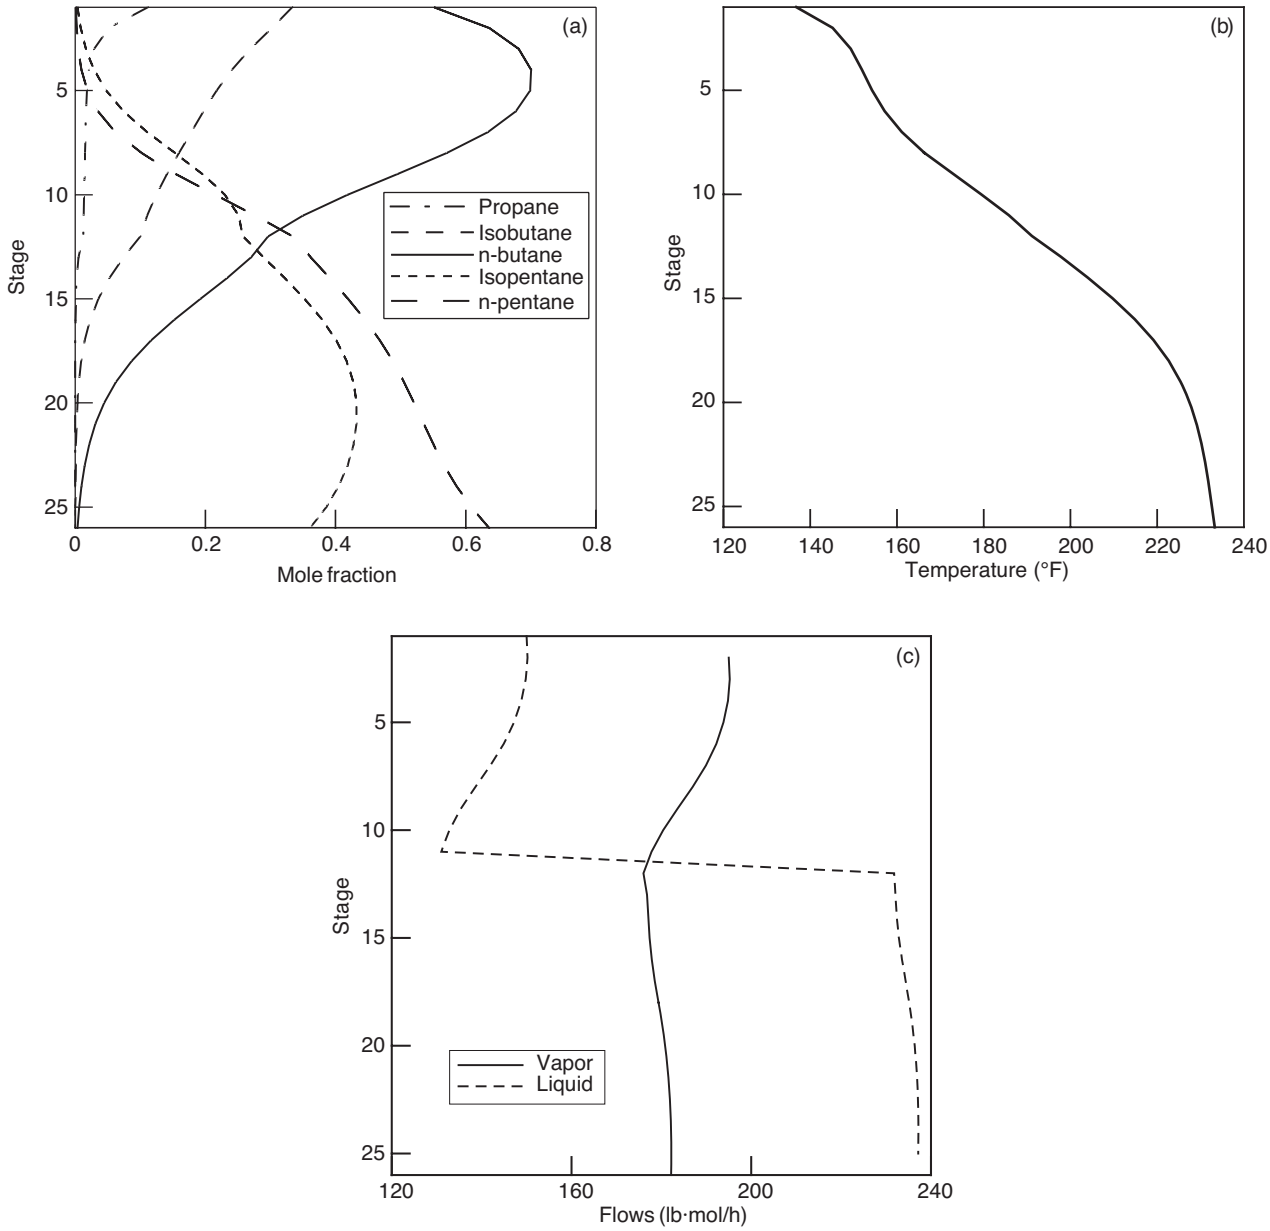

**FIG. 13-42** (*a*) Composition, (*b*) temperature, and (*c*) flow profiles in butane-pentane splitter.

| Mole flows, lb·mol/h | Feed | Top | Bottom | Sidestream |
|---|---|---|---|---|
| Ethane | 3.00 | 3.00 | 0.0 | 0.0 |
| Propane | 20.00 | 18.3 | 0.0 | 1.6 |
| *N*-Butane | 37.00 | 1.7 | 9.6 | 25.7 |
| *N*-Pentane | 35.00 | 0.0 | 25.8 | 9.2 |
| *N*-Hexane | 5.00 | 0.0 | 4.5 | 0.5 |
| Total molar flow | 100.00 | 23.0 | 40.0 | 37.0 |

Convergence of the simultaneous convergence method was obtained in five iterations.

Further improvement in the purity of the sidestream as well as of the other two products could be obtained by increasing the reflux flow rate (or reflux ratio) and the number of stages in each section of the column. If, e.g., we increase the number of stages to 25 (including condenser and reboiler in this total), with the feed to stage 7 and the sidestream removed from stage 17, we obtain the following:

| Mole flows, lb·mol/h | Feed | Top | Bottom | Sidestream |
|---|---|---|---|---|
| Ethane | 3.00 | 3.00 | 0.00 | 0.00 |
| Propane | 20.00 | 19.46 | 0.00 | 0.54 |
| *N*-Butane | 37.00 | 0.54 | 7.46 | 29.00 |
| *N*-Pentane | 35.00 | 0.00 | 27.93 | 7.07 |
| *N*-Hexane | 5.00 | 0.00 | 4.61 | 0.39 |
| Total | 100.0 | 23.0 | 40.0 | 37.00 |

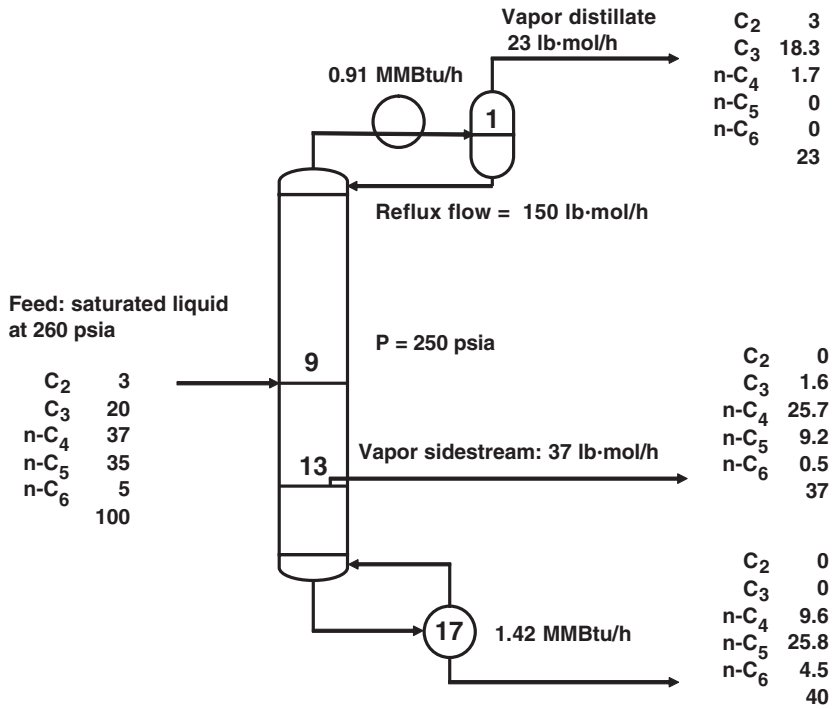

**FIG. 13-43** Specifications and calculated product stream flows and heat duties for light hydrocarbon still. Flows are in pound-moles per hour.

The McCabe-Thiele diagram for this design, showing that the feed is to the optimum stage, is shown in Fig. 13-44. The flow profiles are shown in Fig. 13-45; note the step changes due to both the feed and the sidestream. As was the case in Example 3, the curvature in the flow profiles is due to enthalpy changes.

***Example 5: Absorber*** Compute stage temperatures and interstage vapor and liquid flow rates and compositions for the absorber specifications shown in Fig. 13-46. Note that a second absorber oil feed is used in addition to the main absorber oil and that heat is withdrawn from the seventh theoretical stage. The oil may be taken to be *n*-dodecane.

The specifications made in this case are summarized below:

| Variable | Number | Value(s) |
|---|---|---|
| Number of stages | 1 | 8 |
| Location of feed 1 | 1 | 1 |
| Component flows in feed 1 | $c = 6$ | 0, 0, 0, 0, 0, 250 lb·mol/h |
| Pressure of feed 1 | 1 | 400 psia |
| Temperature of feed 1 | 1 | 80°F |
| Location of feed 2 | 1 | 4 |
| Component flows in feed 2 | $c = 6$ | 13, 3, 4, 5, 5, 135 lb·mol/h |
| Pressure of feed 2 | 1 | 400 psia |
| Temperature of feed 2 | 1 | 80°F |
| Location of feed 3 | 1 | 8 |
| Component flows in feed 3 | $c = 6$ | 360, 40, 25, 15, 15, 10 lb·mol/h |
| Pressure of feed 3 | 1 | 400 psia |
| Temperature of feed 3 | 1 | 80°F |
| Pressure on each stage | $N = 8$ | $P_j = 400$ psia; $j = 1, 2, \ldots, 8$ |
| Heat duty on each stage | $N = 8$ | $Q_j = 0, j = 1, 2, \ldots, 6, 8$; $Q_7 = 150{,}000$ Btu/h |
| Total | 44 | |

The simultaneous solution method solved this example in four iterations. The Peng-Robinson equation of state was used to estimate *K* values and enthalpy departures and by Seader (*Perry's Chemical Engineers' Handbook,* 7th ed.) who solved this problem by using the SR method.

The computed product flows are summarized below:

| Mole flows, lb·mol/h | Lean oil | Secondary oil | Rich gas | Lean gas | Rich oil |
|---|---|---|---|---|---|
| Methane | 0.0 | 13.0 | 360.0 | 303.7 | 69.3 |
| Ethane | 0.0 | 3.0 | 40.0 | 10.7 | 32.3 |
| Propane | 0.0 | 4.0 | 25.0 | 0.2 | 28.8 |
| *N*-Butane | 0.0 | 4.0 | 15.0 | 0.0 | 19.0 |
| *N*-Pentane | 0.0 | 5.0 | 10.0 | 0.0 | 15.0 |
| *N*-Dodecane | 250.0 | 135.0 | 0.0 | 0.0 | 385.0 |
| Total molar flow | 250.0 | 164.0 | 450.0 | 314.6 | 549.4 |

The energy withdrawn from stage 7 has the effect of slightly increasing the absorption of the more volatile species in the rich oil leaving the bottom of the column. Temperature and flow profiles are shown in Fig. 13-47. The temperature profile shows the rise in temperature toward the bottom of the column that is typical of gas absorption processes. The bottom of the column is where the bulk of the absorption takes place, and the temperature rise is a measure of the heat of absorption. The liquid flow profile exhibits a step change due to the secondary oil feed at the midpoint of the column.

***Example 6: Reboiled Stripper*** Compute stage temperatures and interstage vapor and liquid flow rates and compositions and reboiler heat duty for the reboiled stripper shown in Fig. 13-48. Thermodynamic properties may be estimated by using the Grayson-Streed modification of the Chao-Seader method.

The specifications made in this case are summarized in Fig. 13-48 and in the table below. The specified bottoms rate is equivalent to removing most of the *n*-$C_5$ and *n*-$C_6$ in the bottoms.

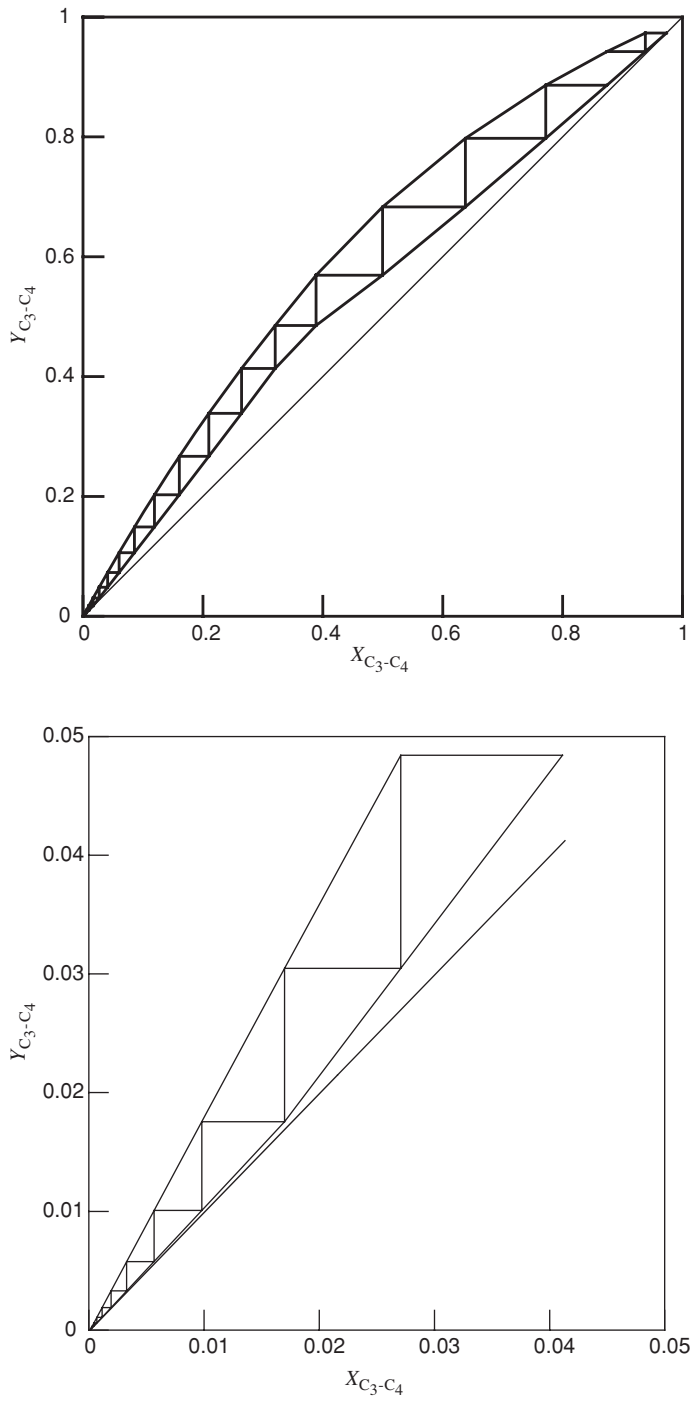

**FIG. 13-44** Multicomponent McCabe-Thiele diagram for the hydrocarbon distillation in Fig. 13-43.

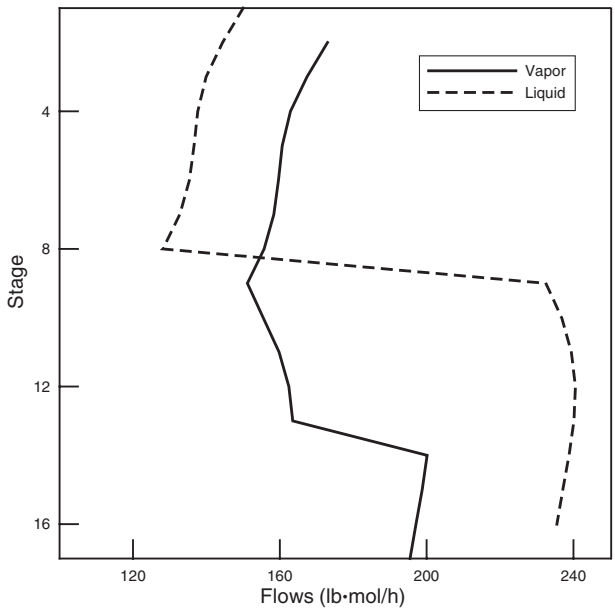

**FIG. 13-45** Flow profiles in hydrocarbon distillation in Fig. 13-43.

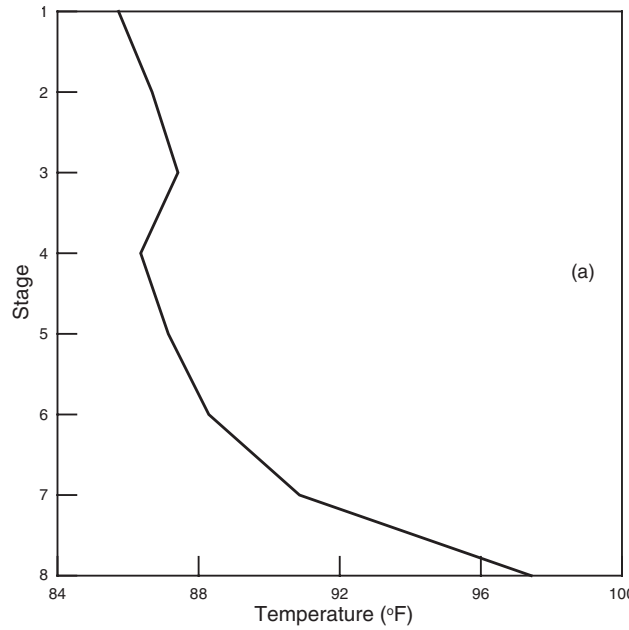

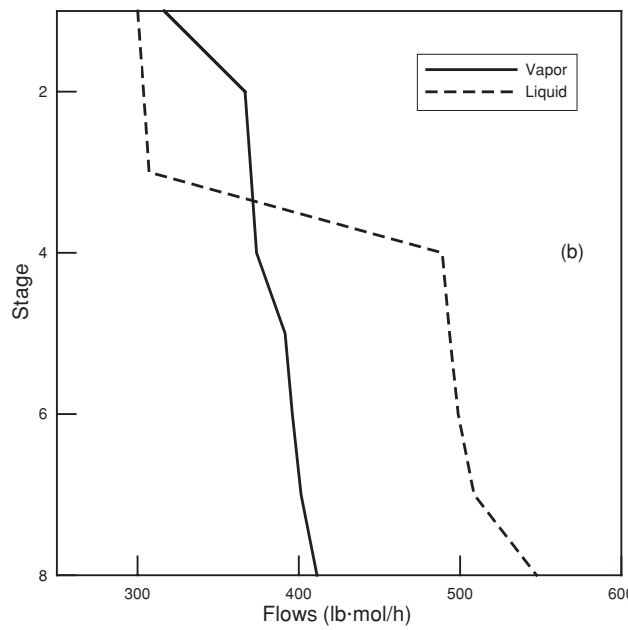

**FIG. 13-47** (*a*) Temperature and (*b*) flow profiles in absorber in Fig. 13-46.

| Variable | Number | Value(s) |
|---|---|---|
| Number of stages | 1 | 8 |
| Component flows in feed | $c = 7$ | 0.22, 59.51, 73.57, 153.2, 173.2, 58.22, 33.63 lb·mol/h |
| Pressure of feed | 1 | 150 psia |
| Temperature of feed | 1 | 40.8°F |
| Pressure on each stage | $N = 8$ | $P_j = 150$ psia; $j = 1, \ldots, 8$ |
| Heat duty on each stage (except reboiler) | $N - 1 = 7$ | $Q_j = 0$, $j = 1, \ldots, 7$ |
| Bottom product flow rate | 1 | 99.33 lb·mol/h |
| Total | 26 | |

Convergence in this case was obtained after four iterations. The computed product flows and reboiler duty are shown alongside the specifications in Fig. 13-48 and in the table below.

| Mole flows, lb·mol/h | Feed | Overhead | Bottoms |
|---|---|---|---|
| Nitrogen | 0.22 | 0.02 | 0.20 |
| Methane | 59.51 | 59.51 | 0.00 |
| Ethane | 73.57 | 73.57 | 0.00 |
| Propane | 153.22 | 153.16 | 0.06 |
| *N*-Butane | 173.22 | 150.09 | 23.13 |
| *N*-Pentane | 58.22 | 13.23 | 44.99 |
| *N*-Hexane | 33.63 | 2.69 | 30.94 |
| Total | 551.59 | 452.26 | 99.33 |

Computed temperature, flow rates, and vapor-phase mole fraction profiles, shown in Fig. 13-49, are not of the shapes that might have been expected. Vapor and liquid flow rates for $n$-$C_4$ change dramatically from stage to stage.

***Example 7: An Industrial* i*-Butane/*n*-Butane Fractionator*** Klemola and Ilme [*Ind. Eng. Chem.*, **35**, 4579 (1996)] and Ilme (Ph.D. thesis, University of Lapeenranta, Finland, 1997) report data from an industrial *i*-butane/*n*-butane fractionator that is used here as the basis for this example.

The column has 74 valve trays, the design details of which can be found in Example 11. The feed was introduced onto tray 37.

To properly model an existing column, it is necessary to know all feed and product conditions (flow rate, temperature, pressure, and composition). Flows, temperatures, and pressures often are available from standard instrumentation. It may be necessary to obtain additional samples of these streams to determine their composition. Such sampling should be scheduled as part of a plant trial to ensure that measured data are consistent. Ideally, multiple sets of plant measurements should be obtained at different operating conditions, and care should be taken to ensure that operating data are obtained at steady state since a steady-state model can only be used to describe a column at steady state. Measurements should be taken over a time interval longer than the residence time in the column and time-averaged to avoid a possible mismatch between feed and product data. Condenser and reboiler heat duties should be known (or available from the appropriate energy balance) whenever possible.

The measured compositions and flow rates of the feed and products for the $C_4$ splitter are summarized in the table below.

Measured Feed and Product Flows and Compositions (Mass %) for *i*-Butane/*n*-Butane Fractionator (Ilme op. cit.)

| Species | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 1.50 | 5.30 | 0.00 |
| Isobutane | 29.4 | 93.5 | 0.30 |
| *n*-Butane | 67.7 | 0.20 | 98.1 |
| $C_4$ olefins | 0.50 | 1.00 | 0.20 |
| Neopentane | 0.10 | 0.00 | 0.20 |
| Isopentane | 0.80 | 0.00 | 1.10 |
| *n*-Pentane | 0.10 | 0.00 | 0.10 |
| Total flow, kg/h | 26,234 | 8011 | 17,887 |

Other measured parameters are as follows:

Other Details of the *i*-Butane/*n*-Butane Fractionator

| | |
|---|---|
| Reflux flow rate, kg/h | 92,838 |
| Reflux temperature, °C | 18.5 |
| Column top pressure, kPa | 658.6 |
| Pressure drop per tray, kPa | 0.47 |
| Feed pressure, kPa | 892.67 |
| Boiler duty, MW | 10.24 |

Rarely, and this is a case in point, are plant data in exact material balance, and it will be necessary to reconcile errors in such measurements before continuing. The feed and product compositions, as adjusted by Ilme so that they satisfy material balance constraints, are provided below. Note how the $C_4$ olefins are assigned to isobutene and 1-butene.

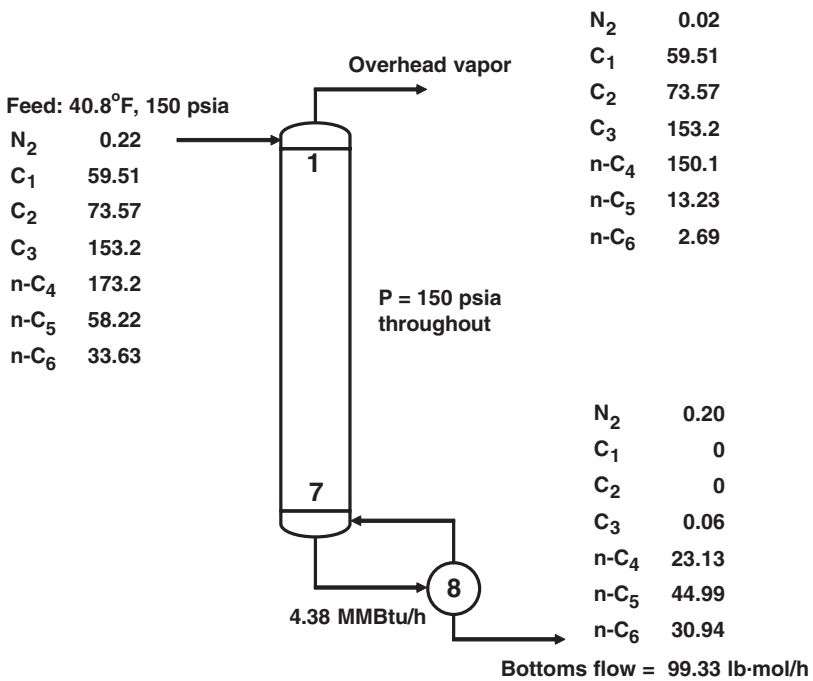

**FIG. 13-48** Specifications and calculated product stream flows and reboiler heat duty for a reboiled stripper. Flows are in pound-moles per hour.

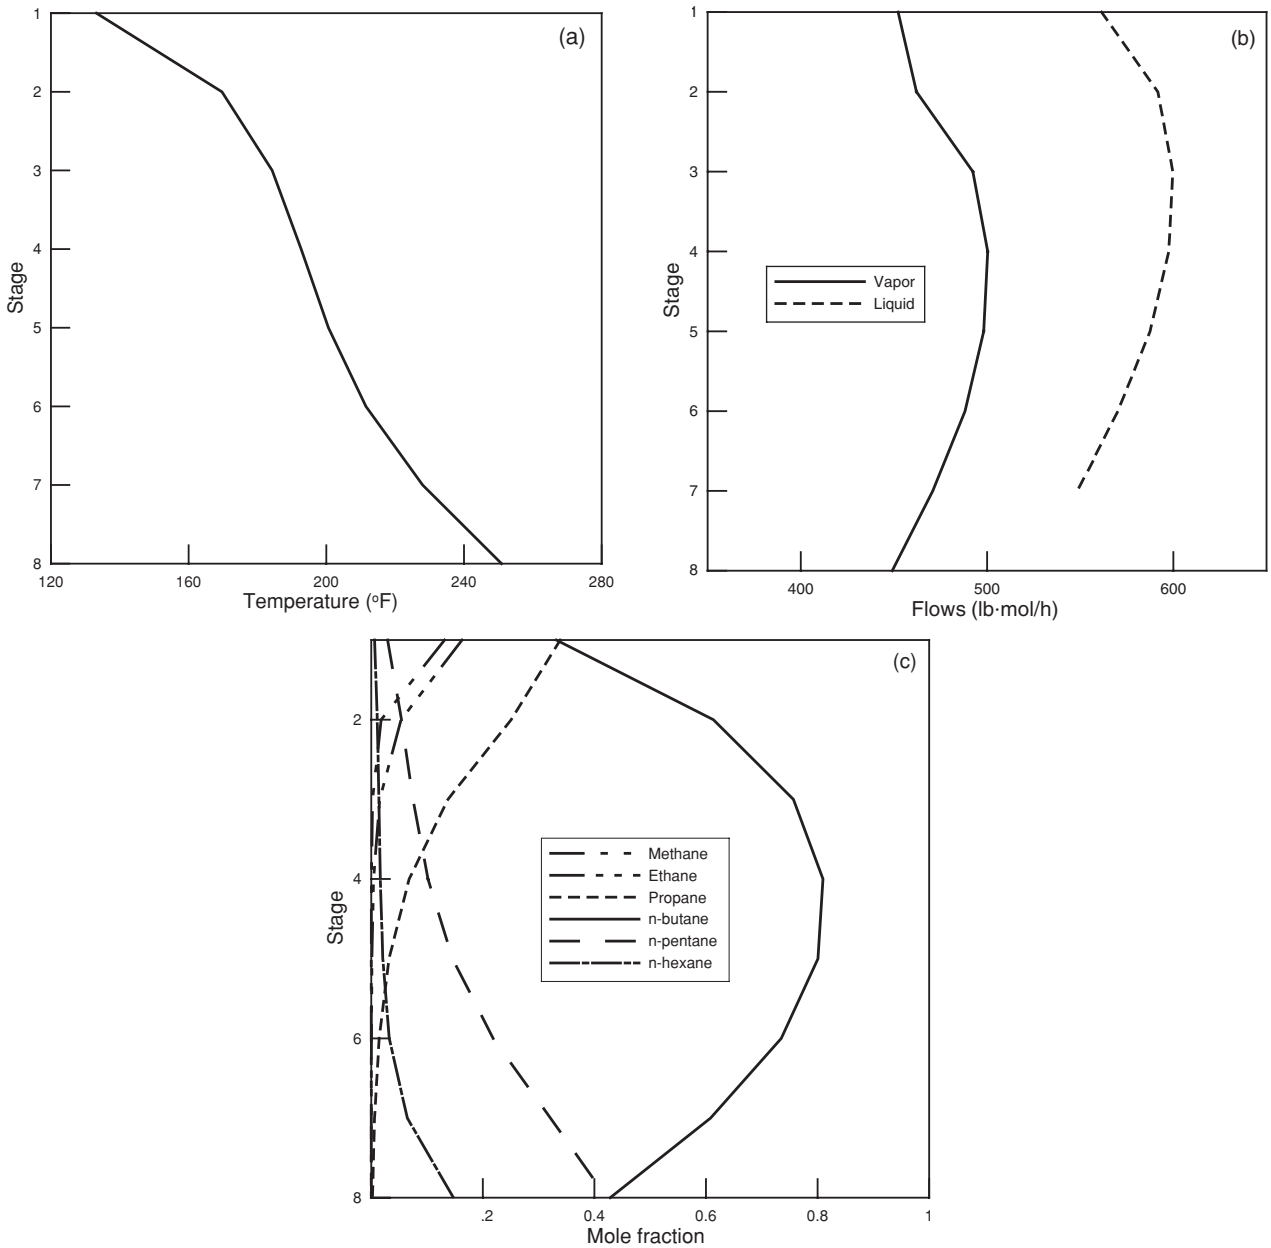

**FIG. 13-49** (*a*) Temperature, (*b*) flow, and (*c*) vapor mole fraction profiles in reboiled stripper in Fig. 13-48.

Adjusted Feed and Product Compositions (Mass %) and Flows for *i*-Butane/*n*-Butane Fractionator (Ilme op. cit.)

| Species | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 1.54 | 4.94 | 0.00 |
| Isobutane | 29.5 | 94.2 | 0.3 |
| *n*-Butane | 67.7 | 0.20 | 98.1 |
| Isobutene | 0.13 | 0.23 | 0.08 |
| 1-Butene | 0.20 | 0.41 | 0.10 |
| Neopentane | 0.11 | 0.00 | 0.17 |
| Isopentane | 0.77 | 0.00 | 1.12 |
| *n*-Pentane | 0.08 | 0.00 | 0.11 |
| Total flow, kg/h | 26,122 | 8123 | 17,999 |

To proceed with building a model of this column, we specify the number of stages equal to the number of trays plus condenser and reboiler ($N = 76$). The common arrangement of locating the actual feed between stages may require modeling as two separate feeds, the liquid portion to the stage below and the vapor portion to the stage above. In this particular illustration the feed is (assumed to be) saturated liquid, and we provide just a single feed to stage 38.

Upon computing the bubble point of the overhead product, we find that the measured reflux temperature is well below the estimated boiling point. Thus, we choose the subcooled condenser model. The steady-state concept of the "subcooled" condenser often does not exist in practice. Instead, the condenser is in vapor-liquid equilibrium with the vapor augmented by a blanket of noncondensable gas (that has the effect of lowering the dew point of the overhead vapor). The subcooled condenser is a convenient work-around for steady-state models (as is needed here), but not for dynamic models. We assume a partial reboiler.

The pressure of the top stage is specified (at 658.6 kPa). The pressures of all trays below the top tray can then be fixed from the knowledge of the per-tray pressure drop (0.47 kPa). The pressure of the condenser is not known here. Thus, in the absence of further information, we make the condenser pressure equal to the top tray pressure (knowing that in practice it will be lower).

It is advisable to use the plant set points in building a model. For example, it is possible that a column simulation might involve the specification of the reflux ratio and bottoms flow rate because such specifications are (relatively) easy to converge. It is quite likely that the column may be controlled by using the temperature at some specific location (e.g., the temperature of tray 48). This specification should be used in building the model. In this case we do not know the set points used for controlling the column, but we do have sufficient information to allow us to compute the reflux ratio from plant flow data ($R = 11.6$). Finally, the bottom product flow is specified as equal to the adjusted value reported above (17,999 kg/h).

The specifications made to model this column are summarized below:

| Variable | Number | Value |
|---|---|---|
| Number of stages | 1 | $N = 76$ |
| Feed stage location | 1 | 39 |
| Component flows in feed | $c = 8$ | See previous table |
| Feed pressure | 1 | 120 psia |
| Feed vapor fraction | 1 | 0 |
| Pressure at the top of the column | 1 | 658.6 kPa |
| Pressure drop per stage | $N - 1 = 75$ | 0.47 kPa |
| Heat duty on each stage except reboilers and condensers | $N - 2 = 74$ | $Q_j = 0$ |
| Reflux ratio (replaces heat duty of condenser) | 1 | $R = 11.588$ |
| Bottoms flow rate (replaces heat duty of reboiler) | 1 | $B = 17{,}999$ kg/h |
| Temperature of reflux | 1 | 291.65 K |
| Total | 165 | |

Finally, we must select appropriate methods of estimating thermodynamic properties. Ilme (op. cit.) used the SRK equation of state to model this column, whereas Klemola and Ilme (op. cit.) had earlier used the UNIFAC model for liquid-phase activity coefficients, the Antoine equation for vapor pressures, and the SRK equation for vapor-phase fugacities only. For this exercise we used the Peng-Robinson equation of state. Computed product compositions and flow rates are shown in the table below.

Specified Feed and Computed Product Compositions (Mass %) and Flows for *i*-Butane/*n*-Butane Fractionator (Ilme op. cit.)

| Compound | Feed | Top | Bottom |
|---|---|---|---|
| Propane | 1.54 | 4.95 | 0.00 |
| Isobutane | 29.49 | 93.67 | 0.53 |
| *n*-Butane | 67.68 | 0.73 | 97.89 |
| Isobutene | 0.13 | 0.29 | 0.06 |
| 1-Butene | 0.20 | 0.36 | 0.13 |
| Neopentane | 0.11 | 0.00 | 0.16 |
| Isopentane | 0.77 | 0.00 | 1.12 |
| *n*-Pentane | 0.08 | 0.00 | 0.12 |
| Total flow, kg/h | 26,122 | 8123.01 | 17,999 |

The agreement with the adjusted material balance (tabulated previously) appears to be quite good, and to a first approximation it seems that we have a good model of the column.

Note that although this column is distilling a mixture containing at least eight identifiable compounds, only two are present in significant amounts, and therefore this is essentially a binary separation. It is usually relatively straightforward to match product compositions in processes involving only two different species simply by adjusting the number of equilibrium stages. We return to this point later.

**Efficiencies** In actual operation the trays of a distillation column rarely, if ever, operate at equilibrium despite attempts to approach this condition by proper design and choice of operating conditions. The usual way of dealing with departures from equilibrium in multistage towers is through the use of stage and/or overall efficiencies.

The overall column efficiency is defined by

$$E_o = \frac{N_{\text{EQ}}}{N_{\text{actual}}} \tag{13-57}$$

where $N_{\text{EQ}}$ is the number of equilibrium stages.

There are many different definitions of stage (or tray) efficiency, with that of Murphree [*Ind. Eng. Chem.*, **17,** 747–750, 960–964 (1925)] being by far the most widely used in separation process calculations:

$$E_i^{MV} = \frac{y_{i,j} - y_{i,j+1}}{y^*_{i,j} - y_{i,j+1}} \tag{13-58}$$

Here $E_{ij}^{MV}$ is the Murphree vapor efficiency for component $i$ on stage $j$, and $y^*_{i,j}$ is the composition of the vapor in equilibrium with the liquid. Other types of efficiency include that of Hausen [*Chemie Ingr. Tech.*, **25,** 595 (1953)], vaporization (see Holland, op. cit.), and generalized Hausen [Standart, *Chem. Eng. Sci.*, **20,** 611 (1965)]. There is by no means a consensus on which is best. Arguments for and against various types are presented by, among others, Standart [op. cit.; *Chem. Eng. Sci.*, **26,** 985 (1971)], Holland and McMahon [*Chem. Eng. Sci.*, **25,** 431 (1972)], and Medina et al. [*Chem. Eng. Sci.*, **33,** 331 (1978), **34,** 1105 (1979)]. Possibly the most soundly based definition, the generalized Hausen efficiency of Standart (op. cit.), is never used in industrial practice. Seader [*Chem. Eng. Progress*, **85**(10), 41 (1989)] summarizes the shortcomings of efficiencies.

The Murphree (and Hausen) efficiencies of both components in a binary mixture are equal; although they cannot be less than 0, they may be greater than 1. A table of typical values of Murphree tray efficiency can be found in Sec. 14. Also described in Sec. 14 are methods for estimating Murphree efficiencies when they are not known.

For multicomponent systems (i.e., those with more than two components) there are $c - 1$ independent component efficiencies, and there are sound theoretical reasons as well as experimental evidence for not assuming the individual component efficiencies to be alike; indeed, they may take values between plus and minus infinity. Component efficiencies are more likely to differ for strongly nonideal mixtures. While models exist for estimating efficiencies in multicomponent systems [see chapter 13 in Taylor and Krishna, (op. cit.) for a review of the literature], they are not widely used and have not (yet) been included in any of the more widely used commercial simulation programs.

The fact that component efficiencies in multicomponent systems are unbounded means that the arithmetic average of the component Murphree efficiencies is useless as a measure of the performance of a multicomponent distillation process. Taylor, Baur, and Krishna [*AIChE J.*, **50,** 3134 (2004)] proposed the following efficiency for multicomponent systems:

$$\varepsilon_j = \frac{\sqrt{\sum_{i=1}^{c} (\Delta y_{ij})^2}}{\sqrt{\sum_{i=1}^{c} (\Delta y^*_{ij})^2}} \tag{13-59}$$

This efficiency has a simple and appealing physical significance; it is the ratio of the length of the actual composition profile (in mole fraction space) to the length of the composition profile given by the equilibrium-stage model. The Taylor-Baur-Krishna (TBK) efficiency has just one value per stage regardless of the number of components in the mixture; it can never be negative. For binary systems in tray columns the TBK average efficiency simplifies to the Murphree efficiency [Taylor, Baur, and Krishna (op. cit.)].

Murphree efficiencies are easily incorporated within simultaneous convergence algorithms (something that is not always easy, or even possible, with some tearing methods). (As an aside, note that vaporization

efficiencies are very easily incorporated in all computer algorithms, a fact that has helped to prolong the use of these quantities in industrial practice despite the lack of any convenient way to relate them to the fundamental processes of heat and mass transfer. Unfortunately, it is not at all easy to include the more fundamentally sound TBK efficiencies in a computer method for equilibrium-stage simulations.)

The Murphree-stage efficiency also makes a good continuation parameter for cases that are hard to converge. For vanishingly small stage efficiencies the column performs no separation, and the streams leaving the stage have essentially the same flow rates, composition, and temperature as the combined feeds to the stage. This fact can be exploited in a simple continuation method for solving difficult equilibrium-stage separation process problems [Muller, Ph.D. Thesis in Chem. Engng., ETH Zurich, 1979; Sereno, Ph.D. Thesis in Chem. Engng., University of Porto, 1985; Vickery, Ferrari, and Taylor, *Comput. Chem. Engng.*, **12,** 99 (1988)]. These methods are very effective at solving difficult problems involving *standard specifications* (in which the reflux ratio and bottoms flow rate are specified); however, they cannot easily handle problems involving nonstandard specifications (e.g., when a product stream purity is specified).

Efficiencies are often used to fit actual operating data, along with the number of equilibrium stages in each section of the column (between feed and product takeoff points). The maximum number of these efficiencies is the number of independent efficiencies per stage ($c - 1$) times the number of stages—potentially a very large number, indeed. This many adjustable parameters may lead to a model that fits the data very well, but has no predictive ability (i.e., cannot describe how the column will behave when something changes). At the other extreme, the overall efficiency defined by Eq. (13-57) is just a single parameter that can improve the robustness of the model and speed of convergence, but it may be difficult to match actual temperature and/or composition profiles since there is unlikely to be a one-to-one correspondence between the model stages and actual trays. A compromise often used in practice is to use just one value for all components and all stages in a single section of a column. Efficiencies should not be used to model condensers and reboilers; it is usually safe to assume that they are equilibrium devices. It is also unwise to employ Murphree efficiencies for trays with a vapor product since any Murphree efficiency less than 1 will necessarily lead to the prediction of a subcooled vapor.

***Example 8: The Industrial* i-*Butane/*n-*Butane Fractionator (Again)*** With the material on efficiencies in mind, we return to the model of the $C_4$ splitter that we developed in Example 7.

It is possible to estimate the overall efficiency for a column such as this one simply by adjusting the number of equilibrium stages in each section of the column that is needed to match the mass fractions of *i*-butane in the distillate and *n*-butane in the bottoms. Using the SRK equation of state for estimating thermodynamic properties, Ilme (op. cit.) found that 82 equilibrium stages (plus condenser and reboiler) and the feed to stage 38 were required. This corresponds to an overall column efficiency of 82/74 = 111 percent. Klemola and Ilme (op. cit.) used the UNIFAC model for liquid-phase activity coefficients, the Antoine equation for vapor pressures, and the SRK equation for vapor-phase fugacities only and found that 88 ideal stages were needed; this corresponded to an overall efficiency of 119 percent. With the Peng-Robinson equation of state for the estimation of thermodynamic properties, we find that 84 stages are needed (while maintaining the feed to the center stage as is the case here); the overall column efficiency for this model is 114 percent. The differences between these efficiencies are not large in this case, but the important point here is that efficiencies—all types—depend on the choice of model used to estimate the thermodynamic properties. Caution must therefore be exercised when one is using efficiencies determined in this way to predict column performance.

As an alternative to varying the number of stages, we may prefer to maintain a one-to-one correspondence between the number of stages and the number of actual trays, 74 in this case (plus condenser and reboiler), with the feed to tray 38. Using the Peng-Robinson equation of state and a Murphree stage efficiency of 116 percent, we find the product mass fractions that are in excellent agreement with the plant data. The McCabe-Thiele (Hengstebeck) diagram for this case, assembled from the results of the simulation, is shown in Fig. 13-50. Composition profiles computed from this model are shown in Fig. 13-51. Note that the mole fractions are shown on a logarithmic axis so that all the composition profiles can easily be seen.

It must be remembered that this is essentially a binary separation and that it is usually relatively straightforward to match product compositions in processes involving only two different species. In other cases involving a greater number of species with significant concentrations, it will likely be necessary to vary both the number of stages and the component efficiencies to match plant data. We do not recommend adjusting thermodynamic model parameters to fit plant data since this can have unfortunate consequences on the prediction of product distributions, process temperatures, and/or pressures.

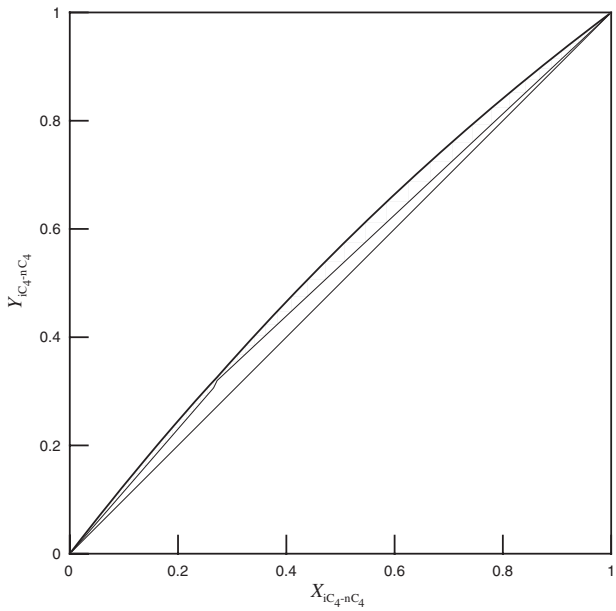

**FIG. 13-50** McCabe-Thiele diagram for $C_4$ splitter.

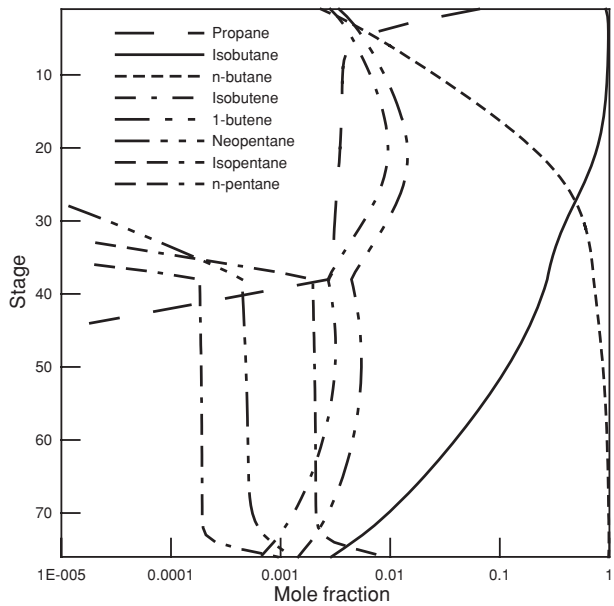

**FIG. 13-51** Liquid-phase mole fraction profiles for *i*-butane/*n*-butane fractionator.

The performance of a packed column often is expressed in terms of the height equivalent to a theoretical plate (HETP) for packed columns. The HETP is related to the height of packing $H$ by

$$\text{HETP} = \frac{H}{N_{EQ}} \tag{13-60}$$

In this case $N_{EQ}$ is the number of equilibrium stages (theoretical plates) needed to accomplish the separation that is possible in a real packed column of height $H$.

***Example 9: HETP of a Packed Absorber*** McDaniel, Bassyoni, and Holland [*Chem. Engng. Sci.*, **25,** 633 (1970)] presented the results of field tests on a packed absorber in a gas plant. The packed section was 23 ft in height, and the column was 3 ft in diameter and filled with 2-in metallic Pall rings. The measured feeds are summarized in the table below.

| Stream | Lean oil | Rich gas |
|---|---|---|
| Pressure, psia | 807 | 807 |
| Temperature, °F | 2.9 | 0 |
| Mole flows, lb·mol/h | | |
| Carbon dioxide | 0.0 | 14.1 |
| Nitrogen | 0.0 | 5.5 |
| Methane | 0.0 | 2655.8 |
| Ethane | 0.0 | 199.9 |
| Propane | 0.0 | 83.2 |
| Isobutane | 0.0 | 19.1 |
| *n*-Butane | 0.0 | 10.9 |
| Isopentane | 0.2 | 3.5 |
| *n*-Pentane | 0.2 | 1.5 |
| *n*-Hexane | 4.5 | 0.4 |
| *n*-Heptane | 17.2 | 0.2 |
| *n*-Octane | 54.5 | 0.1 |
| *n*-Nonane | 50.5 | 0.0 |
| *n*-Decane | 61.7 | 0.0 |
| Total molar flow | 188.9 | 2994.2 |

Determine the number of equilibrium stages needed to match the lean gas product flow for this column (2721.1 lb·mol/h, 93.6% methane).

As a first step, we choose an appropriate thermodynamic model that will be used to estimate $K$ values and enthalpies. Either the Chao-Seader method or the Peng-Robinson equation of state could be considered for this system. It turns out not to be possible to match the plant data with the Chao-Seader method since even one equilibrium stage overpredicts the separation by a very significant amount. It is not even possible to match the exit flows by using the Chao-Seader model combined with a stage efficiency as low as 0.00001. With the Peng-Robinson equation of state, however, it is possible to obtain reasonable agreement with the measured overall product flows by using precisely one equilibrium stage! This suggests that the HETP for this column is 23 ft, a value much higher than any HETP ever published by a packing vendor. In this case the reason for the unrealistic estimate of the HETP has nothing to do with the packing; it is the extreme sensitivity of the simulation to the thermodynamic model, emphasizing the need for caution when one is using efficiencies and HETPs to model some absorption (and distillation) processes.

**Using a Simulator to Solve Distillation Problems** Computer-based methods for solving distillation (and related) column simulation problems now are reasonably reliable. Nevertheless, at times such methods fail to converge. The principal cause of convergence failures is generally a poor initial estimate of the variables being computed. Below we discuss some of the reasons that a simulation might be difficult to converge, along with suggestions on what might make the problem more amenable to solution. The key idea is to modify the problem that is difficult to solve as posed into one that is easy to solve—essentially to provide an improved initial estimate that is more likely to lead to convergence. Note that most simulators allow a calculation to be restarted from an older converged solution. The solution to the "easy" problem may then be used as a starting point for the more difficult problem whose solution is desired. By doing this we are employing a form of continuation (albeit executed manually, at least in part) to solve those problems with which the algorithm at hand may have trouble.

As a rule, the degree of difficulty increases with increasing nonideality. Simultaneous convergence methods are often recommended for simulating strongly nonideal systems (as opposed to tearing or inside-out methods), but even SC methods can experience difficulties with strongly nonideal systems. A possible remedy is to make the system "less" nonideal. It is likely that an activity coefficient model is part of the model used to describe the thermodynamics of these systems, and the source of the convergence difficulties often encountered with such systems. First solving an equivalent ideal system that omits entirely the activity coefficient model (i.e., using Raoult's law) may provide a converged solution that may be an adequate starting point for the nonideal system of interest. However, since many simulators use ideal solution thermodynamic models in any self-initialization method, this technique may not be of sufficient help.

A measure of the nonideality of the system is given by the magnitude of the interaction parameters for the activity coefficient model. It is possible, therefore, to lessen the degree of nonideality by reducing the interaction parameters sufficiently to make the problem easy to solve. The parameters may then be increased in size in a series of steps until the desired values are reached, each time using the solution converged by using the previous set of parameter values as the starting point. It is essential that the parameters return to their correct values in the final step because intermediate solutions have no meaning, serving merely as an aid to convergence. Using the stage efficiency as a continuation parameter also is useful for such cases, provided that the simulation employs standard specifications (more on this topic below).

The most strongly nonideal systems are those that may exhibit two liquid phases. We have avoided detailed discussion of such systems in this section because special algorithms are needed for these cases; see, however, the section on azeotropic distillation and, for example, chapter 8 of Doherty and Malone (op. cit.) for entry points to the literature.

Large heat effects can lead to convergence difficulties. For such systems it is the enthalpies that are the source of the nonlinearity that leads to convergence failures. It is generally not straightforward to modify enthalpies in a simulator because no adjustable parameters exert their influence over the enthalpy in a way comparable to that of the interaction parameters in the activity coefficient model. Use of a constant-enthalpy model in distillation calculations, if available, will lead to constant molar flows from stage to stage (within each separate section of the column), a condition often approached in many real distillation (but not absorption) columns. Thus, if the simulator includes a constant-enthalpy model, then this can be used to obtain a converged solution that may provide a good starting point for the problem with a more realistic enthalpy model.

High pressure adds to the difficulties of converging simulation models. It is likely that an equation of state will be used to estimate fugacity coefficients and enthalpy departures in such systems. Mixtures become increasingly nonideal as the pressure is raised. In some cases the column may operate close to the critical point at which the densities of both phases approach each other. In other cases the iterations may take the estimates of temperature and composition into regions where the equation of state can provide only one mathematically real root for density or compressibility. Occurrences of this behavior often are a source of convergence difficulties. For such systems we suggest reducing the pressure until the problem becomes easy to solve. A converged solution obtained in this way may be used as the starting point for subsequent calculations at increasingly higher pressures (up to that desired).

Very large numbers of stages can pose their own kind of convergence difficulty. A possible remedy is to reduce the number of stages until a converged solution can be obtained. This solution can then be used as the starting point for a problem with more stages. Interpolation will have to be used to estimate values of the flows, temperatures, and mole fractions for any added stages, something not available in all programs.

Nonstandard specifications are very likely to be the source of convergence difficulties. It is all too easy to specify a desired product purity or component flow rate that simply cannot be attained with the specified column configuration. There is always (at least) one solution if the reflux ratio and bottoms flow rate are specified (the so-called standard specifications), which is likely to converge easily. Other specifications that can cause difficulties for similar reasons include specifying temperatures and compositions anywhere in the column and specifying condenser and/or reboiler heat duties. A way to circumvent this kind of difficulty is first to obtain a converged solution for a case involving standard specifications. Once the behavior of the column is

understood, it will be possible to make sensible nonstandard specifications, again using an old converged result as a starting point.

Columns in which temperature and/or compositions change over a wide range in a limited number of stages pose their own particular difficulties. Some highly nonideal systems exhibit this kind of behavior (see Example 11 below). For cases such as this, it is wise to limit periteration changes to temperature and composition. Most modern computer methods will do this as a matter or course, and problems with this cause are not the source of convergence difficulties that they once were.

This is by no means an exhaustive list of the reasons that computer-based simulations fail. Indeed, in many cases it is a combination of more than one of the above factors that leads to difficulty. In those cases it may be necessary to combine several of the strategies outlined above to solve the simulation problem. Often, however, there is no substitute for trial and error. Haas [chap. 4 in Kister (op. cit.), 1992] offers some additional insight on using simulators to solve distillation column models.

***Example 10: Multiple Steady States in Distillation*** This example is one of the most famous in the entire literature on distillation column modeling, having been studied, in one form or another, by many investigators including Magnussen et al. [*I. Chem. E. Symp. Series*, **56** (1979)], Prokopakis and Seider [*AIChE J.*, **29,** 49 (1983)], and Venkataraman and Lucia [*Comput. Chem. Engng.*, **12,** 55 (1988)]. The column simulated here is adapted from the work of Prokopakis and Seider and shown in Fig. 13-52. The ethanol-benzene-water ternary system actually splits into two liquid phases when the overhead vapor is condensed and cooled below its bubble point. One liquid phase is sent to a second column, and the other is returned to the main column as (cold) reflux. Here, in common with others, this column is modeled by ignoring the condenser and decanter. Reflux is simulated by a feed of appropriate composition, temperature, and pressure to the top of the column. The UNIQUAC method was used for estimating the activity coefficients, with parameters given by Prokopakis and Seider. The numerical results are very sensitive to the choice of activity coefficient model and associated parameters; qualitatively, however, the behavior illustrated below is typical of many systems.

This system is considered difficult because convergence of the MESH equations can be difficult to obtain with any algorithm. In fact, for the specifications considered here, there are no less than three solutions; the composition profiles are shown in Fig. 13-53. The goal of the distillation is to recover high-purity ethanol in the bottom stream from the column by using benzene as a mass separating agent. The low-purity profile in Fig. 13-53*a*, containing a large amount of water in the bottom product, is easily obtained from an ideal solution starting point (but with severe restrictions on the maximum allowed temperature change per iteration). The intermediate profile in Fig. 13-53*b* is rather more difficult to obtain. We were able to find it by using, as a starting point, a profile that had been converged at a stage efficiency of 0.7. The high-purity solution in Fig. 13-53*c*, containing very little water in the bottom product, is also easily obtained from an initial profile calculated by assuming that the stage efficiency is quite low (0.3). Multiple solutions for this column have been reported by many authors (including the three cited above). In fact, with the parameters used here, the three solutions exist over a narrow range of ethanol feed flows. Taylor, Achuthan, and Lucia [*Comput. Chem. Engng.*, **20,** 93 (1996)] found complex-valued solutions to the MESH equations for values outside this range.

Multiple steady-state solutions of the MESH equations have been found for many systems, and the literature on this topic is quite extensive. An introduction to the literature is provided by Bekiaris, Guttinger, and Morari [*AIChE J.*, **46,** 955 (2000)]. Chavez, Seader, and Wayburn [*Ind. Eng. Chem. Fundam.*, **25,** 566 (1986)] used homotopy methods to find multiple solutions for some systems of interlinked columns. Parametric continuation has been used to detect multiple solutions of the MESH equations [Ellis et al., *Comput. Chem. Engng.*, **10,** 433 (1986); Kovach and Seider (op. cit.); Burton, Ph.D. Thesis in Chem. Engng., Cambridge University, 1986]. That real distillation columns can possess multiple steady states has been confirmed by the experimental work of Kienle et al. [*Chem. Engng. Sci.*, **50,** 2691 (1995)], Køggersbol et al. [*Comput. Chem. Engng.*, **20,** S835 (1996)], Gaubert et al. [*Ind. Eng. Chem. Res.*, **40,** 2914 (2001)], and others.

## NONEQUILIBRIUM MODELING

Although the widely used equilibrium-stage models for distillation, described above, have proved to be quite adequate for binary and close-boiling, ideal and near-ideal multicomponent vapor-liquid mixtures,

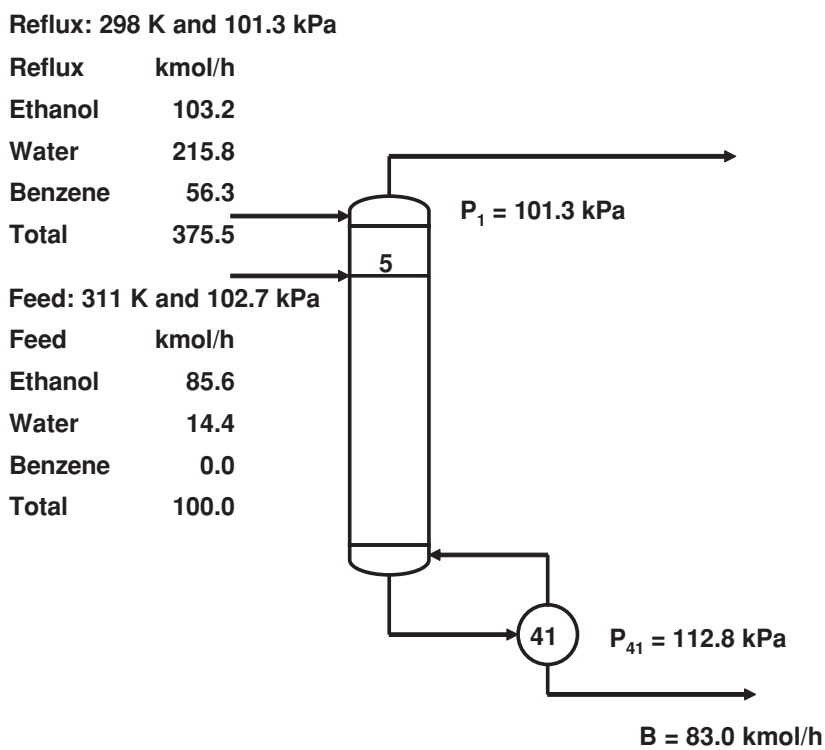

**FIG. 13-52** Azeotropic distillation tower for distillation of an ethanol-water mixture using benzene as a mass separating agent. [*After Prokopakis and Seider (op. cit.).*]

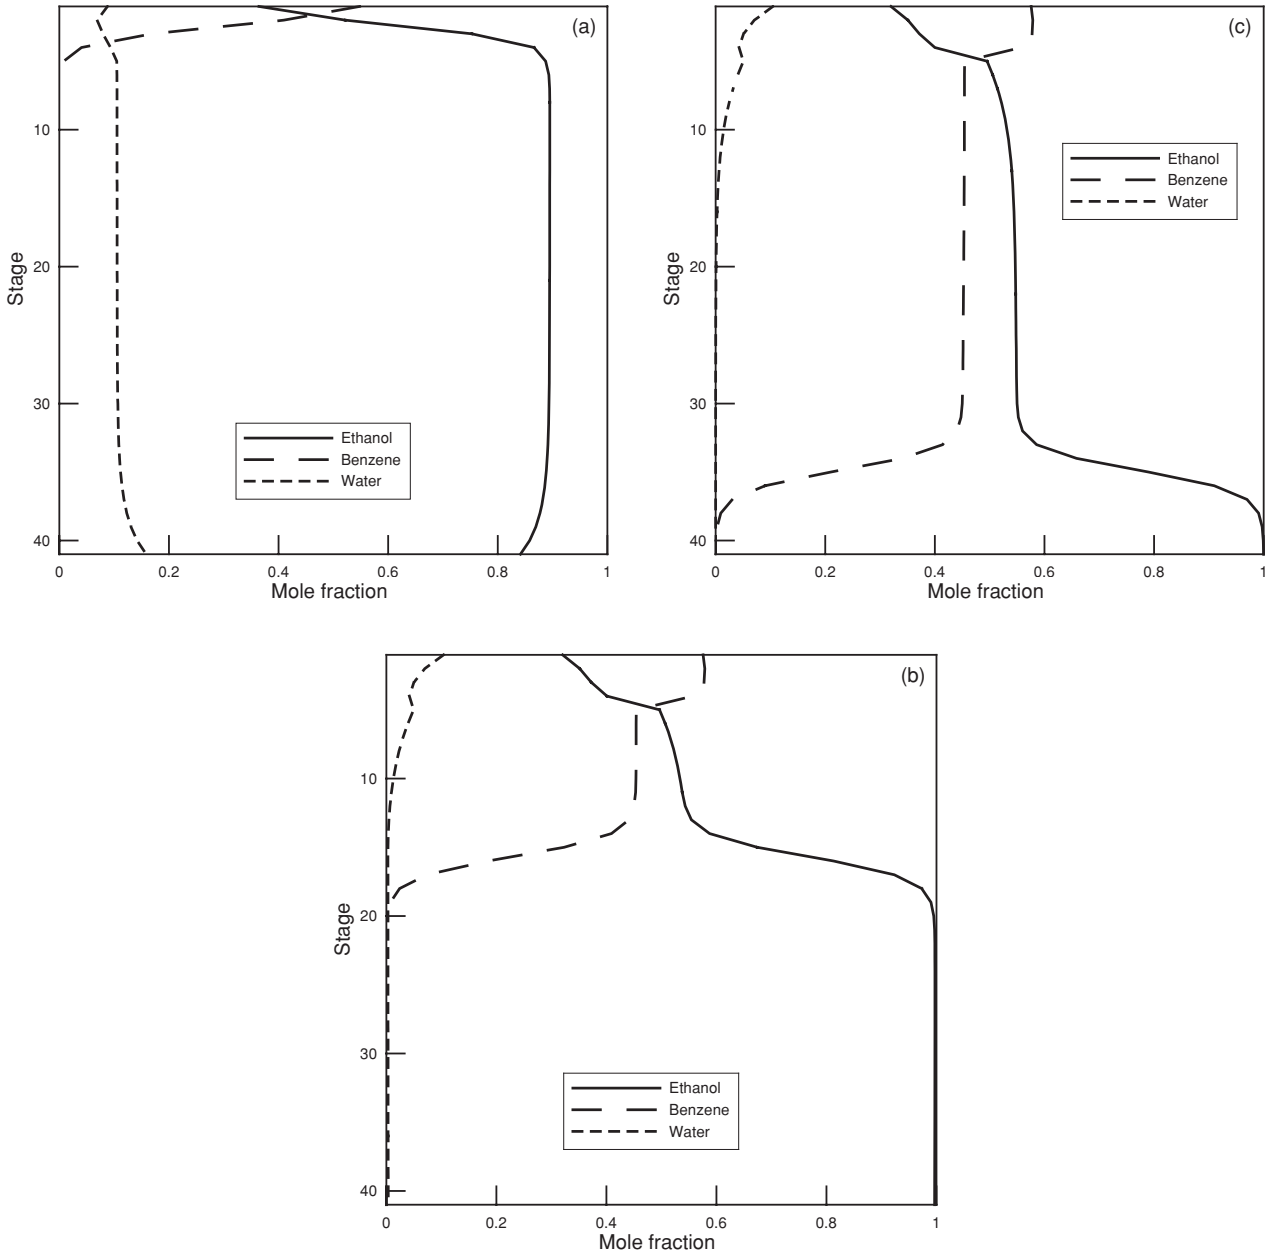

**FIG. 13-53** Liquid-phase mole fraction profiles for ethanol-benzene-water distillation. (*a*) Low-purity profile. (*b*) Intermediate-purity profile. (*c*) High-purity profile.

their deficiencies for general multicomponent mixtures have long been recognized. Even Murphree (op. cit.), who formulated the widely used plate efficiencies that carry his name, pointed out clearly their deficiencies for multicomponent mixtures and when efficiencies are small. Walter and Sherwood [*Ind. Eng. Chem.*, **33,** 493 (1941)] showed that experimentally measured efficiencies could cover an enormous range, with some values less than 10 percent. Toor [*AIChE J.*, **3,** 198 (1957)] predicted that the Murphree vapor efficiencies in some multicomponent systems could cover the entire range of values from minus infinity to plus infinity, a result that was verified experimentally by others.

In recent years a new approach to the modeling of distillation and absorption processes has become available: the *nonequilibrium* or *rate-based* models. These models treat these classical separation processes as the mass-transfer rate governed processes that they really are, and avoid entirely the (a priori) use of concepts such as efficiency and HETP [Krishnamurthy and Taylor, *AIChE J.*, **31,** 449–465 (1985); Taylor, Kooijman, and Hung, *Comput. Chem. Engng.*, **18,** 205–217 (1994)].

A schematic diagram of a nonequilibrium (NEQ) stage is given in Fig. 13-54. This NEQ stage may represent (part of) the two phases on

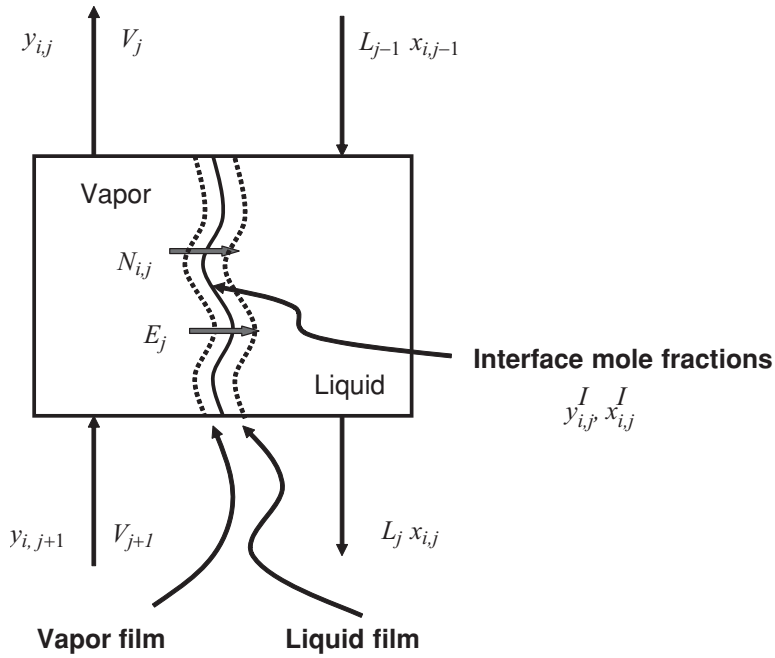

**FIG. 13-54** Schematic diagram of a nonequilibrium stage.

a tray or within a section of a packed column. The wavy line in the middle of the box represents the phase interface. This illustration is intended only to aid in understanding the basic principles of nonequilibrium modeling; the actual flow patterns and the shape of the phase boundary are very complicated and depend upon, among other things, the equipment design, the column operation, and the physical properties of the system.

In a nonequilibrium model, separate balance equations are written for each distinct phase. The material balances for each species in the vapor and liquid phases on an arbitrary stage $j$ are

$$(1 + r_j^V)V_j y_{i,j} - V_{j+1} y_{i,j+1} - f_{i,j}^V + \mathcal{N}_{i,j}^V = 0 \qquad (13\text{-}61)$$

$$(1 + r_j^L)L_j x_{i,j} - L_{j-1} x_{i,j-1} - f_{i,j}^L - \mathcal{N}_{i,j}^L = 0 \qquad (13\text{-}62)$$

where $r_j^V$ and $r_j^L$ are the ratios of sidestream to interstage flows and are defined by Eqs. (13-49); $f_{i,j}^p$ is the external feed flow rate of species $i$ in phase $p$ to stage $j$; and $\mathcal{N}_{i,j}$ is the rate of mass transfer across the phase interface (with units of moles per second or equivalent). Formally, we may write

$$\mathcal{N}_{i,j}^p = \int N_{i,j}^p \, da_j \qquad (13\text{-}63)$$

where $N_{i,j}^p$ is the molar flux in phase $p$ [with units of mol/(m$^2$·s) or equivalent] at a particular point in the two-phase dispersion and $da_j$ is the portion of interfacial area through which that flux passes. A material balance around the interface yields

$$\mathcal{N}_{i,j}^V = \mathcal{N}_{i,j}^L \qquad (13\text{-}64)$$

The sum of the phase and interface balances yields the component material balance for the stage as a whole, the equation used in the equilibrium-stage model.

The energy balance is treated in a similar way, split into two parts—one for each phase, each part containing a term for the rate of energy transfer across the phase interface.

$$(1 + r_j^V)V_j H_j^V - V_{j+1} H_{j+1}^V - F_j^V H_j^{VF} + \mathcal{E}_j^V + Q_j^V = 0 \qquad (13\text{-}65)$$

$$(1 + r_j^L)L_j H_j^L - L_{j-1} H_{j-1}^L - F_j^L H_j^{LF} - \mathcal{E}_j^L + Q_j^L = 0 \qquad (13\text{-}66)$$

where $E_j^p$ is the rate of energy transfer across the phase interface in phase $p$ and is defined by

$$\mathcal{E}_j^p = \int_a E_j^p \, da \qquad (13\text{-}67)$$

where $a$ is the interfacial area and $E_j^p$ is the energy flux across the interface from/to phase $p$. An energy balance at the phase interface yields

$$\mathcal{E}_j^V = \mathcal{E}_j^L \qquad (13\text{-}68)$$

In addition, we need summation equations for the mole fractions in the vapor and liquid phases.

A review of early applications of NEQ models is available in chapter 14 of Taylor and Krishna (op. cit.).

It is worth emphasizing that Eqs. (13-61) to (13-68) hold regardless of the models used to calculate the interphase transport rates $\mathcal{N}_{i,j}$ and $\mathcal{E}_j^p$. With a mechanistic model of sufficient complexity it is possible, at least in principle, to account for mass transfer from bubbles in the froth on a tray as well as to entrained droplets in a spray, as well as transport between the phases flowing over and through the elements of packing in a packed column. However, a completely comprehensive model for estimating mass-transfer rates in all the possible flow regimes does not exist at present, and simpler approaches are used.

The simplest approach is to say that the molar fluxes at a vapor-liquid interface may be expressed as

$$N_i^V = c_t^V k_i^V (y_i^V - y_i^I) + y_i^V N_t^V \qquad (13\text{-}69)$$

with a similar expression for the liquid phase.

$$N_i^L = c_t^L k_i^L (x_i^I - x_i^L) + x_i^L N_t^L \qquad (13\text{-}70)$$

In these equations $c_t^V$ and $c_t^L$ are the molar densities of the superscripted phases, $y_i^V$ is the mole fraction in the bulk vapor phase, $x_i^L$ is the mole fraction in the bulk liquid phase, and $x_i^I$ and $y_i^I$ are the mole fractions of species $i$ at the phase interface. Also $N_t^p$ is the total molar flux in phase $p$, and $k_i^V$ and $k_i^L$ are the mass-transfer coefficients for

the vapor and liquid phases (with units of velocity), respectively. Methods for estimating mass-transfer coefficients in distillation processes are discussed briefly below and at greater length in Section 5 of this handbook.

The second term on the right-hand sides of Eqs. (13-69) and (13-70) is not often important in distillation (its neglect is equivalent to the assumption of equimolar counterflows in the column), but can be quite significant in gas absorption.

The energy fluxes are related by

$$E^V = q^V + \sum_{i=1}^{c} N_i^V \overline{H}_i^V = E = q^L + \sum_{i=1}^{c} N_i^L \overline{H}_i^L = E^L \qquad (13\text{-}71)$$

with

$$q^V = h^V(T^V - T^I) \quad q^L = h^L(T^I - T^L) \qquad (13\text{-}72)$$

where $h^V$ and $h^L$ are the heat-transfer coefficients in the vapor and liquid phases, respectively.

The inclusion in the model of the mass and energy transport equations introduces the mole fractions and temperature at the interface. It is common in almost all treatments of mass transfer across a phase boundary to assume that the mole fractions in the vapor and liquid phases at the interface are in equilibrium with each other. We may, therefore, use the very familiar equations from phase equilibrium thermodynamics to relate the interface mole fractions

$$y_i^I = K_i x_i^I \qquad (13\text{-}73)$$

where the superscript $I$ denotes the interface compositions and $K_i$ is the vapor-liquid equilibrium ratio (or $K$ value) for component $i$. In equilibrium-stage calculations, the equilibrium equations are used to relate the composition of the streams leaving the stage, and the $K$ values are evaluated at the composition of the two exiting streams and the stage temperature (usually assumed to be the same for both phases). In nonequilibrium models the $K$ values are evaluated at the interface composition and temperature by using exactly the same thermodynamic property models as that used in equilibrium-stage simulations. The interface composition and temperature must, therefore, be computed during a nonequilibrium column simulation. Strictly speaking, the composition and temperature at the interface vary with position in two-phase dispersion that exists on a tray or within the confines of a packed bed. In most NEQ models, the interface state is assumed uniform on the stage; thus, the model of a single stage includes one set of mass-transfer, heat-transfer, and phase equilibrium equations.

In equilibrium-stage models, the compositions of the leaving streams are related through the assumption that they are in equilibrium (or by use of an efficiency equation). It is important to recognize that efficiencies are not used in a nonequilibrium model; they may, however, be calculated from the results obtained by solving the model equations.

**Degrees of Freedom** Table 13-10 summarizes the equations for a single nonequilibrium stage. There are $6c + 5$ independent equations per stage. As with the equilibrium-stage model discussed above, we have not included the feed mole fraction summation equation, or those for the vapor and liquid streams coming from adjacent stages.

**TABLE 13-10 Equations for a Nonequilibrium Stage**

| Equation | Equation no. | Number |
|---|---|---|
| Vapor-phase component balance | (13-61) | $c$ |
| Liquid-phase component balance | (13-62) | $c$ |
| Interface material balance | (13-64) | $c$ |
| Vapor bulk mole fraction summation equation | | 1 |
| Liquid bulk mole fraction summation equation | | 1 |
| Vapor-phase energy balance | (13-65) | 1 |
| Liquid-phase energy balance | (13-66) | 1 |
| Equilibrium at the interface | (13-73) | $c$ |
| Mass transfer in the vapor phase | (13-69) | $c - 1$ |
| Mass transfer in the liquid phase | (13-70) | $c - 1$ |
| Energy balance at phase interface | (13-71) | 1 |
| Summation equation for vapor mole fractions at phase interface | | 1 |
| Summation equation for liquid mole fractions at phase interface | | 1 |
| | Total | $6c + 5$ |

**TABLE 13-11 Variables for a Nonequilibrium Stage**

| Variable | Symbol | Number | Specified |
|---|---|---|---|
| Vapor and liquid flow rates | $V_j$, $L_j$ | 2 | |
| Sidestream flow rates | $U_j$, $W_j$ | 2 | Yes |
| Vapor-phase bulk composition | $y_{i,j}$ | $c$ | |
| Liquid-phase bulk composition | $x_{i,j}$ | $c$ | |
| Vapor interface composition | $y_{i,j}^I$ | $c$ | |
| Liquid interface composition | $x_{i,j}^I$ | $c$ | |
| Component feed flow rates | $f_{i,j}^V, f_{i,j}^L$ | $2c$ | Yes |
| Feed pressure and temperature | | 2 | Yes |
| Vapor-phase temperature | $T_j^V$ | 1 | |
| Liquid-phase temperature | $T_j^L$ | 1 | |
| Interface temperature | $T_j^I$ | 1 | |
| Stage pressure | $P_j$ | 1 | Yes |
| Heat loss from vapor phase | $Q_j^V$ | 1 | Yes |
| Heat loss from liquid phase | $Q_j^L$ | 1 | Yes |
| Mass-transfer rates in the vapor phase | $\mathcal{N}_{i,j}^V$ | $c$ | |
| Mass-transfer rates in the liquid phase | $\mathcal{N}_{i,j}^L$ | $c$ | |
| | Total | $8c + 12$ | $2c + 7$ |

The variables appearing in these equations are summarized in Table 13-11.

It is important to recognize that we have not included mass- and heat-transfer coefficients in the table of variables. These quantities are considered analogous to the thermodynamic properties of the equilibrium-stage model and are functions of other variables (as discussed in greater detail below).

The $6c + 5$ variables for each stage determined during the solution of the nonequilibrium model equations are the vapor and liquid flow $V_j$ and $L_j$, respectively; the bulk vapor mole fractions, $y_{i,j}$ ($c$ in number); the bulk liquid mole fractions $x_{i,j}$ ($c$); the vapor and liquid temperatures $T_j^V$ and $T_j^L$, respectively; the interface mole fractions and temperature $y_{i,j}^I$ ($c$), $x_{i,j}^I$ ($c$), and $T_j^I$; and the mass-transfer rates $\mathcal{N}_{i,j}^V$ ($c$) and $\mathcal{N}_{i,j}^L$ ($c$). Note that the interface material balance, Eq. (13-64), means that only one set of mass-transfer rates really needs to be counted in the set of variables for this stage, say, $\mathcal{N}_{i,j}$ (this reduces the number of variables being computed). The remaining variables, $2c + 7$ in number, that need to be specified, are identified in Table 13-11. It is important to recognize that the other flows and composition variables appearing in the nonequilibrium-stage model equations are associated with the equivalent equations for adjacent stages. Although it appears that the number of degrees of freedom is higher for this more complicated model, this is misleading. The additional variables that are specified here take into account that there is one additional heat duty (one per phase) and that the feed is split into vapor and liquid fractions. In practice, the overall feed flow, pressure, temperature (or vapor fraction), and composition would be specified, and the vapor and liquid component flows in the feed determined from an adiabatic flash.

**Physical Properties** The only physical properties needed for an equilibrium-stage simulation are those needed to estimate $K$ values and enthalpies; these same properties are needed for nonequilibrium models as well. Enthalpies are required for the energy balance equations; vapor-liquid equilibrium ratios are needed for the calculation of driving forces for mass and heat transfer. The need for mass- (and heat-) transfer coefficients means that nonequilibrium models are rather more demanding of physical property data than are equilibrium-stage models. These coefficients may depend on a number of other physical properties, as summarized in Table 13-12.

Methods for estimating physical and transport properties are described in Sections 4 and 5 of this handbook [see also Poling et al., *The Properties of Gases and Liquids*, McGraw-Hill, 5th ed. (2001)].

**Flow Models** In a real column the composition of the vapor and liquid phases changes due to flow across a tray or over and around packing. Thus, the bulk phase mole fractions that appear in the rate equations (13-69) and (13-70) vary with position and should not automatically be assumed to be equal to the average exit mole

**TABLE 13-12 Physical Property Needs of Equilibrium and Nonequilibrium Models**

| Property | EQ model | NEQ model | Used for |
|---|---|---|---|
| *K* values | Yes | Yes | Driving forces |
| Enthalpy | Yes | Yes | Energy balances |
| Activity coefficient | Yes | Yes | *K* values, enthalpies |
| Fugacity coefficients | Yes | Yes | *K* values, enthalpies |
| Vapor pressure | Yes | Yes | *K* values |
| Heat capacity | Yes | Yes | Enthalpies, heat-transfer coefficient |
| Mass-transfer coefficients | | Yes | Mass-transfer rate equations |
| Heat-transfer coefficients | | Yes | Energy-transfer rate equation |
| Density | | Yes | Mass-transfer coefficients |
| Diffusion coefficients | | Yes | Mass-transfer coefficients |
| Viscosity | | Yes | Mass-transfer coefficients |
| Surface tension | | Yes | Mass-transfer coefficients |
| Thermal conductivity | | Yes | Heat-transfer coefficients |

fractions that appear in the material balance equations. In practice, we assume a flow pattern for the vapor and liquid phases, and this allows us to determine appropriate average mole fractions for use in the rate equations. There are three flow models in general use: mixed flow, plug flow, and dispersion flow (Lockett, op. cit.). A flow model needs to be identified for each phase. If both phases are assumed well mixed, then the average mole fractions are indeed equal to the mole fractions in the exit streams. This is the simplest (and an often used) approach that leads to the most conservative simulation (lowest mass-transfer rates, tallest column); at the opposite extreme is plug flow. The most realistic model is dispersion flow (see Lockett, op. cit.), but this model is not included in most computer implementations of NEQ models as it is quite complicated. For further discussion of the importance of flow models and the equations used to estimate average compositions, see Taylor and Krishna (op. cit.) and Kooijman and Taylor [*Chem. Engng. J.*, **57,** 177 (1995)].

**Mass-Transfer Coefficients** Mass-transfer coefficients (and the equally important interfacial area, a parameter with which they frequently are combined) may be computed from empirical correlations or theoretical models.

The mass-transfer performance of trays often is expressed by way of a dimensionless group called the number of transfer units [see Lockett (op. cit.), Kister (op. cit.), and Sec. 14 for additional background]. These dimensionless numbers are defined by

$$\mathbb{N}^V = k^V a' t_V = \frac{k^V a h_f}{u_s^V} \tag{13-74}$$

$$\mathbb{N}^L = k^L \bar{a} t_L = \frac{k^L a h_f Z}{Q_L/W} \tag{13-75}$$

where $h_f$ = froth height, m
$Z$ = liquid flow path length, m
$W$ = weir length, m
$Q_L = \dfrac{L}{c_t^L}$ = volumetric liquid flow rate, $m^3/s$
$u_s = \dfrac{V}{c_t^V A_{bub}}$ = superficial vapor velocity, m/s
$A_{bub}$ = bubbling area of tray, $m^2$
$h_L$ = clear liquid height on tray, m
$a'$ = interfacial area per unit volume of vapor, $m^2/m^3$
$\bar{a}$ = interfacial area per unit volume of liquid, $m^2/m^3$

These areas are related to the interfacial area per unit volume of froth $a$ by

$$a' = \frac{1}{1-a} \quad \bar{a} = \frac{a}{\alpha} \tag{13-76}$$

where $\alpha = h_L/h_f$ is the relative froth density. Also $t_V$ and $t_L$ are the vapor- and liquid-phase residence times, defined by

$$t_V = (1-\alpha) h_f u_s \tag{13-77}$$

$$t_L = \frac{Z}{u_L} = \frac{h_L Z W}{Q_L} \tag{13-78}$$

The *AIChE Bubble Tray Design Manual,* published in 1958 [see also Gerster et al., *Tray Efficiencies in Distillation Columns*, AIChE (1958)], presented the first comprehensive procedure for estimating the numbers of transfer units in distillation. For many years this work represented the only such procedure available in the open literature; the work of organizations such as Fractionation Research Incorporated (FRI) was available only to member companies. Other comprehensive procedures for trays appeared in the 1980s [Zuiderweg, *Chem. Engng. Sci.*, **37,** 1441 (1982); Chan and Fair, *Ind. Engng. Chem. Proc. Des. Dev.*, **23,** 814, 820 (1984)]. Readers are referred to Kister (op. cit.), Lockett (op. cit.), Klemola and Ilme (op. cit.), and Sec. 14 of this handbook for summaries and references to what is available in the open literature.

***Example 11: Mass-Transfer Coefficient in a Tray Column*** Consider again the $C_4$ splitter that formed the basis of Examples 7 and 8. The key design parameters for the valve trays are given in the table below (from Klemola and Ilme, op. cit.).

| | | | |
|---|---|---|---|
| Column height | 51.8 m | Downcomer area center | 0.86 $m^2$ |
| Column diameter | 2.9 m | Tray spacing | 0.6 m |
| Number of trays | 74 | Hole diameter | 39 mm |
| Weir length, side | 1.859 m | Total hole area | 0.922 $m^2$ |
| Weir length, center | 2.885 m | Outlet weir height | 51 mm |
| Liquid flow path length | 0.967 m per pass | Tray thickness | 2 mm |
| Active area | 4.9 $m^2$ | Number of valves per tray | 772 |
| Downcomer area, side | 0.86 $m^2$ | Free fractional hole area | 18.82% |

Estimate the mass-transfer coefficients for tray 7 where the flow and physical properties are estimated to be as summarized below:

| | Gas/vapor | Liquid |
|---|---|---|
| Flow, mol/s | 590 | 550 |
| Density, $kg/m^3$ | 16.8 | 520 |
| Viscosity, $N/m^2$ | $8.6 \times 10^{-6}$ | $1.35 \times 10^{-4}$ |
| Molecular weight, kmol/kg | 58.0 | 58.0 |
| Diffusivity, $m^2/s$ | $800 \times 10^{-9}$ | $1.0 \times 10^{-9}$ |
| Surface tension, N/m | 0.014 | |

We use the AIChE correlation to illustrate the general approach, noting that the correlation was not developed specifically for valve trays (few methods were). In this model the number of transfer units is given by

$$\mathbb{N}^V = \frac{0.776 + 4.57\, h_w - 0.238 F_s + 104.8 Q_L/W}{\sqrt{\mathrm{Sc}^V}} \tag{13-79}$$

$$\mathbb{N}^L = 19{,}700\sqrt{D^L}\,(0.4F_s + 0.17)t_L \tag{13-80}$$

In the expressions above $h_w$ is the weir height (m). The vapor-phase Schmidt number $\mathrm{Sc}^V$ is defined by $\mathrm{Sc}^V = \mu^V/(\rho^V D^V)$, which here takes the value $\mathrm{Sc}^V = 0.640$.

The superficial velocity is computed next from $u_s^V = V/(c_t^V A_{bub}) = 0.42$ m/s. Here $F_s$ is the so-called $F$ factor and is $F_s = u_s^V\sqrt{\rho^V} = 1.7$ $(kg/ms)^{1/2}$. The volumetric liquid flow is $Q_L = L/c_t^L = 0.061$ $m^3/s$.

The froth height on the tray is estimated (by using the methods in Sec. 14 of this handbook—see also Lockett, 1986; Kister, 1992) to be $h_f = 0.143$ m. The liquid-phase residence time is $t_L = h_L Z W/Q_L = 4.67$ s.

The number of transfer units follows for the vapor phase from Eq. (13-79) as $\mathbb{N}^V = 2.45$ and for the liquid phase from Eq. (13-80) as $\mathbb{N}^L = 2.33$. The products of the vapor- and liquid-phase mass-transfer coefficients and the interfacial area follow directly from the second parts of the same equations. Note that it is not possible with these correlations to separate the mass-transfer coefficient from the interfacial area. In practice this is not a concern since it is the mass-transfer rates that are needed rather than the fluxes and the product suffices for NEQ model computations.

The diffusivities used in this example were for the light key–heavy key pair of components. For systems similar to this one, the diffusion coefficients of all binary pairs in the mixture would be expected to have similar values. This will not be the case for mixtures of components that differ sharply in their fundamental properties (e.g., size, polarity). For these more highly nonideal mixtures, it is necessary to estimate the mass-transfer coefficients for each of the binary pairs.

The number of transfer units for packed columns is defined by

$$\mathbb{N}^V = \frac{k^V a' H}{u_V} \tag{13-81}$$

$$\mathbb{N}^L = \frac{k^L a' H}{u_L} \tag{13-82}$$

where $u_V = V/(c_t^V A_c)$ and $u_L = L/(c_t^L A_c)$ are the superficial vapor and liquid velocities, with $A_c$ the cross-sectional area of the column; $a'$ is the interfacial area per unit volume. The height of a transfer unit (HTU) is defined as

$$\mathbb{H}^V = \frac{H}{\mathbb{N}^V} = \frac{u_V}{k^V a'} \tag{13-83}$$

$$\mathbb{H}^L = \frac{H}{\mathbb{N}^L} = \frac{u_L}{k^L a'} \tag{13-84}$$

Methods of estimating numbers and/or heights of transfer units and mass-transfer coefficients and interfacial areas in packed columns are reviewed by Ponter and Au Yeung (in *Handbook of Heat and Mass Transfer*, Gulf Pub., 1986), by Wang et al. [*Ind. Eng. Chem. Res.*, **44,** 8715 (2005)], and in Sec. 5 of this handbook; one such method is illustrated below.

***Example 12: Mass-Transfer Coefficients in a Packed Column*** Estimate the mass-transfer coefficients at the top of the packed gas absorber in Example 9. The column has 23 ft of 2-in metallic Pall rings and is 3 ft in diameter. The specific surface area of this packing is 112 $m^2/m^3$. The flows and physical properties are estimated to be as summarized below.

| | Gas/vapor | Liquid |
|---|---|---|
| Flow, mol/s | 332 | 37 |
| Temperature, K | 267 | 266 |
| Density, $kg/m^3$ | 51.2 | 705 |
| Viscosity, $N/m^2$ | $1.17 \times 10^{-5}$ | $2.43 \times 10^{-4}$ |
| Molecular weight, kmol/kg | 16.8 | 87.9 |
| Diffusivity, $m^2/s$ | $100 \times 10^{-9}$ | $4.6 \times 10^{-9}$ |
| Surface tension, N/m | 0.0085 | |

We will use the well-known correlation of Onda et al. (see Sec. 14) to estimate the mass-transfer coefficients. The vapor-phase coefficient is given by

$$\frac{k^V}{a_p D^V} = A\left(\frac{\rho^V u^V}{\mu^V a_p}\right)^{0.7}\left(\frac{\mu^V}{\rho^V D^V}\right)^{0.33}(a_p d_p)^{-2} \tag{13-85}$$

where $d_p$ is the nominal packing size (2 in = 0.0508 m), and $a_p$ is the specific surface area of the packing. Also $A$ is a constant that has the value 2 if nominal packing size is less than 0.012 m, otherwise, $A = 5.23$.

The liquid-phase mass-transfer coefficient is given by

$$k^L = 0.0051\left(\frac{\rho^L}{\mu^L g}\right)^{-1/3}\left(\frac{u_L}{a'\mu^L}\right)^{2/3}\left(\frac{\mu^L}{\rho^L D^L}\right)^{1/2}(a_p d_p)^{0.4} \tag{13-86}$$

Finally, the interfacial area per unit volume is given by

$$a' = a_p\left\{1 - \exp\left[-1.45\left(\frac{\sigma_c}{\sigma^L}\right)^{0.75}\left(\frac{\rho^L u_L}{a_p \mu_L}\right)^{0.1}\left(\frac{a_p u_L^2}{g}\right)^{0.05}\left(\frac{u_L^2 \rho^L}{a_p \sigma^L}\right)^{0.2}\right]\right\} \tag{13-87}$$

The vapor and liquid velocities are calculated to be $u_V = V/(c_t^V A_t) = 0.42$ m/s and $u_L = L/(c_t^L A_t) = 0.0017$ m/s. Substituting the values provided above into Eqs. (13-85) to (13-87) gives $k^V = 0.0021$ m/s, $a' = 96.2$ $m^2/m^3$, and $k^L = 3.17 \times 10^{-4}$ m/s.

**Solving the NEQ Model Equations** In general, a nonequilibrium model of a column has many more equations than does an equivalent equilibrium-stage model. Nevertheless, we use may essentially the same computational approaches to solve the nonequilibrium model equations: simultaneous convergence (Krishnamurthy and Taylor, op. cit.) and continuation methods [Powers et al., *Comput. Chem. Engng.*, **12,** 1229 (1988)]. Convergence of a nonequilibrium model is likely to be slower than that of the equilibrium model because of the greater number of model equations and the associated overhead in evaluating a greater number of physical properties. Finally, we note that the strategies outlined above for helping to converge equilibrium-stage simulation may prove equally useful when simulating distillation operations using the nonequilibrium models described here.

**Equipment Design** As we have already seen, the estimation of mass-transfer coefficients and interfacial areas from empirical correlations nearly always requires us to know something about the column design. At the very least we need to know the diameter and type of internal column (although usually we need to know more than that since most empirical correlations for mass-transfer coefficients have some dependency on equipment design parameters, e.g., weir height of trays). This need for more or less complete equipment design details suggests that nonequilibrium models cannot be used in preliminary process design (before any actual equipment design has been carried out). This is not true, however. Column design methods are available in the literature as well in most process simulation programs, and it is straightforward to carry out equipment sizing calculations at the same time as the stage equations are being solved (Taylor et al., op. cit.). This does not add significantly to the difficulty of the calculation, while providing the very significant advantage of allowing nonequilibrium or rate-based models to be used at all stages of process simulation.

***Example 13: A Nonequilibrium Model of a $C_4$ Splitter*** Consider, again the $C_4$ splitter that formed the basis of Examples 7, 8, and 11.

When we create a nonequilibrium model of this—or any—column, we do not need to guess how many stages to use in each section of the column. The real column had 74 valve trays; the model column includes 74 model trays with the feed to tray 38 [plus a (subcooled) condenser and a reboiler, both of which are modeled as equilibrium stages, as described above]. All operating specifications are the same as for the corresponding equilibrium-stage model and are given in Examples 7 and 8. It is necessary to choose models that allow for the estimation of the rates of interphase mass transfer; that means selecting vapor and liquid flow models and correlations to estimate the mass-transfer coefficients in each phase, as discussed above. In this case the AIChE correlations were used. It is known that this method is more conservative than others (i.e., the predicted efficiencies are lower). The importance of the flow model is clear from the simulation results tabulated below. The predicted component Murphree efficiencies computed with Eq. (13-58) vary more widely from stage to stage and from component to component than might be expected for a system such as this. The TBK efficiency, on the other hand, does not change by more than a few percentage points over the height of the column; the value in the table below is an average of that computed for each tray from the simulation results using Eq. (13-59).

| Vapor flow model | Liquid flow model | *i*-$C_4$ in distillate, % | *n*-$C_4$ in bottoms, % | TBK efficiency, % |
|---|---|---|---|---|
| Mixed | Mixed | 90.2 | 96.3 | 63 |
| Plug | Mixed | 92.2 | 97.2 | 78 |
| Plug | Dispersion | 93.9 | 98.0 | 106 |

Internal vapor and/or liquid composition data rarely are available, but such data are the best possible for model discrimination and validation. It is often relatively easy to match even a simple model only to product compositions. In the absence of composition profiles, the internal temperature profile can often be as useful provided that it is known to which phase a measured temperature pertains. The table below compares the few available measured tray temperatures with those computed during the simulation. The agreement is quite good.

| | Temperature, °C | |
|---|---|---|
| Tray | Measured | Predicted |
| 9 | 47.5 | 48.6 |
| 65 | 62.2 | 62.5 |
| 74 | 63.2 | 63.1 |

A portion of the McCabe-Thiele diagram for the simulation involving plug flow of vapor and dispersion flow of the liquid is shown in Fig. 13-55. For a nonequilibrium column these diagrams can only be constructed from the results of a computer simulation. Note that the triangles that represent the stages extend beyond the curve that represents the equilibrium line; this is so because the efficiencies are greater than 100 percent.

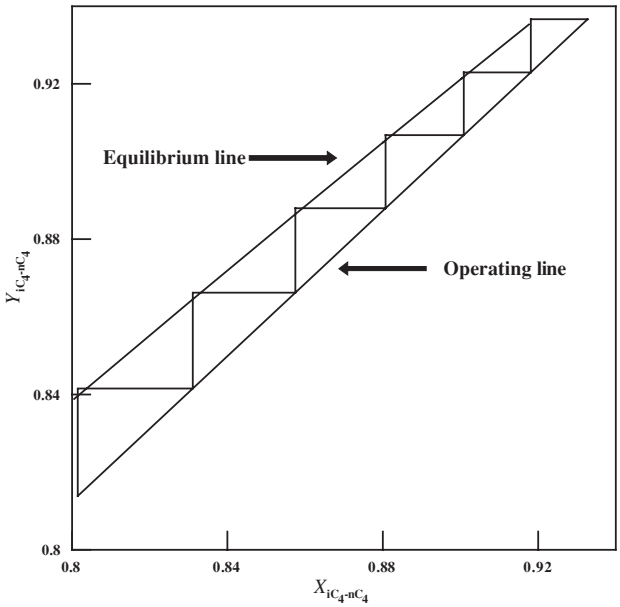

**FIG. 13-55** Expanded view near upper right corner of McCabe-Thiele diagram for $C_4$ splitter.

In this particular case the converged composition and temperature profiles have the same shape as those obtained with the equilibrium-stage model (with specified efficiency) and, therefore, are not shown. The reason for the similarity is that, as noted above, this is basically a binary separation of very similar compounds. The important point here is that, unlike the equilibrium-stage model simulations, the nonequilibrium model predicted how the column would perform; *no parameters were adjusted to provide a better fit to the plant data.* That is not to say, of course, that NEQ models cannot be used to fit plant data. In principle, the mass-transfer coefficients and interfacial area (or parameters in the equations used to estimate them) can be tuned to help the model better fit plant data.

## MAXWELL-STEFAN APPROACH

Strictly speaking, Eqs. (13-69) and (13-70) are valid only for describing mass transfer in binary systems under conditions where the rates of mass transfer are low. Most industrial distillation and absorption processes, however, involve more than two different chemical species. The most fundamentally sound way to model mass transfer in multicomponent systems is to use the Maxwell-Stefan (MS) approach (Taylor and Krishna, op. cit.).

The MS equation for diffusion in a mixture with any number of different species can be written as

$$d_i = -\sum_{k=1}^{c} \frac{x_i x_k (u_i - u_k)}{Đ_{ik}} \tag{13-88}$$

where $Đ_{ik}$ is the Maxwell-Stefan diffusion coefficient for the binary *i-k* pair of components. Methods for estimating these coefficients are discussed by Taylor and Krishna (op. cit.) (see also Section 5 of this handbook and Poling et al., op. cit.).

In Eq. (13-88), $d_i$ is termed the generalized driving force. For an ideal gas mixture the driving force is related to the partial pressure gradient and the mole fraction gradient as follows:

$$d_i = \frac{1}{P}\frac{dp_i}{dz} = \frac{dx_i}{dz} \tag{13-89}$$

For a nonideal fluid, the driving force is related to the chemical potential gradient

$$d_i = \frac{x_i}{RT}\frac{d\mu_i}{dz} \tag{13-90}$$

Equations (13-88) for ideal gas mixtures may be derived by using nothing more complicated than Newton's second law: *The sum of the forces acting on the molecules of a particular species is directly proportional to the rate of change of momentum.* The rate of change of momentum between different species is proportional to the concentrations (mole fractions) of the different species and to their relative velocity [see also Taylor and Krishna (op. cit.) for a more complete derivation]. Equation (13-88) is more familiar in the form

$$d_i = -\sum_{k=1}^{c} \frac{x_i N_k - x_k N_i}{c_t Đ_{ik}} \tag{13-91}$$

where we have replaced the velocities by the molar fluxes $N_i = c_i u_i$ (see Section 5). Only $c - 1$ of Eqs. (13-91) are independent; the mole fraction of the last component is obtained by the mole fraction summation equations for both phases.

Solving the MS equations can be quite involved (see Taylor and Krishna, op. cit.). Most often a simple film model solution of Eqs. (13-91) is used, leading to a simple difference approximation to the MS equations

$$\Delta x_i = -\sum_{k=1}^{c} \frac{\bar{x}_i N_k - \bar{x}_k N_i}{c_t \kappa_{i,k}} \tag{13-92}$$

where $\kappa_{i,k}$ is the mass-transfer coefficient for the binary *i-k* pair of components. The Maxwell-Stefan mass-transfer coefficients can be estimated from existing correlations for mass-transfer coefficients using the binary MS diffusion coefficients.

For a nonideal fluid the driving force is related to the chemical potential gradient

$$d_i = \frac{x_i}{RT}\frac{d\mu_i}{dz} \tag{13-93}$$

The difference approximation of this expression is somewhat more involved since we have to include the derivative of the activity (or fugacity) coefficient in the approximation. If, as often is assumed to be the case (not always with justification), the resistance to mass transfer in the liquid phase is negligible, then the MS equations for the liquid phase can safely be replaced by

$$\Delta x_i = x_i^I - x_i^L = 0 \tag{13-94}$$

The use of the MS equations in place of the simpler Eqs. (13-69) and (13-70) does not change the number of independent model equations or the number of degrees of freedom.

***Example 14: The Need for Rigorous Maxwell-Stefan-Based NEQ Models*** Design a distillation column to separate a feed of 20 mol/s methanol, 10 mol/s isopropanol, and 20 mol/s water. The bottom product is to contain no more than 0.5 mol % methanol, and the distillate is to contain at least 99 mol % methanol but no more than 50 ppm water.

As a first step we attempt to design the column by using the equilibrium-stage model. Following Doherty and Malone (op. cit.), the NRTL model was used for the activity coefficients and the Antoine equation for the vapor pressures. Doherty and Malone estimate the minimum reflux as 5; we used a value 50 percent higher in this example and specified the bottoms product rate at 30 mol/s; this choice provides a consistent basis for the comparison of different models. The number of stages and the location of the feed were varied until a column configuration was obtained that met the desired product purity: 80 total stages (including total condenser and partial reboiler) with the feed to stage 16.

Efficiencies of alcohol-water and alcohol-alcohol systems obtained experimentally in sieve tray columns vary from 60 to 100 percent (Sec. 14 in the seventh

edition of this handbook). After specifying an average efficiency of 80 percent, we find that 99 total stages with the feed to stage 21 were needed to get the distillate product below 50 ppm water.

If we use the nonequilibrium model to design a sieve tray column, it is found that a column with 84 trays (plus condenser and reboiler) and with the feed to tray 21 (stage 22) will produce an overhead product of the desired purity. The reflux ratio and bottoms flows were maintained at the values employed for the equilibrium-stage design. The AIChE method was used for estimating the mass-transfer coefficient–interfacial area products, and the vapor and liquid phases were assumed to be in plug flow. The pressure was assumed constant in the column (an assumption that would need to be relaxed at a later stage of the design exercise). The computer simulation also provided a preliminary tray design; that for the trays above the feed is summarized in the table below.

| | |
|---|---|
| Column diameter, m | 1.76 |
| Total tray area, $m^2$ | 2.43 |
| Number of flow passes | 2 |
| Tray spacing, m | 0.6 |
| Liquid flow path length, m | 0.75 |
| Active area, % total | 91.4 |
| Total hole area, % active | 14 |
| Downcomer area, % total | 4.3 |
| Hole diameter, mm | 5 |
| Hole pitch, mm | 12 |
| Weir type | Segmental |
| Combined weir length, m | 1.55 |
| Weir height, mm | 50 |

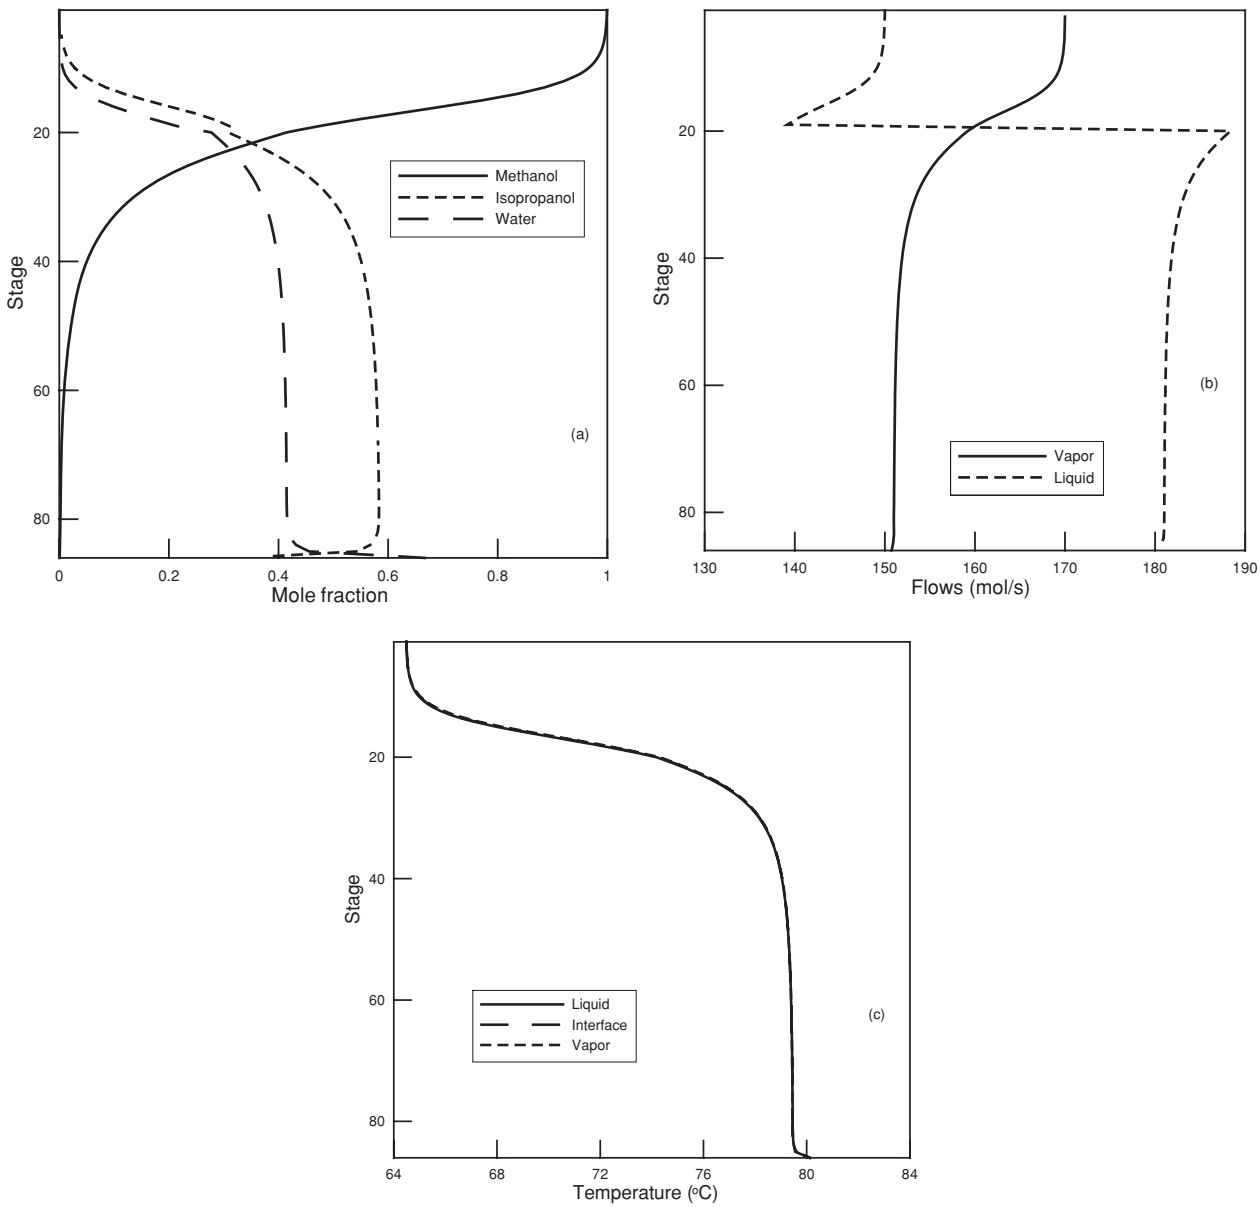

**FIG. 13-56** Composition, flow, and temperature profiles in nonideal distillation process.

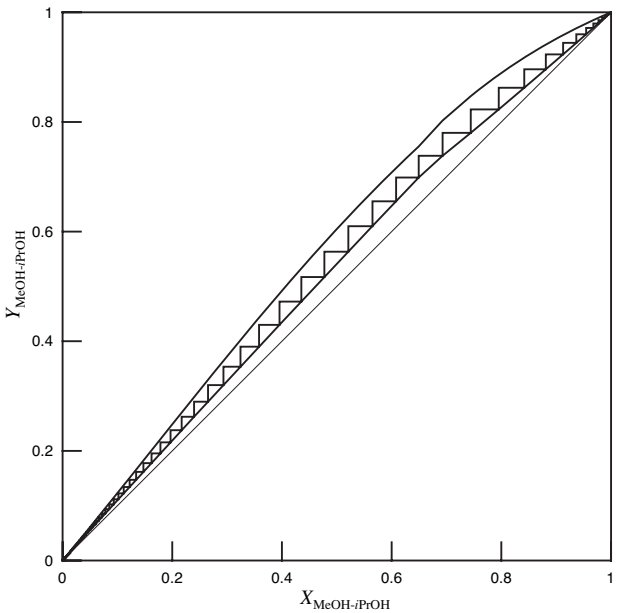

**FIG. 13-57** McCabe-Thiele diagram for nonideal distillation column.

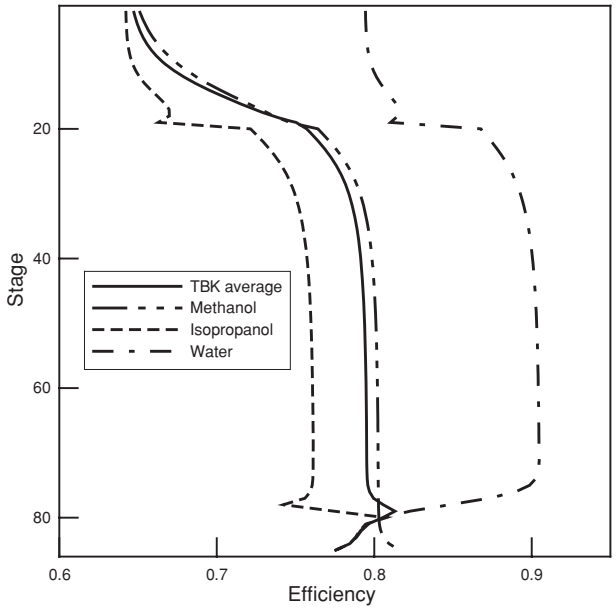

**FIG. 13-58** Component Murphree efficiencies and TBK average efficiency [defined by Eq. (13-59)] for nonideal distillation.

To converge the nonequilibrium model at the specified reflux ratio, it was necessary first to solve the problem at a much lower reflux ratio $R = 2$ and then increase $R$ in steps until the desired value of 7.5 was reached.

The liquid composition, flow, and temperature profiles are shown in Fig. 13-56. In this particular system the vapor and liquid temperatures estimated by the rate-based model are quite close (as often is the case in distillation operations).

The McCabe-Thiele diagram for this column is shown in Fig. 13-57. Note that in this case the triangles that represent the stages do not touch the equilibrium line. The length of the vertical section of each step in Fig. 13-57 is a measure of the efficiency of that tray. The component Murphree efficiencies calculated from the simulation results and Eq. (13-58), as well as the TBK average efficiency defined by Eq. (13-59), are shown in Fig. 13-58. The efficiency of methanol in the stripping section is seen to be around 80 percent, that of isopropanol to be approximately 75 percent, while that of water is close to 90 percent in the bulk of the column before falling off on the bottom few trays. All component efficiencies are found to be lower in the rectifying section. The TBK average efficiency, also shown in Fig. 13-58, is close to the Murphree efficiency of methanol and varies from 60 percent in the top of the column to 78 percent. Thus, the constant value of 80 percent used above appears to be appropriate, and yet, the column designed with the constant-efficiency model required no less than 99 stages (97 trays)!

With 84 trays as opposed to 78 equilibrium stages (not counting condenser and reboiler in either case), we find an overall efficiency of 93 percent, a figure that is quite at odds with the values of the individual component efficiencies seen in Fig. 13-58. How, then, is it possible that the nonequilibrium model suggests that the column needs only 6 trays more than the number of equilibrium stages? It is, in fact, because the efficiency of water is so much higher than that of the alcohols that leads to a column design that can produce high-purity methanol while producing the 50-ppm methanol bottom product in so few extra stages. Note that nonequilibrium models will not always lead to a design with fewer trays than might be suggested by a constant-efficiency model; it is just as likely for the mass-transfer rate-based model to predict that more stages will be needed—it all depends on the differences between the component efficiencies.

Individual component efficiencies can vary as much as they do in this example only when the diffusion coefficients of the three binary pairs that exist in this system differ significantly. For ideal or nearly ideal systems, all models lead to essentially the same results. This example demonstrates the importance of mass-transfer models for nonideal systems, especially when trace components are a concern. For further discussion of this example, see Doherty and Malone (op. cit.) and Baur et al. [*AIChE J.* **51,** 854 (2005)]. It is worth noting that there exists extensive experimental evidence for mass-transfer effects for this system, and it is known that nonequilibrium models accurately describe the behavior of this system, whereas equilibrium models (and equal-efficiency models) sometime predict completely erroneous product compositions [Pelkonen et al., *Ind. Engng. Chem. Res.*, **36,** 5392 (1997) and *Chem. Eng. Process*, **40,** 235 (2001); Baur et al., *Trans. I. Chem. E.*, **77,** 561 (1999)].

Nonequilibrium models should be preferred to equilibrium models when efficiencies are unknown, cannot be reliably predicted, and are low and/or highly variable; in nonideal systems and in processes where trace components are a concern.

There is a rapidly growing body of literature on nonequilibrium modeling of distillation and absorption processes. An extended bibliography is available at www.chemsep.org/publications. A brief review of other applications follows.

Simulation methods currently in use for three-phase systems and systems involving chemical reaction employ the equilibrium-stage model [Doherty and Malone (op. cit.)]. Three-phase distillation remains relatively poorly understood compared to conventional distillation operations involving just a single liquid phase. It is important to be able to correctly predict the location of the stages where a second liquid phase can form (e.g., to determine the appropriate location for a sidestream decanter). The limited experimental data available suggest that efficiencies are low and highly variable with between 25 percent and 50 percent being not uncommon. Clearly, a model based on the assumption of equilibrium on every stage cannot hope to be able to *predict* column performance. Cairns and Furzer [*Ind. Engng. Chem. Res.*, **29,** 5392 (1997)] explicitly warn against incorporating Murphree efficiencies into the equilibrium-stage model for three-phase systems, although Müller and Marquardt [*Ind. Engng. Chem. Res.*, **36,** 5410 (1997)] find that an efficiency modified EQ stage model to be perfectly adequate for their column for the dehydration of ethanol using cyclohexane.

It is possible to develop nonequilibrium models for systems with more than two phases, as shown by Lao and Taylor [*Ind. Engng. Chem. Res.*, **33,** 2367 (1994)], Eckert and Vaněk [*Comput. Chem. Eng.*, **25,** 603 (2001)], and Higler et al. [*Comput. Chem. Eng.*, **28,** 2021 (2004)]. Experimental work that can be used to evaluate these models is scarce; see, however, Cairns and Furzer (op. cit.) and Springer et al. [*Chem. Eng. Res. Design*, **81,** 413 (2003)].

There is now an extensive literature on using nonequilibrium models for reactive distillation; see, e.g., Taylor and Krishna [*Chem. Eng.*

**TABLE 13-13 Selected List of Suppliers of Column Simulation Software**

*Sci.,* **55,** 6139 (2000)], Sundmacher and Kienle (*Reactive Distillation: Status and Future Directions*, Wiley-VCH, 2003), Noeres et al. [*Chem. Engng. Processing*, **42,** 157 (2003)], and Klöcker et al. [*Chem. Engng. Processing*, **44,** 617 (2005)]. Gas absorption accompanied by chemical reaction for a long time has been modeled by using mass-transfer rate-based concepts; see, e.g., Cornelisse et al. [*Chem. Eng. Sci.*, **35,** 1245 (1980)], Pacheco and Rochelle [*Ind. Eng. Chem. Res.*, **37,** 4107 (1998)], and a review by Kenig et al. [*Chem. Eng. Technol.*, **26,** 631 (2003)]. For such systems the chemical reaction influences the efficiencies to such an extent that the concept loses its meaning.

Even at steady state, efficiencies vary from component to component and with position in a column. Thus, if the column is not at steady state, then efficiencies also must vary with time as a result of changes to flow rates and composition inside the column. Thus, equilibrium-stage models with efficiencies should not be used to model the dynamic behavior of distillation and absorption columns. Nonequilibrium models for studying column dynamics are described by, e.g., Kooijman and Taylor [*AIChE J.*, **41,** 1852 (1995)], Baur et al. [*Chem. Eng. Sci.,* **56,** 2085 (2001)], Gunaseelan and Wankat [*Ind. Eng. Chem. Res.*, **41,** 5775 (2002)], Peng et al. [*Chem. Eng. Sci.*, **58,** 2671 (2003)], and Kenig et al. [*Chem. Eng. Sci.*, **54,** 5195 (1999)].

## SOFTWARE FOR DISTILLATION COLUMN SIMULATIONS

Computer software for equilibrium-stage and nonequilibrium column models is available from a number of suppliers. Many other models have been implemented primarily for research purposes and are not available commercially.

In Table 13-13 we list several suppliers of column simulation models that are available commercially, without in any way claiming that this list is exhaustive or providing an endorsement of any particular package. We recommend that users interested in any of these (or other) packages carry out an independent evaluation that focuses on the ability of the package to tackle the simulation problems of direct interest. The simulations described in this subsection were carried out with *ChemSep*.

# DEGREES OF FREEDOM AND DESIGN VARIABLES

## DEFINITIONS

In the models described in previous subsections, we have determined the degrees of freedom on a case-by-case basis. We now develop a general approach to the topic.

For separation processes, a design solution is possible if the number of independent equations equals the number of unknowns

$$N_i = N_v - N_c \tag{13-95}$$

where $N_v$ is the total number of variables (unknowns) involved in the process under consideration, $N_c$ is the number of restricting relationships among the unknowns (independent equations), and $N_i$ is the degrees of freedom that must be specified for there to be exactly the same number of unknowns as there are independent equations in the model. The concept of degrees of freedom in this context is similar to the same concept that appears in the Gibbs phase rule. The degrees of freedom is the number of design variables that must be specified to define one unique operation (solution) of the process.

The variables $N_i$ with which the designer of a separation process must be concerned are

1. Stream concentrations (e.g., mole fractions)
2. Temperatures
3. Pressures
4. Stream flow rates
5. Repetition variables $N_r$

The first three are intensive variables. The fourth is an extensive variable that is not considered in the usual phase rule analysis. The fifth is neither an intensive nor an extensive variable but is a single degree of freedom that the designer uses in specifying how often a particular element is repeated in a unit. For example, a distillation column section is composed of a series of equilibrium stages, and when the designer specifies the number of stages that the section contains, he or she uses the single degree of freedom represented by the repetition variable ($N_r = 1.0$). If the distillation column contains more than one section (such as above and below a feed stage), the number of stages in each section must be specified, and as many repetition variables exist as there are sections, that is, $N_r = 2$.

The various restricting relationships $N_c$ can be classified as

1. Inherent
2. Mass balance
3. Energy balance
4. Phase distribution
5. Chemical equilibrium

The inherent restrictions are usually the result of definitions and take the form of identities. For example, the concept of the equilibrium stage involves the inherent restrictions that $T^V = T^L$ and $P^V = P^L$ where the superscripts $V$ and $L$ refer to the equilibrium exit streams.

The mass balance restrictions are the $C$ balances written for the $C$ components present in the system. (Since we will deal with only nonreactive mixtures, each chemical compound present is a phase rule component.) An alternative is to write $C - 1$ component balances and one overall mass balance.

The phase distribution restrictions reflect the requirement that $f_i^V = f_i^L$ at equilibrium where $f$ is the fugacity. This may be expressed by Eq. (13-1). In vapor-liquid systems, it should always be recognized that all components appear in both phases to some extent and there will be such a restriction for each component in the system. In vapor-liquid-liquid systems, each component will have three such restrictions, but only two are independent. In general, when all components exist in all phases, the number of restricting relationships due to the distribution phenomenon will be $C\,(N_p - 1)$, where $N_p$ is the number of phases present.

For the analysis here, the forms in which the restricting relationships are expressed are unimportant. Only the number of such restrictions is important.

## ANALYSIS OF ELEMENTS

An *element* is defined as part of a more complex *unit.* The unit may be all or only part of an operation or the entire *process.* Our strategy will be to analyze all elements that appear in a separation process and to determine the number of design variables associated with each. The appropriate elements can then be quickly combined to form the desired units and the various units combined to form the entire process. Of course allowance must be made for the connecting streams *(interstreams)* whose variables are counted twice when elements or units are joined.

The simplest element is a *single homogeneous stream.* The variables necessary to define it are

| | $N_v^e$ |
|---|---|
| Compositions | $C-1$ |
| Temperature | 1 |
| Pressure | 1 |
| Flow rate | 1 |
| | $C+2$ |

There are no restricting relationships when the stream is considered only at a point. Henley and Seader *(Equilibrium-Stage Separation Operations in Chemical Engineering,* Wiley, New York, 1981) count all $C$ compositions as variables, but then have to include as a restriction.

$$\sum_i x_i = 1 \quad \text{or} \quad \sum_i y_i = 1 \tag{13-96}$$

A stream divider simply splits a stream into two or more streams of the same composition. Consider Fig. 13-59, which shows the division of the condensed overhead liquid $L_c$ into distillate $D$ and reflux $L_{N+1}$. The divider is permitted to operate nonadiabatically if desired.

Three mass streams and one possible "energy stream" are involved, so

$$N_v^e = 3(C+2) + 1 = 3C + 7 \tag{13-97}$$

Each mass stream contributes $C+2$ variables, but an energy stream has only its rate $q$ as a variable. The independent restrictions are as follows:

| | $N_c^e$ |
|---|---|
| $T$ and $P$ identities between $L_{N+1}$ and $D$ | 2 |
| Composition identities between $L_{N+1}$ and $D$ | $C-1$ |
| Mass balances | $C$ |
| Energy balance | 1 |
| | $2C+2$ |

The number of design variables for the element is given by

$$N_i^e = N_v^e - N_c^e = (3C+7) - (2C+2) = C+5 \tag{13-98}$$

Specification of the feed stream $L_c$ ($C+2$ variables), the ratio $L_{N+1}/D$, the "heat leak" $q$, and the pressure of either stream leaving the divider uses these design variables and defines one unique operation of the divider.

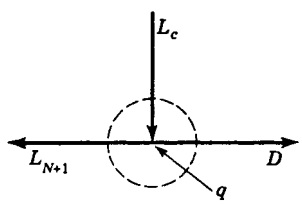

**FIG. 13-59** Stream divider.

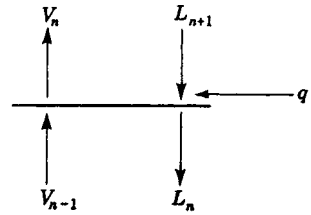

**FIG. 13-60** Simple equilibrium stage.

A simple equilibrium stage (no feed or sidestreams) is depicted in Fig. 13-60. Four mass streams and a heat leak (or heat addition) stream provide the following number of variables:

$$N_v^e = 4(C+2) + 1 = 4C + 9 \tag{13-99}$$

Vapor and liquid streams $V_n$ and $L_n$, respectively, are in equilibrium with each other by definition and therefore are at the same $T$ and $P$. These two inherent identities when added to $C$-component balances, one energy balance, and the $C$ phase distribution relationships give

$$N_v^e = 2C + 3 \tag{13-100}$$

Then

$$N_i^e = N_v^e - N_c^e \tag{13-101}$$

$$= (4C+9) - (2C+3) = 2C + 6 \tag{13-102}$$

These design variables can be used as follows:

| Specifications | $N_i^e$ |
|---|---|
| Specification of $L_{n+1}$ stream | $C+2$ |
| Specification of $V_{n-1}$ stream | $C+2$ |
| Pressure of either leaving stream | 1 |
| Heat leak $q$ | 1 |
| | $2C+6$ |

The results of the analyses for all the various elements commonly encountered in distillation processes are summarized in Table 13-14. Details of the analyses are given by Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1967) and in a somewhat different form by Henley and Seader (op. cit.).

## ANALYSIS OF UNITS

A *unit* is defined as a combination of elements and may or may not constitute the entire process. By definition

$$N_v^u = N_r + \sum_i N_i^e \tag{13-103}$$

and

$$N_i^u = N_v^u - N_c^u \tag{13-104}$$

**TABLE 13-14 Design Variables $N_i^e$ for Various Elements**

| Element | $N_v^e$ | $N_c^e$ | $N_f^e$ |
|---|---|---|---|
| Homogeneous stream | $C+2$ | 0 | $C+2$ |
| Stream divider | $3C+7$ | $2C+2$ | $C+5$ |
| Stream mixer | $3C+7$ | $C+1$ | $2C+6$ |
| Pump | $2C+5$ | $C+1$ | $C+4$ |
| Heater | $2C+5$ | $C+1$ | $C+4$ |
| Cooler | $2C+5$ | $C+1$ | $C+4$ |
| Total condenser | $2C+5$ | $C+1$ | $C+4$ |
| Total reboiler | $2C+5$ | $C+1$ | $C+4$ |
| Partial condenser | $3C+7$ | $2C+3$ | $C+4$ |
| Partial reboiler | $3C+7$ | $2C+3$ | $C+4$ |
| Simple equilibrium stage | $4C+9$ | $2C+3$ | $2C+6$ |
| Feed stage | $5C+11$ | $2C+3$ | $3C+8$ |
| Sidestream stage | $5C+11$ | $3C+4$ | $2C+7$ |
| Adiabatic equilibrium flash | $3C+6$ | $2C+3$ | $C+3$ |
| Nonadiabatic equilibrium flash | $3C+7$ | $2C+3$ | $C+4$ |

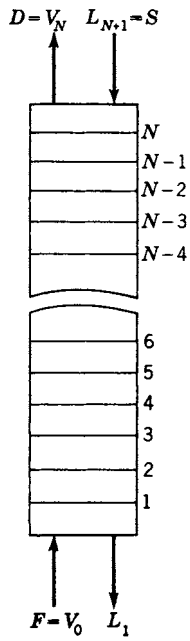

**FIG. 13-61** Simple absorption column.

where $N_c^u$ refers to *new* restricting relationships (identities) that may arise when elements are combined. Here $N_c^u$ does not include any of the restrictions considered in calculating the $N_i^e$'s for the various elements. It includes only the stream identities that exist in each interstream between two elements. The interstream variables $(C + 2)$ were counted in each of the two elements when their respective $N_i^e$'s were calculated. Therefore, $C + 2$ new restricting relationships must be counted for each interstream in the combination of elements to prevent redundancy.

The simple absorber column shown in Fig. 13-61 is analyzed here to illustrate the procedure. This unit consists of a series of simple equilibrium stages of the type in Fig. 13-60. Specification of the number of stages $N$ uses the single repetition variable and

$$N_c^u = N_r + \sum_i N_i^e = 1 + N(2C + 6) \tag{13-105}$$

since $N_i^e = 2C + 6$ for a simple equilibrium stage in Table 13-14. There are $2(N - 1)$ interstreams, and therefore $2(N - 1)(C + 2)$ new identities (not previously counted) come into existence when elements are combined. Subtraction of these restrictions from $N_v^u$ gives $N_i^u$, the design variables that must be specified.

$$N_i^u = N_v^u - N_c^u = N_r + \sum_i N_i^e - N_c^u \tag{13-106}$$

$$= [1 + N(2C + 6)] - 2[(N - 1)(C + 2)] \tag{13-107}$$

$$= 2C + 2N + 5 \tag{13-108}$$

These might be used as follows:

| Specifications | $N_i^u$ |
|---|---|
| Two feed streams | $2C + 4$ |
| Number of stages $N$ | 1 |
| Pressure of either stream leaving each stage | $N$ |
| Heat leak for each stage | $N$ |
| | $2C + 2N + 5$ |

A more complex unit is shown in Fig. 13-62, which is a schematic diagram of a distillation column with one feed, a total condenser, and a partial reboiler. Dotted lines encircle the six connected elements (or units) that constitute the distillation operation. The variables $N_v^u$ that must be considered in the analysis of the entire process are just the sum of the $N_i^e$'s for these six elements since here $N_r = 0$. Using Table 13-14, we get the following:

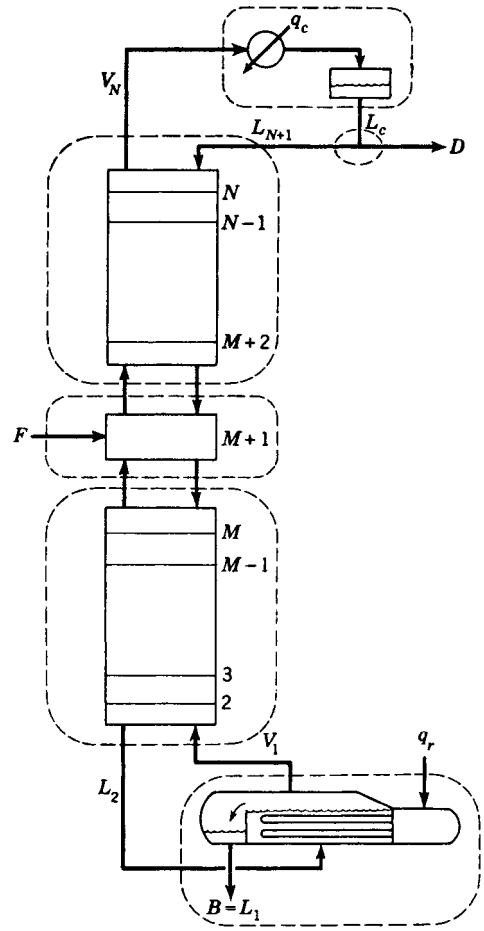

**FIG. 13-62** Distillation column with one feed, a total condenser, and a partial reboiler.

| Element (or unit) | $N_v^u = \sum_i N_i^e$ |
|---|---|
| Total condenser | $C + 4$ |
| Reflux divider | $C + 5$ |
| $N - (M + 1)$ equilibrium stages | $2C + 2(N - M - 1) + 5$ |
| Feed stage | $3C + 8$ |
| $M - 1$ equilibrium stages | $2C + 2(M - 1) + 5$ |
| Partial reboiler | $C + 4$ |
| | $10C + 2N + 27$ |

Here, the two units of $N - (M + 1)$ and $M - 1$ stages are treated just as elements. Nine interstreams are created by the combination of elements, so

$$N_c^u = 9(C + 2) = 9C + 18 \tag{13-109}$$

The number of design variables is

$$N_i^u = C + 2N + 9N_v^u = (10C + 2N + 27) - (9C + 18) \tag{13-110}$$

$$= C + 2N + 9 \tag{13-111}$$

One set of specifications that is particularly convenient for computer solutions is the following:

| Specifications | $N_i^u$ |
|---|---|
| Pressure of either stream leaving each stage (including reboiler) | $N$ |
| Pressure of stream leaving condenser | 1 |
| Pressure of either stream leaving reflux divider | 1 |
| Heat leak for each stage (excluding reboiler) | $N-1$ |
| Heat leak for reflux divider | 1 |
| Feed stream | $C+2$ |
| Reflux temperature | 1 |
| Total number of stages $N$ | 1 |
| Number of stages below feed $M$ | 1 |
| Distillate rate $D/F$ | 1 |
| Reflux ratio $L_{N+1}/D$ | 1 |
| | $C+2N+9$ |

Other specifications often used in place of one or more of the last four listed are the fractional recovery of one component in either $D$ or $B$ and/or the composition of one component in either $D$ or $B$.

## OTHER UNITS AND COMPLEX PROCESSES

In Table 13-15, the number of design variables is summarized for several distillation-type separation operations, most of which are shown in Fig. 13-2. For columns not shown in Figs. 13-1 or 13-2 that involve additional feeds and/or sidestreams, add $C+3$ degrees of freedom for each additional feed ($C+2$ to define the feed and 1 to designate the feed stage) and 2 degrees of freedom for each sidestream (1 for the sidestream flow rate and 1 to designate the sidestream-stage location). Any number of elements or units can be combined to form complex processes. No new rules beyond those developed earlier are necessary for the analysis. Further examples are given in Henley and Seader (op. cit.). An alternative method for determining the degrees of freedom for equipment and processes is given by Pham [*Chem. Eng. Sci.*, **49,** 2507 (1994)].

**TABLE 13-15 Design Variables $N_i^u$ for Separation Units**

| Unit | $N_i^u$* |
|---|---|
| Distillation (partial reboiler-total condenser) | $C+2N+9$ |
| Distillation (partial reboiler-partial condenser) | $C+2N+6$ |
| Absorption | $2C+2N+5$ |
| Rectification (partial condenser) | $C+2N+3$ |
| Stripping | $2C+2N+5$ |
| Reboiled stripping (partial reboiler) | $C+2N+3$ |
| Reboiled absorption (partial reboiler) | $2C+2N+6$ |
| Refluxed stripping (total condenser) | $2C+2N+9$ |
| Extractive distillation (partial reboiler–total condenser) | $2C+2N+12$ |

*$N$ includes reboiler, but not condenser.

# DISTILLATION SYSTEMS

Distillation systems for the separation of nonazeotropic mixtures are discussed in this subsection. Many of the results extend also to azeotropic mixtures when the desired splits do not attempt to break azeotropes or cross a distillation boundary.

Whenever we desire to separate a mixture into multiple products, various combinatorial possibilities of column arrangements are feasible and the optimal (usually the least expensive) column configurations are sought. For example, there are at least two possible ways of separating a ternary mixture of components A, B, and C into pure-product streams (where A is the most volatile and C the least volatile component):

1. *Direct split*, where component A is separated from BC first (A/BC split) and then mixture BC is distilled to separate B from C
2. *Indirect split*, where C is removed first (AB/C) and then mixture AB is distilled

The difference in energy required for these splits can be assessed by simply comparing the total minimum vapor flows (summed over all the columns) for each column sequence. Example calculations were performed for a mixture with relative volatilities $\alpha_A = 4$, $\alpha_B = 2$, and $\alpha_C = 1$ containing 90 percent of A, 5 percent of B, and 5 percent of C in the feed stream. The indirect split requires 58 percent more energy than the direct split, assuming that columns are connected by a liquid stream in both cases. Moreover, the system using more energy requires bigger heat exchangers and larger column diameters, which increase the capital investment costs. Therefore, the direct split configuration would clearly be a better choice in this case.

One of the most important factors that determines the column configuration is the formulation (or goals) of the separation task with respect to the total flow sheet. Although a mixture may consist of $C$ components, it does not mean that all $C$ products are necessary. The components contained in streams recycled into the process (e.g., unreacted reactants recycled to the reactor) usually do not have to be separated from each other. Also separation of streams that are later mixed (blended) should be avoided, if possible. The separation system needs to be optimized together with the entire plant, either simultaneously or in a hierarchical approach, as described by Douglas (*The Conceptual Design of Chemical Processes,* McGraw-Hill, New York, 1988).

Heuristic methods have been widely used for synthesis of distillation sequences to avoid lengthy calculations. Many heuristics are intuitive, e.g., "Remove corrosive components first," "Remove most plentiful components first," or "Remove the lightest component first." Since heuristics are just rules of thumb, they sometimes conflict with one another and may provide wrong answers even if they are not in conflict among themselves [Malone, Glinos, Marques, and Douglas, *AIChE J.*, **31,** 683 (1985)]. More exact, algorithmic synthesis methods and cost optimization should be used in practice. The total energy of separation has been identified as the major component of the total separation system cost and energy-saving distillation schemes for light hydrocarbons with high levels of flexibility and operability, were discussed by Petterson and Wells [*Chem. Engng.*, **84,** (20), 78, 1977]. Tedder and Rudd presented a three-part paper [*AIChE J.*, **24,** 303 (1978)], where they compared eight distillation systems for the separation of ternary mixtures and determined the regions of economic optimality (with respect to feed compositions and relative volatilities). They proposed several heuristics to compare various configurations. They evaluated several rank order functions that allow for comparison of various configurations without detailed cost calculations. Interestingly, one of the rank order functions used successfully to compare various systems was the total minimum vapor flow. Minimum vapor flow will also be used to compare various distillation systems presented here. Finally, in the third part of their paper, Tedder and Rudd proposed a design method for various column networks.

In other approaches, Gomez-Munoz and Seader [*Comp. & Chem. Eng*, **9,** 311 (1985)] proposed an optimization algorithm based on maximum thermodynamic efficiency. However, Smith and Linhoff [*Chem. Eng. Res. Des.*, **66,** 195 (1988)] pointed out the importance of a simultaneous design of the separation network and the rest of the process. They developed a pinch method based on the temperature–heat duty diagram to accomplish this task. Nishida, Stephanopoulos, and Westerberg [*AIChE J.*, **27,** 321 (1981)] presented a comprehensive review of process synthesis, including distillation. Westerberg [*Comp. & Chem. Eng.*, **9,** 421 (1985)] discussed methods for synthesis of distillation systems that include sharp splits, nonsharp splits, thermal linking, and heat integration. More recently, Agrawal [*AIChE J.*, **49,** 379 (2003)] presented a method for systematic generation of distillation configurations, including conventional and complex columns—a detailed discussion of these systems is given below. Sorting through the alternatives and selecting the low-cost systems can be quite tedious and are best done with computer-aided optimization strategies such as those proposed by Caballero and Grossmann [*Ind. Eng. Chem. Res.*, **40,** 2260 (2001)].

## POSSIBLE CONFIGURATIONS OF DISTILLATION COLUMNS

This subsection describes how to generate the feasible combinatorial possibilities of distillation column configurations for separation of mixtures that do not form azeotropes. Components are named A, B, C, D, . . . and they are listed in the order of decreasing volatility (or increasing boiling temperature). We limit our considerations to splits where the most volatile (lightest) component and the least volatile (heaviest) component do not distribute between the top and bottom product. For simplicity, we consider only separations where final products are relatively pure components. Systems containing simultaneously simple and complex distillation columns are considered. Simple columns are the conventional columns with one feed stream and two product streams; complex columns have multiple feeds and/or multiple product streams.

The combinatorial possibilities for separating a three-component mixture ABC into two product streams in which the most volatile component and the least volatile component do not distribute between the top and bottom product are

1. A/BC—Top product A is separated from bottom product BC.
2. AB/BC—Component B distributes between both product streams.
3. AB/C—Top product AB is separated from bottoms C.

These separations are also frequently referred to as splits; sharp splits (none of the components distribute) in cases (1) and (3), and a nonsharp split in case (2). When we add binary separations, the column configuration corresponding to split (1) is known as the direct split; the column configuration corresponding to split (2) is called the prefractionator system, and configuration (3) is called the indirect split (see Fig. 13-63). In the prefractionator system the binary columns separating components AB and BC may be stacked together, forming one column with three products A, B, and C as indicated by the dashed envelope in Fig. 13-63*b*. These systems are called the *basic column configurations*. Basic column configurations are configurations in which the types of interconnecting streams are not defined. The arrows on the flow sheets symbolize the net material flow, but the types of streams connecting the columns (liquid, vapor, two-phase, multiple streams) are not specified. Reboilers and condensers are deliberately not shown in Fig. 13-63, because for some types of interconnecting streams they are not necessary.

Symbolic-network representations of these separation systems, called *state-task networks* (STNs), are shown in Fig. 13-64. In this representation, the states (feeds, intermediate mixtures, and products) are represented by the nodes (ABC, AB, BC, A, B, C) in the network, and the tasks (separations) are depicted as lines (1, 2, . . . , 6) connecting the nodes, where arrows denote the net flow of material. This STN representation was used by Sargent to represent distillation systems [*Comp. & Chem. Eng.*, **22,** 31 (1998)] and has been widely used ever since. Originally STNs were introduced by Kondili, Pantelides, and Sargent [*Comp. & Chem. Eng.*, **17,** 211 (1993)] for representing batch processes.

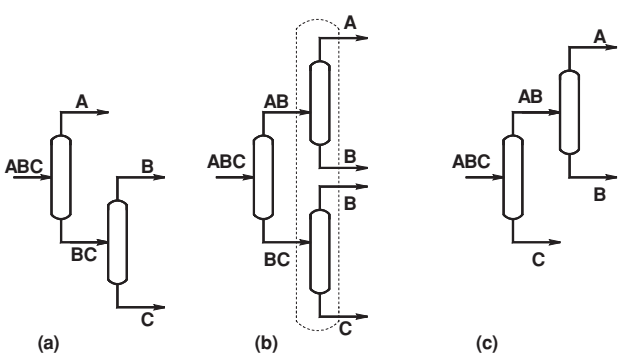

**FIG. 13-63** Basic column configurations. (*a*) Direct split. (*b*) Prefractionator system. (*c*) Indirect split.

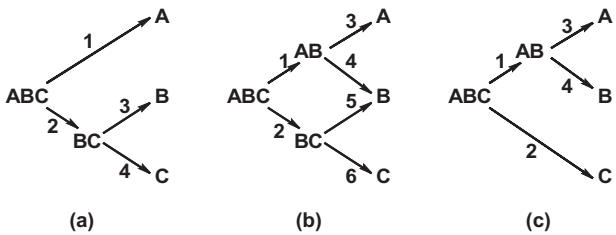

**FIG. 13-64** State-task networks. (*a*) Direct split. (*b*) Prefractionator system. (*c*) Indirect split.

Interconnecting streams may be liquids, vapors, or two-phase mixtures. The total energy of separation can be minimized for the direct split if the two columns have a liquid connection; for the indirect split it is minimized if the columns have a vapor connection, and for the prefractionator system if the top connection is vapor and the bottom connection is liquid. See Fidkowski and Krolikowski [*AIChE J.*, **33,** 643 (1987); **36,** 1275 (1990)].

A complete direct split configuration, including reboilers and condensers, is shown in Fig. 13-65*a*. The numbers used to represent the column sections in this figure correspond to the numbers used to represent the tasks in the STN (Fig. 13-64*a*). By eliminating the reboiler from the first column in Fig. 13-65*a* and supplying the boil-up from the second column, we obtain the side rectifier arrangement, shown in Fig. 13-65*b*. An alternative side rectifier arrangement is seen more clearly in Fig. 13-65*c*, where the stripping section of the binary BC column (section 4) has been moved and lumped with the first column. Note that all these three configurations can be represented by one state-task network, shown in Fig. 13-64*a*. In each configuration in Fig. 13-65, feed ABC is separated in section 1 to get component A and in section 2 to get mixture BC. Then mixture BC is further separated in section 3 to give component B and in section 4 to produce C. Therefore, all these three systems are topologically equivalent to the same basic column configuration represented by the STN in Fig. 13-64*a* and the column arrangement in Fig. 13-63*a*. However, if we take into account reboilers and condensers, we see that only the two side rectifier configurations (Fig. 13-65*b* and *c*) are topologically equivalent. Side stripper configurations can be obtained from the indirect split in an analogous way (Fig. 13-66*a*, *b*, and *c*).

By eliminating the reboiler and condenser in the prefractionator column in Fig. 13-67*a* (the column containing sections 1 and 2) we obtain a *thermally coupled system*, also known as a Petlyuk system, shown in Fig. 13-67*b* [Petlyuk, Platonov, and Slavinskii, *Int. Chem. Eng.*, **5,** 555 (1965)]. Side stripper, side rectifier, and Petlyuk systems can also be built as divided wall columns, as explained in detail in the subsection below on thermally coupled systems.

There are many other possible ternary column systems that have different interconnecting streams between the columns. For example, if we eliminate only the reboiler (or only the condenser) from the prefractionator column in Fig. 13-67*a*, we obtain a partially thermally coupled system [Agrawal and Fidkowski, *AIChE J.*, **45,** 485 (1999), U.S. Patent 5,970,742]. In other instances, one may significantly increase the thermodynamic efficiency of the direct split and the indirect split if a portion of the interconnecting stream is vaporized and fed to the second column below the liquid connection [Agrawal and Fidkowski, *Ind. Eng. Chem. Res.*, **38,** 2065 (1999)].

There are six possible types of splits for a quaternary mixture. The ternary mixtures resulting from these splits may be separated in one of the three possible ternary splits, as described above. Table 13-16 summarizes the resulting number of possible basic column configurations. This number does not account for the various possible types of interconnecting streams.

This method of generating various column configurations [Fidkowski, *AIChE J.*, **52,** 2098 (2006)] is very similar to the methods

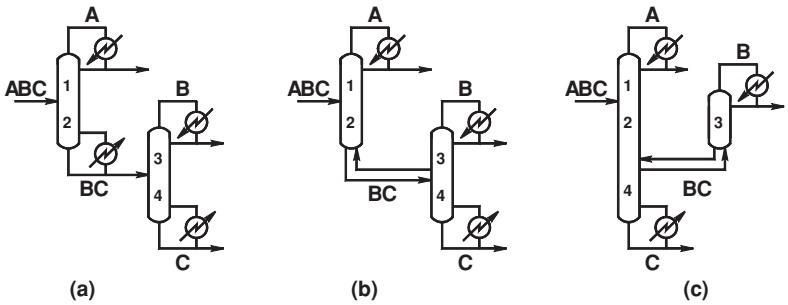

**FIG. 13-65** (*a*) Direct split configuration. (*b*), (*c*) Side rectifier configurations.

used previously for conventional systems; see, e.g., Rathore, Van Wormer, and Powers [*AIChE J.*, **20,** 491 (1974); **20,** 940 (1974)]. The only difference is that in addition to sharp splits, the nonsharp splits are included here, which leads to unconventional systems. Similar methods were proposed by Rong et al. [Rong, Kraslawski, and Turunen, *Ind. Eng. Chem. Res.*, **42,** 1204 (2003)] to generate all the possible quaternary thermally coupled configurations.

The basic column configurations for all 22 quaternary distillation systems are shown in Fig. 13-68. Five of these configurations consist of only sharp splits; hence each species appears in only one product stream. Seventeen of the configurations have at least one nonsharp split, which results in each distributing component appearing in product streams from two different locations. Again, the interconnecting streams could be liquid, vapor, two-phase, or two-way liquid and vapor, as in thermally linked columns. There might also be several alternatives for column stacking, which increases the number of possible configurations even further. Subsequently, one can analyze possible splits for a five-component mixture, etc. These splits create quaternary and ternary products that can be further separated by one of the column configurations discussed above.

## THERMALLY COUPLED SYSTEMS AND DIVIDING WALL COLUMNS

In recent years there has been significant interest in thermally coupled systems and dividing wall columns for ternary mixtures. In this subsection we discuss such column arrangements, their energy requirements, design and optimization methods, controllability and operability, experimental and industrial experience, and extension to more than three components.

Two columns are thermally coupled if a vapor (liquid) stream is sent from the first column to the second column and then a return liquid (vapor) stream is implemented between the same locations. These streams, when introduced at the top or bottom of a column, provide (at least partial) reflux or boil-up to this column.

The development of thermally coupled systems started with attempts to find energy-saving schemes for the separation of ternary mixtures into three products. One of the first industrial applications was the side rectifier configuration for air separation. The side stripper configuration followed naturally. By combining the two we obtain the fully thermally coupled system of Petlyuk, Platonov, and Slavinskii [*Int. Chem. Eng.*, **5,** 555 (1965)]; see Fig. 13-67*b*. It consists of the prefractionator which accepts the ternary feed stream followed by the main column that produces the products (product column).

The dividing wall column was invented as a way of producing three pure products from a single column [Monro, U.S. Patent 2,134,882 (1933); Wright, U.S. Patent 2,471,134 (1949)]. In some cases it is possible to achieve high purity of the intermediate component in the sidestream of a distillation column. This is possible when the sidestream is withdrawn above the feed as a liquid or below the feed as a vapor and when relative volatilities of components differ significantly. In many applications, however, a sidestream is contaminated to an appreciable extent by either the light or the heavy component. For example, if a sidestream is withdrawn from the rectifying section, it must contain not only the intermediate component but also some of the most volatile component. This contamination problem can be eliminated by adding a dividing wall that prevents the most volatile component (and the heaviest component) from entering the zone where the intermediate component is withdrawn; see Fig. 13-69.

The dividing wall column is topologically equivalent to the fully thermally coupled system (Fig. 13-67*b*). The prefractionator and the main product column are built in one shell, separated by a dividing wall (Fig. 13-69*c*). Similarly, the side rectifier (Fig. 13-65*c*) and side stripper (Fig. 13-66*c*) configurations can be built in one shell as dividing wall columns [Agrawal, *Ind. Eng. Chem. Res.*, **40,** 4258 (2001)]. The corresponding dividing wall columns are shown in Fig. 13-69*a*

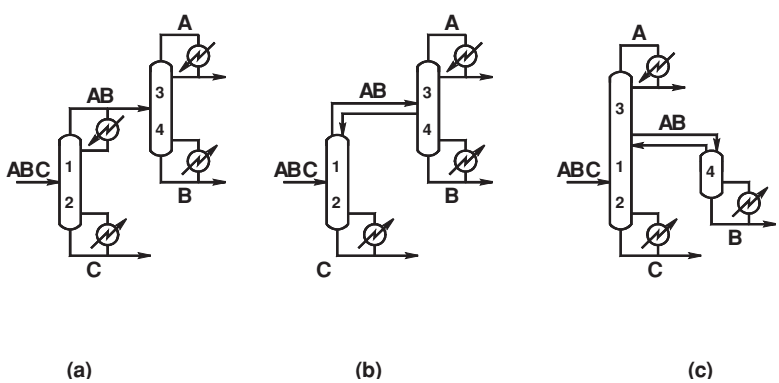

**FIG. 13-66** (*a*) Indirect split configuration. (*b*), (*c*) Side stripper configurations.

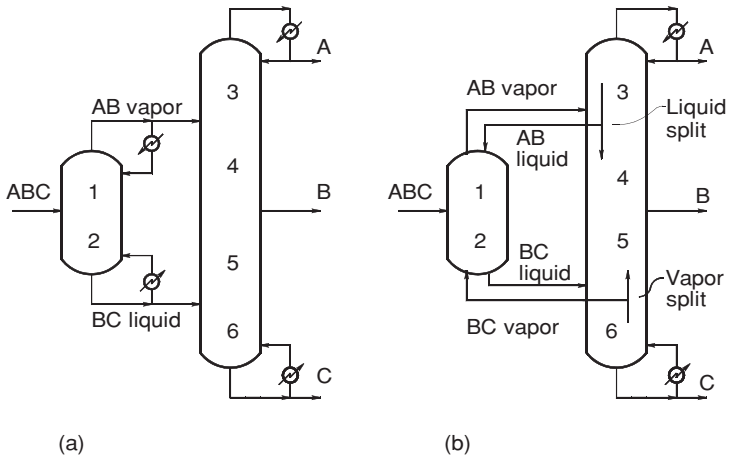

**FIG. 13-67** (*a*) Prefractionator system. (*b*) Thermally coupled system.

and *b,* respectively. The corresponding sections in the thermally coupled systems and the dividing wall columns have exactly the same numbers and perform exactly the same separation tasks, indicating that the column arrangements are topologically equivalent.

Various design, simulation, and evaluation methods have been developed for the distillation systems shown in Figs. 13-65 to 13-67. These include those by Stupin and Lockhart [*Chem. Eng. Prog.*, **68** (10), 71 (1972)]; Fidkowski and Krolikowski [*AIChE J.*, **32,** 537 (1986)]; Nikolaides and Malone [*Ind. Eng. Chem. Res.*, **27,** 811, (1988)]; Rudd [Distillation Supplement to the Chemical Engineer, S14, (1992)]; Triantafyllou and Smith [*Trans. Inst. Chem. Eng.*, **70,** Part A, 118 (1992)]; Finn [*Gas Sep. Purif.*, **10,** 169 (1996)]; Annakou and Mizsey [*Ind. Eng. Chem. Eng.*, **35,** 1877 (1996)]; Hernandez and Jimenez [*Comp. & Chem. Eng.*, **23,** 1005 (1999)]; Dunnebier and Pantelides [*Ind. Eng. Chem. Res.*, **38**, 162 (1999)]; Watzdorf, Bausa, and Marquardt [*AIChE J.*, **45,** 1615 (1999)]; Kim [*J. Chem. Eng. Japan*, **34,** 236 (2001)]. The fully thermally coupled system uses less energy than any other ternary column configuration [Fidkowski and Krolikowski, *AIChE J.*, **33,** 643–653 (1987)]. The energy savings may be on the order of 30 to 50 percent, depending on the feed composition and volatilities of the components. Similar energy savings are possible in partially thermally coupled columns, where only one connection (top or bottom) between the columns is thermally coupled and the other is just a single liquid or vapor stream together with an associated condenser or reboiler, respectively [Agrawal and Fidkowski, *AIChE J.*, **45,** 485 (1999)]. Fidkowski and Krolikowski [*AIChE J.*, **32,** 537 (1986)]

**TABLE 13-16 Number of Basic Column Configurations for Separation of a Four-Component Mixture**

| Split | Distillate/bottoms | Number of configurations |
|---|---|---|
| 1 | A/BCD | 3 |
| 2 | AB/BCD | 3 |
| 3 | AB/CD | 1 |
| 4 | ABC/BCD | $3 \times 3 = 9$ |
| 5 | ABC/CD | 3 |
| 6 | ABC/D | 3 |
| | Total | 22 |

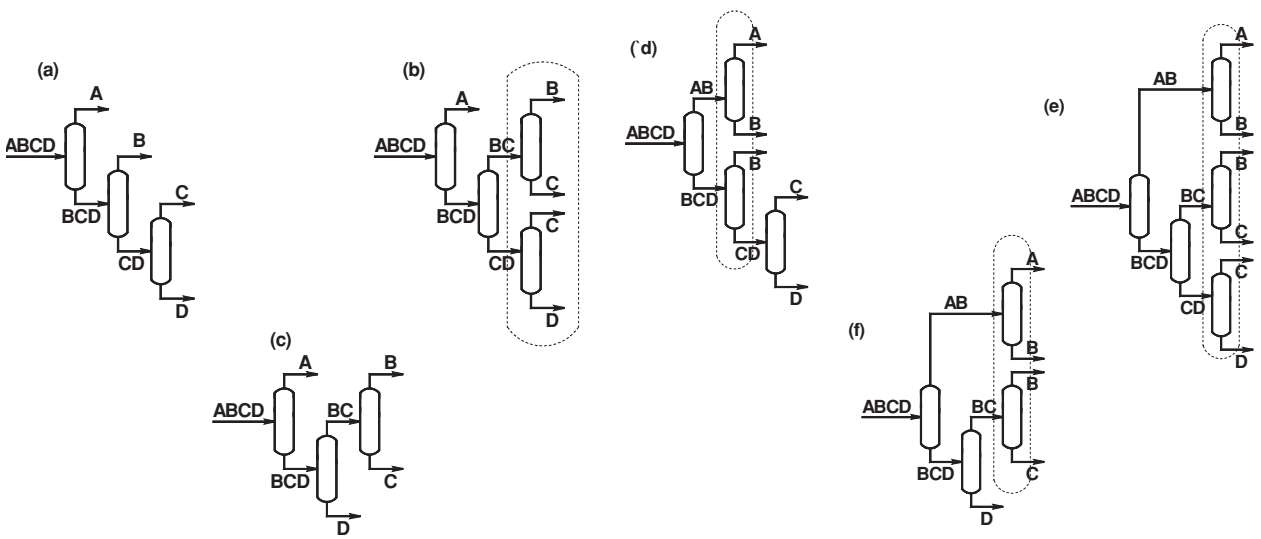

**FIG. 13-68** Basic column configurations for separation of a four-component mixture.

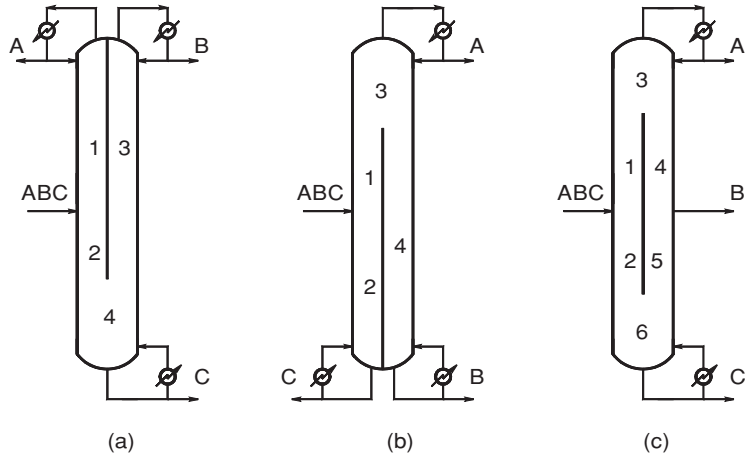

**FIG. 13-69** Dividing wall columns equivalent to (*a*) side rectifier configuration, (*b*) side stripper configuration, (*c*) thermally coupled system.

solved analytically the optimization problem for the minimum vapor boil-up rate from the reboiler in the main column for the fully thermally coupled system (shown in Fig. 13-67*b*), assuming constant molar overflow and constant relative volatilities among the components. The solution depends on the splits of vapor and liquid between the main product column and the prefractionator [or between both sides of the dividing wall (Fig. 13-69*c*)]. The minimum vapor flow for each column in the system is shown in Fig. 13-70 as a function of β, where the parameter β is defined as the fractional recovery of the distributing component B in the top product of the prefractionator

$$\beta = \frac{V_1 y_B - L_1 x_B}{f_B} \tag{13-112}$$

where $V_1$ and $L_1$ are the vapor and liquid flows at the top of the prefractionator (section 1), $y_B$ and $x_B$ are corresponding mole fractions of component B, and $f_B$ denotes the molar flow of component B in the feed stream. The lower line in Fig. 13-70 is the minimum vapor flow in the first column, the prefractionator. At $\beta = 0$ it corresponds to the A/BC split and at $\beta = 1$ to the AB/C split. There is a minimum in the minimum vapor flow in the prefractionator for $\beta = \beta_P$, the so-called transition split; $\beta_P$ can be calculated as

$$\beta_P = \frac{\alpha_B - \alpha_C}{\alpha_A - \alpha_C} \tag{13-113}$$

where the α's are relative to any reference component.

The transition split divides direct-type splits from indirect-type splits as discussed by Doherty and Malone (*Conceptual Design of Distillation Systems*, 2001, chaps. 4 and 5); also see Fidkowski, Doherty, and Malone [*AIChE J.*, **39,** 1301(1993)]. The upper line in Fig. 13-70 is the minimum vapor flow leaving the reboiler of the main column, which also corresponds to the minimum vapor flow for the entire system since all the vapor for the total system is generated by this reboiler. For $\beta = 0$ the minimum vapor flow for the entire thermally coupled system (i.e., main column) becomes equal to the minimum vapor flow for the side rectifier system (i.e., main column of the side-rectifier system; see Fig. 13-65*b* or *c*) $(V_{SR})_{min}$; for $\beta = 1$ it is equal to the minimum vapor flow of the entire side stripper system $(V_{SS})_{min}$ (which is the sum of the vapor flows from both the reboilers in this system; see Fig. 13-66*b* or *c*). Coincidentally, the values of these two minimum vapor flows are always the same: $(V_{SR})_{min} = (V_{SS})_{min}$. For $\beta = \beta_R$ the main column is pinched at both feed locations; i.e., the minimum vapor flows for separations A/B and B/C are equal.

The minimum vapor flow for the entire thermally coupled system is flat over a wide range of β: $\beta_P \le \beta \le \beta_R$. This is the reason why dividing wall columns usually work well without tight control of the vapor or liquid split between both sides of the partition. The optimally designed fully thermally coupled system should operate with a fractional recovery of B in the top product of the prefractionator placed somewhere between points *P* and *R*. The transition split *P* is located at one end of the optimal section *PR*, and it is not a recommended design point for normal operation because process disturbances may move the operating point outside the optimal section *PR* shown in Fig. 13-70.

Although invented long ago, dividing wall columns and fully thermally coupled distillation systems were not implemented in practice until the late 1980s. The major objections concerned controllability and operability. Recently, however, several papers have shown that control of these systems is possible; see, e.g., Hernandez and Jimenez [*Ind. Eng. Chem. Res.*, **38,** 3957 (1999)]; Mutalib, Zeglam, and Smith [*Trans. Inst. Chem. Eng.*, **76,** 319 (1998)]; Halvorsen and Skogestad [*Comp. Chem. Eng.*, **21,** Suppl., S249 (1997)]. A major control problem was attributed to inability to set the vapor split between the main column and prefractionator due to conflicting pressure drop requirements between sections 6 and 2, as well as sections 1 and 3 in Fig. 13-67*b*. For the BC vapor to flow from section 6 to section 2, the pressure in the main column at the top of section 6 must be *higher* than the pressure in the prefractionator at the bottom of section 2. But the pressure at the bottom of section 3 in the main column must be *lower* than the pressure at the top of section 1 in the prefractionator, or else the AB vapor stream will not flow from the prefractionator to the main column. Liquid split control is easier to realize in practice, by using liquid collectors, overflows, or pumps. How much vapor flows straight up the main column and how much vapor splits off to the prefractionator depends on the pressure drops in the middle sections of the main column (sections 4 and 5 in Fig. 13-67*b*, between the interconnecting streams) and in the prefractionator. These pressure drops depend on the height of these sections, type of packing or stages, and liquid flows. Therefore, these pressure drops cannot be easily controlled in the configuration shown in Fig. 13-67*b;* moreover, they may even be such that vapor flows in the wrong direction.

Agrawal and Fidkowski [*AIChE J.*, **44,** 2565 (1998); U.S. Patent 6,106,674] proposed robustly operable two-column configurations that cleverly overcome this design and control problem. One is shown in Fig. 13-71. This new configuration is topologically equivalent to the original thermally coupled configuration in Fig. 13-67*b* and retains its energy advantage. In the new Agrawal and Fidkowski configuration, column section 6 is just shifted from the product column to the

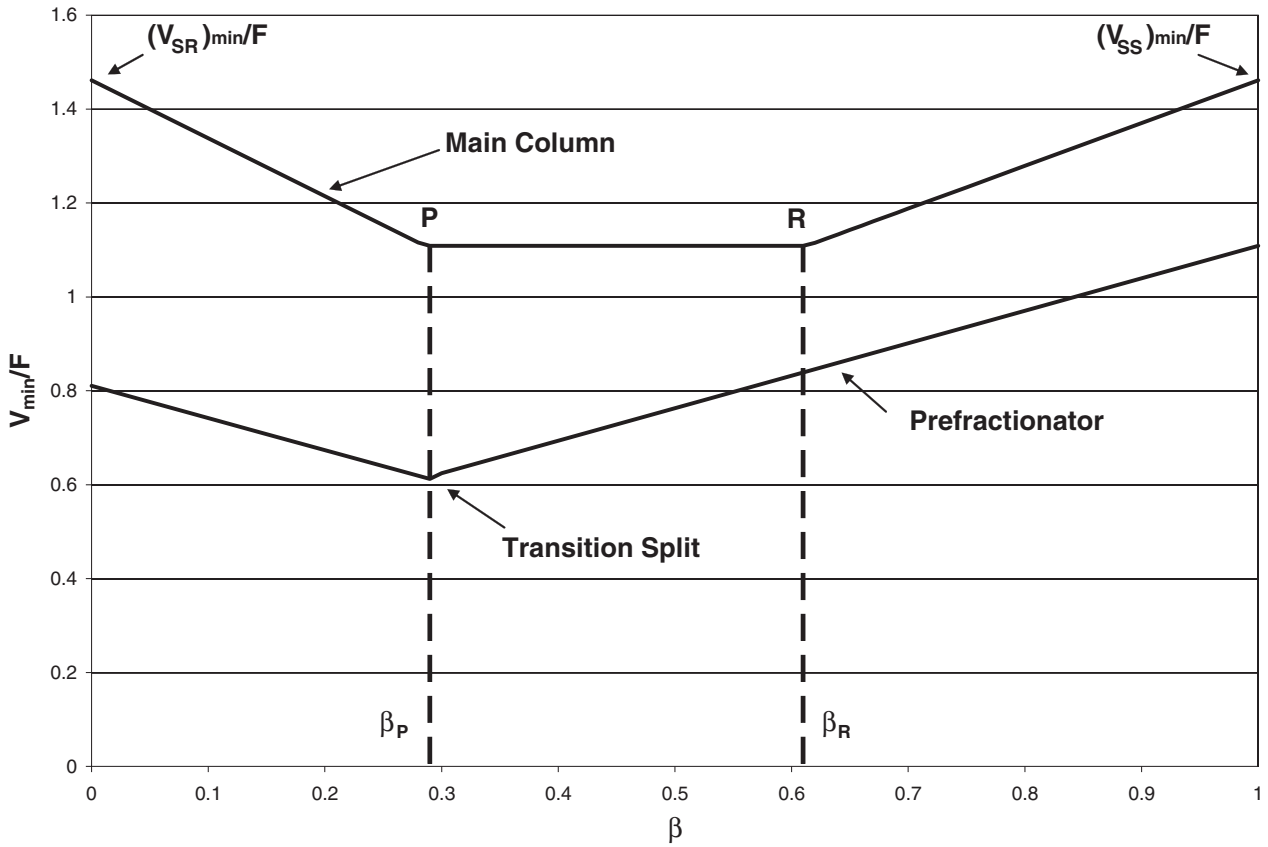

**FIG. 13-70** Minimum vapor flows in the thermally coupled system; bottom curve, minimum vapor flow in prefractionator; top curve, minimum vapor flow from the reboiler of the main column (total minimum vapor flow for entire system) for $\alpha_A = 6.25$, $\alpha_B = 2.5$, $\alpha_C = 1.0$ and feed mole fractions $z_A = 0.33$, $z_B = 0.33$, and $z_C = 0.34$.

bottom of prefractionator; thus the two interconnecting vapor streams flow in the *same direction*. The first column (with sections 1, 2, and 6) in Fig. 13-71 operates at a slightly higher pressure than the second column, and the relative flows of the vapor streams can be changed by using a valve on one of them, as shown in the figure. The Agrawal and Fidkowski thermally coupled systems are expected to have higher investment cost than dividing wall columns, and the same investment cost as a Petlyuk thermally coupled system. However, for certain feed compositions and volatilities, the energy optimum in Fig. 13-70 may be narrow (i.e., the interval *PR* may be short) and dividing wall columns may not be able to operate at the optimum. On the other hand, the Agrawal and Fidkowski configurations are able to operate at the optimum because of better control. Also the Agrawal and Fidkowski configurations are useful in cases where high-purity products (especially B) are required. This is so because the two columns are built in separate shells which may contain more stages in one of the shells than could be accommodated in the corresponding side of the dividing wall column.

Experimental tests of dividing wall columns were carried out by Mutalib, Zeglam, and Smith [*Trans. Inst. Chem. Eng.* **76,** 319 (1998)]. Today there are about 60 dividing wall columns in operation; 42 are owned by BASF (*Parkinson*, CEP, p. 10, July 2005).

Thermally coupled systems can also be devised for multicomponent mixtures. Sargent and Gaminibandara (*Optimization in Action*, L. W. C. Dixon, ed., Academic Press, London, 1976, p. 267) presented a natural extension of the Petlyuk column sequence to multicomponent systems. Agrawal [*Ind. Eng. Chem. Res.*, **35,** 1059 (1996); *Trans. Inst. Chem. Eng.*, **78,** 454 (2000)] presented a method for generating an even more complete superstructure from which all the known column configurations (including thermally coupled systems) can be derived. Fidkowski and Agrawal [*AIChE J.*, **47,** 2713 (2001)] presented a method for calculating the minimum vapor flows in multicomponent thermally coupled systems. They analyzed the quaternary fully thermally coupled system in detail (there are many equivalent column configurations, all with the minimum number of column sections, which is 10, as well as one reboiler and one condenser; one of the configurations is shown in Fig. 13-72). They showed that one of the optimum solutions (with the minimum value of the total minimum vapor flow rate from the single reboiler in the system) occurs when the quaternary feed column (far left column in Fig. 13-72) and both ternary columns (the two middle columns in Fig. 13-72) perform transition splits. They also concluded that the optimized quaternary fully coupled system always requires less energy than the five sharp-split conventional systems (where each column performs a sharp split and has one feed, two products, one reboiler, and one condenser). The basic configurations for these five sharp-split systems are shown in Fig. 13-68*a, c, g, t,* and *v*. Selecting the best thermally coupled column configuration can be tedious without computer-aided tools such as the disjunctive programming approach developed by Caballero and Grossmann [*Ind. Eng. Chem. Res.*, **40,** 2260 (2001)].

All the multicomponent thermally coupled configurations have a corresponding dividing wall column equivalent. Keibel [*Chem. Eng. Technol.*, **10,** 92 (1987)] has shown examples of columns with multiple dividing walls, separating three, four, and six components. Agrawal [*Ind. Eng. Chem. Res.*, **40,** 4258 (2001)] presented several examples of quaternary columns with partitions and multiple reboilers and condensers. One of these examples is shown in Fig. 13-73.

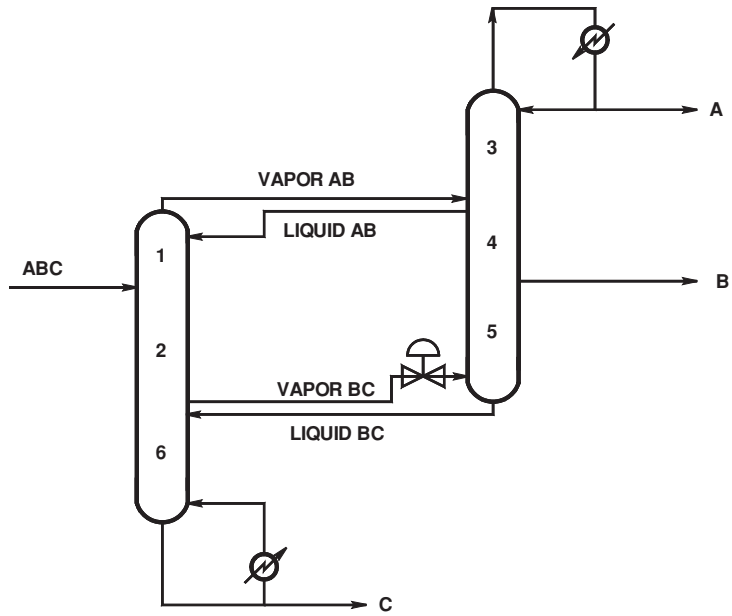

**FIG. 13-71** Agrawal and Fidkowski thermally coupled system (topologically equivalent to the Petlyuk system shown in Fig. 13-67*b*).

## THERMODYNAMIC EFFICIENCY

Thermodynamic efficiency can be a useful figure of merit (in place of total cost, or total vapor rate) for comparing alternative column configurations. This is especially true for cryogenic distillations where very low temperatures are needed and highly efficient "cold box" designs are needed for achieving them. Thermodynamic efficiency of thermally coupled and other distillation systems for the separation of ternary mixtures was analyzed by Agrawal and Fidkowski [*Ind. Eng. Chem. Res.*, **37,** 3444 (1998)]. Feed composition regions for column configurations with the highest thermodynamic efficiency are shown in Fig. 13-74. Often, the efficiency of the direct split or the indirect split is better than the efficiency of thermally coupled systems. This is primarily due to the ability of these configurations to accept or reject heat at the intermediate boiling or condensing temperatures of the binary submixtures. The fully thermally coupled system can only accept heat at the temperature of the highest-boiling component (boiling point of C) and reject heat at the lowest temperature (condensation temperature of A). This conclusion gave rise to new, more thermodynamically efficient thermally coupled configurations, as discussed by Agrawal and Fidkowski [*Ind. Eng. Chem. Res.*, **38,** 2065 (1999); U.S. Patent 6,116,051].

## HEAT INTEGRATION

In this subsection we describe heat pumps, multieffect distillation of binary mixtures, synthesis of multicomponent distillation systems with heat integration, and multieffect distillation for thermally coupled configurations.

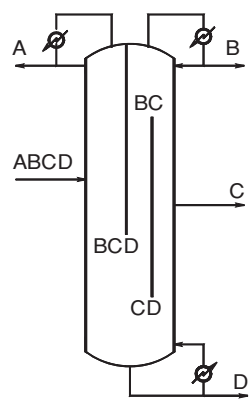

**FIG. 13-73** One possible dividing wall column for separation of a quaternary mixture.

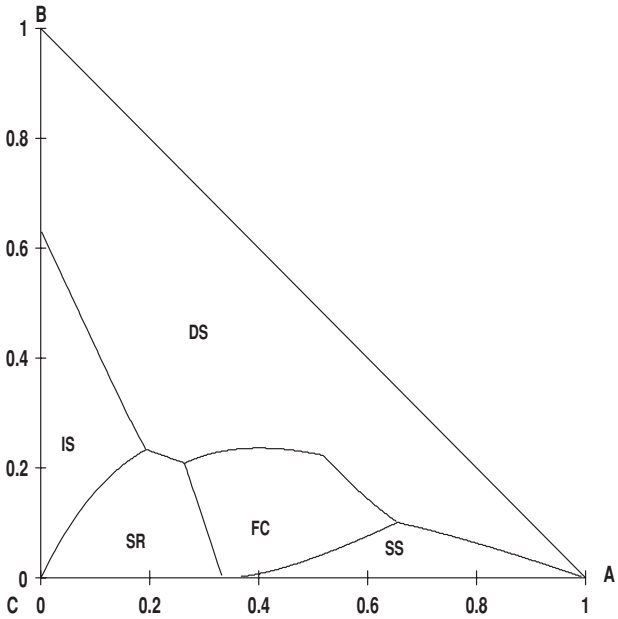

**FIG. 13-74** Feed composition regions of column configurations with highest thermodynamic efficiency; DS—direct split, IS—indirect split, SR—side rectifier, SS—side stripper, FC—fully thermally coupled. Example for $\alpha_A = 4.0$, $\alpha_B = 2.0$, and $\alpha_C = 1.0$.

Two columns are heat-integrated when they exchange heat indirectly through a heat exchanger. This is different than in thermally linked configurations, where the heat exchange between columns is direct, through the material stream connecting the columns. The objective of heat integration in distillation systems is to save energy. Heat integration is realized by matching heat sources (usually condensers) with heat sinks (usually reboilers). The other heat exchangers considered for heat integration might be feed preheaters and product coolers. Typical examples of heat integration schemes are heat transfer from a condenser to a reboiler, or heat exchange between a (hot) column feed and a reboiler. If the temperature of the heat source (condenser) is sufficiently higher than the temperature of the heat sink (reboiler), the opportunity for the match is straightforward. If the condenser temperature is too low, one may increase the condensing pressure or use a heat pump.

For example, the reboiler and condenser from the same column may be heat-integrated by using a heat pump, as discussed by Null [*Chem. Eng. Prog.*, **72**(7), 58 (1976)]. A heat pump may use an external fluid which is vaporized in the condenser, then compressed and condensed in the column reboiler (Fig. 13-75*a*). Another heat pump (Fig. 13-75*b*) uses column overhead vapor, which is compressed and condensed in the reboiler and then returned to the top of the column as reflux. A third possibility is to use the column bottoms, which is let down in pressure and vaporized in the condenser, then compressed and fed back to the bottom of the column as boil-up (Fig. 13-75*c*).

The entire rectifying section can be pressurized, and the heat can be transferred between any desired stages of the rectifying and stripping sections. This is called *secondary reflux and vaporization* (SRV) distillation. It reduces the consumption of both hot and cold utilities, and the sizes of the reboiler and condenser. However, capital cost is increased by additional intermediate heat exchangers; moreover, since the process is more thermodynamically reversible, it requires more stages to achieve the desired separation.

In multiple-column systems, possibilities for heat integration may be created by increasing the pressure in one of the columns, to increase the temperature of the condenser. When the temperature of the condenser becomes higher than the temperature of some other column reboiler, it is possible to heat-integrate these streams via a heat exchanger and reuse the heat rejected from the condenser. However, there are several drawbacks to this procedure. The required heat-transfer area in the integrated exchangers needs to be increased due to smaller temperature differences between the process streams than would normally exist when hot and cold external utilities are used to provide boil-up and condensation. Higher-pressure columns need hotter external heating utilities that are more expensive. Separation in higher-pressure columns is more difficult (because relative volatilities tend to decrease with increasing pressure), and more stages and energy may be required. Finally, higher-pressure column shells and piping may be more expensive, although this is not always certain, since the overall dimensions decrease with pressure.

One of the first industrial applications of heat-integrated distillation was a double column for air separation, developed by Linde in the beginning of the 20th century (Fig. 13-76). Air is compressed (typically to about 6 bar) and fed in the bottom of the high-pressure column. Nitrogen is condensed at the top of the high-pressure column.

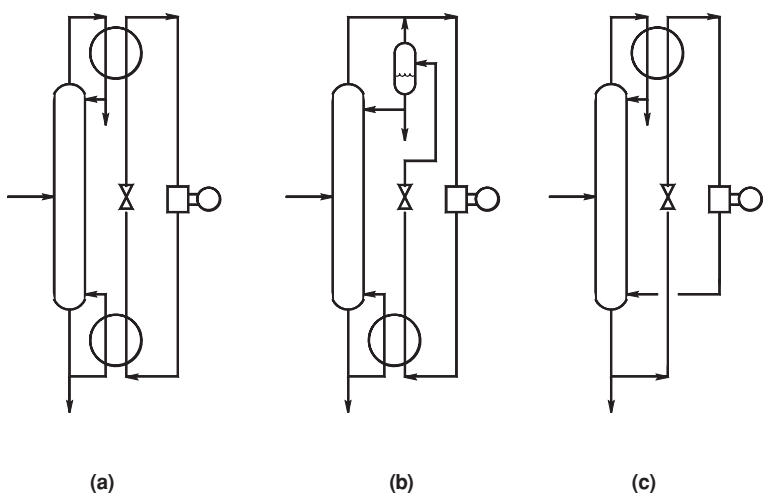

**FIG. 13-75** Heat pumps transfer heat from the top to the bottom of the column. (*a*) External fluid heat pump. (*b*) Heat pump using column overhead. (*c*) Heat pump using column bottoms.

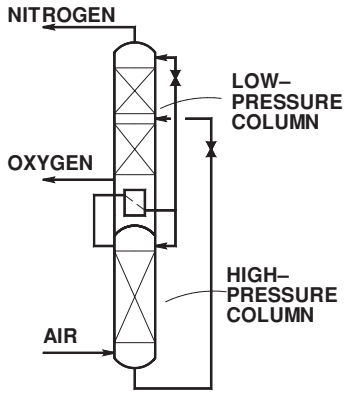

**FIG. 13-76** Double-column arrangement for air separation.

The heat of condensation provides boil-up to the low-pressure column, by vaporizing oxygen in the sump located above the nitrogen condenser. Another industrial example of heat integration occurs in the large-scale methanol-water separation in the production of methanol from synthesis gas; see Siirola [*Adv. Chem. Engng*., **23,** 1 (1996)]. Several alternative designs were evaluated, and the regions of superior cost were developed on volatility-feed composition diagrams. Three heat-integrated designs were better than a single column:

1. *Split feed configuration*, in which the feed is split between the high-pressure and the low-pressure columns
2. *Sloppy first bottom split, second column pressurized*, in which the bottoms from the first column is further separated in the high-pressure column
3. *Sloppy first bottom split, first column pressurized*, in which the bottoms from the first, high-pressure column is further separated in the low-pressure column

These heat-integrated systems were economically advantageous because of the large feed flow rate. The last configuration was built.

Design heuristics and computer-aided design methods for heat-integrated distillation systems have been developed in numerous publications. Wankat [*Ind. Eng. Chem. Res*., **32,** 894 (1993)] analyzed 23 different multieffect distillation systems obtained by dividing a single column into two or three columns and operating them at various pressures or compositions, to obtain the temperatures necessary for heat integration. He developed heuristics to devise a feasible system. Rathore, Van Wormer, and Powers [*AIChE J*., **20,** 491 (1974) and **20,** 940 (1974)] presented an algorithmic synthesis method for multicomponent separation systems with energy integration. The five-component separation problem was solved by decomposing it into all the possible sharp splits and then examining all the possible integrations of heat exchangers. Thermally coupled systems, however, were not considered. Umeda, Niida, and Shiriko [*AIChE J*., **25,** 423 (1979)] published a thermodynamic approach to heat integration in distillation systems based on pinching heat source and heat sink curves on the temperature–heat duty diagram. Linhoff and coworkers (*A User Guide on Process Integration for the Efficient Use of Energy*, Institution of Chemical Engineers, Rugby, U.K., 1982) developed the very successful *pinch technology* approach, commonly used for heat exchanger synthesis and heat integration of entire plants. But, most successfully, Andrechowich and Westerberg [*AIChE J*., **31,** 1461 (1985)] presented a simple conceptual design approach wherein temperature-enthalpy diagrams are used to select the best column stacking. This design method is the recommended starting point for heat integration studies.

Even thermally coupled systems can be heat-integrated, as discovered by Agrawal [*AIChE J*., **46,** 2211 (2000)]. To achieve heat integration without compressors, the vapor connections between the columns must be eliminated. This is shown in Fig. 13-77*a*. The configuration is constructed by extending the prefractionator to a full column with a reboiler and condenser, and adding sections 3x and 6x (analogous to sections 3 and 6 in the product column). By balancing heat duties, only liquid interconnecting streams remain, and the configuration is still thermodynamically equivalent to the original thermally coupled system (Fig. 13-67*b*). It is now possible to heat-integrate the columns by pressurizing one of them and allowing heat transfer from the high-pressure condenser to the low-pressure reboiler (Fig. 13-77*b*). The thermally coupled system and dividing wall column are equally energy-efficient. Therefore, the thermally coupled system with heat integration is even more energy-efficient than the dividing wall column.

There is a significant cost associated with heat integration (e.g., for heat pump compressors, taller columns with more stages, thicker walls of high-pressure equipment, higher cost of high-temperature utilities) which is why such configurations are not widely used. The operational flexibility of a heat-integrated system also becomes more constrained. However, heat-integrated systems can be quite economical for some applications. Typical applications where heat-integrated systems are preferred include

- Cryogenic separation, where very low-temperature cooling utilities do not exist and need to be created, which is very expensive. Therefore, it makes sense to reuse the expensive refrigeration.
- Very large-scale processes, with large feed and product flow rates. Because of the large feed rate, multiple columns may be required to process a given feed anyway. These cases have the potential to save a lot of energy due to heat integration. Also, pressurizing some equipment in these large-scale processes allows for decreased equipment sizes or increased production rate at a fixed equipment size.

## IMBALANCED FEEDS

In many practical cases, feed compositions are far from equimolar, with some components present in very small amount (e.g., less than 2 percent). In these cases the top or bottom product flow rate is less than 2 percent of the feed flow rate. The design for imbalanced feeds may include

- Various column diameters
- Intermittent pumping of heavies from the reboiler
- Intermittent firing up a specially devoted column to purify the dirty product made at a small rate
- In a continuous operation an overrefluxed section (to keep the column diameter the same over the height of the column)
- Producing an impure product to be purified later or discarded

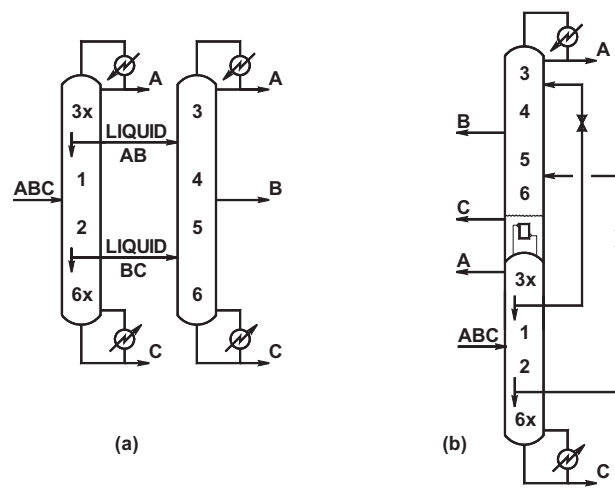

**FIG. 13-77** (*a*) Configuration equivalent to thermally coupled system, but without vapor interconnecting streams. (*b*) Heat-integrated thermally coupled system.

# ENHANCED DISTILLATION

In distillation operations, separation results from differences in vapor- and liquid-phase compositions arising from the partial vaporization of a liquid mixture or the partial condensation of a vapor mixture. The vapor phase becomes enriched in the more volatile components while the liquid phase is depleted of those same components. In many situations, however, the change in composition between the vapor and liquid phases in equilibrium becomes small (so-called pinched condition), and a large number of successive partial vaporizations and partial condensations are required to achieve the desired separation. Alternatively, the vapor and liquid phases may have identical compositions, because of the formation of an azeotrope, and no separation by simple distillation is possible.

Several enhanced distillation-based separation techniques have been developed for close-boiling or low-relative-volatility systems, and for systems exhibiting azeotropic behavior. All these special techniques are ultimately based on the same differences in the vapor and liquid compositions as ordinary distillation; but, in addition, they rely on some additional mechanism to further modify the vapor-liquid behavior of the key components. These enhanced techniques can be classified according to their effect on the relationship between the vapor and liquid compositions:

1. *Azeotropic distillation and pressure-swing distillation.* Methods that cause or exploit azeotrope formation or behavior to alter the boiling characteristics and separability of the mixture.
2. *Extractive distillation and salt distillation.* Methods that primarily modify liquid-phase behavior to alter the relative volatility of the components of the mixture.
3. *Reactive distillation.* Methods that use chemical reaction to modify the composition of the mixture or, alternatively, use existing vapor-liquid differences between reaction products and reactants to enhance the performance of a reaction.

## AZEOTROPY

At low to moderate pressure ranges typical of most industrial applications, the fundamental composition relationship between the vapor and liquid phases in equilibrium can be expressed as a function of the total system pressure, the vapor pressure of each pure component, and the liquid-phase activity coefficient of each component $i$ in the mixture:

$$y_i P = x_i \gamma_i P_i^{\text{sat}} \tag{13-114}$$

In systems that exhibit ideal liquid-phase behavior, the activity coefficients $\gamma_i$ are equal to unity and Eq. (13-114) simplifies to Raoult's law. For nonideal liquid-phase behavior, a system is said to show negative deviations from Raoult's law if $\gamma_i < 1$ and, conversely, positive deviations from Raoult's law if $\gamma_i > 1$. In sufficiently nonideal systems, the deviations may be so large that the temperature-composition phase diagrams exhibit extrema, as shown in Figs. 13-6, 13-7, and 13-8. At such maxima or minima, the equilibrium vapor and liquid compositions are identical. Thus,

$$y_i = x_i \qquad \text{for all } i = 1, \ldots, c \tag{13-115}$$

and the system is said to form an azeotrope (from the Greek word meaning "to boil unchanged"). Azeotropic systems show a minimum in the $T$ vs. $x$, $y$ diagram when the deviations from Raoult's law are positive (Fig. 13-6) and a maximum in the $T$ vs. $x$, $y$ diagram when the deviations from Raoult's law are negative (Fig. 13-7). If, at these two conditions, a single liquid phase is in equilibrium with the vapor phase, the azeotrope is homogeneous. If multiple-liquid-phase behavior is exhibited at the azeotropic condition, the azeotrope is heterogeneous. For heterogeneous azeotropes, the vapor-phase composition is equal to the *overall* composition of the two (or more) liquid phases (Fig. 13-8). These conditions are consequences of the general definition of an azeotrope in any kind of mixture (i.e., homogeneous, heterogeneous, reactive, or in any combination), which is as follows: An *azeotropic state* is one in which mass transfer occurs between phases in a closed system while the composition of each phase remains constant, but not necessarily equal (see Prigogine and Defay, *Chemical Thermodynamics*, 4th ed., Longmans Green and Co., London, 1967; Rowlinson, *Liquids and Liquid Mixtures*, 2d ed., Butterworths, London, 1969; Doherty and Malone, *Conceptual Design of Distillation Systems*, McGraw-Hill, 2001, chaps. 5, 8, App. C).

Mixtures with only small deviations from Raoult's law (i.e., ideal or nearly ideal mixtures) may form an azeotrope but only if the saturated vapor pressure curves of the two pure components cross each other (such a point is called a Bancroft point). In such a situation, the azeotrope occurs at the temperature and pressure where the curves cross, and perhaps also in the vicinity close to the Bancroft point [e.g., cyclohexane (n.b.p. 80.7°C) and benzene (n.b.p. 80.1°C) form an almost ideal mixture yet exhibit a minimum-boiling azeotrope with roughly equal proportions of each component]. As the boiling point difference between the components increases, the composition of the azeotrope shifts closer to one of the pure components (toward the lower-boiling pure component for minimum-boiling azeotropes, and toward the higher-boiling pure component for maximum-boiling azeotropes). For example, the minimum-boiling azeotrope between methanol (n.b.p. 64.5°C) and toluene (n.b.p. 110.6°C) occurs at ≈ 90 mol % methanol, and the minimum-boiling azeotrope between methyl acetate (n.b.p. 56.9°C) and water (n.b.p. 100°C) occurs at ≈ 90 mol % methyl acetate. Mixtures of components whose boiling points differ by more than about 50°C generally do not exhibit azeotropes distinguishable from the pure components even if large deviations from Raoult's law are present. As a qualitative guide to liquid-phase activity coefficient behavior, Robbins [*Chem. Eng. Prog.*, **76**(10), 58 (1980)] developed a matrix of chemical families, shown in Table 13-17, which indicates expected deviations from Raoult's law.

The formation of two liquid phases within some boiling temperature range is generally an indication that the system will also exhibit a minimum-boiling azeotrope, since two liquid phases may form when deviations from Raoult's law are large and positive. The fact that immiscibility does occur, however, does not guarantee that the azeotrope will be heterogeneous since the azeotropic composition may not necessarily fall within the composition range of the two-liquid phase region, as is the case for the methyl acetate–water and tetrahydrofuran-water systems. Since strong positive deviations from Raoult's law are required for liquid-liquid phase splitting, maximum-boiling azeotropes ($\gamma_i < 1$) are never heterogeneous.

Additional general information on the thermodynamics of phase equilibria and azeotropy is available in Malesinski (*Azeotropy and Other Theoretical Problems of Vapour-Liquid Equilibrium*, Interscience, London, 1965), Swietoslawski (*Azeotropy and Polyazeotropy*, Pergamon, London, 1963), Van Winkle (*Distillation*, McGraw-Hill, New York, 1967), Smith and Van Ness (*Introduction to Chemical Engineering Thermodynamics*, McGraw-Hill, New York, 1975), Wizniak [*Chem. Eng. Sci.*, **38,** 969 (1983)], and Walas (*Phase Equilibria in Chemical Engineering*, Butterworths, Boston, 1985). Horsley (*Azeotropic Data-III*, American Chemical Society, Washington, 1983) compiled an extensive list of experimental azeotropic boiling point and composition data for binary and some multicomponent mixtures. Another source for azeotropic data and activity coefficient model parameters is the multivolume *Vapor-Liquid Equilibrium Data Collection* (DECHEMA, Frankfort, 1977), a compendium of published experimental VLE data. Most of the data have been tested for thermodynamic consistency and have been fitted to the Wilson, UNIQUAC, Van Laar, Margules, and NRTL equations. An extensive two-volume compilation of azeotropic data for 18,800 systems involving 1700 compounds, entitled *Azeotropic Data* by Gmehling et al., was published in 1994 by VCH Publishers, Deerfield Beach, Fla. A computational method for determining the temperatures and compositions of all homogeneous azeotropes of a multicomponent mixture, from liquid-phase activity coefficient correlations, by a differential arclength homotopy continuation method is given by Fidkowski, Malone, and Doherty [*Computers and Chem. Eng.*, **17,** 1141 (1993)]. The method was generalized to determine all homogeneous and heterogeneous azeotropes by Wasylkiewicz, Doherty, and Malone [*Ind. Eng. Chem. Res.*, **38,** 4901 (1999)].

## RESIDUE CURVE MAPS AND DISTILLATION REGION DIAGRAMS

The simplest form of distillation involves boiling a multicomponent liquid mixture in an open evaporation from a single-stage batch still. As the liquid is boiled, the vapor generated is removed from contact with the liquid as soon as it is formed. Because the vapor is richer in the more volatile components than the liquid, the composition and boiling temperature of the liquid remaining in the still change continuously over time and move progressively toward less volatile compositions and higher temperatures until the last drop is vaporized. This last composition may be a pure-component species, or a maximum-boiling azeotrope, and it may depend on the initial composition of the mixture charged to the still.

The trajectory of liquid compositions starting from some initial composition is called a residue curve, the collection of all such curves for a given mixture is called a residue curve map. Arrows are usually added to these curves, pointing in the direction of increasing time, which corresponds to increasing temperature, and decreasing volatility. If the liquid is well mixed and the vaporization is slow, such that the escaping vapor is in phase equilibrium with the residual liquid, then residue curve maps contain exactly the same information as the corresponding phase equilibrium diagram for the mixture, but they represent it in a way that is much more useful for understanding distillation systems. Composition changes taking place in simple batch distillation can be described mathematically by the following ordinary differential equation

$$\frac{dx_i}{d\xi} = x_i - y_i \qquad \text{for all } i = 1, \ldots, c \tag{13-116}$$

where $\xi$ is a dimensionless nonlinear time scale. Normally, $y_i$ and $x_i$ are related by an isobaric VLE model. Integrating these equations forward in time leads to the less volatile final compositions; integrating them backward in time leads to the more volatile compositions which would produce a residue curve passing through the specified initial composition. A *residue curve map* (RCM) is generated by varying the initial composition and integrating Eq. (13-116) both forward and backward in time [Doherty and Perkins, *Chem. Eng. Sci.,* **33,** 281 (1978); Doherty and Malone, op. cit., chap. 5]. Unlike a binary $y$-$x$ plot, relative-volatility information is not represented on an RCM. Therefore, it is difficult to determine the ease of separation from a residue curve map alone. The steady states of Eq. (13-116) are the constant-composition trajectories corresponding to $dx_i/d\xi = 0$ for all $i = 1, \ldots, c$. The steady states therefore correspond to *all* the pure components and *all* the azeotropes in the mixture.

Residue curve maps can be constructed for mixtures of any number of components, but can be pictured graphically only up to four components. For binary mixtures, a $T$ vs. $x$, $y$ diagram or a $y$-$x$ diagram suffices; the system is simple enough that vapor-phase information can be included with liquid-phase information without confusion. For ternary mixtures, liquid-phase compositions are plotted on a triangular diagram, similar to that used in liquid-liquid extraction. Four-component systems can be plotted in a three-dimensional tetrahedron. The vertices of the triangular diagram or tetrahedron represent the pure components. Any binary, ternary, and quaternary azeotropes are placed at the appropriate compositions on the edges and/or interior of the triangle and tetrahedron.

The simplest form of ternary RCM, as exemplified for the ideal normal-paraffin system of pentane-hexane-heptane, is illustrated in Fig. 13-78*a*, using a right-triangle diagram. Maps for all other nonazeotropic ternary mixtures are qualitatively similar. Each of the infinite number of possible residue curves originates at the pentane vertex, travels toward and then away from the hexane vertex, and terminates at the heptane vertex. The family of all residue curves that originate at one composition and terminate at another composition defines a *distillation region*. Systems that do not involve azeotropes have only one region—the entire composition space. However, for many systems, not all residue curves originate or terminate at the same two compositions. Such systems will have more than one distillation region. The residue curve that divides two distillation regions in which adjacent residue curves originate from different compositions or terminate at different compositions is called a *simple batch distillation boundary* or *separatrix.* Distillation boundaries are related to the existence of azeotropes. In the composition space for a binary system, the distillation boundary is a point (the azeotropic composition). For three components, the distillation boundary is a curve; for four components, the boundary is a surface; and so on.

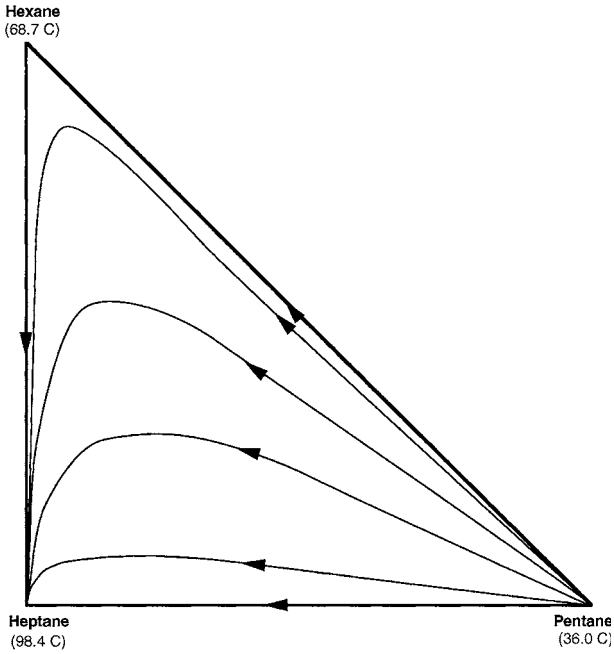

**FIG. 13-78*a*** Residue curve map: Nonazeotropic pentane-hexane-heptane system at 1 atm.

The boundaries of the composition diagram (e.g., the edges of a composition triangle) also form region boundaries since they divide physically realistic residue curves with positive compositions from unrealistic curves with negative compositions. All pure components and azeotropes in a system lie on region boundaries. Within each region, the most volatile composition on the boundary (either a pure component or a minimum-boiling azeotrope, and the origin of all residue curves in that region) is called the *low-boiling node.* The least-volatile composition on the boundary (either a pure component or a maximum-boiling azeotrope, and the terminus of all residue curves in that region) is called the *high-boiling node.* All other pure components and azeotropes are called *intermediate-boiling saddles*. Adjacent regions may share some (but not all) nodes and saddles. Pure components and azeotropes are labeled as nodes and saddles as a result of the boiling points of all the components and azeotropes in a system. If one species is removed, the labeling of all remaining pure components and azeotropes, particularly those that were saddles, may change. Distillation boundaries always originate or terminate at saddle azeotropes, but never at pure component saddles—distillation boundaries can be calculated by using the method proposed by Lucia and Taylor [*AIChE J.*, **52,** 582 (2006)]. Ternary saddle azeotropes are particularly interesting because they are more difficult to detect experimentally (being neither minimum-boiling nor maximum-boiling). However, their presence in a mixture implies the existence of distillation boundaries which may have an important impact on the design of a separation system. The first ternary saddle azeotrope to be detected experimentally was reported by Ewell and Welch [*Ind. Eng. Chem.*, **37,** 1224 (1945)], and a particularly comprehensive set of experimental residue curves were reported by Bushmakin and Kish [*J. Appl. Chem. USSR (Engl. Trans.)*, **30,** 205 (1957)] for a ternary mixture with a ternary saddle azeotrope (reproduced as fig. 5.9 in Doherty and Malone, op. cit.). More ternary saddle azeotropes are reported in Gmehling et al. (*Azeotropic Data*, 1994).

Both methylethylketone (MEK) and methylisopropylketone (MIPK) form minimum-boiling homogeneous azeotropes with water (Fig. 13-78*b*). In this ternary system, a distillation boundary connects the binary azeotropes and divides the RCM into two distillation regions, I and II. The high-boiling node of region I is pure water, while the low-boiling node is the MEK-water azeotrope. In region II, the high- and low-boiling nodes are MIPK and the MEK-water azeotrope, respectively. These two regions, however, have a different number of saddles—one in region I and two in region II. This leads to region I having three sides, while region II has four sides. The more complicated cyclohexane-ethanol-water system (Fig. 13-78*c*) has three boundaries and three regions, all of which are four-sided and share the ternary azeotrope as the low-boiling node.

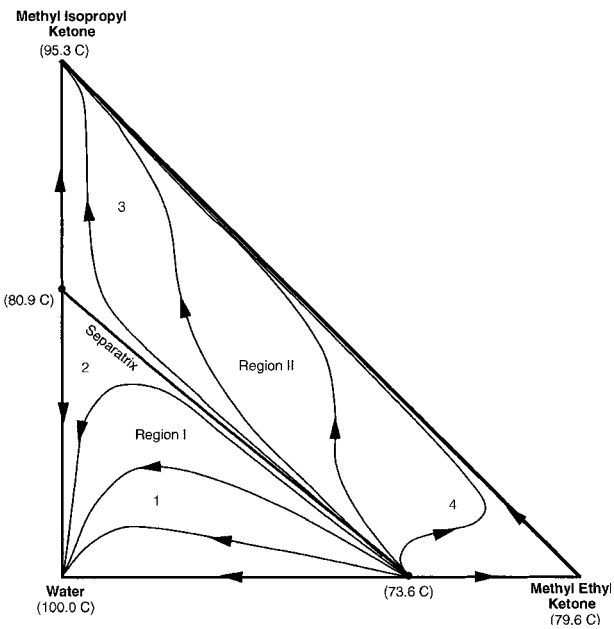

**FIG. 13-78*b*** Residue curve map: MEK-MIPK-water system at 1 atm containing two minumum-boiling binary azeotropes.

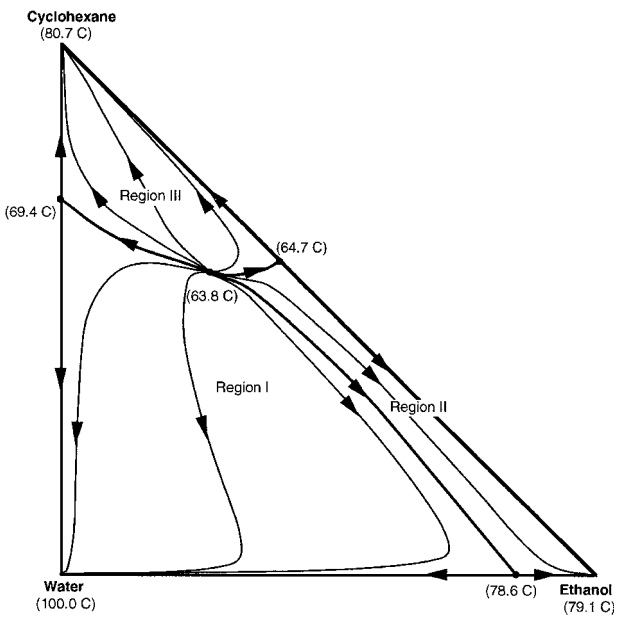

**FIG. 13-78*c*** Residue curve map: Ethanol-cyclohexane-water system at 1 atm containing four minimum-boiling azeotropes (three binary and one ternary) and three distillation regions.

The liquid composition profiles in continuous staged or packed distillation columns operating at infinite reflux and boil-up are closely approximated by simple distillation residue curves [Van Dongen and Doherty, *Ind. Eng. Chem. Fundam.*, **24,** 454 (1985)]. Residue curves are also indicative of many aspects of the general behavior of continuous columns operating at more practical reflux ratios. For example, to a first approximation, the stage-to-stage liquid compositions (along with the distillate and bottoms compositions) of a single-feed, two-product, continuous distillation column lie on the same residue curve. Therefore, for systems with distillation boundaries and multiple regions, distillation composition profiles are constrained to lie in specific regions. The precise boundaries of these distillation regions are a function of reflux ratio, but they are closely approximated by the RCM distillation boundaries. If a RCM distillation boundary exists in a system, a corresponding continuous distillation boundary will also exist. Both types of boundaries correspond exactly at all pure components and azeotropes.

Residue curves can be constructed from experimental data or can be calculated by integrating Eq. (13-116) if equation-of-state or activity-coefficient expressions are available (e.g., Wilson binary-interaction parameters, UNIFAC groups). However, considerable information on system behavior can still be deduced from a simple qualitative sketch of the RCM distillation boundaries based only on pure-component and azeotrope boiling point data and approximate azeotrope compositions. Rules for constructing such qualitative *distillation region diagrams* (DRDs) are given by Foucher et al. [*Ind. Eng. Chem. Res.*, **30,** 760, 2364 (1991)]. For ternary systems containing no more than one ternary azeotrope and no more than one binary azeotrope between each pair of components, 125 such DRDs are mathematically possible [Matsuyama and Nishimura, *J. Chem. Eng. Japan*, **10,** 181 (1977); Doherty and Caldarola, *Ind. Eng. Chem. Fundam.*, **24,** 474 (1985); Peterson and Partin, *Ind. Eng. Chem. Res.*, **36,** 1799 (1997)], although only a dozen or so represent most systems commonly encountered in practice.

Figure 13-79 illustrates all the 125 possible DRDs for ternary systems [see Peterson and Partin, *Ind. Eng. Chem. Res.*, **36,** 1799 (1997)]. Azeotropes are schematically depicted generally to have equimolar composition, distillation boundaries are shown as straight lines, and the arrows on the distillation boundaries indicate increasing temperature. These DRDs are indexed in Table 13-18 according to a temperature profile sequence of position numbers, defined in a keyed triangular diagram at the bottom of the table, arranged by increasing boiling point. Positions 1, 3, and 5 are the pure components in order of decreasing volatility. Positions 2, 4, and 6 are binary azeotropes at the positions shown in the keyed triangle, and position 7 is the ternary azeotrope. Azeotrope position numbers are deleted from the temperature profile if the corresponding azeotrope is known not to exist. Note that not every conceivable temperature profile corresponds to a thermodynamically consistent system, and such combinations have been excluded from the index. As is evident from the index, some DRDs are consistent with more than one temperature profile. Also some temperature profiles are consistent with more than one DRD. In such cases, the correct diagram for a system must be determined from residue curves obtained from experimental or calculated data.

Schematic DRDs are particularly useful in determining the implications of possibly unknown ternary saddle azeotropes by postulating position 7 at interior positions in the temperature profile. Also note that some combinations of binary azeotropes require the existence of a ternary saddle azeotrope. As an example, consider the system acetone (56.4°C), chloroform (61.2°C), and methanol (64.7°C) at 1-atm pressure. Methanol forms minimum-boiling azeotropes with both acetone (54.6°C) and chloroform (53.5°C), and acetone-chloroform forms a maximum-boiling azeotrope (64.5°C). Experimentally there are no data for maximum- or minimum-boiling ternary azeotropes for this mixture. Assuming no ternary azeotrope, the temperature profile for this system is 461325, which from Table 13-18 is consistent with DRD 040 and DRD 042. However, Table 13-18 also indicates that the pure-component and binary azeotrope data are consistent with three temperature profiles involving a ternary saddle azeotrope, namely, 4671325, 4617325, and 4613725. All three of these temperature profiles correspond to DRD 107. Calculated residue curve trajectories for the acetone-chloroform-methanol system at 1-atm pressure, as shown in Fig. 13-80, suggest the existence of a ternary saddle azeotrope and DRD 107 as the correct approximation of the distillation regions. Ewell and Welch [*Ind. Eng. Chem.*, **37,** 1224 (1945)] confirmed experimentally such a ternary saddle at 57.5°C.

## APPLICATIONS OF RCM AND DRD

Residue curve maps and distillation region diagrams are very powerful tools for understanding all types of batch and continuous distillation operations, particularly when combined with other information such as liquid-liquid binodal curves. Applications include

1. *System visualization.* Location of distillation boundaries, azeotropes, distillation regions, feasible products, and liquid-liquid regions.
2. *Evaluation of laboratory data.* Location and confirmation of saddle ternary azeotropes and a thermodynamic consistency check of data.
3. *Process synthesis.* Concept development, construction of flow sheets for new processes, and redesign or modification of existing process flow sheets.
4. *Process modeling.* Identification of infeasible or problematic column specifications that could cause simulation convergence difficulties or failure, and determination of initial estimates of column parameters including feed-stage location, number of stages in the stripping and enriching sections, reflux ratio, and product compositions.
5. *Control analysis/design.* Analysis of column balances and profiles to aid in control system design and operation.
6. *Process trouble shooting.* Analysis of separation system operation and malfunction, examination of composition profiles, and tracking of trace impurities with implications for corrosion and process specifications.

Material balances for mixing or continuous separation operations are represented graphically on triangular composition diagrams such as residue curve maps or distillation region diagrams by straight lines connecting pertinent compositions. The straight lines are exact representations of the compositions due to the lever rule. Overall flow rates are found by the inverse-lever-arm rule. Distillation material balance lines are governed by two constraints:

1. The bottoms, distillate, and overall feed compositions must lie on the same straight line.
2. The bottoms and distillate compositions must lie (to a very close approximation) on the same residue curve.

Since residue curves do not cross simple batch distillation boundaries, the distillate and bottoms compositions must be in the same distillation region with the mass balance line intersecting a residue curve in two places. Mass balance lines for mixing and for other separations not involving vapor-liquid equilibria, such as extraction and decantation, are of course not limited by distillation boundaries.

For a given multicomponent mixture, a single-feed, two-product distillation column (simple column) can be designed with sufficient stages, reflux, and material balance control to produce separations ranging from the *direct-split* mode of operation (low-boiling node taken as distillate) to the *indirect-split* mode (high-boiling node taken as bottoms). The bow tie shaped set of reachable product compositions for a simple distillation column is roughly bounded by the (straight) material balance lines connecting the feed composition to the sharpest direct separation and the sharpest indirect separation possible (see Fig. 13-81). A more accurate approximation involves replacing two of the straight-line segments of the bow tie with the residue curve through the feed composition [Stichlmair and Herguijuela, *AIChE J.*, **38,** 1523 (1992)]. The exact shape of the reachable product composition regions involves replacing two of the straight-line segments of the bow tie with a locus of pinch points, as explained by Wahnschafft et al. [*Ind. Eng. Chem. Res.*, **31,** 2345 (1992)] and Fidkowski, Doherty, and Malone [*AIChE J.*, **39,** 1303 (1993)]. Since residue curves are deflected by saddles, it is generally not possible to obtain a saddle product (pure component or azeotrope) from a simple distillation column.

Consider the recovery of MIPK from an MEK-MIPK-water mixture. The approximate bow tie regions of product compositions for three different feeds are shown in Fig 13-81. From feed F3, which is situated in a different distillation region than the desired product, pure MIPK cannot be obtained at all. Feed F2 is more favorable, with the upper edge of the bow tie region along the MEK-MIPK (water-free) face of the composition triangle and part of the lower

edge along the MEK-water (MIPK-free) face. There are conditions under which both the water in the MIPK bottoms product can be driven to low levels (high-product purity) and MIPK in the distillate can be driven to low levels (high-product recovery), although achieving such an operation depends on having an adequate number of stages and reflux ratio.

Although feed F2 lies in the same distillation region as F1, the bow tie region for feed F2 is significantly different than that for F1, with the upper edge along the water-MIPK (MEK-free) face of the triangle and the lower edge along the distillation boundary. From this feed it is not possible to simultaneously achieve a high-purity MIPK specification while obtaining high MIPK recovery. If the column is operated to get a high purity of MIPK, then the material balance line runs into the distillation boundary. Alternatively, if the column is operated to obtain a high recovery of MIPK (by removing the MEK-water azeotrope as distillate), the material balance requires the bottoms to lie on the water-MIPK face of the triangle.

The number of saddles in a particular distillation region can have significant impact on column profile behavior, process stability, and convergence behavior in process simulation of the system. Referring to the MIPK-MEK-water system in Fig. 13-78*b*, region I contains one saddle (MIPK-water azeotrope), while region II contains two saddles (pure MEK and the MIPK-water azeotrope). These are three- and four-sided regions, respectively. In a three-sided region, all residue curves track toward the solitary saddle. However, in a four- (or more) sided region with saddles on either side of a node, some residue curves will tend to track toward one saddle, while others track toward another saddle. For example, residue curve 1 in region I originates from the MEK-water azeotrope low-boiling node and travels first toward the single saddle of the region (MIPK-water azeotrope) before ending at the water high-boiling node. Likewise, residue curve 2 and all other residue curves in region I follow the same general path.

In region II, residue curve 3 originates from the MEK-water azeotrope, travels toward the MIPK-water saddle azeotrope, and ends at pure MIPK. However, residue curve 4 follows a completely different path, traveling toward the pure MEK saddle before ending at pure MIPK. Some multicomponent columns have been designed for operation in four-sided regions with the feed composition adjusted so that both the high-boiling and low-boiling nodes can be obtained simultaneously as products. However, small perturbations in feed composition or reflux can result in feasible operation on many different residue curves that originate and terminate at these product compositions. Multiple steady states and composition profiles that shift dramatically from tracking toward one saddle to the other are possible [Kovach and Seider, *AIChE J.*, **33,** 1300 (1987); Pham, Ryan, and Doherty, *AIChE J.*, **35,** 1585 (1989)]. Consider a column operating in region II of the MIPK-MEK-water diagram. Figure 13-82 shows the composition and temperature profiles for the column operating at three different sets of

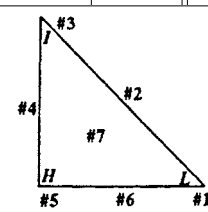
Ternary DRD table lookup procedure:

1. Classify a system by writing down each position number in ascending order of boiling points.
   - A position number is not written down if there is no azeotrope at that position.
   - The resulting sequence of numbers is known as the *temperature profile.*
   - Each temperature profile will have a minimum of three numbers and a maximum of seven numbers.
   - List multiple temperature profiles when you have incomplete azeotropic data.
   - All seven position numbers are shown on the diagram.
2. Using the table, look up the temperature profile(s) to find the corresponding DRD #.

*Table 13-18 and Fig. 13-79 developed by Eric J. Peterson, Eastman Chemical Co.



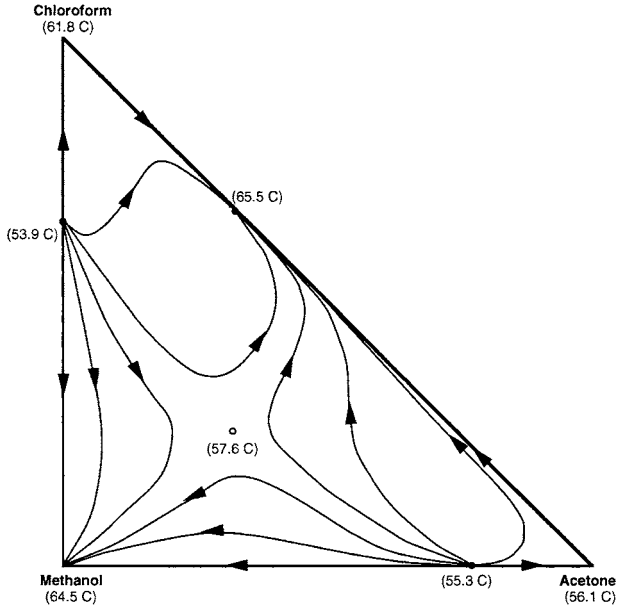


**FIG. 13-80** Residue curves for acetone-chloroform-methanol system at 1-atm pressure suggesting a ternary saddle azeotrope.

operating conditions and two feed locations, as given in Table 13-19. The desired product specification is 97 mol % MIPK, no more than 3 mol % MEK, and less than 10 ppm residual water. For case A (Fig. 13-82*a*), the column profile tracks up the water-free side of the diagram. A pinched zone (i.e., section of little change in tray temperature and composition) occurs above the feed between the feed tray (tray 4) and tray 18. The temperature remains constant at about 93°C throughout the pinch zone. Product specifications are met.

When the feed composition becomes slightly enriched in water, as with case B, the column profile changes drastically (Fig. 13-82*b*). At the same reflux and boil-up, the column no longer meets specifications. The MIPK product is lean in MIPK and too rich in water. The profile now tracks generally up the left side of region II. Note also the dramatic change in the temperature profile. A pinched zone still exists above the feed between trays 4 and 18, but the tray temperature in the zone has dropped to 80°C (from 93°C). Most of the trays are required to move through the vicinity of the saddle. Typically, pinches (if they exist) occur close to saddles and nodes.

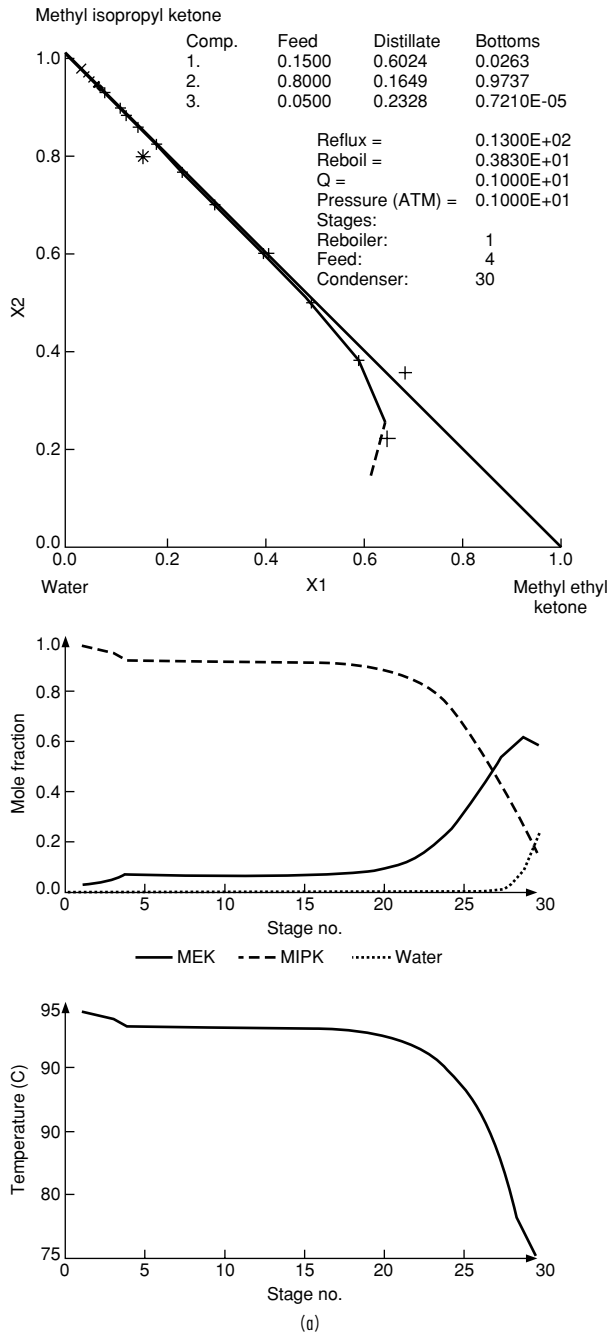

**FIG. 13-82** Sensitivity of composition and temperature profiles for MEK-MIPK-water system at 1 atm.

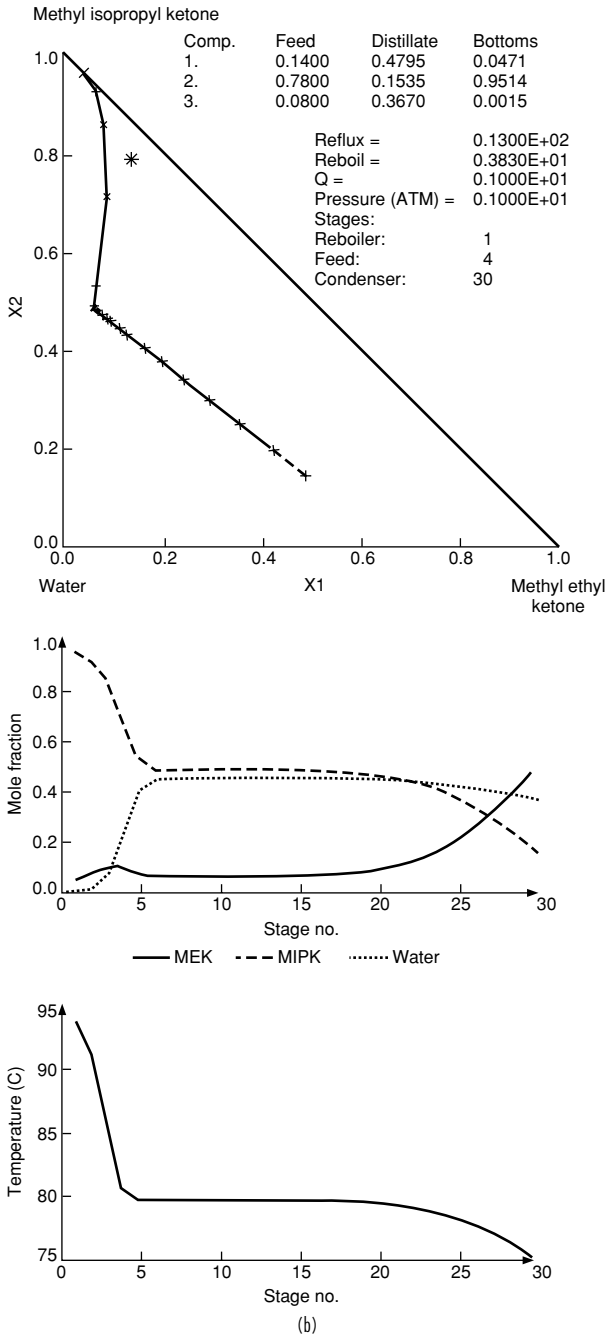

**FIG. 13-82** (*Continued*)

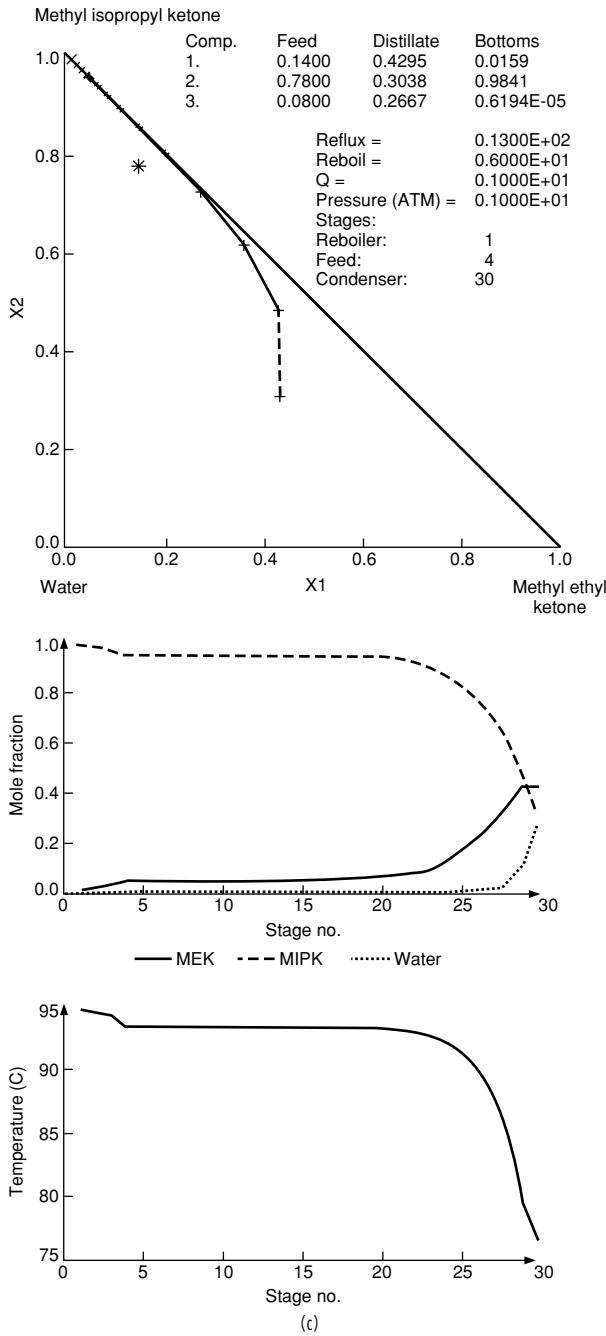

**FIG. 13-82** (*Continued*)

In case C (Fig. 13-82*c*), increasing the boil-up ratio to 6 brings the MIPK product back within specifications, but the production rate and recovery have dropped off. In addition, the profile has switched back to the right side of the region; and the temperatures on trays in the pinched zone (trays 4 through 18) are back to 93°C. Such a drastic fluctuation in tray temperature with a relatively minor adjustment of the manipulated variable (boil-up in this case) can make control difficult. This is especially true if the control strategy involves maintaining a constant temperature on one of the trays between trays 4 and 18. If a tray is selected that exhibits wide temperature swings, the control system may have a difficult time compensating for disturbances. Such columns are also often difficult to model with a process simulator. Design algorithms often rely on perturbation of a variable (such as reflux or reboil) while checking for convergence of column heat and

**TABLE 13-19 Sets of Operating Conditions for Fig. 13-82**

| Case | Reflux ratio | Reboil ratio | | Feed composition | Distillate composition | Bottoms composition |
|---|---|---|---|---|---|---|

material balances. In situations where the column profile is altered drastically by minor changes in the perturbed variable, the simulator may be close to a feasible solution, but successive iterations may appear to be very far apart. The convergence routine may continue to oscillate between column profiles and never reach a solution. Likewise, when an attempt is made to design a column to obtain product compositions in different distillation regions, the simulation will never converge.

## AZEOTROPIC DISTILLATION

The term *azeotropic distillation* has been applied to a broad class of fractional distillation-based separation techniques when specific azeotropic behavior is exploited to effect a separation. The agent that causes the specific azeotropic behavior, often called the *entrainer,* may already be present in the feed mixture (a self-entraining mixture) or may be an added mass separation agent. Azeotropic distillation techniques are used throughout the petrochemical and chemical processing industries for the separation of close-boiling, pinched, or azeotropic systems for which simple distillation is either too expensive or impossible. With an azeotropic feed mixture, presence of the azeotroping agent results in the formation of a more favorable azeotropic pattern for the desired separation. For a close-boiling or pinched feed mixture, the azeotroping agent changes the dimensionality of the system and allows separation to occur along a less pinched path. Within the general heading of azeotropic distillation techniques, several approaches have been followed in devising azeotropic distillation flow sheets including

1. Choosing an entrainer to give a residue curve map with specific distillation regions and node temperatures
2. Exploiting changes in azeotropic composition with total system pressure
3. Exploiting curvature of distillation region boundaries
4. Choosing an entrainer to cause azeotrope formation in combination with liquid-liquid immiscibility

The first three of these are solely VLE-based approaches, involving a series of simple distillation column operations and recycles. The final approach relies on distillation (VLE), but also exploits another physical phenomenon, liquid-liquid phase formation (phase splitting), to assist in entrainer recovery. This approach is the most powerful and versatile. Examples of industrial uses of azeotropic distillation grouped by method are given in Table 13-20.

The choice of the appropriate azeotropic distillation method and the resulting flow sheet for the separation of a particular mixture are strong functions of the separation objective. For example, it may be desirable to recover all constituents of the original feed mixture as pure components, or only some as pure components and others as azeotropic mixtures suitable for recycle. Not every objective may be obtainable by azeotropic distillation for a given mixture and portfolio of candidate entrainers.

**Exploiting Homogeneous Azeotropes** Homogeneous azeotropic distillation refers to a flow sheet structure in which azeotrope formation is exploited or avoided in order to accomplish the desired separation in one or more distillation columns. Either the azeotropes in the system do not exhibit two-liquid-phase behavior, or the liquid-phase behavior is not or cannot be exploited in the separation sequence. The structure of a particular sequence will depend on the geometry of the residue curve map or distillation region diagram for the feed mixture-entrainer system. Two approaches are possible:

1. Selection of an entrainer such that the desired products all lie within the *same* distillation region (the products may be pure components or azeotropic mixtures)
2. Selection of an entrainer such that some type of distillation boundary-crossing mechanism is employed to separate desired products that lie in *different* regions.

As mentioned previously, ternary mixtures can be represented by 125 different residue curve maps or distillation region diagrams. However, feasible distillation sequences using the first approach can be developed for breaking homogeneous binary azeotropes by the addition of a third component only for those more restricted systems that do not have a distillation boundary connected to the azeotrope and for which one of the original components is a node. For example, from Fig. 13-79, the following eight residue curve maps are suitable for breaking homogeneous minimum-boiling azeotropes: DRD 002, 027, 030, 040, 051, 056, 060, and 061 as collected in Fig. 13-83. To produce the necessary distillation region diagrams, an entrainer must be found that is either: (1) an intermediate boiler that forms no azeotropes (DRD 002), or (2) lowest-boiling or intermediate-boiling and forms a maximum-boiling azeotrope with the lower-boiling original component (A). In these cases, the entrainer may also optionally form a minimum-boiling azeotrope with the higher boiling of the original components or a minimum-boiling ternary azeotrope. In all cases, after the addition of the entrainer, the higher-boiling original component (B) is a high-boiling node and is removed as bottoms product from a first column operated in the indirect-split mode with the lower-boiling original component recovered as distillate in a second column; see flow sheet in Fig. 13-83.

The seven residue curve maps suitable for breaking homogeneous maximum-boiling binary azeotropes (DRD 028, 031, 035, 073, 078, 088, 089) are shown in Fig. 13-84. In this case, the entrainer must form a minimum-boiling azeotrope with the higher-boiling original component and either a maximum-boiling azeotrope or no azeotrope with the lower-boiling original component. In all cases, after the addition of the entrainer, the lower-boiling original component is a low-boiling node and is removed as distillate from a first column operated in the direct-split mode with the higher-boiling original component recovered as bottoms product in a second column; see flow sheet in Fig. 13-84.

The restrictions on the boiling point and azeotrope formation of the entrainer act as efficient screening criteria for entrainer selection. Entrainers that do not show appropriate boiling point characteristics can be discarded without detailed analysis. However, the entrainers in Fig. 13-83 do suffer from serious drawbacks that limit their practical application. DRD 002 requires that the entrainer be an intermediate-boiling component that forms no azeotropes. Unfortunately these are often difficult criteria to meet, as any intermediate boiler will be closer-boiling to both of the original components and, therefore, will be more likely to be at least pinched or even form azeotropes. The remaining feasible distillation region diagrams require that the entrainer form a maximum-boiling azeotrope with the lower-boiling original component. Because maximum-boiling azeotropes are relatively rare, finding a suitable entrainer may be difficult.

For example, the dehydration of organics that form homogeneous azeotropes with water is a common industrial problem. It is extremely difficult to find an intermediate-boiling entrainer that also does not form an azeotrope with water. Furthermore, the resulting separation is likely to be close-boiling or pinched throughout most of the column, requiring a large number of stages. For example, consider the separation of valeric acid (187.0°C) and water. This system exhibits a minimum-boiling azeotrope (99.8°C) with a composition and boiling point close to those of pure water. Ignoring for the moment potentially severe corrosion problems, formic acid (100.7°C), which is an intermediate boiler and which forms a maximum-boiling azeotrope with water (107.1°C), is a candidate entrainer (DRD 030, Fig. 13-85*a*). In the conceptual sequence shown in Fig. 13-85*b*, a recycle of the formic acid–water maximum-boiling azeotrope is added to the

**TABLE 13-20 Examples of Azeotropic Distillation**

| System | Type | Entrainer(s) | Remark |
|---|---|---|---|
| Exploitation of homogeneous azeotropes | | | |
| No known industrial examples | | | |
| Exploitation of pressure sensitivity | | | |
| THF-water | Minimum-boiling azeotrope | None | Alternative to extractive distillation |
| Methyl acetate-methanol | Minimum-boiling azeotrope | None | Element of recovery system for alternative to production of methyl acetate by reactive distillation; alternative to azeotropic, extractive distillation |
| Alcohol-ketone systems | Minimum-boiling azeotropes | None | |
| Ethanol-water | Minimum-boiling azeotrope | None | Alternative to extractive distillation, salt extractive distillation, heterogeneous azeotropic distillation; must reduce pressure to less than 11.5 kPa for azeotrope to disappear |

| Pyridine-water | Minimum-boiling azeotrope | Benzene | Alternative to extractive distillation |
| Hydrocarbon-water | Minimum-boiling azeotrope | Self-entraining | |

original valeric acid–water feed, which may be of any composition. Using the indirect-split mode of operation, the high-boiling node valeric acid is removed in high purity and high recovery as bottoms in a first column, which by mass balance produces a formic acid–water distillate. This binary mixture is fed to a second column that produces pure water as distillate and the formic acid–water azeotrope as bottoms for recycle to the first column. The inventory of formic acid is an important optimization variable in this theoretically feasible but difficult separation scheme.

**Exploiting Pressure Sensitivity** Breaking a homogeneous azeotrope that is part of a distillation boundary (i.e., the desired products lie in different distillation regions on either side of the boundary) requires that the boundary be "crossed" by the separation system. This may be done by mixing some external stream with the original feed stream in one region such that the resulting composition is in another region for further processing. However, the external stream must be completely regenerated, and mass balance must be preserved. For example, it is not possible to break a homogeneous binary azeotrope simply by adding one of the products to cross the azeotropic composition.

The composition of many azeotropes varies with the system pressure (Horsley, *Azeotropic Data-III,* American Chemical Society, Washington, 1983; Gmehling et al., *Azeotropic Data,* VCH Publishers, Deerfield Beach, Fla., 1994). This effect can be exploited to separate azeotropic mixtures by so-called pressure-swing distillation if at some pressure the azeotrope simply disappears, such as does the ethanol-water azeotrope at pressures below 11.5 kPa. However, pressure sensitivity can still be exploited if the azeotropic composition and related distillation boundary change sufficiently over a moderate change in total system pressure. A composition in one distillation region under one set of conditions could be in a different region under a different set of conditions. A two-column sequence for separating a binary maximum-boiling azeotrope is shown in Fig. 13-86 for a system in which the azeotropic composition at pressure P1 is richer in component B than the azeotropic composition at pressure P2. The first column, operating at pressure P1, is fed a mixture of fresh feed plus recycle stream from the second column such that the overall composition lies on the A-rich side of the azeotropic composition at P1. Pure component A is recovered as distillate, and a mixture near the azeotropic composition is produced as bottoms. The pressure of this bottoms stream is changed to P2 and fed to the second column. This feed is on the B-rich side of the azeotropic composition at P2. Pure component B is now recovered as the distillate, and the azeotropic bottoms composition is recycled to the first column. An analogous flow sheet can be used for separating binary homogeneous minimum-boiling azeotropes. In this case the pure components are recovered as bottoms in both columns, and the distillate from each column is recycled to the other column.

For pressure-swing distillation to be practical, the azeotropic composition must vary at least 5 percent (preferably 10 percent or more) over a moderate pressure range (not more than 10 atm between the two pressures). With a very large pressure range, refrigeration may be required for condensation of the low-pressure distillate, or an impractically high reboiler temperature may result in the high-pressure column. The smaller the variation of azeotrope composition over the pressure range, the larger the recycle flow rates between the two columns. In particular, for minimum-boiling azeotropes, the pressure-swing distillation approach requires high energy usage and high capital

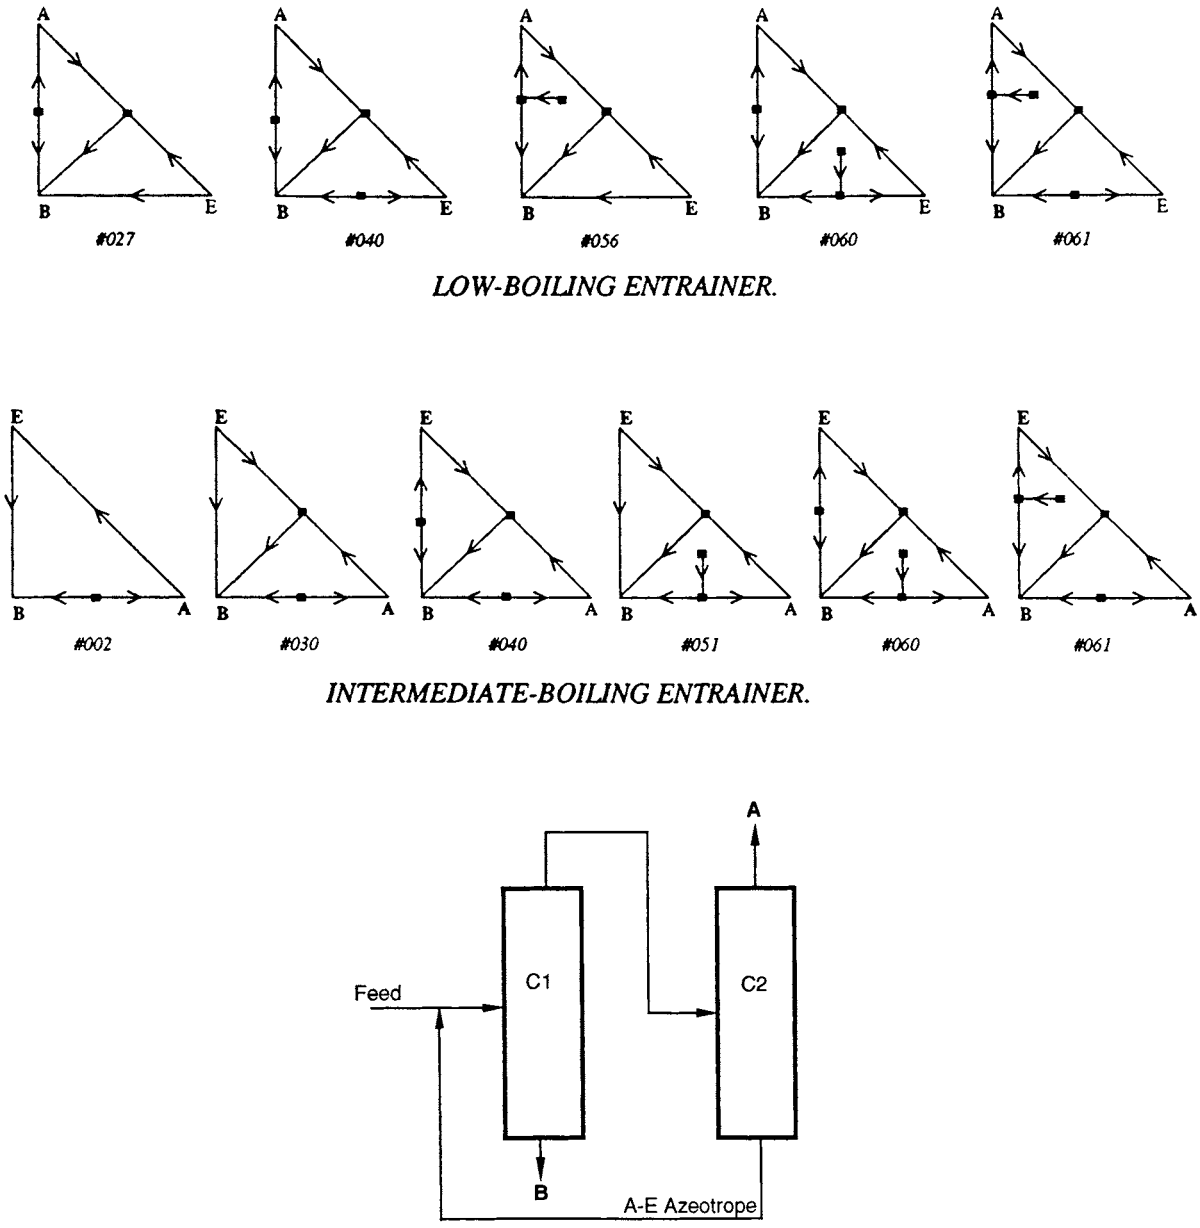

**FIG. 13-83** Feasible distillation region diagrams and associated distillation system for breaking a homogeneous minimum-boiling binary azeotrope A-B. Component B boils at a higher temperature than does A.

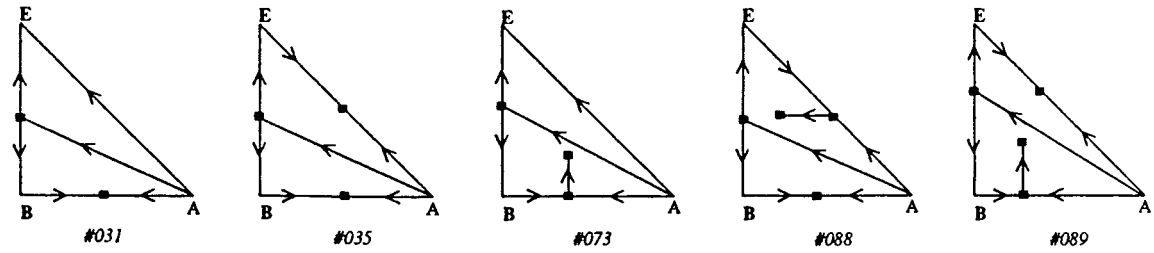
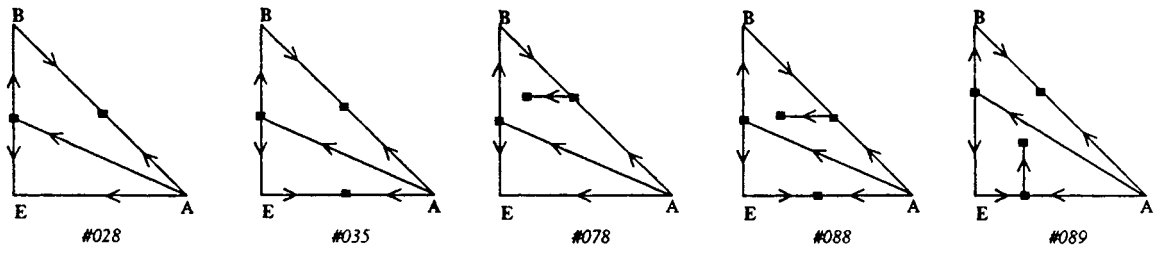
costs (large-diameter columns) because both recycled azeotropic compositions must be taken overhead. Moreover, one lobe of an azeotropic VLE diagram is often pinched regardless of pressure; and, therefore, one of the columns will require a large number of stages to produce the corresponding pure-component product.

General information on pressure-swing distillation can be found in Van Winkle (*Distillation,* McGraw-Hill, New York, 1967), Wankat (*Equilibrium-Staged Separations,* Elsevier, New York, 1988), and Knapp and Doherty [*Ind. Eng. Chem. Res.,* **31,** 346 (1992)]. Only a relatively small fraction of azeotropes are sufficiently pressure-sensitive for a pressure-swing process to be economical. Some applications include the minimum-boiling azeotrope tetrahydrofuran-water [Tanabe et al.; U.S. Patent 4,093,633 (1978)], and maximum-boiling azeotropes of hydrogen chloride–water and formic acid–water (Horsley, *Azeotropic Data-III,* American Chemical Society, Washington, 1983). Since distillation boundaries move with pressure-sensitive azeotropes, the pressure-swing principle can also be used for overcoming distillation boundaries in multicomponent azeotropic mixtures.

**Exploiting Boundary Curvature** A second approach to boundary crossing exploits boundary curvature to produce compositions in different distillation regions. When distillation boundaries exhibit extreme curvature, it may be possible to design a column such that the distillate and bottoms compositions are on the same residue curve in one distillation region, while the feed composition (which is not



*INTERMEDIATE-BOILING ENTRAINER.*



*HIGH-BOILING ENTRAINER.*

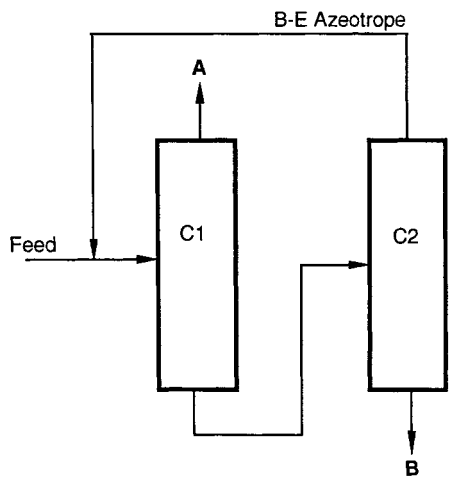


**FIG. 13-84** Feasible distillation region diagrams and associated distillation system for breaking a homogeneous maximum-boiling binary azeotrope A-B. Component B boils at a higher temperature than does A.

required to lie on the column composition profile) is in another distillation region. For such a column to meet material balance constraints (i.e., bottom, distillate, feed compositions on a straight line), the feed must be located in a region where the boundary is concave.

As an example, Van Dongen (Ph.D. Thesis, University of Massachusetts, 1983) considered the separation of a methanol–methyl acetate mixture, which forms a homogeneous azeotrope, using *n*-hexane as an entrainer. The distillation boundaries for this system (Fig. 13-87*a*) are somewhat curved. A separation sequence that exploits this boundary curvature is shown in Fig. 13-87*b*. Recycled methanol–methyl acetate binary azeotrope and methanol–methyl acetate–hexane ternary azeotrope are added to the original feed F0 to produce a net feed composition F1 for column C1 designed to lie on a line between pure methanol and the curved part of the boundary between regions I and II. Column C1 is operated in the indirect-split mode, producing the high-boiling node methanol as a bottoms product, and by mass balance, a distillate near the curved boundary. The distillate, although in region I, becomes feed F2 to column C2 which is operated in the direct-split mode entirely in region II, producing the low-boiling node ternary azeotrope as distillate and by mass balance, a methanol–methyl acetate mixture as bottoms (B2). This bottoms mixture is on the opposite side of the methanol–methyl acetate azeotrope than the original feed F0. The bottoms from C2 is finally fed to binary distillation column C3, which produces pure methyl acetate as bottoms product (B3)

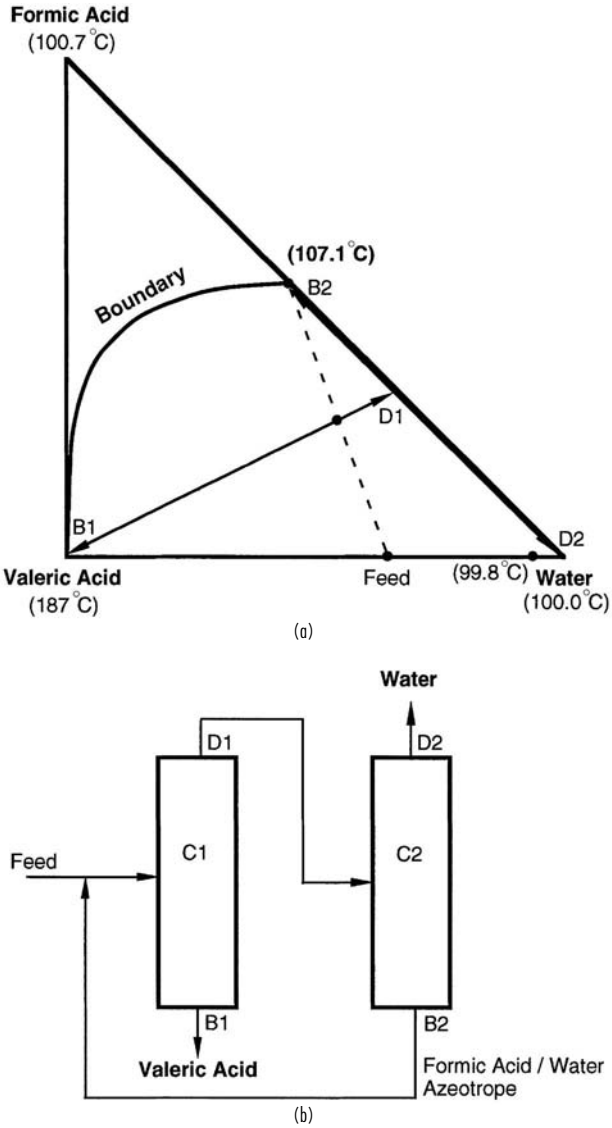

**FIG. 13-85** Valeric acid-water separation with formic acid. (*a*) Mass balances on distillation region diagram. (*b*) Conceptual sequence.

and the methanol–methyl acetate azeotrope as distillate (D3). The distillates from columns C2 and C3 are recycled to column C1. The distillate and bottoms compositions for column C2 lie on the same residue curve, and the composition profile lies entirely within region II, even though its feed composition is in region I. Additional information on exploiting boundary curvature, including the useful concept of a *pitchfork distillation boundary*, can be found in Doherty and Malone (*Conceptual Design of Distillation Systems*, McGraw-Hill, 2001, sec. 5.4).

Exploiting boundary curvature for breaking azeotropes is very similar to exploiting pressure sensitivity from a mass balance point of view, and suffers from the same disadvantages. Separation schemes have large recycle flows, and in the case of minimum-boiling azeotropes, the recycle streams are distillates. However, in the case of maximum-boiling azeotropes, these recycles are bottoms products, and the economics are improved. One such application, illustrated in Fig. 13-88, is the separation of the maximum-boiling nitric acid–water azeotrope by adding sulfuric acid. Recycled sulfuric acid is added to a

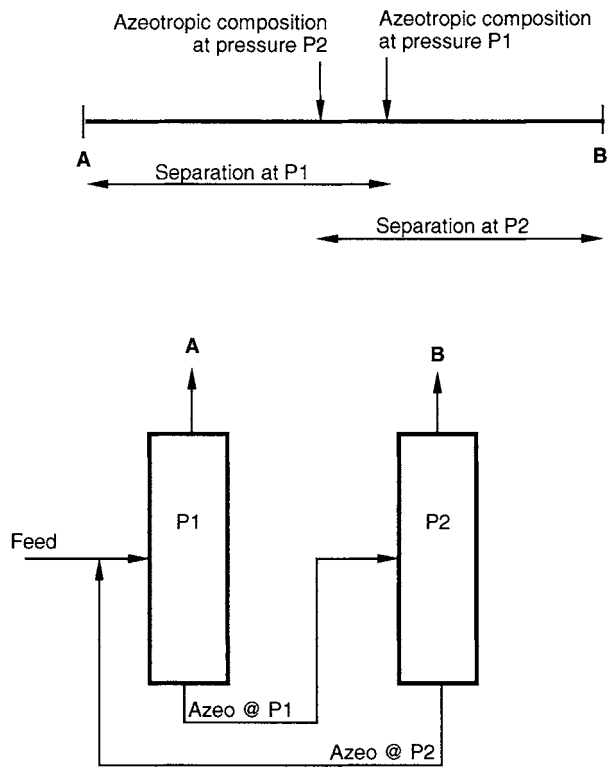

**FIG. 13-86** Conceptual sequence for separating maximum-boiling binary azeotrope with pressure-swing distillation.

nitric acid–water mixture near the azeotropic composition to produce a net feed F1 in region II. The first column, operated in the direct-split mode, produces a nitric acid distillate and a bottoms product, by mass balance, near the distillation boundary. In this case, sulfuric acid associates with water so strongly and the distillation boundary is so curved and nearly tangent to the water–sulfuric acid edge of the composition diagram that the second column operating in the indirect-split mode in region I, producing sulfuric acid as bottoms product, also produces a distillate close enough to the water specification that a third column is not required [Thiemann et al., in *Ullmann's Encyclopedia of Industrial Chemistry*, 5th ed., vol. **A17,** VCH Verlagsgesellschaft mbH, Weinheim, (1991)].

**Exploiting Azeotropy and Liquid-Phase Immiscibility** One powerful and versatile separation approach exploits several physical phenomena simultaneously including nonideal vapor-liquid behavior, where possible, and liquid-liquid behavior to bypass difficult distillation separations. For example, the overall separation of close-boiling mixtures can be made easier by the addition of an entrainer that introduces liquid-liquid immiscibility and forms a heterogeneous minimum-boiling azeotrope with one (generally the lower-boiling) of the key components. Two-liquid-phase formation provides a means of breaking this azeotrope, thus simplifying the entrainer recovery and recycle process. Moreover, since liquid-liquid tie lines are unaffected by distillation boundaries (and the separate liquid phases are often located in different distillation regions), liquid-liquid phase splitting is a powerful mechanism for crossing distillation boundaries. The phase separator is usually a simple decanter, but sometimes a multistage extractor is substituted. The decanter or extractor can also be replaced by some other non-VLE-based separation technique such as membrane permeation, chromatography, adsorption, or crystallization. Also sequences may include additional separation operations (distillations or other methods) for preconcentration of the feed mixture, entrainer recovery, and final-product purification.

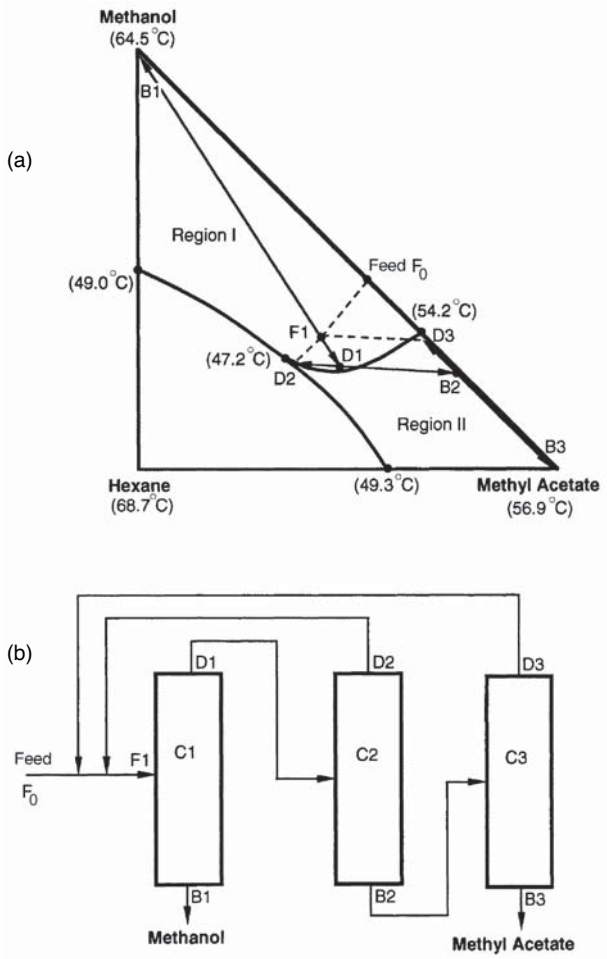

**FIG. 13-87** Separation of methanol–methyl acetate by exploitation of distillation boundary curvature.

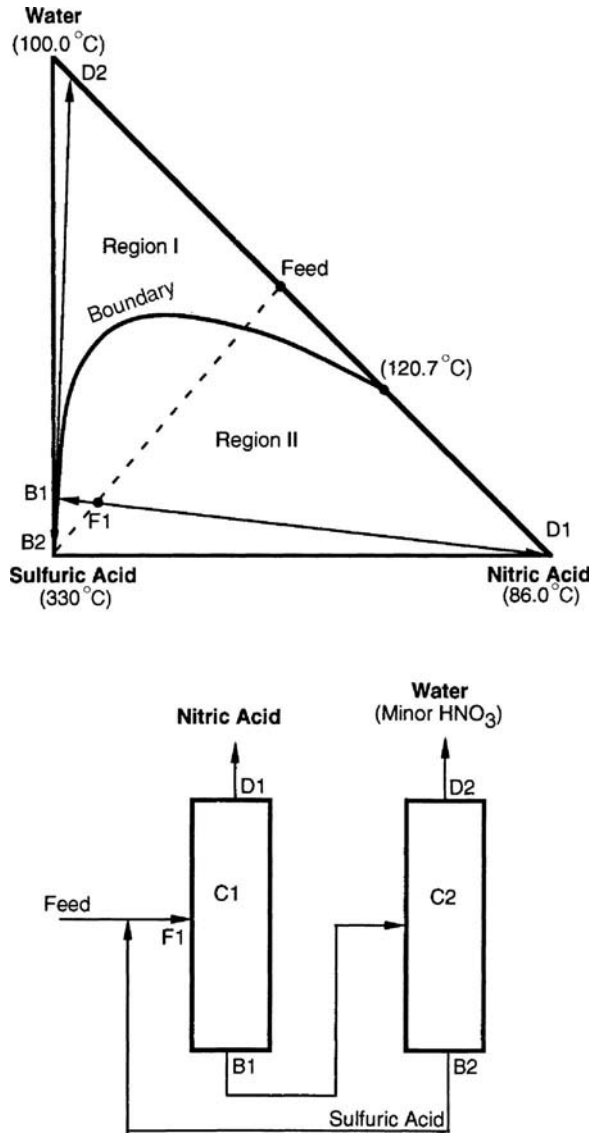

**FIG. 13-88** Separation of nitric acid–water system with sulfuric acid in a two-column sequence exploiting extreme boundary curvature.

The simplest case of combining VLE and LLE is the separation of a binary heterogeneous azeotropic mixture. One example is the dehydration of 1-butanol, a self-entraining system, in which butanol (117.7°C) and water form a minimum-boiling heterogeneous azeotrope (93.0°C). As shown in Fig. 13-89, the fresh feed may be added to either column C1 or C2, depending on whether the feed is on the organic-rich side or the water-rich side of the azeotrope. The feed may also be added into the decanter directly if it does not move the overall composition of the decanter outside of the two-liquid phase region. Column C1 produces anhydrous butanol as a bottoms product and a composition close to the butanol-water azeotrope as the distillate. After condensation, the azeotrope rapidly phase-separates in the decanter. The upper layer, consisting of 78 wt % butanol, is refluxed totally to column C1 for further butanol recovery. The water layer, consisting of 92 wt % water, is fed to column C2. This column produces pure water as a bottoms product and, again, a composition close to the azeotrope as distillate for recycle to the decanter. Sparged steam may be used in C2, saving the cost of a reboiler. A similar flow sheet can be used for dehydration of hydrocarbons and other species that are largely immiscible with water.

A second example of the use of liquid-liquid immiscibilities in an azeotropic distillation sequence is the separation of the ethanol-water minimum-boiling homogeneous azeotrope. For this separation, a number of entrainers have been proposed, which are usually chosen to be immiscible with water and form a ternary minimum-boiling (preferably heterogeneous) azeotrope with ethanol and water (and, therefore, usually also binary minimum-boiling azeotropes with both ethanol and water). All such systems correspond to DRD 058, although the labeling of the vertices depends on whether the entrainer is lower-boiling than ethanol, intermediate-boiling, or higher-boiling than water. The residue curve map for the case of cyclohexane as entrainer was illustrated in Fig. 13-78*c*. One three-column distillation sequence is shown in Fig. 13-90. Other two-, three-, or four-column sequences have been described by Knapp and Doherty (*Kirk-Othmer Encyclopedia of Chemical Technology,* 5th ed., vol. 8, p. 786, Wiley, New York, 2004).

Fresh aqueous ethanol feed is first preconcentrated to nearly the azeotropic composition in column C3, while producing a water bottoms product. The distillate from C3 is sent to column C1, which is refluxed with the entire organic (entrainer-rich) layer, recycled from a decanter. Mixing of these two streams is the key to this sequence as it allows the overall feed composition to cross the distillation boundary

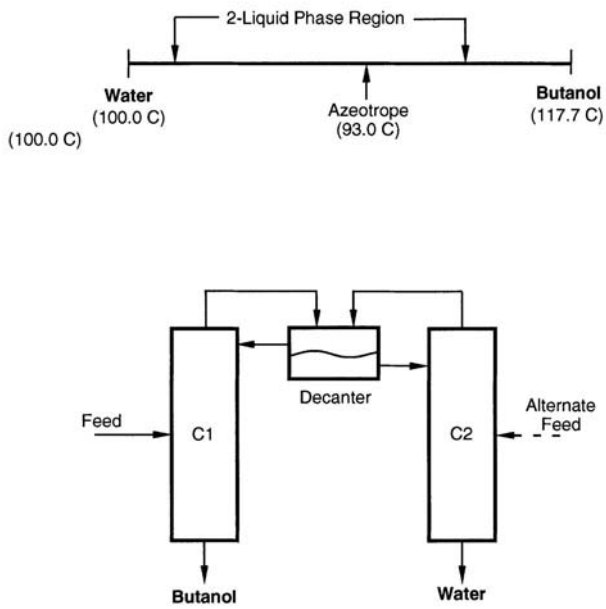

**FIG. 13-89** Separation of butanol-water with heterogeneous azeotropic distillation.

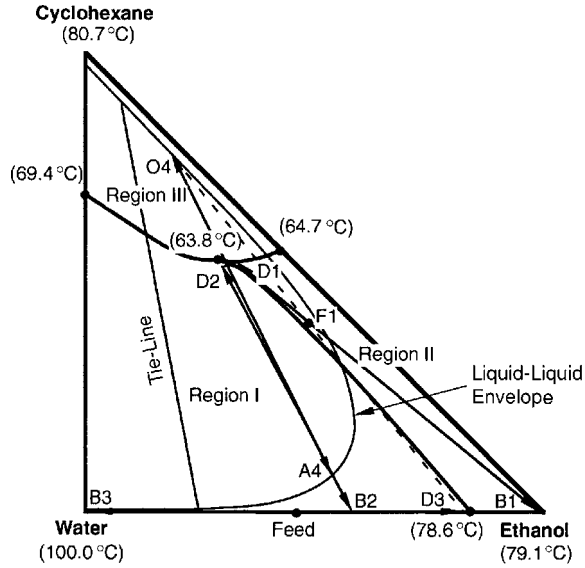
into region II. Column C1 is operated to recover pure high-boiling node ethanol as a bottoms product and to produce a distillate close to the ternary azeotrope. If the ternary azeotrope is heterogeneous (as it is in this case), it is sent to the decanter for phase separation. If the ternary azeotrope is homogeneous (as it is in the alternative case of ethyl acetate as the entrainer), the distillate is first mixed with water before being sent to the decanter. The inventory of entrainer is adjusted to allow column C1 to operate essentially between two nodes, although such practice, as discussed previously, is relatively susceptible to instabilities from minor feed or reflux perturbations. Refluxing a fraction of the water-rich decanter layer results in an additional degree of freedom to mitigate against variability in the feed composition. The remaining portion of the water layer from the decanter is stripped of residual cyclohexane in column C2, which may be operated either in the direct-split mode (producing low-boiling node ternary azeotrope as distillate and, by mass balance, an ethanol-water bottoms for recycle to C3) or in the indirect-split mode (producing high-boiling node water as bottoms and, by mass balance, a ternary distillate near the distillation boundary). (The distillate may be recycled to the decanter, the top of column C1, or the C1 feed.) The indirect-split mode alternatives are discussed in greater detail by Knapp and Doherty (*Kirk-Othmer Encyclopedia of Chemical Technology*, 5th ed., vol. 8, p. 786, Wiley, New York, 2004).

**Design and Operation of Azeotropic Distillation Columns** Simulation and design of azeotropic distillation columns are a difficult computational problem, but one that is readily handled, in most cases, by widely available commercial computer process simulation packages [Glasscock and Hale, *Chem. Eng.*, **101**(11), 82 (1994)]. Most simulators are capable of modeling the steady-state and dynamic behavior of both homogeneous azeotropic distillation systems and those systems involving two-liquid phase behavior within the column, if accurate thermodynamic data and activity coefficient or equation-of-state models are available. However, VLE and VLLE estimated or extrapolated from binary data or predicted from such methods as UNIFAC may not be able to accurately locate boundaries and predict the extent of liquid immiscibilities. Moreover, different activity coefficient models fit to the same experimental data often give very different results for the shape of distillation boundaries and liquid-liquid regions. Therefore the design of separation schemes relying on boundary curvature should not be attempted unless accurate, reliable experimental equilibrium data are available.



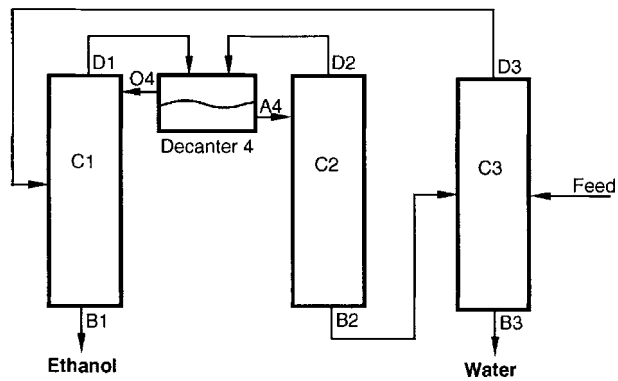


**FIG. 13-90** Three-column sequence for ethanol dehydration with cyclohexane (operating column C2 in the direct-split mode).

Two liquid phases can occur within a column in the distillation of heterogeneous systems. Older references, e.g., Robinson and Gilliland (*Elements of Fractional Distillation*, McGraw-Hill, New York, 1950), state that the presence of two liquid phases in a column should be avoided as much as possible because performance may be reduced. However, more recent studies indicate that problems with two-phase flow have been overstated [Herron et al., *AIChE J.*, **34,** 1267 (1988); and Harrison, *Chem. Eng. Prog.*, **86**(11), 80 (1990)]. Based on case history data and experimental evidence, there is no reason to expect unusual capacity or pressure-drop limitations, and standard correlations for these parameters should give acceptable results. Because of the intense nature of the gas-liquid-liquid mixing on trays, mass-transfer efficiencies are relatively unaffected by liquid-liquid phase behavior. The falling-film nature of gas-liquid-liquid contact in packing, however, makes that situation more uncertain. Reduced efficiencies may be expected in systems where one of the keys distributes between the phases.

## EXTRACTIVE DISTILLATION

Extractive distillation is a partial vaporization process in the presence of a miscible, high-boiling, nonvolatile mass separation agent, normally

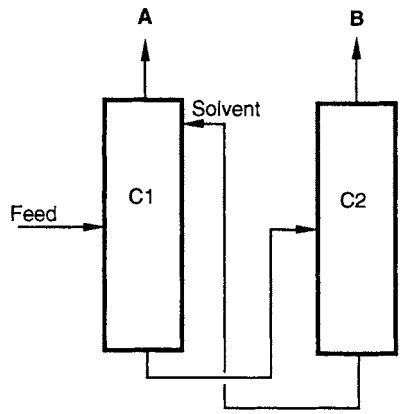

**FIG. 13-91** Typical extractive distillation sequence. Component A is less associated with the solvent.

called the *solvent,* which is added to an azeotropic or nonazeotropic feed mixture to alter the volatilities of the key components without the formation of any additional azeotropes. Extractive distillation is used throughout the petrochemical and chemical processing industries for the separation of close-boiling, pinched, or azeotropic systems for which simple single-feed distillation is either too expensive or impossible. It can also be used to obtain products which are residue curve saddles, a task not generally possible with single-feed distillation.

Figure 13-91 illustrates the classical implementation of an extractive distillation process for the separation of a binary mixture. The configuration consists of a double-feed extractive column (C1) and a solvent recovery column (C2). The components A and B may have a low relative volatility or form a minimum-boiling azeotrope. The solvent is introduced into the extractive column at a high concentration a few stages below the condenser, but above the primary-feed stage. Since the solvent is chosen to be nonvolatile, it remains at a relatively high concentration in the liquid phase throughout the sections of the column below the solvent-feed stage.

One of the components, A (not necessarily the most volatile species of the original mixture), is withdrawn as an essentially pure distillate stream. Because the solvent is nonvolatile, at most a few stages above the solvent-feed stage are sufficient to rectify the solvent from the distillate. The bottoms product, consisting of B and the solvent, is sent to the recovery column. The distillate from the recovery column is pure B, and the solvent-bottoms product is recycled to the extractive column.

Extractive distillation works by the exploitation of the selective solvent-induced enhancements or moderations of the liquid-phase nonidealities of the original components to be separated. The solvent selectively alters the activity coefficients of the components being separated. To do this, a high concentration of solvent is necessary. Several features are essential:

1. The solvent must be chosen to affect the liquid-phase behavior of the key components differently; otherwise, no enhancement in separability will occur.
2. The solvent must be higher-boiling than the key components of the separation and must be relatively nonvolatile in the extractive column, in order to remain largely in the liquid phase.
3. The solvent should not form additional azeotropes with the components in the mixture to be separated.
4. The extractive column *must* be a double-feed column, with the solvent feed above the primary feed. The column must have an extractive section (middle section) between the rectifying section and the stripping section.

As a consequence of these restrictions, separation of binary mixtures by extractive distillation corresponds to only two possible three-component distillation region diagrams, depending on whether the binary mixture is pinched or close-boiling (DRD 001), or forms a minimum-boiling azeotrope (DRD 003). The addition of high-boiling solvents can also facilitate the breaking of maximum-boiling azeotropes (DRD 014), for example, splitting the nitric acid–water azeotrope with sulfuric acid. However, as explained in the subsection on azeotropic distillation, this type of separation might better be characterized as exploiting extreme boundary curvature rather than extractive distillation, as the important liquid-phase activity coefficient modification occurs in the bottom of the column. Although many references show sulfuric acid being introduced high in the column, in fact two separate feeds are not required.

Examples of industrial uses of extractive distillation grouped by distillation region diagram type are given in Table 13-21. Achievable product compositions in double-feed extractive distillation columns are very different from the bow tie regions for single-feed columns. For a given solvent, only one of the pure components in the original binary mixture can be obtained as distillate from the extractive column (the higher-boiling of which is a saddle for close-boiling systems, and both of which are saddles for minimum-boiling azeotropic systems). However, different solvents are capable of selecting either A or B as distillate (but not both). Simple tests are available for determining which component is the distillate, as discussed below.

Extractive distillation is generally only applicable to systems in which the components to be separated contain one or more different functional groups. Extractive distillation is usually uneconomical for separating stereoisomers, homologs, or structural isomers containing the same functional groups, unless the differences in structure also contribute to significantly different polarity, dipole moment, or hydrophobic character. One such counterexample is the separation of ethanol from isopropanol, where the addition of methyl benzoate raises the relative volatility from 1.09 to 1.27 [Berg et al., *Chem. Eng. Comm.*, **66,** 1 (1988)].

**Solvent Effects in Extractive Distillation** In the ordinary distillation of ideal or nonazeotropic mixtures, the component with the lowest pure-component boiling point is always recovered primarily in the distillate, while the highest boiler is recovered primarily in the bottoms. The situation is not as straightforward for an extractive distillation operation. With some solvents, the key component with the lower pure-component boiling point in the original mixture will be recovered in the distillate as in ordinary distillation. For another solvent, the expected order is reversed, and the component with the higher pure-component boiling point will be recovered in the distillate. The possibility that the expected relative volatility may be reversed by the addition of solvent is entirely a function of the way the solvent interacts with and modifies the activity coefficients and, thus, the volatility of the components in the mixture.

In normal applications of extractive distillation (i.e., pinched, close-boiling, or azeotropic systems), the relative volatilities between the light and heavy key components will be unity or close to unity. Assuming an ideal vapor phase and subcritical components, the relative volatility between the light and heavy keys of the desired separation can be written as the product of the ratios of the pure-component vapor pressures and activity coefficients whether the solvent is present or not:

$$\alpha_{L,H} = \left(\frac{P_L^{\text{sat}}}{P_H^{\text{sat}}}\right)\left(\frac{\gamma_L}{\gamma_H}\right) \tag{13-117}$$

where $L$ and $H$ denote the lower-boiling and higher-boiling key pure component, respectively.

The addition of the solvent has an indirect effect on the vapor-pressure ratio. Because the solvent is high-boiling and is generally added at a relatively high mole ratio to the primary-feed mixture, the temperature of an extractive distillation process tends to increase over that of a simple distillation of the original mixture (unless the system pressure is lowered). The result is a corresponding increase in the vapor pressure of both key components. However, the rise in operating temperature generally *does not* result in a significant modification of the relative volatility, because the ratio of vapor pressures often remains approximately constant, unless the slopes of the vapor-pressure curves differ significantly. The ratio of the vapor pressures typically remains greater than unity, following the "natural" volatility of the system.

**TABLE 13-21 Examples of Extractive Distillation, Salt Extractive Distillation**

| System | Type | Solvent(s) | Remark |
|---|---|---|---|
| Ethanol-water | Minimum-boiling azeotrope | Ethylene glycol, acetate salts for salt process | Alternative to azeotropic distillation, pressure swing distillation |
| Benzene-cyclohexane | Minimum-boiling azeotrope | Aniline | |
| Ethyl acetate-ethanol | Minimum-boiling azeotrope | Higher esters or alcohols, aromatics | Process similar for other alcohol-ester systems |
| THF-water | Minimum-boiling azeotrope | Propylene glycol | Alternative to pressure swing distillation |
| Acetone-methanol | Minimum-boiling azeotrope | Water, aniline, ethylene glycol | |
| Isoprene-pentane | Minimum-boiling azeotrope | Furfural, DMF, acetonitrile | |
| Pyridine-water | Minimum-boiling azeotrope | Bisphenol | |
| Methyl acetate-methanol | Minimum-boiling azeotrope | Ethylene glycol monomethyl ether | Element of recovery system for alternative to production of methyl acetate by reactive distillation; alternative to azeotropic, pressure, swing distillation |
| C4 alkenes/C4 alkanes/ C4 dienes | Close-boiling and minimum-boiling azeotropes | Furfural, DMF, acetonitrile, *n*-methylpyrolidone | |
| C5 alkenes/C5 alkanes/ C5 dienes | Close-boiling and minimum-boiling azeotropes | Furfural, DMF, acetonitrile, *n*-methylpyrolidone | |
| Heptane isomers-cyclohexane | Close-boiling | Aniline, phenol | |
| Heptane isomers-toluene | Close-boiling and minimum-boiling azeotropes | Aniline, phenol | |
| Vinyl acetate-ethyl acetate | Close-boiling | Phenol, aromatics | Alternative to simple distillation |
| Propane-propylene | Close-boiling | Acrylonitrile | Alternative to simple distillation, adsorption |
| Ethanol-isopropanol | Close-boiling | Methyl benzoate | Alternative to simple distillation |
| Hydrochloric acid-water | Maximum-boiling azeotrope | Sulfuric acid, calcium chloride for salt process | Sulfuric acid process relies heavily on boundary curvature |
| Nitric acid-water | Maximum-boiling azeotrope | Sulfuric acid, magnesium nitrate for salt process | Sulfuric acid process relies heavily on boundary curvature |

Since activity coefficients have a strong dependence on composition, the effect of the solvent on the activity coefficients is generally more pronounced. However, the magnitude and direction of change are highly dependent on the solvent concentration as well as on the liquid-phase interactions between the solvent and the key components. The solvent acts to lessen the nonidealities of the key component whose liquid-phase behavior is similar to that of the solvent, while enhancing the nonideal behavior of the dissimilar key. The solvent and the key component that show most similar liquid-phase behavior tend to exhibit weak molecular interactions. These components form an ideal or nearly ideal liquid solution. The activity coefficient of this key approaches unity, or may even show negative deviations from Raoult's law if solvating or complexing interactions occur. On the other hand, the dissimilar key and the solvent demonstrate unfavorable molecular interactions, and the activity coefficient of this key increases. The positive deviations from Raoult's law are further enhanced by the diluting effect of the high-solvent concentration, and the value of the activity coefficient of this key may approach the infinite dilution value, often a very large number.

The natural relative volatility of the system is enhanced when the activity coefficient of the lower-boiling pure component is increased by the solvent addition ($\gamma_L/\gamma_H$ increases and $P_L^{sat}/P_H^{sat} > 1$). In this case, the lower-boiling pure component will be recovered in the distillate as expected. For the higher-boiling pure component to be recovered in the distillate, the addition of the solvent must decrease the ratio $\gamma_L/\gamma_H$ such that the product of $\gamma_L/\gamma_H$ and $P_L^{sat}/P_H^{sat}$ (that is, $\alpha_{LH}$) in the presence of the solvent is less than unity. Generally, the latter is more difficult to achieve and requires higher solvent-to-feed ratios. It is normally better to select a solvent that forces the lower-boiling component overhead.

The effect of solvent concentration on the activity coefficients of the key components is shown in Fig. 13-92 for the system methanol-acetone with either water or methylisopropylketone (MIPK) as solvent. For an initial feed mixture of 50 mol % methanol and 50 mol % acetone (no solvent present), the ratio of activity coefficients of methanol and acetone is close to unity. With water as the solvent, the activity coefficient of the similar key (methanol) rises slightly as the solvent concentration increases, while the coefficient of acetone approaches the relatively large infinite dilution value. With methylisopropylketone as the solvent, acetone is the similar key and its activity coefficient drops toward unity as the solvent concentration increases, while the activity coefficient of the methanol increases.

Several methods are available for determining whether the lower- or higher-boiling pure component will be recovered in the distillate. For a series of solvent concentrations, the binary *y-x* phase diagram for the low-boiling and high-boiling keys can be plotted on a solvent-free basis. At a particular solvent concentration (dependent on the selected solvent and keys), the azeotropic point in the binary plot disappears at one of the pure-component corners. The component corresponding to the corner where the azeotrope disappears is recovered in the distillate (Knapp and Doherty, *Kirk-Othmer Encyclopedia of Chemical Technology,* 5th ed., vol. 8, p. 786, Wiley, New York, 2004). LaRoche et al. [*Can. J. Chem. Eng.,* **69,** 1302 (1991)] present a related method in which the $\alpha_{LH} = 1$ line is plotted on the ternary composition diagram. If this line intersects the lower-boiling pure component + solvent binary face, then the lower-boiling component will be recovered in the distillate, and vice versa if the $\alpha_{LH} = 1$ line intersects the higher-boiling pure component + solvent face. A very simple method, if a rigorous residue curve map is available, is to examine the shape and inflection of the residue curves as they approach the pure solvent vertex. Whichever solvent-key component face the residue curves predominantly tend toward as they approach the solvent vertex is the key component that will be recovered in the bottoms with the solvent (see property 6, p. 193, in Doherty and Malone, *op. cit.*). In Fig. 13-93*a,* all residue curves approaching the water (solvent) vertex are inflected toward the methanol-water face, with the result that methanol will be recovered in the bottoms and acetone in the distillate. Alternatively, with MIPK as the solvent, all residue curves show inflection toward the acetone-MIPK face (Fig. 13-93*b*), indicating that acetone will be recovered in the bottoms and methanol in the distillate.

**Extractive Distillation Design and Optimization** Extractive distillation column composition profiles have a very characteristic

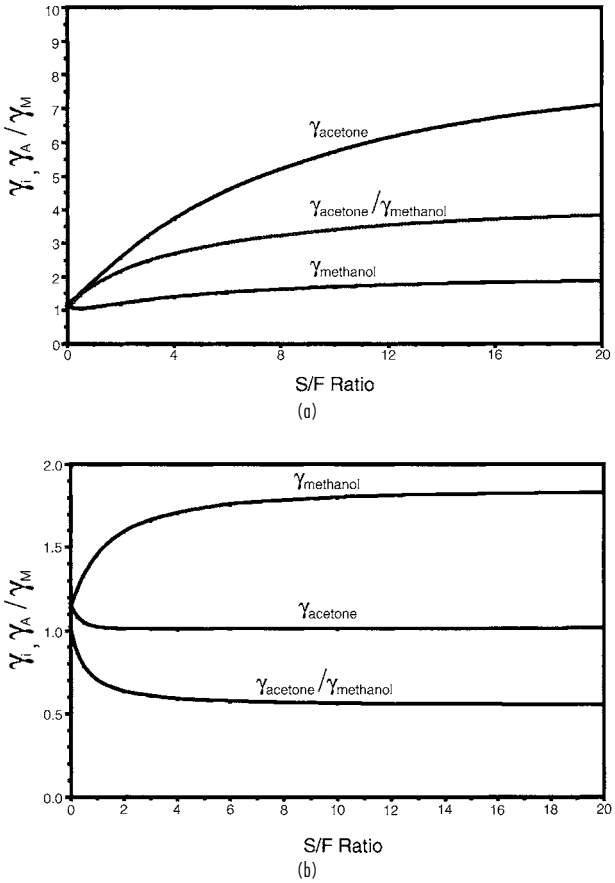

**FIG. 13-92** Effect of solvent concentration on activity coefficients for acetone-methanol system. (*a*) Water solvent. (*b*) MIPK solvent.

shape on a ternary diagram. The composition profile for the separation of methanol-acetone with water is given in Fig. 13-94. Stripping and rectifying profiles start at the bottoms and distillate compositions, respectively, track generally along the faces of the composition triangle, and then turn toward the high-boiling (solvent) node and low-boiling node, respectively. For a feasible single-feed design, these profiles must cross at some point. However, in an extractive distillation they cannot cross. The extractive section profile acts at the bridge between these two sections. Most of the key component separation occurs in this section in the presence of high-solvent composition.

The variable that has the most significant impact on the economics of an extractive distillation is the solvent-to-feed flow rate ratio *S/F*. For close-boiling or pinched nonazeotropic mixtures, no minimum-solvent flow rate is required to effect the separation, as the separation is always theoretically possible (if not economical) in the absence of the solvent. However, the extent of enhancement of the relative volatility is largely determined by the solvent composition in the lower column sections and hence the *S/F* ratio. The relative volatility tends to increase as the *S/F* ratio increases. Thus, a given separation can be accomplished in fewer equilibrium stages. As an illustration, the total number of theoretical stages required as a function of *S/F* ratio is plotted in Fig. 13-95*a* for the separation of the nonazeotropic mixture of vinyl acetate and ethyl acetate using phenol as the solvent.

For the separation of a minimum-boiling binary azeotrope by extractive distillation, there is clearly a minimum-solvent flow rate below which the separation is impossible (due to the azeotrope). For azeotropic separations, the number of equilibrium stages is infinite at or below $(S/F)_{min}$ and decreases rapidly with increasing solvent feed

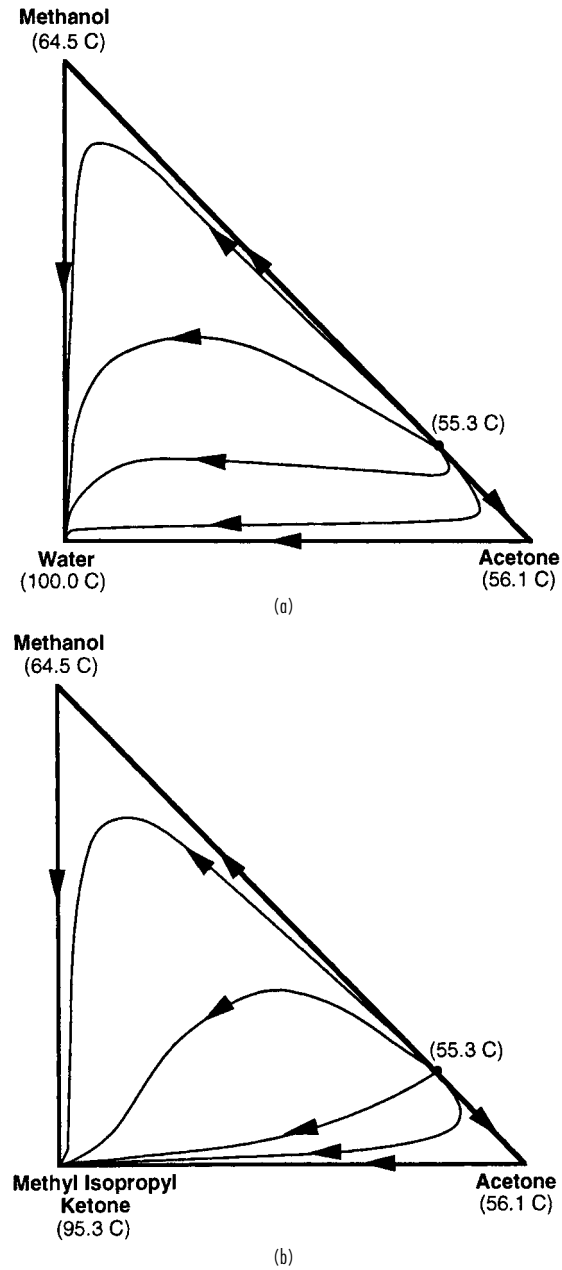

**FIG. 13-93** Residue curve maps for acetone-methanol systems. (*a*) With water. (*b*) With MIPK.

flow, and then may asymptote, or rise slowly. The relationship between the total number of stages and the *S/F* ratio for a given purity and recovery for the azeotropic acetone-methanol system with water as solvent is shown in Fig 13-95*b*. A rough idea of $(S/F)_{min}$ can be determined from a pseudobinary diagram or by plotting the $\alpha_{L,H} = 1$ line on a ternary diagram. The solvent composition at which the azeotrope disappears in a corner of the pseudobinary diagram is an indication of $(S/F)_{min}$ [LaRoche et al., *Can. J. Chem. Eng.*, **69,** 1302 (1991)]. An exact method for calculating $(S/F)_{min}$ is given by Knapp and Doherty [*AIChE J.*, **40,** 243 (1994)]. Typically, operating *S/F* ratios for economically acceptable solvents are between 2 and 5. Higher

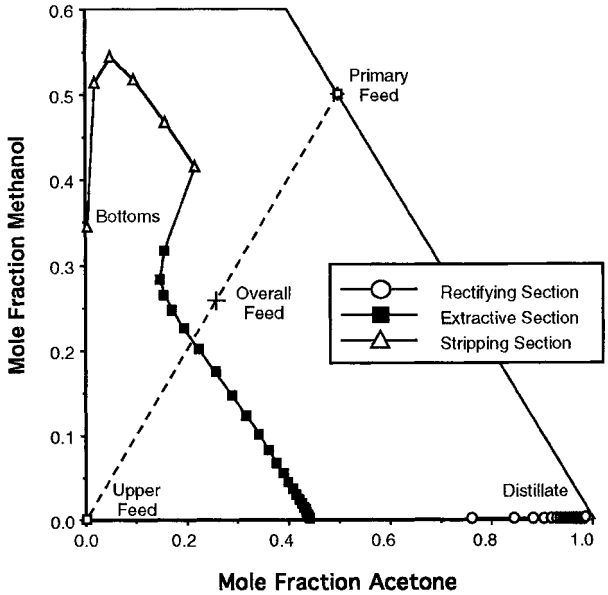

**FIG. 13-94** Extractive distillation column composition profile for the separation of acetone-methanol with water.

*S/F* ratios tend to increase the diameter of both the extractive column and the solvent recovery columns, but reduce the required number of equilibrium stages and minimum reflux ratio. Moreover, higher *S/F* ratios lead to higher reboiler temperatures, resulting in the use of higher-cost utilities, higher utility usages, and greater risk of degradation.

Knight and Doherty [*Ind. Eng. Chem. Fundam.,* **28,** 564 (1989)] have published rigorous methods for computing minimum reflux for extractive distillation; they found that an operating reflux ratio of 1.2 to 1.5 times the minimum value is usually acceptable. Interestingly, unlike other forms of distillation, in extractive distillation the distillate purity or recovery does not increase monotonically with increasing reflux ratio for a given number of stages. Above a maximum reflux ratio the separation can no longer be achieved, and the distillate purity actually decreases for a given number of stages [LaRoche et al., *AIChE J.,* **38,** 1309 (1992)]. The difference between $R_{min}$ and $R_{max}$ increases as the *S/F* ratio increases. Large amounts of reflux lowers the solvent composition in the upper section of the column, degrading rather than enhancing column performance. Because the reflux ratio goes through a maximum, the conventional control strategy of increasing reflux to maintain purity can be detrimental rather than beneficial. However, $R_{max}$ generally occurs at impractically high reflux ratios and is typically not of major concern.

The thermal quality of the solvent feed has no effect on the value of $S/F_{min}$, but does affect the minimum reflux to some extent, especially as the *S/F* ratio increases. The maximum reflux ratio $R_{max}$ occurs at higher values of the reflux ratio as the upper-feed quality decreases; a subcooled upper feed provides additional refluxing capacity and less external reflux is required for the same separation. It is also sometimes advantageous to introduce the primary feed to the extractive distillation column as a vapor to help maintain a higher solvent composition on the feed tray and the trays immediately below.

Robinson and Gilliland (*Elements of Fractional Distillation,* McGraw-Hill, New York, 1950), Smith (*Design of Equilibrium Stage Processes,* McGraw-Hill, New York, 1963), Van Winkle (*Distillation,* McGraw-Hill, New York, 1967), and Walas (*Chemical Process Equipment,* Butterworths, Boston, 1988) discuss rigorous stage-to-stage design techniques as well as shortcut and graphical methods for determining minimum stages, $(S/F)_{min}$, minimum reflux, and the optimum locations of the solvent and primary feed points. Knapp and Doherty [*AIChE J.,* **40,** 243 (1994)] have published column design methods

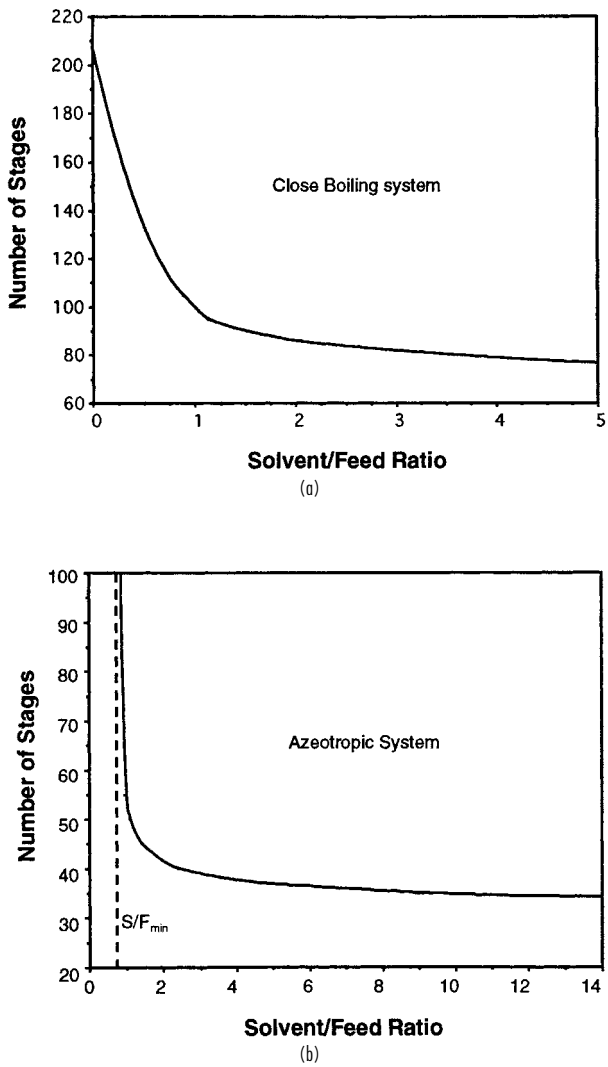

**FIG. 13-95** Number of theoretical stages versus solvent-to-feed ratio for extractive distillation. (*a*) Close-boiling vinyl acetate–ethyl acetate system with phenol solvent. (*b*) Azeotropic acetone-methanol system with water solvent.

based on geometric arguments and fixed-point analysis that are capable of calculating $(S/F)_{min}$, as well as the minimum and maximum reflux ratio. Most commercial simulators are capable of solving multiple-feed extractive distillation heat and material balances, but do not include straightforward techniques for calculating $(S/F)_{min}$, or the minimum and maximum reflux ratio.

**Solvent Screening and Selection** Choosing an effective solvent can have the most profound effect on the economics of an extractive distillation process. The approach most often adopted is to first generate a short list of potential solvents by using simple qualitative screening and selection methods. Experimental verification is best undertaken only after a list of promising candidate solvents has been generated and some chance at economic viability has been demonstrated via preliminary process modeling.

Solvent selection and screening approaches can be divided into two levels of analysis. The first level focuses on identification of functional groups or chemical families that are likely to give favorable solvent–key component molecular interactions. The second level of analysis identifies and compares individual candidate solvents. The

various methods of analysis are described briefly and illustrated with an example of choosing a solvent for the methanol-acetone separation.

***First Level: Broad Screening by Functional Group or Chemical Family***

*Homologous series.* Select candidate solvents from the high-boiling homologous series of both light and heavy key components. Favor homologs of the heavy key, as this tends to enhance the natural relative volatility of the system. Homologous components tend to form ideal solutions and are unlikely to form azeotropes [Scheibel, *Chem. Eng. Prog.*, **44**(12), 927 (1948)].

*Robbins chart.* Select candidate solvents from groups in the Robbins chart (Table 13-17) that tend to give positive (or no) deviations from Raoult's law for the key component desired in the distillate and negative (or no) deviations for the other key.

*Hydrogen-bonding characteristics.* Select candidate solvents from groups that are likely to cause the formation of hydrogen bonds with the key component to be removed in the bottoms, or disruption of hydrogen bonds with the key to be removed in the distillate. Formation and disruption of hydrogen bonds are often associated with strong negative and positive deviations, respectively, from Raoult's law. Several authors have developed charts indicating expected hydrogen bonding interactions between families of compounds [Ewell et al., *Ind. Eng. Chem.*, **36,** 871 (1944); Gilmont et al., *Ind. Eng. Chem.*, **53,** 223 (1961); and Berg, *Chem. Eng. Prog.*, **65**(9), 52 (1969)]. Table 13-22 presents a hydrogen bonding classification of chemical families and a summary of deviations from Raoult's law.

*Polarity characteristics.* Select candidate solvents from chemical groups that tend to show higher polarity than one key component or lower polarity than the other key. Polarity effects are often cited as a factor in causing deviations from Raoult's law [Hopkins and Fritsch, *Chem. Eng. Prog.*, **51**(8), (1954); Carlson et al., *Ind. Eng. Chem.*, **46,** 350 (1954); and Prausnitz and Anderson, *AIChE J.*, **7**, 96 (1961)]. The general trend in polarity based on the functional group of a molecule is given in Table 13-23. The chart is best for molecules of similar size. A more quantitative measure of the polarity of a molecule is the polarity contribution to the three-term Hansen solubility parameter. A tabulation of calculated three-term solubility parameters is provided by Barton (*CRC Handbook of Solubility Parameters and Other Cohesion Parameters*, CRC Press, Boca Raton, Fla., 1991), along with a group contribution method for calculating the three-term solubility parameters of compounds not listed in the reference.

***Second Level: Identification of Individual Candidate Solvents***

*Boiling point characteristics.* Select only candidate solvents that boil at least 30 to 40°C above the key components to ensure that the solvent is relatively nonvolatile and remains largely in the liquid phase. With this boiling point difference, the solvent should also not form azeotropes with the other components.

*Selectivity at infinite dilution.* Rank candidate solvents according to their selectivity at infinite dilution. The selectivity at infinite

$\gamma^{\infty}_{MeOH} = 1.81$ (in acetone)

dilution is defined as the ratio of the activity coefficients at infinite dilution of the two key components in the solvent. Since solvent effects tend to increase as solvent concentration increases, the infinite-dilution selectivity gives an upper bound on the efficacy of a solvent. Infinite-dilution activity coefficients can be predicted by using such methods as UNIFAC, ASOG, MOSCED (Reid et al., *Properties of Gases and Liquids,* 4th ed., McGraw-Hill, New York, 1987). They can be found experimentally by using a rapid gas-liquid chromatography method based on relative retention times in candidate solvents (Tassios, in *Extractive and Azeotropic Distillation,* Advances in Chemistry Series 115, American Chemical Society, Washington, 1972), and they can be correlated to bubble point data [Kojima and Ochi, *J. Chem. Eng. Japan,* **7**(2), 71 (1974)]. DECHEMA (*Vapor-Liquid Equilibrium Data Collection,* Frankfort, 1977) has also published a compilation of experimental infinite-dilution activity coefficients.

*Experimental measurement of relative volatility.* Rank candidate solvents by the increase in relative volatility caused by the addition of the solvent. One technique is to experimentally measure the relative volatility of a fixed-composition, key component + solvent mixture (often a 1/1 ratio of each key, with a 1/1 to 3/1 solvent/key ratio) for various solvents [Carlson et al., *Ind. Eng. Chem.,* **46,** 350 (1954)]. The Othmer equilibrium still is the apparatus of choice for these measurements [Zudkevitch, *Chem. Eng. Comm.,* **116,** 41 (1992)].

At atmospheric pressure, methanol and acetone boil at 64.5 and 56.1°C, respectively, and form a minimum-boiling azeotrope at 55.3°C. The natural volatility of the system is acetone > methanol, so the favored solvents most likely will be those that cause acetone to be recovered in the distillate. However, for the purposes of the example, a solvent that reverses the natural volatility will also be identified. First, by examining the polarity of ketones and alcohols (Table 13-23), solvents favored for the recovery of methanol in the bottoms would come from groups more polar than methanol, such as acids, water, and polyols. Turning to the Robbins chart (Table 13-17), we see favorable groups are amines, alcohols, polyols, and water since these show expected positive deviations for acetone and zero or negative deviations for methanol. For reversing the natural volatility, solvents should be chosen that are less polar than acetone, such as ethers, hydrocarbons, and aromatics. Unfortunately, both ethers and hydrocarbons are expected to give positive deviations for both acetone and methanol, so should be discarded. Halohydrocarbons and ketones are expected to give positive deviations for methanol and either negative or no deviations for acetone. The other qualitative indicators show that both homologous series (ketones and alcohols) look promising. Thus, after discounting halohydrocarbons for environmental reasons, the best solvents will probably come from alcohols, polyols, and water for recovering methanol in the bottoms and ketones for recovering acetone in the bottoms. Table 13-24 shows the boiling points and experimental or estimated infinite-dilution activity coefficients for several candidate solvents from the aforementioned groups. Methylethylketone boils too low, as does ethanol, and also forms an azeotrope with methanol. These two candidates can be discarded. Other members of the homologous series, along with water and ethylene glycol, have acceptable boiling points (at least 30°C higher than those of the keys). Of these, water (the solvent used industrially) clearly has the largest effect on the activity coefficients, followed by ethylene glycol. Although inferior to water or ethylene glycol, both MIPK and MIBK would probably be acceptable for reversing the natural volatility of the system.

**Extractive Distillation by Salt Effects** A second method of modifying the liquid-phase behavior (and thus the relative volatility) of a mixture to effect a separation is by the addition of a nonvolatile, soluble, ionic salt. The process is analogous to extractive distillation with a high-boiling liquid. In the simplest case, for the separation of a binary mixture, the salt is fed at the top of the column by dissolving it in the hot reflux stream before introduction into the column. To function effectively, the salt must be adequately soluble in both components throughout the range of compositions encountered in the column. Since the salt is completely nonvolatile, it remains in the liquid phase on each tray and alters the relative volatility throughout the length of the column. No rectification section is needed above the salt feed. The bottoms product is recovered from the salt solution by evaporation or drying, and the salt is recycled. The ions of a salt are typically capable of causing much larger and more selective effects on liquid-phase behavior than the molecules of a liquid solvent. As a result, salt-to-feed ratios of less than 0.1 are typical.

The use of a salting agent presents a number of problems not associated with a liquid solvent, such as the difficulty of transporting and metering a solid or saturated salt solution, slow mixing or dissolution rate of the salt, limits to solubility in the feed components, and potential for corrosion. However, in the limited number of systems for which an effective salt can be found, the energy usage, equipment size, capital investment, and ultimate separation cost can be significantly reduced compared to that for extractive distillation using a liquid solvent [Furter, *Chem. Eng. Commun.,* **116,** 35 (1992)]. Applications of salt extractive distillation include acetate salts to produce absolute ethanol, magnesium nitrate for the production of concentrated nitric acid as an alternative to the sulfuric acid solvent process, and calcium chloride to produce anhydrous hydrogen chloride. Other examples are noted by Furter [*Can. J. Chem. Eng.,* **55,** 229 (1977)].

One problem limiting the consideration of salt extractive distillation is the fact that the performance and solubility of a salt in a particular system are difficult to predict without experimental data. Some recent advances have been made in modeling the VLE behavior of organic aqueous salt solutions using modified UNIFAC, NRTL, UNIQUAC, and other approaches [Kumar, *Sep. Sci. Tech.,* **28**(1), 799 (1993)].

## REACTIVE DISTILLATION

Reactive distillation is a unit operation in which chemical reaction and distillation are carried out simultaneously within a fractional distillation apparatus. Reactive distillation may be advantageous for liquid-phase reaction systems when the reaction must be carried out with a large excess of one or more of the reactants, when a reaction

can be driven to completion by removal of one or more of the products as they are formed, or when the product recovery or by-product recycle scheme is complicated or made infeasible by azeotrope formation.

For consecutive reactions in which the desired product is formed in an intermediate step, excess reactant can be used to suppress additional series reactions by keeping the intermediate-species concentration low. A reactive distillation can achieve the same result by removing the desired intermediate from the reaction zone as it is formed. Similarly, if the equilibrium constant of a reversible reaction is small, high conversions of one reactant can be achieved by use of a large excess of the other reactant. Alternatively, by Le Chatelier's principle, the reaction can be driven to completion by removal of one or more of the products as they are formed. Typically, reactants can be kept much closer to stoichiometric proportions in a reactive distillation.

When a reaction mixture exhibits azeotropes, the recovery of products and recycle of excess reagents can be quite complicated and expensive. Reactive distillation can provide a means of breaking azeotropes by altering or eliminating the condition for azeotrope formation in the reaction zone through the combined effects of vaporization-condensation and consumption-production of the species in the mixture. Alternatively, a reaction may be used to convert the species to components that are more easily distilled. In each of these situations, the conversion and selectivity often can be improved markedly, with much lower reactant inventories and recycle rates, and much simpler recovery schemes. The capital savings can be quite dramatic. A list of applications of reactive distillation appearing in the literature is given in Table 13-25. Additional industrial applications are described by Sharma and Mahajani (chap. 1 in Sundmacher and Kienle, eds., *Reactive Distillation*, Wiley-VCH, 2003).

Although reactive distillation has many potential applications, it is not appropriate for all situations. Since it is in essence a distillation process, it has the same range of applicability as other distillation operations. Distillation-based equipment is not designed to effectively handle solids, supercritical components (where no separate vapor and liquid phases exist), gas-phase reactions, or high-temperature or high-pressure reactions such as hydrogenation, steam reforming, gasification, and hydrodealkylation.

**Simulation, Modeling, and Design Feasibility** Because reaction and separation phenomena are closely coupled in a reactive distillation process, simulation and design are significantly more complex than those of sequential reaction and separation processes. In spite of the complexity, however, most commercial computer process modeling packages offer reliable and flexible routines for simulating steady-state reactive distillation columns, with either equilibrium or kinetically controlled reaction models [Venkataraman et al., *Chem. Eng. Prog.,* **86**(6), 45 (1990)]. As with other enhanced distillation processes, the results are very sensitive to the thermodynamic models chosen and the accuracy of the VLE data used to generate model parameters. Of equal, if not greater significance is the accuracy of data and models for reaction rate as a function of catalyst concentration, temperature, and composition. Very different conclusions can be drawn about the feasibility of a reactive distillation if the reaction is assumed to reach chemical equilibrium on each stage of the column or if the reaction is assumed to be kinetically controlled [Barbosa and Doherty, *Chem. Eng. Sci.,* **43,** 541 (1988); Chadda, Malone, and Doherty, *AIChE J.,* 47, 590 (2001)]. Tray holdup and stage requirements are two important variables directly affected by the reaction time relative to the residence time inside the column. Unlike distillation without reaction, product feasibility can be quite sensitive to changes in tray holdup and production rate.

When an equilibrium reaction occurs in a vapor-liquid system, the phase compositions depend not only on the relative volatility of the components in the mixture, but also on the consumption (and production) of species. Thus, the condition for azeotropy in a nonreactive system ($y_i = x_i$ for all $i$) no longer holds true in a reactive system and must be modified to include reaction stoichiometry:

$$\frac{y_1 - x_1}{v_1 - v_T x_1} = \frac{y_i - x_i}{v_i - v_T x_i} \qquad \text{for all } i = 1, \ldots, c \qquad (13\text{-}118)$$

where $$v_T = \sum_{i=1}^{c} v_i$$

and $v_i$ represents the stoichiometric coefficient of component $i$ (negative for reactants, positive for products).

Phase compositions that satisfy Eq. (13-118) are stationary points on a phase diagram and have been labeled *reactive azeotropes* by Barbosa and Doherty [*Chem. Eng. Sci.,* **43,** 529 (1988)]. At a reactive azeotrope the mass exchange between the vapor and liquid phases and the generation (or consumption) of each species are balanced such that the composition of neither phase changes. Reactive azeotropes show the same distillation properties as ordinary azeotropes and therefore affect the achievable products. Reactive azeotropes are predicted to exist in numerous reacting mixtures and have been confirmed experimentally in the reactive boiling mixture of acetic acid + isopropanol + isopropyl acetate + water [Song et al., *Nature,* **388,** 561 (1997); Huang et al., *Chem. Eng. Sci.,* **60,** 3363 (2005)].

Reactive azeotropes are not easily visualized in conventional $y$-$x$ coordinates but become apparent upon a transformation of coordinates which depends on the number of reactions, the order of each reaction (for example, $A + B \rightleftharpoons C$ or $A + B \rightleftharpoons C + D$), and the presence of nonreacting components. The general vector-matrix form of

the transform for $c$ reacting components, with $R$ reactions, and $I$ nonreacting components, has been derived by Ung and Doherty [*Chem. Eng. Sci.*, **50,** 23 (1995)]. For the transformed mole fraction of component $i$ in the liquid phase $X_i$, they give

$$X_i = \left[ \frac{x_i - \mathbf{v}_i^T(\boldsymbol{\nu}_{\text{Ref}})^{-1}\,\mathbf{x}_{\text{Ref}}}{1 - \mathbf{v}_{\text{TOT}}^T(\boldsymbol{\nu}_{\text{Ref}})^{-1}\mathbf{x}_{\text{Ref}}} \right] \qquad i = 1, \ldots, c - R \qquad (13\text{-}119)$$

where $\mathbf{v}_i^T$ = row vector of stoichiometric coefficients of component $i$ for each reaction
$\boldsymbol{\nu}_{\text{Ref}}$ = square matrix of stoichiometric coefficients for $R$ reference components in $R$ reactions
$\mathbf{x}_{\text{Ref}}$ = column vector of mole fractions for $R$ reference components in liquid phase
$\mathbf{v}_{\text{TOT}}^T$ = row vector composed of sum of stoichiometric coefficients for each reaction

An equation identical to (13-119) defines the transformed mole fraction of component $i$ in the vapor phase $Y_i$, where the terms in $x$ are replaced by terms in $y$.

The transformed variables describe the system composition with or without reaction and sum to unity as do $x_i$ and $y_i$. The condition for reactive azeotropy becomes $X_i = Y_i$. Barbosa and Doherty have shown that phase diagrams and distillation diagrams constructed by using the transformed composition coordinates have the same properties as phase and distillation diagrams for nonreactive systems and similarly can be used to assist in design feasibility and operability studies [*Chem. Eng. Sci.*, **43,** 529, 541, 1523, and 2377 (1988)]. Residue curve maps in transformed coordinates for the reactive system methanol–acetic acid–methyl acetate–water are shown in Fig. 13-96. Note that the nonreactive azeotrope between water and methyl acetate has disappeared, while the methyl acetate–methanol azeotrope remains intact. Only those azeotropes containing all the reactants or products will be altered by the reaction (water and methyl acetate can back-react to form acetic acid and methanol, whereas methanol and methyl acetate cannot further react in the absence of either water or acetic acid). This reactive system consists of only one distillation region in which the methanol–methyl acetate azeotrope is the low-boiling node and acetic acid is the high-boiling node.

The situation becomes more complicated when the reaction is kinetically controlled and does not come to complete chemical equilibrium under the conditions of temperature, liquid holdup, and rate of vaporization in the column reactor. Venimadhavan et al. [*AIChE J.*, **40,** 1814 (1994); **45,** 546 (1999)] and Rev [*Ind. Eng. Chem. Res.*, **33,** 2174 (1994)] show that the concept of a reactive azeotrope generalizes to the concept of a *reactive fixed point*, whose existence and location are a function of approach to equilibrium as well as the evaporation rate [see also Frey and Stichlmair, *Trans IChemE,* **77,** Part A, 613 (1999); Chadda, Malone, and Doherty, *AIChE J.*, 47, 590 (2001); Chiplunkar et al., *AIChE J.*, **51,** 464 (2005)]. In the limit of simultaneous phase and reaction equilibrium, a reactive fixed point becomes identical to the thermodynamic concept of a reactive azeotrope.

These ideas have been extended to reacting systems with (1) multiple chemical reactions [Ung and Doherty, *Ind. Eng. Chem. Res.*, **34,** 3195, 2555 (1995)], (2) multiple liquid phases [Ung and Doherty, *Chem. Eng. Sci.*, **50,** 3201 (1995); Qi, Kolah, and Sundmacher, *Chem. Eng. Sci.*, **57,** 163 (2002); Qi and Sundmacher, *Comp. Chem. Eng.*, **26,** 1459 (2002)], (3) membrane separations [Huang et al., *Chem. Eng. Sci.*, **59,** 2863 (2004)], (4) finite rates of vapor-liquid mass transfer [Baur, Taylor, and Krishna, *Chem. Eng. Sci.*, **56,** 2085 (2001); Nisoli, Doherty, and Malone, *AIChE J.*, **50,** 1795 (2004)], (5) column design and multiple steady-states (Guttinger, Dorn, and Morari, *Ind. Eng. Chem. Res.*, **36,** 794 (1997); Hauan, Hertzberg, and Lien, *Comput. Chem. Eng.*, **21,** 1117 (1997); Sneesby et al., *Ind. Eng. Chem. Res.*, **36,** 1855 (1997); Bessling et al., *Chem. Eng. Technol.*, **21,** 393 (1998); Okasinski and Doherty, *Ind. Eng. Chem. Res.*, **37,** 2821 (1998); Sneesby, Tade, and Smith, *Trans IChemE,* **76,** Part A, 525 (1998); Guttinger and Morari, *Ind. Eng. Chem. Res.*, **38,** 1633, 1649 (1999); Higler, Taylor, and Krishna, *Chem. Eng. Sci.*, **54,** 1389 (1999); Mohl et al., *Chem. Eng. Sci.*, **54,** 1029 (1999); Chen et al., *Comput. Chem. Eng.*, **26,** 81 (2002)]. Much useful information is available in Taylor and Krishna [*Chem. Eng. Sci*., **55,** 5183 (2000)] and Sundmacher and Kienle (*Reactive Distillation*, Wiley-VCH, 2003).

**Mechanical Design and Implementation Issues** The choice of catalyst has a significant impact on the mechanical design and operation of the reactive column. The catalyst must allow the reaction to occur at reasonable rates at the relatively low temperatures and pressures common in distillation operations (typically less than 10 atm and between 50 and 250°C). Selection of a homogeneous catalyst, such as a high-boiling mineral acid, allows the use of more traditional tray designs and internals (albeit designed with exotic materials of construction to avoid corrosion, and allowance for high-liquid holdups to achieve suitable reaction contact times). With a homogeneous catalyst, lifetime is not a problem, as it is added (and withdrawn) continuously. Alternatively, heterogeneous solid catalysts

require either complicated mechanical means for continuous replenishment or relatively long lifetimes to avoid constant maintenance. As with other multiphase reactors, use of a solid catalyst adds an additional resistance to mass transfer from the bulk liquid (or vapor) to the catalyst surface, which may be the limiting resistance. The catalyst containment system must be designed to ensure adequate liquid-solid contacting and minimize bypassing. A number of specialized column internal designs, catalyst containment methods, and catalyst replenishment systems have been proposed for both homogeneous and heterogeneous catalysts. A partial list of these methods is given in Table 13-26; see also the useful ideas presented by Krishna [*Chem. Eng. Sci.*, **57,** 1491 (2002); and chap. 7 in Sundmacher and Kienle, eds., *Reactive Distillation*, Wiley-VCH, 2003].

Heat management is another important consideration in the implementation of a reactive distillation process. Conventional reactors for highly exothermic or endothermic reactions are often designed as modified shell-and-tube heat exchangers for efficient heat transfer. However, a trayed or packed distillation column is a rather poor mechanical design for the management of the heat of reaction. Although heat can be removed or added in the condenser or reboiler easily, the only mechanism for heat transfer in the column proper is through vaporization (or condensation). For highly exothermic reactions, a large excess of reactants may be required as a heat sink, necessitating high-reflux rates and larger-diameter columns to return the vaporized reactants back to the reaction zone. Often a prereactor of conventional design is used to accomplish most of the reaction and heat removal before feeding to the reactive column for final conversion, as exemplified in most processes for the production of tertiary amyl methyl ether (TAME) [Brockwell et al., *Hyd. Proc.,* **70**(9), 133 (1991)]. Highly endothermic reactions may require intermediate reboilers. None of these heat management issues preclude the use of reactive distillation, but must be taken into account during the design phase. Comparison of heat of reaction and average heat of vaporization data for a system, as in Fig. 13-97, gives some indication of potential heat imbalances [Sundmacher, Rihko, and Hoffmann, *Chem. Eng. Comm.*, **127,** 151 (1994)]. The heat-neutral systems [$-\Delta H_{react} \approx \Delta H_{vap}$ (avg)]

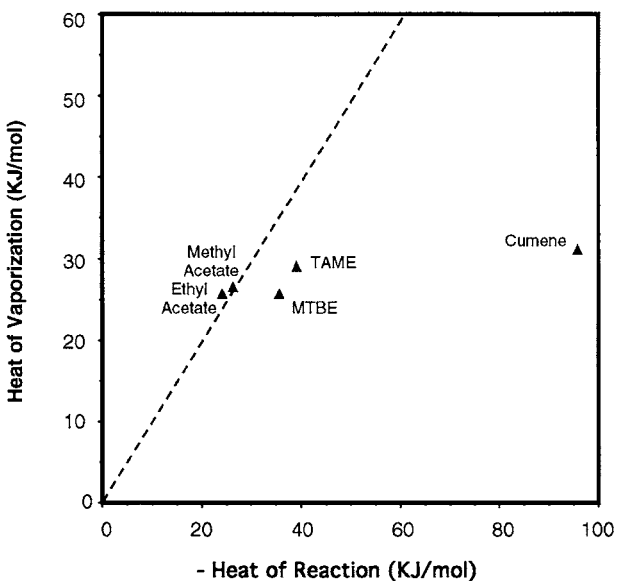

**FIG. 13-97** Similarity of heats of reaction and vaporization for compounds made by reactive distillation.

such as methyl acetate and other esters can be accomplished in one reactive column, whereas the MTBE and TAME processes, with higher heats of reaction than that of vaporization, often include an additional prereactor. One exception is the catalytic distillation process for cumene production, which is accomplished without a prereactor. Three moles of benzene reactant are vaporized (and refluxed) for every mole of cumene produced. The relatively high heat of reaction is advantageous in this case as it reduces the overall

heat duty of the process by about 30 percent [Shoemaker and Jones, *Hyd. Proc.*, **57**(6), 57 (1987)].

Distillation columns with multiple conventional side reactors were first suggested by Schoenmakers and Buehler [*German Chem. Eng.*, **5,** 292 (1982)] and have the potential to accommodate gas-phase reactions, highly exo- or endothermic reactions, catalyst deactivation, and operating conditions outside the normal range suitable for distillation (e.g., short contact times, high temperature and pressure, etc). Krishna (chap. 7 in Sundmacher and Kienle, eds., *Reactive Distillation*, Wiley-VCH, 2003).

**Process Applications** The production of esters from alcohols and carboxylic acids illustrates many of the principles of reactive distillation as applied to equilibrium-limited systems. The true thermodynamic equilibrium constants for esterification reactions are usually in the range of 5 to 20. Large excesses of alcohols must be used to obtain acceptable yields, resulting in large recycle flow rates. In a reactive distillation scheme, the reaction is driven to completion by removal of the water of esterification. The method used for removal of the water depends on the boiling points, compositions, and liquid-phase behavior of any azeotropes formed between the products and reactants and largely dictates the structure of the reactive distillation flow sheet.

When the ester forms a binary low-boiling azeotrope with water or a ternary alcohol-ester-water azeotrope and that azeotrope is heterogeneous (or can be moved into the two-liquid phase region), the flow sheet illustrated in Fig. 13-98 can be used. Such a flow sheet works for the production of ethyl acetate and higher homologs. In this process scheme, acetic acid and the alcohol are continuously fed to the reboiler of the esterification column, along with a homogeneous strong-acid catalyst. Since the catalyst is largely nonvolatile, the reboiler acts as the primary reaction section. The alcohol is usually fed in slight excess to ensure complete reaction of the acid and to compensate for alcohol losses through distillation of the water-ester-(alcohol) azeotrope. The esterification column is operated such that the low-boiling, water-laden azeotrope is taken as the distillation product. Upon cooling, the distillate separates into two liquid phases. The aqueous layer is steam-stripped, with the organics recycled to the decanter or reactor. The ester layer from the decanter contains some water and possibly alcohol. Part of this layer may be refluxed to the esterification column. The remainder is fed to a low-boiler column where the water-ester and alcohol-ester azeotropes are removed overhead and recycled to the decanter or reactor. The dry, alcohol-free ester is then optionally taken overhead in a final refining column. Additional literature on the application of reactive distillation to ester production includes papers by Hanika, Kolena, and Smejkal [*Chem. Eng. Sci.*, **54,** 5205 (1999)], Schwarzer and Hoffmann [*Chem. Eng. Technol.*, **25,** 975 (2002)], Steinigeweg and Gmehling [*Ind. Eng. Chem. Res.*, **41,** 5483 (2002)], and Omata, Dimian, and Bliek [*Chem. Eng. Sci.*, **58,** 3159, 3175 (2003)].

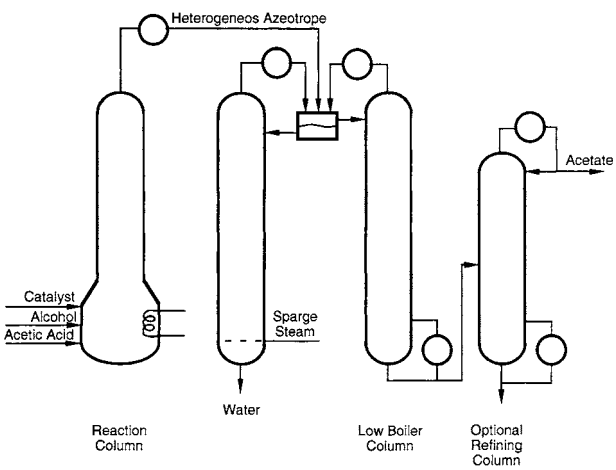

**FIG. 13-98** Flow sheet for making esters which form a heterogeneous minimum-boiling azeotrope with water.

Methyl acetate cannot be produced in high purity by using the simple esterification scheme described above. The methyl acetate–methanol–water system does not exhibit a ternary minimum-boiling azeotrope, the methyl acetate–methanol azeotrope is lower-boiling than the water–methyl acetate azeotrope, a distillation boundary extends between these two binary azeotropes, and the heterogeneous region does not include either azeotrope, nor does it cross the distillation boundary. Consequently, the water of esterification cannot be removed effectively, and methyl acetate cannot be separated from the methanol and water azeotropes by a simple decantation in the same manner as outlined above. Conventional sequential reaction-separation processes rely on large excesses of acetic acid to drive the reaction to higher conversion to methyl acetate, necessitating a capital- and energy-intensive acetic acid–water separation and large recycle streams. The crude methyl acetate product, contaminated with water and methanol, can be purified by a number of enhanced distillation techniques such as pressure-swing distillation (Harrison, U.S. Patent 2,704,271, 1955), extractive distillation with ethylene glycol monomethylether as the solvent (Kumerle, German Patent 1,070,165, 1959), or azeotropic distillation with an aromatic or ketone entrainer (Yeomans, Eur. Patent Appl. 060717 and 060719, 1982). The end result is a capital- and energy-intensive process typically requiring multiple reactors and distillation columns.

The reactive distillation process in Fig. 13-99 provides a mechanism for overcoming both the limitations on conversion due to chemical

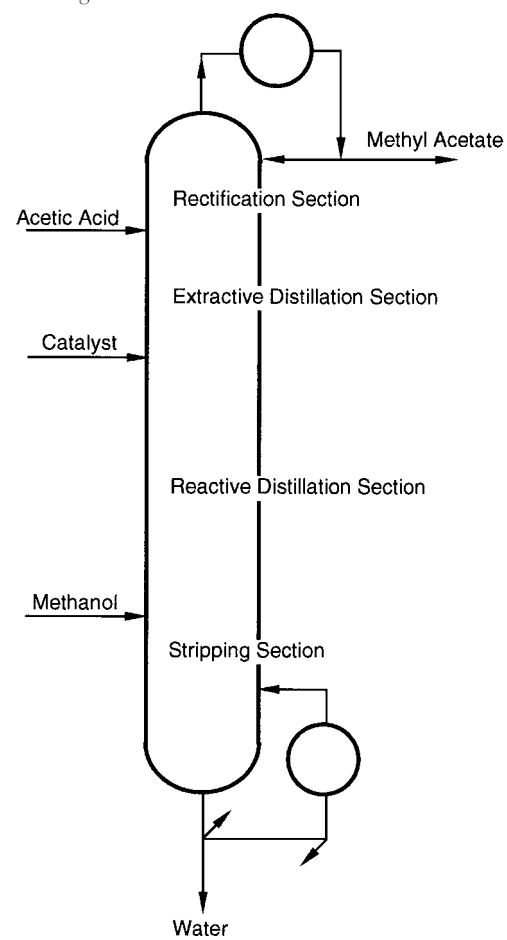

**FIG. 13-99** Integrated reactive-extractive distillation column for the production of methyl acetate.

equilibrium as well as the difficulties in purification imposed by the water–methyl acetate and methanol–methyl acetate azeotropes [Agreda and Partin, U.S. Patent 4,435,595, 1984; Agreda, Partin, and Heise, *Chem. Eng. Prog.*, **86**(2), 40 (1990)]. Conceptually, this flow sheet can be thought of as four heat-integrated distillation columns (one of which is also a reactor) stacked on top of each other. The primary reaction zone consists of a series of countercurrent flashing stages in the middle of the column. Adequate residence time for the reaction is provided by high-liquid-holdup bubble cap trays with specially designed downcomer sumps to further increase tray holdup. A nonvolatile homogeneous catalyst is fed at the top of the reactive section and exits with the underflow water by-product. The extractive distillation section, immediately above the reactive section, is critical in achieving high methyl acetate purity. As shown in Fig. 13-96, simultaneous reaction and distillation eliminates the water–methyl acetate azeotrope (and the distillation boundary of the nonreactive system). However, pure methyl acetate remains a saddle in the reactive system and cannot be obtained as a pure component by simple reactive distillation. The acetic acid feed acts as a solvent in an extractive-distillation section placed above the reaction section, breaking the methanol-methyl acetate azeotrope, and yielding a pure methyl acetate distillate product. The uppermost rectification stages serve to remove any acetic acid from the methyl acetate product, and the bottommost stripping section removes any methanol and methyl acetate from the water by-product. The countercurrent flow of the reactants results in high local excesses at each end of the reactive section, even though the overall feed to the reactive column is stoichiometric. Therefore, the large excess of acetic acid at the top of the reactive section prevents methanol from reaching the distillate; similarly, methanol at the bottom of the reactive section keeps acetic acid from the water bottoms. Temperature and composition profiles for this reactive extractive distillation column are shown in Fig. 13-100*a* and *b*, respectively.

Much has been written about this reactive distillation scheme, including works by Bessling et al. [*Chem. Eng. Tech.*, **21,** 393 (1998)], Song et al., [*Ind. Eng. Chem. Res.*, **37,** 1917 (1998)], Huss et al. [*Comput. Chem. Eng.*, **27,** 1855 (2003)], Siirola ("An Industrial Perspective on Process Synthesis," pp. 222–233 in Biegler and Doherty, eds., *Foundations of Computer-Aided Process Design*, AIChE, New York, 1995), and Krishna (chap. 7 in Sundmacher and Kienle, eds., *Reactive Distillation*, Wiley-VCH, 2003).

## SYNTHESIS OF MULTICOMPONENT SEPARATION SYSTEMS

The sequencing of distillation columns and other types of equipment for the separation of multicomponent mixtures has received much attention in recent years. Although one separator of complex design can sometimes be devised to produce more than two products, more often a sequence of two-product separators is preferable. Often, the sequence includes simple distillation columns. A summary of sequencing methods, prior to 1977, that can lead to optimal or near-optimal designs, is given by Henley and Seader (op. cit.). Modern methods for distillation column sequencing are reviewed by Modi and Westerberg [*Ind. Eng. Chem. Res.*, **31,** 839 (1992)], who also present a more generally applicable method based on a marginal price that is the change in price of a separation operation when the separation is carried out in the absence of nonkey components. The synthesis of sequences that consider a wide range of separation operations in a knowledge-based approach is given by Barnicki and Fair for liquid mixtures [*Ind. Eng. Chem. Res.*, **29,** 421 (1990)] and for gas/vapor mixtures [*Ind. Eng. Chem. Res.*, **31,** 1679 (1992)]. The problem decomposition approach of Wahnschafft, Le Rudulier, and Westerberg [*Ind. Eng. Chem. Res.*, **32,** 1121 (1993)] is directed to the synthesis of complex separation sequences that involve nonsharp splits and recycle, including azeotropic distillation. The method is applied by using a computer-aided separation process designer called *SPLIT.* An expert system, called *EXSEP,* for the synthesis of solvent-based separation trains is presented by Brunet and Liu [*Ind. Eng. Chem. Res.*, **32,** 315 (1993)]. The use of ternary composition diagrams and residue curve maps is reviewed and evaluated for application to the synthesis of complex separation sequences by Fien and Liu [*Ind. Eng. Chem. Res.*, **33,** 2506 (1994)]. In recent years many optimization-based process synthesis schemes have been proposed for distillation systems. The key research groups are led by Grossmann at Carnegie Mellon University, Manousiouthakis at UCLA, and Pistikopoulos at Imperial College, London. Further information about their methods and availability of computer programs can be obtained from the principals.

Synthesis schemes for reactive distillation have been proposed by Ismail, Proios, and Pistikopoulos [*AIChE J.*, **47,** 629 (2001)], Jackson and Grossmann [*Comput. Chem. Eng.*, **25,** 1661 (2001)], Schembecker and Tlatlik [*Chem. Eng. Process.*, **42,** 179 (2003)], and Burri and Manousiouthakis [*Comput. Chem. Eng.*, **28,** 2509 (2004)].

# PETROLEUM AND COMPLEX-MIXTURE DISTILLATION

Although the principles of multicomponent distillation apply to petroleum, synthetic crude oil, and other complex mixtures, this subject warrants special consideration for the following reasons:

1. Such feedstocks are of exceedingly complex composition, consisting of, in the case of petroleum, many different types of hydrocarbons and perhaps of inorganic and other organic compounds. The number of carbon atoms in the components may range from 1 to more than 50, so that the compounds may exhibit atmospheric-pressure boiling points from −162°C (−259°F) to more than 538°C (1000°F). In a given boiling range, the number of different compounds that exhibit only small differences in volatility multiplies rapidly with increasing boiling point. For example, 16 of the 18 octane isomers boil within a range of only 12°C (22°F).

2. Products from the distillation of complex mixtures are in themselves complex mixtures. The character and yields of these products vary widely, depending upon the source of the feedstock. Even crude oils from the same locality may exhibit marked variations.

3. The scale of petroleum-distillation operations is generally large, and as discussed in detail by Nelson (*Petroleum Refinery Engineering,* 4th ed., McGraw-Hill, New York, 1958) and Watkins (*Petroleum Refinery Distillation,* 2d ed., Gulf, Houston, 1979), such operations are common in several petroleum refinery processes including atmospheric distillation of crude oil, vacuum distillation of bottoms residuum obtained from atmospheric distillation, main fractionation of gaseous effluent from catalytic cracking of various petroleum fractions, and main fractionation of effluent from thermal coking of various petroleum fractions. These distillation operations are conducted in large pieces of equipment that can consume large quantities of energy. Therefore, optimization of design and operation is very important and frequently leads to a relatively complex equipment configuration.

## CHARACTERIZATION OF PETROLEUM AND PETROLEUM FRACTIONS

Although much progress has been made in identifying the chemical species present in petroleum, it is generally sufficient for purposes of design and analysis of plant operation of distillation to characterize petroleum and petroleum fractions by gravity, laboratory distillation curves, component analysis of light ends, and hydrocarbon-type analysis of middle and heavy ends. From such data, as discussed in the *Technical Data Book—Petroleum Refining* [American Petroleum Institute (API), Washington], five different average boiling points and an index of paraffinicity can be determined. These are then used to predict the physical properties of complex mixtures by a number of well-accepted correlations, whose use will be explained in detail and illustrated with examples. Many other characterizing properties or attributes such as sulfur content, pour point, water and sediment content, salt content, metals content, Reid vapor pressure, Saybolt Universal viscosity, aniline point, octane number, freezing point, cloud point, smoke point, diesel index, refractive index, cetane index, neutralization number, wax content, carbon content, and penetration are generally measured for a crude oil or certain of its fractions according to well-specified ASTM tests. But these attributes are of much less interest here even though feedstocks and products may be required to meet certain specified values of the attributes.

Gravity of a crude oil or petroleum fraction is generally measured by the ASTM D 287 test or the equivalent ASTM D 1298 test and may be reported as specific gravity (SG) 60/60°F [measured at 60°F (15.6°C) and referred to water at 60°F (15.6°C)] or, more commonly, as API gravity, which is defined as

$$\text{API gravity} = 141.5/(\text{SG } 60/60°\text{F}) - 131.5 \qquad (13\text{-}120)$$

Water, thus, has an API gravity of 10.0, and most crude oils and petroleum fractions have values of API gravity in the range of 10 to 80. Light hydrocarbons (*n*-pentane and lighter) have values of API gravity ranging upward from 92.8.

The volatility of crude oil and petroleum fractions is characterized in terms of one or more laboratory distillation tests that are summarized in Table 13-27. The ASTM D 86 and D 1160 tests are reasonably rapid batch laboratory distillations involving the equivalent of approximately one equilibrium stage and no reflux except for that caused by heat losses. Apparatus typical of the D 86 test is shown in Fig. 13-101 and consists of a heated 100-mL or 125-mL Engler flask containing a calibrated thermometer of suitable range to measure the temperature of the vapor at the inlet to the condensing tube, an inclined brass condenser in a cooling bath using a suitable coolant, and a graduated cylinder for collecting the distillate. A stem correction is not applied to the temperature reading. Related tests using similar apparatus are the D 216 test for natural gasoline and the Engler distillation.

In the widely used ASTM D 86 test, 100 mL of sample is charged to the flask and heated at a sufficient rate to produce the first drop of distillate from the lower end of the condenser tube in 5 to 15 min, depending on the nature of the sample. The temperature of the vapor at that instant is recorded as the initial boiling point (IBP). Heating is continued at a rate such that the time from the IBP to 5 vol % recovered of the sample in the cylinder is 60 to 75 s. Again, vapor temperature is recorded. Then successive vapor temperatures are recorded for 10 to 90 percent recovered in intervals of 10, and at 95 percent recovered, with the heating rate adjusted so that 4 to 5 mL is collected per minute. At 95 percent recovered, the burner flame is increased if necessary to achieve a maximum vapor temperature, referred to as the endpoint (EP) in 3 to 5 additional min. The percent recovery is reported as the maximum percent recovered in the cylinder. Any residue remaining in the flask is reported as percent residue, and percent loss is reported as the difference between 100 mL and the sum of the percent recovery and percent residue. If the atmosphere test pressure $P$ is other than 101.3 kPa (760 torr), temperature readings may be adjusted to that pressure by the Sidney Young equation, which for degrees Fahrenheit is

$$T_{760} = T_P + 0.00012(760 - P)(460 + T_P) \qquad (13\text{-}121)$$

Another pressure correction for percent loss can also be applied, as described in the ASTM test method.

**TABLE 13-27 Laboratory Distillation Tests**

| Test name | Reference | Main applicability |
|---|---|---|
| ASTM (atmospheric) | ASTM D 86 | Petroleum fractions or products, including gasolines, turbine fuels, naphthas, kerosines, gas oils, distillate fuel oils, and solvents that do not tend to decompose when vaporized at 760 mmHg |
| ASTM [vacuum, often 10 torr (1.3 kPa)] | ASTM D 1160 | Heavy petroleum fractions or products that tend to decompose in the ASTM D 86 test but can be partially or completely vaporized at a maximum liquid temperature of 750°F (400°C) at pressures down to 1 torr (0.13 kPa) |
| TBP [atmospheric or 10 torr (1.3 kPa)] | Nelson,* ASTM D 2892 | Crude oil and petroleum fractions |
| Simulated TBP (gas chromatography) | ASTM D 2887 | Crude oil and petroleum fractions |
| EFV (atmospheric, superatmospheric, or subatmospheric) | Nelson† | Crude oil and petroleum fractions |

*Nelson, *Petroleum Refinery Engineering,* 4th ed., McGraw-Hill, New York, 1958, pp. 95–99.
†Ibid., pp. 104–105.

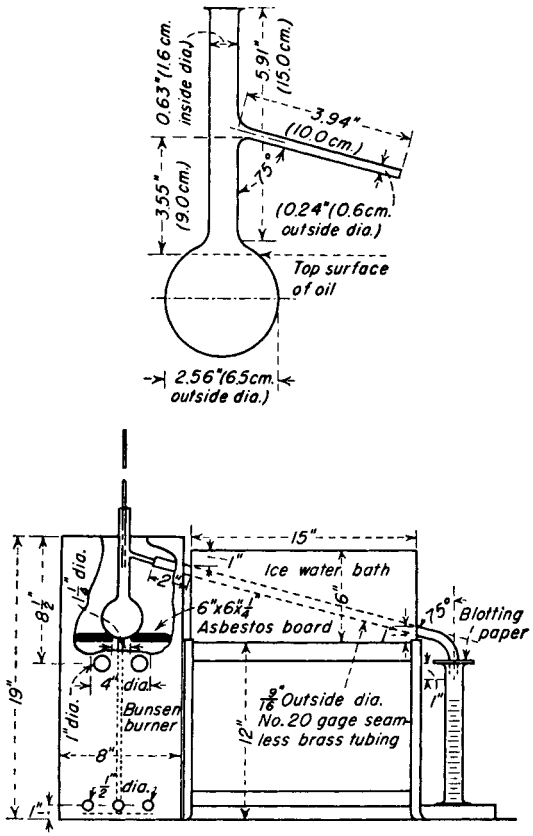

**FIG. 13-101** ASTM distillation apparatus; detail of distilling flask is shown in the upper figure.

Results of a typical ASTM distillation test for an automotive gasoline are given in Table 13-28, in which temperatures have already been corrected to a pressure of 101.3 kPa (760 torr). It is generally assumed that percent loss corresponds to volatile noncondensables that are distilled off at the beginning of the test. In that case, the percent recovered values in Table 13-28 do not correspond to percent evaporated values, which are of greater scientific value. Therefore, it is common to adjust the reported temperatures according to a linear interpolation procedure given in the ASTM test method to obtain corrected temperatures in terms of percent evaporated at the standard intervals as included in Table 13-28. In the example, the corrections are not large because the loss is only 1.5 vol %.

**TABLE 13-28 Typical ASTM D 86 Test Results for Automobile Gasoline Pressure, 760 torr (101.3 kPa)**

| Percent recovered basis (as measured) | | | Percent evaporated basis (as corrected) | | |
|---|---|---|---|---|---|
| Percent recovered | $T$, °F | Percent evaporated | Percent evaporated | $T$, °F | Percent recovered |
| 0(IBP) | 98 | 1.5 | 1.5 | 98 | (IBP) |
| 5 | 114 | 6.5 | 5 | 109 | 3.5 |
| 10 | 120 | 11.5 | 10 | 118 | 8.5 |
| 20 | 150 | 21.5 | 20 | 146 | 18.5 |
| 30 | 171 | 31.5 | 30 | 168 | 28.5 |
| 40 | 193 | 41.5 | 40 | 190 | 38.5 |
| 50 | 215 | 51.5 | 50 | 212 | 48.5 |
| 60 | 243 | 61.5 | 60 | 239 | 58.5 |
| 70 | 268 | 71.5 | 70 | 264 | 68.5 |
| 80 | 300 | 81.5 | 80 | 295 | 78.5 |
| 90 | 340 | 91.5 | 90 | 334 | 88.5 |
| 95 | 368 | 96.5 | 95 | 360 | 93.5 |
| EP | 408 | | | 408 | (EP) |

NOTE: Percent recovery = 97.5; percent residue = 1.0; percent loss = 1.5. To convert degrees Fahrenheit to degrees Celsius, °C = (°F − 32)/1.8.

Although most crude petroleum can be heated to 600°F (316°C) without noticeable cracking, when ASTM temperatures exceed 475 °F (246°C), fumes may be evolved, indicating decomposition, which may cause thermometer readings to be low. In that case, the following correction attributed to S. T. Hadden may be applied:

$$\Delta T_{\text{corr}} = 10^{-1.587 + 0.004735T} \tag{13-122}$$

where $T$ = measured temperature, °F
$\Delta T_{\text{corr}}$ = correction to be added to $T$, °F

At 500 and 600°F (260 and 316°C), the corrections are 6 and 18°F (3.3 and 10°C), respectively.

As discussed by Nelson (op. cit.), virtually no fractionation occurs in an ASTM distillation. Thus, components in the mixture do distill one by one in the order of their boiling points but as mixtures of successively higher boiling points. The IBP, EP, and intermediate points have little theoretical significance, and, in fact, components boiling below the IBP and above the EP are present in the sample. Nevertheless, because ASTM distillations are quickly conducted, have been successfully automated, require only a small sample, and are quite reproducible, they are widely used for comparison and as a basis for specifications on a large number of petroleum intermediates and products, including many solvents and fuels. Typical ASTM curves for several such products are shown in Fig. 13-102.

Data from a *true boiling point* (TBP) distillation test provide a much better theoretical basis for characterization. If the sample contains compounds that have moderate differences in boiling points such as in

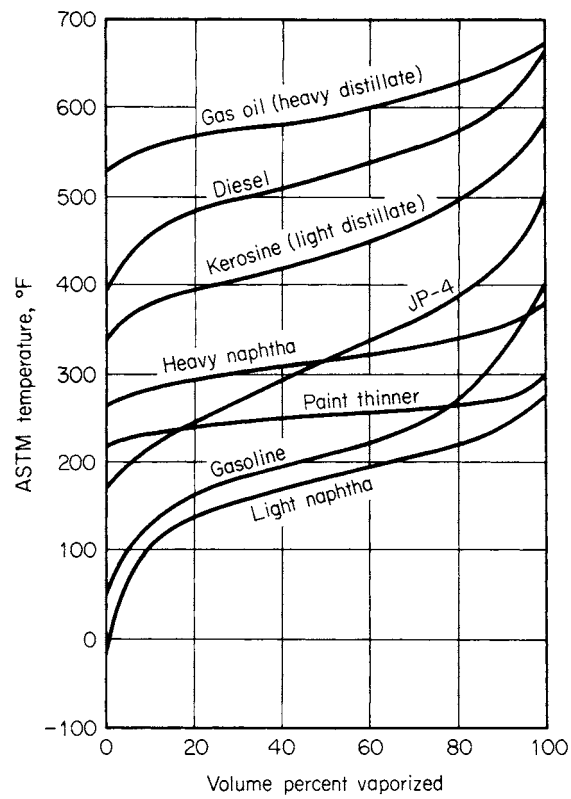

**FIG. 13-102** Representative ASTM D 86 distillation curves.

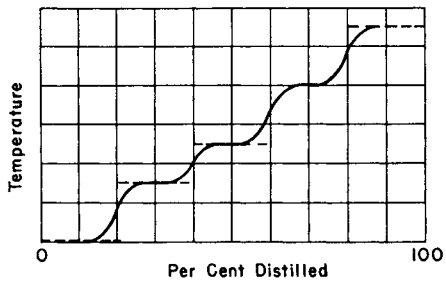

**FIG. 13-103** Variation of boiling temperature with percent distilled in TBP distillation of light hydrocarbons.

a light gasoline containing light hydrocarbons (e.g., isobutane, *n*-butane, isopentane), a plot of overhead vapor distillate temperature versus percent distilled in a TBP test would appear in the form of steps as in Fig. 13-103. However, if the sample has a higher average boiling range when the number of close-boiling isomers increases, the steps become indistinct and a TBP curve such as that in Fig. 13-104 results. Because the degree of separation for a TBP distillation test is much higher than that for an ASTM distillation test, the IBP is lower and the EP is higher for the TBP method as compared with the ASTM method, as shown in Fig. 13-104.

A standard TBP laboratory distillation test method has not been well accepted. Instead, as discussed by Nelson (op. cit., pp. 95–99), batch distillation equipment that can achieve a good degree of fractionation is usually considered suitable. In general, TBP distillations are conducted in columns with 15 to 100 theoretical stages at reflux ratios of 5 or greater. Thus, the new ASTM D 2892 test method, which involves a column with 14 to 17 theoretical stages and a reflux ratio of 5, essentially meets the minimum requirements. Distillate may be collected at a constant or a variable rate. Operation may be at 101.3-kPa (760-torr) pressure or at a vacuum at the top of the column as low as 0.067 kPa (0.5 torr) for high-boiling fractions, with 1.3 kPa (10 torr) being common. Results from vacuum operation are extrapolated to 101.3 kPa (760 torr) by the vapor-pressure correlation of Maxwell and Bonner [*Ind. Eng. Chem.*, **49,** 1187 (1957)], which is given in great detail in the API *Technical Data Book—Petroleum Refining* (op. cit.) and in the ASTM D 2892 test method. It includes a correction for the nature of the sample (paraffin, olefin, naphthene, and aromatic content) in terms of the UOP characterization factor, UOP-K, as given by

$$\text{UOP-K} = \frac{(T_B)^{1/3}}{\text{SG}} \tag{13-123}$$

where $T_B$ is the mean average boiling point in degrees Rankine, which is the arithmetic average of the molal average boiling point and the cubic volumetric average boiling point. Values of UOP-K for *n*-hexane, 1-hexene, cyclohexene, and benzene are 12.82, 12.49, 10.99, and 9.73, respectively. Thus, paraffins with their lower values of specific gravity tend to have high values, and aromatics tend to have low values of UOP-K. A movement toward an international TBP standard is discussed by Vercier and Mouton [*Oil Gas J.*, **77**(38), 121 (1979)].

A crude oil assay always includes a whole crude API gravity and a TBP curve. As discussed by Nelson (op. cit., pp. 89–90) and as shown in Fig. 13-105, a reasonably consistent correlation (based on more than 350 distillation curves) exists between whole crude API gravity and the TBP distillation curve at 101.3 kPa (760 torr). Exceptions not correlated by Fig. 13-105 are highly paraffinic or naphthenic crude oils.

An alternative to TBP distillation is simulated distillation by gas chromatography. As described by Green, Schmauch, and Worman [*Anal. Chem.*, **36,** 1512 (1965)] and Worman and Green [*Anal. Chem.*, **37,** 1620 (1965)], the method is equivalent to a 100-theoretical-plate TBP distillation; is very rapid, reproducible, and easily automated; requires only a small microliter sample; and can better define initial and final boiling points. The ASTM D 2887 standard test method is based on such a simulated distillation and is applicable to samples having a boiling range greater than 55°C (100°F) for temperature determinations as high as 538°C (1000°F). Typically, the test is conducted with a gas chromatograph having a thermal conductivity detector, a programmed temperature capability, helium or hydrogen carrier gas, and column packing of silicone gum rubber on a crushed firebrick or diatomaceous earth support.

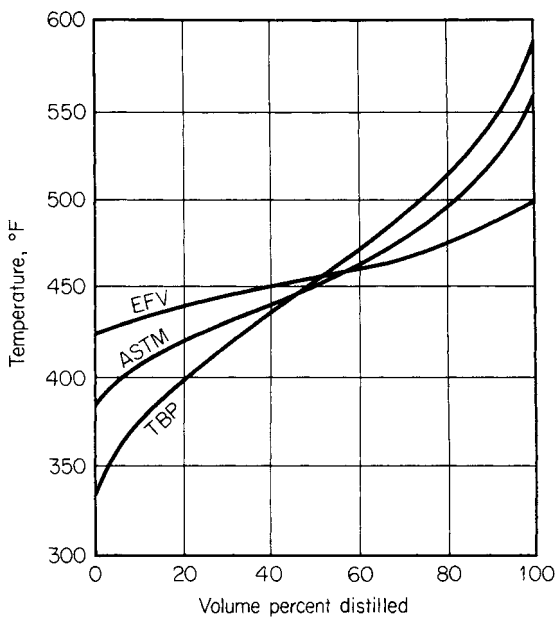

**FIG. 13-104** Comparison of ASTM, TBP, and EFV distillation curves for kerosine.

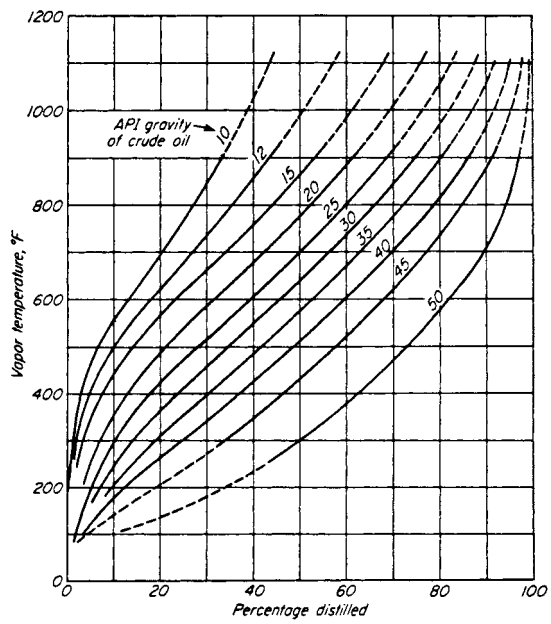

**FIG. 13-105** Average true-boiling-point distillation curves of crude oils. *(From W. E. Edmister,* Applied Hydrocarbon Thermodynamics, *vol. 1, 1st ed., 1961 Gulf Publishing Company, Houston, Texas, Used with permission. All rights reserved.)*

It is important to note that simulated distillation does not always separate hydrocarbons in the order of their boiling points. For example, high-boiling multiple-ring-type compounds may be eluted earlier than normal paraffins (used as the calibration standard) of the same boiling point. Gas chromatography is also used in the ASTM D 2427 test method to determine quantitatively ethane through pentane hydrocarbons.

A third fundamental type of laboratory distillation, which is the most tedious to perform of the three types of laboratory distillations, is equilibrium flash vaporization (EFV), for which no standard test exists. The sample is heated in such a manner that the total vapor produced remains in contact with the total remaining liquid until the desired temperature is reached at a set pressure. The volume percent vaporized at these conditions is recorded. To determine the complete flash curve, a series of runs at a fixed pressure is conducted over a range of temperatures sufficient to cover the range of vaporization from 0 to 100 percent. As seen in Fig. 13-104, the component separation achieved by an EFV distillation is much less than that by the ASTM or TBP distillation tests. The initial and final EFV points are the bubble point and the dew point, respectively, of the sample. If desired, EFV curves can be established at a series of pressures.

Because of the time and expense involved in conducting laboratory distillation tests of all three basic types, it has become increasingly common to use empirical correlations to estimate the other two distillation curves when the ASTM, TBP, or EFV curve is available. Preferred correlations given in the API *Technical Data Book—Petroleum Refining* (op. cit.) are based on the work of Edmister and Pollock [*Chem. Eng. Prog.*, **44,** 905 (1948)], Edmister and Okamoto [*Pet. Refiner,* **38**(8), 117 (1959); **38**(9), 271 (1959)], Maxwell (*Data Book on Hydrocarbons,* Van Nostrand, Princeton, N.J., 1950), and Chu and Staffel [*J. Inst. Pet.*, **41,** 92 (1955)]. Because of the lack of sufficiently precise and consistent data on which to develop the correlations, they are, at best, first approximations and should be used with caution. Also, they do not apply to mixtures containing only a few components of widely different boiling points. Perhaps the most useful correlation of the group is Fig. 13-106 for converting between ASTM D 86 and TBP distillations of petroleum fractions at 101.3 kPa (760 torr). The ASTM D 2889 test method, which presents a standard method for calculating EFV curves from the results of an ASTM D 86 test for a petroleum fraction having a 10 to 90 vol % boiling range of less than 55°C (100°F), is also quite useful.

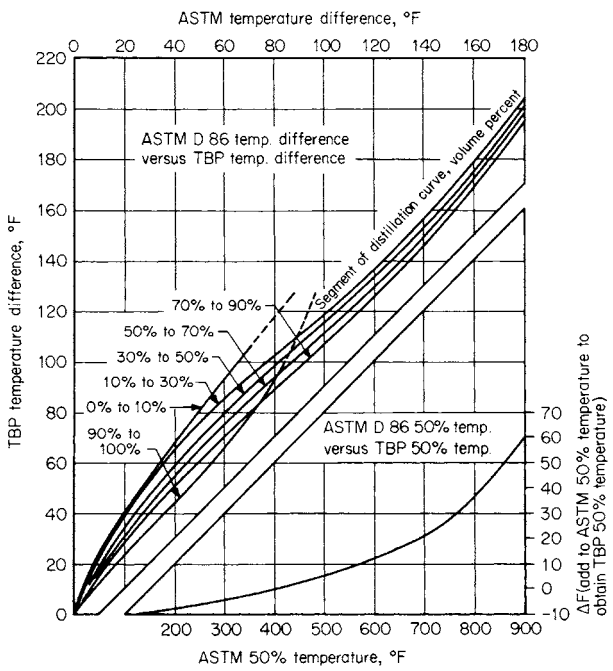

**FIG. 13-106** Relationship between ASTM and TBP distillation curves. *(From W. C. Edmister,* Applied Hydrocarbon Thermodynamics, *vol. 1, 1st ed., 1961 Gulf Publishing Company, Houston, Tex. Used with permission. All rights reserved.)*

## APPLICATIONS OF PETROLEUM DISTILLATION

Typical equipment configurations for the distillation of crude oil and other complex hydrocarbon mixtures in a crude unit, a catalytic cracking unit, and a delayed coking unit of a petroleum refinery are shown in Figs. 13-107, 13-108, and 13-109. The initial separation of crude oil into fractions is conducted in two main columns, shown in Fig. 13-107. In the first column, called the atmospheric tower or topping still, partially vaporized crude oil, from which water, sediment, and salt have been removed, is mainly rectified, at a feed tray pressure of no more than about 276 kPa (40 psia), to yield a noncondensable light-hydrocarbon gas, a light naphtha, a heavy naphtha, a light distillate (kerosine), a heavy distillate (diesel oil), and a bottoms residual of components whose TBP exceeds approximately 427°C (800°F). Alternatively, other fractions, shown in Fig. 13-102, may be withdrawn. To control the IBP of the ASTM D 86 curves, each of the sidestreams of the atmospheric tower and the vacuum and main fractionators of Figs. 13-107, 13-108, and 13-109 may be sent to side-cut strippers, which use a partial reboiler or steam stripping. Additional stripping by steam is commonly used in the bottom of the atmospheric tower as well as in the vacuum tower and other main fractionators.

Additional distillate in the TBP range of approximately 427 to 593°C (800 to 1100°F) is recovered from bottoms residuum of the atmospheric tower by rectification in a vacuum tower, also shown in Fig. 13-107, at the minimum practical overhead condenser pressure, which is typically 1.3 kPa (10 torr). Use of special low-pressure-drop trays or column packing permits the feed tray pressure to be approximately 5.3 to 6.7 kPa (40 to 50 torr) to obtain the maximum degree of vaporization. Vacuum towers may be designed or operated to produce several different products including heavy distillates, gas-oil feedstocks for catalytic cracking, lubricating oils, bunker fuel, and bottoms residua of asphalt (5 to 8 API gravity) or pitch (0 to 5 API gravity). The catalytic cracking process of Fig. 13-108 produces a superheated vapor at approximately 538°C (1000°F) and 172 to 207 kPa (25 to 30 psia) of a TBP range that covers hydrogen to compounds with normal boiling points above 482°C (900°F). This gas is sent directly to a main fractionator for rectification to obtain products that are typically gas and naphtha [204°C (400°F) ASTM EP approximately], which are often fractionated further to produce relatively pure light hydrocarbons and gasoline; a light cycle oil [typically 204 to 371°C (400 to 700°F) ASTM D 86 range], which may be used for heating oil, hydrocracked, or recycled to the catalytic cracker; an intermediate cycle oil [typically 371 to 482°C (700 to 900°F) ASTM D 86 range], which is generally recycled to the catalytic cracker to extinction; and a heavy gas oil or bottom slurry oil.

Vacuum-column bottoms, bottoms residuum from the main fractionation of a catalytic cracker, and other residua can be further processed at approximately 510°C (950°F) and 448 kPa (65 psia) in a delayed-coker unit, as shown in Fig. 13-109, to produce petroleum coke and gas of TBP range that covers methane (with perhaps a small amount of hydrogen) to compounds with normal boiling points that may exceed 649°C (1200°F). The gas is sent directly to a main fractionator that is similar to the type used in conjunction with a catalytic cracker, except that in the delayed-coking operation the liquid to be coked first enters into and passes down through the bottom trays of the main fractionator to be preheated by and to scrub coker vapor of entrained coke particles and condensables for recycling to the delayed coker. Products produced from the main fractionator are similar to those produced in a catalytic cracking unit, except for more unsaturated cyclic compounds, and include gas and coker naphtha, which are further processed to separate out light hydrocarbons and a coker naphtha that generally needs hydrotreating; and light and heavy coker gas oils, both of which may require hydrocracking to become suitable blending stocks.

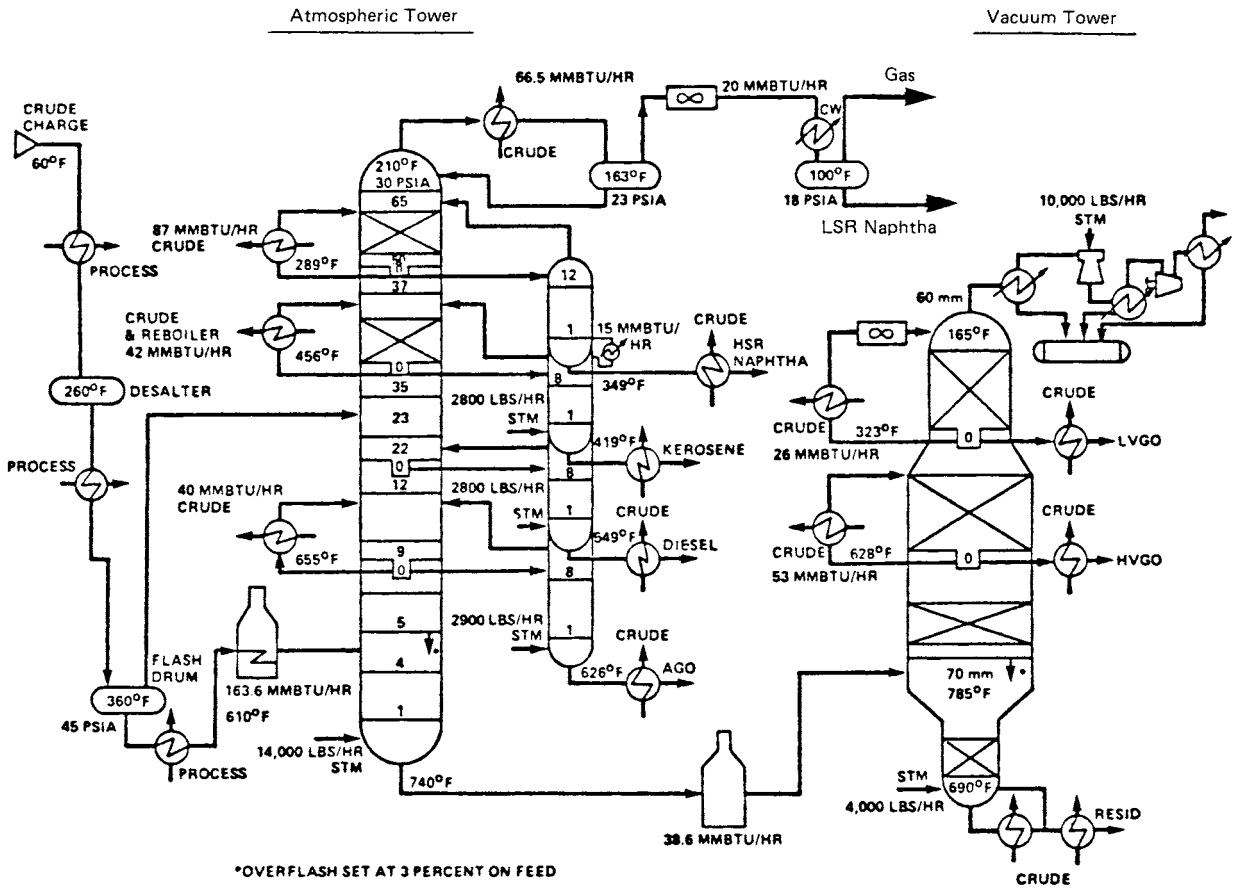

**FIG. 13-107** Crude unit with atmospheric and vacuum towers. [*Kleinschrodt and Hammer,* Chem. Eng. Prog., ***79(7),*** *33 (1983).*]

## DESIGN PROCEDURES

Two general procedures are available for designing fractionators that process petroleum, synthetic crude oils, and complex mixtures. The first, which was originally developed for crude units by Packie [*Trans. Am. Inst. Chem. Eng. J.*, **37,** 51 (1941)], extended to main fractionators by Houghland, Lemieux, and Schreiner [*Proc. API,* sec. III, *Refining,* 385 (1954)], and further elaborated and described in great detail by Watkins (op. cit.), uses material and energy balances, with empirical correlations to establish tray requirements, and is essentially a hand calculation procedure that is a valuable learning experience and is suitable for preliminary designs. Also, when backed by sufficient experience from previous designs, this procedure is adequate for final design.

In the second procedure, which is best applied with a digital computer, the complex mixture being distilled is represented by actual components at the light end and by perhaps 30 pseudocomponents (e.g., petroleum fractions) over the remaining portion of the TBP distillation curve for the column feed. Each of the pseudocomponents is characterized by a TBP range, an average normal boiling point, an average API gravity, and an average molecular weight. Rigorous material balance, energy balance, and phase equilibrium calculations are then made by an appropriate equation-tearing method, as shown by Cecchetti et al. [*Hydrocarbon Process.*, **42**(9), 159 (1963)] or a simultaneous-correction procedure as shown, e.g., by Goldstein and Stanfield [*Ind. Eng. Chem. Process Des. Dev.*, **9,** 78 (1970)] and Hess et al. [*Hydrocarbon Process.*, **56**(5), 241 (1977)]. Highly developed procedures of the latter type, suitable for preliminary or final design, are included in most computer-aided steady-state process design and simulation programs as a special case of interlinked distillation, wherein the crude tower or fractionator is converged simultaneously with the sidecut stripper columns.

Regardless of the procedure used, certain initial steps must be taken for the determination or specification of certain product properties and yields based on the TBP distillation curve of the column feed, method of providing column reflux, column-operating pressure, type of condenser, and type of sidecut strippers and stripping requirements. These steps are developed and illustrated with several detailed examples by Watkins (op. cit.). Only one example, modified from one given by Watkins, is considered briefly here to indicate the approach taken during the initial steps.

For the atmospheric tower shown in Fig. 13-110, suppose distillation specifications are as follows:

- Feed: 50,000 bbl (at 42 U.S. gal each) per stream day (BPSD) of 31.6 API crude oil.
- Measured light-ends analysis of feed:

| Component | Volume percent of crude oil |
|---|---|
| Ethane | 0.04 |
| Propane | 0.37 |
| Isobutane | 0.27 |
| *n*-Butane | 0.89 |
| Isopentane | 0.77 |
| *n*-Pentane | 1.13 |
| | 3.47 |

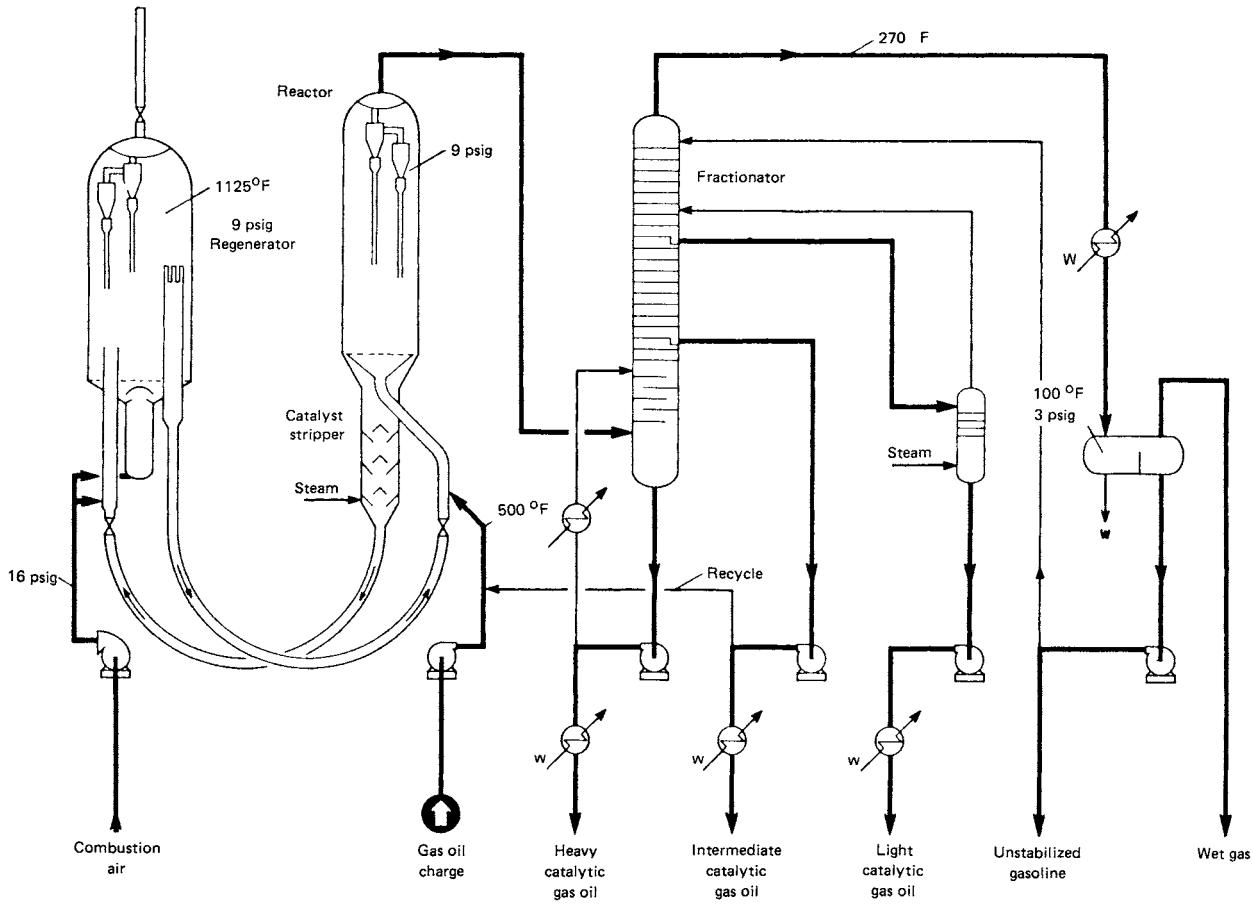

**FIG. 13-108** Catalytic cracking unit. [*New Horizons*, Lummus Co., New York (1954)].

- Measured TBP and API gravity of feed, computed atmospheric pressure EFV (from API *Technical Data Book*), and molecular weight of feed:

| Volume percent vaporized | TBP, °F | EFV, °F | °API | Molecular weight |
|---|---|---|---|---|
| 0 | –130 | 179 | | |
| 5 | 148 | 275 | 75.0 | 91 |
| 10 | 213 | 317 | 61.3 | 106 |
| 20 | 327 | 394 | 50.0 | 137 |
| 30 | 430 | 468 | 41.8 | 177 |
| 40 | 534 | 544 | 36.9 | 223 |
| 50 | 639 | 619 | 30.7 | 273 |
| 60 | 747 | 696 | 26.3 | 327 |
| 70 | 867 | 777 | 22.7 | 392 |
| 80 | 1013 | 866 | 19.1 | 480 |

- Product specifications:

| | ASTM D 86, °F | | |
|---|---|---|---|
| Desired cut | 5% | 50% | 95% |
| Overhead (OV) | | | 253 |
| Heavy naphtha (HN) | 278 | 314 | 363 |
| Light distillate (LD) | 398 | 453 | 536 |
| Heavy distillate (HD) | 546 | 589 | |
| Bottoms (B) | | | |

NOTE: To convert degrees Fahrenheit to degrees Celsius, °C = (°F – 32)/1.8.

- TBP cut point between the heavy distillate and the bottoms = 650 °F.
- Percent overflash = 2 vol % of feed
- Furnace outlet temperature = 343°C (650 °F) maximum
- Overhead temperature in reflux drum = 49°C (120°F) minimum

From the product specifications, distillate yields are computed as follows: From Fig. 13-106 and the ASTM D 86 50 percent temperatures, TBP 50 percent temperatures of the three intermediate cuts are obtained as 155, 236, and 316°C (311, 456, and 600°F) for the HN, LD, and HD, respectively. The TBP cut points, corresponding volume fractions of crude oil, and flow rates of the four distillates are readily obtained by starting from the specified 343°C (650°F) cut point as follows, where CP is the cut point and $T$ is the TBP temperature (°F):

$$\mathrm{CP}_{\mathrm{HD,B}} = 650°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{HD,B}} - T_{\mathrm{HD}_{50}} = 650 - 600 = 50°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{LD,HD}} = T_{\mathrm{HD}_{50}} - 50 = 600 - 50 = 550°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{LD,HD}} - T_{\mathrm{LD}_{50}} = 550 - 456 = 94°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{HN,LD}} = T_{\mathrm{LD}_{50}} - 94 = 456 - 94 = 362°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{HN,LD}} - T_{\mathrm{HN}_{50}} = 362 - 311 = 51°\mathrm{F}$$
$$\mathrm{CP}_{\mathrm{OV,HN}} = T_{\mathrm{HN}_{50}} - 51 = 311 - 51 = 260°\mathrm{F}$$

These cut points are shown as vertical lines on the crude oil TBP plot of Fig. 13-111, from which the following volume fractions and flow

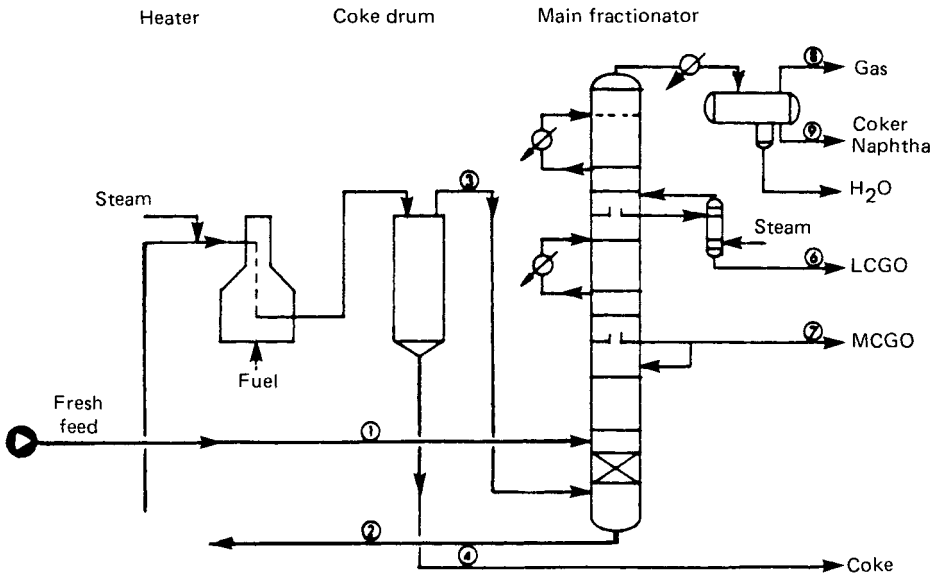

**FIG. 13-109** Delayed-coking unit. (Watkins, *Petroleum Refinery Distillation*, 2d ed., Gulf, Houston, Tex., 1979).

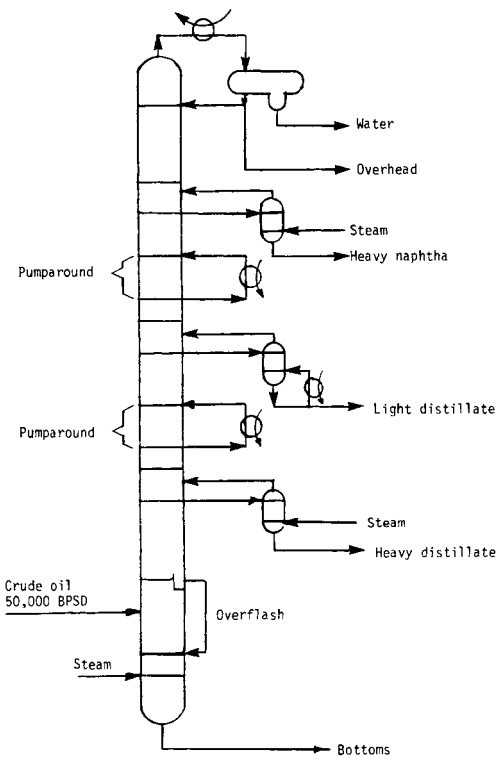

**FIG. 13-110** Crude atmospheric tower.

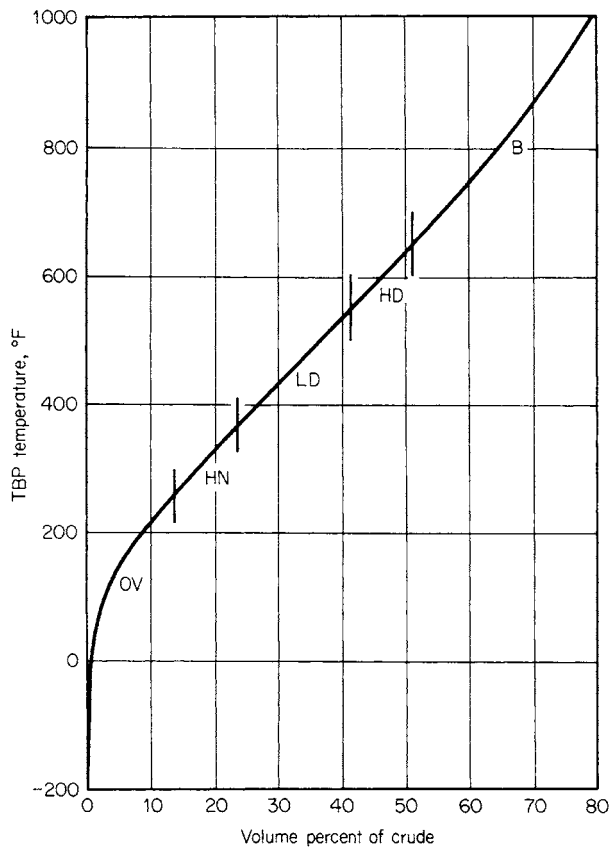

**FIG. 13-111** Example of crude oil TBP cut points.

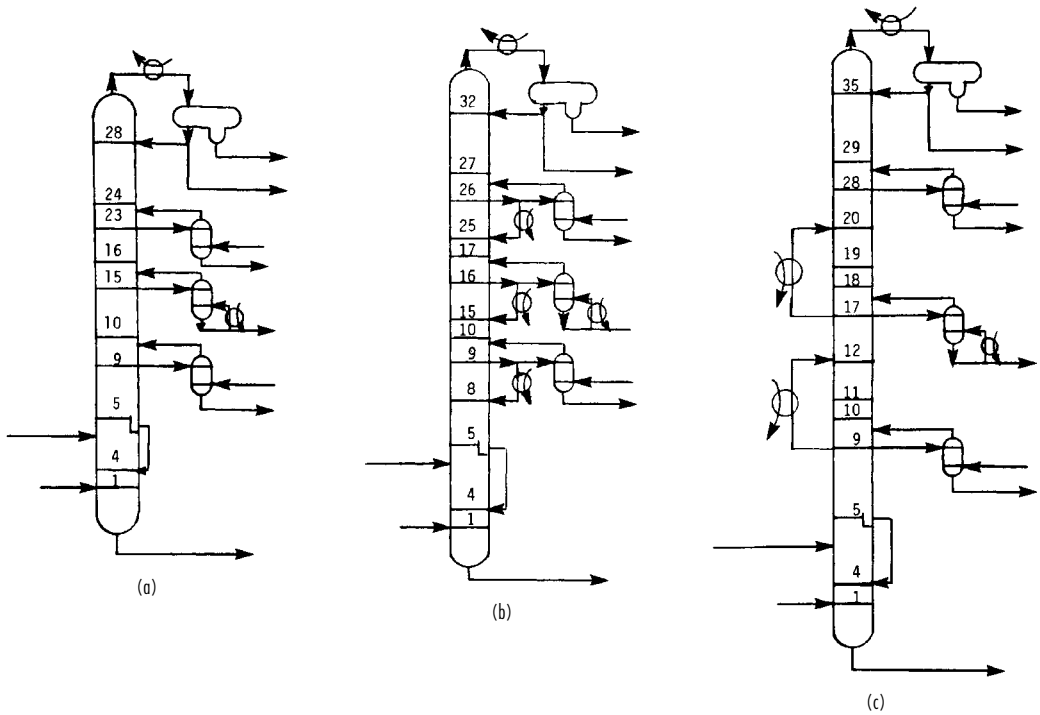

**FIG. 13-112** Methods of providing reflux to crude units. (*a*) Top reflux. (*b*) Pump-back reflux. (*c*) Pump-around reflux.

rates of product cuts are readily obtained:

| Desired cut | Volume percent of crude oil | BPSD |
|---|---|---|
| Overhead (OV) | 13.4 | 6,700 |
| Heavy naphtha (HN) | 10.3 | 5,150 |
| Light distillate (LD) | 17.4 | 8,700 |
| Heavy distillate (HD) | 10.0 | 5,000 |
| Bottoms (B) | 48.9 | 24,450 |
| | 100.0 | 50,000 |

As shown in Fig. 13-112, methods of providing column reflux include *(a)* conventional top-tray reflux, *(b)* pump-back reflux from sidecut strippers, and *(c)* pump-around reflux. The latter two methods essentially function as intercondenser schemes that reduce the top-tray reflux requirement. As shown in Fig. 13-113 for the example being considered, the internal-reflux flow rate decreases rapidly from the top tray to the feed-flash zone for case *a*. The other two cases, particularly case *c*, result in better balancing of the column-reflux traffic. Because of this and the opportunity provided to recover energy at a moderate- to high-temperature level, pump-around reflux is the most commonly used technique. However, not indicated in Fig. 13-113 is the fact that in cases *b* and *c* the smaller quantity of reflux present in the upper portion of the column increases the tray requirements. Furthermore, the pump-around circuits, which extend over three trays each, are believed to be equivalent for mass-transfer purposes to only one tray each. Representative tray requirements for the three cases are included in Fig. 13-112. In case *c*, heat-transfer rates associated with the two pump-around circuits account for approximately 40 percent of the total heat removed in the overhead condenser and from the two pump-around circuits combined.

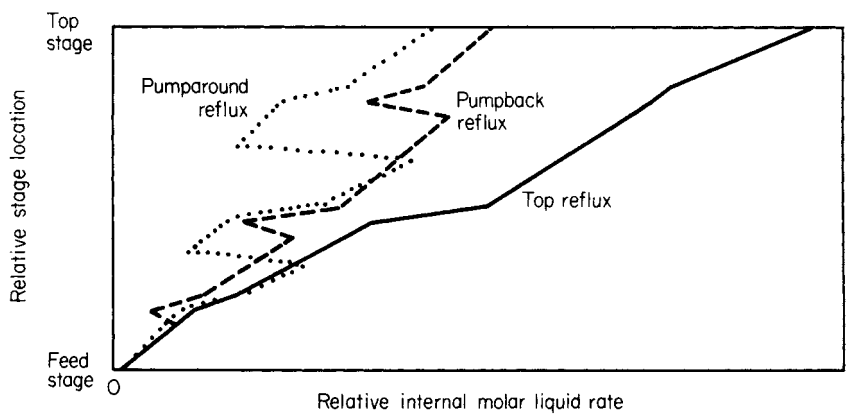

**FIG. 13-113** Comparison of internal reflux rates for three methods of providing reflux.

Bottoms and three sidecut strippers remove light ends from products and may use steam or reboilers. In Fig. 13-112 a reboiled stripper is used on the light distillate, which is the largest sidecut withdrawn. Steam-stripping rates in sidecut strippers and at the bottom of the atmospheric column may vary from 0.45 to 4.5 kg (1 to 10 lb) of steam per barrel of stripped liquid, depending on the fraction of stripper feed liquid that is vaporized.

Column pressure at the reflux drum is established so as to condense totally the overhead vapor or some fraction thereof. Flash-zone pressure is approximately 69 kPa (10 psia) higher. Crude oil feed temperature at flash-zone pressure must be sufficient to vaporize the total distillates plus the overflash, which is necessary to provide reflux between the lowest sidestream-product drawoff tray and the flash zone. Calculations are made by using the crude oil EFV curve corrected for pressure. For the example being considered, percent vaporized at the flash zone must be 53.1 percent of the feed.

Tray requirements depend on internal reflux ratios and ASTM 5-95 gaps or overlaps and may be estimated by the correlation of Packie (op. cit.) for crude units and the correlation of Houghland, Lemieux, and Schreiner (op. cit.) for main fractionators.

***Example 15: Simulation Calculation of an Atmospheric Tower*** The ability of a rigorous calculation procedure to simulate operation of an atmospheric tower with its accompanying sidecut strippers may be illustrated by comparing commercial-test data from an actual operation with results computed with the REFINE program of ChemShare Corporation, Houston, Texas. (See also DESIGN II program from WinSim, Inc., Sugar Land, Texas; http://www.winsim.com.) The tower configuration and plant operating conditions are shown in Fig. 13-114.

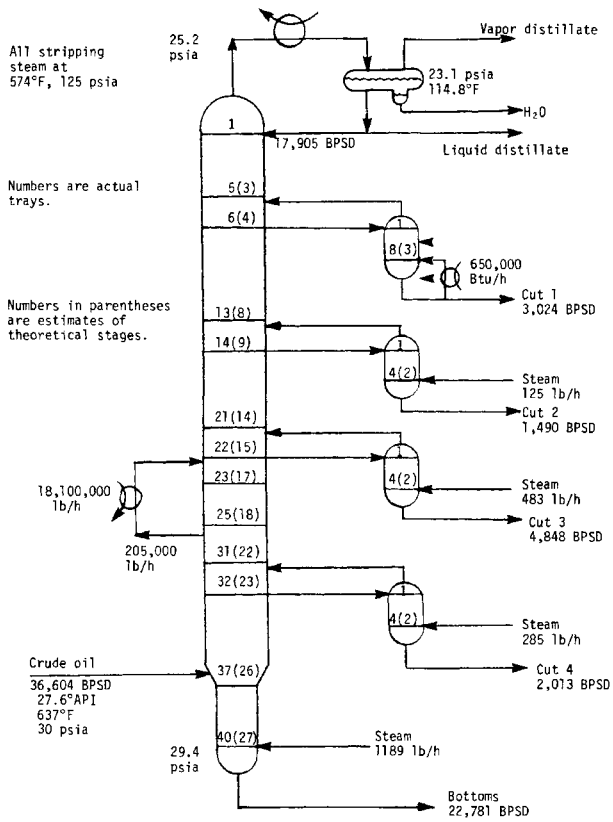

**FIG. 13-114** Configuration and conditions for the simulation of the atmospheric tower of crude unit.

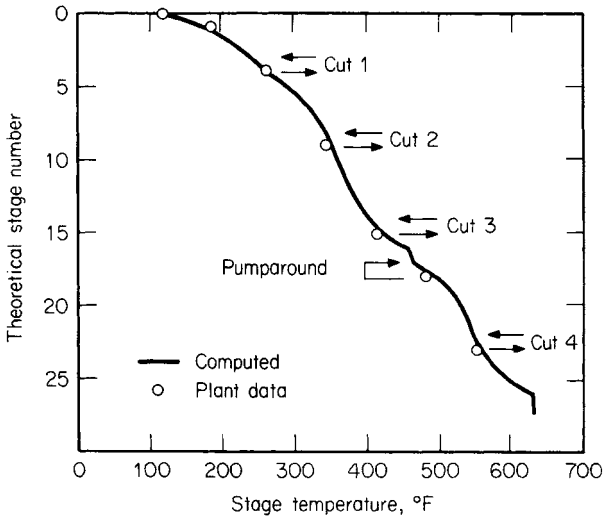

**FIG. 13-115** Comparison of computed stage temperatures with plant data for the example of Fig. 13-114.

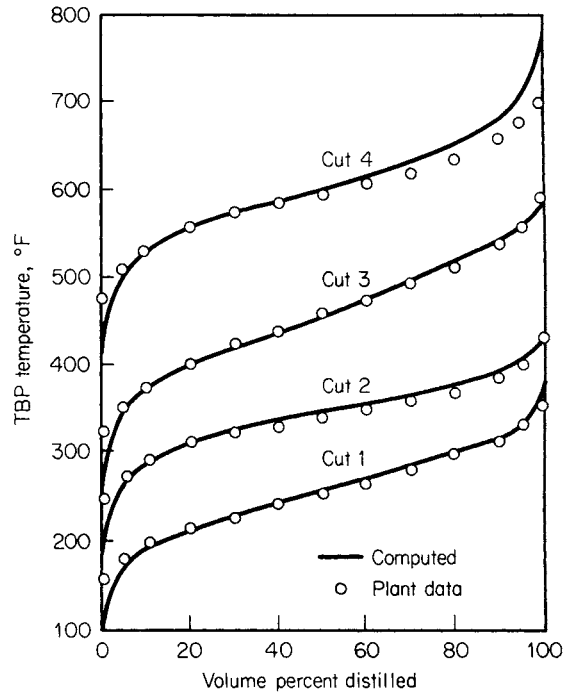

**FIG. 13-116** Comparison of computed TBP curves with plant data for the example of Fig. 13-114.

Light-component analysis and the TBP and API gravity for the feed are given in Table 13-29. Representation of this feed by pseudocomponents is given in Table 13-30 based on 16.7°C (30°F) cuts from 82 to 366°C (180 to 690°F), followed by 41.7°C (75°F) and then 55.6°C (100°F) cuts. Actual tray numbers are shown in Fig. 13-114. Corresponding theoretical-stage numbers, which were determined by trial and error to obtain a reasonable match of computed- and measured-product TBP distillation curves, are shown in parentheses. Overall tray efficiency appears to be approximately 70 percent for the tower and 25 to 50 percent for the sidecut strippers.

Results of rigorous calculations and comparison to plant data, when possible, are shown in Figs. 13-115, 13-116, and 13-117. Plant temperatures are in good agreement with computed values in Fig. 13-115. Computed sidestream-product TBP distillation curves are in reasonably good agreement with values converted from plant ASTM distillations, as shown in Fig. 13-116. Exceptions are the initial points of all four cuts and the higher-boiling end of the heavy-distillate curve. This would seem to indicate that more theoretical stripping stages should be added and that either the percent vaporization of the tower feed in the simulation is too high or the internal reflux rate at the lower draw-off tray is too low. The liquid-rate profile in the tower is shown in Fig. 13-117. The use of two or three pump-around circuits instead of one would result in a better traffic pattern than that shown.

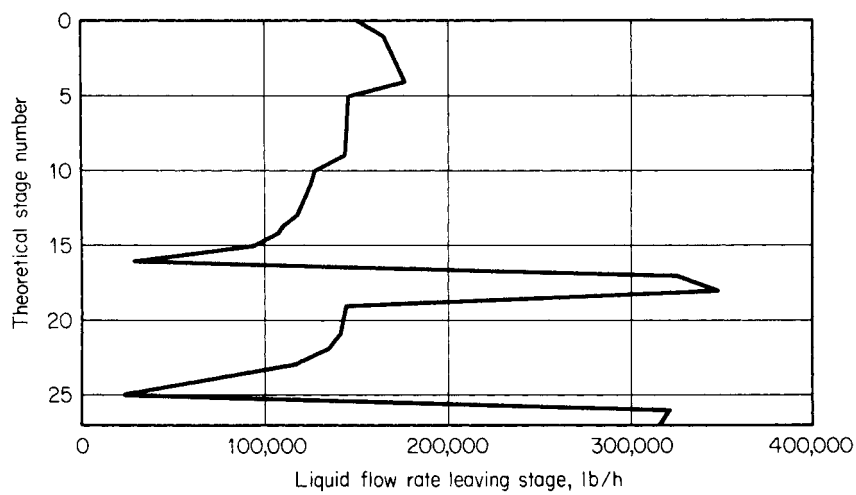

**FIG. 13-117** Liquid rate profile for the example of Fig. 13-114.

# BATCH DISTILLATION

Batch distillation, which is the process of separating a specific quantity (the charge) of a liquid mixture into products, is used extensively in the laboratory and in small production units that may have to serve for many mixtures. When there are $C$ components in the feed, one batch column will often suffice where $C - 1$ simple continuous distillation columns would be required.

Many larger installations also feature a batch still. The material to be separated may be high in solids content, or it might contain tars or resins that would plug or foul a continuous unit. Use of a batch unit can keep solids separated and permit convenient removal at the termination of the process.

## SIMPLE BATCH DISTILLATION

The simplest form of batch distillation consists of a heated vessel (pot or boiler), a condenser, and one or more receiving tanks. No trays or packing is provided. Feed is charged into the vessel and brought to boiling. Vapors are condensed and collected in a receiver. No reflux is returned. The rate of vaporization is sometimes limited to prevent "bumping" the charge and to avoid overloading the condenser, but other controls are minimal. This process is often referred to as a Rayleigh distillation.

If we represent the moles of vapor by $V$, the moles of liquid in the pot by $H$, the mole fraction of the more volatile component in this liquid by $x$, and the mole fraction of the same component in the vapor by $y$, a material balance yields

$$-y\,dV = d(Hx) \tag{13-124}$$

Since $dV = -dH$, substitution and expansion give

$$y\,dH = H\,dx + x\,dH \tag{13-125}$$

Rearranging and integrating give

$$\ln \frac{H_i}{H_f} = \int_{x_f}^{x_i} \frac{dx}{y - x} \tag{13-126}$$

where subscript $i$ represents the initial condition and $f$ the final condition of the liquid in the pot. The integration limits have been reversed to obtain a positive integral. Equation (13-126) is equivalent to an integrated form of the defining expression for residue curves in Eq. (13-116), with appropriate substitutions for the variable $\xi$ (see below).

If phase equilibrium is assumed between liquid and vapor, the right-hand side of Eq. (13-126) may be evaluated from the area under a curve of $1/(y - x)$ versus $x$ between the limits $x_i$ and $x_f$. If the mixture is a binary system for which the relative volatility $\alpha$ can be approximated as a constant over the range considered, then the VLE relationship

$$y = \frac{\alpha x}{1 + (\alpha - 1)x} \tag{13-127}$$

can be substituted into Eq. (13-126) and a direct integration can be made:

$$\ln\left(\frac{H_f}{H_i}\right) = \frac{1}{\alpha - 1} \ln\left[\frac{x_f/(1 - x_f)}{x_i/(1 - x_i)}\right] + \ln\left(\frac{1 - x_i}{1 - x_f}\right) \tag{13-128}$$

For any two components $A$ and $B$ of a multicomponent mixture, if constant $\alpha$ values can be assumed for all pairs of components, then $dH_A/dH_B = y_A/y_B = \alpha_{A,B}(x_A/x_B)$. When this is integrated, we obtain

$$\ln\left(\frac{H_{Af}}{H_{A,i}}\right) = \alpha_{A,B} \ln\left(\frac{H_{Bf}}{H_{B,i}}\right) \tag{13-129}$$

where $H_{A,i}$ and $H_{A,f}$ are the moles of component $A$ in the pot before and after distillation and $H_{B,i}$ and $H_{B,f}$ are the corresponding moles of component $B$. Mixtures that cannot be accurately described by using a constant relative volatility require some form of numerical or graphical integration for the solution of Eq. (13-126).

As an example, consider the distillation of an ethanol-water mixture at 101.3 kPa (1 atm). The initial charge is 100 mol of liquid containing 18 mol % ethanol, and the mixture must be reduced to a maximum ethanol concentration in the still of 6 mol %. By using equilibrium data interpolated from Gmehling and Onken [*Vapor-Liquid Equilibrium Data Collection*, DECHEMA Chemistry Data Ser., vol. 1, Part 1, Frankfurt (1977)], we get the following:

| $x$ | $y$ | $y - x$ | $1/(y - x)$ |
|---|---|---|---|
| 0.18 | 0.517 | 0.337 | 2.97 |
| 0.16 | 0.502 | 0.342 | 2.91 |
| 0.14 | 0.485 | 0.345 | 2.90 |
| 0.12 | 0.464 | 0.344 | 2.90 |
| 0.10 | 0.438 | 0.338 | 2.97 |
| 0.08 | 0.405 | 0.325 | 3.08 |
| 0.06 | 0.353 | 0.293 | 3.41 |

The area under a curve of $1/(y - x)$ versus $x$ between $x = 0.06$ and 0.18 is $0.358 = \ln(H_i/H_f)$, so that $H_f = 100/1.43 = 70.0$ mol. The liquid remaining consists of $(70.0)(0.06) = 4.2$ mol of ethanol and 65.8 mol of water. By material balance, the total accumulated distillate must contain $18.0 - 4.2 = 13.8$ mol of alcohol and $82.0 - 65.8 = 16.2$ mol of water. The total distillate is 30 mol, and the average distillate composition is $13.8/30 = 0.46$ mole fraction ethanol. The time, rate of heating, and vapor rate required to carry out the process are related by the energy balance and operating policy, which can be considered separately.

Graphical solutions of models lend significant insight, but there are many cases where such solutions are not possible or where repeated solutions are desired for different conditions. Progress in computer-based models, ranging from specialized simulation software to more general-purpose tools, now permits rapid solutions of most models. One solution of the example above using a general-purpose modeling tool Mathematica® is shown in Fig. 13-118.

The simple batch still provides only one theoretical plate of separation. Its use is usually restricted to laboratory work or preliminary manufacturing in which the products will be held for additional separation at a later time, when most of the volatile component must be removed from the batch before it is processed further, for separation of the batch from heavy undesired components.

## BATCH DISTILLATION WITH RECTIFICATION

To obtain products with a narrow composition range, a batch rectifying still is commonly used. The *batch rectifier* consists of a pot (or reboiler) as in simple distillation, plus a rectifying column, a condenser, some means of accumulating and splitting off a portion of the condensed vapor (distillate) for reflux, and one or more product receivers (Fig. 13-119).

The temperature of the distillate is controlled near the bubble point, and reflux is returned at or near the upper column temperature to permit a true indication of reflux quantity and to improve the column operation. A heat exchanger is used to subcool the remainder of the distillate, which is sent to a product receiver. The column may operate at an elevated pressure or at vacuum, in which case appropriate additional devices must be included to obtain the desired pressure. Equipment design methods for batch still components, except for the pot, typically follow the same principles as those presented for continuous distillation under the assumption of conditions close to a steady state (but see the comments below on the effects of holdup). The design should be checked for each mixture if several mixtures are to be processed. The design should be checked at more than one point for each mixture, since the compositions in the pot and in the column change as the distillation proceeds. The pot design is based on the batch size and the vaporization rate, which are related to the time and rate of heating and cooling available. For existing equipment, the pot size will determine the size of the batch or at least a range of feasible sizes $H_i$.

In operation, a batch of liquid is charged to the pot, and the system is first brought to steady state under total reflux. A portion of the overhead condensate is then continuously withdrawn in accordance with

the established reflux policy. "Cuts" are made by switching to alternate receivers, at which time the operating conditions, e.g., reflux rate, may also be altered. The entire column operates as an enriching or rectifying section. As time proceeds, the composition of the liquid in the pot becomes less rich in the more volatile components, and distillation of a cut is stopped when the accumulated distillate attains the desired average composition.

## OPERATING METHODS

A batch distillation can be operated in several ways:

1. *Constant reflux, varying overhead composition.* The reflux is set at a predetermined value at which it is maintained for the entire run. Since the pot liquid composition is changing, the instantaneous composition of the distillate also changes. The progress of the distillate and pot compositions in a particular binary separation is illustrated in Fig. 13-120. The variation of the distillate composition for a multicomponent batch distillation is shown in Fig. 13-121 (these distillate product cuts have relatively low purity). The shapes of the curves are functions of volatility, reflux ratio, and number of theoretical plates. The distillation is continued until the average distillate composition is at the desired value. In the case of a binary mixture, the overhead is then typically diverted to another receiver, and an intermediate or "slop" cut is withdrawn until the remaining pot liquid meets the required specification. The intermediate cut is usually added to the next batch, which can therefore have a somewhat different composition from the previous batch. For a multicomponent mixture, two or more intermediate cuts may be taken between the product cuts. It is preferred to limit the size of the intermediate cuts as far as practical because they reduce the total amount of feed that can be processed.

2. *Constant overhead composition, varying reflux.* If it is desired to maintain a constant overhead composition in the case of a binary mixture, the amount of reflux returned to the column must be constantly increased throughout the run. As time proceeds, the pot is gradually depleted of the lighter component. The increase in reflux is typically gradual at first and more rapid near the end of a cut. Finally, a point is reached at which there is little of the lighter component remaining in the pot and the reflux ratio has attained a very high value. The receivers are then changed, the reflux is reduced, and an intermediate cut is taken as before. This technique can also be extended to a multicomponent mixture.

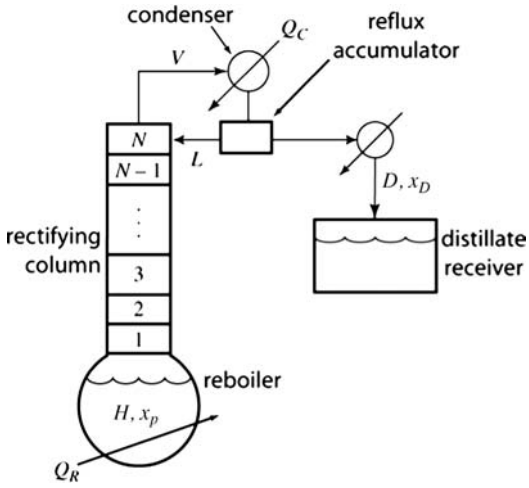

**FIG. 13-119** Schematic of a batch rectifier.

3. *Other methods.* A cycling procedure can also be used for the column operation. The unit operates at total reflux until a steady state is established. The distillate is then taken as total drawoff for a short time, after which the column is returned to total reflux operation. This cycle is repeated throughout the course of distillation. Another possibility is to optimize the reflux ratio to achieve the desired separation in a minimum time. More complex operations may involve withdrawal of sidestreams, provision for intercondensers, addition of feeds to trays, and periodic feed additions to the pot.

## APPROXIMATE CALCULATION PROCEDURES FOR BINARY MIXTURES

A useful analysis for a binary mixture employs the McCabe-Thiele graphical method. In addition to the usual assumptions of an adiabatic column and constant molar overflow on the trays, the following procedure assumes that the holdup of liquid on the trays, in the column,

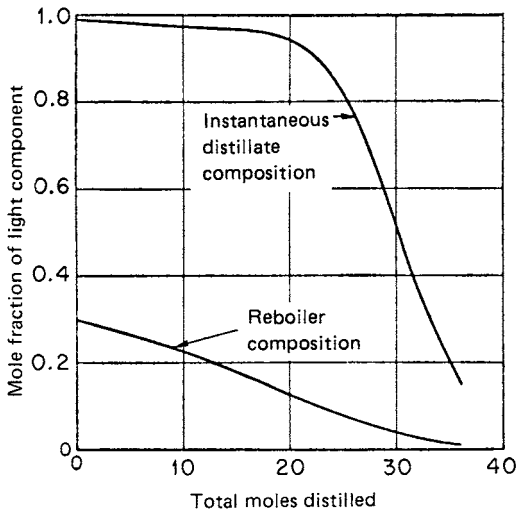

**FIG. 13-120** Variation in distillate and reboiler compositions with the amount distilled in binary batch distillation at a constant reflux ratio.

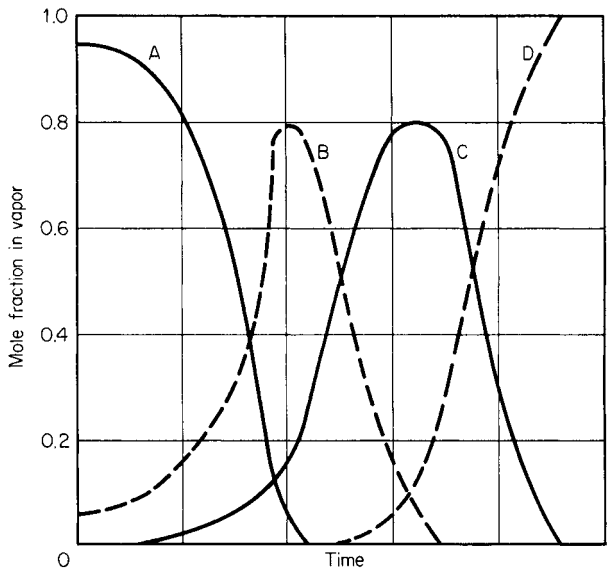

**FIG. 13-121** Distillate composition for a batch distillation of a four-component mixture at a constant reflux ratio.

and in the condenser is negligible compared to the holdup in the pot. (The effects of holdup can be significant and are discussed in a later section.)

As a first step, the minimum reflux ratio should be determined. Point $D$ in Fig. 13-122 represents the desired distillate composition and is located on the diagonal since a total condenser is assumed and $x_D = y_D$. Point $F$ represents the initial composition in the pot $x_{pi}$ and for the vapor entering the bottom of the rectifying column $y_{pi}$. The minimum internal reflux is found from the slope of the line $DF$

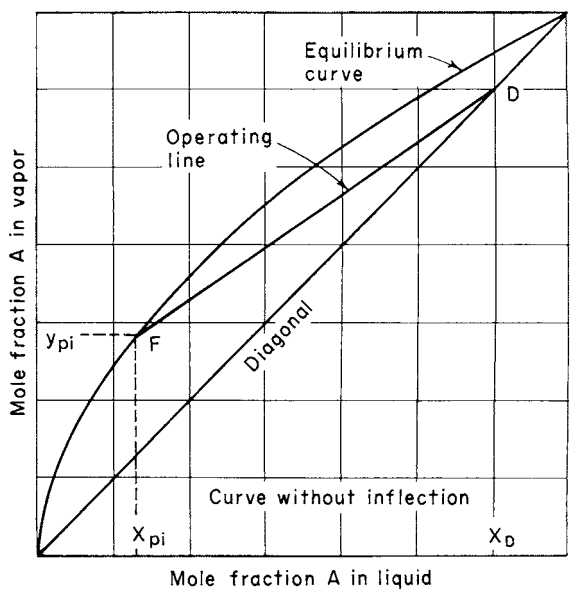

**FIG. 13-122** Determination of the minimum reflux for a relatively ideal equilibrium curve.

$$\left(\frac{L}{V}\right)_{\min} = \frac{y_D - y_{pi}}{x_D - x_{pi}} \tag{13-130}$$

where $L$ is the liquid flow rate and $V$ is the vapor rate, both in moles per hour. Since $V = L + D$ (where $D$ is distillate rate) and the external reflux ratio $R$ is defined as $R = L/D$,

$$\frac{L}{V} = \frac{R}{R+1} \tag{13-131}$$

or

$$R_{\min} = \frac{(L/V)_{\min}}{1 - (L/V)_{\min}} \tag{13-132}$$

The condition of minimum reflux for an equilibrium curve with an inflection point $P$ is shown in Fig. 13-123. In this case the minimum internal reflux is

$$\left(\frac{L}{V}\right)_{\min} = \frac{y_D - y_P}{x_D - x_P} \tag{13-133}$$

The operating reflux ratio is usually 1.5 to 10 times the minimum. By using the ethanol-water equilibrium curve for 101.3-kPa (1-atm) pressure shown in Fig. 13-123 but extending the line to a convenient point for readability, $(L/V)_{\min} = (0.800 - 0.695)/(0.800 - 0.600) = 0.52$ and $R_{\min} = 1.083$.

**Batch Rectification at Constant Reflux** Using an analysis similar to the simple batch still, Smoker and Rose [*Trans. Am. Inst. Chem. Eng.*, **36,** 285 (1940)] developed the following equation:

$$\ln \frac{H_i}{H_f} = \int_{x_{pf}}^{x_{pi}} \frac{dx_p}{x_D - x_p} \tag{13-134}$$

An overall material balance on the light component gives the average or accumulated distillate composition $x_{D,\text{avg}}$.

$$x_{D,\text{avg}} = \frac{H_i x_{pi} - H_f x_{pf}}{H_i - H_f} \tag{13-135}$$

If the integral on the right side of Eq. (13-134) is denoted by $\xi$, the time $\theta$ for distillation can be found by

$$\theta = (R+1)\frac{H_i(e^{\xi} - 1)}{Ve^{\xi}} \tag{13-136}$$

An alternative equation is

$$\theta = \frac{R+1}{V}(H_i - H_f) \tag{13-137}$$

Development of these equations is given by Block [*Chem. Eng.*, **68,** 88 (Feb. 6, 1961)]. The calculation process is illustrated schematically in Fig. 13-124. Operating lines are drawn with the same slope but intersecting the 45° line at different points. The number of theoretical plates under consideration is stepped off to find the corresponding bottoms composition (i.e., still pot composition) for each distillate composition. In Fig. 13-124, operating line $L - 1$ with slope $L/V$ drawn from point $D_1$ where the distillate composition is $x_{D1}$ and the pot composition is $x_{p1\text{-}3}$ for three theoretical plates, $x_{D2}$ has a corresponding pot composition of $x_{p2\text{-}3}$, etc. By using these pairs of distillate and pot compositions, the right-hand side of Eq. (13-134) can be evaluated and $x_{D,\text{avg}}$ can be found from Eq. (13-135). An iterative calculation is required to find the value of $H_f$ that corresponds to a specified $x_{D,\text{avg}}$.

To illustrate the use of these equations, consider a charge of 520 mol of an ethanol-water mixture containing 18 mol % ethanol to be distilled at 101.3 kPa (1 atm). Suppose that the vaporization rate is 75 mol/h, and the product specification is 80 mol % ethanol. Let $L/V = 0.75$, corresponding to a reflux ratio $R = 3.0$. If the column section has six theoretical plates and the pot provides an additional seventh, find how many moles of product will be obtained, what the composition of the pot residue will be, and the time that the distillation will take.

Using the vapor-liquid equilibrium data, plot a $y$-$x$ diagram. Draw a number of operating lines at a slope of 0.75. Note the composition at the 45° intersection, and step off seven stages on each to find the equilibrium value of the bottoms pot composition. Some of the results are tabulated in the following table:

| $x_D$ | $x_p$ | $x_D - x_p$ | $1/(x_D - x_p)$ |
|---|---|---|---|
| 0.800 | 0.323 | 0.477 | 2.097 |
| 0.795 | 0.245 | 0.550 | 1.820 |
| 0.790 | 0.210 | 0.580 | 1.725 |
| 0.785 | 0.180 | 0.605 | 1.654 |
| 0.780 | 0.107 | 0.673 | 1.487 |
| 0.775 | 0.041 | 0.734 | 1.362 |

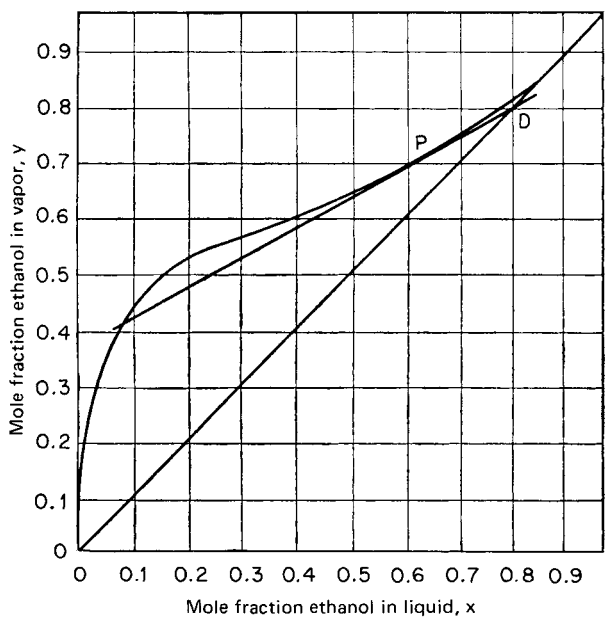

**FIG. 13-123** Determination of minimum reflux for an equilibrium curve with an inflection point.

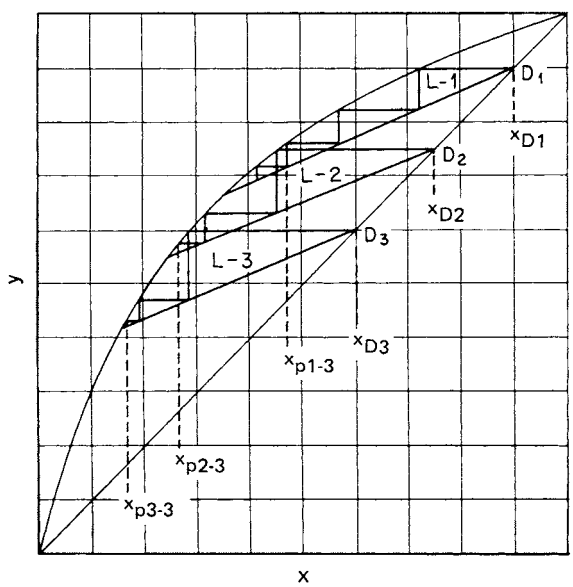

**FIG. 13-124** Graphical method for constant-reflux operation.

By using an iterative procedure, integrating between $x_{pi}$ of 0.18 and various lower limits, it is found that $x_{D,avg} = 0.80$ when $x_{pf} = 0.04$, at which time the value of the integral = 0.205 = ln $(H_i/H_f)$, so that $H_f$ = 424 mol. The product collected = $H_i - H_f$ = 520 − 424 = 96 mol. From Eq. (13-136),

$$\theta = \frac{(4)(520)(e^{0.205} - 1)}{75(e^{0.205})} = 5.2 \text{ h} \qquad (13\text{-}138)$$

**Batch Rectification at Constant Distillate Composition** Bogart [*Trans. Am. Inst. Chem. Eng.*, **33,** 139 (1937)] developed the following equation for constant distillate composition with the column holdup assumed to be negligible:

$$\theta = \frac{H_i(x_D - x_{pi})}{V} \int_{x_{pf}}^{x_{pi}} \frac{dx_p}{(1 - L/V)(x_D - x_p)^2} \qquad (13\text{-}139)$$

and where the terms are defined as before. The quantity distilled can then be found by material balance once the initial and final pot compositions are known.

$$H_i - H_f = \frac{H_i(x_{pi} - x_{pf})}{x_D - x_{pf}} \qquad (13\text{-}140)$$

A schematic example is shown in Fig. 13-125. The distillate composition is held constant by increasing the reflux as the pot composition becomes more dilute. Operating lines with varying slopes (= $L/V$) are drawn from the known distillate composition, and the given number of stages is stepped off to find the corresponding bottoms (still pot) compositions.

As an example, consider the same ethanol-water mixture used above to illustrate constant reflux but now with a constant distillate composition of $x_D = 0.90$. The following table is compiled:

| $L/V$ | $R$ | $x_p$ | $x_D - x_p$ | $1/(1 - L/V)(x_D - x_p)^2$ |
|---|---|---|---|---|
| 0.600 | 1.50 | 0.654 | 0.147 | 115.7 |
| 0.700 | 2.33 | 0.453 | 0.348 | 27.5 |
| 0.750 | 3.00 | 0.318 | 0.483 | 17.2 |
| 0.800 | 4.00 | 0.143 | 0.658 | 11.5 |
| 0.850 | 5.67 | 0.054 | 0.747 | 11.9 |
| 0.900 | 9.00 | 0.021 | 0.780 | 16.4 |

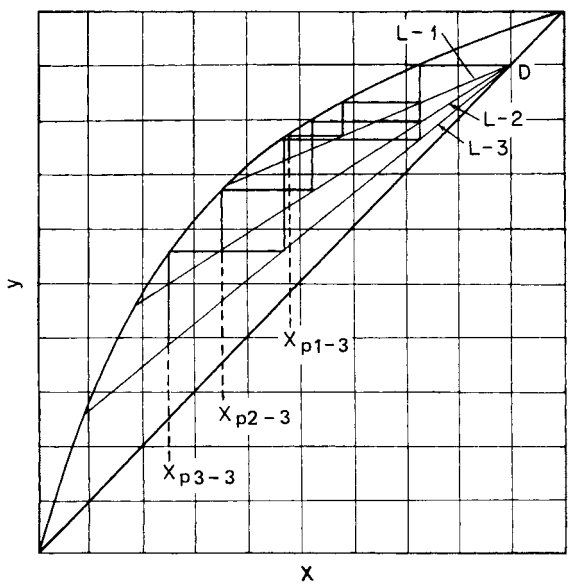

**FIG. 13-125** Schematic of constant distillate composition operation.

If the right-hand side of Eq. (13-139) is integrated by using a limit for $x_{pf}$ of 0.04, the value of the integral is 1.615 and the time is

$$\theta = \frac{(520)(0.800 - 0.180)(1.615)}{75} = 7.0 \text{ h} \qquad (13\text{-}141)$$

The quantity distilled can be found from Eq. (13-140):

$$H_i - H_f = \frac{(520)(0.180 - 0.040)}{0.800 - 0.040} = 96 \text{ mol} \qquad (13\text{-}142)$$

**Other Operating Methods and Optimization** A useful control method for difficult industrial or laboratory distillations is *cycling operation.* The most common form of cycling control is to operate the column at total reflux until steady state is established, take off the complete distillate for a short time, and then return to total reflux. An alternative scheme is to interrupt vapor flow to the column periodically by the use of a solenoid-operated butterfly valve in the vapor line from the pot. In both cases, the equations necessary to describe the system are complex, as shown by Schrodt et al. [*Chem. Eng. Sci.*, **22,** 759 (1967)]. The most reliable method for establishing the cycle relationships is by experimental trial on an operating column. Several investigators have also proposed that batch distillation be programmed to attain *time optimization* by proper variation of the reflux ratio. A comprehensive discussion was first presented by Coward [*Chem. Eng. Sci.*, **22,** 503 (1967)] and reviewed and updated by Kim and Diwekar [*Rev. Chem. Eng.*, **17,** 111 (2001)].

The *choice of operating mode* depends upon characteristics of the specific system, the product specifications, and the engineer's preference in setting up a control sequence. Probably the most direct and most common method is *constant reflux.* Operation can be regulated by a timed reflux splitter, a ratio controller, or simply a pair of flowmeters. Since composition is changing with time, some way must be found to estimate the average accumulated distillate composition in order to define the endpoint. This is no problem when the specification is not critical or the change in distillate composition is sharply defined. However, when the composition of the distillate changes slowly with time, the cut point is more difficult to determine. Operating with *constant composition* (varying reflux), the specification is automatically achieved if control can be linked to composition or some composition-sensitive physical variable. The relative advantage of the two modes depends upon the materials being separated and upon the number of theoretical plates in the column. A comparison of distillation rates using the same initial and final pot composition for the system benzene-toluene is given in Fig. 13-126. Typical control instrumentation is described by Block [*Chem. Eng.*, **74,** 147 (Jan. 16, 1967)]. Control procedures for *reflux and vapor cycling* operation and for the *time-optimal* process are largely a matter of empirical trial.

**Effects of Column Holdup** When the holdup of liquid on the trays and in the condenser and reflux accumulator is not negligible compared with the holdup in the pot, the distillate composition at constant reflux ratio changes with time at a different rate than when the column holdup is negligible because of two separate effects.

First, with an appreciable column holdup, the composition of the charge to the pot will be higher in the light component than the pot composition at the start of the distillation. The reason is that before product takeoff begins, the column holdup must be supplied, and due to the rectification, its average composition is higher in the lighter component than that of the liquid charged as feed to the pot. Thus, when overhead takeoff begins, the pot composition is lower than it would be if there were negligible column holdup and the separation is more difficult than expected based on the composition of the feed. The second effect of column holdup is to slow the rate of exchange of the components; the holdup exerts an inertial effect, which prevents compositions from changing as rapidly as they would otherwise, and the degree of separation is usually improved.

Both these effects occur at the same time and change in importance during the course of distillation. Although a number of studies were made and approximate methods developed for predicting the effect of liquid holdup during the 1950s and 1960s (summarized in the 6th edition of *Perry's Chemical Engineers' Handbook*), it is now best to use simulation methods to determine the effect of holdup on a case-by-case basis.

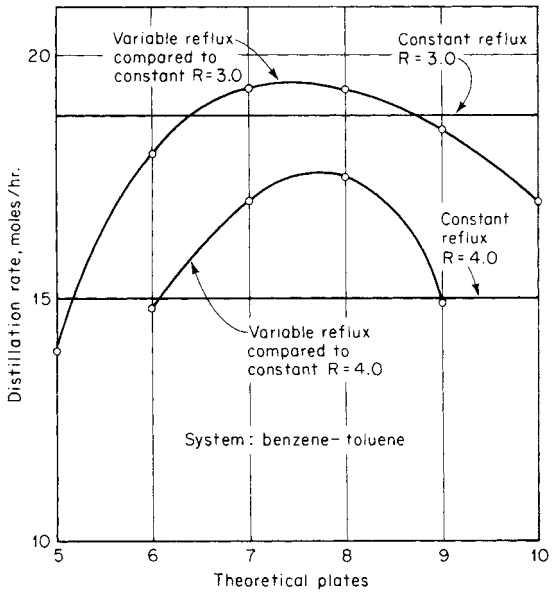

**FIG. 13-126** Comparison of operating modes for a batch column.

As an example, consider a batch rectifier fed with a 1:1 mixture of ethanol and *n*-propanol. The rectifier has eight theoretical stages in the column and is operated at a reflux ratio of 19. The distillate and pot compositions are shown in Fig. 13-127 for various values of the holdups.

In Fig. 13-127*a*, the holdup on each stage is 0.01 percent of the initial pot holdup, and in the reflux accumulator it is 0.1 percent of the initial pot holdup (for a total of 0.108 percent). Because this model calculation does not begin with a total reflux period, there is a small initial distillate cut with relatively low ethanol purity. This is followed by a high-purity distillate cut. An intermediate cut of approximately 10 percent of the initial batch size can be collected, leaving the pot with a high purity of *n*-propanol. The column holdup for the case shown in Fig. 13-127*b* is 1 percent of the initial batch size on each stage while the reflux accumulator holdup remains small at 0.1 percent (for a total of 8.1 percent). In this case, both the first low-purity cut and the intermediate cut are somewhat larger for the same purity specifications. These effects are substantially larger when the reflux accumulator has a more significant holdup, as shown in Fig. 13-127*c*, corresponding to a holdup of 1 percent on each stage and 5 percent in the reflux accumulator (for a total of 13 percent). Similar effects are found for multicomponent mixtures. The impact of column and condenser holdup is most important when a high-purity cut is desired for a component that is present in relatively small amounts in the feed.

## SHORTCUT METHODS FOR MULTICOMPONENT BATCH RECTIFICATION

For preliminary studies of batch rectification of multicomponent mixtures, shortcut methods that assume constant molar overflow and negligible vapor and liquid holdup are useful in some cases (see the discussion above concerning the effects of holdup). The method of Diwekar and Madhaven [*Ind. Eng. Chem. Res.*, **30,** 713 (1991)] can be used for constant reflux or constant overhead rate. The method of Sundaram and Evans [*Ind. Eng. Chem. Res.*, **32,** 511 (1993)] applies only to the case of constant reflux, but is easy to implement. Both methods employ the Fenske-Underwood-Gilliland (FUG) shortcut procedure at successive time steps. Thus, batch rectification is treated as a sequence of continuous, steady-state rectifications.

## CALCULATION METHODS AND SIMULATION

Model predictions such as those shown in Fig. 13-126 or 13-127 are relatively straightforward to obtain by using modern simulation models and software tools. As discussed in earlier editions of this handbook, such models and algorithms for their solutions have been the subject of intensive study since the early 1960s when digital computing became practical. Detailed calculation procedures for binary and multicomponent batch distillation were initially focused on binary mixtures of constant relative volatility. For example, Huckaba and Danly [*AIChE J.*, **6,** 335 (1960)] developed a simulation model that incorporated more details than can be included in the simple analytical models described above. They assumed constant-mass tray holdups, adiabatic tray operation, and linear enthalpy relationships, but did include energy balances around each tray and permitted the use of nonequilibrium trays by means of specified tray efficiencies. Experimental data were provided to validate the simulation. Meadows [*Chem. Eng. Prog. Symp. Ser.* **46,** 59, 48 (1963)] presented a multicomponent batch distillation model that included equations for energy, material, and volume balances around theoretical trays. The only assumptions made were perfect mixing on each tray, negligible vapor holdup, adiabatic operation, and constant-volume tray holdup. Distefano [*AIChE. J.*, **14,** 190 (1968)] extended the model and developed a procedure that was used to simulate several commercial batch distillation columns successfully. Boston et al. (*Foundations of Computer-Aided Chemical Process Design*, vol. 2, Mah and Seider, eds., *American Institute of Chemical Engineers*, New York, 1981, p. 203) further extended the model, provided a variety of practical sets of specifications, and utilized modern numerical procedures and equation formulations to handle efficiently the nonlinear and often stiff nature of the multicomponent batch distillation problem.

It is important to note that in using computer-aided models for batch distillation, the various assumptions of the model can have a significant impact on the accuracy of the results; e.g., see the discussion of the effects of holdup above. Uncertainties in the physical and chemical parameters in the models can be addressed most effectively by a combination of sensitivity calculations using simulation tools, along with comparison to data. The mathematical treatment of stiffness in the model equations can also be very important, and there is often a substantial advantage in using simulation tools that take special account of this stiffness. (See the 7th edition of *Perry's Chemical Engineers' Handbook* for a more detailed discussion of this aspect).

The availability of detailed models and solution methods has enabled many new studies of complex, mixtures, configurations, and operating and control strategies for batch distillation.

## CONSTANT-LEVEL DISTILLATION

Manipulation of the operating conditions such as reflux ratio or pressure during a batch distillation can be useful. In addition, the feed to the batch distillation may vary during the process. A common application is to replace one solvent with another in the presence of a heavy nonvolatile product, as may be encountered in pharmaceutical production. One option for switching solvents is to use simple distillation repeatedly. Initially, a portion of the first solvent is removed by boiling. Then the second solvent is added, and a simple distillation removes more of the first solvent along with some of the second. Repetition of the latter step can be used to reduce the concentration of the first solvent to very small levels.

Gentilcore [*Chem. Eng. Progr.*, **98**(1), 56 (Jan. 2002)] describes an alternative strategy of "constant-level" batch distillation where the replacement solvent is added at a rate to keep the volume of liquid in the pot constant. For simple distillation without rectification the analog of Eq. (13-126) is

$$\frac{S}{H} = \int_{x_f}^{x_i} \frac{dx}{y} \tag{13-143}$$

and the analog of Eq. (13-128) is

$$\frac{S}{H} = \frac{1}{\alpha} \ln \frac{x_i}{x_f} + \frac{\alpha - 1}{\alpha}(x_i - x_f) \tag{13-144}$$

where the mole fractions refer to the compositions of the original solvent and $S$ is the amount of the second solvent added to the batch. The amount of solute, a nonvolatile heavy product, is small compared to the size of the batch (alternatively, the analysis can be done on a

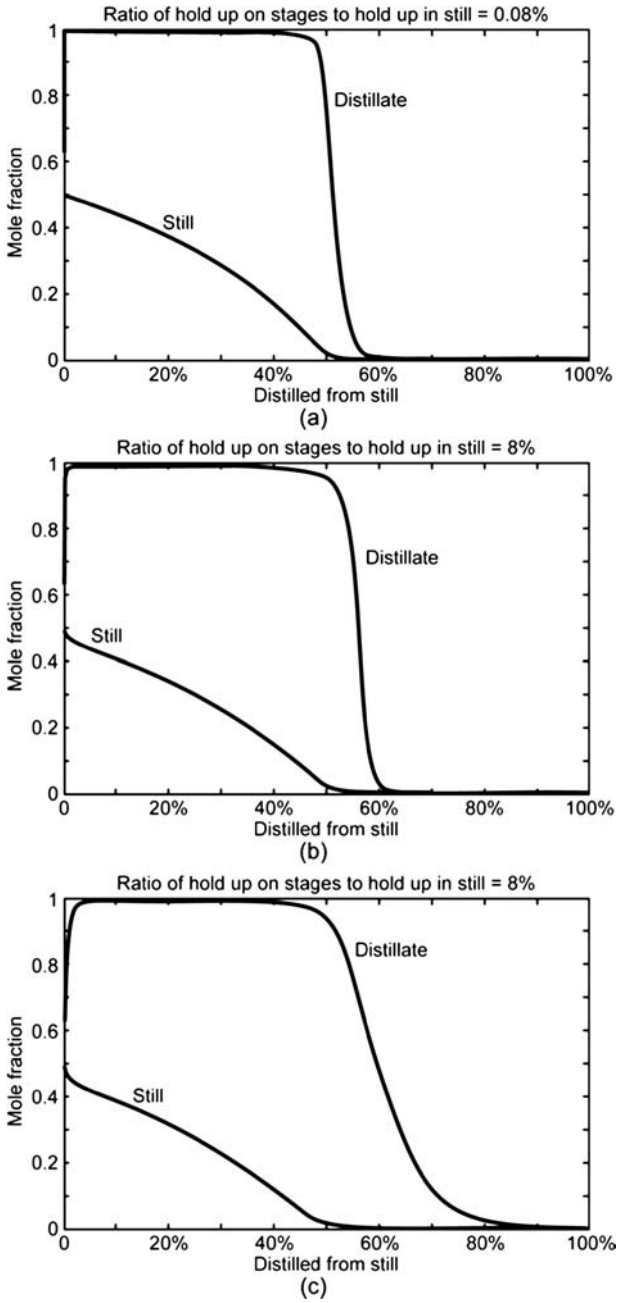

**FIG. 13-127** Effects of holdup on batch rectifier.

solute-free basis). The second solvent is assumed to be pure, and the rate of addition is manipulated to keep a constant level in the pot. Compared to the repeated application of simple distillation, this semibatch operation can typically reduce solvent use by one-half or more depending on the volatility and the desired compositions. This is also a more efficient use of equipment at the expense of a somewhat more complex operation.

An example provided by Gentilcore considers a simple batch still that operates with an initial charge of 80 mol and a minimum of 20 mol. The original solvent use has a volatility $\alpha = 3$ relative to that of the replacement solvent. If simple distillation is used, 60 mol of the original solvent is initially boiled off and then 60 mol of the second solvent is added. A second distillation of this mixture begins with a composition $x_i = 0.25$ of the original solvent. The solution of Eq. (13-128) by trial and error or root finding gives $x_f = 0.03$ for $H_i = 80$ and $H_f = 20$. Of the 60 mol removed as distillate in this second distillation, 20 – 0.03 = 19.97 mol is the original solvent and 60 – 19.97 = 40.03 mol is the replacement. An alternative constant-level batch distillation in the same equipment according to Eq. (13-144) with $H = 20$, $x_i = 0.25$, and $x_f = 0.03$ requires the addition of $S = 35.6$ mol of replacement solvent. The still contains 20 mol of the solvent; 16.2 mol is distilled compared to 40.3 mol in the simple distillation. This 60 percent savings in the use of replacement solvent arises because the distillation takes place beginning with a higher concentration of the original solvent for the second step.

## ALTERNATIVE EQUIPMENT CONFIGURATIONS

The batch rectifier shown schematically in Fig. 13-119 is by far the most common configuration of equipment. Several alternative special-purpose configurations have been studied and offer potential advantages in particular applications. Also see Doherty and Malone (*Conceptual Design of Distillation Systems,* McGraw-Hill, 2001, pp. 407–409, 417–419).

For instance, a simple batch distillation can be combined with a stripping column to give the batch stripper shown in Fig. 13-128. The pot holds the batch charge and provides liquid reflux into the stripping section. The reboiler provides vapor to the column and has relatively small holdup. The product stream $B$ in the bottom is concentrated in the higher-boiling compound, and the pot gradually becomes more concentrated in the lighter component. Multiple "cuts" can be taken as products, and the reboil rate either can be constant or can be adjusted by analogy with the reflux ratio in the batch rectifier.

For mixtures containing large concentrations of a heavy component, the batch stripper can be advantageous.

The more complex "middle vessel" column combines aspects of both the batch rectifier and the batch stripper, as shown in Fig. 13-129. The middle vessel arrangement was described qualitatively by Robinson and Gilliland (*Elements of Fractional Distillation,* McGraw-Hill, 1950, p. 388) and analyzed by Bortolini and Guirase [*Quad. Ing. Chim. Ital.,* **6,** 150 (1970)]. This configuration requires more equipment and is more complex, but can produce both distillate and bottoms product cuts simultaneously. Barolo and Botteon [*AIChE J.,* **43,** 2601 (1997)] pointed out that the middle vessel configuration at total reflux and reboil and with the appropriate collection equipment for distillate and bottoms products (not shown in Fig. 13-129) can concentrate a ternary mixture into its three pure fractions. This and analogous configurations for mixtures with more components have been studied by Hasebe et al. [*J. Chem. Eng. Japan,* **29,** 1000 (1996); *Computers Chem. Engng.,* **23,**

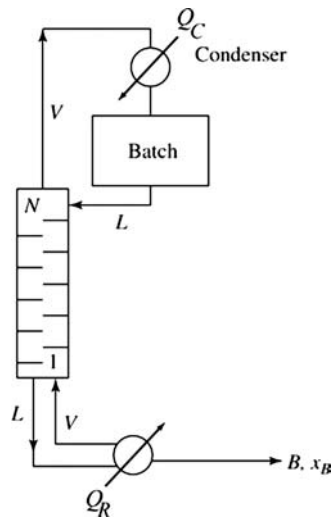

**FIG. 13-128** Schematic of a batch stripper.

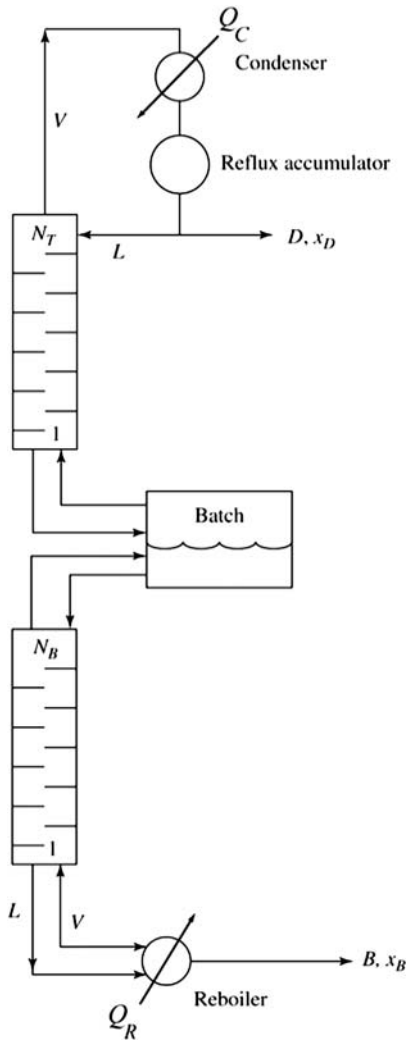

**FIG. 13-129** Middle vessel batch distillation.

523 (1999)] and experimentally by Wittgens and Skogestad [*IChemE Symp Ser.*, **142,** 239 (1997).]

The batch stripper and the middle vessel configurations provide the capability to make separations for certain azeotropic mixtures that are not possible or that cannot be done efficiently in the batch rectifier.

## BATCH DISTILLATION OF AZEOTROPIC MIXTURES

Although azeotropic distillation is covered in an earlier subsection, it is appropriate to consider the application of residue curve maps to batch distillation here. (See the subsection Enhanced Distillation for a discussion of residue curve maps.) An essential point is that the sequence, number, and limiting composition of each cut from a batch distillation depend on the form of the residue curve map and the composition of the initial charge to the still. As with continuous distillation operation, the set of reachable products (cuts) for a given charge to a batch distillation is constrained by the residue curve–map distillation boundaries. Furthermore, some pure components can be produced as products from the batch stripper, but not the batch rectifier and vice versa. Doherty and Malone (*Conceptual Design of Distillation Systems,* chap. 9, McGraw-Hill, 2001) give more details, but the main points are the following.

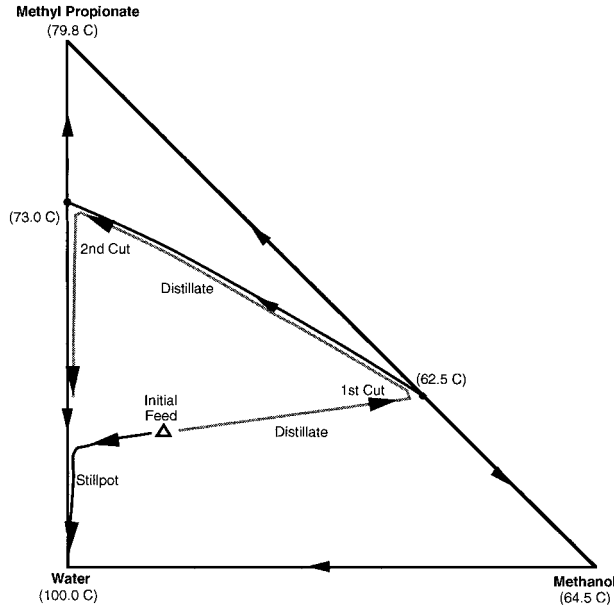

**FIG. 13-130** Residue curve map and batch rectifier paths for methanol, methyl propionate, and water.

In the batch rectifier, the limiting cuts, obtainable with a sufficiently large number of stages and reflux, begin with the low-boiling node that defines the distillation region containing the feed composition. For the batch stripper, the first limiting cut is the high-boiling node. In either case, the subsequent cuts depend on the structure of the residue curve map.

For the batch rectifier, as the low-boiling component or azeotrope is removed, the still composition moves along a straight material balance line through the initial feed composition and the low-boiling node and away from the initial composition until it reaches the edge of the composition triangle or a distillation boundary. The path then follows the edge or distillation boundary to the high-boiling node of the region.

As an example, consider the residue curve map structure shown in Fig. 13-130 for a mixture of methanol, methyl propionate, and water at a pressure of 1 atm. There are two minimum-boiling binary azeotropes joined by a distillation boundary that separates the compositions into two distillation regions. Feeds in the upper and lower regions will have different distillate products. For the sample feed shown, and with a sufficient number of theoretical stages and reflux, the distillate will rapidly approach the low-boiling azeotrope of methanol and methyl propionate at 62.5°C. The still pot composition changes along the straight-line segment as shown until it is nearly free of methanol. At that point, the distillate composition changes rapidly along the distillation boundary to a composition for the second cut at or near the methyl propionate–water azeotrope. The still pot composition eventually approaches pure water. The rate of change and the precise approach to these compositions require more detailed study.

For the same feed, a batch stripper can be used to remove a bottoms product that approaches pure water. The pot composition (overhead) will contain all three components near the point of intersection of the distillation boundary with a straight line extended from the water vertex through the feed composition.

For this mixture it is not possible to isolate the pure components in a batch rectifier or batch stripper. The use of additional equipment such as a decanter to exploit liquid-liquid phase behavior or the addition of a fourth component or chemical reactions can sometimes be used to effect the separation.

The product cuts for azeotropic mixtures are also sensitive to the curvature of the distillation boundaries; see Doherty and Malone (*Conceptual Design of Distillation Systems,* McGraw-Hill, 2001; pp. 403–404) and additional references there.

## EQUIPMENT FOR DISTILLATION AND GAS ABSORPTION: TRAY COLUMNS

Definitions . . . 14-26
Tray Area Definitions . . . 14-26
Vapor and Liquid Load Definitions . . . 14-27
Flow Regimes on Trays . . . 14-27
Primary Tray Considerations . . . 14-29
Number of Passes . . . 14-29
Tray Spacing . . . 14-29
Outlet Weir . . . 14-29
Downcomers . . . 14-29
Clearance under the Downcomer . . . 14-31
Hole Sizes . . . 14-31
Fractional Hole Area . . . 14-31
Multipass Balancing . . . 14-32
Tray Capacity Enhancement . . . 14-32
Truncated Downcomers/Forward Push Trays . . . 14-32
High Top to Bottom Downcomer Area and Forward Push . . . 14-34
Large Number of Truncated Downcomers . . . 14-34
Radial Trays . . . 14-34
Centrifugal Force Deentrainment . . . 14-34
Other Tray Types . . . 14-34
Bubble-Cap Trays . . . 14-34
Dual-Flow Trays . . . 14-34
Baffle Trays . . . 14-34
Flooding . . . 14-36
Entrainment (Jet) Flooding . . . 14-36
Spray Entrainment Flooding Prediction . . . 14-36
Example 9: Flooding of a Distillation Tray . . . 14-38
System Limit (Ultimate Capacity) . . . 14-38
Downcomer Backup Flooding . . . 14-38
Downcomer Choke Flooding . . . 14-39
Derating ("System") Factors . . . 14-40
Entrainment . . . 14-40
Effect of Gas Velocity . . . 14-40
Effect of Liquid Rate . . . 14-40
Effect of Other Variables . . . 14-40
Entrainment Prediction . . . 14-41
Example 10: Entrainment Effect on Tray Efficiency . . . 14-42
Pressure Drop . . . 14-42
Example 11: Pressure Drop, Sieve Tray . . . 14-44
Loss under Downcomer . . . 14-44
Other Hydraulic Limits . . . 14-44
Weeping . . . 14-44
Dumping . . . 14-46
Turndown . . . 14-47
Vapor Channeling . . . 14-47
Transition between Flow Regimes . . . 14-47
Froth-Spray . . . 14-47

Valve Trays . . . 14-48
Tray Efficiency . . . 14-48
Definitions . . . 14-48
Fundamentals . . . 14-48
Factors Affecting Tray Efficiency . . . 14-49
Obtaining Tray Efficiency . . . 14-50
Rigorous Testing . . . 14-50
Scale-up from an Existing Commercial Column . . . 14-50
Scale-up from Existing Commercial Column to Different Process Conditions . . . 14-50
Experience Factors . . . 14-50
Scale-up from a Pilot or Bench-Scale Column . . . 14-51
Empirical Efficiency Prediction . . . 14-52
Theoretical Efficiency Prediction . . . 14-53
Example 12: Estimating Tray Efficiency . . . 14-53

## EQUIPMENT FOR DISTILLATION AND GAS ABSORPTION: PACKED COLUMNS

Packing Objectives . . . 14-53
Random Packings . . . 14-53
Structured Packings . . . 14-54
Packed-Column Flood and Pressure Drop . . . 14-55
Flood-Point Definition . . . 14-56
Flood and Pressure Drop Prediction . . . 14-57
Pressure Drop . . . 14-59
Example 13: Packed-Column Pressure Drop . . . 14-62
Packing Efficiency . . . 14-63
HETP vs. Fundamental Mass Transfer . . . 14-63
Factors Affecting HETP: An Overview . . . 14-63
HETP Prediction . . . 14-63
Underwetting . . . 14-67
Effect of Lambda . . . 14-67
Pressure . . . 14-67
Physical Properties . . . 14-67
Errors in VLE . . . 14-68
Comparison of Various Packing Efficiencies for Absorption and Stripping . . . 14-68
Summary . . . 14-69
Maldistribution and Its Effects on Packing Efficiency . . . 14-69
Modeling and Prediction . . . 14-69
Implications of Maldistribution to Packing Design Practice . . . 14-70
Packed-Tower Scale-up . . . 14-72
Diameter . . . 14-72
Height . . . 14-72
Loadings . . . 14-73
Wetting . . . 14-73
Underwetting . . . 14-73
Preflooding . . . 14-73
Sampling . . . 14-73
Aging . . . 14-73
Distributors . . . 14-73
Liquid Distributors . . . 14-73
Flashing Feed and Vapor Distributors . . . 14-76
Other Packing Considerations . . . 14-76
Liquid Holdup . . . 14-76
Minimum Wetting Rate . . . 14-79
Two Liquid Phases . . . 14-79
High Viscosity and Surface Tension . . . 14-80

## OTHER TOPICS FOR DISTILLATION AND GAS ABSORPTION EQUIPMENT

Comparing Trays and Packings . . . 14-80
Factors Favoring Packings . . . 14-80
Factors Favoring Trays . . . 14-80
Trays vs. Random Packings . . . 14-81
Trays vs. Structured Packings . . . 14-81
Capacity and Efficiency Comparison . . . 14-81
System Limit: The Ultimate Capacity of Fractionators . . . 14-81
Wetted-Wall Columns . . . 14-82
Flooding in Wetted-Wall Columns . . . 14-85
Column Costs . . . 14-85
Cost of Internals . . . 14-85
Cost of Column . . . 14-86

## PHASE DISPERSION

Basics of Interfacial Contactors . . . 14-86
Steady-State Systems: Bubbles and Droplets . . . 14-86
Unstable Systems: Froths and Hollow Cone Atomizing Nozzles . . . 14-88
Surface Tension Makes Liquid Sheets and Liquid Columns Unstable . . . 14-88
Little Droplets and Bubbles vs. Big Droplets and Bubbles—Coalescence vs. Breakup . . . 14-88
Empirical Design Tempered by Operating Data . . . 14-88
Interfacial Area—Impact of Droplet or Bubble Size . . . 14-88
Example 14: Interfacial Area for Droplets/Gas in Cocurrent Flow . . . 14-88
Example 15: Interfacial Area for Droplets Falling in a Vessel . . . 14-88
Example 16: Interfacial Area for Bubbles Rising in a Vessel . . . 14-88
Rate Measures, Transfer Units, Approach to Equilibrium, and Bypassing . . . 14-89
What Controls Mass/Heat Transfer: Liquid or Gas Transfer or Bypassing . . . 14-89
Liquid-Controlled . . . 14-89
Gas-Controlled . . . 14-89
Bypassing-Controlled . . . 14-89
Rate Measures for Interfacial Processes . . . 14-89
Approach to Equilibrium . . . 14-89
Example 17: Approach to Equilibrium—Perfectly Mixed, Complete Exchange . . . 14-89
Example 18: Approach to Equilibrium—Complete Exchange but with 10 Percent Gas Bypassing . . . 14-89
Approach to Equilibrium—Finite Contactor with No Bypassing . . . 14-89
Example 19: Finite Exchange, No Bypassing, Short Contactor . . . 14-89
Example 20: A Contactor That Is Twice as Long, No Bypassing . . . 14-90
Transfer Coefficient—Impact of Droplet Size . . . 14-90
Importance of Turbulence . . . 14-90
Examples of Contactors . . . 14-90
High-Velocity Pipeline Contactors . . .
Example 21: Doubling the Velocity in a Horizontal Pipeline Contactor—Impact on Effective Heat Transfer . . . 14-90
Vertical Reverse Jet Contactor . . . 14-90
Example 22: The Reverse Jet Contactor, U.S. Patent 6,339,169 . . . 14-91
Simple Spray Towers . . . 14-91
Bypassing Limits Spray Tower Performance in Gas Cooling . . . 14-91
Spray Towers in Liquid-Limited Systems—Hollow Cone Atomizing Nozzles . . . 14-91
Devolatilizers . . . 14-91
Spray Towers as Direct Contact Condensers . . . 14-91
Converting Liquid Mass-Transfer Data to Direct Contact Heat Transfer . . . 14-91
Example 23: Estimating Direct Contact Condensing Performance Based on $k_L a$ Mass-Transfer Data . . . 14-91
Example 24: HCl Vent Absorber . . . 14-91
Liquid-in-Gas Dispersions . . . 14-91
Liquid Breakup into Droplets . . . 14-91
Droplet Breakup—High Turbulence . . . 14-92
Liquid-Column Breakup . . . 14-92
Liquid-Sheet Breakup . . . 14-92
Isolated Droplet Breakup—in a Velocity Field . . . 14-92
Droplet Size Distribution . . . 14-93
Atomizers . . . 14-93
Hydraulic (Pressure) Nozzles . . . 14-93
Effect of Physical Properties on Drop Size . . . 14-93
Effect of Pressure Drop and Nozzle Size . . . 14-93
Spray Angle . . . 14-93
Two-Fluid (Pneumatic) Atomizers . . . 14-94
Rotary Atomizers . . . 14-95
Pipeline Contactors . . . 14-95
Entrainment due to Gas Bubbling/Jetting through a Liquid . . . 14-96
"Upper Limit" Flooding in Vertical Tubes . . . 14-97
Fog Condensation—The Other Way to Make Little Droplets . . . 14-97
Spontaneous (Homogeneous) Nucleation . . . 14-98
Growth on Foreign Nuclei . . . 14-98
Dropwise Distribution . . . 14-98
Gas-in-Liquid Dispersions . . . 14-98
Objectives of Gas Dispersion . . . 14-99
Theory of Bubble and Foam Formation . . . 14-100
Characteristics of Dispersion . . . 14-102
Methods of Gas Dispersion . . . 14-104
Equipment Selection . . . 14-106
Mass Transfer . . . 14-108
Axial Dispersion . . . 14-111

## PHASE SEPARATION

Gas-Phase Continuous Systems . . . 14-111
Definitions: Mist and Spray . . . 14-112
Gas Sampling . . . 14-112
Particle Size Analysis . . . 14-112
Collection Mechanisms . . . 14-113
Procedures for Design and Selection of Collection Devices . . . 14-113
Collection Equipment . . . 14-114
Energy Requirements for Inertial-Impaction Efficiency . . . 14-123
Collection of Fine Mists . . . 14-124
Fiber Mist Eliminators . . . 14-125
Electrostatic Precipitators . . . 14-125
Electrically Augmented Collectors . . . 14-125
Particle Growth and Nucleation . . . 14-126
Other Collectors . . . 14-126
Continuous Phase Uncertain . . . 14-126
Liquid-Phase Continuous Systems . . . 14-126
Types of Gas-in-Liquid Dispersions . . . 14-126
Separation of Unstable Systems . . . 14-127
Separation of Foam . . . 14-127
Physical Defoaming Techniques . . . 14-128
Chemical Defoaming Techniques . . . 14-128
Foam Prevention . . . 14-129
Automatic Foam Control . . . 14-129

**Nomenclature**

| | | | |
|---|---|---|---|
| $a, a_e$ | Effective interfacial area | $m^2/m^3$ | $ft^2/ft^3$ |
| $a_p$ | Packing surface area per unit volume | $m^2/m^3$ | $ft^2/ft^3$ |
| $A$ | Absorption factor $L_M/(mG_M)$ | -/- | -/- |
| $A$ | Cross-sectional area | $m^2$ | $ft^2$ |
| $A_a$ | Active area, same as bubbling area | $m^2$ | $ft^2$ |
| $A_B$ | Bubbling (active) area | $m^2$ | $ft^2$ |
| $A_D$ | Downcomer area (straight vertical downcomer) | $m^2$ | $ft^2$ |
| $A_{da}$ | Downcomer apron area | $m^2$ | $ft^2$ |
| $A_{DB}$ | Area at bottom of downcomer | $m^2$ | $ft^2$ |
| $A_{DT}$ | Area at top of downcomer | $m^2$ | $ft^2$ |
| $A_e$, $A'$ | Effective absorption factor (Edmister) | -/- | -/- |
| $A_f$ | Fractional hole area | -/- | -/- |
| $A_h$ | Hole area | $m^2$ | $ft^2$ |
| $A_N$ | Net (free) area | $m^2$ | $ft^2$ |
| $A_S$ | Slot area | $m^2$ | $ft^2$ |
| $A_{SO}$ | Open slot area | $m^2$ | $ft^2$ |
| $A_T$ | Tower cross-section area | $m^2$ | $ft^2$ |
| $c$ | Concentration | kg·mol/$m^3$ | lb·mol/$ft^3$ |
| $c'$ | Stokes-Cunningham correction factor for terminal settling velocity | -/- | -/- |
| $C$ | $C$-factor for gas loading, Eq. (14-77) | m/s | ft/s |
| $C_1$ | Coefficient in regime transition correlation, Eq. (14-129) | -/- | -/- |
| $C_1$, $C_2$ | Parameters in system limit equation | m/s | ft/s |
| $C_3$, $C_4$ | Constants in Robbins' packing pressure drop correlation | -/- | -/- |
| CAF | Flood $C$-factor, Eq. (14-88) | m/s | ft/s |
| $CAF_0$ | Uncorrected flood $C$-factor, Fig. 14-30 | — | ft/s |
| $C_d$ | Coefficient in clear liquid height correlation, Eq. (14-116) | -/- | -/- |
| $C_G$ | Gas $C$-factor; same as $C$ | m/s | ft/s |
| $C_L$ | Liquid loading factor, Eq. (14-144) | m/s | ft/s |
| $C_{LG}$ | A constant in packing pressure drop correlation, Eq. (14-143) | $(m/s)^{0.5}$ | $(ft/s)^{0.5}$ |
| CP | Capacity parameter (packed towers), Eq. (14-140) | | |
| $C_{SB}$, $C_{sb}$ | $C$-factor at entrainment flood, Eq. (14-80) | m/s | ft/s |
| $C_{sbf}$ | Capacity parameter corrected for surface tension | m/s | ft/s |
| $C_c$, $C_V$ | Discharge coefficient, Fig. 14-35 | -/- | -/- |
| $C_w$ | A constant in weep rate equation, Eq. (14-123) | -/- | -/- |
| $C_{XY}$ | Coefficient in Eq. (14-159) reflecting angle of inclination | -/- | -/- |
| $d$ | Diameter | m | ft |
| $d_b$ | Bubble diameter | m | ft |
| $d_h$, $d_H$ | Hole diameter | mm | in |
| $d_o$ | Orifice diameter | m | ft |
| $d_{pc}$ | Cut size of a particle collected in a device, 50% mass efficiency | μm | ft |
| $d_{psd}$ | Mass median size particle in the pollutant gas | μm | ft |
| $d_{pa50}$ | Aerodynamic diameter of a real median size particle | μm | ft |
| $d_w$ | Weir diameter, circular weirs | mm | in |
| $D$ | Diffusion coefficient | $m^2/s$ | $ft^2/s$ |
| $D$ | Tube diameter (wetted-wall columns) | m | ft |
| $D_{32}$ | Sauter mean diameter | m | ft |
| $D_g$ | Diffusion coefficient | $m^2/s$ | $ft^2/h$ |
| $D_p$ | Packing particle diameter | m | ft |
| $D_T$ | Tower diameter | m | ft |
| $D_{tube}$ | Tube inside diameter | m | ft |
| $D_{vm}$ | Volume mean diameter | m | ft |
| $e$ | Absolute entrainment of liquid | kg·mol/h | lb·mol/h |
| $e$ | Entrainment, mass liquid/mass gas | kg/kg | lb/lb |
| $E$ | Plate or stage efficiency, fractional | -/- | -/- |
| $E$ | Power dissipation per mass | W | Btu/lb |
| $E_a$ | Murphree tray efficiency, with entrainment, gas concentrations, fractional | -/- | -/- |
| $E_g$ | Point efficiency, gas phase only, fractional | -/- | -/- |
| $E_{oc}$ | Overall column efficiency, fractional | -/- | -/- |
| $E_{OG}$ | Overall point efficiency, gas concentrations, fractional | -/- | -/- |
| $E_{mv}$, $E_{MV}$ | Murphree tray efficiency, gas concentrations, fractional | -/- | -/- |
| $E_s$ | Entrainment, kg entrained liquid per kg gas upflow | kg/kg | lb/lb |
| $f$ | Fractional approach to flood | -/- | -/- |
| $f$ | Liquid maldistribution fraction | -/- | -/- |
| $f_{max}$ | Maximum value of $f$ above which separation cannot be achieved | -/- | -/- |
| $f_w$ | Weep fraction, Eq. (14–121) | -/- | -/- |
| $F$ | Fraction of volume occupied by liquid phase, system limit correlation, Eq. (14-170) | -/- | -/- |
| $F$ | F-factor for gas loading Eq. (14-76) | $m/s(kg/m^3)^{0.5}$ | $ft/s(lb/ft^3)^{0.5}$ |
| $F_{LG}$ | Flow parameter, Eq. (14-89) and Eq. (14-141) | -/- | -/- |
| $F_p$ | Packing factor | $m^{-1}$ | $ft^{-1}$ |
| $F_{pd}$ | Dry packing factor | $m^{-1}$ | $ft^{-1}$ |
| FPL | Flow path length | m | ft |
| Fr | Froude number, clear liquid height correlation, Eq. (14-120) | -/- | -/- |
| $Fr_h$ | Hole Froude number, Eq. (14-114) | -/- | -/- |
| $F_w$ | Weir constriction correction factor, Fig. 14-38 | -/- | -/- |
| $g$ | Gravitational constant | $m/s^2$ | $ft/s^2$ |
| $g_c$ | Conversion factor | 1.0 kg·m/($N·s^2$) | 32.2 lb·ft/($lbf·s^2$) |
| $G$ | Gas phase mass velocity | kg/($s.m^2$) | lb/($hr·ft^2$) |
| $G_f$ | Gas loading factor in Robbins' packing pressure drop correlation | kg/($s·m^2$) | lb/($h·ft^2$) |
| $G_M$ | Gas phase molar velocity | kg·mol/($s.m^2$) | lb·mol/($h.ft^2$) |
| GPM | Liquid flow rate | — | gpm |
| $h$ | Pressure head | mm | in |
| $h'_{dc}$ | Froth height in downcomer | mm | in |
| $h'_L$ | Pressure drop through aerated mass on tray | mm | in |
| $h_c$ | Clear liquid height on tray | mm | in |
| $h_{cl}$ | Clearance under downcomer | mm | in |
| $h_{ct}$ | Clear liquid height at spray to froth transition | mm | in |
| $h_d$ | Dry pressure drop across tray | mm | in |
| $h_{da}$ | Head loss due to liquid flow under downcomer apron | mm | in |
| $h_{dc}$ | Clear liquid height in downcomer | mm | in |
| $h_{ds}$ | Calculated clear liquid height, Eq. (14-108) | mm | in |
| $h_f$ | Height of froth | mm | in |
| $h_{fow}$ | Froth height over the weir, Eq. (14-117) | mm | in |
| $h_{hg}$ | Hydraulic gradient | mm | in |
| $h_{Lo}$ | Packing holdup in preloading regime, fractional | -/- | -/- |
| $h_{Lt}$ | Clear liquid height at froth to spray transition, corrected for effect of weir height, Eq. (14-96) | mm | in |
| $h_{ow}$ | Height of crest over weir | mm | in |
| $h_T$ | Height of contacting | m | ft |
| $h_t$ | Total pressure drop across tray | mm | in |
| $h_w$ | Weir height | mm | in |
| $H$ | Height of a transfer unit | m | ft |
| $H$ | Henry's law constant | kPa/mol fraction | atm /mol fraction |
| $H'$ | Henry's law constant | kPa/(kmol·$m^3$) | psi/(lb·mol.$ft^3$) |
| $H_G$ | Height of a gas phase transfer unit | m | ft |
| $H_L$ | Height of a liquid phase transfer unit | m | ft |
| $H_{OG}$ | Height of an overall transfer unit, gas phase concentrations | m | ft |
| $H_{OL}$ | Height of an overall transfer unit, liquid phase concentrations | m | ft |

**Nomenclature** (*Continued*)

| | | | |
|---|---|---|---|
| $H'$ | Henry's law coefficient | kPa/mol frac | atm/mol frac |
| HETP | Height equivalent to a theoretical plate or stage | m | ft |
| $J_G^*$ | Dimensionless gas velocity, weep correlation, Eq. (14-124) | -/- | -/- |
| $J_L^*$ | Dimensionless liquid velocity, weep correlation, Eq. (14-125) | -/- | -/- |
| $k$ | Individual phase mass transfer coefficient | kmol /(s·m²· mol frac) | lb·mol/(s·ft²· mol frac) |
| $k_1$ | First order reaction velocity constant | 1/s | 1/s |
| $k_2$ | Second order reaction velocity constant | m³/(s·kmol) | ft³/(h·lb·mol) |
| $k_g$ | Gas mass-transfer coefficient, wetted-wall columns [see Eq. (14-171) for unique units] | | |
| $k_G$ | gas phase mass transfer coefficient | kmol /(s·m²· mol frac) | lb.mol/(s·ft²· mol frac) |
| $k_L$ | liquid phase mass transfer coefficient | kmol /(s·m²· mol frac) | lb·mol/(s·ft²· mol frac) |
| $K$ | Constant in trays dry pressure drop equation | mm·s²/m² | in·s²/ft² |
| $K$ | Vapor-liquid equilibrium ratio | -/- | -/- |
| $K_C$ | Dry pressure drop constant, all valves closed | mm·s²/m² | in·s²/ft² |
| $K_D$ | Orifice discharge coefficient, liquid distributor | -/- | -/- |
| $K_g$ | Overall mass-transfer coefficient | kg·mol/ (s·m²·atm) | lb·mol/ (h·ft²·atm) |
| $K_O$ | Dry pressure drop constant, all valves open | mm·s²/m² | in·s²/ft² |
| $K_{OG}$, $K_G$ | Overall mass transfer coefficient, gas concentrations | kmol / (s·m²·mol) frac) | lb·mol/ (s·ft²·mol frac) |
| $K_{OL}$ | Overall mass transfer coefficient, liquid concentrations | kmol/ (s·m²·mol frac) | lb.mol/ (s·ft²·mol frac) |
| $L$ | Liquid mass velocity | kg/(m²·s) | lb/ft²·h |
| $L_f$ | Liquid loading factor in Robbins' packing pressure drop correlation | kg/(s·m²) | lb/(h·ft²) |
| $L_m$ | Molar liquid downflow rate | kg·mol/h | lb·mol/h |
| $L_M$ | Liquid molar mass velocity | kmol/(m²·s) | lb·mol/(ft²·h) |
| $L_S$ | Liquid velocity, based on superficial tower area | m/s | ft/s |
| $L_w$ | Weir length | m | in |
| $m$ | An empirical constant based on Wallis' countercurrent flow limitation equation, Eqs. (14-123) and (14-143) | -/- | -/- |
| $m$ | Slope of equilibrium curve = $dy^*/dx$ | -/- | -/- |
| $M$ | Molecular weight | kg/kmol | lb/(lb·mol) |
| $n$ | Parameter in spray regime clear liquid height correlation, Eq. (14-84) | mm | in |
| $n_A$ | Rate of solute transfer | kmol/s | lb·mol/s |
| $n_D$ | Number of holes in orifice distributor | -/- | -/- |
| $N_a$ | Number of actual trays | -/- | -/- |
| $N_A$, $N_t$ | Number of theoretical stages | -/- | -/- |
| $N_{OG}$ | Number of overall gas-transfer units | -/- | -/- |
| $N_p$ | Number of tray passes | -/- | -/- |
| $p$ | Hole pitch (center-to-center hole spacing) | mm | in |
| $p$ | Partial pressure | kPa | atm |
| $P_{BM}$ | Logarithmic mean partial pressure of inert gas | kPa | atm |
| $P$, $p_T$ | Total pressure | kPa | atm |
| $P^0$ | Vapor pressure | kpa | atm |
| $Q$, $q$ | Volumetric flow rate of liquid | m³/s | ft³/s |
| $Q'$ | Liquid flow per serration of serrated weir | m·³/s | ft³/s |
| $Q_D$ | Downcomer liquid load, Eq. (14-79) | m/s | ft/s |
| $Q_L$ | Weir load, Eq. (14-78) | m³/(h·m) | gpm/in |
| $Q_{MW}$ | Minimum wetting rate | m³/(h·m²) | gpm/ft² |
| $R$ | Reflux flow rate | kg·mol/h | lb·mol/h |
| $R$ | Gas constant | | |
| $R_h$ | Hydraulic radius | m | ft |
| $R_{vw}$ | Ratio of valve weight with legs to valve weight without legs, Table (14-11) | -/- | -/- |
| $S$ | Length of corrugation side, structured packing | m | ft |
| $S$ | Stripping factor $mG_M/L_M$ | -/- | -/- |
| $S$ | Tray spacing | mm | in |
| $S_e$, $S'$ | Effective stripping factor (Edmister) | -/- | -/- |
| SF | Derating (system) factor, Table 14-9 | -/- | -/- |
| $t_t$ | Tray thickness | mm | in |
| $t_v$ | Valve thickness | mm | in |
| $T$ | Absolute temperature | K | °R |

# INTRODUCTION

**Definitions** Gas absorption is a unit operation in which soluble components of a gas mixture are dissolved in a liquid. The inverse operation, called stripping or desorption, is employed when it is desired to transfer volatile components from a liquid mixture into a gas. Both absorption and stripping, in common with distillation (Sec. 13), make use of special equipment for bringing gas and liquid phases into intimate contact. This section is concerned with the design of gas-liquid contacting equipment, as well as with the design of absorption and stripping processes.

**Equipment** Absorption, stripping, and distillation operations are usually carried out in vertical, cylindrical columns or towers in which devices such as plates or packing elements are placed. The gas and liquid normally flow countercurrently, and the devices serve to provide the contacting and development of interfacial surface through which mass transfer takes place. Background material on this mass transfer process is given in Sec. 5.

**Design Procedures** The procedures to be followed in specifying the principal dimensions of gas absorption and distillation equipment are described in this section and are supported by several worked-out examples. The experimental data required for executing the designs are keyed to appropriate references or to other sections of the handbook.

For absorption, stripping, and distillation, there are three main steps involved in design:

1. *Data on the gas-liquid or vapor-liquid equilibrium for the system at hand.* If absorption, stripping, and distillation operations are considered equilibrium-limited processes, which is the usual approach, these data are critical for determining the maximum possible separation. In some cases, the operations are considered rate-based (see Sec. 13) but require knowledge of equilibrium at the phase interface. Other data required include physical properties such as viscosity and density and thermodynamic properties such as enthalpy. Section 2 deals with sources of such data.

2. *Information on the liquid- and gas-handling capacity of the contacting device chosen for the particular separation problem.* Such information includes pressure drop characteristics of the device, in order that an optimum balance between capital cost (column cross section) and energy requirements might be achieved. Capacity and pressure drop characteristics of the available devices are covered later in this Sec. 14.

3. *Determination of the required height of contacting zone for the separation to be made as a function of properties of the fluid mixtures and mass-transfer efficiency of the contacting device.* This determination involves the calculation of mass-transfer parameters such as heights of transfer units and plate efficiencies as well as equilibrium or rate parameters such as theoretical stages or numbers of transfer units. An additional consideration for systems in which chemical reaction occurs is the provision of adequate residence time for desired reactions to occur, or minimal residence time to prevent undesired reactions from occurring. For equilibrium-based operations, the parameters for required height are covered in the present section.

**Data Sources in the Handbook** Sources of data for the analysis or design of absorbers, strippers, and distillation columns are manifold, and a detailed listing of them is outside the scope of the presentation in this section. Some key sources within the handbook are shown in Table 14-1.

**Equilibrium Data** Finding reliable gas-liquid and vapor-liquid equilibrium data may be the most time-consuming task associated with the design of absorbers and other gas-liquid contactors, and yet it may be the most important task at hand. For gas solubility, an important data source is the set of volumes edited by Kertes et al., *Solubility Data Series*, published by Pergamon Press (1979 ff.). In the introduction to each volume, there is an excellent discussion and definition of the various methods by which gas solubility data have been reported, such as the Bunsen coefficient, the Kuenen coefficient, the Ostwalt coefficient, the absorption coefficient, and the Henry's law coefficient. The fifth edition of *The Properties of Gases and Liquids* by Poling, Prausnitz, and O'Connell (McGraw-Hill, New York, 2000) provides data and recommended estimation methods for gas solubility as well as the broader area of vapor-liquid equilibrium. Finally, the Chemistry Data Series by Gmehling et al., especially the title *Vapor-Liquid Equilibrium Collection* (DECHEMA, Frankfurt, Germany, 1979 ff.), is a rich source of data evaluated against the various models used for interpolation and extrapolation. Section 13 of this handbook presents a good discussion of equilibrium *K* values.

# DESIGN OF GAS ABSORPTION SYSTEMS

**General Design Procedure** The design engineer usually is required to determine (1) the best solvent; (2) the best gas velocity through the absorber, or, equivalently, the vessel diameter; (3) the height of the vessel and its internal members, which is the height and type of packing or the number of contacting trays; (4) the optimum solvent circulation rate through the absorber and stripper; (5) temperatures of streams entering and leaving the absorber and stripper, and the quantity of heat to be removed to account for the heat of solution and other thermal effects; (6) pressures at which the absorber and stripper will operate; and (7) mechanical design of the absorber and stripper vessels (predominantly columns or towers), including flow distributors and packing supports. This section covers these aspects.

The problem presented to the designer of a gas absorption system usually specifies the following quantities: (1) gas flow rate; (2) gas composition of the component or components to be absorbed; (3) operating pressure and allowable pressure drop across the absorber; (4) minimum recovery of one or more of the solutes; and, possibly, (5) the solvent to be employed. Items 3, 4, and 5 may be subject to economic considerations and therefore are left to the designer. For determination of the number of variables that must be specified to fix a unique solution for the absorber design, one may use the same phase-rule approach described in Sec. 13 for distillation systems.

Recovery of the solvent, occasionally by chemical means but more often by distillation, is almost always required and is considered an integral part of the absorption system process design. A more complete solvent-stripping operation normally will result in a less costly absorber because of a lower concentration of residual solute in the regenerated (lean) solvent, but this may increase the overall cost of the entire absorption system. A more detailed discussion of these and other economical considerations is presented later in this section.

The design calculations presented in this section are relatively simple and usually can be done by using a calculator or spreadsheet. In many cases, the calculations are explained through design diagrams. It is recognized that most engineers today will perform rigorous, detailed calculations using process simulators. The design procedures presented in this section are intended to be complementary to the rigorous computerized calculations by presenting approximate estimates and insight into the essential elements of absorption and stripping operations.

**Selection of Solvent and Nature of Solvents** When a choice is possible, preference is given to solvents with high solubilities for the target solute and high selectivity for the target solute over the other species in the gas mixture. A high solubility reduces the amount of liquid to be circulated. The solvent should have the advantages of low volatility, low cost, low corrosive tendencies, high stability, low viscosity, low tendency to foam, and low flammability. Since the exit gas normally leaves saturated with solvent, solvent loss can be costly and can cause environmental problems. The choice of the solvent is a key part of the process economic analysis and compliance with environmental regulations.

Typically, a solvent that is chemically similar to the target solute or that reacts with it will provide high solubility. Water is often used for polar and acidic solutes (e.g., HCl), oils for light hydrocarbons, and special chemical solvents for acid gases such as $CO_2$, $SO_2$, and $H_2S$. Solvents are classified as physical and chemical. A chemical solvent forms complexes or chemical compounds with the solute, while physical solvents have only weaker interactions with the solute. Physical and chemical solvents are compared and contrasted by examining the solubility of $CO_2$ in propylene carbonate (representative physical solvent) and aqueous monoethanolamine (MEA; representative chemical solvent).

Figures 14-1 and 14-2 present data for the solubility of $CO_2$ in the two representative solvents, each at two temperatures: 40 and 100°C.

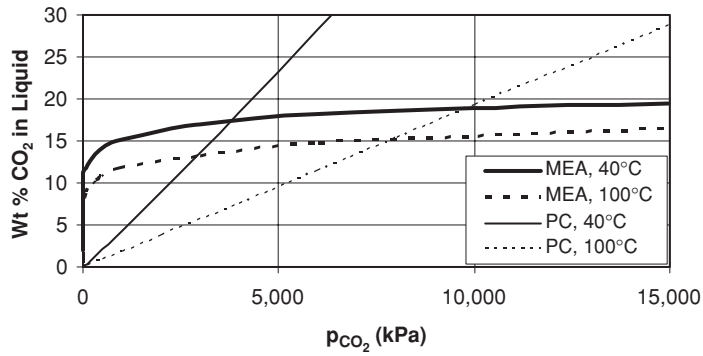

**FIG. 14-1** Solubility of $CO_2$ in 30 wt% MEA and propylene carbonate. Linear scale.

The propylene carbonate data are from Zubchenko et al. [*Zhur. Priklad. Khim.*, **44**, 2044–2047 (1971)], and the MEA data are from Jou, Mather, and Otto [*Can. J. Chem. Eng.*, **73**, 140–147 (1995)]. The two figures have the same content, but Fig. 14-2 focuses on the low-pressure region by converting both composition and pressure to the logarithm scale. Examination of the two sets of data reveals the following characteristics and differences of physical and chemical solvents, which are summarized in the following table:

| Characteristic | Physical solvent | Chemical solvent |
|---|---|---|
| Solubility variation with pressure | Relatively linear | Highly nonlinear |
| Low-pressure solubility | Low | High |
| High-pressure solubility | Continues to increase | Levels off |
| Heat of solution—related to variation of solubility with temperature at fixed pressure | Relatively low and approximately constant with loading | Relatively high and decreases somewhat with increased solute loading |

Chemical solvents are usually preferred when the solute must be reduced to very low levels, when high selectivity is needed, and when the solute partial pressure is low. However, the strong absorption at low solute partial pressures and the high heat of solution are disadvantages for stripping. For chemical solvents, the strong nonlinearity of the absorption makes it necessary that accurate absorption data for the conditions of interest be available.

**Selection of Solubility Data** Solubility values are necessary for design because they determine the liquid rate necessary for complete or economic solute recovery. Equilibrium data generally will be found in one of three forms: (1) solubility data expressed either as weight or mole percent or as Henry's law coefficients; (2) pure-component vapor pressures; or (3) equilibrium distribution coefficients ($K$ values). Data for specific systems may be found in Sec. 2; additional references to sources of data are presented in this section.

To define completely the solubility of gas in a liquid, it is generally necessary to state the temperature, equilibrium partial pressure of the solute gas in the gas phase, and the concentration of the solute gas in the liquid phase. Strictly speaking, the total pressure of the system should also be identified, but for low pressures (less than about 507 kPa or 5 atm), the solubility for a particular partial pressure of the solute will be relatively independent of the total pressure.

For many physical systems, the equilibrium relationship between solute partial pressure and liquid-phase concentration is given by Henry's law:

$$p_A = Hx_A \tag{14-1}$$

or

$$p_A = H'c_A \tag{14-2}$$

where $H$ is Henry's law coefficient expressed in kPa per mole fraction solute in liquid and $H'$ is Henry's law coefficient expressed in kPa·m$^3$/kmol.

Figure 14-1 indicates that Henry's law is valid to a good approximation for the solubility $CO_2$ in propylene carbonate. In general, Henry's law is a reasonable approximation for physical solvents. If Henry's law holds, the solubility is defined by knowing (or estimating) the value of the constant $H$ (or $H'$).

Note that the assumption of Henry's law will lead to incorrect results for solubility of chemical systems such as $CO_2$-MEA (Figs. 14-1 and 14-2) and HCl-$H_2O$. Solubility modeling for chemical systems requires the use of a *speciation model*, as described later in this section.

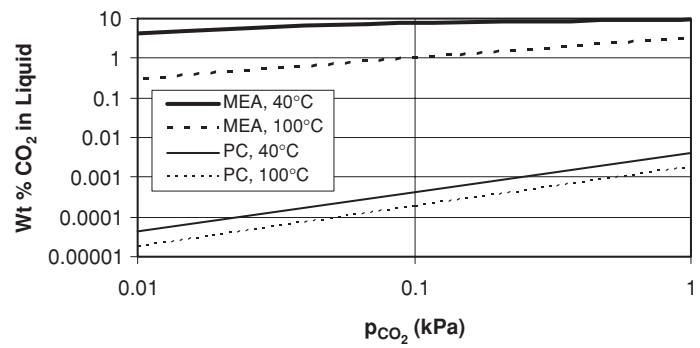

**FIG. 14-2** Solubility of $CO_2$ in 30 wt% MEA and propylene carbonate. Logarithm scale and focus on low-pressure region.

For quite a number of physically absorbed gases, Henry's law holds very well when the partial pressure of the solute is less than about 101 kPa (1 atm). For partial pressures above 101 kPa, $H$ may be independent of the partial pressure (Fig. 14-1), but this needs to be verified for the particular system of interest. The variation of $H$ with temperature is a strongly nonlinear function of temperature as discussed by Poling, Prausnitz, and O'Connell (*The Properties of Gases and Liquids,* 5th ed., McGraw-Hill, New York, 2000). Consultation of this reference is recommended when temperature and pressure extrapolations of Henry's law data are needed.

The use of Henry's law constants is illustrated by the following example.

***Example 1: Gas Solubility*** It is desired to find out how much hydrogen can be dissolved in 100 weights of water from a gas mixture when the total pressure is 101.3 kPa (760 torr; 1 atm), the partial pressure of the $H_2$ is 26.7 kPa (200 torr), and the temperature is 20°C. For partial pressures up to about 100 kPa the value of $H$ is given in Sec. 3 as $6.92 \times 10^6$ kPa ($6.83 \times 10^4$ atm) at 20°C. According to Henry's law,

$$x_{H_2} = p_{H_2}/H_{H_2} = 26.7/6.92 \times 10^6 = 3.86 \times 10^{-6}$$

The mole fraction $x$ is the ratio of the number of moles of $H_2$ in solution to the total moles of all constituents contained. To calculate the weights of $H_2$ per 100 weights of $H_2O$, one can use the following formula, where the subscripts $A$ and $w$ correspond to the solute (hydrogen) and solvent (water):

$$\left(\frac{x_A}{1-x_A}\right)\frac{M_A}{M_W}100 = \left(\frac{3.86 \times 10^{-6}}{1-3.86 \times 10^{-6}}\right)\frac{2.02}{18.02}100$$

$$= 4.33 \times 10^{-5} \text{ weights } H_2/100 \text{ weights } H_2O$$

$$= 0.43 \text{ parts per million weight}$$

Pure-component vapor pressure can be used for predicting solubilities for systems in which **Raoult's law** is valid. For such systems $p_A = p^0_A x_A$, where $p^0_A$ is the pure-component vapor pressure of the solute and $p_A$ is its partial pressure. Extreme care should be exercised when using pure-component vapor pressures to predict gas absorption behavior. Both vapor-phase and liquid-phase nonidealities can cause significant deviations from Raoult's law, and this is often the reason particular solvents are used, i.e., because they have special affinity for particular solutes. The book by Poling, Prausnitz, and O'Connell (op. cit.) provides an excellent discussion of the conditions where Raoult's law is valid. Vapor-pressure data are available in Sec. 3 for a variety of materials.

Whenever data are available for a given system under similar conditions of temperature, pressure, and composition, **equilibrium distribution coefficients** ($K = y/x$) provide a much more reliable tool for predicting vapor-liquid distributions. A detailed discussion of equilibrium $K$ values is presented in Sec. 13.

**Calculation of Liquid-to-Gas Ratio** The minimum possible liquid rate is readily calculated from the composition of the entering gas and the solubility of the solute in the exit liquor, with equilibrium being assumed. It may be necessary to estimate the temperature of the exit liquid based upon the heat of solution of the solute gas. Values of latent heat and specific heat and values of heats of solution (at infinite dilution) are given in Sec. 2.

The actual liquid-to-gas ratio (solvent circulation rate) normally will be greater than the minimum by as much as 25 to 100 percent, and the estimated factor may be arrived at by economic considerations as well as judgment and experience. For example, in some packed-tower applications involving very soluble gases or vacuum operation, the minimum quantity of solvent needed to dissolve the solute may be insufficient to keep the packing surface thoroughly wet, leading to poor distribution of the liquid stream.

When the solvent concentration in the inlet gas is low and when a significant fraction of the solute is absorbed (this often the case), the approximation

$$y_1 G_M = x_1 L_M = (y_1^0/m)L_M \tag{14-3}$$

leads to the conclusion that the ratio $mG_M/L_M$ represents the fractional approach of the exit liquid to saturation with the inlet gas, i.e.,

$$mG_M/L_M = y_1^0/y_1 \tag{14-4}$$

Optimization of the liquid-to-gas ratio in terms of total annual costs often suggests that the molar liquid-to-gas ratio $L_M/G_M$ should be about 1.2 to 1.5 times the theoretical minimum corresponding to equilibrium at the rich end of the tower (infinite height or number of trays), provided flooding is not a problem. This, for example, would be an alternative to assuming that $L_M/G_M \approx m/0.7$.

When the exit-liquor temperature rises because of the heat of absorption of the solute, the value of $m$ changes through the tower, and the liquid-to-gas ratio must be chosen to give reasonable values of $m_1G_M/L_M$ and $m_2G_M/L_M$, where the subscripts 1 and 2 refer to the bottom and top of the absorber, respectively. For this case, the value of $m_2G_M/L_M$ will be taken to be somewhat less than 0.7, so that the value of $m_1G_M/L_M$ will not approach unity too closely. This rule-of-thumb approach is useful only when the solute concentration is low and heat effects are negligible.

When the solute has a large heat of solution or when the feed gas contains high concentrations of the solute, one should consider the use of internal cooling coils or intermediate liquid withdrawal and cooling to remove the heat of absorption.

**Selection of Equipment** Trays and random packings have been extensively used for gas absorption; structured packings are less common. Compared to trays, random packings have the advantages of availability in low-cost, corrosion-resistant materials (such as plastics and ceramics), low pressure drop (which can be an advantage when the tower is in the suction of a fan or compressor), easy and economic adaptability to small-diameter (less than 0.6-m or 2-ft) columns, and excellent handling of foams. Trays are much better for handling solids and fouling applications, offer greater residence time for slow absorption reactions, can better handle high $L/G$ ratios and intermediate cooling, give better liquid turndown, and are more robust and less prone to reliability issues such as those resulting from poor distribution. Details on the operating characteristics of tray and packed towers are given later in this section.

**Column Diameter and Pressure Drop** Flooding determines the minimum possible diameter of the absorber column, and the usual design is for 60 to 80 percent of the flooding velocity. In near-atmospheric applications, pressure drop usually needs to be minimized to reduce the cost of energy for compression of the feed gas. For systems having a significant tendency to foam, the maximum allowable velocity will be lower than the estimated flooding velocity. Methods for predicting flooding velocities and pressure drops are given later in this section.

**Computation of Tower Height** The required height of a gas absorption or stripping tower for physical solvents depends on (1) the phase equilibria involved; (2) the specified degree of removal of the solute from the gas; and (3) the mass-transfer efficiency of the device. These three considerations apply to both tray and packed towers. Items 1 and 2 dictate the required number of theoretical stages (tray tower) or transfer units (packed tower). Item 3 is derived from the tray efficiency and spacing (tray tower) or from the height of one transfer unit (packed tower). Solute removal specifications are usually derived from economic considerations.

For tray towers, the approximate design methods described below may be used in estimating the number of theoretical stages, and the tray efficiencies and spacings for the tower can be specified on the basis of the information given later. Considerations involved in the rigorous design of theoretical stages for tray towers are treated in Sec. 13.

For packed towers, the continuous differential nature of the contact between gas and liquid leads to a design procedure involving the solution of differential equations, as described in the next subsection. Note that the design procedures discussed in this section are not applicable to reboiled absorbers, which should be designed according to the procedures described in Sec. 13.

Caution is advised in distinguishing between systems involving pure physical absorption and those in which chemical reactions can significantly affect design procedures. Chemical systems require additional procedures, as described later in this section.

**Selection of Stripper Operating Conditions** Stripping involves the removal of one or more components from the solvent through the application of heat or contacting it with a gas such as steam, nitrogen,

or air. The operating conditions chosen for stripping normally result in a low solubility of solute (i.e., high value of $m$), so that the ratio $mG_M/L_M$ will be larger than unity. A value of 1.4 may be used for rule-of-thumb calculations involving pure physical absorption. For tray-tower calculations, the stripping factor $S = KG_M/L_M$, where $K = y^0/x$ usually is specified for each tray.

When the solvent from an absorption operation must be regenerated for recycling to the absorber, one may employ a "pressure-swing" or "temperature-swing" concept, or a combination of the two, in specifying the stripping operation. In pressure-swing operation, the temperature of the stripper is about the same as that of the absorber, but the stripping pressure is much lower. In temperature-swing operation, the pressures are about equal, but the stripping temperature is much higher than the absorption temperature.

In pressure-swing operation, a portion of the gas may be "sprung" from the liquid by the use of a flash drum upstream of the stripper feed point. This type of operation has been discussed by Burrows and Preece [*Trans. Inst. Chem. Eng.*, **32,** 99 (1954)] and by Langley and Haselden [*Inst. Chem. Eng. Symp. Ser. (London)*, no. 28 (1968)]. If the flashing of the liquid takes place inside the stripping tower, this effect must be accounted for in the design of the upper section in order to avoid overloading and flooding near the top of the tower.

Often the rate at which residual absorbed gas can be driven from the liquid in a stripping tower is limited by the rate of a chemical reaction, in which case the liquid-phase residence time (and hence the tower liquid holdup) becomes the most important design factor. Thus, many stripper regenerators are designed on the basis of liquid holdup rather than on the basis of mass-transfer rate.

Approximate design equations applicable only to the case of pure physical desorption are developed later in this section for both packed and tray stripping towers. A more rigorous approach using distillation concepts may be found in Sec. 13. A brief discussion of desorption with chemical reaction is given in the subsection "Absorption with Chemical Reaction."

**Design of Absorber-Stripper Systems** The solute-rich liquor leaving a gas absorber normally is distilled or stripped to regenerate the solvent for recirculation back to the absorber, as depicted in Fig. 14-3. It is apparent that the conditions selected for the absorption step (e.g., temperature, pressure, $L_M/G_M$) will affect the design of the stripping tower, and conversely, a selection of stripping conditions will affect the absorber design. The choice of optimum operating conditions for an absorber-stripper system therefore involves a combination of economic factors and practical judgments as to the operability of the system within the context of the overall process flow sheet. In Fig. 14-3, the stripping vapor is provided by a reboiler; alternately, an extraneous stripping gas may be used.

An appropriate procedure for executing the design of an absorber-stripper system is to set up a carefully selected series of design cases and then evaluate the investment costs, the operating costs, and the operability of each case. Some of the economic factors that need to be considered in selecting the optimum absorber-stripper design are discussed later in the subsection "Economic Design of Absorption Systems."

**Importance of Design Diagrams** One of the first things a designer should do is to lay out a carefully constructed equilibrium curve $y^0 = F(x)$ on an $xy$ diagram, as shown in Fig. 14-4. A horizontal line corresponding to the inlet-gas composition $y_1$ is then the locus of feasible outlet-liquor compositions, and a vertical line corresponding to the inlet-solvent-liquor composition $x_2$ is the locus of outlet-gas compositions. These lines are indicated as $y = y_1$ and $x = x_2$, respectively on Fig. 14-4.

For gas absorption, the region of feasible operating lines lies above the equilibrium curve; for stripping, the feasible region for operating lines lies below the equilibrium curve. These feasible regions are bounded by the equilibrium curve and by the lines $x = x_2$ and $y = y_1$. By inspection, one should be able to visualize those operating lines that are feasible and those that would lead to "pinch points" within the tower. Also, it is possible to determine if a particular proposed design for solute recovery falls within the feasible envelope.

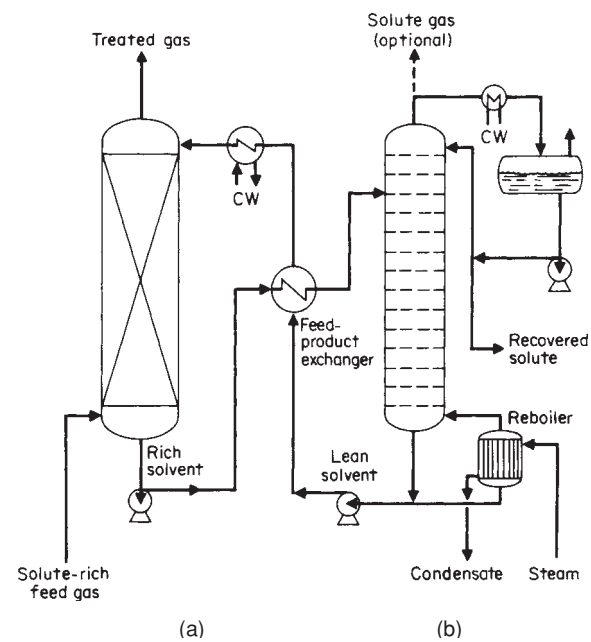

**FIG. 14-3** Gas absorber using a solvent regenerated by stripping. (*a*) Absorber. (*b*) Stripper.

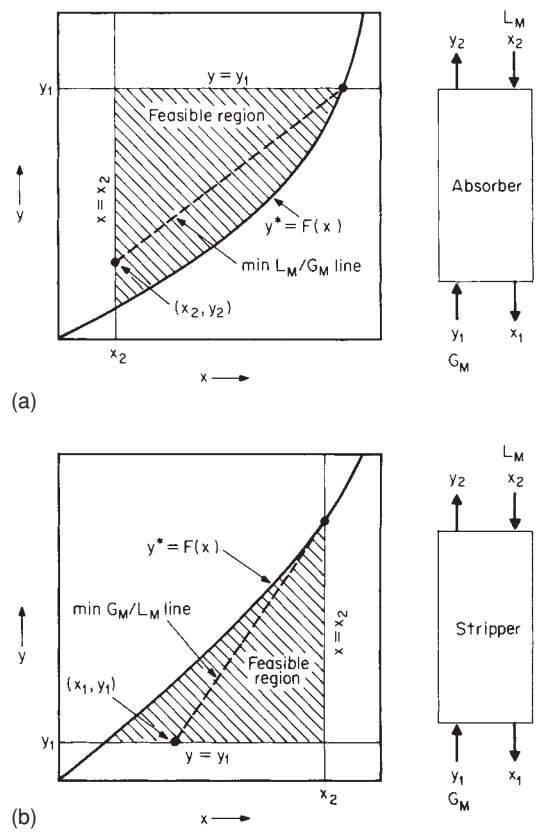

**FIG. 14-4** Design diagrams for (*a*) absorption and (*b*) stripping.

Once the design recovery for an absorber has been established, the operating line can be constructed by first locating the point $x_2$, $y_2$ on the diagram. The intersection of the horizontal line corresponding to the inlet gas composition $y_1$ with the equilibrium curve $y^0 = F(x)$ defines the theoretical minimum liquid-to-gas ratio for systems in which there are no intermediate pinch points. This operating line which connects this point with the point $x_2$, $y_2$ corresponds to the minimum value of $L_M/G_M$. The actual design value of $L_M/G_M$ should normally be around 1.2 to 1.5 times this minimum value. Thus, the actual design operating line for a gas absorber will pass through the point $x_2$, $y_2$ and will intersect the line $y = y_1$ to the left of the equilibrium curve.

For stripping one begins by using the design specification to locate the point $x_1$, $y_1$; then the intersection of the vertical line $x = x_2$ with the equilibrium curve $y^0 = F(x)$ defines the theoretical minimum gas-to-liquid ratio. The actual value of $G_M/L_M$ is chosen to be about 20 to 50 percent higher than this minimum, so the actual design operating line will intersect the line $x = x_2$ at a point somewhat below the equilibrium curve.

## PACKED-TOWER DESIGN

Methods for estimating the height of the active section of counterflow differential contactors such as packed towers, spray towers, and falling-film absorbers are based on rate expressions representing mass transfer at a point on the gas-liquid interface and on material balances representing the changes in bulk composition in the two phases that flow past each other. The rate expressions are based on the interphase mass-transfer principles described in Sec. 5. Combination of such expressions leads to an integral expression for the number of transfer units or to equations related closely to the number of theoretical stages. The paragraphs which follow set forth convenient methods for using such equations, first in a general case and then for cases in which simplifying assumptions are valid.

**Use of Mass-Transfer-Rate Expression** Figure 14-5 shows a section of a packed absorption tower together with the nomenclature that will be used in developing the equations that follow. In a differential section $dh$, we can equate the rate at which solute is lost from the gas phase to the rate at which it is transferred through the gas phase to the interface as follows:

$$-d(G_M y) = -G_M\,dy - y\,dG_M = N_A a\,dh \tag{14-5}$$

In Eq. (14-5), $G_M$ is the gas-phase molar velocity [kmol/(s·m$^2$)], $N_A$ is the mass-transfer flux [kmol/(s·m$^2$)], and $a$ is the effective interfacial area (m$^2$/m$^3$).

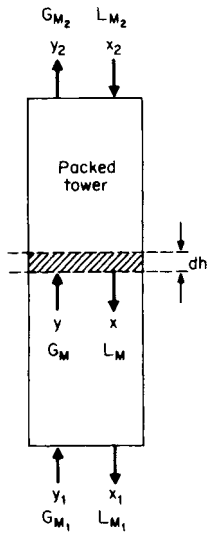

**FIG. 14-5** Nomenclature for material balances in a packed-tower absorber or stripper.

When only one component is transferred,

$$dG_M = -N_A a\,dh \tag{14-6}$$

Substitution of this relation into Eq. (14-5) and rearranging yield

$$dh = -\frac{G_M\,dy}{N_A a\,(1-y)} \tag{14-7}$$

For this derivation we use the gas-phase rate expression $N_A = k_G(y - y_i)$ and integrate over the tower to obtain

$$h_T = \int_{y_2}^{y_1} \frac{G_M\,dy}{k_G a(1-y)(y-y_i)} \tag{14-8}$$

Multiplying and dividing by $y_{BM}$ place Eq. (14-8) into the $H_G N_G$ format

$$h_T = \int_{y_2}^{y_1} \left(\frac{G_M}{k_G a y_{BM}}\right) \frac{y_{BM}\,dy}{(1-y)(y-y_i)}$$

$$= H_{G,\text{av}} \int_{y_2}^{y_1} \frac{y_{BM}\,dy}{(1-y)(y-y_i)} = H_{G,\text{av}} N_G \tag{14-9}$$

The general expression given by Eq. (14-8) is more complex than normally is required, but it must be used when the mass-transfer coefficient varies from point to point, as may be the case when the gas is not dilute or when the gas velocity varies as the gas dissolves. The values of $y_i$ to be used in Eq. (14-8) depend on the local liquid composition $x_i$ and on the temperature. This dependency is best represented by using the operating and equilibrium lines as discussed later.

Example 2 illustrates the use of Eq. (14-8) for scrubbing chlorine from air with aqueous caustic solution. For this case one can make the simplifying assumption that $y_i$, the interfacial partial pressure of chlorine over the caustic solution, is zero due to the rapid and complete reaction of the chlorine after it dissolves. We note that the feed gas is not dilute.

***Example 2: Packed Height Requirement*** Let us compute the height of packing needed to reduce the chlorine concentration of 0.537 kg/(s·m$^2$), or 396 lb/(h·ft$^2$), of a chlorine-air mixture containing 0.503 mole-fraction chlorine to 0.0403 mole fraction. On the basis of test data described by Sherwood and Pigford (*Absorption and Extraction,* McGraw-Hill, 1952, p. 121) the value of $k_G a y_{BM}$ at a gas velocity equal to that at the bottom of the packing is equal to 0.1175 kmol/(s·m$^3$), or 26.4 lb·mol/(h·ft$^3$). The equilibrium back pressure $y_i$ can be assumed to be negligible.

*Solution.* By assuming that the mass-transfer coefficient varies as the 0.8 power of the local gas mass velocity, we can derive the following relation:

$$\hat{K}_G a = k_G a y_{BM} = 0.1175 \left[\frac{71y + 29(1-y)}{71y_1 + 29(1-y_1)} \left(\frac{1-y_1}{1-y}\right)\right]^{0.8}$$

where 71 and 29 are the molecular weights of chlorine and air respectively. Noting that the inert-gas (air) mass velocity is given by $G'_M = G_M(1-y) = 5.34 \times 10^{-3}$ kmol/(s·m$^2$), or 3.94 lb·mol/(h·ft$^2$), and introducing these expressions into the integral gives

$$h_T = 1.82 \int_{0.0403}^{0.503} \left[\frac{1-y}{29+42y}\right]^{0.8} \frac{dy}{(1-y)^2 \ln\,[1/(1-y)]}$$

This definite integral can be evaluated numerically by the use of Simpson's rule to obtain $h_T = 0.305$ m (1 ft).

**Use of Operating Curve** Frequently, it is not possible to assume that $y_i = 0$ as in Example 2, due to diffusional resistance in the liquid phase or to the accumulation of solute in the liquid stream. When the backpressure cannot be neglected, it is necessary to supplement the equations with a material balance representing the operating line or curve. In view of the countercurrent flows into and from the differential section of packing shown in Fig. 14-5, a steady-state material balance leads to the following equivalent relations:

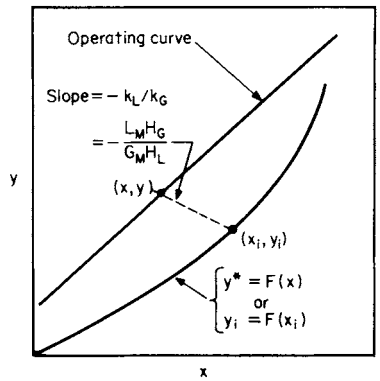

**FIG. 14-6** Relationship between equilibrium curve and operating curve in a packed absorber; computation of interfacial compositions.

$$d(G_M y) = d(L_M x) \tag{14-10}$$

$$G'_M \frac{dy}{(1-y)^2} = L'_M \frac{dx}{(1-x)^2} \tag{14-11}$$

where $L'_M$ = molar mass velocity of the inert-liquid component and $G'_M$ = molar mass velocity of the inert gas; $L_M$, $L'_M$, $G_M$, and $G'_M$ are superficial velocities based upon the total tower cross section.

Equation (14-11) is the differential equation of the operating curve, and its integral around the upper portion of the packing is the equation for the operating curve.

$$G'_M\left[\frac{y}{1-y} - \frac{y_2}{1-y_2}\right] = L'_M\left[\frac{x}{1-x} - \frac{x_2}{1-x_2}\right] \tag{14-12}$$

For dilute solutions in which the mole fractions of $x$ and $y$ are small, the total molar flows $G_M$ and $L_M$ will be nearly constant, and the operating-curve equation is

$$G_M(y - y_2) = L_M(x - x_2) \tag{14-13}$$

This equation gives the relation between the bulk compositions of the gas and liquid streams at each height in the tower for conditions in which the operating curve can be approximated as a straight line.

Figure 14-6 shows the relationship between the operating curve and the equilibrium curve $y_i = F(x_i)$ for a typical example involving solvent recovery, where $y_i$ and $x_i$ are the interfacial compositions (assumed to be in equilibrium). Once $y$ is known as a function of $x$ along the operating curve, $y_i$ can be found at corresponding points on the equilibrium curve by

$$(y - y_i)/(x_i - x) = k_L/k_G = L_M H_G/G_M H_L \tag{14-14}$$

where $L_M$ = molar liquid mass velocity, $G_M$ = molar gas mass velocity, $H_L$ = height of one transfer unit based upon liquid-phase resistance, and $H_G$ = height of one transfer unit based upon gas-phase resistance. Using this equation, the integral in Eq. (14-8) can be evaluated.

**Calculation of Transfer Units** In the general case, the equations described above must be employed in calculating the height of packing required for a given separation. However, if the local mass-transfer coefficient $k_G a y_{BM}$ is approximately proportional to the first power of the local gas velocity $G_M$, then the height of one gas-phase transfer unit, defined as $H_G = G_M/k_G a y_{BM}$, will be constant in Eq. (14-9). Similar considerations lead to an assumption that the height of one overall gas-phase transfer unit $H_{OG}$ may be taken as constant. The height of packing required is then calculated according to the relation

$$h_T = H_G N_G = H_{OG} N_{OG} \tag{14-15}$$

where $N_G$ = number of gas-phase transfer units and $N_{OG}$ = number of overall gas-phase transfer units. When $H_G$ and $H_{OG}$ are not constant, it may be valid to employ averaged values between the top and bottom of the tower and the relation

$$h_T = H_{G,av} N_G = H_{OG,av} N_{OG} \tag{14-16}$$

In these equations, the terms $N_G$ and $N_{OG}$ are defined by Eqs. (14-17) and (14-18).

$$N_G = \int_{y_2}^{y_1} \frac{y_{BM}\,dy}{(1-y)(y-y_i)} \tag{14-17}$$

$$N_{OG} = \int_{y_2}^{y_1} \frac{y^o_{BM}\,dy}{(1-y)(y-y^o)} \tag{14-18}$$

Equation (14-18) is the more useful one in practice. It requires either actual experimental $H_{OG}$ data or values estimated by combining individual measurements of $H_G$ and $H_L$ by Eq. (14-19). Correlations for $H_G$, $H_L$, and $H_{OG}$ in nonreacting systems are presented in Sec. 5.

$$H_{OG} = \frac{y_{BM}}{y^o_{BM}} H_G + \frac{mG_M}{L_M}\frac{x_{BM}}{y^o_{BM}} H_L \tag{14-19a}$$

$$H_{OL} = \frac{x_{BM}}{x^o_{BM}} H_L + \frac{L_M}{mG_M}\frac{y_{BM}}{x^o_{BM}} H_G \tag{14-19b}$$

On occasion, the changes in gas flow and in the mole fraction of inert gas can be neglected so that inclusion of terms such as $1 - y$ and $y^0_{BM}$ can be approximated, as is shown below.

One such simplification was suggested by Wiegand [*Trans. Am. Inst. Chem. Eng.*, **36,** 679 (1940)], who pointed out that the logarithmic-mean mole fraction of inert gas $y^0_{BM}$ (or $y_{BM}$) is often very nearly equal to the arithmetic mean. Thus, substitution of the relation

$$\frac{y^o_{BM}}{(1-y)} = \frac{(1-y^o)+(1-y)}{2(1-y)} = \frac{y-y^o}{2(1-y)} + 1 \tag{14-20}$$

into the equations presented above leads to the simplified forms

$$N_G = \frac{1}{2}\ln\frac{1-y_2}{1-y_1} + \int_{y2}^{y1}\frac{dy}{y-y_i} \tag{14-21}$$

$$N_{OG} = \frac{1}{2}\ln\frac{1-y_2}{1-y_1} + \int_{y2}^{y1}\frac{dy}{y-y^o} \tag{14-22}$$

The second (integral) terms represent the numbers of transfer units for an infinitely dilute gas. The first terms, usually only a small correction, give the effect of a finite level of gas concentration.

The procedure for applying Eqs. (14-21) and (14-22) involves two steps: (1) evaluation of the integrals and (2) addition of the correction corresponding to the first (logarithmic) term. The discussion that follows deals only with the evaluation of the integral term (first step).

The simplest possible case occurs when (1) both the operating and equilibrium lines are straight (i.e., the solutions are dilute); (2) Henry's law is valid ($y^0/x = y_i/x_i = m$); and (3) absorption heat effects are negligible. Under these conditions, the integral term in Eq. (14-21) may be computed by Colburn's equation [*Trans. Am. Inst. Chem. Eng.*, **35,** 211 (1939)]:

$$N_{OG} = \frac{1}{1 - mG_M/L_M}\ln\left[\left(1 - \frac{mG_M}{L_M}\right)\left(\frac{y_1 - mx_2}{y_2 - mx_2}\right) + \frac{mG_M}{L_M}\right] \tag{14-23}$$

Figure 14-7 is a plot of Eq. (14-23) from which the value of $N_{OG}$ can be read directly as a function of $mG_M/L_M$ and the ratio of concentrations. This plot and Eq. (14-23) are equivalent to the use of a logarithmic mean of terminal driving forces, but they are more convenient because one does not need to compute the exit-liquor concentration $x_1$.

In many practical situations involving nearly complete cleanup of the gas, an approximate result can be obtained from the equations just presented even when the simplifications are not valid, i.e., solutions are concentrated and heat effects occur. In such cases the driving forces in the upper part of the tower are very much smaller than those at the bottom, and the value of $mG_M/L_M$ used in the equations should be the ratio of the operating line $L_M/G_M$ in the low-concentration region near the top of the tower.

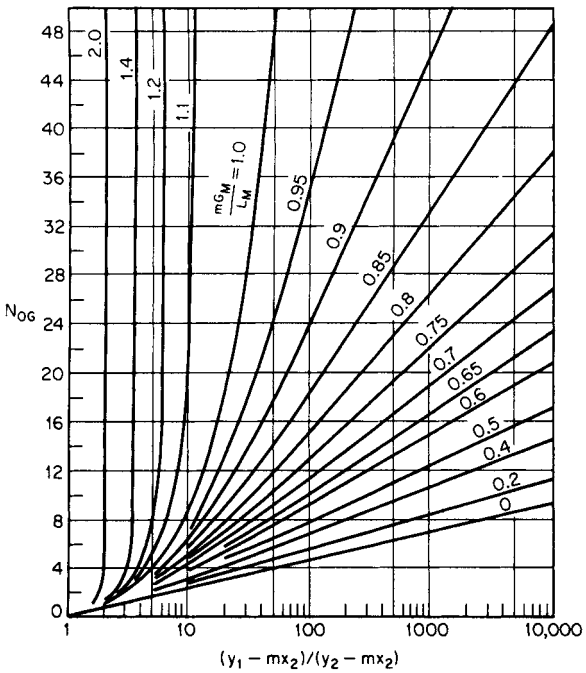

**FIG. 14-7** Number of overall gas-phase mass-transfer units in a packed absorption tower for constant $mG_M/L_M$; solution of Eq. (14-23). (*From Sherwood and Pigford,* Absorption and Extraction, *McGraw-Hill, New York, 1952.*)

Another approach is to divide the tower arbitrarily into a lean section (near the top) where approximate methods are valid, and to deal with the rich section separately. If the heat effects in the rich section are appreciable, consideration should be given to installing cooling units near the bottom of the tower. In any event, a design diagram showing the operating and equilibrium curves should be prepared to check the applicability of any simplified procedure. Figure 14-10, presented in Example 6, is one such diagram for an adiabatic absorption tower.

**Stripping Equations** Stripping or desorption involves the removal of a volatile component from the liquid stream by contact with an inert gas such as nitrogen or steam or the application of heat. Here the change in concentration of the liquid stream is of prime importance, and it is more convenient to formulate the rate equation analogous to Eq. (14-6) in terms of the liquid composition $x$. This leads to the following equations defining the number of transfer units and height of transfer units based on liquid-phase resistance:

$$h_T = H_L \int_{x_2}^{x_1} \frac{x_{BM}\,dx}{(1-x)(x_i - x)} = H_L N_L \tag{14-24}$$

$$h_T H_{OL} \int_{x_2}^{x_1} \frac{x^o_{BM}\,dx}{(1-x)(x^o - x)} = H_{OL} N_{OL} \tag{14-25}$$

where, as before, subscripts 1 and 2 refer to the bottom and top of the tower, respectively (see Fig. 14-5).

In situations where one cannot assume that $H_L$ and $H_{OL}$ are constant, these terms need to be incorporated inside the integrals in Eqs. (14-24) and (14-25), and the integrals must be evaluated numerically (using Simpson's rule, for example). In the normal case involving stripping without chemical reactions, the liquid-phase resistance will dominate, making it preferable to use Eq. (14-25) together with the approximation $H_L \approx H_{OL}$.

The Weigand approximations of the above integrals, in which arithmetic means are substituted for the logarithmic means ($x_{BM}$ and $x^0_{BM}$), are

$$N_L = \frac{1}{2} \ln \frac{1-x_1}{1-x_2} + \int_{x_1}^{x_2} \frac{dx}{x - x_i} \tag{14-26}$$

$$N_{OL} = \frac{1}{2} \ln \frac{1-x_1}{1-x_2} + \int_{x_1}^{x_2} \frac{dx}{x - x^o} \tag{14-27}$$

In these equations, the first term is a correction for finite liquid-phase concentrations, and the integral term represents the numbers of transfer units required for dilute solutions. In most practical stripper applications, the first (logarithmic) term is relatively small.

For dilute solutions in which both the operating and the equilibrium lines are straight and in which heat effects can be neglected, the integral term in Eq. (14-27) is

$$N_{OL} = \frac{1}{1 - L_M/mG_M} \ln \left[ \left(1 - \frac{L_M}{mG_M}\right) \left( \frac{x_2 - y_1/m}{x_1 - y_1/m} \right) + \frac{L_M}{mG_M} \right] \tag{14-28}$$

This equation is analogous to Eq. (14-23). Thus, Fig. 14-7 is applicable if the concentration ratio $(x_2 - y_1/m)/(x_1 - y_1/m)$ is substituted for the abscissa and the parameter on the curves is identified as $L_M/mG_M$.

***Example 3: Air Stripping of VOCs from Water*** A 0.45-m diameter packed column was used by Dvorack et al. [*Environ. Sci. Tech.* **20,** 945 (1996)] for removing trichloroethylene (TCE) from wastewater by stripping with atmospheric air. The column was packed with 25-mm Pall rings, fabricated from polypropylene, to a height of 3.0 m. The TCE concentration in the entering water was 38 parts per million by weight (ppmw). A molar ratio of entering water to entering air was kept at 23.7. What degree of removal was to be expected? The temperatures of water and air were 20°C. Pressure was atmospheric.

*Solution.* For TCE in water, the Henry's law coefficient may be taken as 417 atm/mf at 20°C. In this low-concentration region, the coefficient is constant and equal to the slope of the equilibrium line $m$. The solubility of TCE in water, based on $H = 417$ atm, is 2390 ppm. Because of this low solubility, the entire resistance to mass transfer resides in the liquid phase. Thus, Eq. (14-25) may be used to obtain $N_{OL}$, the number of overall liquid phase transfer units.

In the equation, the ratio $x_{BM}/(1-x)$ is unity because of the very dilute solution. It is necessary to have a value of $H_L$ for the packing used, at given flow rates of liquid and gas. Methods for estimating $H_L$ may be found in Sec. 5. Dvorack et al. found $H_{OL} = 0.8$ m. Then, for $h_T = 3.0$ m, $N_L = N_{OL} = 3.0/0.8 = 3.75$ transfer units.

Transfer units may be calculated from Eq. 14-25, replacing mole fractions with ppm concentrations, and since the operating and equilibrium lines are straight,

$$N_{OL} = \frac{38 - (\text{ppm})_{\text{exit}}}{\ln 38/(\text{ppm})_{\text{exit}}} = 3.75$$

Solving, $(\text{ppm})_{\text{exit}} = 0.00151$. Thus, the stripped water would contain 1.51 parts per billion of TCE.

**Use of HTU and $K_G a$ Data** In estimating the size of a commercial gas absorber or liquid stripper it is desirable to have data on the overall mass-transfer coefficients (or heights of transfer units) for the system of interest, and at the desired conditions of temperature, pressure, solute concentration, and fluid velocities. Such data should best be obtained in an apparatus of pilot-plant or semiworks size to avoid the abnormalities of scale-up. Within the packing category, there are both random and ordered (structured) packing elements. Physical characteristics of these devices will be described later.

When no $K_G a$ or HTU data are available, their values may be estimated by means of a generalized model. A summary of useful models is given in Sec. 5. The values obtained may then be combined by use of Eq. (14-19) to obtain values of $H_{OG}$ and $H_{OL}$. This simple procedure is not valid when the rate of absorption is limited by chemical reaction.

**Use of HETP Data for Absorber Design** Distillation design methods (see Sec. 13) normally involve determination of the number of theoretical equilibrium stages $N$. Thus, when packed towers are employed in distillation applications, it is common practice to rate the efficiency of tower packings in terms of the height of packing equivalent to one theoretical stage (HETP).

The HETP of a packed-tower section, valid for either distillation or dilute-gas absorption and stripping systems in which constant molal overflow can be assumed and in which no chemical reactions occur, is related to the height of one overall gas-phase mass-transfer unit $H_{OG}$ by the equation

$$\text{HETP} = H_{OG}\frac{\ln\left(mG_M/L_M\right)}{\left(mG_M/L_M - 1\right)} \tag{14-29}$$

For gas absorption systems in which the inlet gas is concentrated, the corrected equation is

$$\text{HETP} = \left(\frac{y^0_{BM}}{1-y}\right)_{\text{av}} H_{OG}\frac{\ln\left(mG_M/L_M\right)}{mG_M/L_M - 1} \tag{14-30}$$

where the correction term $y^0_{BM}/(1-y)$ is averaged over each individual theoretical stage. The equilibrium compositions corresponding to each theoretical stage may be estimated by the methods described in the next subsection, "Tray-Tower Design." These compositions are used in conjunction with the local values of the gas and liquid flow rates and the equilibrium slope $m$ to obtain values for $H_G$, $H_L$, and $H_{OG}$ corresponding to the conditions on each theoretical stage, and the local values of the HETP are then computed by Eq. (14-30). The total height of packing required for the separation is the summation of the individual HETPs computed for each theoretical stage.

## TRAY-TOWER DESIGN

The design of a tray tower for gas absorption and gas-stripping operations involves many of the same principles employed in distillation calculations, such as the determination of the number of theoretical trays needed to achieve a specified composition change (see Sec. 13). Distillation differs from absorption because it involves the separation of components based upon the distribution of the various substances between a vapor phase and a liquid phase when all components are present in both phases. In distillation, the new phase is generated from the original phase by the vaporization or condensation of the volatile components, and the separation is achieved by introducing reflux to the top of the tower.

In gas absorption, the new phase consists of a relatively nonvolatile solvent (absorption) or a relatively insoluble gas (stripping), and normally no reflux is involved. This section discusses some of the considerations peculiar to gas absorption calculations for tray towers and some of the approximate design methods that can be applied (when simplifying assumptions are valid).

**Graphical Design Procedure** Construction of design diagrams ($xy$ curves showing the equilibrium and operating curves) should be an integral part of any design involving the distribution of a single solute between an inert solvent and an inert gas. The number of theoretical trays can be stepped off rigorously, provided the curvatures of the operating and equilibrium lines are correctly represented in the diagram. The procedure is valid even though an inert solvent is present in the liquid phase and an inert gas is present in the vapor phase.

Figure 14-8 illustrates the graphical method for a three theoretical stage system. Note that in gas absorption the operating line is above the equilibrium curve, whereas in distillation this does not happen. In gas stripping, the operating line will be below the equilibrium curve.

On Fig. 14-8, note that the stepping-off procedure begins on the operating line. The starting point $x_f$, $y_3$ represents the compositions of the entering lean wash liquor and of the gas exiting from the top of the tower, as defined by the design specifications. After three steps one reaches the point $x_1$, $y_f$ representing the compositions of the solute-rich feed gas $y_f$ and of the solute-rich liquor leaving the bottom of the tower $x_1$.

**Algebraic Method for Dilute Gases** By assuming that the operating and equilibrium curves are straight lines and that heat effects are negligible, Souders and Brown [*Ind. Eng. Chem.*, **24,** 519 (1932)] developed the following equation:

$$\left(y_1 - y_2\right)/\left(y_1 - y_2^0\right) = \left(A^{N+1} - A\right)/\left(A^{N+1} - 1\right) \tag{14-31}$$

where $N$ = number of theoretical trays, $y_1$ = mole fraction of solute in the entering gas, $y_2$ = mole fraction of solute in the leaving gas, $y_2^0 = mx_2$ = mole fraction of solute in equilibrium with the incoming solvent

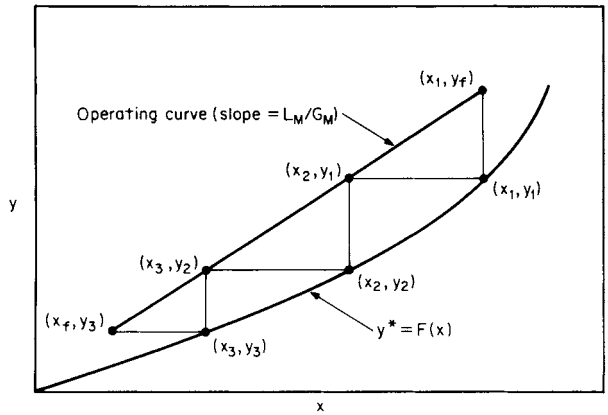

**FIG. 14-8** Graphical method for a three-theoretical-plate gas-absorption tower with inlet-liquor composition $x_f$ and inlet-gas composition $y_f$.

(zero for a pure solvent), and $A$ = absorption factor = $L_M/mG_M$. Note that the absorption factor is the reciprocal of the expression given in Eq. (14-4) for packed columns.

Note that for the limiting case of $A = 1$, the solution is given by

$$\left(y_1 - y_2\right)/\left(y_1 - y_2^0\right) = N/(N+1) \tag{14-32}$$

Although Eq. (14-31) is convenient for computing the composition of the exit gas as a function of the number of theoretical stages, an alternative equation derived by Colburn [*Trans. Am. Inst. Chem. Eng.*, **35,** 211 (1939)] is more useful when the number of theoretical plates is the unknown:

$$N = \frac{\ln\left[\left(1 - A^{-1}\right)\left(y_1 - y_2^0\right)/\left(y_2 - y_2^0\right) + A^{-1}\right]}{\ln\left(A\right)} \tag{14-33}$$

The numerical results obtained by using either Eq. (14-31) or Eq. (14-33) are identical. Thus, the two equations may be used interchangeably as the need arises.

Comparison of Eqs. (14-33) and (14-23) shows that

$$N_{OG}/N = \ln\left(A\right)/\left(1 - A^{-1}\right) \tag{14-34}$$

thus revealing the close relationship between theoretical stages in a plate tower and mass-transfer units in a packed tower. Equations (14-23) and (14-33) are related to each other by virtue of the relation

$$h_T = H_{OG}N_{OG} = (\text{HETP})N \tag{14-35}$$

**Algebraic Method for Concentrated Gases** When the feed gas is concentrated, the absorption factor, which is defined in general as $A = L_M/KG_M$ and where $K = y^0/x$, can vary throughout the tower due to changes in temperature and composition. An approximate solution to this problem can be obtained by substituting the "effective" adsorption factors $A_e$ and $A'$ derived by Edmister [*Ind. Eng. Chem.* **35,** 837 (1943)] into the equation

$$\frac{y_1 - y_2}{y_1} = \left[1 - \frac{1}{A'}\frac{\left(L_M x\right)_2}{\left(G_M y\right)_1}\right]\frac{A_e^{N+1} - A_e}{A_e^{N+1} - 1} \tag{14-36}$$

where subscripts 1 and 2 refer to the bottom and top of the tower, respectively, and the absorption factors are defined by the equations

$$A_e = \sqrt{A_1\left(A_2 + 1\right) + 0.25} - 0.5 \tag{14-37}$$

$$A' = A_1\left(A_2 + 1\right)/\left(A_1 + 1\right) \tag{14-38}$$

This procedure has been applied to the absorption of $C_5$ and lighter hydrocarbon vapors into a lean oil, for example.

**Stripping Equations** When the liquid feed is dilute and the operating and equilibrium curves are straight lines, the stripping equations analogous to Eqs. (14-31) and (14-33) are

$$\left(x_2 - x_1\right)/\left(x_2 - x_1^0\right) = \left(S^{N+1} - S\right)/\left(S^{N+1} - 1\right) \tag{14-39}$$

where $x_1^0 = y_1/m$; $S = mG_M/L_M = A^{-1}$; and

$$N = \frac{\ln [(1 - A)(x_2 - x_1^0)/(x_1 - x_1^0) + A]}{\ln (S)} \tag{14-40}$$

For systems in which the concentrations are large and the stripping factor $S$ may vary along the tower, the following Edmister equations [*Ind. Eng. Chem.*, **35,** 837 (1943)] are applicable:

$$\frac{x_2 - x_1}{x_2} = \left[1 - \frac{1}{S'} \frac{(G_M y)_1}{(L_M x)_2}\right] \frac{S_e^{N+1} - S_e}{S_e^{N+1} - 1} \tag{14-41}$$

where

$$S_e = \sqrt{S_2(S_1 + 1) + 0.25} - 0.5 \tag{14-42}$$

$$S' = S_2(S_1 + 1)/(S_2 + 1) \tag{14-43}$$

and the subscripts 1 and 2 refer to the bottom and top of the tower respectively.

Equations (14-37) and (14-42) represent two different ways of obtaining an effective factor, and a value of $A_e$ obtained by taking the reciprocal of $S_e$ from Eq. (14-42) will not check exactly with a value of $A_e$ derived by substituting $A_1 = 1/S_1$ and $A_2 = 1/S_2$ into Eq. (14-37). Regardless of this fact, the equations generally give reasonable results for approximate design calculations.

It should be noted that throughout this section the subscripts 1 and 2 refer to the bottom and to the top of the apparatus respectively regardless of whether it is an absorber or a stripper. This has been done to maintain internal consistency among all the equations and to prevent the confusion created in some derivations in which the numbering system for an absorber is different from the numbering system for a stripper.

**Tray Efficiencies in Tray Absorbers and Strippers** Computations of the theoretical trays $N$ assume that the liquid on each tray is completely mixed and that the vapor leaving the tray is in equilibrium with the liquid. In practice, complete equilibrium cannot exist since interphase mass transfer requires a finite driving force. This leads to the definition of an overall tray efficiency

$$E = N_{\text{theoretical}}/N_{\text{actual}} \tag{14-44}$$

which can be correlated with the system design variables.

Mass-transfer theory indicates that for trays of a given design, the factors that have the biggest influence on $E$ in absorption and stripping towers are the physical properties of the fluids and the dimensionless ratio $mG_M/L_M$. Systems in which mass transfer is gas-film-controlled may be expected to have efficiencies as high as 50 to 100 percent, whereas tray efficiencies as low as 1 percent have been reported for the absorption of low-solubility (large-$m$) gases into solvents of high viscosity.

The fluid properties of interest are represented by the Schmidt numbers of the gas and liquid phases. For gases, the Schmidt numbers are normally close to unity and independent of temperature and pressure. Thus, gas-phase mass-transfer coefficients are relatively independent of the system.

By contrast, the liquid-phase Schmidt numbers range from about $10^2$ to $10^4$ and depend strongly on temperature. The temperature dependence of the liquid-phase Schmidt number derives primarily from the strong dependence of the liquid viscosity on temperature.

Consideration of the preceding discussion in connection with the relationship between mass-transfer coefficients (see Sec. 5)

$$1/K_G = 1/k_G + m/k_L \tag{14-45}$$

indicates that the variations in the overall resistance to mass transfer in absorbers and strippers are related primarily to variations in the liquid-phase viscosity $\mu$ and the slope $m$. O'Connell [*Trans. Am. Inst. Chem. Eng.*, **42,** 741 (1946)] used the above findings and correlated the tray efficiency in terms of the liquid viscosity and the gas solubility. The O'Connell correlation for absorbers (Fig. 14-9) has Henry's law constant in lb·mol/(atm·ft$^3$), the pressure in atmospheres, and the liquid viscosity in centipoise.

The best procedure for making tray efficiency corrections (which can be quite significant, as seen in Fig. 14-9) is to use experimental data from a prototype system that is large enough to be representative of the actual commercial tower.

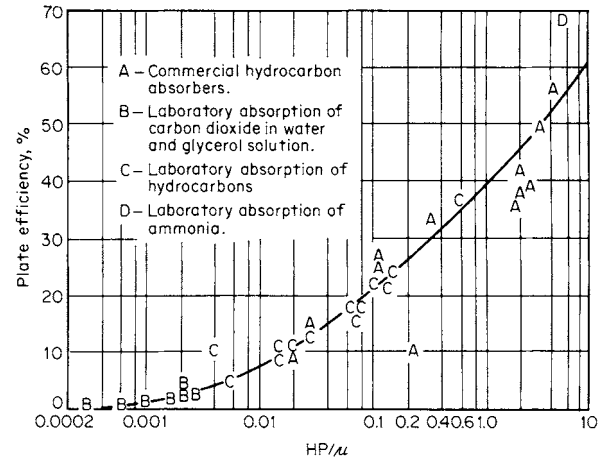

**FIG. 14-9** O'Connell correlation for overall column efficiency $E_{oc}$ for absorption. $H$ is in lb·mol/(atm·ft$^3$), $P$ is in atm, and $\mu$ is in cP. To convert $HP/\mu$ in pound-moles per cubic foot-centipoise to kilogram-moles per cubic meter-pascal-second, multiply by $1.60 \times 10^4$. [*O'Connell,* Trans. Am. Inst. Chem. Eng., ***42,*** 741 (*1946*).]

***Example 4: Actual Trays for Steam Stripping*** The number of actual trays required for steam-stripping an acetone-rich liquor containing 0.573 mole percent acetone in water is to be estimated. The design overhead recovery of acetone is 99.9 percent, leaving 18.5 ppm weight of acetone in the stripper bottoms. The design operating temperature and pressure are 101.3 kPa and 94°C respectively, the average liquid-phase viscosity is 0.30 cP, and the average value of $K = y^o/x$ for these conditions is 33.

By choosing a value of $mG_M/L_M = S = A^{-1} = 1.4$ and noting that the stripping medium is pure steam (i.e., $x_2^o = 0$), the number of theoretical trays according to Eq. (14-40) is

$$N = \frac{\ln [(1 - 0.714)(1000) + 0.714]}{\ln (1.4)} = 16.8$$

The O'Connell parameter for gas absorbers is $\rho_L/KM\mu_L$, where $\rho_L$ is the liquid density, lb/ft$^3$; $\mu_L$ is the liquid viscosity, cP; $M$ is the molecular weight of the liquid; and $K = y^o/x$. For the present design

$$\rho_L/KM\mu_L = 60.1/(33 \times 18 \times 0.30) = 0.337$$

and according to the O'Connell graph for absorbers (Fig. 14-7) the overall tray efficiency for this case is estimated to be 30 percent. Thus, the required number of actual trays is 16.8/0.3 = 56 trays.

## HEAT EFFECTS IN GAS ABSORPTION

**Overview** One of the most important considerations involved in designing gas absorption towers is to determine whether temperatures will vary along the height of the tower due to heat effects; note that the solute solubility usually depends strongly on temperature. The simplified design procedures described earlier in this section become more complicated when heat effects cannot be neglected. The role of this section is to enable understanding and design of gas absorption towers where heat effects are important and cannot be ignored.

Heat effects that cause temperatures to vary from point to point in a gas absorber are (1) the heat of solution (including heat of condensation, heat of mixing, and heat of reaction); (2) the heat of vaporization or condensation of the solvent; (3) the exchange of sensible heat between the gas and liquid phases; and (4) the loss of sensible heat from the fluids to internal or external coils.

There are a number of systems where heat effects definitely cannot be ignored. Examples include the absorption of ammonia in

water, dehumidification of air using concentrated $H_2SO_4$, absorption of HCl in water, absorption of $SO_3$ in $H_2SO_4$, and absorption of $CO_2$ in alkanolamines. Even for systems where the heat effects are mild, they may not be negligible; an example is the absorption of acetone in water.

Thorough and knowledgeable discussions of the problems involved in gas absorption with significant heat effects have been presented by Coggan and Bourne [*Trans. Inst. Chem. Eng.*, **47,** T96, T160 (1969)]; Bourn, von Stockar, and Coggan [*Ind. Eng. Chem. Proc. Des. Dev.*, **13,** 115, 124 (1974)]; and von Stockar and Wilke [*Ind. Eng. Chem. Fundam.*, **16,** 89 (1977)]. The first two of these references discuss tray-tower absorbers and include experimental studies of the absorption of ammonia in water. The third reference discusses the design of packed-tower absorbers and includes a shortcut design method based on a semitheoretical correlation of rigorous design calculations. All these authors demonstrate that when the solvent is volatile, the temperature inside an absorber can go through a maximum. They note that the least expensive and most common of solvents—water—is capable of exhibiting this "hot-spot" behavior.

Several approaches may be used in modeling absorption with heat effects, depending on the job at hand: (1) treat the process as isothermal by assuming a particular temperature, then add a safety factor; (2) employ the classical adiabatic method, which assumes that the heat of solution manifests itself only as sensible heat in the liquid phase and that the solvent vaporization is negligible; (3) use semitheoretical shortcut methods derived from rigorous calculations; and (4) employ rigorous methods available from a process simulator.

While simpler methods are useful for understanding the key effects involved, rigorous methods are recommended for final designs. This subsection also discusses the range of safety factors that are required if simpler methods are used.

**Effects of Operating Variables** Conditions that give rise to significant heat effects are (1) an appreciable heat of solution and/or (2) absorption of large amounts of solute in the liquid phase. The second condition is favored when the solute concentration in the inlet gas is large, when the liquid flow rate is relatively low (small $L_M/G_M$), when the solubility of the solute in the liquid is high, and/or when the operating pressure is high.

If the solute-rich gas entering the bottom of an absorber tower is cold, the liquid phase may be cooled somewhat by transfer of sensible heat to the gas. A much stronger cooling effect can occur when the solute is volatile and the entering gas is not saturated with respect to the solvent. It is possible to experience a condition in which solvent is being evaporated near the bottom of the tower and condensed near the top. Under these conditions a pinch point may develop in which the operating and equilibrium curves approach each other at a point inside the tower.

In the references previously cited, the authors discuss the influence of operating variables upon the performance of towers when large heat effects are involved. Some key observations are as follows:

***Operating Pressure*** Raising the pressure may increase the separation effectiveness considerably. Calculations for the absorption of methanol in water from water-saturated air showed that doubling the pressure doubles the allowable concentration of methanol in the feed gas while still achieving the required concentration specification in the off gas.

***Temperature of Lean Solvent*** The temperature of the entering (lean) solvent has surprisingly little influence upon the temperature profile in an absorber since any temperature changes are usually caused by the heat of solution or the solvent vaporization. In these cases, the temperature profile in the liquid phase is usually dictated solely by the internal-heat effects.

***Temperature and Humidity of the Rich Gas*** Cooling and consequent dehumidification of the feed gas to an absorption tower can be very beneficial. A high humidity (or relative saturation with the solvent) limits the capacity of the gas to take up latent heat and hence is unfavorable to absorption. Thus dehumidification of the inlet gas is worth considering in the design of absorbers with large heat effects.

***Liquid-to-Gas Ratio*** The *L/G* ratio can have a significant influence on the development of temperature profiles in gas absorbers. High *L/G* ratios tend to result in less strongly developed temperature profiles due to the increased heat capacity of the liquid phase. As the *L/G* ratio is increased, the operating line moves away from the equilibrium line and more solute is absorbed per stage or packing segment. However, there is a compensating effect; since more heat is liberated in each stage or packing segment, the temperatures will rise, which causes the equilibrium line to shift up. As the *L/G* ratio is decreased, the concentration of solute tends to build up in the upper part of the absorber, and the point of highest temperature tends to move upward in the tower until finally the maximum temperature occurs at the top of the tower. Of course, the capacity of the liquid to absorb solute falls progressively as *L/G* is reduced.

***Number of Stages or Packing Height*** When the heat effects combine to produce an extended zone in the tower where little absorption takes place (i.e., a pinch zone), the addition of trays or packing height will have no useful effect on separation efficiency. In this case, increases in absorption may be obtained by increasing solvent flow, introducing strategically placed coolers, cooling and dehumidifying the inlet gas, and/or raising the tower pressure.

**Equipment Considerations** When the solute has a large heat of solution and the feed gas contains a high concentration of solute, as in absorption of HCl in water, the effects of heat release during absorption may be so pronounced that the installation of heat-transfer surface to remove the heat of absorption may be as important as providing sufficient interfacial area for the mass-transfer process itself. The added heat-transfer area may consist of internal cooling coils on the trays, or the liquid may be withdrawn from the tower, cooled in an external heat exchanger, and then returned to the tower.

In many cases the rate of heat liberation is largest near the bottom of the tower, where the solute absorption is more rapid, so that cooling surfaces or intercoolers are required only at the lower part of the column. Coggan and Bourne [*Trans. Inst. Chem. Eng.*, **47,** T96, T160 (1969)] found, however, that the optimal position for a single interstage cooler does not necessarily coincide with the position of the maximum temperature of the center of the pinch. They found that in a 12-tray tower, two strategically placed interstage coolers tripled the allowable ammonia feed concentration for a given off-gas specification. For a case involving methanol absorption, it was found that greater separation was possible in a 12-stage column with two intercoolers than in a simple column with 100 stages and no intercoolers.

In the case of HCl absorption, a shell-and-tub heat exchanger often is employed as a cooled wetted-wall vertical-column absorber so that the exothermic heat of reaction can be removed continuously as it is released into a liquid film.

Installation of heat-exchange equipment to precool and dehumidify the feed gas to an absorber also deserves consideration, in order to take advantage of the cooling effects created by vaporization of solvent in the lower sections of the tower.

**Classical Isothermal Design Method** When the feed gas is sufficiently dilute, the exact design solution may be approximated by the isothermal one over the broad range of *L/G* ratios, since heat effects are generally less important when washing dilute-gas mixtures. The problem, however, is one of defining the term *sufficiently dilute* for each specific case. For a new absorption duty, the assumption of isothermal operation must be subjected to verification by the use of a rigorous design procedure.

When heat-exchange surface is being provided in the design of an absorber, the isothermal design procedure can be rendered valid by virtue of the exchanger design specification. With ample surface area and a close approach, isothermal operation can be guaranteed.

For preliminary screening and feasibility studies or for rough estimates, one may wish to employ a version of the isothermal design method which assumes that the liquid temperatures in the tower are everywhere equal to the inlet-liquid temperature. In their analysis of packed-tower designs, von Stockar and Wilke [*Ind. Eng. Chem. Fundam.*, **16,** 89 (1977)] showed that the isothermal method tended to underestimate the required height of packing by a factor of as much as

1.5 to 2. Thus, for rough estimates one may wish to employ the assumption that the absorber temperature is equal to the inlet-liquid temperature and then apply a design factor to the result.

Another instance in which the constant-temperature method is used involved the direct application of experimental $K_G a$ values obtained at the desired conditions of inlet temperatures, operating pressures, flow rates, and feed-stream compositions. The assumption here is that, regardless of any temperature profiles that may exist within the actual tower, the procedure of "working the problem in reverse" will yield a correct result. One should, however, be cautious about extrapolating such data from the original basis and be careful to use compatible equilibrium data.

**Classical Adiabatic Design Method** The classical adiabatic design method assumes that the heat of solution serves only to heat up the liquid stream and there is no vaporization of the solvent. This assumption makes it feasible to relate increases in the liquid-phase temperature to the solute concentration $x$ by a simple enthalpy balance. The equilibrium curve can then be adjusted to account for the corresponding temperature rise on an $xy$ diagram. The adjusted equilibrium curve will be concave upward as the concentration increases, tending to decrease the driving forces near the bottom of the tower, as illustrated in Fig. 14-10 in Example 6.

Colburn [*Trans. Am. Inst. Chem. Eng.*, **35,** 211 (1939)] has shown that when the equilibrium line is straight near the origin but curved slightly at its upper end, $N_{OG}$ can be computed approximately by assuming that the equilibrium curve is a parabolic arc of slope $m_2$ near the origin and passing through the point $x_1, K_1x_1$ at the upper end. The Colburn equation for this case is

$$N_{OG} = \frac{1}{1 - m_2 G_M/L_M} \times \ln\left[\frac{(1 - m_2 G_M/L_M)^2}{1 - K_1 G_M/L_M}\left(\frac{y_1 - m_2 x_2}{y_2 - m_2 x_2}\right) + \frac{m_2 G_M}{L_M}\right] \quad (14\text{-}46)$$

Comparison by von Stockar and Wilke [*Ind. Eng. Chem. Fundam.*, **16,** 89 (1977)] between the rigorous and the classical adiabatic design methods for packed towers indicates that the simple adiabatic design methods underestimate packing heights by as much as a factor of 1.25 to 1.5. Thus, when using the classical adiabatic method, one should probably apply a design safety factor.

A slight variation of the above method accounts for increases in the solvent content of the gas stream between the inlet and the outlet of the tower and assumes that the evaporation of solvent tends to cool the liquid. This procedure offsets a part of the temperature rise that would have been predicted with no solvent evaporation and leads to the prediction of a shorter tower.

**Rigorous Design Methods** A detailed discussion of rigorous methods for the design of packed and tray absorbers when large heat effects are involved is beyond the scope of this subsection. In principle, material and energy balances may be executed under the same constraints as for rigorous distillation calculations (see Sec. 13). Further discussion on this subject is given in the subsection "Absorption with Chemical Reaction."

**Direct Comparison of Design Methods** The following problem, originally presented by Sherwood, Pigford, and Wilke (*Mass Transfer*, McGraw-Hill, New York, 1975, p. 616) was employed by von Stockar and Wilke (op. cit.) as the basis for a direct comparison between the isothermal, adiabatic, semitheoretical shortcut, and rigorous design methods for estimating the height of packed towers.

***Example 5: Packed Absorber, Acetone into Water*** Inlet gas to an absorber consists of a mixture of 6 mole percent acetone in air saturated with water vapor at 15°C and 101.3 kPa (1 atm). The scrubbing liquor is pure water at 15°C, and the inlet gas and liquid rates are given as 0.080 and 0.190 kmol/s respectively. The liquid rate corresponds to 20 percent over the theoretical minimum as calculated by assuming a value of $x_1$ corresponding to complete equilibrium between the exit liquor and the incoming gas. $H_G$ and $H_L$ are given as 0.42 and 0.30 m respectively, and the acetone equilibrium data at 15°C are $p_A^0 =$ 19.7 kPa (147.4 torr), $\gamma_A = 6.46$, and $m_A = 6.46 \times 19.7/101.3 = 1.26$. The heat of solution of acetone is 7656 cal/gmol (32.05 kJ/gmol), and the heat of vaporization of solvent (water) is 10,755 cal/gmol (45.03 kJ/gmol). The problem calls for determining the height of packing required to achieve a 90 percent recovery of the acetone.

The following table compares the results obtained by von Stockar and Wilke (op. cit.) for the various design methods:

| Design method used | $N_{OG}$ | Packed height, m | Design safety factor |
|---|---|---|---|
| Rigorous | 5.56 | 3.63 | 1.00 |
| Shortcut rigorous | 5.56 | 3.73 | 0.97 |
| Classical adiabatic | 4.01 | 2.38 | 1.53 |
| Classical isothermal | 3.30 | 1.96 | 1.85 |

It should be clear from this example that there is considerable room for error when approximate design methods are employed in situations involving large heat effects, even for a case in which the solute concentration in the inlet gas is only 6 mole percent.

***Example 6: Solvent Rate for Absorption*** Let us consider the absorption of acetone from air at atmospheric pressure into a stream of pure water fed to the top of a packed absorber at 25°C. The inlet gas at 35°C contains 2 percent by volume of acetone and is 70 percent saturated with water vapor (4 percent $H_2O$ by volume). The mole-fraction acetone in the exit gas is to be reduced to 1/400 of the inlet value, or 50 ppmv. For 100 kmol of feed-gas mixture, how many kilomoles of fresh water should be fed to provide a positive-driving force throughout the packing? How many transfer units will be needed according to the classical adiabatic method? What is the estimated height of packing required if $H_{OG} = 0.70$ m?

The latent heats at 25°C are 7656 kcal/kmol for acetone and 10,490 kcal/kmol for water, and the differential heat of solution of acetone vapor in pure water is given as 2500 kcal/kmol. The specific heat of air is 7.0 kcal/(kmol·K).

Acetone solubilities are defined by the equation

$$K = y^\circ/x = \gamma_a p_a/p_T \quad (14\text{-}47)$$

where the vapor pressure of pure acetone in mmHg (torr) is given by (Sherwood et al., *Mass Transfer,* McGraw-Hill, New York, 1975, p. 537):

$$p_A^0 = \exp(18.1594 - 3794.06/T) \quad (14\text{-}48)$$

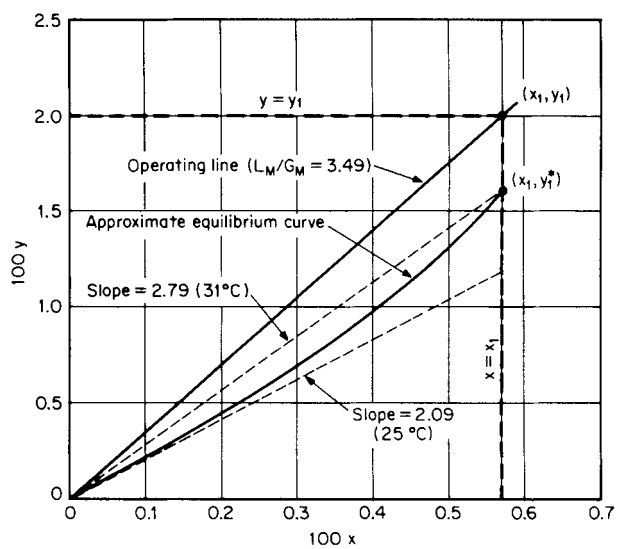

**FIG. 14-10** Design diagram for adiabatic absorption of acetone in water, Example 6.

and the liquid-phase-activity coefficient may be approximated for low concentrations ($x \leq 0.01$) by the equation

$$\gamma_a = 6.5 \exp (2.0803 - 601.2/T) \tag{14-49}$$

Typical values of acetone solubility as a function of temperature at a total pressure of 760 mmHg are shown in the following table:

| $t$, °C | 25 | 30 | 35 | 40 |
|---|---|---|---|---|
| $\gamma_a$ | 6.92 | 7.16 | 7.40 | 7.63 |
| $p_a$, mmHg | 229 | 283 | 346 | 422 |
| $K = \gamma_a p_a^0/760$ | 2.09 | 2.66 | 3.37 | 4.23 |

For dry gas and liquid water at 25°C, the following enthalpies are computed for the inlet- and exit-gas streams (basis, 100 kmol of gas entering):

Entering gas:

| | | |
|---|---|---|
| Acetone | $2(2500 + 7656) =$ | 20,312 kcal |
| Water vapor | $4(10,490) =$ | 41,960 |
| Sensible heat | $(100)(7.0)(35 - 25) =$ | 7,000 |
| | | 69,272 kcal |

Exit gas (assumed saturated with water at 25°C):

| | | |
|---|---|---|
| Acetone | $(2/400)(94/100)(2500) =$ | 12 kcal |
| Water vapor | $94\left(\frac{23.7}{760 - 23.7}\right)(10,490) =$ | 31,600 |
| | | 31,612 kcal |

Enthalpy change of liquid = 69,272 − 31,612 = 37,660 kcal/100 kmol gas. Thus, $\Delta t = t_1 - t_2 = 37{,}660/18L_M$, and the relation between $L_M/G_M$ and the liquid-phase temperature rise is

$$L_M/G_M = (37{,}660)/(18)(100)\ \Delta t = 20.92/\Delta t$$

The following table summarizes the critical values for various assumed temperature rises:

| $\Delta t$, °C | $L_M/G_M$ | $K_1$ | $K_1G_M/L_M$ | $m_2G_M/L_M$ |
|---|---|---|---|---|
| 0 | | 2.09 | 0. | 0. |
| 2 | 10.46 | 2.31 | 0.221 | 0.200 |
| 3 | 6.97 | 2.42 | 0.347 | 0.300 |
| 4 | 5.23 | 2.54 | 0.486 | 0.400 |
| 5 | 4.18 | 2.66 | 0.636 | 0.500 |
| 6 | 3.49 | 2.79 | 0.799 | 0.599 |
| 7 | 2.99 | 2.93 | 0.980 | 0.699 |

Evidently a temperature rise of 7°C would not be a safe design because the equilibrium line nearly touches the operating line near the bottom of the tower, creating a pinch. A temperature rise of 6°C appears to give an operable design, and for this case $L_M$ = 349 kmol per 100 kmol of feed gas.

The design diagram for this case is shown in Fig. 14-10, in which the equilibrium curve is drawn so that the slope at the origin $m_2$ is equal to 2.09 and passes through the point $x_1 = 0.02/3.49 = 0.00573$ at $y_1^\circ = 0.00573 \times 2.79 = 0.0160$.

The number of transfer units can be calculated from the adiabatic design equation, Eq. (14-46):

$$N_{OG} = \frac{1}{1 - 0.599} \ln \left[ \frac{(1 - 0.599)^2}{(1 - 0.799)} (400) + 0.599 \right] = 14.4$$

The estimated height of tower packing by assuming $H_{OG}$ = 0.70 m and a design safety factor of 1.5 is

$$h_T = (14.4)(0.7)(1.5) = 15.1 \text{ m } (49.6 \text{ ft})$$

For this tower, one should consider the use of two or more shorter packed sections instead of one long section.

Another point to be noted is that this calculation would be done more easily today by using a process simulator. However, the details are presented here to help the reader gain familiarity with the key assumptions and results.

## MULTICOMPONENT SYSTEMS

When no chemical reactions are involved in the absorption of more than one soluble component from an insoluble gas, the design conditions (temperature, pressure, liquid-to-gas ratio) are normally determined by the volatility or physical solubility of the least soluble component for which the recovery is specified.

The more volatile (i.e., less soluble) components will only be partially absorbed even for an infinite number of trays or transfer units. This can be seen in Fig. 14-9, in which the asymptotes become vertical for values of $mG_M/L_M$ greater than unity. If the amount of volatile component in the fresh solvent is negligible, then the limiting value of $y_1/y_2$ for each of the highly volatile components is

$$y_1/y_2 = S/(S - 1) \tag{14-50}$$

where $S = mG_M/L_M$ and the subscripts 1 and 2 refer to the bottom and top of the tower, respectively.

When the gas stream is dilute, absorption of each constituent can be considered separately as if the other components were absent. The following example illustrates the use of this principle.

***Example 7: Multicomponent Absorption, Dilute Case*** Air entering a tower contains 1 percent acetaldehyde and 2 percent acetone. The liquid-to-gas ratio for optimum acetone recovery is $L_M/G_M$ = 3.1 mol/mol when the fresh-solvent temperature is 31.5°C. The value of $y^\circ/x$ for acetaldehyde has been measured as 50 at the boiling point of a dilute solution, 93.5°C. What will the percentage recovery of acetaldehyde be under conditions of optimal acetone recovery?

*Solution.* If the heat of solution is neglected, $y^\circ/x$ at 31.5°C is equal to 50(1200/7300) = 8.2, where the factor in parentheses is the ratio of pure-acetaldehyde vapor pressures at 31.5 and 93.5°C respectively. Since $L_M/G_M$ is equal to 3.1, the value of $S$ for the aldehyde is $S = mG_M/L_M = 8.2/3.1 = 2.64$, and $y_1/y_2 = S/(S - 1) = 2.64/1.64 = 1.61$. The acetaldehyde recovery is therefore equal to $100 \times 0.61/1.61 = 38$ percent recovery.

In concentrated systems the change in gas and liquid flow rates within the tower and the heat effects accompanying the absorption of all the components must be considered. A trial-and-error calculation from one theoretical stage to the next usually is required if accurate results are to be obtained, and in such cases calculation procedures similar to those described in Sec. 13 normally are employed. A computer procedure for multicomponent adiabatic absorber design has been described by Feintuch and Treybal [*Ind. Eng. Chem. Process Des. Dev.*, **17,** 505 (1978)]. Also see Holland, *Fundamentals and Modeling of Separation Processes*, Prentice Hall, Englewood Cliffs, N.J., 1975.

In concentrated systems, the changes in the gas and liquid flow rates within the tower and the heat effects accompanying the absorption of all components must be considered. A trial-and-error calculation from one theoretical stage to the next is usually required if accurate and reliable results are to be obtained, and in such cases calculation procedures similar to those described in Sec. 13 need to be employed.

When two or more gases are absorbed in systems involving chemical reactions, the system is much more complex. This topic is discussed later in the subsection "Absorption with Chemical Reaction."

**Graphical Design Method for Dilute Systems** The following notation for multicomponent absorption systems has been adapted from Sherwood, Pigford, and Wilke (*Mass Transfer*, McGraw-Hill, New York, 1975, p. 415):

$L_M^s$ = moles of solvent per unit time

$G_M^0$ = moles of rich feed gas to be treated per unit time

$X$ = moles of one solute per mole of solute-free solvent fed to top of tower

$Y$ = moles of one solute in gas phase per mole of rich feed gas

Subscripts 1 and 2 refer to the bottom and the top of the tower, respectively, and the material balance for any one component may be written as

$$L_M^s(X - X_2) = G_M^0(Y - Y_2) \tag{14-51}$$

or else as

$$L_M^s(X_1 - X) = G_M^0(Y_1 - Y) \tag{14-52}$$

For the special case of absorption from lean gases with relatively large amounts of solvent, the equilibrium lines are defined for each component by the relation

$$Y^0 = K'X \tag{14-53}$$

Thus, the equilibrium line for each component passes through the origin with slope $K'$, where

$$K' = K(G_M/G_M^0)/(L_M/L_M^S) \tag{14-54}$$

and $K = y^0/x$. When the system is sufficiently dilute, $K' = K$.

The liquid-to-gas ratio is chosen on the basis of the least soluble component in the feed gas that must be absorbed completely. Each component will then have its own operating line with slope equal to $L_M^S/G_M^0$ (i.e., the operating lines for the various components will be parallel).

A typical diagram for the complete absorption of pentane and heavier components is shown in Fig. 14-11. The oil used as solvent is assumed to be solute-free (i.e., $X_2 = 0$), and the "key component," butane, was identified as that component absorbed in appreciable amounts whose equilibrium line is most nearly parallel to the operating lines (i.e., the $K$ value for butane is approximately equal to $L_M^S/G_M^0$).

In Fig. 14-11, the composition of the gas with respect to components more volatile than butane will approach equilibrium with the liquid phase at the bottom of the tower. The gas compositions of the components less volatile (heavier) than butane will approach equilibrium with the oil entering the tower, and since $X_2 = 0$, the components heavier than butane will be completely absorbed.

Four theoretical trays have been stepped off for the key component (butane) on Fig. 14-11, and are seen to give a recovery of 75 percent of the butane. The operating lines for the other components have been drawn with the same slope and placed so as to give approximately the same number of theoretical trays. Figure 14-11 shows that equilibrium is easily achieved in fewer than four theoretical trays and that for the heavier components nearly complete recovery is obtained in four theoretical trays. The diagram also shows that absorption of the light components takes place in the upper part of the tower, and the final recovery of the heavier components takes place in the lower section of the tower.

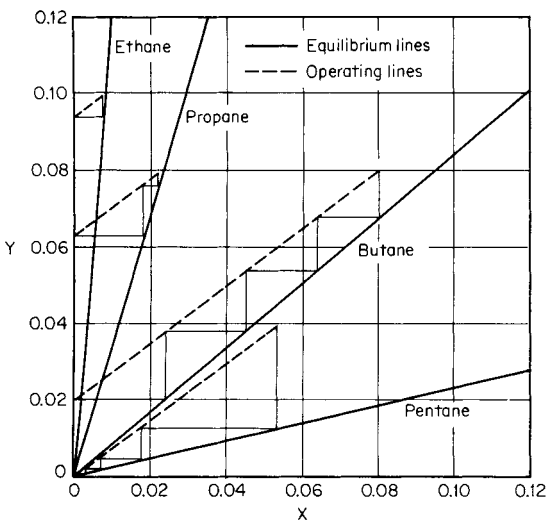

**FIG. 14-11** Graphical design method for multicomponent systems; absorption of butane and heavier components in a solute-free lean oil.

**Algebraic Design Method for Dilute Systems** The design method described above can be performed algebraically by employing the following modified version of the Kremser formula:

$$\frac{Y_1 - Y_2}{Y_1 - mX_2} = \frac{(A^0)^{N+1} - A^0}{(A^0)^{N+1} - 1} \tag{14-55}$$

where for dilute gas absorption $A^0 = L_M^S/mG_M^0$ and $m \approx K = y^0/x$.

The left side of Eq. (14-55) represents the efficiency of absorption of any one component of the feed gas mixture. If the solvent is solute-free so that $X_2 = 0$, the left side is equal to the fractional absorption of the component from the rich feed gas. When the number of theoretical trays $N$ and the liquid and gas feed rates $L_M^S$ and $G_M^0$ have been fixed, the fractional absorption of each component may be computed directly, and the operating lines need not be placed by trial and error as in the graphical method described above.

According to Eq. (14-55), when $A^0$ is less than unity and $N$ is large,

$$(Y_1 - Y_2)/(Y_1 - mX_2) = A^0 \tag{14-56}$$

Equation (14-56) may be used to estimate the fractional absorption of more volatile components when $A^0$ of the component is greater than $A^0$ of the key component by a factor of 3 or more.

When $A^0$ is much larger than unity and $N$ is large, the right side of Eq. (14-55) becomes equal to unity. This signifies that the gas will leave the top of the tower in equilibrium with the incoming oil, and when $X_2 = 0$, it corresponds to complete absorption of the component in question. Thus, the least volatile components may be assumed to be at equilibrium with the lean oil at the top of the tower.

When $A^0 = 1$, the right side of Eq. (14-56) simplifies as follows:

$$(Y_1 - Y_2)/(Y_1 - mX_2) = N/(N+1) \tag{14-57}$$

For systems in which the absorption factor $A^0$ for each component is not constant throughout the tower, an effective absorption factor for use in the equations just presented can be estimated by the Edmister formula

$$A_e^0 = \sqrt{A_1^0(A_2^0 + 1) + 0.25} - 0.5 \tag{14-58}$$

This procedure is a reasonable approximation only when no pinch points exist within the tower and when the absorption factors vary in a regular manner between the bottom and the top of the tower.

***Example 8: Multicomponent Absorption, Concentrated Case*** A hydrocarbon feed gas is to be treated in an existing four-theoretical-tray absorber to remove butane and heavier components. The recovery specification for the key component, butane, is 75 percent. The composition of the exit gas from the absorber and the required liquid-to-gas ratio are to be estimated. The feed-gas composition and the equilibrium $K$ values for each component at the temperature of the (solute-free) lean oil are presented in the following table:

| Component | Mole % | $K$ value |
|---|---|---|
| Methane | 68.0 | 74.137 |
| Ethane | 10.0 | 12.000 |
| Propane | 8.0 | 3.429 |
| Butane | 8.0 | 0.833 |
| Pentane | 4.0 | 0.233 |
| $C_6$ plus | 2.0 | 0.065 |

For $N = 4$ and $Y_2/Y_1 = 0.25$, the value of $A^0$ for butane is found to be equal to 0.89 from Eq. (14-55) by using a trial-and-error method. The values of $A^0$ for the other components are then proportional to the ratios of their $K$ values to that of butane. For example, $A^0 = 0.89(0.833/12.0) = 0.062$ for ethane. The values of $A^0$ for each of the other components and the exit-gas composition as computed from Eq. (14-55) are shown in the following table:

| Component | $A^0$ | $Y_2$, mol/mol feed | Exit gas, mole % |
|---|---|---|---|
| Methane | 0.010 | 67.3 | 79.1 |
| Ethane | 0.062 | 9.4 | 11.1 |
| Propane | 0.216 | 6.3 | 7.4 |
| Butane | 0.890 | 2.0 | 2.4 |
| Pentane | 3.182 | 0.027 | 0.03 |
| $C_6$ plus | 11.406 | 0.0012 | 0.0014 |

The molar liquid-to-gas ratio required for this separation is computed as $L_M^*/G_M^0 = A^0 \times K = 0.89 \times 0.833 = 0.74$.

We note that this example is the analytical solution to the graphical design problem shown in Fig. 14-11, which therefore is the design diagram for this system.

The simplified design calculations presented in this section are intended to reveal the key features of gas absorption involving multicomponent systems. It is expected that rigorous computations, based upon the methods presented in Sec. 13, will be used in design practice. Nevertheless, it is valuable to study these simplified design methods and examples since they provide insight into the key elements of multicomponent absorption.

## ABSORPTION WITH CHEMICAL REACTION

**Introduction** Many present-day commercial gas absorption processes involve systems in which chemical reactions take place in the liquid phase; an example of the absorption of $CO_2$ by MEA has been presented earlier in this section. These reactions greatly increase the capacity of the solvent and enhance the rate of absorption when compared to physical absorption systems. In addition, the selectivity of reacting solutes is greatly increased over that of nonreacting solutes. For example, MEA has a strong selectivity for $CO_2$ compared to chemically inert solutes such as $CH_4$, CO, or $N_2$. Note that the design procedures presented here are theoretically and practically related to biofiltration, which is discussed in Sec. 25 (Waste Management).

A necessary prerequisite to understanding the subject of absorption with chemical reaction is the development of a thorough understanding of the principles involved in physical absorption, as discussed earlier in this section and in Sec. 5. Excellent references on the subject of absorption with chemical reactions are the books by Dankwerts (*Gas-Liquid Reactions*, McGraw-Hill, New York, 1970) and Astarita et al. (*Gas Treating with Chemical Solvents*, Wiley, New York, 1983).

**Recommended Overall Design Strategy** When one is considering the design of a gas absorption system involving chemical reactions, the following procedure is recommended:

1. Consider the possibility that the physical design methods described earlier in this section may be applicable.
2. Determine whether commercial design overall $K_G a$ values are available for use in conjunction with the traditional design method, being careful to note whether the conditions under which the $K_G a$ data were obtained are essentially the same as for the new design. Contact the various tower-packing vendors for information as to whether $K_G a$ data are available for your system and conditions.
3. Consider the possibility of scaling up the design of a new system from experimental data obtained in a laboratory bench-scale or small pilot-plant unit.
4. Consider the possibility of developing for the new system a rigorous, theoretically based design procedure which will be valid over a wide range of design conditions. Note that commercial software is readily available today to develop a rigorous model in a relatively small amount of time.

These topics are further discussed in the subsections that follow.

**Dominant Effects in Absorption with Chemical Reaction** When the solute is absorbing into a solution containing a reagent that chemically reacts with it, diffusion and reaction effects become closely coupled. It is thus important for the design engineer to understand the key effects. Figure 14-12 shows the concentration profiles that occur when solute *A* undergoes an irreversible second-order reaction with component *B*, dissolved in the liquid, to give product *C*.

$$A + bB \rightarrow cC \tag{14-59}$$

The rate equation is

$$r_A = -k_2 C_A C_B \tag{14-60}$$

Figure 14-12 shows that the fast reaction takes place entirely in the liquid film. In such instances, the dominant mass-transfer mechanism is physical absorption, and physical design methods are applicable but the resistance to mass transfer in the liquid phase is lower due to the reaction. On the other extreme, a slow reaction occurs in the bulk of the liquid, and its rate has little dependence on the resistance to diffusion in either the gas or the liquid films. Here the mass-transfer mechanism is that of chemical reaction, and holdup in the bulk liquid is the determining factor.

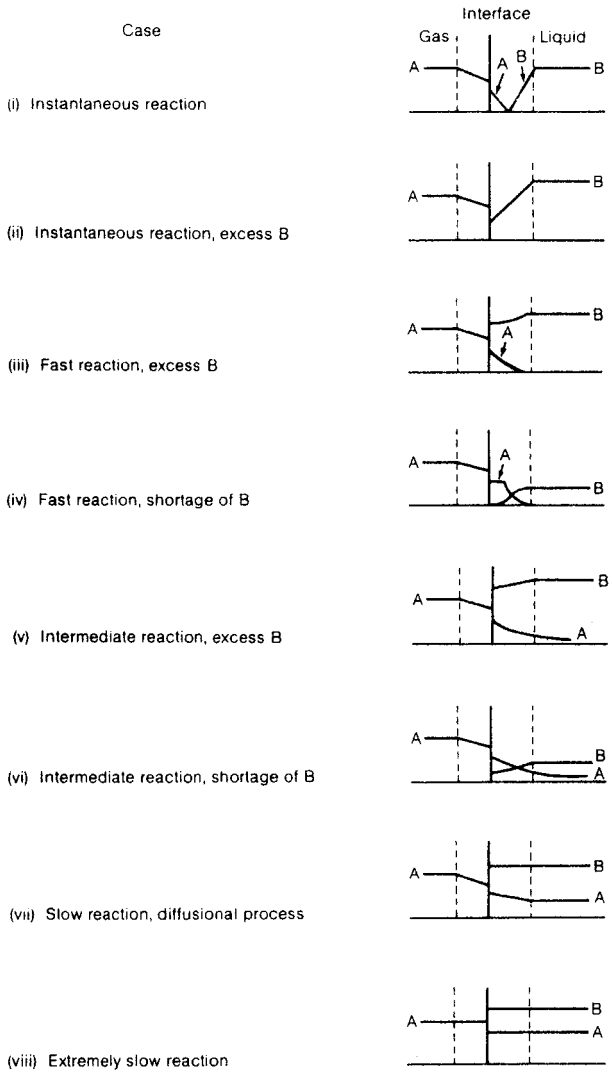

**FIG. 14-12** Vapor- and liquid-phase concentration profiles near an interface for absorption with chemical reaction.

The Hatta number is a dimensionless group used to characterize the importance of the speed of reaction relative to the diffusion rate.

$$N_{\mathrm{Ha}} = \frac{\sqrt{D_A k_2 C_{B0}}}{k_L^0} \tag{14-61}$$

As the Hatta number increases, the effective liquid-phase mass-transfer coefficient increases. Figure 14-13, which was first developed by Van Krevelen and Hoftyzer [*Rec. Trav. Chim.*, **67,** 563 (1948)] and later refined by Perry and Pigford and by Brian et al. [*AIChE J.*, **7,** 226 (1961)], shows how the enhancement (defined as the ratio of the effective liquid-phase mass-transfer coefficient to its physical equivalent $\phi = k_L/k_L^0$) increases with $N_{\mathrm{Ha}}$ for a second-order, irreversible reaction of the kind defined by Eqs. (14-60) and (14-61). The various curves in Fig. 14-13 were developed based upon penetration theory and

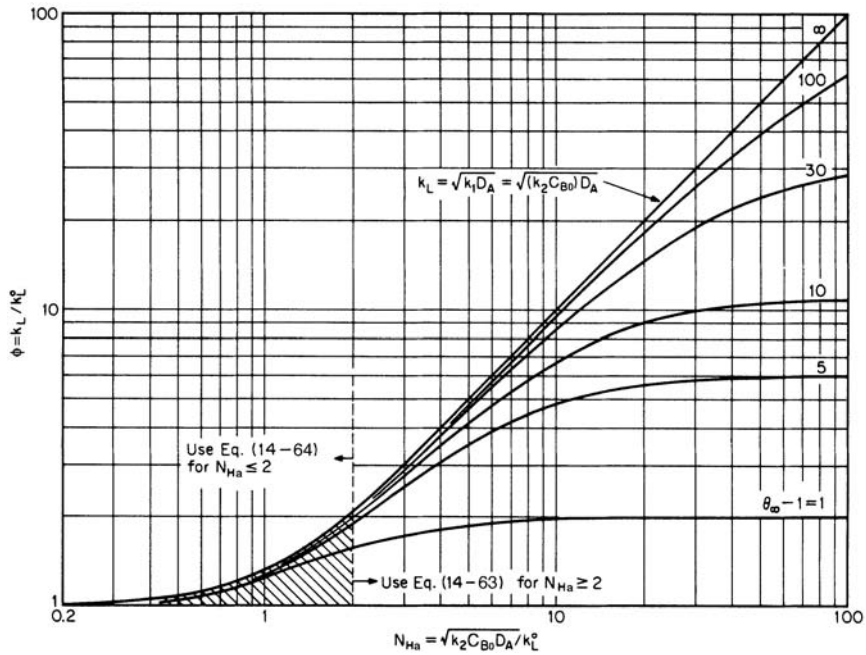

**FIG. 14-13** Influence of irreversible chemical reactions on the liquid-phase mass-transfer coefficient $k_L$. [*Adapted from Van Krevelen and Hoftyzer,* Rec. Trav. Chim., ***67,*** *563 (1948).*]

depend on the parameter $\phi_\infty - 1$, which is related to the diffusion coefficients and reaction coefficients, as shown below.

$$\phi_\infty = \sqrt{\frac{D_A}{D_B}} + \sqrt{\frac{D_A}{D_B}} \left( \frac{C_B}{C_A b} \right) \qquad (14\text{-}62)$$

For design purposes, the entire set of curves in Fig. 14-13 may be represented by the following two equations:
For, $N_{Ha} \ge 2$:

$$k_L/k_L^0 = 1 + (\phi_\infty - 1)\{1 - \exp[-(N_{Ha} - 1)/(\phi_\infty - 1)]\} \qquad (14\text{-}63)$$

For, $N_{Ha} \le 2$:

$$k_L/k_L^0 = 1 + (\phi_\infty - 1)\{1 - \exp[-(\phi_\infty - 1)^{-1}]\} \exp[1 - 2/N_{Ha}] \qquad (14\text{-}64)$$

Equation (14-64) was originally reported by Porter [*Trans. Inst. Chem. Eng.*, **44,** T25 (1966)], and Eq. (14-64) was derived by Edwards and first reported in the 6th edition of this handbook.

The Van Krevelen-Hoftyzer (Fig. 14-13) relationship was tested by Nijsing et al. [*Chem. Eng. Sci.*, **10,** 88 (1959)] for the second-order system in which $CO_2$ reacts with either NaOH or KOH solutions. Nijsing's results are shown in Fig. 14-14 and can be seen to be in excellent

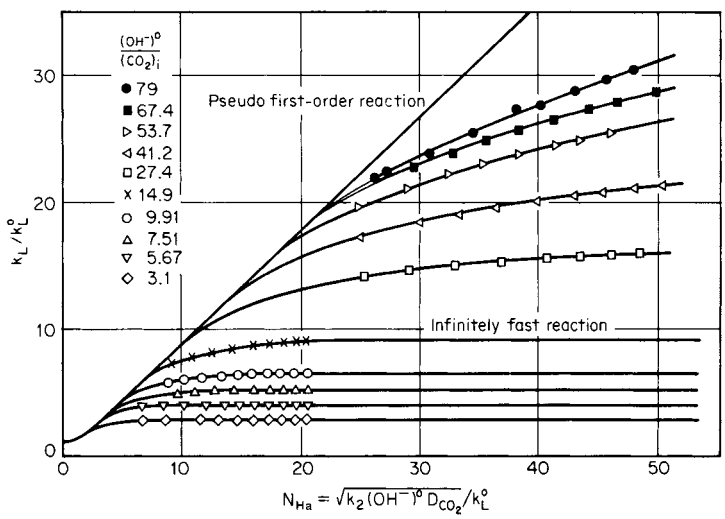

**FIG. 14-14** Experimental values of $k_L/k_L^0$ for absorption of $CO_2$ into NaOH solutions at 20°C. [*Data of Nijsing et al.,* Chem. Eng. Sci., ***10,*** 88 (1959).]

agreement with the second-order-reaction theory. Indeed, these experimental data are well described by Eqs. (14-62) and (14-63) when values of $b = 2$ and $D_A/D_B = 0.64$ are employed in the equations.

**Applicability of Physical Design Methods** Physical design models such as the classical isothermal design method or the classical adiabatic design method may be applicable for systems in which chemical reactions are either extremely fast or extremely slow, or when chemical equilibrium is achieved between the gas and liquid phases.

If the chemical reaction is extremely fast and irreversible, the rate of absorption may in some cases be completely governed by gas-phase resistance. For practical design purposes, one may assume, e.g., that this gas-phase mass-transfer-limited condition will exist when the ratio $y_i/y$ is less than 0.05 everywhere in the apparatus.

From the basic mass-transfer flux relationship for species $A$ (Sec. 5)

$$N_A = k_G(y - y_i) = k_L(x_i - x) \tag{14-65}$$

one can readily show that this condition on $y_i/y$ requires that the ratio $x/x_i$ be negligibly small (i.e., a fast reaction) and that the ratio $mk_G/k_L = mk_G/k_L^0\phi$ be less than 0.05 everywhere in the apparatus. The ratio $mk_G/k_L^0\phi$ will be small if the equilibrium backpressure of the solute over the liquid is small (i.e., small $m$ or high reactant solubility), or the reaction enhancement factor $\phi = k_L/k_L^0$ is very large, or both. The reaction enhancement factor $\phi$ will be large for all extremely fast pseudo-first-order reactions and will be large for extremely fast second-order irreversible reaction systems in which there is sufficiently large excess of liquid reagent.

Figure 14-12, case (ii), illustrates the gas-film and liquid-film concentration profiles one might find in an extremely fast (gas-phase mass-transfer-limited), second-order irreversible reaction system. The solid curve for reagent $B$ represents the case in which there is a large excess of bulk liquid reagent $B^0$. Figure 14-12, case (iv), represents the case in which the bulk concentration $B^0$ is not sufficiently large to prevent the depletion of $B$ near the liquid interface.

Whenever these conditions on the ratio $y_i/y$ apply, the design can be based upon the physical rate coefficient $k_G$ or upon the height of one gas-phase mass-transfer unit $H_G$. The gas-phase mass-transfer-limited condition is approximately valid for the following systems: absorption of $NH_3$ into water or acidic solutions, absorption of $H_2O$ into concentrated sulfuric acid, absorption of $SO_2$ into alkali solutions, absorption of $H_2S$ from a gas stream into a strong alkali solution, absorption of HCl into water or alkaline solutions, or absorption of $Cl_2$ into strong alkali solutions.

When the liquid-phase reactions are extremely slow, the gas-phase resistance can be neglected and one can assume that the rate of reaction has a predominant effect upon the rate of absorption. In this case the differential rate of transfer is given by the equation

$$dn_A = R_A f_H S\, dh = (k_L^0 a/\rho_L)(c_i - c)S\, dh \tag{14-66}$$

where $n_A$ = rate of solute transfer, $R_A$ = volumetric reaction rate (function of $c$ and $T$), $f_H$ = fractional liquid volume holdup in tower or apparatus, $S$ = tower cross-sectional area, $h$ = vertical distance, $k_L^0$ = liquid-phase mass-transfer coefficient for pure physical absorption, $a$ = effective interfacial mass-transfer area per unit volume of tower or apparatus, $\rho_L$ = average molar density of liquid phase, $c_i$ = solute concentration in liquid at gas-liquid interface, and $c$ = solute concentration in bulk liquid.

Although the right side of Eq. (14-66) remains valid even when chemical reactions are extremely slow, the mass-transfer driving force may become increasingly small, until finally $c \approx c_i$. For extremely slow first-order irreversible reactions, the following rate expression can be derived from Eq. (14-66):

$$R_A = k_1 c = k_1 c_i/(1 + k_1\rho_L f_H/k_L^0 a) \tag{14-67}$$

where $k_1$ = first-order reaction rate coefficient.

For dilute systems in countercurrent absorption towers in which the equilibrium curve is a straight line (i.e., $y_i = mx_i$), the differential relation of Eq. (14-66) is formulated as

$$dn_A = -G_M S\, dy = k_1 c f_H S\, dh \tag{14-68}$$

where $G_M$ = molar gas-phase mass velocity and $y$ = gas-phase solute mole fraction.

Substitution of Eq. (14-67) into Eq. (14-68) and integration lead to the following relation for an extremely slow first-order reaction in an absorption tower:

$$y_2 = y_1 \exp\left[-\frac{k_1\rho_L f_H h_T/(mG_m)}{1 + k_1\rho_L f_H/(k_L^0 a)}\right] \tag{14-69}$$

In Eq. (14-69) subscripts 1 and 2 refer to the bottom and top of the tower, respectively.

As discussed above, the Hatta number $N_{Ha}$ usually is employed as the criterion for determining whether a reaction can be considered extremely slow. A reasonable criterion for slow reactions is

$$N_{Ha} = \sqrt{k_1 D_A}/k_L^0 \le 0.3 \tag{14-70}$$

where $D_A$ = liquid-phase diffusion coefficient of the solute in the solvent. Figure 14-12, cases (vii) and (viii), illustrates the concentration profiles in the gas and liquid films for the case of an extremely slow chemical reaction.

Note that when the second term in the denominator of the exponential in Eq. (14-69) is very small, the liquid holdup in the tower can have a significant influence upon the rate of absorption if an extremely slow chemical reaction is involved.

When chemical equilibrium is achieved quickly throughout the liquid phase, the problem becomes one of properly defining the physical and chemical equilibria for the system. It is sometimes possible to design a tray-type absorber by assuming chemical equilibrium relationships in conjunction with a stage efficiency factor, as is done in distillation calculations. Rivas and Prausnitz [*AIChE J.*, **25,** 975 (1979)] have presented an excellent discussion and example of the correct procedures to be followed for systems involving chemical equilibria.

**Traditional Design Method** The traditional procedure for designing packed-tower gas absorption systems involving chemical reactions makes use of overall mass-transfer coefficients as defined by the equation

$$K_G a = n_A/(h_T S p_T \Delta y^\circ_{1\,m}) \tag{14-71}$$

where $K_G a$ = overall volumetric mass-transfer coefficient, $n_A$ = rate of solute transfer from the gas to the liquid phase, $h_T$ = total height of tower packing, $S$ = tower cross-sectional area, $p_T$ = total system pressure, and $\Delta y^\circ_{1\,m}$ is defined by the equation

$$\Delta y^\circ_{1\,m} = \frac{(y - y^\circ)_1 - (y - y^\circ)_2}{\ln\left[(y - y^\circ)_1/(y - y^\circ)_2\right]} \tag{14-72}$$

in which subscripts 1 and 2 refer to the bottom and top of the absorption tower respectively, $y$ = mole-fraction solute in the gas phase, and $y^\circ$ = gas-phase solute mole fraction in equilibrium with bulk-liquid-phase solute concentration $x$. When the equilibrium line is straight, $y^\circ = mx$.

The traditional design method normally makes use of overall $K_G a$ values even when resistance to transfer lies predominantly in the liquid phase. For example, the $CO_2$-NaOH system which is most commonly used for comparing $K_G a$ values of various tower packings is a liquid-phase-controlled system. When the liquid phase is controlling, extrapolation to different concentration ranges or operating conditions is not recommended since changes in the reaction mechanism can cause $k_L$ to vary unexpectedly and the overall $K_G a$ do not capture such effects.

Overall $K_G a$ data may be obtained from tower-packing vendors for many of the established commercial gas absorption processes. Such data often are based either upon tests in large-diameter test units or upon actual commercial operating data. Since application to untried operating conditions is not recommended, the preferred procedure for applying the traditional design method is equivalent to duplicating a previously successful commercial installation. When this is not possible, a commercial demonstration at the new operating conditions may be required, or else one could consider using some of the more rigorous methods described later.

While the traditional design method is reported here because it has been used extensively in the past, it should be used with extreme

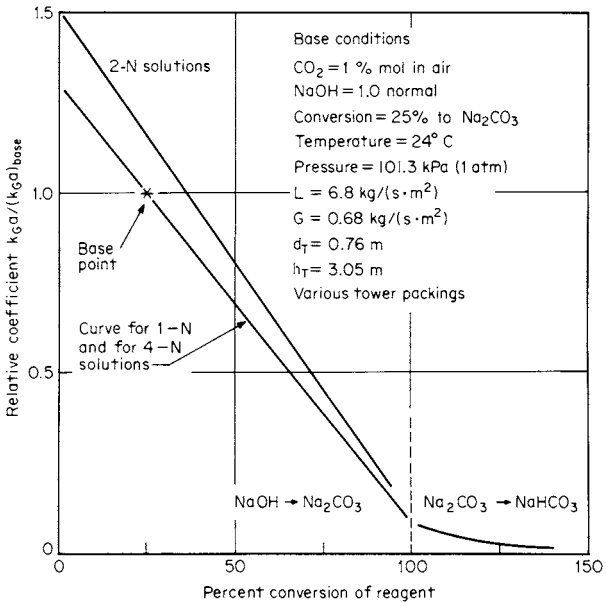

**FIG. 14-15** Effects of reagent-concentration and reagent-conversion level upon the relative values of $K_Ga$ in the $CO_2$-NaOH-$H_2O$ system. [*Adapted from Eckert et al.,* Ind. Eng. Chem., ***59****(2), 41 (1967).*]

caution. In addition to the lack of an explicit liquid-phase resistance term, the method has other limitations. Equation (14-71) assumes that the system is dilute ($y_{BM} \approx 1$) and that the operating and equilibrium lines are straight, which are weak assumptions for reacting systems. Also, Eq. (14-65) is strictly valid only for the temperature and solute partial pressure at which the original test was done even though the total pressure $p_T$ appears in the denominator.

In using Eq. (14-71), therefore, it should be understood that the numerical values of $K_Ga$ will be a complex function of pressure, temperature, the type and size of packing employed, the liquid and gas mass flow rates, and the system composition (e.g., the degree of conversion of the liquid-phase reactant).

Figure 14-15 illustrates the influence of system composition and degree of reactant conversion upon the numerical values of $K_Ga$ for the absorption of $CO_2$ into sodium hydroxide at constant conditions of temperature, pressure, and type of packing. An excellent experimental study of the influence of operating variables upon overall $K_Ga$ values is that of Field et al. (*Pilot-Plant Studies of the Hot Carbonate Process for Removing Carbon Dioxide and Hydrogen Sulfide*, U.S. Bureau of Mines Bulletin 597, 1962).

Table 14-2 illustrates the observed variations in $K_Ga$ values for different packing types and sizes for the $CO_2$-NaOH system at a 25 percent reactant conversion for two different liquid flow rates. The lower rate of 2.7 kg/(s·m²) or 2000 lb/(h·ft²) is equivalent to 4 U.S. gal/(min·ft²) and is typical of the liquid rates employed in fume scrubbers. The higher rate of 13.6 kg/(s·m²) or 10,000 lb/(h·ft²) is equivalent to 20 U.S. gal/(min·ft²) and is more typical of absorption towers such as used in $CO_2$ removal systems, for example. We also note that two gas velocities are represented in the table, corresponding to superficial velocities of 0.59 and 1.05 m/s (1.94 and 3.44 ft/s).

Table 14-3 presents a typical range of $K_Ga$ values for chemically reacting systems. The first two entries in the table represent systems that can be designed by the use of purely physical design methods, because they are completely gas-phase mass-transfer-limited. To ensure a negligible liquid-phase resistance in these two tests, the HCl was absorbed into a solution maintained at less than 8 wt % HCl, and the $NH_3$ was absorbed into a water solution maintained below pH 7 by the addition of acid. The last two entries in Table 14-3 represent liquid-phase mass-transfer-limited systems.

**Scaling Up from Laboratory Data** Laboratory experimental techniques offer an efficient and cost-effective route to develop commercial absorption designs. For example, Ouwerkerk (*Hydrocarbon Process.*, April 1978, 89–94) revealed that both laboratory and small-scale pilot plant data were employed as the basis for the design of an 8.5-m (28-ft) diameter commercial Shell Claus off-gas treating (SCOT) tray-type absorber. Ouwerkerk claimed that the cost of developing comprehensive design procedures can be minimized, especially in the development of a new process, by the use of these modern techniques.

In a 1966 paper that is considered a classic, Dankwerts and Gillham [*Trans. Inst. Chem. Eng.*, 44, T42 (1966)] showed that data taken in a small stirred-cell laboratory apparatus could be used in the design of a packed-tower absorber when chemical reactions are involved. They showed that if the packed-tower mass-transfer coefficient in the absence of reaction ($k_L^0$) can be reproduced in the laboratory unit, then the rate of absorption in the laboratory apparatus will respond to chemical reactions in the same way as in the packed column, even though the means of agitating the liquid in the two systems may be quite different.

According to this method, it is not necessary to investigate the kinetics of the chemical reactions in detail; nor is it necessary to determine the solubilities or diffusivities of the various reactants in their unreacted forms. To use the method for scaling up, it is necessary to independently obtain data on the values of the interfacial area per unit volume $a$ and the physical mass-transfer coefficient $k_L^0$ for the commercial packed tower. Once these data have been measured and tabulated, they can be used directly for scaling up the experimental laboratory data for any new chemically reacting system.

Dankwerts and Gillham did not investigate the influence of the gas-phase resistance in their study (for some processes, gas-phase resistance

**TABLE 14-2 Typical Effects of Packing Type, Size, and Liquid Rate on $K_Ga$ in a Chemically Reacting System, $K_Ga$, kmol/(h·m³)**

Operating conditions (see text): 38-mm ceramic Intalox saddles; solute gases, 0.5–1.0 percent mole; reagent conversions = 33 percent; pressure, 101 kPa (1 atm); temperature, 16–24°C; gas rate = 1.3 kg/(s·m²) = 1.1 m/s; liquid rates = 3.4 to 6.8 kg/(s·m²); packed height, 3.05 m; tower diameter, 0.76 m. Multiply table values by 0.0624 to convert to (lb·mol)/(h·ft³).

may be neglected). However, in 1975 Dankwerts and Alper [*Trans. Inst. Chem. Eng.*, 53, T42 (1975)] showed that by placing a stirrer in the gas space of the stirred-cell laboratory absorber, the gas-phase mass-transfer coefficient $k_G$ in the laboratory unit could be made identical to that in a packed-tower absorber. When this was done, laboratory data for chemically reacting systems having a significant gas-side resistance could successfully be scaled up to predict the performance of a commercial packed-tower absorber.

If it is assumed that the values for $k_G$, $k_L^0$, and $a$ have been measured for the commercial tower packing to be employed, the procedure for using the laboratory stirred-cell reactor is as follows:

1. The gas-phase and liquid-phase stirring rates are adjusted so as to produce the same values of $k_G$ and $k_L^0$ as will exist in the commercial tower.
2. For the reaction system under consideration, experiments are made at a series of bulk-liquid and bulk-gas compositions representing the compositions to be expected at different levels in the commercial absorber (on the basis of material balance).
3. The ratios of $r_A(c_bB^0)$ are measured at each pair of gas and liquid compositions.

For the dilute-gas systems, one form of the equation to be solved in conjunction with these experiments is

$$h_T = \frac{G_M}{a}\int_{y2}^{y1}\frac{dy}{r_A} \tag{14-73}$$

where $h_T$ = height of commercial tower packing, $G_M$ = molar gas-phase mass velocity, $a$ = effective mass-transfer area per unit volume in the commercial tower, $y$ = mole fraction solute in the gas phase, and $r_A$ = experimentally determined rate of absorption per unit of exposed interfacial area.

By using the series of experimentally measured rates of absorption, Eq. (14-73) can be integrated numerically to determine the height of packing required in the commercial tower.

A number of different types of experimental laboratory units could be used to develop design data for chemically reacting systems. Charpentier [*ACS Symp. Ser.*, **72,** 223–261 (1978)] has summarized the state of the art with respect to methods of scaling up laboratory data and has tabulated typical values of the mass-transfer coefficients, interfacial areas, and contact times to be found in various commercial gas absorbers, as well as in currently available laboratory units.

The laboratory units that have been employed to date for these experiments were designed to operate at a total system pressure of about 101 kPa (1 atm) and at near-ambient temperatures. In practical situations, it may become necessary to design a laboratory absorption unit that can be operated either under vacuum or at elevated pressure and over a range of temperatures in order to apply the Dankwerts method.

It would be desirable to reinterpret existing data for commercial tower packings to extract the individual values of the interfacial area $a$ and the mass-transfer coefficients $k_G$ and $k^0_L$ to facilitate a more general usage of methods for scaling up from laboratory experiments. Some progress has already been made, as described later in this section. In the absence of such data, it is necessary to operate a pilot plant or a commercial absorber to obtain $k_G$, $k_L^0$, and $a$ as described by Ouwerkerk (op. cit.).

Modern techniques use rigorous modeling computer-based methods to extract fundamental parameters from laboratory-scale measurements and then apply them to the design of commercial absorption towers. These techniques are covered next.

**Rigorous Computer-Based Absorber Design** While the techniques described earlier in this section are very useful to gain an understanding of the key effects in commercial absorbers, current design methods used in industrial practice for chemically reactive systems are increasingly often based upon computerized rigorous methods, which are commercially available from software vendors. The advantages of these rigorous methods are as follows: (1) Approximations do not have to be made for special cases (e.g., fast chemical reactions or mass-transfer resistance dominated by the gas or liquid phase), and all effects can be simultaneously modeled. (2) Fundamental quantities such as kinetic parameters and mass-transfer coefficients can be extracted from laboratory equipment and applied to commercial absorber towers. (3) Integrated models can be developed for an entire absorption process flowsheet (e.g., the absorber-stripper system with heat integration presented in Fig. 14-3), and consequently the entire system may be optimized.

Computer programs for chemically reacting systems are available from several vendors, notably the following:

| Program | Vendor | Reference |
|---|---|---|
| AMSIM | Schlumberger Limited | Zhang and Ng, *Proc. Ann. Conv.—Gas Proc. Assoc.,* Denver, Colo.; 1996, p. 22. |
| ProTreat | Sulphur Experts | Weiland and Dingman, *Proc. Ann. Conv., Gas Proc. Assoc.,* Houston, Tex., 2001, p. 80. |
| TSWEET | Bryan Research and Engineering | Polasek, Donnelly, and Bullin, Proc. 71st GPA Annual Conv., 1992, p. 58. |
| RateSep | Aspen Technology | Chen et al., AIChE Annual Meeting, San Francisco, Nov. 12–17, 2006. |

The specific approaches used to model the chemically reacting absorption system are slightly different among the different vendors. The general approach used and the benefits obtained are highlighted

by considering a specific example: removal of $CO_2$ from flue gases discharged by a power plant using aqueous monoethanolamine (MEA), as presented by Freguia and Rochelle [*AIChE J.*, **49,** 1676 (2003)].

The development and application of a rigorous model for a chemically reactive system typically involves four steps: (1) development of a thermodynamic model to describe the physical and chemical equilibrium; (2) adoption and use of a modeling framework to describe the mass transfer and chemical reactions; (3) parameterization of the mass-transfer and kinetic models based upon laboratory, pilot-plant, or commercial-plant data; and (4) use of the integrated model to optimize the process and perform equipment design.

**Development of Thermodynamic Model for Physical and Chemical Equilibrium** The first and perhaps most important step in the development of the thermodynamic model is the *speciation,* or representation of the set of chemical reactions. For $CO_2$ absorption in aqueous MEA solutions, the set of reactions is

$$CO_2 + MEA + H_2O \leftrightarrow MEACOO^- + H_3O^+ \quad (14\text{-}74a)$$

$$CO_2 + OH^- \leftrightarrow HCO_3^- \quad (14\text{-}74b)$$

$$HCO_3^- + H_2O \leftrightarrow CO_3^{2-} + H_3O^+ \quad (14\text{-}74c)$$

$$MEAH^+ + H_2O \leftrightarrow MEA + H_3O^+ \quad (14\text{-}74d)$$

$$2H_2O \leftrightarrow H_3O^+ + OH^- \quad (14\text{-}74e)$$

In addition, a model is needed that can describe the nonideality of a system containing molecular and ionic species. Freguia and Rochelle adopted the model developed by Chen et al. [*AIChE J.*, **25,** 820 (1979)] and later modified by Mock et al. [*AIChE J.*, **32,** 1655 (1986)] for mixed-electrolyte systems. The combination of the speciation set of reactions [Eqs. (14-74*a*) to (14-74*e*)] and the nonideality model is capable of representing the solubility data, such as presented in Figs. 14-1 and 14-2, to good accuracy. In addition, the model accurately and correctly represents the actual species present in the aqueous phase, which is important for faithful description of the chemical kinetics and species mass transfer across the interface. Finally, the thermodynamic model facilitates accurate modeling of the heat effects, such as those discussed in Example 6.

Rafal et al. (Chapter 7, "Models for Electrolyte Solutions," in *Models for Thermodynamic and Phase Equilibria Calculations*, S. I. Sandler, ed., Marcel Dekker, New York, 1994, p. 686) have provided a comprehensive discussion of speciation and thermodynamic models.

**Adoption and Use of Modeling Framework** The rate of diffusion and species generation by chemical reaction can be described by film theory, penetration theory, or a combination of the two. The most popular description is in terms of a two-film theory, which is diagrammed in Fig. 14-16 for absorption. Accordingly, there exists a stable interface separating the gas and the liquid. A certain distance from the interface, large fluid motions exist, and these distribute the material rapidly and equally so that no concentration gradients develop. Next to the interface, however, there are regions in which the fluid motion is slow; in these regions, termed *films*, material is transferred by diffusion alone. At the gas-liquid interface, material is transferred instantaneously, so that the gas and liquid are in physical equilibrium at the interface. The rate of diffusion in adsorption is therefore the rate of diffusion in the gas and liquid films adjacent to the interface. The model framework is completed by including terms for species generation (chemical equilibrium *and* chemical kinetics) in the gas and liquid film and bulk regions. Taylor, Krishna, and Kooijman (*Chem. Eng. Progress*, July 2003, p. 28) have provided an excellent discussion of rate-based models; these authors emphasize that the diffusion flux for multicomponent systems must be based upon the Maxwell-Stefan approach. The book by Taylor and Krishna (*Multicomponent Mass Transfer*, Wiley, New York, 1993) provides a detailed discussion of the Maxwell-Stefan approach. More details and discussion have been provided by the program vendors listed above.

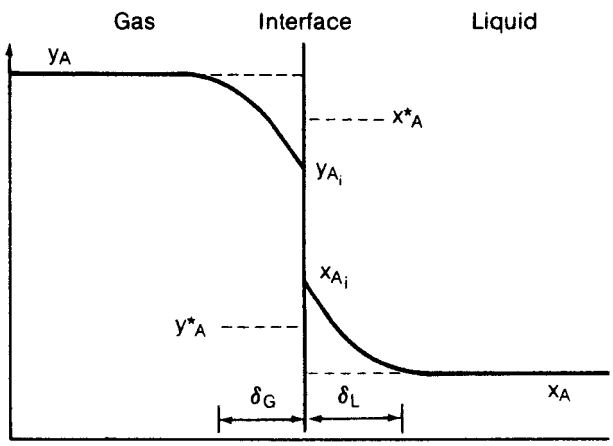

**FIG. 14-16** Concentration profiles in the vapor and liquid phases near an interface.

**Parameterization of Mass-Transfer and Kinetic Models** The mass-transfer and chemical kinetic rates required in the rigorous model are typically obtained from the literature, but must be carefully evaluated; and fine-tuning through pilot-plant and commercial data is highly recommended.

Mass-transfer coefficient models for the vapor and liquid coefficients are of the general form

$$k^L_{ij} = a\rho_L f(D^m_{ij}, \mu_L, \rho_V, a, \text{internal characteristics}) \quad (14\text{-}75a)$$

$$k^V_{ij} = aP f(D^m_{ij}, \mu_V, \rho_V, a, \text{internal characteristics}) \quad (14\text{-}75b)$$

where $a$ = effective interfacial area per unit volume, $D^m_{ij}$ are the Stefan-Maxwell diffusion coefficients, $P$ = pressure, $\rho$ = molar density, and $\mu$ = viscosity. The functions in Eqs. (14-75*a*) and (14-75*b*) are correlations that depend on the column internals. Popular correlations in the literature are those by Onda at al. [*J. Chem.. Eng. Jap.*, **1,** 56 (1968)] for random packing, Bravo and Fair [*Ind. Eng. Chem. Proc. Des. Dev.*, **21,** 162 (1982)] for structured packing, Chan and Fair [*Ind. Eng. Chem. Proc. Des. Dev.*, **23,** 814 (1984)] for sieve trays, Scheffe and Weiland [*Ind. Eng. Chem. Res.*, **26,** 228 (1987)] for valve trays, and Hughmark [*AIChE J.*, **17,** 1295 (1971)] for bubble-cap trays.

It is highly recommended that the mass-transfer correlations be tested and improved by using laboratory, pilot-plant, or commercial data for the specific application. Commercial software generally provides the capability for correction factors to adjust generalized correlations to the particular application.

Kinetic models are usually developed by replacing a subset of the speciation reactions by kinetically reversible reactions. For example, Freguia and Rochelle replaced equilibrium reactions (14-74*a*) and (14-74*b*) with kinetically reversible reactions and retained the remaining three reactions as very fast and hence effectively at equilibrium. The kinetic constants were tuned using wetted-wall column data from Dang (M.S. thesis, University of Texas, Austin, 2001) and field data from a commercial plant.

Modern commercial software provides powerful capability to deploy literature correlations and to customize models for specific applications.

**Deployment of Rigorous Model for Process Optimization and Equipment Design** Techniques similar to those described above may be used to develop models for the stripper as well as other pieces of plant equipment, and thus an integrated model for the entire absorption system may be produced. The value of integrated models is that they can be used to understand the combined effects of many variables that determine process performance and to rationally optimize process performance. Freguia and Rochelle have shown that the reboiler duty (the dominant source of process operating costs) may be reduced by 10 percent if the absorber height is increased by 20 percent and by 4 percent if the absorber is intercooled with a duty equal to one-third of the reboiler duty. They also show that the power plant lost work is affected by varying stripper

pressure, but not significantly, so any convenient pressure can be chosen to operate the stripper.

In this section, we have used the example of $CO_2$ removal from flue gases using aqueous MEA to demonstrate the development and application of a rigorous model for a chemically reactive system. Modern software enables rigorous description of complex chemically reactive systems, but it is very important to carefully evaluate the models and to tune them using experimental data.

**Use of Literature for Specific Systems** A large body of experimental data obtained in bench-scale laboratory units and in small-diameter packed towers has been published since the early 1940s. One might wish to consider using such data for a particular chemically reacting system as the basis for scaling up to a commercial design. Extreme caution is recommended in interpreting such data for the purpose of developing commercial designs, as extrapolation of the data can lead to serious errors. Extrapolation to temperatures, pressures, or liquid-phase reagent conversions different from those that were employed by the original investigators definitely should be regarded with caution.

Bibliographies presented in the General References listed at the beginning of this section are an excellent source of information on specific chemically reacting systems. *Gas-Liquid Reactions* by Dankwerts (McGraw-Hill, New York, 1970) contains a tabulation of references to specific chemically reactive systems. *Gas Treating with Chemical Solvents* by Astarita et al. (Wiley, New York, 1983) deals with the absorption of acid gases and includes an extensive listing of patents. *Gas Purification* by Kohl and Nielsen (Gulf Publishing, Houston, 1997) provides a practical description of techniques and processes in widespread use and typically also sufficient design and operating data for specific applications.

In searching for data on a particular system, a computerized search of *Chemical Abstracts, Engineering Index,* and *National Technical Information Service* (NTIS) databases is recommended. In addition, modern search engines will rapidly uncover much potentially valuable information.

The experimental data for the system $CO_2$-NaOH-$Na_2CO_3$ are unusually comprehensive and well known as the result of the work of many experimenters. A serious study of the data and theory for this system therefore is recommended as the basis for developing a good understanding of the kind and quality of experimental information needed for design purposes.

# EQUIPMENT FOR DISTILLATION AND GAS ABSORPTION: TRAY COLUMNS

Distillation and gas absorption are the prime and most common gas-liquid mass-transfer operations. Other operations that are often performed in similar equipment include stripping (often considered part of distillation), direct-contact heat transfer, flashing, washing, humidification, and dehumidification.

The most common types of contactors by far used for these are tray and packed towers. These are the focus of this subsection. Other contactors used from time to time and their applications are listed in Table 14-4.

In this subsection, the terms *gas* and *vapor* are used interchangeably. *Vapor* is more precise for distillation, where the gas phase is at equilibrium. Also, the terms *tower* and *column* are used interchangeably.

A crossflow tray (Fig. 14-17) consists of the *bubbling area* and the *downcomer*. Liquid descending the downcomer from the tray above enters the bubbling area. Here, the liquid contacts gas ascending through the tray perforations, forming froth or spray. An *outlet weir* on the downstream side of the bubbling area helps maintain liquid level on the tray. Froth overflowing the weir enters the outlet downcomer. Here, gas disengages from the liquid, and the liquid descends to the tray below. The bubbling area can be fitted with numerous types of tray hardware. The most common types by far are:

*Sieve trays* (Fig. 14-18*a*) are perforated plates. The velocity of upflowing gas keeps the liquid from descending through the perforations (weeping). At low gas velocities, liquid weeps through the perforations, bypassing part of the tray and reducing tray efficiency. Because of this, sieve trays have relatively poor turndown.

*Fixed valve trays* (Fig. 14-18*b*) have the perforations covered by a fixed cover, often a section of the tray floor pushed up. Their performance is similar to that of sieve trays.

*Moving valve trays* (Fig. 14-18*c*) have the perforations covered by movable disks (valves). Each valve rises as the gas velocity increases. The upper limit of the rise is controlled by restricting legs on the bottom of the valve (Fig. 14-18*c*) or by a cage structure around the valve. As the gas velocity falls, some valves close completely, preventing weeping. This gives the valve tray good turndown.

Table 14-5 is a general comparison of the three main tray types, assuming proper design, installation, and operation. Sieve and valve trays are comparable in capacity, efficiency, entrainment, and pressure drop. The turndown of moving valve trays is much better than that of sieve and fixed valve trays. Sieve trays are least expensive; valve trays cost only slightly more. Maintenance, fouling tendency, and effects of corrosion are least troublesome in fixed valve and sieve trays (provided the perforations or fixed valves are large enough) and most troublesome with moving valve trays.

Fixed valve and sieve trays prevail when fouling or corrosion is expected, or if turndown is unimportant. Valve trays prevail when high turndown is required. The energy saved, even during short turndown periods, usually justifies the small additional cost of the moving valve trays.

## DEFINITIONS

**Tray Area Definitions** Some of these are illustrated in Fig. 14-17.

***Total tower cross-section area*** $\mathbf{A_T}$ The inside cross-sectional area of the empty tower (without trays or downcomers).

***Net area*** $\mathbf{A_N}$ **(also called *free area*)** The total tower cross-sectional area $A_T$ minus the area at the top of the downcomer $A_{DT}$. The

**TABLE 14-4 Equipment for Liquid-Gas Systems**

| Equipment designation | Mode of flow | Gross mechanism | Continuous phase | Primary process applications |
|---|---|---|---|---|
| Tray column | Cross-flow, countercurrent | Integral | Liquid and/or gas | Distillation, absorption, stripping, DCHT, washing |
| Packed column | Countercurrent, cocurrent | Differential | Liquid and/or gas | Distillation, absorption, stripping, humidification, dehumidification, DCHT, washing |
| Wetted-wall (falling-film) column | Countercurrent, cocurrent | Differential | Liquid and/or gas | Distillation, absorption, stripping, evaporation |
| Spray chamber | Cocurrent, cross-flow, countercurrent | Differential | Gas | Absorption, stripping, humidification, dehumidification |
| Agitated vessel | Complete mixing | Integral | Liquid | Absorption |
| Line mixer | Cocurrent | Differential | Liquid or gas | Absorption, stripping |

DCHT = direct contact heat transfer.

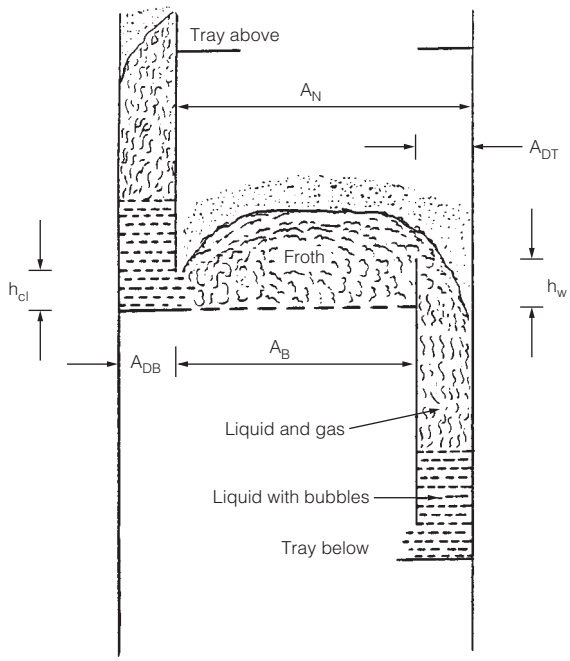

**FIG. 14-17** Schematic of a tray operating in the froth regime. (*Based on H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.*)

net area represents the smallest area available for vapor flow in the intertray spacing.

***Bubbling area* $A_B$ *(also called active area)*** The total tower cross-sectional area minus the sum of downcomer top area $A_{DT}$, downcomer seal area $A_{DB}$, and any other nonperforated areas on the tray. The bubbling area represents the area available for vapor flow just above the tray floor.

***Hole area* $A_h$** The total area of the perforations on the tray. The hole area is the smallest area available for vapor passage on a sieve tray.

***Slot area* $A_S$** The total (for all open valves) vertical curtain area through which vapor passes in a horizontal direction as it leaves the valves. It is a function of the narrowest opening of each valve and the number of valves that are open. The slot area is normally the smallest area available for vapor flow on a valve tray.

***Open slot area* $A_{SO}$** The slot area when all valves are open.

***Fractional hole area* $A_f$** The ratio of hole area to bubbling area (sieve trays) or slot area to bubbling area (valve trays).

**Vapor and Liquid Load Definitions**

**F-*factor* F** This is the square root of the kinetic energy of the gas, defined by Eq. (14-76). The velocity in Eq. (14-76) is usually (not always) based on the tower cross-sectional area $A_T$, the net area $A_N$, or the bubbling area $A_B$. The user should beware of any data for which the area basis is not clearly specified.

$$F = u\sqrt{\rho_G} \tag{14-76}$$

**C-*factor* C** The *C*-factor, defined in Eq. (14-77), is the best gas load term for comparing capacities of systems of different physical properties. It has the same units as velocity (m/s or ft/s) and is directly related to droplet entrainment. As with the *F*-factor, the user should beware of any data for which the area basis is not clearly specified.

$$C = u\sqrt{\frac{\rho_G}{\rho_L - \rho_G}} \tag{14-77}$$

***Weir load*** For trays (as distinct from downcomers), liquid load is normally defined as

$$Q_L = \frac{\text{volume of liquid}}{\text{length of outlet weir}} = \frac{Q}{L_w} \tag{14-78}$$

This definition describes the flux of liquid horizontally across the tray. Units frequently used are $m^3/(h\cdot m)$, $m^3/(s\cdot m)$, and gpm/in.

***Downcomer liquid load*** For downcomer design, the liquid load is usually defined as the liquid velocity at the downcomer entrance (m/s or ft/s):

$$Q_D = \frac{\text{volume of liquid}}{\text{downcomer entrance area}} = \frac{Q}{A_{DT}} \tag{14-79}$$

## FLOW REGIMES ON TRAYS

Three main flow regimes exist on industrial distillation trays. These regimes may all occur on the same tray under different liquid and gas flow rates (Fig. 14-19). Excellent discussion of the fundamentals and modeling of these flow regimes was presented by Lockett (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, 1986). An excellent overview of these as well as of less common flow regimes was given by Prince (*PACE,* June 1975, p. 31; July 1975, p. 18).

*Froth regime (or mixed regime; Fig. 14-20a).* This is the most common operating regime in distillation practice. Each perforation bubbles vigorously. The bubbles circulate rapidly through the liquid, are of nonuniform sizes and shapes, and travel at varying velocities. The froth surface is mobile and not level, and is generally covered by droplets. Bubbles are formed at the tray perforations and are swept away by the froth.

As gas load increases in the froth regime, jetting begins to replace bubbling in some holes. The fraction of holes that is jetting increases with gas velocity. When jetting becomes the dominant mechanism, the dispersion changes from froth to spray. Prado et al. [*Chemical Engineering Progr.* **83**(3), p. 32, (1987)] showed the transition from froth to spray takes place gradually as jetting replaces bubbling in 45 to 70 percent of the tray holes.

*Emulsion regime (Fig. 14-20b).* At high liquid loads and relatively low gas loads, the high-velocity liquid bends the swarms of gas bubbles leaving the orifices, and tears them off, so most of the gas becomes emulsified as small bubbles within the liquid. The mixture behaves as a uniform two-phase fluid, which obeys the Francis weir formula [see the subsection "Pressure Drop" and Eq. (14-109) *(Hofhuis and Zuiderweg, IChemE Symp. Ser.* **56,** p. 2.2/1 (1979); Zuiderweg, *Int. Chem. Eng.* **26**(1), 1 (1986)]. In industrial practice, the emulsion regime is the most common in high-pressure and high-liquid-rate operation.

*Spray regime (or drop regime, Fig. 14-20c).* At high gas velocities and low liquid loads, the liquid pool on the tray floor is shallow and easily atomized by the high-velocity gas. The dispersion becomes a turbulent cloud of liquid droplets of various sizes that reside at high elevations above the tray and follow free trajectories. Some droplets are entrained to the tray above, while others fall back into the liquid pools and become reatomized. In contrast to the liquid-continuous froth and emulsion regimes, the phases are reversed in the spray regime: here the gas is the continuous phase, while the liquid is the dispersed phase.

The spray regime frequently occurs where gas velocities are high and liquid loads are low (e.g., vacuum and rectifying sections at low liquid loads).

*Three-layered structure.* Van Sinderen, Wijn, and Zanting [*Trans. IChemE,* **81,** Part A, p. 94 (January 2003)] postulate a tray dispersion consisting of a bottom liquid-rich layer where jets/bubbles form; an intermediate liquid-continuous froth layer where bubbles erupt, generating drops; and a top gas-continuous layer of drops. The intermediate layer that dampens the bubbles and

**TABLE 14-5 Comparison of the Common Tray Types**

| | Sieve trays | Fixed valve tray | Moving valve tray |
|---|---|---|---|
| Capacity | High | High | High to very high |
| Efficiency | High | High | High |
| Turndown | About 2:1. Not generally suitable for operation under variable loads | About 2.5:1. Not generally suitable for operation under variable loads | About 4:1 to 5:1. Some special designs achieve 8:1 or more |
| Entrainment | Moderate | Moderate | Moderate |
| Pressure drop | Moderate | Moderate | Slightly higher |
| Cost | Low | Low | About 20 percent higher |
| Maintenance | Low | Low | Moderate |
| Fouling tendency | Low to very low | Low to very low | Moderate |
| Effects of corrosion | Low | Very low | Moderate |
| Main applications | (1) Most columns when turndown is not critical (2) High fouling and corrosion potential | (1) Most columns when turndown is not critical (2) High fouling and corrosion potential | (1) Most columns (2) Services where turndown is important |

jets disappears at low liquid rates, and the drop layer approaches the tray floor, similar to the classic spray regime.

## PRIMARY TRAY CONSIDERATIONS

**Number of Passes** Tray liquid may be split into two or more flow passes to reduce tray liquid load $Q_L$ (Fig. 14-21). Each pass carries $1/N_p$ fraction of the total liquid load (e.g., $\frac{1}{4}$ in four-pass trays). Liquid in each pass reverses direction on alternate trays. Two-pass trays have perfect symmetry with full remixing in the center downcomers. Four-pass trays are symmetric along the centerline, but the side and central passes are nonsymmetric. Also, the center and off-center downcomers only partially remix the liquid, allowing any maldistribution to propagate. Maldistribution can cause major loss of efficiency and capacity in four-pass trays. Three-pass trays are even more prone to maldistribution due to their complete nonsymmetry. Most designers avoid three-pass trays altogether, jumping from two to four passes. Good practices for liquid and vapor balancing and for avoiding maldistribution in multipass trays were described by Pilling [*Chemical Engineering Progr.*, p. 22 (June 2005)], Bolles [*AIChE J.*, **22**(1), p. 153 (1976)], and Kister (*Distillation Operation*, McGraw-Hill, New York, 1990).

Common design practice is to minimize the number of passes, resorting to a larger number only when the liquid load exceeds 100 to 140 $m^3/(h \cdot m)$ (11 to 15 gpm/in) of outlet weir length [*Davies and Gordon, Petro/Chem Eng.*, p. 228 (December 1961)]. Trays smaller than 1.5-m (5-ft) diameter seldom use more than a single pass; those with 1.5- to 3-m (5- to 10-ft) diameters seldom use more than two passes. Four-pass trays are common in high liquid services with towers larger than 5-m (16-ft) diameter.

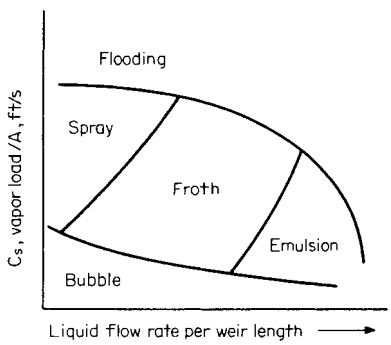

**FIG. 14-19** The flow regime likely to exist on a distillation tray as a function of vapor and liquid loads. *(From H. Z. Kister,* Distillation Design, *copyright ©1992 by McGraw-Hill; reprinted by permission.)*

**Tray Spacing** Taller spacing between successive trays raises capacity, leading to a smaller tower diameter, but also raises tower height. There is an economic tradeoff between tower height and diameter. As long as the tradeoff exists, tray spacing has little effect on tower economies and is set to provide adequate access. In towers with larger than 1.5-m (5-ft) diameter, tray spacing is typically 600 mm (24 in), large enough to permit a worker to crawl between trays. In very large towers (>6-m or 20-ft diameter), tray spacings of 750 mm (30 in) are often used. In chemical towers (as distinct from petrochemical, refinery, and gas plants), 450 mm (18 in) has been a popular tray spacing. With towers smaller than 1.5 m (5 ft), tower walls are reachable from the manways, there is no need to crawl, and it becomes difficult to support thin and tall columns, so smaller tray spacing (typically 380 to 450 mm or 15 to 18 in) is favored. Towers taller than 50 m (160 ft) also favor smaller tray spacings (400 to 450 mm or 16 to 18 in). Finally, cryogenic towers enclosed in cold boxes favor very small spacings, as small as 150 to 200 mm (6 to 8 in), to minimize the size of the cold box.

More detailed considerations for setting tray spacing were discussed by Kister (*Distillation Operation*, McGraw-Hill, New York, 1990) and Mukherjee [*Chem. Eng.* p. 53 (September 2005)].

**Outlet Weir** The outlet weir should maintain a liquid level on the tray high enough to provide sufficient gas-liquid contact without causing excessive pressure drop, downcomer backup, or a capacity limitation. Weir heights are usually set at 40 to 80 mm (1.5 to 3 in). In this range, weir heights have little effect on distillation efficiency [Van Winkle, *Distillation*, McGraw-Hill, New York, 1967; Kreis and Raab, *IChemE Symp. Ser.* **56,** p. 3.2/63 (1979)]. In operations where long residence times are necessary (e.g., chemical reaction, absorption, stripping) taller weirs do improve efficiency, and weirs 80 to 100 mm (3 to 4 in) are more common (Lockett, *Distillation Tray Fundamentals*, Cambridge University Press, Cambridge, England, 1986).

Adjustable weirs (Fig. 14-22*a*) are used to provide additional flexibility. They are uncommon with conventional trays, but are used with some proprietary trays. Swept-back weirs (Fig. 14-22*b*) are used to extend the effective length of side weirs, either to help balance liquid flows to nonsymmetric tray passes or/and to reduce the tray liquid loads. Picket fence weirs (Fig. 14-22*c*) are used to shorten the effective length of a weir, either to help balance multipass trays' liquid flows (they are used in center and off-center weirs) or to raise tray liquid load and prevent drying in low-liquid-load services. To be effective, the pickets need to be tall, typically around 300 to 400 mm (12 to 16 in) above the top of the weir. An excellent discussion of weir picketing practices was provided by Summers and Sloley (*Hydroc. Proc.*, p. 67, January 2007).

**Downcomers** A downcomer is the drainpipe of the tray. It conducts liquid from one tray to the tray below. The fluid entering the downcomer is far from pure liquid; it is essentially the froth on the tray, typically 20 to 30 percent liquid by volume, with the balance being gas. Due to the density difference, most of this gas disengages in the downcomer and vents back to the tray from the downcomer entrance. Some gas bubbles usually remain in the liquid even at the bottom of the downcomer, ending on the tray below [Lockett and Gharani, *IChemE Symp. Ser.* **56,** p. 2.3/43 (1979)].

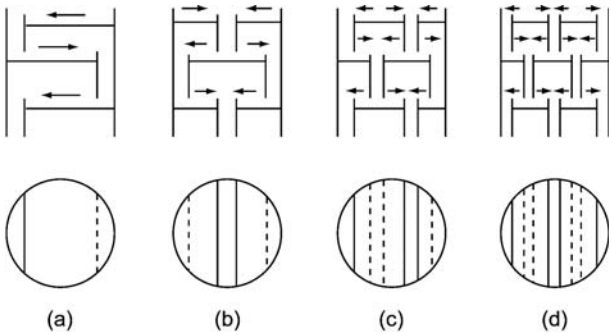

**FIG. 14-21** Flow passes on trays. (*a*) Single-pass. (*b*) Two-pass. (*c*) Three-pass. (*d*) Four-pass.

The straight, segmental vertical downcomer (Fig. 14-23*a*) is the most common downcomer geometry. It is simple and inexpensive and gives good utilization of tower area for downflow. Circular downcomers (downpipes) (Fig. 14-23*b*), are cheaper, but poorly utilize tower area and are only suitable for very low liquid loads. Sloped downcomers (Fig. 14-23*c, d*) improve tower area utilization for downflow. They provide sufficient area and volume for gas-liquid disengagement at the top of the downcomer, gradually narrowing as the gas disengages, minimizing the loss of bubbling area at the foot of the downcomer. Sloped downcomers are invaluable when large downcomers are required such as at high liquid loads, high pressures, and foaming systems. Typical ratios of downcomer top to bottom areas are 1.5 to 2.

*Antijump baffles* (Fig. 14-24) are sometimes installed just above center and off-center downcomers of multipass trays to prevent liquid from one pass skipping across the downcomer onto the next pass. Such liquid jump adds to the liquid load on each pass, leading to premature flooding. These baffles are essential with proprietary trays that induce forward push (see below).

**Clearance under the Downcomer** Restricting the downcomer bottom opening prevents gas from the tray from rising up the downcomer and interfering with its liquid descent (*downcomer unsealing*). A common design practice makes the downcomer clearance 13 mm (0.5 in) lower than the outlet weir height (Fig. 14-25) to ensure submergence at all times [Davies and Gordon, *Petro/Chem Eng.,* p. 250 (November 1961)]. This practice is sound in the froth and emulsion regimes, where tray dispersions are liquid-continuous, but is ineffective in the spray regime where tray dispersions are gas-continuous and there is no submergence. Also, this practice can be unnecessarily restrictive at high liquid loads where high crests over the weirs sufficiently protect the downcomers from gas rise. Generally, downcomer clearances in the spray regime need to be smaller, while those in the emulsion regime can be larger, than those set by the above practice. Seal pans and inlet weirs are devices sometimes used to help with downcomer sealing while keeping downcomer clearances large. Details are in Kister's book (*Distillation Operation,* McGraw-Hill, New York, 1990).

**Hole Sizes** Small holes slightly enhance tray capacity when limited by entrainment flood. Reducing sieve hole diameters from 13 to 5 mm ($\frac{1}{2}$ to $\frac{3}{16}$ in) at a fixed hole area typically enhances capacity by 3 to 8 percent, more at low liquid loads. Small holes are effective for reducing entrainment and enhancing capacity in the spray regime ($Q_L$ < 20 $m^3$/hm of weir). Hole diameter has only a small effect on pressure drop, tray efficiency, and turndown.

On the debit side, the plugging tendency increases exponentially as hole diameters diminish. Smaller holes are also more prone to corrosion. While 5-mm ($\frac{3}{16}$-in) holes easily plug even by scale and rust, 13-mm ($\frac{1}{2}$-in) holes are quite robust and are therefore very common. The small holes are only used in clean, noncorrosive services. Holes smaller than 5 mm are usually avoided because they require drilling (larger holes are punched), which is much more expensive. For highly fouling services, 19- to 25-mm ($\frac{3}{4}$- to 1-in) holes are preferred.

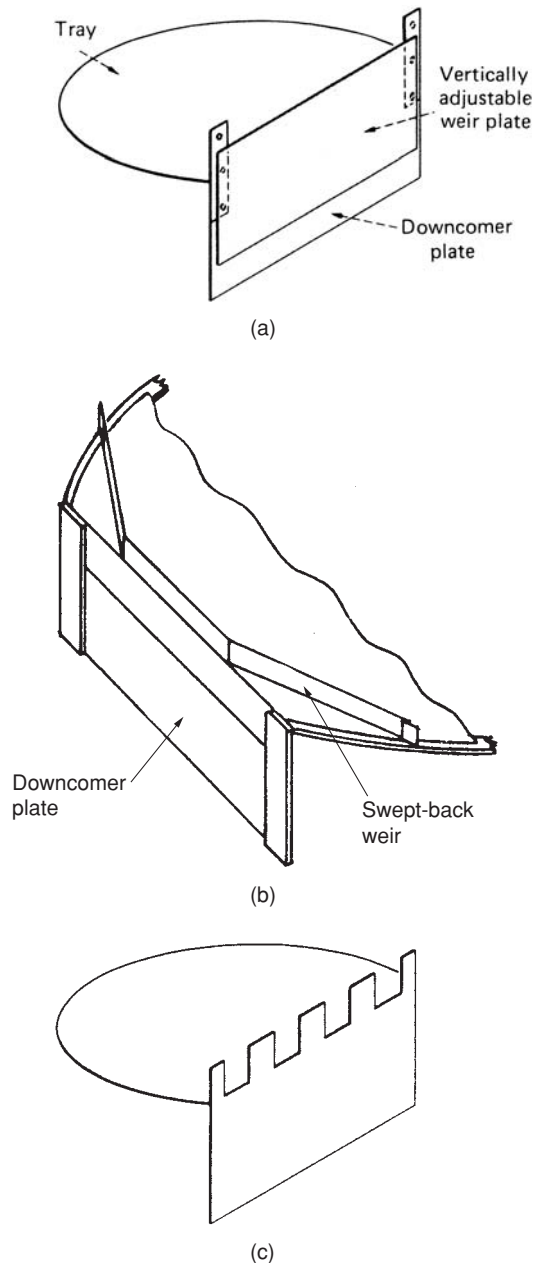

**FIG. 14-22** Unique outlet weir types. (*a*) Adjustable. (*b*) Swept back. (*c*) Picket fence. *(Parts a, c, from H. Z. Kister,* Distillation Operation, *copyright © 1990 by McGraw-Hill; reprinted by permission. Part b, courtesy of Koch-Glitsch LP.)*

Similar considerations apply to fixed valves. Small fixed valves have a slight capacity advantage, but are far more prone to plugging than larger fixed valves.

For round moving valves, common orifice size is 39 mm ($1^{17}\!/_{32}$ in). The float opening is usually of the order of 8 to 10 mm (0.3 to 0.4 in).

In recent years there has been a trend toward minivalves, both fixed and moving. These are smaller and therefore give a slight capacity advantage while being more prone to plugging.

**Fractional Hole Area** Typical sieve and fixed valve tray hole areas are 8 to 12 percent of the bubbling areas. Smaller fractional hole

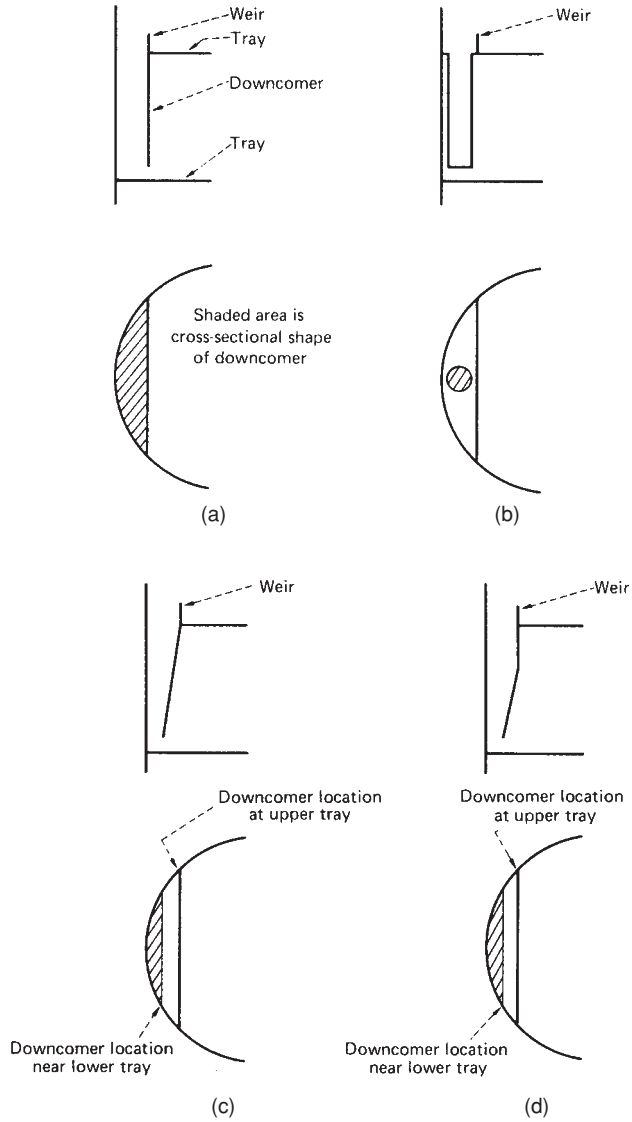

**FIG. 14-23** Common downcomer types. (*a*) Segmental. (*b*) Circular. (*c, d*) Sloped. (*From Henry Z. Kister,* Chem. Eng., *December 29, 1980; reprinted courtesy of* Chemical Engineering.)

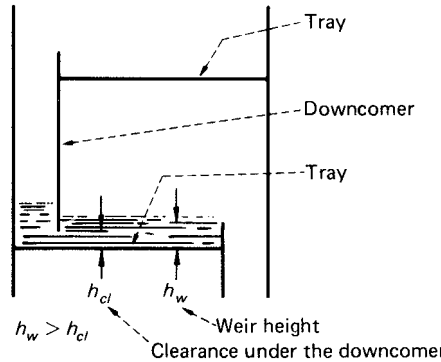

**FIG. 14-25** A common design practice of ensuring a positive downcomer seal. (*From Henry Z. Kister,* Chem. Eng., *December 29, 1980; reprinted courtesy of* Chemical Engineering.)

areas bring about a capacity reduction when limited by entrainment or downcomer backup flood or by excessive pressure drop. At above 12 percent of the bubbling areas, the capacity gains from higher hole areas become marginal while weeping and, at high liquid loads also channeling, escalate.

Typical open-slot areas for moving valve trays are 14 to 15 percent of the bubbling area. Here the higher hole areas can be afforded due to the high turndown of the valves.

Moving valves can have a sharp or a smooth ("venturi") orifice. The venturi valves have one-half the dry pressure drop of the sharp-orifice valves, but are far more prone to weeping and channeling than the sharp-orifice valves. Sharp orifices are almost always preferred.

**Multipass Balancing** There are two balancing philosophies: equal bubbling areas and equal flow path lengths. Equal bubbling areas means that all active area panels on Fig. 14-21*d* are of the same area, and each panel has the same hole (or open-slot) area. In a four-pass tray, one-quarter of the gas flows through each panel. To equalize the *L/G* ratio on each panel, the liquid needs to be split equally to each panel. Since the center weirs are longer than the side weirs, more liquid tends to flow toward the center weir. To equalize, side weirs are often swept back (Fig. 14-22*b*) while center weirs often contain picket fences (Fig. 14-22*c*).

The alternative philosophy (equal flow path lengths) provides more bubbling and perforation areas in the central panels of Fig. 14-21*d* and less in the side panels. To equalize the *L/G* ratio, less liquid needs to flow toward the sides, which is readily achieved, as the center weirs are naturally longer than the side weirs. Usually there is no need for swept-back weirs, and only minimal picket-fencing is required at the center weir.

Equal flow path panels are easier to fabricate and are cheaper, while equal bubbling areas have a robustness and reliability advantage due to the ease of equally splitting the fluids. The author had good experience with both when well-designed. Pass balancing is discussed in detail by Pilling [*Chem. Eng. Prog.,* p. 22 (June 2005)] and by Jaguste and Kelkar [*Hydroc. Proc.,* p. 85 (March 2006)].

## TRAY CAPACITY ENHANCEMENT

High-capacity trays evolved from conventional trays by including one or more capacity enhancement features such as those discussed below. These features enhance not only the capacity but usually also the complexity and cost. These features have varying impact on the efficiency, turndown, plugging resistance, pressure drop, and reliability of the trays.

**Truncated Downcomers/Forward Push Trays** Truncated downcomers/forward push trays include the Nye™ Tray, Maxfrac™ (Fig. 14-26*a*), Triton™, and MVGT™. In all these, the downcomer from the tray above terminates about 100 to 150 mm (4 to 6 in) above the tray floor. Liquid from the downcomer issues via holes or slots,

(*b*) High top-to-bottom area ratio illustrated with a two-pass Superfrac™ tray. Note the baffle in the front side downcomer that changes the side downcomer shape from segmental to multichordal. Also note the bubble promoters on the side of the upper tray and in the center of the lower tray, which give forward push to the tray liquid. (*c*) Top view of an MD™ tray with four downcomers. The decks are perforated. The holes in the downcomer lead the liquid to the active area of the tray below, which is rotated 90°. (*d*) Schematic of the Slit™ tray, type A, showing distribution pipes. Heavy arrows depict liquid movement; open arrows, gas movement. (*e*) The ConSep™ tray. The right-hand side shows sieve panels. On the left-hand side, these sieve panels were removed to permit viewing the contact cyclones that catch the liquid from the tray below. directed downward or in the direction of liquid flow. The tray floor under each downcomer is equipped with fixed valves or side perforations. Gas issuing in this region, typically 10 to 20 percent of the total tray gas, is deflected horizontally in the direction of liquid flow by the downcomer floor. This horizontal gas flow pushes liquid droplets toward the tower wall directly above the outlet downcomer. The tower wall catches this liquid, and directs it downward into the downcomer. This deentrains the gas space. In multipass trays, antijump baffles (Fig. 14-24), typically 300 mm or taller, are installed above center and off-center downcomers to catch the liquid and prevent its jumping from pass to pass. The rest of the tray features are similar to those of conventional trays. The tray floor may contain fixed valves, moving valves, or sieve holes.

Trays from this family are proprietary, and have been extensively used in the last two to three decades with great success. Compared to equivalent conventional trays, the truncated downcomer/forward push trays give about 8 to 12 percent more gas-handling capacity at much the same efficiency.

**High Top-to-Bottom Downcomer Area and Forward Push** Sloping downcomers from top to bottom raises the available tray bubbling area and, therefore, the gas-handling capacity (see "Downcomers"). As long as the ratio of top to bottom areas is not excessive, sloping does not lower downcomer capacity. Downcomer choke flood restricts the downcomer entrance, not exit, because there is much less gas at the downcomer bottom. However, a high top-to-bottom area ratio makes the downcomer bottom a very short chord, which makes distribution of liquid to the tray below difficult. To permit high top-to-bottom area ratios, some trays use a special structure (Fig. 14-26*b*) to change the downcomer shape from segmental to semiarc or multichordal. This high ratio of top to bottom areas, combined with forward push (above) imparted by bubblers and directional fixed or moving valves, and sometimes directional baffles, is used in trays including Superfrac™ III (Fig. 14-26*b*) and IV and V-Grid Plus™. When the downcomer inlet areas are large, these trays typically gain 15 to 20 percent capacity compared to equivalent conventional trays at much the same efficiency. Trays from this family are proprietary, and have been used successfully for about a decade.

**Large Number of Truncated Downcomers** These include the MD™ (Fig. 14-26*c*) and Hi-Fi™ trays. The large number of downcomers raises the total weir length, moving tray operation toward the peak capacity point of 20 to 30 $m^3$/hm (2 to 3 gpm/in) of outlet weir (see Fig. 14-29). The truncated downcomers extend about halfway to the tray below, discharging their liquid via holes or slots at the downcomer floor. The area directly under the downcomers is perforated or valved, and there is enough open height between the tray floor and the bottom of the downcomer for this perforated or valved area to be effective in enhancing the tray bubbling area.

Trays from this family are proprietary and have been successfully used for almost four decades. Their strength is in high-liquid-load services where reducing weir loads provides major capacity gains. Compared to conventional trays, they can gain as much as 20 to 30 percent capacity but at an efficiency loss. The efficiency loss is of the order of 10 to 20 percent due to the large reduction in flow path length (see "Efficiency"). When using these trays, the separation is maintained by either using more trays (typically at shorter spacing) or raising reflux and boilup. This lowers the net capacity gains to 10 to 20 percent above conventional trays. In some variations, forward push slots and antijump baffles are incorporated to enhance the capacity by another 10 percent.

**Radial Trays** These include the Slit™ tray and feature radial flow of liquid. In the efficiency-maximizing A variation (Fig. 14-26*d*), a multipipe distributor conducts liquid from each center downcomer to the periphery of the tray below, so liquid flow is from periphery to center on each tray. The capacity-maximizing B variation has central and peripheral (ring) downcomers on alternate trays, with liquid flow alternating from center-to-periphery to periphery-to-center on successive trays. The trays are arranged at small spacing (typically, 200 to 250 mm, or 8 to 10 in) and contain small fixed valves. Slit trays are used in chemical and pharmaceutical low-liquid-rate applications (<40 $m^3$/hm or 4 gpm/in of outlet weir), typically at pressures ranging from moderate vacuum to slight superatmospheric.

**Centrifugal Force Deentrainment** These trays use a contact step similar to that in conventional trays, followed by a separation step that disentrains the tray dispersion by using centrifugal force. Separation of entrained liquid before the next tray allows very high gas velocities, as high as 25 percent above the system limit (see "System Limit"), to be achieved. The capacity of these trays can be 40 percent above that of conventional trays. The efficiency of these trays can be 10 to 20 percent less than that of conventional trays due to their typical short flow paths (see "Efficiency").

These trays include the Ultrfrac™, the ConSep™ (Fig. 14-26*e*), and the Swirl Tube™ trays. This technology has been sporadically used in eastern Europe for quite some time. It is just beginning to make inroads into distillation in the rest of the world, and looks very promising.

## OTHER TRAY TYPES

**Bubble-Cap Trays** (Fig. 14-27*a*) These are flat perforated plates with risers (chimneylike pipes) around the holes, and caps in the form of inverted cups over the risers. The caps are usually (but not always) equipped with slots through which some of the gas comes out, and may be round or rectangular. Liquid and froth are trapped on the tray to a depth at least equal to the riser or weir height, giving the bubble-cap tray a unique ability to operate at very low gas and liquid rates.

The bubble-cap tray was the workhorse of distillation before the 1960s. It was superseded by the much cheaper (as much as 10 times) sieve and valve trays. Compared to the bubble-cap trays, sieve and valve trays also offer slightly higher capacity and efficiency and lower entrainment and pressure drop, and are less prone to corrosion and fouling. Today, bubble-cap trays are only used in special applications where liquid or gas rates are very low. A large amount of information on bubble-cap trays is documented in several texts (e.g., Bolles in B. D. Smith, *Design of Equilibrium Stage Processes,* McGraw-Hill, 1963; Bolles, *Pet. Proc.,* February 1956, p. 65; March 1956, p. 82; April 1956, p. 72; May 1956, p. 109; Ludwig, *Applied Process Design for Chemical and Petrochemical Plants,* 2d ed., vol. 2, Gulf Publishing, Houston, 1979).

**Dual-Flow Trays** These are sieve trays with no downcomers (Fig. 14-27*b*). Liquid continuously weeps through the holes, hence their low efficiency. At peak loads they are typically 5 to 10 percent less efficient than sieve or valve trays, but as the gas rate is reduced, the efficiency gap rapidly widens, giving poor turndown. The absence of downcomers gives dual-flow trays more area, and therefore greater capacity, less entrainment, and less pressure drop, than conventional trays. Their pressure drop is further reduced by their large fractional hole area (typically 18 to 30 percent of the tower area). However, this low pressure drop also renders dual-flow trays prone to gas and liquid maldistribution.

In general, gas and liquid flows pulsate, with a particular perforation passing both gas and liquid intermittently, but seldom simultaneously. In large-diameter (>2.5-m, or 8-ft) dual-flow trays, the pulsations sometimes develop into sloshing, instability, and vibrations. The Ripple Tray™ is a proprietary variation in which the tray floor is corrugated to minimize this instability.

With large holes (16 to 25 mm), these trays are some of the most fouling-resistant and corrosion-resistant devices in the industry. This defines their main application: highly fouling services, slurries, and corrosive services. Dual-flow trays are also the least expensive and easiest to install and maintain.

A wealth of information for the design and rating of dual-flow trays, much of it originating from FRI data, was published by Garcia and Fair [*Ind. Eng. Chem. Res.* **41:**1632 (2002)].

**Baffle Trays** Baffle trays ("shed decks," "shower decks") (Fig. 14-28*a*) are solid half-circle plates, sloped slightly in the direction of outlet flow, with weirs at the end. Gas contacts the liquid as it showers from the plate. This contact is inefficient, typically giving 30 to 40 percent of the efficiency of conventional trays. This limits their application mainly to heat-transfer and scrubbing services. The capacity is high and pressure drop is low due to the high open area (typically 50 percent of the tower cross-sectional area). Since there is not much

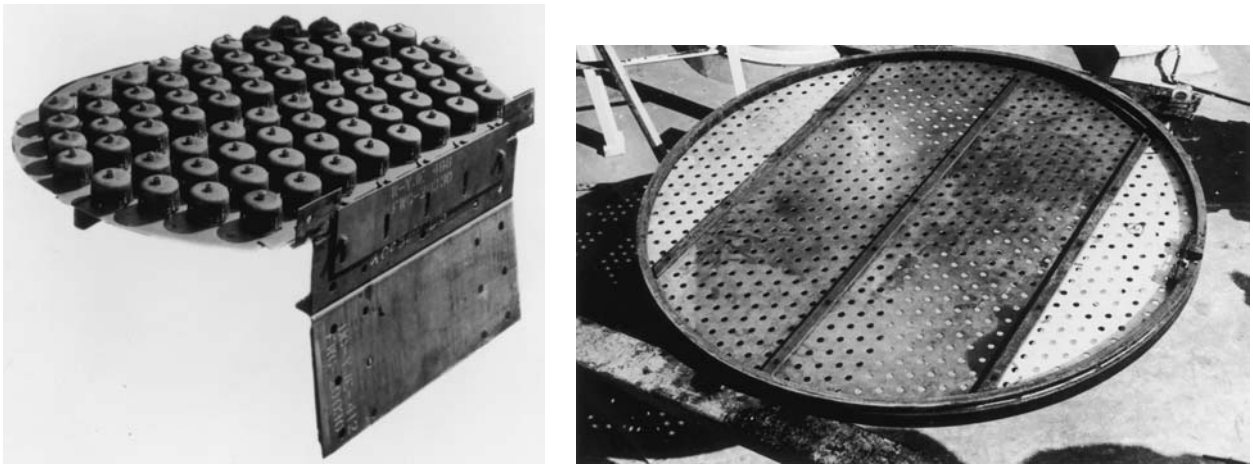

**FIG. 14-27** Other trays. (*a*) Bubble-cap tray. (*b*) Dual-flow tray. [*Part a, courtesy of Koch-Glitsch LP; part b, courtesy of Fractionation Research Inc. (FRI).*]

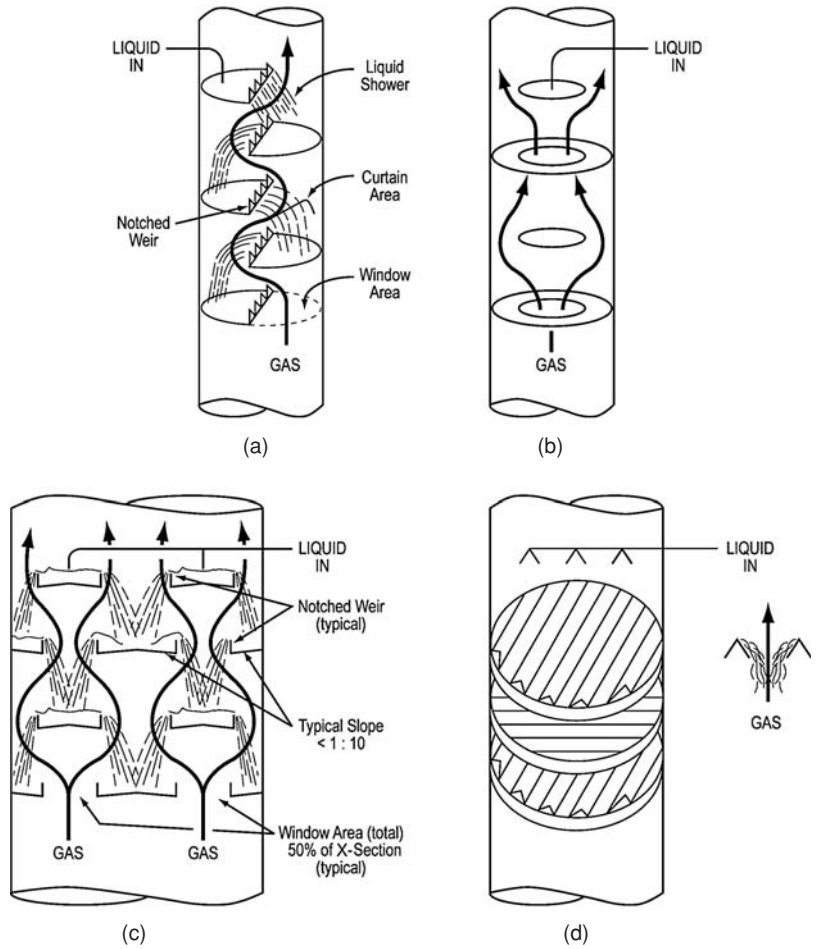

**FIG. 14-28** Baffle tray variations. (*a*) Segmental. (*b*) Disk and doughnut. (*c*) Multipass. (*d*) Angle irons.

that can plug up, the baffle trays are perhaps the most fouling-resistant device in the industry, and their main application is in extremely fouling services. To be effective in these services, their liquid rate needs to exceed 20 $m^3$/hm (2 gpm/in) of outlet weir and dead spots formed due to poor support design (Kister, *Distillation Troubleshooting,* Wiley, 2006) eliminated.

There are several geometric variations. The disk and doughnut trays (Fig. 14-28*b*) replace the half-circle segmental plates by alternate plates shaped as disks and doughnuts, each occupying about 50 percent of the tower cross-sectional area. In large towers, multipass baffle trays (Fig. 14-28*c*) are common. Another variation uses angle irons, with one layer oriented at 90° to the one below (Fig. 14-28*d*). Multipass baffle trays, as well as angle irons, require good liquid (and to a lesser extent, also good gas) distribution, as has been demonstrated from field heat-transfer measurements [Kister and Schwartz, *Oil & Gas J.,* p. 50 (May 20, 2002)]. Excellent overviews of the fundamentals and design of baffle trays were given by Fair and Lemieux [Fair, *Hydro. Proc.,* p. 75 (May 1993); Lemieux, *Hydroc. Proc.,* p. 106 (September 1983)]. Mass-transfer efficiency data with baffle trays by Fractionation Research Inc. (FRI) have been released and presented together with their correlation (Fair, Paper presented at the AIChE Annual Meeting, San Francisco, November 2003).

## FLOODING

Flooding is by far the most common upper capacity limit of a distillation tray. Column diameter is set to ensure the column can achieve the required throughput without flooding. Towers are usually designed to operate at 80 to 90 percent of the flood limit.

Flooding is an excessive accumulation of liquid inside a column. Flood symptoms include a rapid rise in pressure drop (the accumulating liquid increases the liquid head on the trays), liquid carryover from the column top, reduction in bottom flow rate (the accumulating liquid does not reach the tower bottom), and instability (accumulation is non-steady-state). This liquid accumulation is generally induced by one of the following mechanisms.

**Entrainment (Jet) Flooding** Froth or spray height rises with gas velocity. As the froth or spray approaches the tray above, some of the liquid is aspirated into the tray above as entrainment. Upon a further increase in gas flow rate, massive entrainment of the froth or spray begins, causing liquid accumulation and flood on the tray above.

Entrainment flooding can be subclassified into *spray entrainment flooding* (common) and *froth entrainment flooding* (uncommon). Froth entrainment flooding occurs when the froth envelope approaches the tray above, and is therefore only encountered with small tray spacings (<450 mm or 18 in) in the froth regime. At larger (and often even lower) tray spacing, the froth breaks into spray well before the froth envelope approaches the tray above.

The entrainment flooding prediction methods described here are based primarily on spray entrainment flooding. Considerations unique to froth entrainment flooding can be found elsewhere (Kister, *Distillation Design,* McGraw-Hill, New York, 1992).

**Spray Entrainment Flooding Prediction** Most entrainment flooding prediction methods derive from the original work of Souders and Brown [*Ind. Eng. Chem.* **26**(1), 98 (1934)]. Souders and Brown theoretically analyzed entrainment flooding in terms of droplet settling velocity. Flooding occurs when the upward vapor velocity is high enough to suspend a liquid droplet, giving

$$C_{SB} = u_{S,\text{flood}}\sqrt{\frac{\rho_G}{\rho_L - \rho_G}} \tag{14-80}$$

The Souders and Brown constant $C_{SB}$ is the $C$-factor [Eq. (14-77)] at the entrainment flood point. Most modern entrainment flooding correlations retain the Souders and Brown equation (14-80) as the basis, but depart from the notion that $C_{SB}$ is a constant. Instead, they express $C_{SB}$ as a weak function of several variables, which differ from one correlation to another. Depending on the correlation, $C_{SB}$ and $u_{S,\text{flood}}$ are based on either the net area $A_N$ or on the bubbling area $A_B$.

The constant $C_{SB}$ is roughly proportional to the tray spacing to a power of 0.5 to 0.6 (Kister, *Distillation Design,* McGraw-Hill, New York, 1992). Figure 14-29 demonstrates the effect of liquid rate and fractional hole area on $C_{SB}$. As liquid load increases, $C_{SB}$ first increases, then peaks, and finally declines. Some interpret the peak as the transition from the froth to spray regime [Porter and Jenkins, *I. Chem. E. Symp. Ser.* **56,** Summary Paper, London (1979)]. $C_{SB}$ increases slightly with fractional hole area at lower liquid rates, but there is little effect of fractional hole area on $C_{SB}$ at high liquid rates. $C_{SB}$, slightly increases as hole diameter is reduced.

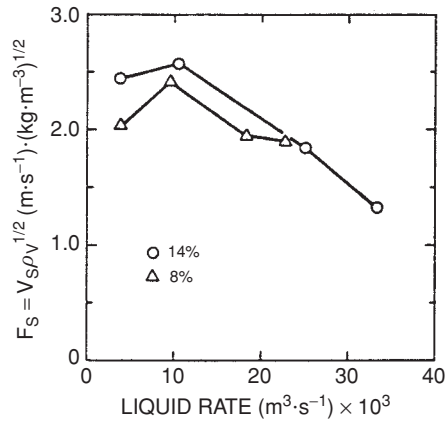

**FIG. 14-29** Effect of liquid rate and fractional hole area on flood capacity. FRI sieve tray test data, cyclohexane/*n*-heptane, 165 kPa (24 psia), $D_T$ = 1.2 m (4 ft), $S$ = 610 mm (24 in), $h_w$ = 51 mm (2 in), $d_H$ = 12.7 mm (0.5 in), straight downcomers, $A_D/A_T$ = 0.13. *(From T. Yanagi and M. Sakata,* Ind. Eng. Chem. Proc. Des. Dev. ***21,*** 712; copyright © 1982, *American Chemical Society, reprinted by permission.)*

For sieve trays, the entrainment flood point can be predicted by using the method by Kister and Haas [*Chem. Eng. Progr.*, **86**(9), 63 (1990)]. The method is said to reproduce a large database of measured flood points to within ± 15 percent. $C_{SB,\text{flood}}$ is based on the net area. The equation is

$$C_{SB,\text{flood}} = 0.0277(d_h^2\sigma/\rho_L)^{0.125}(\rho_G/\rho_L)^{0.1}(\text{TS}/h_{ct})^{0.5} \tag{14-81}$$

where $d_h$ = hole diameter, mm
$\sigma$ = surface tension, mN/m (dyn/cm)
$\rho_G$, $\rho_L$ = vapor and liquid densities, kg/m$^3$
TS = tray spacing, mm
$h_{ct}$ = clear liquid height at the froth-to-spray transition, mm; obtained from:

$$h_{ct} = h_{ct,\text{H}_2\text{O}}\,(996/\rho_L)^{0.5(1-n)} \tag{14-82}$$

$$h_{ct,\text{H}_2\text{O}} = \frac{0.497\,A_f^{-0.791}d_h^{\,0.833}}{1 + 0.013\,Q_L^{-0.59}A_f^{-1.79}} \tag{14-83}$$

$$n = 0.00091 d_h/A_f \tag{14-84}$$

In Eq. (14-83), $Q_L$ = m$^3$ liquid downflow/(h·m weir length) and $A_f$ = fractional hole area based on active ("bubbling") area; for instance, $A_f = A_h/A_a$.

The Kister and Haas method can also be applied to valve trays, but the additional approximations reduce its data prediction accuracy for valve trays to within ±20 percent. For valve trays, adaptations of Eqs. (14-81) to (14-84) are required:

$$d_h = \frac{4 \times (\text{area of opening of one fully open valve})}{\text{wetted perimeter of opening of one fully open valve}} \tag{14-85}$$

$$A_f = \frac{\text{no. valves} \times (\text{area of opening of one fully open valve})}{\text{active (bubbling) area}} \tag{14-86}$$

A correlation for valve tray entrainment flooding that has gained respect and popularity throughout the industry is the Glitsch "Equation 13" (Glitsch, Inc., *Ballast Tray Design Manual,* 6th ed., 1993;

available from Koch-Glitsch, Wichita, Kans.). This equation has been applied successfully for valve trays from different manufacturers, as well as for sieve trays with large fractional hole areas (12 to 15 percent). With tray spacings of 600 mm and higher, its flood prediction accuracy for valve trays has generally been within ±10 percent in the author's experience. The Glitsch correlation is

$$\frac{\%\ \text{flood}}{100} = \frac{C_B}{\text{CAF}} + 1.359\frac{Q\ \text{FPL}}{A_B\ \text{CAF}} \tag{14-87}$$

where

$$\text{CAF} = 0.3048\ \text{CAF}_0\ \text{SF} \tag{14-88}$$

$C_B$ is the operating $C$-factor based on the bubbling area, m/s; $Q$ is the liquid flow rate, $m^3/s$; $A_B$ is the bubbling area, $m^2$; FPL is the flow path length, m, i.e., the horizontal distance between the inlet downcomer and the outlet weir. The flow path length becomes shorter as the number of passes increases. $\text{CAF}_0$ and CAF are the flood $C$-factors. $\text{CAF}_0$ is obtained from Fig. 14-30 in English units (ft/s). Equation (14-88) converts $\text{CAF}_0$ to the metric CAF (m/s), and corrects it by using a system factor SF. Values of SF are given in Table 14-9.

The Fair correlation [*Pet/Chem Eng.* **33**(10), 45 (September 1961)] for decades has been the standard of the industry for entrainment flood prediction. It uses a plot (Fig. 14-31) of surface-tension-corrected Souders and Brown flood factor $C_{SB}$ against the dimensionless flow parameter shown in Fig. 14-31. The flow parameter represents a ratio of liquid to vapor kinetic energies:

$$F_{LG} = \frac{L}{G}\left(\frac{\rho_G}{\rho_L}\right)^{0.5} \tag{14-89}$$

Low values of $F_{LG}$ indicate vacuum operation, high values indicate operation at higher pressures or at high liquid/vapor loadings. The liquid/gas ratio $L/G$ is based on mass flow rates. For multipass trays, the ratio needs to be divided by the number of passes. The strength of the correlation is at the lower flow parameters. At higher flow parameters (high $L/G$ ratios, high pressures, emulsion flow), Fig. 14-31 gives excessively conservative predictions, with the low values of $C_{sbf}$ to the right likely to result from downcomer flow restrictions rather than excessive entrainment. The curves may be expressed in equation form as [Lygeros and Magoulas, *Hydrocarbon Proc.* **65**(12), 43 (1986)]:

$$C_{sbf} = 0.0105 + 8.127(10^{-4})(\text{TS}^{0.755})\exp[-1.463\ F_{LG}^{0.842}] \tag{14-90}$$

where TS = plate spacing, mm.

Figure 14-31 or Eq. (14-90) may be used for sieve, valve, or bubble-cap trays. The value of the capacity parameter (ordinate term in Fig. 14-31) may be used to calculate the maximum allowable vapor velocity through the net area of the plate:

$$U_{nf} = C_{sbf}\left(\frac{\sigma}{20}\right)^{0.2}\left(\frac{\rho_L - \rho_g}{\rho_g}\right)^{0.5} \tag{14-91}$$

where $U_{nf}$ = gas velocity through net area at flood, m/s
$C_{sbf}$ = capacity parameter corrected for surface tension, m/s

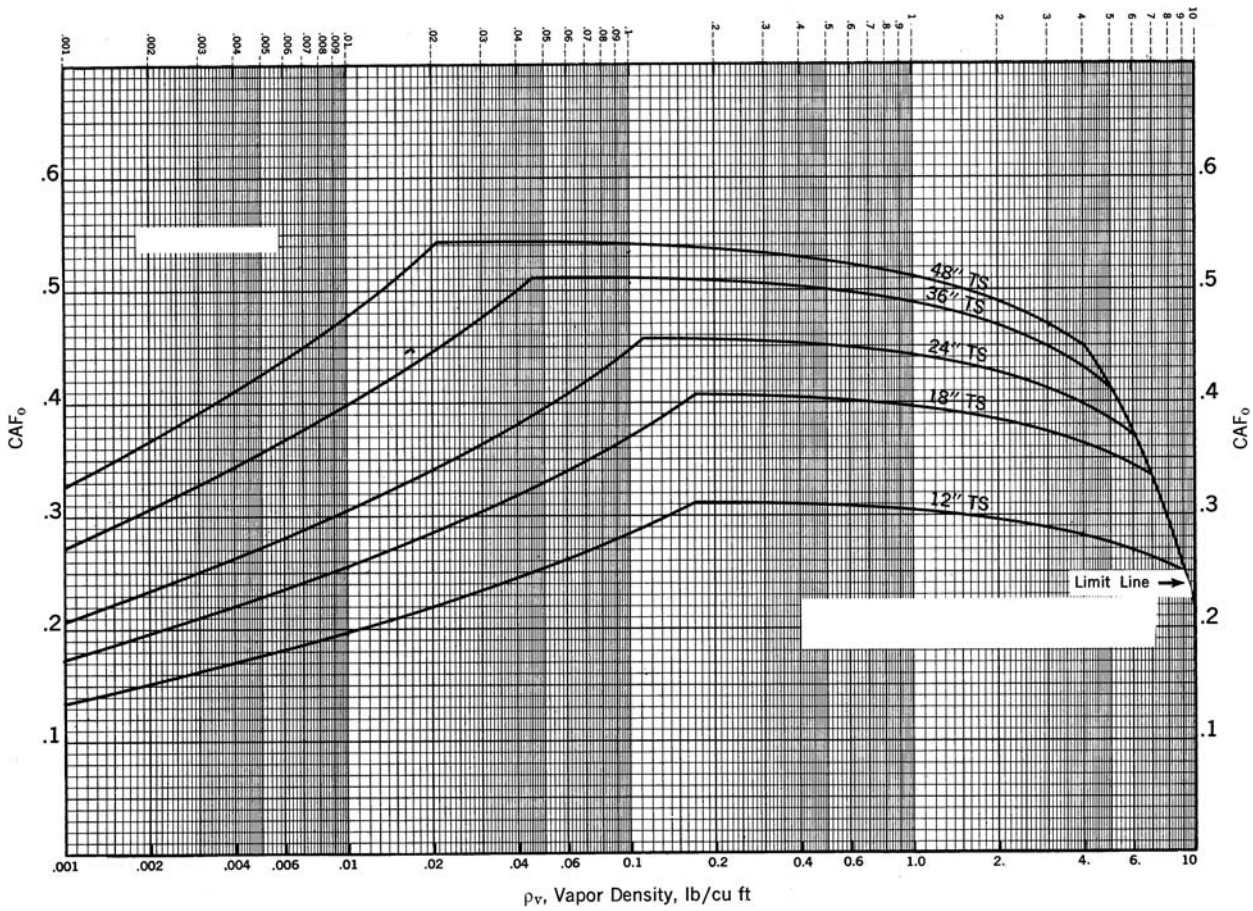

**FIG. 14-30** Flood capacity of moving valve trays. *(Courtesy of Koch-Glitch LP.)*

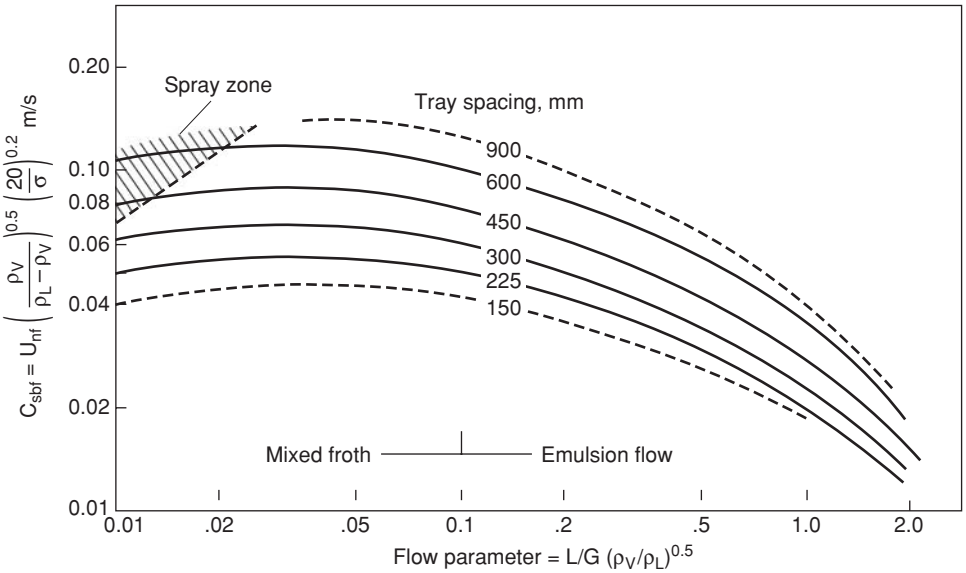

**FIG. 14-31** Fair's entrainment flooding correlation for columns with crossflow trays (sieve, valve, bubble-cap). [*Fair, Pet/Chem Eng 33(10), 45 (September 1961).*]

$\sigma$ = liquid surface tension, mN/m (dyn/cm)
$\rho_L$ = liquid density, kg/m$^3$
$\rho_G$ = gas density, kg/m$^3$

The application of the correlation is subject to the following restrictions:

1. System is low or nonfoaming.
2. Weir height is less than 15 percent of tray spacing.
3. Sieve-tray perforations are 13 mm (½ in) or less in diameter.
4. Ratio of slot (bubble cap), perforation (sieve), or full valve opening (valve plate) area $A_h$ to active area $A_a$ is 0.1 or greater. Otherwise the value of $U_{nf}$ obtained from Fig. 14-31 should be corrected:

| $A_h/A_a$ | $U_{nf}/U_{nf,\text{Fig. 14-31}}$ |
|---|---|
| 0.10 | 1.00 |
| 0.08 | 0.90 |
| 0.06 | 0.80 |

where $A_h$ = total slot, perforated, or open-valve area on tray.

***Example 9: Flooding of a Distillation Tray*** An available sieve tray column of 2.5-m diameter is being considered for an ethylbenzene/styrene separation. An evaluation of loading at the top tray will be made. Key dimensions of the single-pass tray are:

| | |
|---|---|
| Column cross section, m$^2$ | 4.91 |
| Downcomer area, m$^2$ | 0.25 |
| Net area, m$^2$ | 4.66 |
| Active area, m$^2$ | 4.41 |
| Hole area, m$^2$ | 0.617 |
| Hole diameter, mm | 4.76 |
| Weir length, m | 1.50 |
| Weir height, mm | 38 |
| Tray spacing, mm | 500 |

Conditions and properties at the top tray are:

| | |
|---|---|
| Temperature, °C | 78 |
| Pressure, torr | 100 |
| Vapor flow, kg/h | 25,500 |
| Vapor density, kg/m$^3$ | 0.481 |
| Liquid flow, kg/h | 22,000 |
| Liquid density, kg/m$^3$ | 841 |
| Surface tension, mN/m | 25 |

*Solution.* The method of Kister and Haas gives:

$$Q_L = \frac{22{,}000}{841 \times 1.50} = 17.44 \text{ m}^3\text{/h·m weir}$$

$$A_f = \frac{0.617}{4.41} = 0.14$$

By Eq. (14-83), $h_{ct,H_2O} = 7.98$ mm

Eq. (14-84): $n = 0.0309$

Eq. (14-82): $h_{ct} = 8.66$ mm

Finally, by Eq. (14-81),

$$C_{SB,\text{flood}} = 0.0277[(4.76^2)(25/841)]^{0.125} \times (0.481/841)^{0.1}(500/8.66)^{0.5}$$
$$= 0.0947 \text{ m/s}$$

Alternatively, applying the Fair correlation:

The flow parameter $F_{LG} = 0.021$ [Eq. (14-89)]. From Fig. 14-31, $C_{sbf} = 0.095$ m/s. Then, based on the net area,

$$C_{SB} = 0.095(25/20)^{0.2} = 0.0993 \text{ m/s}$$

about 5 percent higher than the answer obtained from Kister and Haas.

For the design condition, the $C$-factor based on the net area is

$$C = \frac{25{,}500}{3600(0.481)(4.66)} \sqrt{\frac{0.481}{841 - 0.481}} = 0.0756 \text{ m/s}$$

or about 80 percent of flood. The proposed column is entirely adequate for the service required.

**System Limit (Ultimate Capacity)** This limit is discussed later under "System Limit."

**Downcomer Backup Flooding** Aerated liquid backs up in the downcomer because of tray pressure drop, liquid height on the tray, and frictional losses in the downcomer apron (Fig. 14-32). All these increase with increasing liquid rate. Tray pressure drop also increases as the gas rate rises. When the backup of aerated liquid exceeds the tray spacing, liquid accumulates on the tray above, causing downcomer backup flooding.

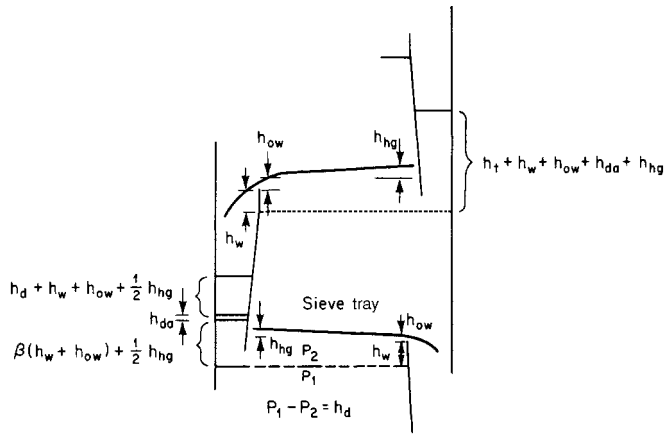

**FIG. 14-32** Pressure-drop contributions for trays. $h_d$ = pressure drop through cap or sieve, equivalent height of tray liquid; $h_w$ = height of weir; $h_{ow}$ = weir crest; $h_{hg}$ = hydraulic gradient; $h_{da}$ = loss under downcomer.

Downcomer backup is calculated from the pressure balance

$$h_{dc} = h_t + h_w + h_{ow} + h_{da} + h_{hg} \tag{14-92}$$

where $h_{dc}$ = clear liquid height in downcomer, mm liquid
$h_t$ = total pressure drop across the tray, mm liquid
$h_w$ = height of weir at tray outlet, mm liquid
$h_{ow}$ = height of crest over weir, mm liquid
$h_{da}$ = head loss due to liquid flow under downcomer apron, mm liquid
$h_{hg}$ = liquid gradient across tray, mm liquid

The heights of head losses in Eq. (14-92) should be in consistent units, e.g., millimeters or inches of liquid under operating conditions on the tray.

As noted, $h_{dc}$ is calculated in terms of equivalent clear liquid. Actually, the liquid in the downcomer is aerated and actual backup is

$$h'_{dc} = \frac{h_{dc}}{\phi_{dc}} \tag{14-93}$$

where $\phi_{dc}$ is an average *relative* froth density (ratio of froth density to liquid density) in the downcomer. Design must not permit $h'_{dc}$ to exceed the value of tray spacing plus weir height; otherwise, flooding can be precipitated.

The value of $\phi_{dc}$ depends upon the tendency for gas and liquid to disengage (froth to collapse) in the downcomer. For cases favoring rapid bubble rise (low gas density, low liquid viscosity, low system foamability) collapse is rapid, and fairly clear liquid fills the bottom of the downcomer (Fig. 14-17). For such cases, it is usual practice to employ a higher value of $\phi_{dc}$. For cases favoring slow bubble rise (high gas density, high liquid viscosity, high system foamability), lower values of $\phi_{dc}$ should be used. As the critical point is approached in high-pressure distillations and absorptions, special precautions with downcomer sizing are mandatory. Table 14-6 lists values of $\phi_{dc}$ commonly used by the industry.

**Downcomer Choke Flooding** This is also called downcomer entrance flood or downcomer velocity flood. A downcomer must be sufficiently large to transport all the liquid downflow. Excessive friction losses in the downcomer entrance, and/or excessive flow rate of gas venting from the downcomer in counterflow, will impede liquid downflow, initiating liquid accumulation (termed downcomer choke flooding) on the tray above. The prime design parameter is the downcomer top area. Further down the downcomer, gas disengages from the liquid and the volumes of aerated liquid downflow and vented gas

**TABLE 14-6 Criteria for Downcomer Aeration Factors**

| Foaming tendency | Bolles' criterion* | | Glitsch's criterion† | | Fair et al.'s criterion‡ | |
|---|---|---|---|---|---|---|
| | Examples | $\phi_{dc}$ | Examples | $\phi_{dc}$ | Examples | $\phi_{dc}$ |
| Low | Low-molecular-weight hydrocarbons§ and alcohols | 0.6 | $\rho_G < 1.0$ lb/ft$^3$ | 0.6 | Rapid bubble rise systems, such as low gas density, low liquid viscosity | 0.5 |
| Moderate | Distillation of medium-molecular-weight hydrocarbons | 0.5 | $1.0 < \rho_G < 3.0$ lb/ft$^3$ | 0.5 | | |
| High | Mineral oil absorbers | 0.4 | $\rho_G > 3.0$ lb/ft$^3$ | 0.4 | | |
| Very high | Amines, glycols | 0.3 | | | Slow bubble rise systems, such as high gas density, high liquid viscosity, foaming systems | 0.2 – 0.3 |

*"Distillation Theory and Practice—an Intensive Course," University of New South Wales/University of Sydney, August 9–11, 1977.
† Glitsch, Inc., *Ballast Tray Design Manual,* 6th ed., 1993; available from Koch-Glitsch LP, Wichita, Kans.
‡ R. H. Perry and D. W. Green (eds.), *Perry's Chemical Engineers' Handbook,* 7th ed., McGraw-Hill, 1997.
§ The author believes that low-molecular-weight hydrocarbons refers to light hydrocarbons at near atmospheric pressure or under vacuum. The foam stability of light-hydrocarbon distillation at medium and high pressure is best inferred from the Glitsch criterion.
To convert from lb/ft$^3$, to kg/m$^3$, multiply by 16.0.

upflow are greatly reduced. With sloped downcomers, the downcomer bottom area is normally set at 50 to 60 percent of the top downcomer area. This taper is small enough to keep the downcomer top area the prime choke variable.

There is no satisfactory published correlation for downcomer choke. The best that can be done in the absence of data or correlation is to apply the criteria for maximum velocity of clear liquid at the downcomer entrance. Kister *(Distillation Operation,* McGraw-Hill, New York, 1990) surveyed the multitude of published criteria for maximum downcomer velocity and incorporated them into a single set of guidelines (Table 14-7). The values for 30-in spacing were revised to reflect the author's recent experiences. The values given in Table 14-7 are not conservative. For a conservative design, multiply the values from Table 14-7 by a safety factor of 0.75. For very highly foaming systems, where antifoam application is undesirable, there are benefits for reducing downcomer design velocities down to 0.1 to 0.15 ft/s.

Another criterion sometimes used is to provide sufficient residence time in the downcomer to allow adequate disengagement of gas from the descending liquid, so that the liquid is relatively gas-free by the time it enters the tray below. Inadequate removal of gas from the liquid may choke the downcomer. Kister (loc. cit.) reviewed various published criteria for downcomer residence times and recommended those by Bolles (private communication, 1977) and Erbar and Maddox (Maddox, *Process Engineer's Absorption Pocket Handbook,* Gulf Publishing, Houston, 1985). Both sets of guidelines are similar and are summarized in Table 14-8. The residence times in Table 14-8 are *apparent residence times*, defined as the ratio of the total downcomer volume to the clear liquid flow in the downcomer.

As a segmental downcomer becomes smaller, its width decreases faster than its length, turning the downcomer into a long, narrow slot. This geometry increases the resistance to liquid downflow and to the upflow of disengaging gas. Small downcomers are also extremely sensitive to foaming, fouling, construction tolerances, and the introduction of debris. Generally, segmental downcomers smaller than 5 percent of the column cross-sectional area should be avoided. Additional discussion of small downcomers is available (Kister, *Distillation Operation,* McGraw-Hill, New York, 1990).

**Derating ("System") Factors** With certain systems, traditional flooding equations consistently give optimistic predictions. To allow for this discrepancy, an empirical derating or system factor (SF < 1.0) is applied. To obtain the actual or derated flood load, the flood gas load (entrainment flooding) or flood liquid load (downcomer choke) obtained from the traditional equations is multiplied by the derating factor. In the case of downcomer backup flood, the froth height from the traditional flood equation is divided by the derating factor.

Derating factors are vaguely related to the foaming tendency, but are also applied to nonfoaming systems where standard flooding equations consistently predict too high. Sometimes, derating factors are used solely as overdesign factors. Brierley *(Chem. Eng. Prog.,* July 1994, p. 68) states that some derating factors actually evolved from plant misoperation or from misinterpretation of plant data. Kister (loc. cit.) compiled the derating factors found in the literature into Table 14-9.

The application of derating factors is fraught with inconsistent practices and confusion. Caution is required. The following need to be carefully specified:

1. The flooding mechanism to which the derating factor applies (entrainment, downcomer backup, downcomer choke, or all these) must be specified.
2. Avoiding double derating. For instance, the values in Table 14-9 may apply with Eq. (14-81) because Eq. (14-81) does not take foaminess into account. However, they will double-derate a flood calculation that is made with a correlation or criteria that already take foaminess into account, such as the criteria for downcomer choke in Tables 14-7 and 14-8. Similarly, two different factors from Table 14-9 may apply to a single system; only one should be used.
3. Derating factors vary from source to source, and may depend on the correlation used as well as the system. For instance, some caustic wash applications have a track record of foaming more severely than other caustic wash applications (see note in Table 14-9). The derating factors in Table 14-9 are a useful guide, but are far from absolute.

## ENTRAINMENT

Entrainment (Fig. 14-33) is liquid transported by the gas to the tray above. As the lower tray liquid is richer with the less-volatile components, entrainment counteracts the mass-transfer process, reducing tray efficiency. At times entrainment may transport nonvolatile impurities upward to contaminate the tower overhead product, or damage rotating machinery located in the path of the overhead gas.

**Effect of Gas Velocity** Entrainment increases with gas velocity to a high power. Generally, smaller powers, indicative of a relatively gradual change, are typical of low-pressure systems. Higher powers, which indicate a steep change, are typical of high-pressure systems.

Due to the steep change of entrainment with gas velocity at high pressure, the gas velocity at which entrainment becomes significant tends to coincide with the flood point. At low pressure, the rate of change of entrainment with gas velocity is much slower, and entrainment can be significant even if the tray is operating well below the flood point. For this reason, excessive entrainment is a common problem in low-pressure and vacuum systems, but is seldom troublesome with high-pressure systems. If encountered at high pressure, entrainment usually indicates flooding or abnormality.

**Effect of Liquid Rate** As the liquid rate is raised at constant gas rate, entrainment first diminishes, then passes through a minimum, and finally increases [Sakata and Yanagi, *I. Chem. E. Symp. Ser.* **56,** 3.2/21 (1979); Porter and Jenkins, *I. Chem. E. Symp. Ser.* **56,** Summary Paper, 1979; Friend, Lemieux, and Schreiner, *Chem. Eng.,* October 31, 1960, p. 101]. The entrainment minima coincide with the maxima in plots of entrainment flood *F*-factor against liquid load (Fig. 14-29). At the low liquid loads (spray regime), an increase in liquid load suppresses atomization, drop formation, and consequently entrainment. At higher liquid loads, an increase in liquid load reduces the effective tray spacing, thereby increasing entrainment. The entrainment minima have been interpreted by many workers as the tray dispersion change from predominantly spray to the froth regime [Porter and Jenkins, loc. cit.; Kister and Haas, *I. Chem. E. Symp. Ser.* **104,** p. A483 (1987)].

**Effect of Other Variables** Entrainment diminishes with higher tray spacing and increases with hole diameter [Kister and Haas, *I.*

**TABLE 14-7 Maximum Downcomer Velocities**

| Foaming tendency | Example | Clear liquid velocity in downcomer, ft/s: 18-in spacing | 24-in spacing | 30-in spacing |
|---|---|---|---|---|
| Low | Low-pressure (<100 psia) light hydrocarbons, stabilizers, air-water simulators | 0.4–0.5 | 0.5–0.6 | 0.5–0.6* |
| Medium | Oil systems, crude oil distillation, absorbers, midpressure (100–300 psia) hydrocarbons | 0.3–0.4 | 0.4–0.5 | 0.4–0.5* |
| High | Amines, glycerine, glycols, high-pressure (>300 psia) light hydrocarbons | 0.2–0.25 | 0.2–0.25 | 0.2–0.3 |

*Revised from previous versions.

To convert from ft/s to m/s, multiply by 0.3048; from in to mm, multiply by 25.4; from psia to bar, multiply by 0.0689.

SOURCE: From H. Z. Kister, *Distillation Operation,* copyright 1990 by McGraw-Hill, Inc.; reprinted by permission.

**TABLE 14-8 Recommended Minimum Residence Time in the Downcomer**

| Foaming tendency | Example | Residence time, s |
|---|---|---|
| Low | Low-molecular-weight hydrocarbons,* alcohols | 3 |
| Medium | Medium-molecular-weight hydrocarbons | 4 |
| High | Mineral oil absorbers | 5 |
| Very high | Amines and glycols | 7 |

*The author believes that low-molecular-weight hydrocarbons refers to light hydrocarbons at atmospheric conditions or under vacuum. The foaming tendency of light-hydrocarbon distillation at medium pressure [>7 bar (100 psia)] is medium; at high pressure [>21 bar (300 psia)], it is high.

SOURCE: W. L. Bolles (Monsanto Company), private communication, 1977.

*Chem. E. Symp. Ser.* **104,** p. A483 (1987); *Ind. Eng. Chem. Res.* **27,** p. 2331 (1988); Lemieux and Scotti, *Chem. Eng. Prog.* **65**(3), 52 (1969)]. The hole diameter effect is large in the spray regime but small in the froth regime. In the spray regime, entrainment also increases as the fractional hole area is lowered, but this variable has little effect in the froth regime [Yanagi and Sakata, *Ind. Eng. Chem. Proc. Des. Dev.* **21,** 712 (1982); and Kister and Haas, loc. cit.].

**Entrainment Prediction** For spray regime entrainment, the Kister and Haas correlation was shown to give good predictions to a wide commercial and pilot-scale data bank [*I. Chem. E. Symp. Ser.* **104,** A483 (1987)]. The correlation is

$$E_S = 4.742^{(10/\sqrt{\sigma})^{1.64}}\,\chi^{(10/\sqrt{\sigma})} \tag{14-94}$$

where

$$\chi = 872\left(\frac{u_B h_{Lt}}{\sqrt{d_H S}}\right)^4\left(\frac{\rho_G}{Q_L\rho_L}\right)\left(\frac{\rho_L-\rho_G}{\sigma}\right)^{0.25} \tag{14-95}$$

and

$$h_{Lt} = \frac{h_{ct}}{1+0.00262h_w} \tag{14-96}$$

The terms in Eqs. (14-94) through (14-96) are in the metric units described in the Nomenclature table at the beginning of this section.

The recommended range of application of the correlation is given in Table 14-10. The clear liquid height at the froth-to-spray transition $h_{ct}$ is calculated using the corrected Jeronimo and Sawistowski [*Trans. Inst. Chem. Engnrs.* **51,** 265 (1973)] correlation as per Eqs. (14-82) to (14-84).

For decades, the Fair correlation [*Pet/Chem. Eng.*, **33**(10), 45 (September 1961)] has been used for entrainment prediction. In the spray regime the Kister and Haas correlation was shown to be more accurate [Koziol and Mackowiak, *Chem. Eng. Process.*, **27,** p. 145 (1990)]. In the froth regime, the Kister and Haas correlation does not apply, and Fair's correlation remains the standard of the industry. Fair's correlation (Fig. 14–34) predicts entrainment in terms of the flow parameter [Eq. (14-89)] and the ratio of gas velocity to entrainment flooding gas velocity. The ordinate values $\Psi$ are fractions of gross liquid downflow, defined as follows:

$$\psi = \frac{e}{L_m+e} \tag{14-97}$$

where $e$ = absolute entrainment of liquid, mol/time
$L_m$ = liquid downflow rate without entrainment, mol/time

Figure 14-34 also accepts the validity of the Colburn equation [*Ind. Eng. Chem.*, **28,** 526 (1936)] for the effect of entrainment on efficiency:

$$\frac{E_a}{E_{mv}} = \frac{1}{1+E_{mv}[\psi/(1-\psi)]} \tag{14-98}$$

where $E_{mv}$ = Murphree vapor efficiency [see Eq. (14-134)]
$E_a$ = Murphree vapor efficiency, corrected for recycle of liquid entrainment

The Colburn equation is based on complete mixing on the tray. For incomplete mixing, e.g., liquid approaching plug flow on the tray, Rahman and Lockett [*I. Chem. E. Symp. Ser. No. 61,* 111 (1981)] and Lockett et al. [*Chem. Eng. Sci.*, **38,** 661 (1983)] have provided corrections.

**TABLE 14-9 Derating ("System") Factors**

| System | Factor | Reference | Notes |
|---|---|---|---|
| Nonfoaming regular systems | 1.0 | 1–4 | |
| High pressure ($\rho_G$ >1.8 lb/ft$^3$) | 2.94/ $\rho_G^{0.32}$ | 2 | Do not double-derate. |
| **Low-foaming** | | | |
| Depropanizers | 0.9 | 4 | |
| $H_2S$ strippers | 0.9 | 3, 4 | |
| | 0.85 | 2 | |
| Fluorine systems (freon, $BF_3$) | 0.9 | 1, 4 | |
| Hot carbonate regenerators | 0.9 | 2, 4 | |
| **Moderate-foaming** | | | |
| Deethanizers | | | |
| Absorbing type, top section | 0.85 | 1–4 | |
| Absorbing type, bottom section | 1.0 | 3 | |
| | 0.85 | 1, 2, 4 | |
| Refrigerated type, top section | 0.85 | 4 | |
| | 0.8 | 3 | |
| Refrigerated type, bottom section | 1.0 | 1, 3 | |
| | 0.85 | 4 | |
| Demethanizers | | | |
| Absorbing type, top section | 0.85 | 1–3 | |
| Absorbing type, bottom section | 1.0 | 3 | |
| | 0.85 | 1, 2 | |
| Refrigerated type, top section | 0.8 | 3 | |
| Refrigerated type, bottom section | 1.0 | 3 | |
| Oil absorbers | | | |
| Above 0°F | 0.85 | 1–4 | Ref. 2 proposes these for "absorbers" rather than "oil absorbers." |
| Below 0°F | 0.95 | 3 | |
| | 0.85 | 1, 4 | |
| | 0.8 | 2 | |
| Crude towers | 1.0 | 3 | |
| | 0.85 | 4 | |
| Crude vacuum towers | 1.0 | 3 | |
| | 0.85 | 2 | |
| Furfural refining towers | 0.85 | 2 | |
| | 0.8 | 4 | |
| Sulfolane systems | 1.0 | 3 | |
| | 0.85 | 4 | |
| Amine regenerators | 0.85 | 1–4 | |
| Glycol regenerators | 0.85 | 1, 4 | |
| | 0.8 | 3 | |
| | 0.65 | 2 | |
| Hot carbonate absorbers | 0.85 | 1, 4 | |
| Caustic wash | 0.65 | 2 | The author suspects that this low factor refers only to some caustic wash applications but not to others. |
| **Heavy-foaming** | | | |
| Amine absorbers | 0.8 | 2 | |
| | 0.75 | 3, 4 | |
| | 0.73 | 1 | |
| Glycol contactors | 0.73 | 1 | Ref. 2 recommends 0.65 for glycol contactors in glycol synthesis gas service, 0.5 for others. |
| | 0.65 | 3, 4 | |
| | 0.50 | 2 | |
| Sour water strippers | 0.5–0.7 | 3 | |
| | 0.6 | 2 | |

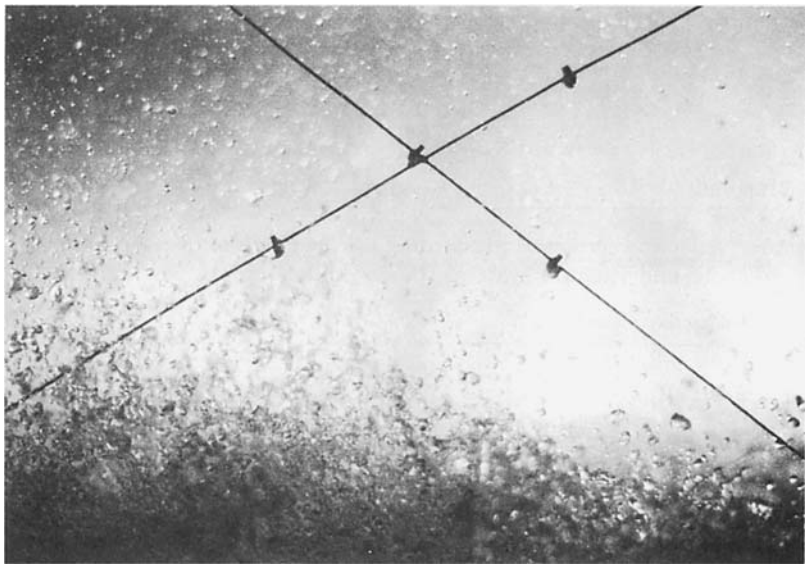

**FIG. 14-33** Entrainment. [*Reprinted courtesy of Fractionation Research Inc. (FRI).*]

Fair (paper presented at the AIChE Annual Meeting, Chicago, Ill., November 1996) correlated data for efficiency reduction due to the rise of entrainment near entrainment flood, getting

$$\ln \psi = A + B\Phi + C\Phi^2 \qquad (14\text{-}99)$$

where $\Phi$ is the fractional approach to entrainment flood and $A$, $B$, and $C$ are constants given by

| | $A$ | $B$ | $C$ |
|---|---|---|---|
| Highest likely efficiency loss | –3.1898 | –4.7413 | 7.5312 |
| Median (most likely) efficiency loss | –3.2108 | –8.9049 | 11.6291 |
| Lowest likely efficiency loss | 4.0992 | –29.9141 | 25.3343 |

Either the Kister and Haas or the Fair method can be used to evaluate $\Phi$. The correlation has been tested with sieve trays in the flow parameter range of 0.024 to 0.087.

***Example 10: Entrainment Effect on Tray Efficiency*** For the column in Example 9, estimate the efficiency loss should the operation be pushed from the design 80 percent of flood to 90 percent of flood. The midrange dry Murphree tray efficiency is 70 percent.

*Solution* The vapor and liquid densities and $L/V$ ratio remain unchanged from Example 9, and so is the flow parameter (calculated 0.021 in Example 9). At 80 and 90 percent of flood, respectively, Fig. 14-34 gives $\psi = 0.15$ and 0.24. The respective efficiency reductions are calculated from Eq. (14-98),

**TABLE 14-10 Recommended Range of Application for the Kister and Haas Spray Regime Entrainment Correlation**

| | |
|---|---|
| Flow regime | Spray only |
| Pressure | 20–1200 kPa (3–180 psia) |
| Gas velocity | 0.4–5 m/s (1.3–15 ft/s) |
| Liquid flow rate | 3–40 $m^3/(m \cdot h)$ (0.5–4.5 gpm/in) |
| Gas density | 0.5–30 $kg/m^3$ (0.03–2 $lb/ft^3$) |
| Liquid density | 450–1500 $kg/m^3$ (30–90 $lb/ft^3$) |
| Surface tension | 5–80 mN/m |
| Liquid viscosity | 0.05–2 cP |
| Tray spacing | 400–900 mm (15–36 in) |
| Hole diameter | 3–15 mm (0.125–0.75 in) |
| Fractional hole area | 0.07–0.16 |
| Weir height | 10–80 mm (0.5–3 in) |

$$\frac{E_a}{E_{mv}} = \frac{1}{1 + 0.70[0.15/(1 - 0.15)]} = 0.89$$

$$\frac{E_a}{E_{mv}} = \frac{1}{1 + 0.70[0.24/(1 - 0.24)]} = 0.82$$

signifying an efficiency loss from 62 to 57 percent.

Alternatively, at 80 and 90 percent of entrainment flood, the median value of $\psi$ from Eq. (14-99) is

$$\ln \psi = -3.2108 - 8.9049(0.80) + 11.6291(0.80^2)$$

giving $\psi = 0.056$ and from Eq. (14-98) $E_o/E_{mv} = 0.96$

$$\ln \psi = -3.2108 - 8.9049(0.90) + 11.6291(0.90^2)$$

giving $\psi = 0.164$ and from Eq. (14-98) $E_o/E_{mv} = 0.88$

signifying an efficiency reduction from 67 to 62 percent.

## PRESSURE DROP

In vacuum distillation, excessive pressure drop causes excessive bottom temperatures which, in turn, increase degradation, polymerization, coking, and fouling, and also loads up the column, vacuum system, and reboiler. In the suction of a compressor, excessive pressure drop increases the compressor size and energy usage. Such services attempt to minimize tray pressure drop. Methods for estimating pressure drops are similar for most conventional trays. The total pressure drop across a tray is given by

$$h_t = h_d + h'_L \qquad (14\text{-}100)$$

where $h_t$ = total pressure drop, mm liquid
$h_d$ = pressure drop across the dispersion unit (dry hole for sieve trays; dry valve for valve trays), mm liquid
$h'_L$ = pressure drop through aerated mass over and around the disperser, mm liquid

It is convenient and consistent to relate all of these pressure-drop terms to height of equivalent clear liquid (deaerated basis) on the tray, in either millimeters or inches of liquid.

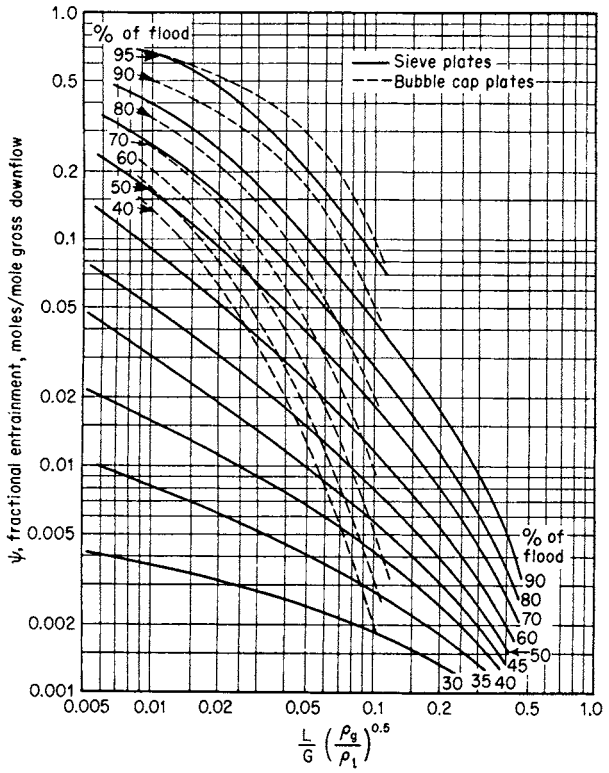

**FIG. 14-34** Entrainment correlation. $L/G$ = liquid-gas mass ratio; and $\rho_l$ and $\rho_g$ = liquid and gas densities. [*Fair,* Pet./Chem. Eng., **33**(10), *45 (September 1961).*]

Pressure drop across the disperser is calculated by variations of the standard orifice equation:

$$h_d = K\left(\frac{\rho_G}{\rho_L}\right)U_h^2 \qquad (14\text{-}101)$$

where $U_h$ = linear gas velocity through slots (valve trays) or perforations (sieve tray), m/s.

For sieve trays, $K = 50.8/C_v^2$. Values of $C_v$ are taken from Fig. 14-35. Values from Fig. 14-35 may be calculated from

$$C_v = 0.74(A_h/A_a) + \exp[0.29(t_t/d_h) - 0.56] \qquad (14\text{-}102)$$

For Sulze's fixed valve trays, Summers and van Sinderen (*Distillation 2001: Topical Conference Proceedings,* AIChE Spring National Meeting, p. 444, Houston, April 22–26, 2001) provided the following equation for $K$:

$$K = 58 + 386A_f \quad \text{for MVG fixed valves} \qquad (14\text{-}103a)$$

$$K = 58 + 461A_f \quad \text{for SVG and LVG fixed valves} \qquad (14\text{-}103b)$$

Figure 14-36 illustrates the pressure drop of a typical moving valve tray as a function of gas velocity. At low velocities, all valves are closed. Gas rises through the crevices between the valves and the tray deck, with increasing pressure drop as the gas velocity rises. Once point *A,* the closed balance point (CBP), is reached, some valves begin to open. Upon further increase in gas velocity, more valves open until point *B,* the open balance point (OBP), is reached. Between points *A* and *B,* gas flow area increases with gas velocity, keeping pressure drop constant. Further increases in gas velocity increase pressure drop similar to that in a sieve tray.

The term $K$ in Eq. (14-101) depends on valve slot area, orifice geometry, deck thickness, and the type, shape, and weight of the valves. These are best obtained from the manufacturer's literature,

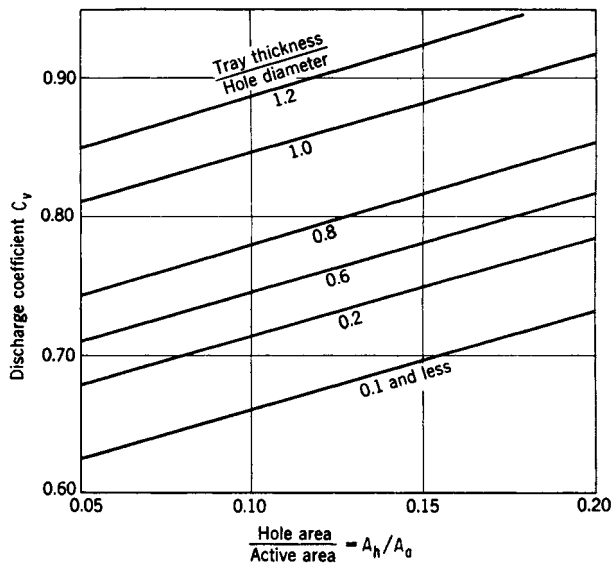

**FIG. 14-35** Discharge coefficients for gas flow, sieve trays. [*Liebson, Kelley, and Bullington,* Pet. Refiner, ***36***(3), *288 (1957).*]

but can also be calculated from Bolles' [*Chem. Eng. Prog.* **72**(9), 43 (1976)], Lockett's *(Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, England, 1986), and Klein's *(Chem. Eng.,* May 3, 1982, p. 81) methods.

For valve trays, Klein gives the following values for $K$ (in $s^2 \cdot mm/m^2$) in Eq. (14-101), when based on the total hole area (not slot area):

| | Sharp orifice | Venturi valve |
|---|---|---|
| All valves open ($K_O$) | $254.5(2.64/t_t)^{0.5}$ | 122 |
| All valves closed ($K_C$) | 1683 | 841 |

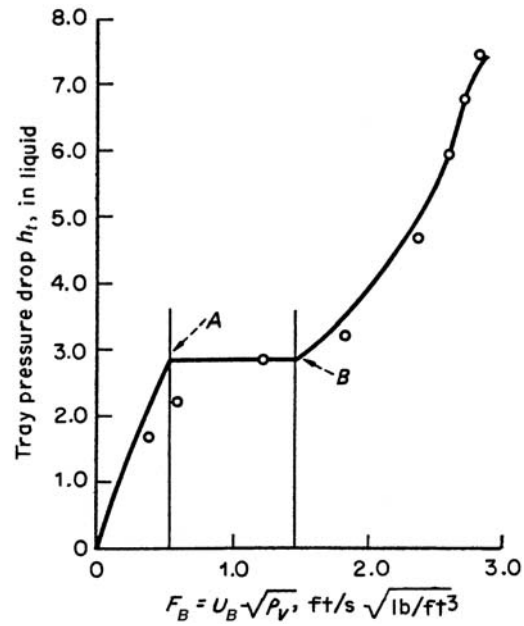

**FIG. 14-36** Typical moving valve tray pressure-drop profile. *(From G. F. Klein,* Chem. Eng., *May 3, 1982, p. 81; reprinted courtesy of* Chemical Engineering.*)*

The velocity at which the valves start to open (point *A*) is given by

$$U_{h,\text{closed}} = 1.14[t_v(R_{vw}/K_C)(\rho_M/\rho_G)]^{0.5} \quad (14\text{-}104)$$

where $U_{h,\text{closed}}$ = hole area at point *A*, m/s; $t_v$ = valve thickness, mm; $R_{vw}$ = ratio of valve weight with legs to valve weight without legs, given in Table 14-11; $K_C$ = orifice coefficient with all valves closed (see above), $s^2 \cdot mm/m^2$; $\rho_M$ = valve metal density, $kg/m^3$ (about 8000 $kg/m^3$ for steel); $\rho_G$ = gas density, $kg/m^3$.

The velocity at which all the valves are open $U_{h,\text{open}}$ can be calculated from

$$U_{h,\text{open}} = U_{h,\text{closed}}(K_C/K_O)^{0.5} \quad (14\text{-}105)$$

Pressure drop through the aerated liquid [$h'_L$, in Eq. (14-100)] is calculated by

$$h'_L = \beta h_{ds} \quad (14\text{-}106)$$

where $\beta$ = aeration factor, dimensionless
$h_{ds}$ = calculated height of clear liquid, mm (dynamic seal)

The aeration factor $\beta$ has been determined from Fig. 14-37 for valve and sieve trays. For sieve trays, values of $\beta$ in the figure may be calculated from

$$\beta = 0.0825 \ln \frac{Q}{L_w} - 0.269 \ln F_h + 1.679 \quad (14\text{-}107)$$

where $L_w$ = weir length, m
$F_h$ = *F*-factor for flow through holes, $F_h = U_h\rho_G^{0.5}$, m/s $(kg/m^3)^{0.5}$

For sieve and valve trays,

$$h_{ds} = h_w + h_{ow} + 0.5h_{hg} \quad (14\text{-}108)$$

where $h_w$ = weir height, mm
$h_{ow}$ = height of crest over weir, mm clear liquid
$h_{hg}$ = hydraulic gradient across tray, mm clear liquid

The value of weir crest $h_{ow}$ may be calculated from the Francis weir equation and its modifications for various weir types. For a segmental weir and for height in millimeters of clear liquid,

$$h_{ow} = 664\left(\frac{Q}{L_w}\right)^{2/3} \quad (14\text{-}109)$$

where $Q$ = liquid flow, $m^3/s$
$L_w$ = weir length, m

For serrated weirs,

$$h_{ow} = 851\left(\frac{Q'}{\tan\theta/2}\right)^{0.4} \quad (14\text{-}110)$$

where $Q'$ = liquid flow, $m^3/s$ per serration
$\theta$ = angle of serration, deg

For circular weirs,

$$h_{ow} = 44{,}300\left(\frac{Q}{d_w}\right)^{0.704} \quad (14\text{-}111)$$

where $q$ = liquid flow, $m^3/s$
$d_w$ = weir diameter, mm

For most sieve and valve trays, the hydraulic gradient is small and can be dropped from Eq. (14-108). Some calculation methods are available and are detailed in previous editions of this handbook. A rule of thumb by the author is 17 mm/m (0.2 in/ft) of flow path length. This rule only applies in the liquid-loaded froth and emulsion regimes ($Q_L$ >50 $m^3$/hm or >5.5 gpm/in of outlet weir length). At lower liquid loads, the hydraulic gradient is less.

As noted, the weir crest $h_{ow}$ is calculated on an equivalent clear-liquid basis. A more realistic approach is to recognize that in general a froth or spray flows over the outlet weir (settling can occur upstream of the weir if a large "calming zone" with no dispersers is used). Bennett et al. [*AIChE J.*, **29,** 434 (1983)] allowed for froth overflow in a comprehensive study of pressure drop across sieve trays; their correlation for residual pressure drop $h'_L$ in Eq. (14-100) is presented in detail in the previous (seventh) edition of this handbook, including a worked example. Although more difficult to use, the method of Bennett et al. was recommended when determination of pressure drop is of critical importance.

***Example 11: Pressure Drop, Sieve Tray*** For the conditions of Example 9, estimate the pressure drop for flow across one tray. The thickness of the tray metal is 2 mm. The superficial *F*-factor is 2.08 $m/s(kg/m^3)^{1/2}$.

*Solution* Equations (14-100), (14-106), and (14-107), where $h_t = h_d + \beta(h_w + h_{ow})$, are used. For $F_S = 2.08$, $F_B = 2.32$ and $F_H = 16.55$. From Example 9, $L_w$ = 1.50 m and $h_w$ = 38 mm. For a liquid rate of 22,000 kg/hr, $Q = 7.27(10^{-3})$ $m^3/s$, and $Q/L_w = 4.8(10^{-3})$. By Eq. (14-107) or Fig. 14-37, $\beta = 0.48$. From Eq. (14-102) or Fig. 14-35, $C_v = 0.75$. Then, by Eq. (14-101), $h_d$ = 29.0 mm liquid. Using Eq. (14-109), $h_{ow}$ = 18.9 mm. Finally, $h_t = h_d + \beta(h_w + h_{ow}) = 29.0 + 0.48(38 + 18.9) = 56.4$ mm liquid.

When straight or serrated segmental weirs are used in a column of circular cross section, a correction may be needed for the distorted pattern of flow at the ends of the weirs, depending on liquid flow rate. The correction factor $F_w$ from Fig. 14-38 is used directly in Eq. (14-109). Even when circular downcomers are utilized, they are often fed by the overflow from a segmental weir.

**Loss under Downcomer** The head loss under the downcomer apron, as millimeters of liquid, may be estimated from

$$h_{da} = 165.2\left(\frac{Q}{A_{da}}\right)^2 \quad (14\text{-}112)$$

where $Q$ = volumetric flow of liquid, $m^3/s$ and $A_{da}$ = most restrictive (minimum) area of flow under the downcomer apron, $m^2$. Equation (14-112) was derived from the orifice equation with an orifice coefficient of 0.6. Although the loss under the downcomer is small, the clearance is significant from the aspect of tray stability and liquid distribution.

The term $A_{da}$ should be taken as the most restrictive area for liquid flow in the downcomer outlet. Usually, this is the area under the downcomer apron (i.e., the downcomer clearance times the length of the segmental downcomer), but not always. For instance, if an inlet weir is used and the area between the segmental downcomer and the inlet weir is smaller than the area under the downcomer apron, the smaller area should be used.

**TABLE 14-11 $R_{VW}$ Values for Eq. (14-104)**

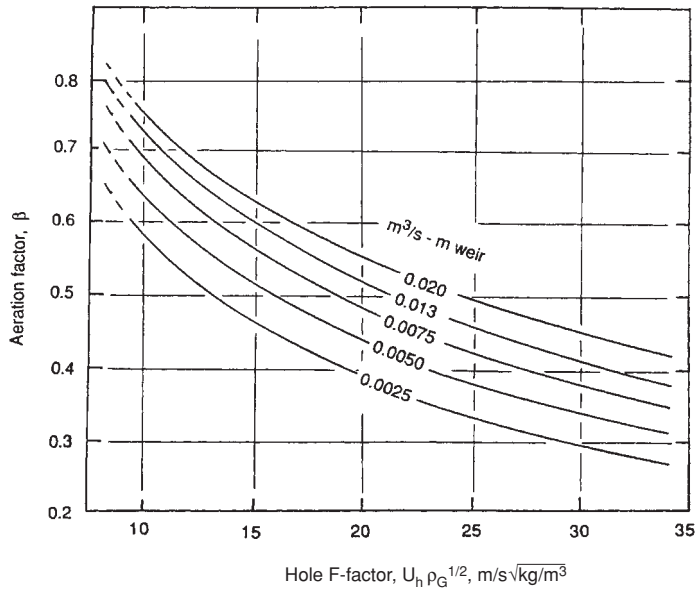
| Valve type | Sharp | Venturi |
|---|---|---|
| Three-leg | 1.23 | 1.29 |
| Four-leg | 1.34 | 1.45 |
| Cages (no legs) | 1.00 | 1.00 |

## OTHER HYDRAULIC LIMITS

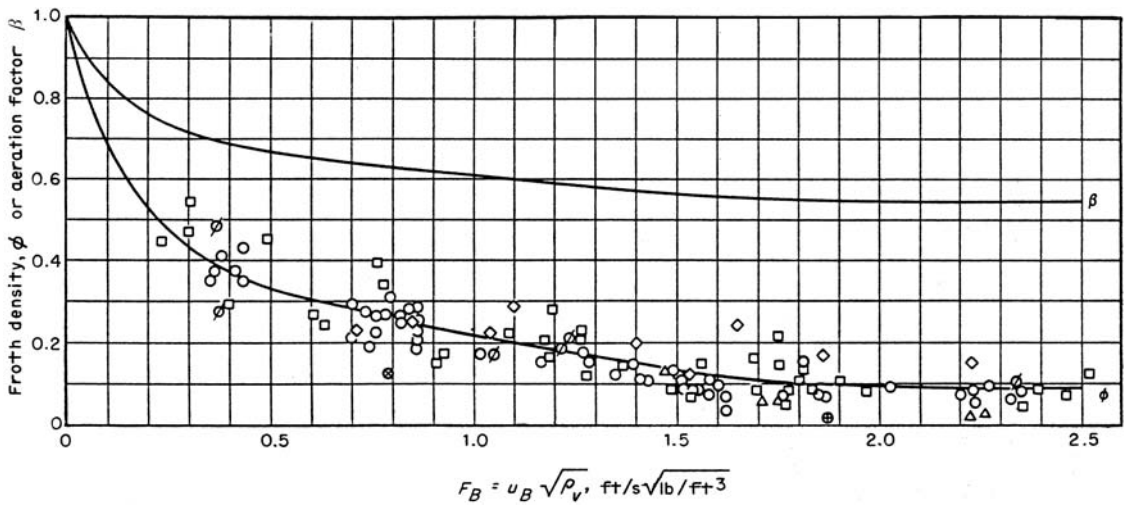
**Weeping** Weeping is liquid descending through the tray perforations, short-circuiting the contact zone, which lowers tray efficiency. At the tray floor, liquid static head that acts to push liquid down the perforations is counteracted by the gas pressure drop that acts to hold the liquid on the tray. When the static head overcomes the gas pressure drop, weeping occurs.

Some weeping usually takes place under all conditions due to sloshing and oscillation of the tray liquid. Generally, this weeping is too small to appreciably affect tray efficiency. The *weep point* is the gas velocity at which weeping first becomes noticeable. At this point, little efficiency is lost. As gas velocity is reduced below the weep point, the weep rate increases. When the weep rate becomes large enough to significantly reduce tray efficiency, the lower tray operating limit is reached.

The main factor that affects weeping is the fractional hole area. The larger it is, the smaller the gas pressure drop and the greater the weeping tendency. Larger liquid rates and taller outlet weirs increase



(a)



(b)

**FIG. 14-37** Aeration factor for pressure drop calculation. (*a*) Sieve trays. [*Bolles and Fair,* Encyclopedia of Chemical Processing and Design, *vols. 16, 86. J. M. McKetta (ed.), Marcel Dekker, New York, 1982.*] (*b*) Valve trays. (*From G. F. Klein,* Chem. Eng., *May 3, 1982, p. 81; reprinted courtesy of* Chemical Engineering.)

liquid heads and therefore weeping. Hole diameter has a complex effect on weeping, detailed by Lockett and Banik [*Ind. Eng. Chem. Proc. Des. Dev.* **25,** 561 (1986)].

Tests by Lockett and Banik (loc. cit.) show that weeping is often nonuniform, with some hydraulic conditions favoring weeping from the tray inlet and others from the tray outlet. Weeping from the tray inlet is particularly detrimental to tray efficiency because the weeping liquid bypasses two trays.

***Weep Rate Prediction*** Lockett and Banik (loc. cit.) and Hsieh and McNulty (*Chem. Eng. Progr.,* July 1993, p. 71) proposed correlations for predicting weep rates from sieve trays. Colwell and O'Bara (Paper presented at the AIChE Meeting, Houston, April 1989) recommended the Lockett and Banik correlation for low pressures (<1100 kPa or 165 psia), and the Hsieh and McNulty correlation for high pressures (>1100 kPa or 165 psia). They also corrected the Lockett and Banik correlation to improve its accuracy near the weep point.

The *Lockett and Banik correlation* (as corrected by Colwell and O'Bara) is

$$\frac{W}{A_h} = \frac{29.45}{\sqrt{\mathrm{Fr}_h}} - 44.18 \qquad \mathrm{Fr}_h < 0.2 \qquad (14\text{-}113a)$$

$$\frac{W}{A_h} = \frac{1.841}{\mathrm{Fr}_h^{1.533}} \qquad \mathrm{Fr}_h > 0.2 \qquad (14\text{-}113b)$$

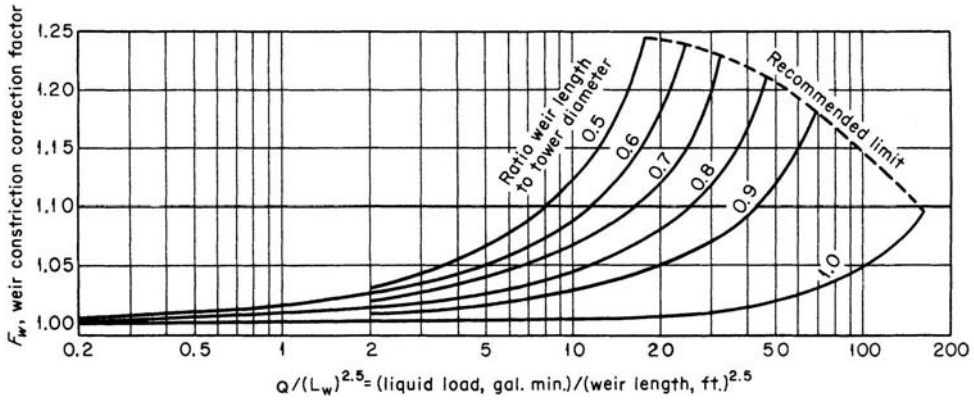


**FIG. 14-38** Correction for effective weir length. To convert gallons per minute to cubic meters per second, multiply by $6.309 \times 10^{-5}$; to convert feet to meters, multiply by 0.3048. [*Bolles,* Pet. Refiner, **25,** *613 (1946).*]

where
$$\mathrm{Fr}_h = 0.373 \frac{u_h^2}{h_c} \frac{\rho_V}{\rho_L - \rho_V} \tag{14-114}$$

Equations (14-113) and (14-114) use English units: $W$ is the weep rate, gpm; $A_h$ is the hole area, ft$^2$; $u_h$ is the hole velocity, ft/s; and $h_c$ is the clear liquid height, in. Colwell's [*Ind. Eng. Chem. Proc. Des. Dev.* **20**(2), 298 (1981)] method below has been recommended for obtaining the clear liquid height $h_c$ in Eq. (14-114).

$$h_c = \phi_f \left\{ 0.527 \left( \frac{Q_L(1 - f_w)}{C_d \phi_f} \right)^{2/3} + h_w \right\} \tag{14-115}$$

where $\phi_f$ is given by Eq. (14-119) and $C_d$ is given by Eq. (14-116)

$$\left.\begin{aligned} C_d &= 0.61 + 0.08 \frac{h_{fow}}{h_w} \qquad \frac{h_{fow}}{h_w} < 8.135 \\ C_d &= 1.06 \left( 1 + \frac{h_w}{h_{fow}} \right)^{1.5} \qquad \frac{h_{fow}}{h_w} > 8.135 \end{aligned}\right\} \tag{14-116}$$

$$h_{fow} = h_f - h_w \tag{14-117}$$

where $h_f$ is given by Eq. (14-122). The froth density $\phi_f$ is calculated from

$$\eta = 12.6 \mathrm{Fr}^{0.4} \left( \frac{A_B}{A_h} \right)^{0.25} \tag{14-118}$$

$$\phi_f = \frac{1}{\eta + 1} \tag{14-119}$$

$$\mathrm{Fr} = 0.37 \frac{\rho_V u_B^2}{h_c(\rho_L - \rho_V)} \tag{14-120}$$

The term $f_w$ in Eq. (14-115) is the ratio of weep rate from the tray to the total liquid flow entering the tray, calculated as follows:

$$f_w = W/\mathrm{GPM} \tag{14-121}$$

Some trial and error is required in this calculation because the clear liquid height $h_c$ and the froth density $\phi_f$ depend on each other, and the weep fraction $f_w$ depends on the clear liquid height $h_c$. Clear liquid height is related to froth height and froth density by

$$h_c = \phi_f h_f \tag{14-122}$$

The terms in Eqs. (14-115) to (14-122) are in the English units and are explained in the Nomenclature.

With large-diameter trays and low liquid loads, a small ratio of $W/A_h$ corresponds to a large fractional weep. Under these conditions, the Lockett and Banik correlation is inaccurate. The correlation is unsuitable for trays with very small (<3-mm or $\frac{1}{8}$-in) holes. The correlation appears to fit most data points to an accuracy of ±15 to ±30 percent. The *Hsieh and McNulty correlation* (loc. cit.) is

$$\sqrt{J_G^s} + m\sqrt{J_L^s} = C_w \tag{14-123}$$

where
$$J_G^s = u_h \left[ \frac{\rho_G}{gZ(\rho_L - \rho_G)} \right]^{0.5} \tag{14-124}$$

and
$$J_L^s = \frac{W}{448.83 A_h} \left[ \frac{\rho_L}{gZ(\rho_L - \rho_G)} \right]^{0.5} \tag{14-125}$$

$$Z = h_c^{1.5}/(12 d_H^{0.5}) \tag{14-126}$$

The terms in Eqs. (14-123) to (14-126) are in English units and are explained in the Nomenclature. For sieve trays, $m = 1.94$ and $C_w = 0.79$. Note that the constants are a slight revision of those presented in the original paper (C. L. Hsieh, private communication, 1991). Clear liquid height is calculated from Colwell's correlation [Eqs. (14-115) to (14-122)]. The Hsieh and McNulty correlation applies to trays with 9 percent and larger fractional hole area. For trays with smaller hole area, Hsieh and McNulty expect the weeping rate to be smaller than predicted.

***Weeping from Valve Trays*** An analysis of weeping from valve trays [Bolles, *Chem. Eng. Progs.* **72**(9), 43 (1976)] showed that in a well-designed valve tray, the weep point is below the gas load at which the valves open; and throughout the valve opening process, the operating point remains above the weep point. In contrast, if the tray contains too many valves, or the valves are too light, excessive valve opening occurs before the gas pressure drop is high enough to counter weeping. In this case, weeping could be troublesome.

Weep point correlations for valve trays were presented by Bolles (loc. cit.) and by Klein (*Chem. Eng.*, Sept. 17, 1984, p. 128). Hsieh and McNulty (loc. cit.) gave a complex extension of their weep rate correlation to valve trays.

**Dumping** As gas velocity is lowered below the weep point, the fraction of liquid weeping increases until all the liquid fed to the tray weeps through the holes and none reaches the downcomer. This is the *dump point*, or the *seal point*. The dump point is well below the range of acceptable operation of distillation trays. Below the dump point, tray efficiency is slashed, and mass transfer is extremely poor. Operation below the dump point can be accompanied by severe hydraulic instability due to unsealing of downcomers.

Extensive studies on dumping were reported by Prince and Chan [*Trans. Inst. Chem. Engr.* **43,** T49 (1965)]. The Chan and Prince

dump-point correlation was recommended and is presented in detail elsewhere (Kister, *Distillation Design,* McGraw-Hill, 1992). Alternatively, the dump point can be predicted by setting the weep rate equal to 100 percent of the liquid entering the tray in the appropriate weep correlation.

**Turndown** The turndown ratio is the ratio of the normal operating (or design) gas throughput to the minimum allowable gas throughout. The minimum allowable throughput is usually set by excessive weeping, while normal operating throughput is a safe margin away from the relevant flooding limit.

*Sieve and fixed valve trays* have a poor turndown ratio (about 2:1). Their turndown can be improved by blanking some rows of tray holes, which reduces the tendency to weep, but will also reduce the tray's maximum capacity. Turndown of *moving valve trays* is normally between about 4:1 to 5:1. Special valve designs can achieve even better turndown ratios, between 6:1 and 10:1, and even more. Turndown can also be enhanced by blanking strips (which require valve removal) or valve leg crimping. Sloley and Fleming *(Chem. Eng. Progr.,* March 1994, p. 39) stress that correct implementation of turndown enhancement is central to achieving a desired turndown. When poorly implemented, turndown may be restricted by poor vapor-liquid contact rather than by weeping.

**Vapor Channeling** All the correlations in this section assume an evenly distributed tray vapor. When the vapor preferentially channels through a tray region, premature entrainment flood and excessive entrainment take place due to a high vapor velocity in that region. At the same time, other regions become vapor-deficient and tend to weep, which lowers tray efficiency.

Work by Davies [*Pet. Ref.* **29**(8), p. 93, and **29**(9), p. 121 (1950)] based on bubble-cap tray studies suggests that the vapor pressure drop of the tray (the *dry pressure drop*) counteracts channeling. The higher the dry tray pressure drop, the greater the tendency for vapor to spread uniformly over the bubbling area. If the dry tray pressure drop is too small compared with the channeling potential, channeling prevails.

Perhaps the most common vapor channeling mechanism is *vapor crossflow channeling (VCFC,* Fig. 14-39). The hydraulic gradient on the tray induces preferential vapor rise at the outlet and middle of the tray, and a vapor-deficient region near the tray inlet. The resulting high vapor velocities near the tray outlet step up entrainment, while the low vapor velocities near the tray inlet induce weeping. Interaction between adjacent trays (Fig. 14-39) accelerates both the outlet entrainment and the inlet weeping. The net result is excessive entrainment and premature flooding at the tray middle and outlet, simultaneous with weeping from the tray inlet, accompanied by a loss of efficiency and turndown.

VCFC takes place when the following four conditions exist simultaneously [Kister, Larson, and Madsen, *Chem. Eng. Progr.,* p. 86 (Nov. 1992); Kister, *The Chemical Engineer*, **544,** p. 18 (June 10, 1993)]:

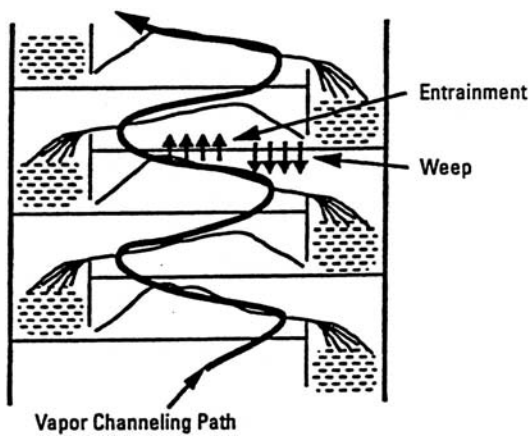

**FIG. 14-39** Vapor crossflow channeling. Note entrainment near the tray middle and outlet, and weep near the tray inlet. *(Kister, H. Z., K. F. Larson, and P. Madsen,* Chem. Eng. Prog., *Nov. 1992, p. 86; reproduced with permission.)*

1. Absolute pressure < 500 kPa (70 psia).
2. High liquid rates [>50 $m^3/(m \cdot h)$ or 6 gpm/in of outlet weir].
3. High ratio (>2:1) of flow path length to tray spacing.
4. Low dry tray pressure drop. On sieve and fixed valve trays, this means high (>11 percent) fractional hole area. On moving valve trays, this means venturi valves (smooth orifices) or long-legged valves (>15 percent slot area). On all trays, the channeling tendency and severity escalate rapidly as the dry pressure drop diminishes (e.g., as fractional hole area increases).

Hartman (*Distillation 2001: Topical Conference Proceedings,* AIChE Spring National Meeting, p. 108, Houston, Tex. (April 22–26, 2001)] reports VCFC even with conventional valve trays (14 percent slot area) at very high ratio (3.6:1) of flow path length to tray spacing and tray truss obstruction.

VCFC is usually avoided by limiting fractional hole areas, avoiding venturi valves, and using forward-push devices. Resitarits and Pappademos [Paper presented at the AIChE Annual Meeting, Reno, Nev. (November 2001)] cited tray inlet inactivity as a contributor to VCFC, and advocate inlet forward-push devices to counter it.

## TRANSITION BETWEEN FLOW REGIMES

**Froth-Spray** Froth-spray transition has been investigated for sieve trays using a variety of techniques. The gradual nature of this transition bred a multitude of criteria for defining it, and made its correlation difficult. Excellent overviews were given by Lockett (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, England, 1986) and Prado, Johnson, and Fair [*Chem. Eng. Progr.* **83**(3), p. 32 (1987)]. Porter and Jenkins [*I. Chem. E. Symp. Ser.* **56,** Summary Paper (1979)] presented a simple correlation for the froth-to-spray transition.

$$F_{LG} \frac{N_p A_B}{L_w} = 0.0191 \tag{14-127}$$

The terms of this equation are in English units and are explained in the Nomenclature. This correlation is based on the premise that froth-to-spray transition occurs when the entrainment vs. liquid load relationship passes through a minimum (see "Entrainment"). Alternatively, it was argued that the minimum represents a transition from the froth regime to a partially developed spray region (Kister, Pinczewski, and Fell, Paper presented in the 90th National AIChE Meeting, Houston, April 1981). If this alternative argument is valid, then when the correlation predicts froth, it is highly unlikely that the column operates in the spray regime; but when it predicts spray, the column may still be operating in the froth regime. Recent entrainment studies by Ohe [*Distillation 2005: Topical Conference Proceedings,* AIChE Spring National Meeting, p. 283, Atlanta (April 10–13, 2005)] argue that the entrainment minima represent minimum liquid residence times on the tray, and are unrelated to the froth-spray transition.

A second correlation is by Pinczeweski and Fell [*Ind. Eng. Chem. Proc. Des. Dev.* **21,** p. 774 (1982)]

$$u_B \sqrt{\rho_G} = 2.25 \left( \frac{Q_L \sqrt{\rho_L}}{100} \right)^n \tag{14-128}$$

The terms of Eq. (14-128) are in English units and are explained in the Nomenclature. The exponent $n$ is calculated from Eq. (14-84). Equation (14-128) is based on transition data obtained from orifice jetting measurements for the air-water system and on entrainment minimum data for some hydrocarbon systems.

A third recent correlation by Johnson and Fair (loc. cit.) is

$$U_a^* = C_1 \rho_G^{-0.50} \rho_L^{0.692} \sigma^{0.06} A_f^{0.25} \left( \frac{q}{L_w} \right)^{0.05} d_h^{0.1} \tag{14-129}$$

where $U_a^*$ = gas velocity through active area at inversion, m/s
$\rho_G$ = gas density, $kg/m^3$
$\rho_L$ = liquid density, $kg/m^3$
$\sigma$ = surface tension, mN/m
$A_f$ = hole/active area ratio

$q/L_w$ = liquid flow, $m^3/(s \cdot m)$ weir
$d_h$ = hole diameter, mm
$C_1$ = 0.0583 for 25.4-mm overflow weirs
= 0.0568 for 50.4-mm overflow weirs
= 0.0635 for 101.6-mm overflow weirs

**Froth-Emulsion** Froth-emulsion transition occurs [Hofhuis and Zuiderweg, *I. Chem. E. Symp. Ser.* **56,** p. 2, 2/1 (1979)] when the aerated mass begins to obey the Francis weir formula. Using this criterion, the latest version of this transition correlation is

$$F_{LG} \frac{N_p A_B}{L_w h_c} = 0.0208 \tag{14-130}$$

The terms of this equation are in English units and are explained in the Nomenclature; $h_c$ is calculated from the Hofhuis and Zuiderweg (loc. cit.) equation.

$$h_c = 2.08 \left( F_{LG} \frac{N_p A_B}{L_w} p \right)^{0.25} h_w^{0.5} \tag{14-131}$$

An inspection of the experimental data correlated shows that this, too, is a gradual transition, which occurs over a range of values rather than at a sharp point.

**Valve Trays** The amount of work reported thus far on valve tray regime transition is small and entirely based on air-water tests. Correlations proposed to date require the knowledge of liquid holdup at transition, which is generally not available, and are therefore of limited application for commercial columns.

## TRAY EFFICIENCY

### Definitions

***Overall Column Efficiency*** This is the ratio of the number of theoretical stages to the number of actual stages

$$E_{OC} = N_t / N_a \tag{14-132}$$

Since tray efficiencies vary from one section to another, it is best to apply Eq. (14-132) separately for the rectifying and stripping sections. In practice, efficiency data and prediction methods are often too crude to give a good breakdown between the efficiencies of different sections, and so Eq. (14-132) is applied over the entire column.

***Point Efficiency*** This is defined by Eq. (14-133) (Fig. 14-40*a*):

$$E_{OG} = \left( \frac{y_n - y_{n-1}}{y_n^* - y_{n-1}} \right)_{\text{point}} \tag{14-133}$$

where $y_n^*$ is the composition of vapor in equilibrium with the liquid at point $n$. The term $y_n$ is actual vapor composition at that point. The point efficiency is the ratio of the change of composition at a point to the change that would occur on a theoretical stage. As the vapor composition at a given point cannot exceed the equilibrium composition, fractional point efficiencies are always lower than 1. If there is a composition gradient on the tray, point efficiency will vary between points on the tray.

***Murphree Tray Efficiency*** [*Ind. Eng. Chem.* **17,** 747 (1925)] This is the same as point efficiency, except that it applies to the entire tray instead of to a single point (Fig. 14-40*b*):

$$E_{MV} = \left( \frac{y_n - y_{n-1}}{y_n^* - y_{n-1}} \right)_{\text{tray}} \tag{14-134}$$

If both liquid and vapor are perfectly mixed, liquid and vapor compositions on the tray are uniform, and the Murphree tray efficiency will coincide with the point efficiency at any point on the tray. In practice, a concentration gradient exists in the liquid, and $x_n$ at the tray outlet is lower than $x_n'$ on the tray (see Fig. 14-40*b*). This frequently lowers $y_n^*$ relative to $y_n$, thus enhancing tray efficiency [Eq. (14-134)] compared with point efficiency. The value of $y_n^*$ may even drop below $y_n$. In this case, $E_{MV}$ exceeds 100 percent [Eq. (14-134)].

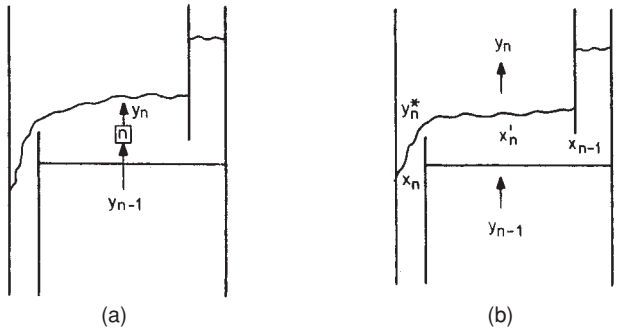

**FIG. 14-40** Point and Murphree efficiencies. (*a*) Point. (*b*) Murphree. *(From H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.)*

Overall column efficiency can be calculated from the Murphree tray efficiency by using the relationship developed by Lewis [*Ind. Eng. Chem.* **28,** 399 (1936)].

$$E_{OC} = \frac{\ln[1 + E_{MV}(\lambda - 1)]}{\ln \lambda} \tag{14-135}$$

where

$$\lambda = m \frac{G_M}{L_M} \tag{14-136}$$

Equation (14-135) is based on the assumption of constant molar overflow and a constant value of $E_{MV}$ from tray to tray. It needs to be applied separately to each section of the column (rectifying and stripping) because $G_M/L_M$, and therefore $\lambda$, varies from section to section. Where molar overflow or Murphree efficiencies vary throughout a section of column, the section needs to be divided into subsections small enough to render the variations negligible.

The point and Murphree efficiency definitions above are expressed in terms of vapor concentrations. Analogous definitions can be made in terms of liquid concentrations. Further discussion is elsewhere (Lockett, *Distillation Tray Fundamentals,* Cambridge University, Press, Cambridge, England, 1986).

**Fundamentals** Figure 14-41 shows the sequence of steps for converting phase resistances to a tray efficiency. Gas and liquid film resistances are added to give the point efficiency. Had both vapor and liquid on the tray been perfectly mixed, the Murphree tray efficiency would have equaled the point efficiency. Since the phases are not perfectly mixed, a model of the vapor and liquid mixing patterns is needed for converting point efficiency to tray efficiency. Liquid mixture patterns are plug flow, backmixing, and stagnant zones, while vapor-mixing patterns are perfect mixing and plug flow.

Lewis (loc. cit.) was the first to derive quantitative relationships between the Murphree and the point efficiency. He derived three mixing cases, assuming plug flow of liquid in all. The Lewis cases give the maximum achievable tray efficiency. In practice, efficiency is lower due to liquid and vapor nonuniformities and liquid mixing.

Most tray efficiency models are based on Lewis case 1 with vapor perfectly mixed between trays. For case 1, Lewis derived the following relationship:

$$E_{MV,\text{dry}} = \frac{\exp(\lambda E_{OG}) - 1}{\lambda} \tag{14-137}$$

The "dry" Murphree efficiency calculated thus far takes into account the vapor and liquid resistances and the vapor-liquid contact patterns, but is uncorrected for the effects of entrainment and weeping. This correction converts the dry efficiency to a "wet" or actual Murphree tray efficiency. Colburn [Eq. (14-98), under "Entrainment"] incorporated the effect of entrainment on efficiency, assuming perfect mixing of liquid on the tray.

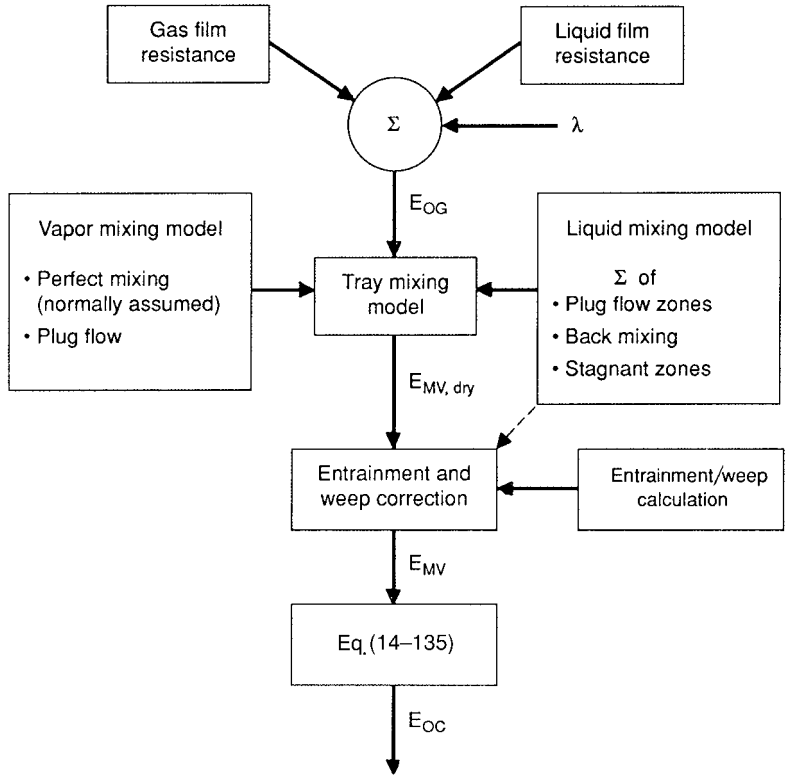

**FIG. 14-41** Sequence of steps for theoretical prediction of tray efficiency. (*From H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.*)

**Factors Affecting Tray Efficiency** Below is a summary based on the industry's experience. A detailed discussion of the fundamentals is found in Lockett's book (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, England, 1986). A detailed discussion of the reported experience, and the basis of statements made in this section are in Kister's book (*Distillation Design,* McGraw-Hill, New York, 1992).

***Errors in Vapor-Liquid Equilibrium (VLE)*** Errors in relative volatility are the most underrated factor affecting tray efficiency. Figure 14-42 shows the direct effect of the errors [Deibele and Brandt, *Chem. Ing. Tech.* **57**(5), p. 439 (1985); Roy P. and G. K. Hobson, *I. Chem. E. Symp. Ser.* **104,** p. A273 (1987)]. At very low relative volatilities ($\alpha < 1.2$), small errors in VLE have a huge impact on tray efficiency. For instance, at $\alpha = 1.1$, a –3 percent error gives a tray efficiency 40 to 50 percent higher than its true value (Fig. 14-42). Since VLE errors are seldom lower than ±2 to 3 percent, tray efficiencies of low-volatility systems become meaningless unless accompanied by VLE data. Likewise, comparing efficiencies derived for a low-volatility system by different sources is misleading unless one is using identical VLE.

Figure 14-42 shows that errors in relative volatility are a problem only at low relative volatilities; for $\alpha > 1.5$ to 2.0, VLE errors have negligible direct impact on tray efficiency.

Most efficiency data reported in the literature are obtained at total reflux, and there are no indirect VLE effects. For measurements at finite reflux ratios, the indirect effects below compound the direct effect of Fig. 14-42. Consider a case where $\alpha_{apparent} < \alpha_{true}$ and test data at a finite reflux are analyzed to calculate tray efficiency. Due to the volatility difference $R_{min,apparent} > R_{min,true}$. Since the test was conducted at a fixed reflux flow rate, $(R/R_{min})_{apparent} < (R/R_{min})_{true}$. A calculation based on the apparent $R/R_{min}$ will give more theoretical stages than a calculation based on the true $R/R_{min}$. This means a higher apparent efficiency than the true value.

The indirect effects add to those of Fig. 14-42, widening the gap between true and apparent efficiency. The indirect effects exponentially escalate as minimum reflux is approached. Small errors in VLE or reflux ratio measurement (this includes column material balance as well as reflux rate) alter $R/R_{min}$. Near minimum reflux, even small $R/R_{min}$ errors induce huge errors in the number of stages, and therefore in tray efficiency. Efficiency data obtained near minimum reflux are therefore meaningless and potentially misleading.

***Liquid Flow Patterns on Large Trays*** The most popular theoretical models (below) postulate that liquid crosses the tray in plug flow with superimposed backmixing, and that the vapor is perfectly mixed. Increasing tray diameter promotes liquid plug flow and suppresses backmixing.

The presence of stagnant zones on large-diameter distillation trays is well established, but the associated efficiency loss is poorly understood; in some cases, significant efficiency losses, presumably due to stagnant zones, were reported [Weiler, Kirkpatrick, and Lockett, *Chem. Eng. Progr.* **77**(1), 63 (1981)], while in other cases, no efficiency difference was observed [Yanagi and Scott, *Chem. Eng. Progr.*, **69**(10), 75 (1973)]. Several techniques are available for eliminating stagnant regions (see Kister, *Distillation Design,* McGraw-Hill, New York, 1992, for some), but their effectiveness for improving tray efficiency is uncertain.

***Weir Height*** Taller weirs raise the liquid level on the tray in the froth and emulsion regimes. This increases interfacial area and vapor contact time, which should theoretically enhance efficiency. In the spray regime, weir height affects neither liquid level nor efficiency. In distillation systems, the improvement of tray efficiency due to taller weirs is small, often marginal.

***Length of Liquid Flow Path*** Longer liquid flow paths enhance the liquid-vapor contact time, the significance of liquid plug flow, and therefore raise efficiency. Typically, doubling the flow path length

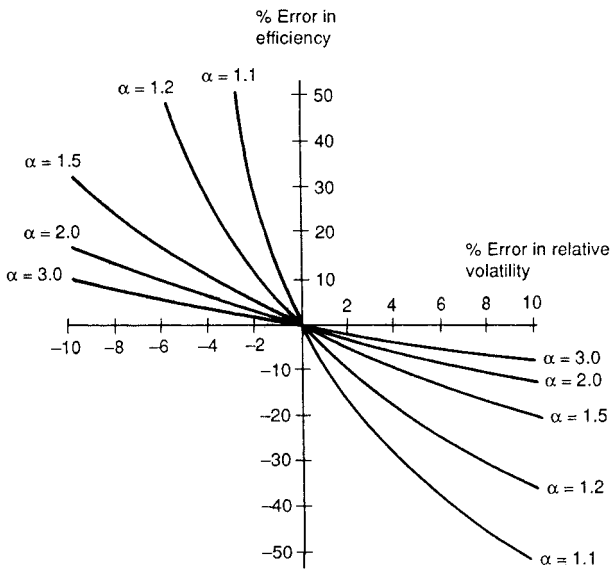

**FIG. 14-42** Direct effect of errors in relative volatility on error in tray efficiency. *(From H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.)*

(such as going from two-pass to one-pass trays at a constant tower diameter) raises tray efficiency by 5 to 15 percent.

***Fractional Hole Area*** Efficiency increases with a reduction in fractional hole area. Yanagi and Sakata [*Ind. Eng. Chem. Proc. Des. Dev.* **21,** 712 (1982)] tests in commercial-scale towers show a 5 to 15 percent increase in tray efficiency when fractional hole area was lowered from 14 to 8 percent (Fig. 14-43).

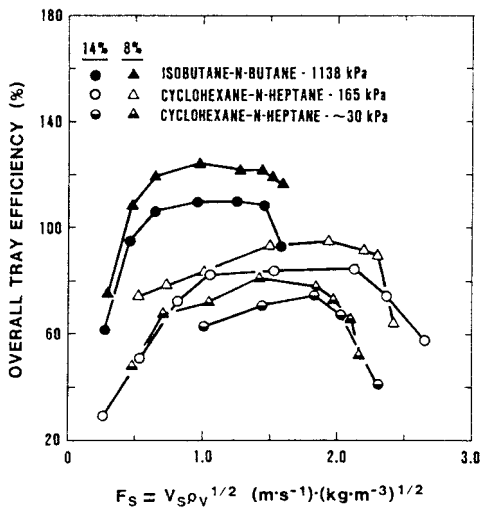

**FIG. 14-43** Efficiency reduction when fractional hole area is increased, also showing little effect of vapor and liquid loads on efficiency in the normal operating range (between excessive weeping and excessive entrainment). Also shown is the small increase in efficiency with pressure. FRI data, total reflux, $D_T = 1.2$ m, $S = 610$ mm, $h_w = 50.8$ mm, $d_H = 12.7$ mm. *(Reprinted with permission from T. Yanagi and M. Sakata,* Ind. Eng. Chem. Proc. Des. Dev. ***21,*** *712; copyright © 1982, American Chemical Society.)*

***Hole Diameter*** The jury is out on the effect of hole diameter on tray efficiency. There is, however, a consensus that the effect of hole diameter on efficiency is small, often negligible.

***Vapor-Liquid Loads and Reflux Ratio*** Vapor and liquid loads, as well as the reflux ratio, have a small effect on tray efficiency (Fig. 14-43) as long as no capacity or hydraulic limits (flood, weep, channeling, etc.) are violated.

***Viscosity, Relative Volatility*** Efficiency increases as liquid viscosity and relative volatility diminish. These effects are reflected in the O'Connell correlation (below).

***Surface Tension*** There is uncertainty regarding the effect of surface tension on tray efficiency. Often, it is difficult to divorce the surface tension effects from those of other physical properties.

***Pressure*** Tray efficiency slightly increases with pressure (Fig. 14-43), reflecting the rise of efficiency with a reduction in liquid viscosity and in relative volatility, which generally accompany a distillation pressure increase.

At pressures exceeding 10 to 20 bar (150 to 300 psia), and especially at high liquid rates, vapor entrainment into the downcomer liquid becomes important, and tray efficiency decreases with further increases in pressure [Zuiderweg, *Int. Chem. Eng.* **26**(1), 1 (1986)].

***Maldistribution*** Maldistribution can cause major efficiency reduction in multipass trays (>two passes). Further discussion is given under "Number of Passes."

## OBTAINING TRAY EFFICIENCY

Efficiency prediction methods are listed here in decreasing order of reliability.

**Rigorous Testing** Rigorous testing of a plant column is generally the most reliable method of obtaining tray efficiency. Test procedures can be found elsewhere (AIChE Equipment Testing Procedures Committee, *AIChE Equipment Testing Procedure—Tray Distillation Columns,* 2d ed., 1987; Kister, *Distillation Operation,* McGraw-Hill, New York, 1990).

**Scale-up from an Existing Commercial Column** As long as data are for the same system under similar process conditions, loadings, and operating regime, data obtained in one column directly extend to another. Fractional hole area and the number of tray passes will have a small but significant effect on efficiency, and any changes in these parameters need to be allowed for during scale-up. The empirical information in the section "Factors Affecting Tray Efficiency" can be used to estimate the magnitude of the changes on efficiency.

**Scale-up from Existing Commercial Column to Different Process Conditions** During scale-up, test data are analyzed by computer simulation. The number of theoretical stages is varied until the simulated product compositions and temperature profile match the test data. Tray efficiency is determined by the ratio of theoretical stages to actual trays. In this procedure, errors in VLE are offset by compensating errors in tray efficiency. For instance, if the relative volatility calculated by the simulation is too high, fewer stages will be needed to match the measured data, i.e., "apparent" tray efficiency will be lower. Scale-up will be good as long as the VLE and efficiency errors continue to offset each other equally. This requires that process conditions (feed composition, feed temperature, reflux ratio, etc.) remain unchanged during scale-up.

When process conditions change, the VLE and efficiency errors no longer offset each other equally. If the true relative volatility is higher than simulated, then the scale-up will be conservative. If the true relative volatility is lower than simulated, scale-up will be optimistic. A detailed discussion is found in Kister, *Distillation Design,* McGraw-Hill, New York, 1992.

**Experience Factors** These are tabulations of efficiencies previously measured for various systems. Tray efficiency is insensitive to tray geometry (above), so in the absence of hydraulic anomalies and issues with VLE data, efficiencies measured in one tower are extensible to others distilling the same system. A small allowance to variations in tray geometry as discussed above is in order. Caution is required with mixed aqueous-organic systems, where concentration may have a marked effect on physical properties, relative volatility, and efficiency. Table 14-12 shows typical tray efficiencies reported in the literature.

**TABLE 14-12 Representative Tray Efficiencies**

| Tray | System | Column diameter, ft | Tray spacing, in | Pressure, psia | Efficiency, % | % hole (slot) area | Ref. |
|---|---|---|---|---|---|---|---|
| Sieve | Methanol-water | 3.2 | 15.7 | 14.7 | 70–90 | 10.8 | 2 |
| | Ethanol-water | 2.5 | 14 | 14.7 | 75–85 | 10.4 | 1 |
| | Methanol-water | 3.2 | 15.7 | 14.7 | 90–100 | 4.8 | 2 |
| | Ethylbenzene-styrene | 2.6 | 19.7 | 1.9 | 70 | 12.3 | 5 |
| | Benzene-toluene | 1.5 | 15.7 | 14.7 | 60–75 | 8 | 10 |
| | Methanol-*n* propanol-sec butanol | 6.0 | 18 | 18 | 64* | | 6 |
| | Mixed xylene + $C_8$-$C_{10}$ paraffins and naphthenes | 13.0 | 21 | 25 | 86* | | 4 |
| | Cyclohexane-*n*-heptane | 4.0 | 24 | 5 | 60–70 | 14 | 9 |
| | | | | 24 | 80 | 14 | 9 |

Vital, Grossel and Olsen [*Hydroc. Proc.* **63,** 11, p. 147 (1984)] and Garcia and Fair [*Ind. Eng. Chem. Res.* **39,** p. 1809 (2000)] present an extensive tabulation of tray efficiency data collected from the published literature.

The *GPSA Engineering Data Book* (10th ed., Gas Processors Association, 1987) and Kaes (*Refinery Process Modeling—A Practical Guide to Steady State Modeling of Petroleum Processes Using Commercial Simulators*, Athens Printing Co., Athens, Ga., 2000) tabulate typical efficiencies in gas plant and refinery columns, respectively. Pilling (Paper presented at the 4th Topical Conference on Separations Science and Technology, November 1999, available from Sulzer Chemtech, Tulsa, Okla.) tabulated more typical efficiencies. Similar information is often available from simulation guide manuals. The quality and reliability of efficiencies from these sources vary and are generally lower than the reliability of actual measured data.

**Scale-up from a Pilot- or Bench-Scale Column** This is a very common scale-up. No reduction in efficiency on scale-up is expected as long as several precautions are observed. These precautions, generally relevant to pilot- or bench-scale columns, are spelled out with specific reference to the Oldershaw column.

***Scale-up from Oldershaw Columns*** One laboratory-scale device that found wide application in efficiency investigations is the Oldershaw column [Fig. 14-44, Oldershaw, *Ind. Eng. Chem. Anal. Ed.* **13,** 265 (1941)]. This column is available from a number of laboratory supply houses and can be constructed from glass for atmospheric operation or from metal for higher pressures. Typical column diameters are 25 to 100 mm (1 to 4 in), with tray spacing the same as the column diameter.

Fair, Null, and Bolles [*Ind. Eng. Chem. Process Des. Dev.* **22,** 53 (1983)] found that efficiency measurements in Oldershaw columns closely approach the point efficiencies [Eq. (14-133)] measured in

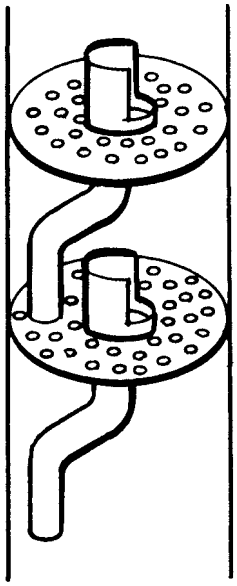

**FIG. 14-44** An Oldershaw column. *(From H. Z. Kister,* Distillation Design, *copyright © 1992 by McGraw-Hill; reprinted by permission.)*

commercial sieve-tray columns (Fig. 14-45) providing (1) the systems being distilled are the same, (2) comparison is made at the same relative approach to the flood point, (3) operation is at total reflux, and (4) a standard Oldershaw device is used in the laboratory experimentation. Fair et al. compared several systems, utilizing as large-scale information the published efficiency studies of Fractionation Research, Inc. (FRI).

A mixing model can be used to convert the Oldershaw point efficiencies to overall column efficiencies. This enhances the commercial column efficiency estimates. A conservative approach suggested by Fair et al. is to apply the Oldershaw column efficiency as the estimate for the overall column efficiency of the commercial column, taking no credit for the greater plug-flow character upon scale-up. The author prefers this conservative approach, considering the poor reliability of mixing models.

Previous work with Oldershaw columns [Ellis, Barker, and Contractor, *Trans. Instn. Chem. Engnrs.* **38,** 21 (1960)], spells an additional note of caution. Cellular (i.e., wall-supported) foam may form in pilot or Oldershaw columns, but is rare in commercial columns. For a given system, higher Oldershaw column efficiencies were measured under cellular foam conditions than under froth conditions. For this reason, Gerster [*Chem. Eng. Progr.* **59**(3), 35 (1963)] warned that when cellular foam can form, scale-up from an Oldershaw column may be dangerous. The conclusions presented by Fair et al. do not extend to Oldershaw columns operating in the cellular foam regime. Cellular foam can be identified by lower pilot column capacity compared to a standard mixture that is visualized not to form cellular foam.

Heat losses are a major issue in pilot and Oldershaw columns and can lead to optimistic scale-up. Special precautions are needed to keep these at a minimum. Vacuum jackets with viewing ports are commonly used.

Uses of Oldershaw columns to less conventional systems and applications were described by Fair, Reeves, and Seibert [Topical Conference on Distillation, AIChE Spring Meeting, New Orleans, p. 27 (March 10–14, 2002)]. The applications described include scale-up in the absence of good VLE, steam stripping efficiencies, individual component efficiencies in multicomponent distillation, determining component behavior in azeotropic separation, and foam testing.

**Empirical Efficiency Prediction** Two empirical correlations which have been the standard of the industry for distillation tray efficiency prediction are the Drickamer and Bradford, in Fig. 14-46 [*Trans. Am. Inst. Chem. Eng.* **39,** 319 (1943)] and a modification of it by O'Connell [*Trans. Am. Inst. Chem. Eng.* **42,** 741 (1946)], in Fig. 14-47. The Drickamer-Bradford plot correlates efficiency as a function of liquid viscosity only, which makes it useful for petroleum cuts. O'Connell added the relative volatility to the $x$ axis.

Lockett *(Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, England, 1986) noted some theoretical sense in O'Connell's correlation. Higher viscosity usually implies lower diffusivity, and therefore greater liquid-phase resistance and lower efficiency. Higher relative volatility increases the significance of the liquid-phase resistance, thus reducing efficiency. Lockett expresses the O'Connell plot in equation form:

$$E_{OC} = 0.492(\mu_L \alpha)^{-0.245} \qquad (14\text{-}138)$$

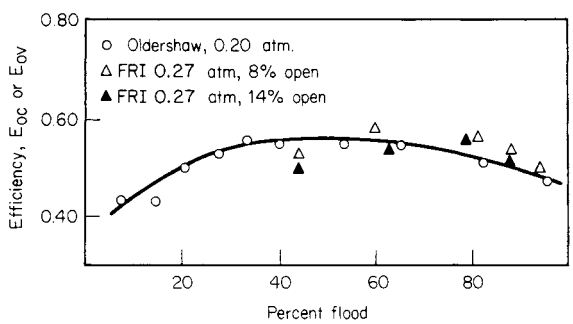

**FIG. 14-45** Overall column efficiency of 25-mm Oldershaw column compared with point efficiency of 1.22-m-diameter-sieve sieve-plate column of Fractionation Research, Inc. System = cyclohexane-*n*-heptane. [*Fair, Null, and Bolles,* Ind. Eng. Chem. Process Des. Dev., **22,** 53 (1982).]

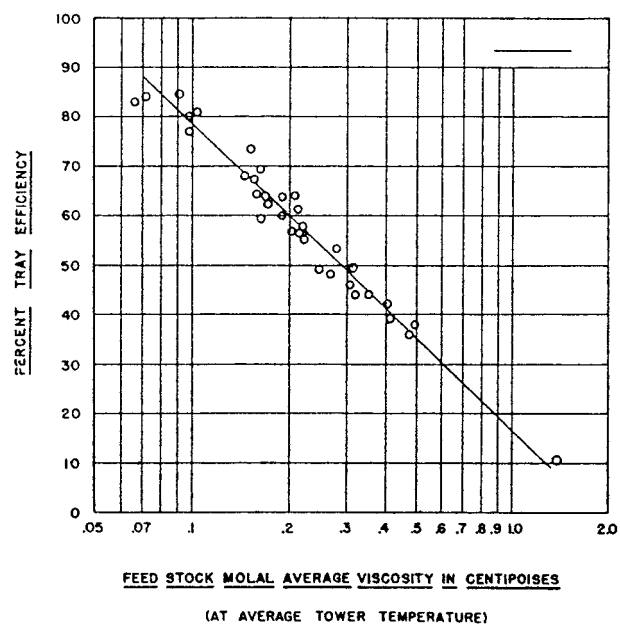

**FIG. 14-46** The Drickamer and Bradford tray efficiency correlation for refinery towers. To convert centipoise to pascal-seconds, multiply by 0.0001. [*From Drickamer and Bradford,* Trans. Am. Inst. Chem. Eng. **39,** 319 *(1943). Reprinted courtesy of the AIChE.*]

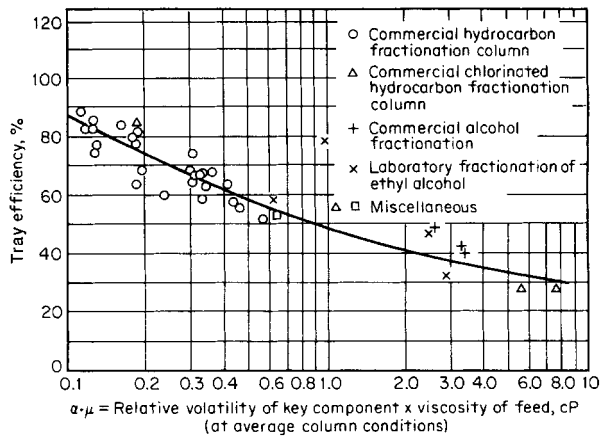

**FIG. 14-47** O'Connell correlation for overall column efficiency $E_{oc}$ for distillation. To convert centipoises to pascal-seconds, multiply by $10^{-3}$. [*O'Connell,* Trans. Am. Inst. Chem. Eng., ***42,*** 741 (*1946*).]

(The viscosity is in cP and $E_{OC}$ is fractional.) The volatility and viscosity are evaluated at the average arithmetic temperature between the column top and bottom temperatures. The relative volatility is between the key components.

The O'Connell correlation was based on data for bubble-cap trays. For sieve and valve trays, its predictions are likely to be slightly conservative.

**Theoretical Efficiency Prediction** Theoretical tray efficiency prediction is based on the two-film theory and the sequence of steps in Fig. 14-41. Almost all methods evolved from the AIChE model (AIChE Research Committee, *Bubble Tray Design Manual,* New York, 1958). This model was developed over 5 years in the late 1950s in three universities. Since then, several aspects of the AIChE model have been criticized, corrected, and modified. Reviews are given by Lockett (*Distillation Tray Fundamentals,* Cambridge University Press, Cambridge, England, 1986) and Chan and Fair [*Ind. Eng. Chem. Proc. Des. Dev.* **23,** 814 (1984)]. An improved version of the AIChE model, which alleviated several of its shortcomings and updated its hydraulic and mass-transfer relationships, was produced by Chan and Fair.

The Chan and Fair correlation generally gave good predictions when tested against a wide data bank, but its authors also observed some deviations. Its authors described it as "tentative until more data become available." The Chan and Fair correlation is considered the most reliable fundamental correlation for tray efficiency, but even this correlation has been unable to rectify several theoretical and practical limitations inherited from the AIChE correlation (see Kister, *Distillation Design,* McGraw-Hill, New York, 1992). Recently, Garcia and Fair (*Ind. Eng. Chem. Res.* **39,** 1818, 2000) proposed a more fundamental and accurate model that is also more complicated to apply.

The prime issue that appears to plague fundamental tray efficiency methods is their tendency to predict efficiencies of 80 to 100 percent for distillation columns larger than 1.2 m (4 ft) in diameter. In the real world, most columns run closer to 60 percent efficiency. Cai and Chen (Distillation 2003: Topical Conference Proceedings, AIChE Spring National Meeting, New Orleans, La., March 30–April 3, 2003) show that published eddy diffusivity models, which are based on small-column work, severely underestimate liquid backmixing and overestimate plug flow in commercial-scale columns, leading to optimistic efficiency predictions. Which other limitations (if any) in the theoretical methods contribute to the mismatch, and to what degree, is unknown. For this reason, the author would not recommend any currently published theoretical tray efficiency correlation for obtaining design efficiencies.

***Example 12: Estimating Tray Efficiency*** For the column in Example 9, estimate the tray efficiency, given that at the relative volatility near the feed point is 1.3 and the viscosity is 0.25 cP.

*Solution* Table 14-12 presents measurements by Billet (loc. cit.) for ethylbenzene-styrene under similar pressure with sieve and valve trays. The column diameter and tray spacing in Billet's tests were close to those in Example 9. Since both have single-pass trays, the flow path lengths are similar. The fractional hole area (14 percent in Example 9) is close to that in Table 14-12 (12.3 percent for the tested sieve trays, 14 to 15 percent for standard valve trays). So the values in Table 14-12 should be directly applicable, that is, 70 to 85 percent. So a conservative estimate would be 70 percent. The actual efficiency should be about 5 to 10 percent higher.

Alternatively, using Eq. (14-138) or Fig. 14-47, $E_{OC} = 0.492(0.25 \times 1.3)^{-0.245} = 0.65$ or 65 percent. As stated, the O'Connell correlation tends to be slightly conservative. This confirms that the 70 percent above will be a good estimate.

# EQUIPMENT FOR DISTILLATION AND GAS ABSORPTION: PACKED COLUMNS

Packings are generally divided into three classes:

1. *Random or dumped packings* (Figs. 14-48 and 14-49) are discrete pieces of packing, of a specific geometric shape, that are "dumped" or randomly packed into the column shell.

2. *Structured or systematically arranged packings* (Fig. 14-50) are crimped layers of corrugated sheets (usually) or wire mesh. Sections of these packings are stacked in the column.

3. *Grids.* These are also systematically arranged packings, but instead of wire mesh or corrugated sheets, these use an open-lattice structure.

Random and structured packings are common in commercial practice. The application of grids is limited primarily to heat-transfer and wash services and/or where a high fouling resistance is required. Grids are discussed in detail elsewhere (Kister, *Distillation Design,* McGraw-Hill, New York, 1992).

Figure 14-51 is an illustrative cutaway of a packed tower, depicting typical internals. This tower has a structured-packed top bed and a random-packed bottom bed. Each bed rests on a support grid or plate. The lower bed has a holddown grid at its top to restrict packing uplift. Liquid to each of the beds is supplied by a liquid distributor. An intermediate distributor, termed a *redistributor,* is used to introduce feed and/or to remix liquid at regular height intervals. The intermediate distributor in Fig. 14-51 is not self-collecting, so a chevron collector is used to collect the liquid from the bed above. An internal pipe passes this liquid to the distributor below. The collected liquid is mixed with the fresh feed (not shown) before entering the distributor. The reboiler return enters behind a baffle above the bottom sump.

As illustrated, the packing needs to be interrupted and a distributor added at each point where a feed enters or a product leaves. A simple distillation tower with a single feed will have a minimum of two beds, a rectifying bed and a stripping bed.

**Packing Objectives** The objective of any packing is to maximize efficiency for a given capacity, at an economic cost. To achieve these goals, packings are shaped to

1. *Maximize the specific surface area, i.e., the surface area per unit volume.* This maximizes vapor-liquid contact area, and, therefore, efficiency. A corollary is that efficiency generally increases as the random packing size is decreased or as the space between structured packing layers is decreased.

2. *Spread the surface area uniformly.* This improves vapor-liquid contact, and, therefore, efficiency. For instance, a Raschig ring (Fig. 14-48*a*) and a Pall® ring (Fig. 14-48*c*) of an identical size have identical surface areas per unit volume, but the Pall® ring has a superior spread of surface area and therefore gives much better efficiency.

3. *Maximize the void space per unit column volume.* This minimizes resistance to gas upflow, thereby enhancing packing capacity.

A corollary is that capacity increases with random packing size or with the space between structured packing layers. Comparing with the first objective, a tradeoff exists; the ideal size of packing is a compromise between maximizing efficiency and maximizing capacity.

4. *Minimize friction.* This favors an open shape that has good aerodynamic characteristics.

5. *Minimize cost.* Packing costs, as well as the requirements for packing supports and column foundations, generally rise with the weight per unit volume of packing. A corollary is that packings become cheaper as the size increases (random packing) and as the space between layers increases (structured packing).

**Random Packings** Historically, there were three generations of evolution in random packings. The first generation (1907 to the 1950s) produced two basic simple shapes—the Raschig ring and the Berl saddle (Fig. 14-48*a, b*) that became the ancestors of modern random packings. These packings have been superseded by more modern packing and are seldom used in modern distillation practice.

The second generation (late 1950s to the early 1970s) produced two popular geometries—the Pall® ring, which evolved from the Raschig ring, and the Intalox® saddle (Fig. 14-48*c–f*), which evolved from the Berl saddle.

BASF developed the Pall® ring by cutting windows in the Raschig ring and bending the window tongues inward. This opened up the ring, lowering the aerodynamic resistance and dramatically enhancing capacity. The bent tongues improved area distribution around the particle, giving also better efficiency. These improvements made the first generation Raschig rings obsolete for distillation.

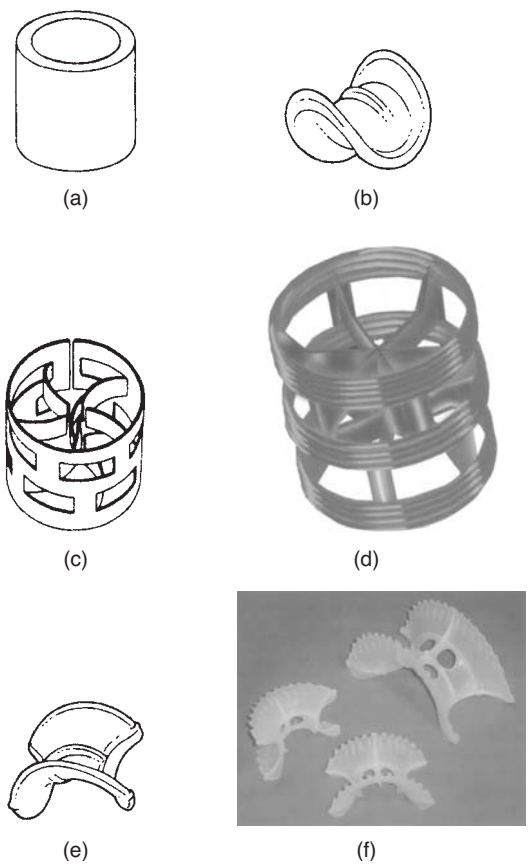

**FIG. 14-48** Common first- and second-generation random packings. (*a*) Raschig ring (metal, plastic, ceramic). (*b*) Berl saddle (ceramic). (*c*) Pall ring (metal). (*d*) Pall ring (plastic). (*e*) Intalox saddle (ceramic). (*f*) Super Intalox saddle (plastic). *(Parts d, f, courtesy of Koch-Glitsch LP.)*

Berl saddles (ceramics) are still used due to their good breakage resistance.

The second-generation packings are still popular and extensively used in modern distillation practice. The third generation (the mid-1970s until present) has produced a multitude of popular geometries, most of which evolved from the Pall® ring and Intalox® saddle. Some are shown in Fig. 14-49. A more comprehensive description of the various packings is given elsewhere (Kister, *Distillation Design,* McGraw-Hill, New York, 1992).

The third generation of packing was a significant, yet not large, improvement over the second generation, so second-generation packings are still commonly used.

**Structured Packings** Structured packings have been around since as early as the 1940s. First-generation structured packings, such as Panapak, never became popular, and are seldom used nowadays.

The second generation of structured packings began in the late 1950s with high-efficiency wire-mesh packings such as Goodloe®, Hyperfil®, and the Sulzer® (wire-mesh) packings. By the early 1970s, these packings had made substantial inroads into vacuum distillation, where their low pressure drop per theoretical stage is a major advantage. In these services, they are extensively used today. Their high cost, high sensitivity to solids, and low capacity hindered their application outside vacuum distillation.

The corrugated-sheet packing, first introduced by Sulzer in the late 1970s, started a third generation of structured packings. With a high capacity, lower cost, and lower sensitivity to solids, while still retaining a high efficiency, these corrugated-sheet packings became competitive with conventional internals, especially for revamps. The 1980s saw an accelerated rise in popularity of structured packings, to the point of their becoming one of the most popular column internals in use today.

Corrugated structured packings are fabricated from thin, corrugated (crimped) metal sheets, arranged parallel to one another. The corrugated sheets are assembled into an element (Figs. 14-50*a, c* and 14-51). The sheets in each element are arranged at a fixed angle to the vertical. Table 14-14 contains geometric data for several corrugated packings.

***Geometry*** (Fig. 14-52) The crimp size defines the opening between adjacent corrugated layers. Smaller *B, h,* and *S* yield narrower openings, more sheets (and, therefore, greater surface area) per unit volume, and more efficient packing, but higher resistance to gas upflow, lower capacity, and enhanced sensitivity to plugging and fouling.

The corrugations spread gas and liquid flow through a single element in a series of parallel planes. To spread the gas and liquid uniformly in all radial planes, adjacent elements are rotated so that sheets of one element are at a fixed angle to the layer below (Fig. 14-51). For good spread, element height *s* is relatively short (typically 200 to 300 mm, 8 to 12 in) and the angle of rotation is around 90°.

The surfaces of a few structured packings (especially those used in highly fouling environments) are smooth. Most structured packings have a roughened or enhanced surface that assists the lateral spread of liquid, promotes film turbulence, and enhances the area available for mass transfer. Texturing commonly employed is embossing and grooving (Fig. 14-50*a, b*).

The surfaces of most (but not all) structured packings contain holes that serve as communication channels between the upper and lower surfaces of each sheet. If the holes are too small, or nonexistent, both sides of a sheet will be wet only at low liquid rates. At high liquid rates, *sheeting* or *blanking* will cause liquid to run down the top surface with little liquid wetting the bottom surface [Chen and Chuang, *Hydroc. Proc.* **68**(2), 37 (1989)], which may lower efficiency. Usually, but not always, the holes are circular (Fig. 14-50*a, b*), about 4 mm in diameter. Olujic et al. (Distillation 2003: Topical Conference Proceedings, p. 523, AIChE, 2003, Spring National Meeting, New Orleans, La.) showed that the hole diameter has a complex effect, strongly dependent on packing size, on both capacity and efficiency.

***Inclination Angle*** In each element, corrugated sheets are most commonly inclined at about 45° to the vertical (typically indicated by the letter 'Y' following the packing size). This angle is large enough for good drainage of liquid, avoiding stagnant pockets and regions of liquid accumulation, and small enough to prevent gas from bypassing the metal surfaces. In some packings, the inclination angle to the vertical is steepened to 30° (typically indicated by the letter X following the

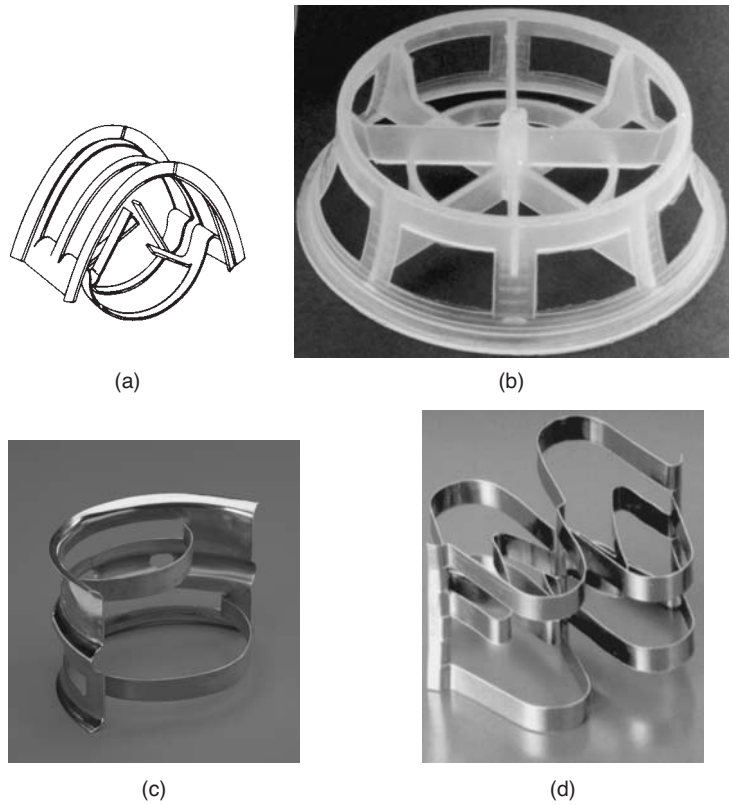

**FIG. 14-49** Common third-generation random packings. (*a*) Intalox metal tower packing (IMTP). (*b*) Cascade mini-ring (CMR) (plastic). (*c*) Nutter ring (metal). (*d*) Raschig Super-Ring (metal). *(Parts a, b, courtesy of Koch-Glitsch LP; part c, courtesy of Sulzer Chemtech; part d, courtesy of Rashig AG.)*

packing size). This improves drainage, and therefore capacity, but at the expense of reduced gas-liquid contact, and therefore efficiency.

A recent development followed the realization that liquid drainage was restricted at the element-to-element transition rather than inside elements (Lockett and Billingham, *IChemE Symp. Ser.* **152,** London, 2006). This means that the liquid accumulation leading to flood initiates at the transition region. A fourth generation of structured packing started, in which the main body of each element has layers inclined at 45°, but the ends of each element are almost vertical to permit drainage at this end region (Fig. 14-50*d*; but keep in mind that successive elements are rotated 90° rather than continuous, as shown in Fig. 14-50*d*). These S-shaped or high-capacity packings offer greater capacity compared to equivalent 45° inclined packings with efficiency the same with some (Pilling and Haas, Topical Conference Proceedings, p. 132, AIChE Spring Meeting, New Orleans, March 10–14, 2002; McNulty and Sommerfeldt in "Distillation: Horizons for the New Millennium," Topical Conference Proceedings, p. 89, AIChE Spring Meeting, Houston, Tex., March 1999) and lower with others [Olujic et al., *Chem. Eng. and Proc.,* **42,** p. 55 (2003)].

## PACKED-COLUMN FLOOD AND PRESSURE DROP

Pressure drop of a gas flowing upward through a packing countercurrently to liquid flow is characterized graphically in Fig. 14-53. At very low liquid rates, the effective open cross section of the packing is not appreciably different from that of dry packing, and pressure drop is due to flow through a series of variable openings in the bed. Thus, pressure drop is proportional approximately to the square of the gas velocity, as indicated in the region *AB*. At higher liquid rates, the effective open cross section is smaller because of the presence of liquid (region A′B′). The pressure drop is higher, but still proportional to the square of the gas velocity.

At higher gas rates, a portion of the energy of the gas stream is used to support an increasing quantity of liquid in the column. For all liquid rates, a zone is reached where pressure drop is proportional to a gas flow rate to a power distinctly higher than 2; this zone is called the *loading zone*. The increase in pressure drop is due to the liquid accumulation in the packing voids (region *BC* or *B′C′*)

As the liquid holdup increases, the effective orifice diameter may become so small that the liquid surface becomes continuous across the cross section of the column. Column instability occurs concomitantly with a rising continuous-phase liquid body in the column. Pressure drop shoots up with only a slight change in gas rate (condition *C* or *C′*). The phenomenon is called *flooding* and is analogous to entrainment flooding in a tray column.

Alternatively, a phase inversion occurs, and gas bubbles through the liquid. The column is not unstable and can be brought back to gas-phase continuous operation by merely reducing the gas rate. A stable operating condition beyond flooding (region *CD* or *C′D′*) may form with the liquid as the continuous phase and the gas as the dispersed phase [Lerner and Grove, *Ind. Eng. Chem.* **43,** 216 (1951); Teller, *Chem. Eng.* **61**(9), 168 (1954); Leung et al., *Ind. Eng. Chem. Fund.* **14** (1), 63 (1975); Buchanan, *Ind. Eng. Chem. Fund.* **15** (1), 87 (1976)].

For total-reflux distillation in packed columns, regions of loading and flooding are identified by their effects on mass-transfer efficiency, as shown in Fig. 14-54. Gas and liquid rate increase together, and a

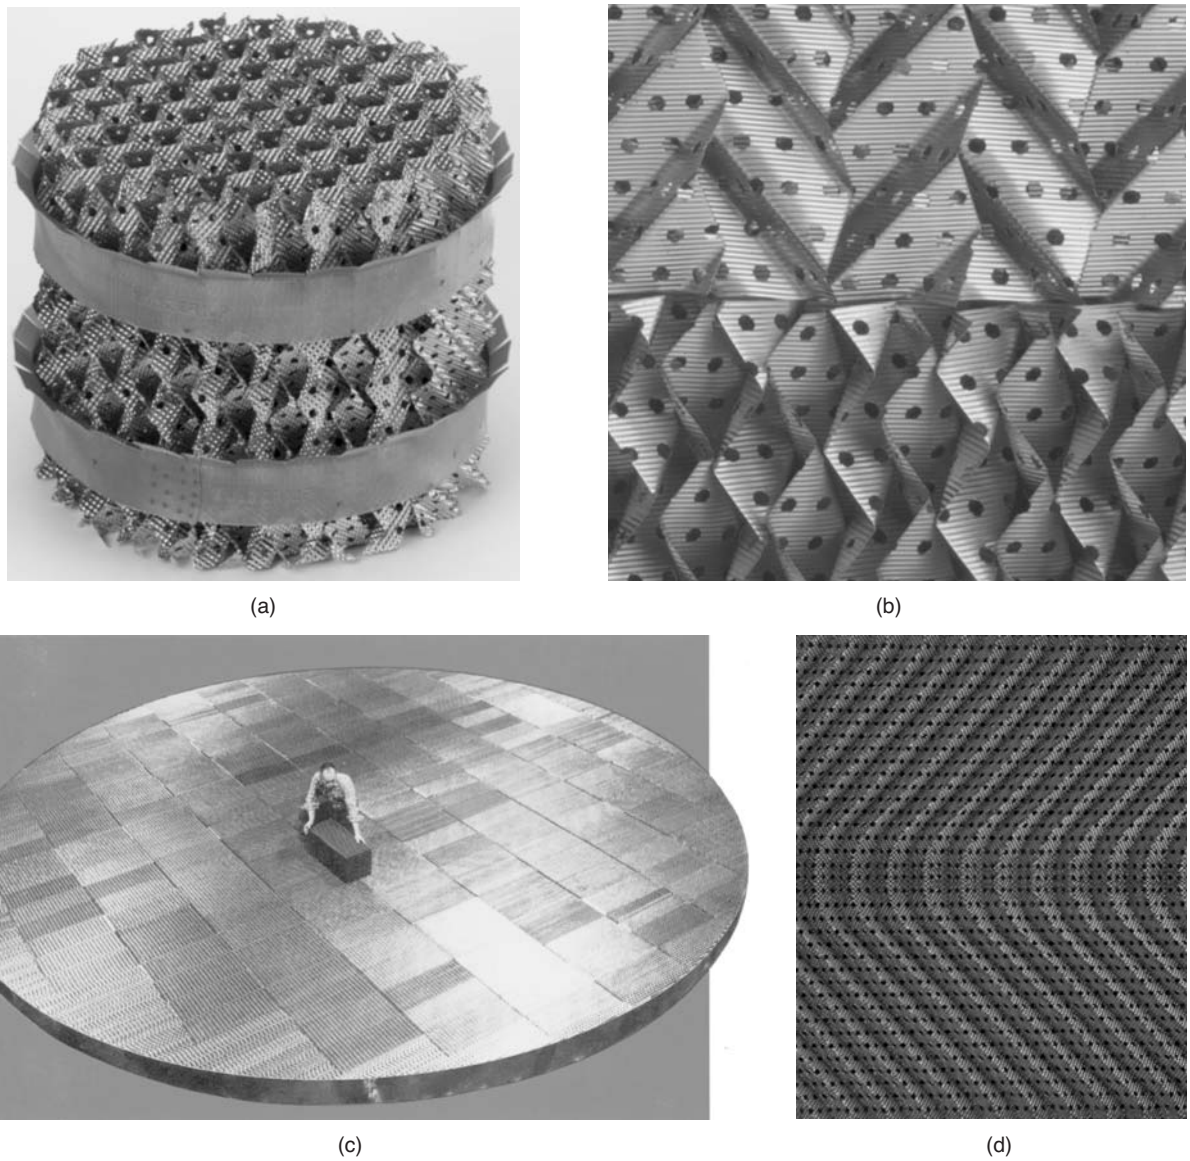

**FIG. 14-50** Common structured packings. (*a*) A small element of Mellapak™ showing embossed surface, holes, and corrugated-sheet arrangement. (*b*) A closeup of the surface of Flexipac™ showing grooved surface and holes. (*c*) Fitting structured packing elements to a large-diameter tower. (*d*) Mellapak Plus™, a fourth-generation structured packing, showing a 45° inclination angle in the element and near-vertical inclination at the element-to-element transition. Note that in the tower, the successive layers will be oriented 90° to each other as in part *b*. (*Parts a, d, courtesy of Sulzer Chemtech; parts b, c, courtesy of Koch-Glitsch LP.*)

point is reached at which liquid accumulates rapidly (point *B*) and effective surface for mass transfer decreases rapidly.

**Flood-Point Definition** In 1966, Silvey and Keller [*Chem. Eng. Progr.* **62**(1), 68 (1966)] listed 10 different flood point definitions that have been used by different literature sources. A later survey (Kister and Gill, *Proceedings of Chemeca 92,* p. 185-2, Canberra, Australia, 1992) listed twice that many. As Silvey and Keller pointed out, the existence of so many definitions puts into question what constitutes flooding in a packed tower, and at what gas rate it occurs. Symptoms used to identify flood in these definitions include appearance of liquid on top of the bed, excessive entrainment, a sharp rise in pressure drop, a sharp rise in liquid holdup, and a sharp drop in efficiency. The survey of Kister and Gill suggests that most flood point definitions describe the point of flooding initiation (*incipient flooding*; point *C* or *C′* on Figs. 14-53 and 14-54). The different incipient flooding definitions gave surprisingly little scatter of flood point data (for a given packing under similar operating conditions). It follows that any definition describing flooding initiation should be satisfactory.

The author believes that due to the variations in the predominant symptom with the system and the packing, the use of multiple symptoms is most appropriate. The author prefers the following definition

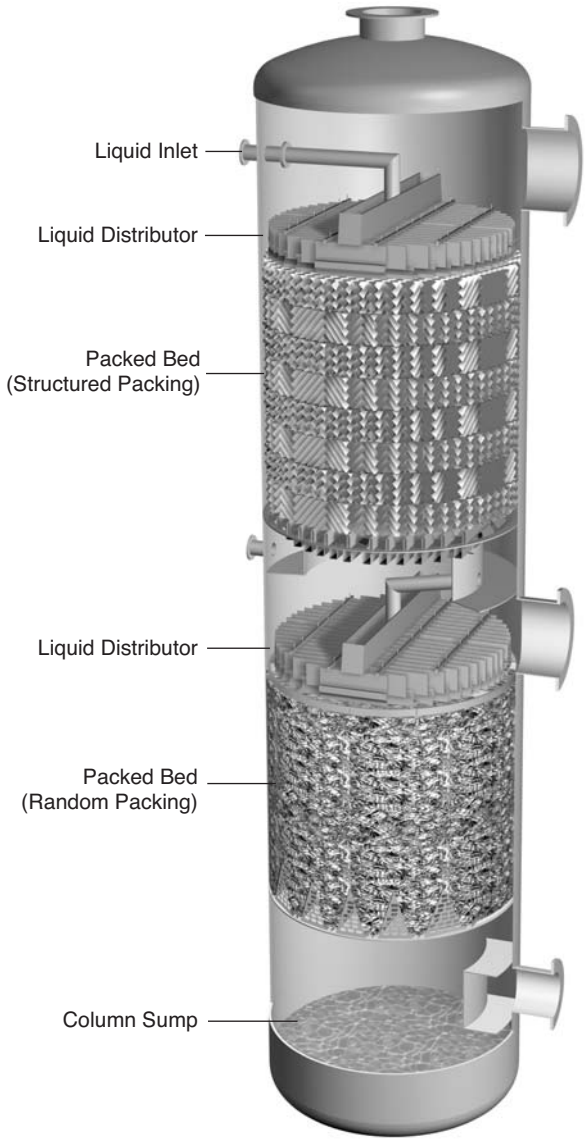

**FIG. 14-51** Illustrative cutaway of a packed tower, depicting an upper bed of structured packing and a lower bed of random packing. *(Courtesy of Sulzer Chemtech.)*

by Fair and Bravo [*Chem. Eng. Symp. Ser.* **104,** A183 (1987)]: "A region of rapidly increasing pressure drop with simultaneous loss of mass transfer efficiency. Heavy entrainment is also recognized as a symptom of this region." An almost identical definition was presented earlier by Billet (*Distillation Engineering,* Chem. Publishing Co., New York, 1979).

The maximum operational capacity or throughput (often also referred to as maximum efficient capacity) is defined (Strigle, *Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) as the "Maximum vapor rate that provides normal efficiency of a packing" (i.e., point B in Fig. 14-54). The MOC is clear-cut in Fig. 14-54. On the other hand, locating the MOC in other cases is difficult and leaves a lot of room for subjectivity.

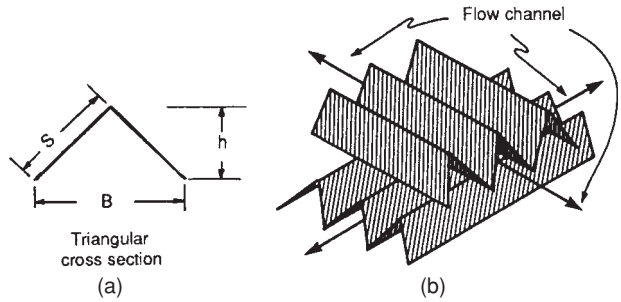

**FIG. 14-52** Crimp geometry in structured packings. (*a*) Flow channel cross section. (*b*) Flow channel arrangement. *(From J. R. Fair and J. L. Bravo,* Chem. Eng. Progr., *Jan. 1990, p. 19; reproduced courtesy of the American Institute of Chemical Engineers.)*

In most cases, [Kister and Gill, *Chem. Eng. Progr.* **87**(2), 32 (1991)], the velocity at which MOC is reached is related to the flood point velocity by

$$u_{S,\mathrm{MOC}} = 0.95\, u_{S,\mathrm{Fl}} \tag{14-139}$$

**Flood and Pressure Drop Prediction** The first generalized correlation of packed-column flood points was developed by Sherwood, Shipley, and Holloway [*Ind. Eng. Chem.,* **30,** 768 (1938)] on the basis of laboratory measurements primarily on the air-water system with random packing. Later work with air and liquids other than water led to modifications of the Sherwood correlation, first by Leva [*Chem. Eng. Progr. Symp. Ser.,* **50**(1), 51 (1954)], who also introduced the pressure drop curves, and later in a series of papers by Eckert. The generalized flooding–pressure drop chart by Eckert [*Chem. Eng. Progr.* **66**(3), 39 (1970)], included in previous editions of this handbook, was modified and simplified by Strigle (*Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) (Fig. 14-55). It is often called the generalized pressure drop correlation (GPDC). The ordinate is a capacity parameter [Eq. (14-140)] related to the Souders-Brown coefficient used for tray columns.

$$\mathrm{CP} = C_S F_p^{0.5} \nu^{0.05} = U_S \left( \frac{\rho_G}{\rho_L - \rho_G} \right)^{0.50} F_p^{0.5} \nu^{0.05} \tag{14-140}$$

where $U_S$ = superficial gas velocity, ft/s
$\rho_G$, $\rho_L$ = gas and liquid densities, lb/ft$^3$ or kg/m$^3$

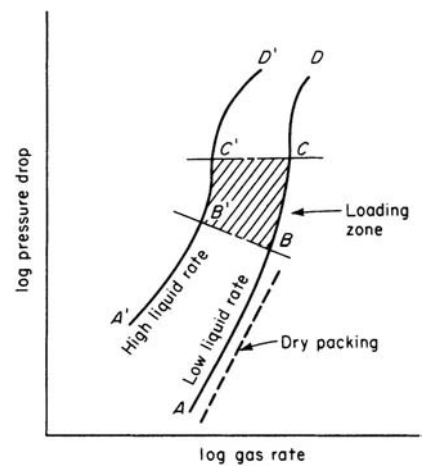

**FIG. 14-53** Pressure-drop characteristics of packed columns.

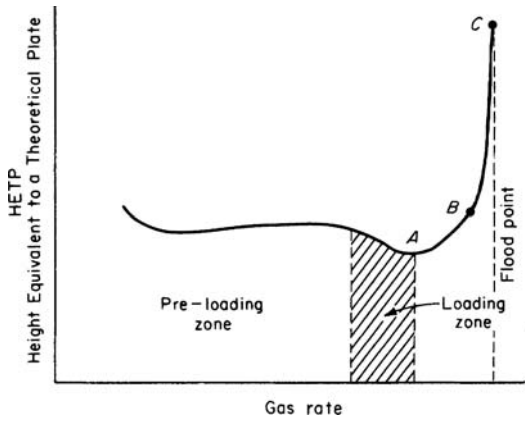

**FIG. 14-54** Efficiency characteristics of packed columns (total-reflux distillation.)

$F_p$ = packing factor, $ft^{-1}$
$\nu$ = kinematic viscosity of liquid, cS
$C_S$ = $C$-factor, Eq. (14-77), based on tower superficial cross-sectional area, ft/s
CP = capacity factor, dimensional [units consisted with Eq. (14-140) and its symbols]

The abscissa scale term is the same flow parameter used for tray (dimensionless):

$$F_{LG} = \frac{L}{G}\left(\frac{\rho_G}{\rho_L}\right)^{0.5} \tag{14-141}$$

For structured packing, Kister and Gill [*Chem. Eng. Symp. Ser.* **128,** A109 (1992)] noticed a much steeper rise of pressure drop with flow parameter than that predicted from Fig. 14-55, and presented a modified chart (Fig. 14-56).

The GPDC charts in Figs. 14-55 and 14-56 do not contain specific flood curves. Both Strigle and Kister and Gill recommend calculating the flood point from the flood pressure drop, given by the Kister and Gill equation

$$\Delta P_{\text{flood}} = 0.12F_p^{0.7} \tag{14-142}$$

Equation (14-142) permits finding the pressure drop curve in Fig. 14-55 or 14-56 at which incipient flooding occurs.

For low-capacity random packings, such as the small first-generation packings and those smaller than 1-in diameter ($F_p > 60\ ft^{-1}$), calculated flood pressure drops are well in excess of the upper pressure drop curve in Fig. 14-55. For these packings only, the original Eckert flood correlation [*Chem. Eng. Prog.* **66**(3), 39 (1970)] found in pre-1997 editions of this handbook and other major distillation texts is suitable.

The packing factor $F_p$ is empirically determined for each packing type and size. Values of $F_p$, together with general dimensional data for individual packings, are given for random packings in Table 14-13 (to go with Fig. 14-55) and for structured packings in Table 14-14 (to go with Fig. 14-56).

Packing flood and pressure drop correlations should always be used with caution. Kister and Gill [*Chem. Eng. Progr.,* **87**(2), 32 (1991)] showed that deviations from the GPDC predictions tend to be systematic and not random. To avoid regions in which the systematic deviations lead to poor prediction, they superimposed experimental data points for each individual packing on the curves of the GPDC. Figure 14-57 is an example. This method requires a single chart for each packing type and size. It provides the highest possible accuracy as it interpolates measured data and identifies uncertain regions. A set of charts is in Chapter 10 of Kister's book (*Distillation Design,* McGraw-Hill, New York, 1992) with

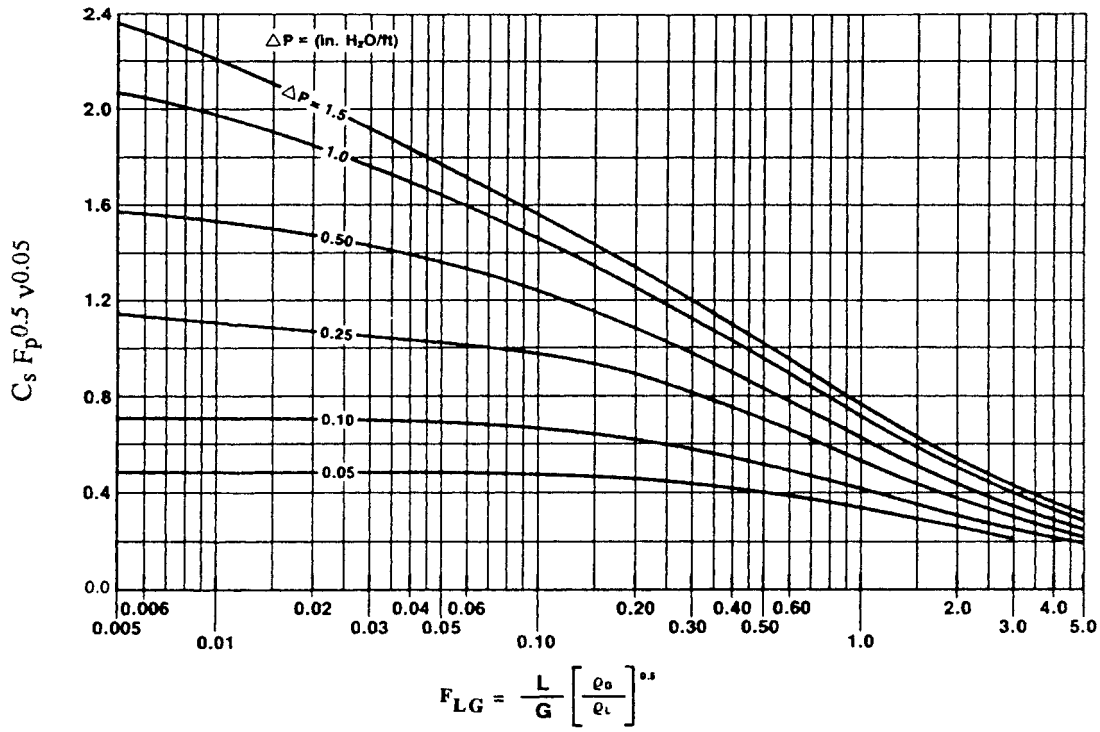

**FIG. 14-55** Generalized pressure drop correlation of Eckert as modified by Strigle. Used with permission. All rights reserved.)*

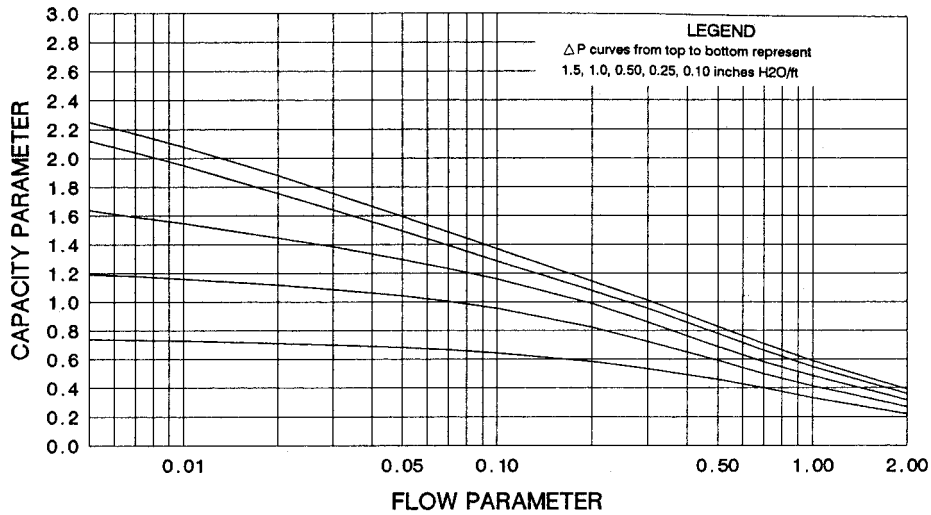

**FIG. 14-56** The Kister and Gill GPDC (SP) chart for structured packings only. Abscissa and ordinate same as in Fig. 14-55. *(From Kister, H. Z., and D. R. Gill,* IChemE Symp. Ser. ***128,** p. A109, 1992. Reprinted courtesy of IChemE.)*

updates in Kister, Lason, and Gill, Paper presented at the AIChE Spring National Meeting, Houston, Tex., March 19–23, 1995; and in Kister, Scherffius, Afshar, and Abkar, in Distillation 2007: *Topical Conference Proceedings,* 2007 AIChE Spring National Meeting, Houston, Texas. The latter reference also discusses correct and incorrect applications of those interpolation charts.

There are many alternative methods for flood and pressure drop prediction. The Billet and Schultes [*IChemE Symp. Ser.* **104,** pp. A171 and B255 (1987)] and the Maćkowiak ("Fluiddynamik von Kolonnen mit Modernen Füllkorpern und Packungen für Gas/Flussigkeitssysteme," Otto Salle Verlag, Frankfurt am Main und Verlag Sauerländer Aarau, Frankfurt am Main, 1991) correlations are versions of the GPDC that take the liquid holdup into account. The Eiden and Bechtel correlation [*IChemE Symp. Ser.* **142,** p. 757 (1997)] is a version of the GPDC in which accuracy is improved by using constants representative of packing shape instead of packing factors. The Lockett and Billingham correlation (*IChemE Symp. Ser.* **152,** p. 400, London, 2006) uses a Wallis correlation

$$C_G^{0.5} + mC_L^{0.5} = C_{LG} \tag{14-143}$$

where

$$C_L = u_L[\rho_L/(\rho_L - \rho_G)]^{0.5} \tag{14-144}$$

and was shown to work well for high-surface-area (>400 $m^2/m^3$) structured packings. Here $C_G$ is the gas *C*-factor, Eq. (14-77), based on the tower superficial cross-sectional area, and $m$ and $C_{LG}$ are constants, available from the cited reference for some packing.

A drawback of most of these correlations (except that of Eiden and Bechtel) is the unavailability of constants for many, often most, of the modern popular packings.

The above methods apply to nonfoaming systems. Foaming systems can be handled either by applying additional derating (system) factors to the flood correlation (see Table 14-9) or by limiting the calculated pressure drop to 0.25 in of water per foot of packing (Hausch, "Distillation Tools for the Practicing Engineer," Topical Conference Proceedings, p. 119, AIChE Spring Meeting, New Orleans, March 10–14, 2002).

**Pressure Drop** The GPDC discussed above (Figs. 14-55 and 14-56) and the Kister and Gill interpolation charts provide popular methods for calculating packing pressure drops. An alternative popular method that is particularly suitable for lower liquid loads was presented by Robbins (below).

For gas flow through dry packings, pressure drop may be estimated by use of an orifice equation. For irrigated packings, pressure drop increases because of the presence of liquid, which effectively decreases the available cross section for gas flow (Fig. 14-53). In principle, there should be a method for correcting the dry pressure drop for the presence of liquid. This approach was used by Leva [*Chem. Eng. Progr. Symp. Ser. No. 10,* **50,** 51 (1954)]. A more recent method by Robbins [*Chem. Eng. Progr.,* p. 87 (May 1991)] utilizes the same approach and is described here. The total pressure drop is

$$\Delta P_t = \Delta P_d + \Delta P_L \tag{14-145}$$

where $\Delta P_t$ = total pressure drop, inches $H_2O$ per foot of packing

$$\Delta P_d = \text{dry pressure drop} = C_3 G_f^2 10^{(C_4 L_f)} \tag{14-146}$$

$\Delta P_L$ = pressure drop due to liquid presence

$$= 0.4[L_f/20{,}000]^{0.1}[C_3 G_f^2 10^{(C_4 L_f)}]^4 \tag{14-147}$$

$$G_f = \text{gas loading factor} = 986 F_s (F_{pd}/20)^{0.5} \tag{14-148}$$

$$L_f = \text{liquid loading factor} = L(62.4/\rho_L)(F_{pd}/20)^{0.5}\mu_L^{0.1} \tag{14-149}$$

The term $F_{pd}$ is a dry packing factor, specific for a given packing type and size. Values of $F_{pd}$ are given in Tables 14-13 and 14-14. For operating pressures above atmospheric, and for certain packing sizes, $L_f$ and $G_f$ are calculated differently:

$$G_f = 986 F_s (F_{pd}/20)^{0.5} 10^{0.3\rho_G} \tag{14-150}$$

$$L_f = L(62.4/\rho_L)(F_{pd}/20)^{0.5}\mu_L^{0.2} \qquad F_{pd} > 200 \tag{14-151a}$$

$$L_f = L(62.4/\rho_L)(20/F_{pd})^{0.5}\mu_L^{0.1} \qquad F_{pd} < 15 \tag{14-151b}$$

The Robbins equations require careful attention to dimensions. However, use of the equations has been simplified through the introduction of Fig. 14-58. The terms $L_f$ and $G_f$ are evaluated, and the $\Delta P_L$ is obtained directly from the chart. Basic nomenclature for the Robbins method follows:

$C_3 = 7.4(10)^{-8}$
$C_4 = 2.7(10)^{-5}$
$F_{pd}$ = dry packing factor, $ft^{-1}$
$F_s$ = superficial *F*-factor for gas, $U_t\rho_g^{0.5}$, $ft/s(lb/ft^3)^{0.5}$
$G$ = gas mass velocity, $lb/hr{\cdot}ft^2$
$G_f$ = gas loading factor, $lb/hr{\cdot}ft^2$
$L$ = liquid mass velocity, $lb/hr{\cdot}ft^2$
$L_f$ = liquid loading factor, $lb/hr{\cdot}ft^2$
$\Delta P$ = pressure drop, inches $H_2O$/ft packing (× 83.3 = mm $H_2O$/m packing)

$\rho_G$ = gas density, lb/ft$^3$
$\rho_L$ = liquid density, lb/ft$^3$
$\mu_L$ = liquid viscosity, cP

The Robbins correlation applies near atmospheric pressure and under vacuum, but is not suitable above 3 bar absolute. For high (>0.3) flow parameters [Eq. (14-141)], the correlation has only been tested with air-water data.

For flood and MOC predictions, Robbins recommends his pressure drop method together with Eqs. (14-142) (flood) and (14-139) (MOC).

The GPDC and Robbins correlations are empirical. Fundamental correlations are also available. Most of these use the channel model, which attributes the pressure drop to the resistance to flow in a multitude of parallel channels. The channels may have bends, expansions, and contractions. Popular application of this approach are the Rocha et al. correlation [Rocha, Bravo, and Fair, *Ind. Eng. Chem. Res.* **32,** 641 (1993)] for structured packing and the Maćkowiak ("Fluiddynamik von Kolonnen mit Modernen Füllkorpern und Packungen für Gas/Flussigkeitssysteme," Otto Salle Verlag, Frankfurt am Main und Verlag Sauerländer Aarau, Frankfurt am Main, 1991) and Billet (*Packed Column*

‡Dry packing factors from Robbins, *Chem. Eng. Prog.*, p. 87, May 1991.

§These packing factors supplied by the packing vendor.

¶These are expanded metal packings.

‖First figure is for hydrocarbon service, second figure for aqueous service.

Vendors: Sulzer Chemtech Ltd., Winterthur, Switzerland; Koch-Glitsch LLP, Wichita, Kansas; Raschig GmbH, Ludwigshafen/Rhein, Germany; Julius Montz GmbH, Hilden, Germany; Knit Mesh/Enhanced Separation Technologies, Houston, Texas; Kuhni Ltd., Allschwil, Switzerland.

*Analysis and Design*, Ruhr University, Bochum, Germany, 1989) methods. Stichlmair et al. (*Distillation Principles and Practices*, Wiley, New York, 1998; *Gas Sep. Purif.* **3,** March 1989, p. 19) present alternative correlations using the particle model, that attributes packing pressure drop to friction losses due to drag of a particle. This is similar to the Ergun model for single-phase flow [*Chem. Eng. Prog.* **48**(2), 89 (1952)].

***Example 13: Packed-Column Pressure Drop*** Air and water are flowing countercurrently through a bed of 2-inch metal Pall rings. The air mass velocity is 2.03 kg/s·m$^2$ (1500 lbs/hr·ft$^2$), and the liquid mass velocity is 12.20 kg/s·m$^2$ (9000 lbs/hr·ft$^2$). Calculate the pressure drop by the generalized pressure drop (GPDC, Fig. 14-55) and the Robbins methods. Properties: $\rho_G = 0.074$ lbs/ft$^3$; $\rho_L = 62.4$ lbs/ft$^3$, $\mu_L = 1.0$ cP, $\nu = 1.0$ cS. The packing factor $F_p = 27$ ft$^{-1}$. For Robbins, $F_{pd} = 24$ ft$^{-1}$. The flow parameter $F_{LG} = L/G\ (\rho_G/\rho_L)^{0.5} = (9000/1500)\ (0.074/62.4)^{0.5} = 0.207$. The $F$-factor = $F_s = U_t\rho_G^{0.5} = G/(\rho_G^{0.5}3600) = 1500/[(0.074)^{0.5}\ (3600)] = 1.53$ ft/s(lb/ft$^3$)$^{0.5}$.

Using the GPDC method, the capacity parameter [by Eq. (14-140)] = $U_t[\rho_G/(\rho_L - \rho_G)]^{0.5} F_p^{0.5} \nu^{0.05}$, which is roughly equivalent to

$$\frac{F_s}{\rho_L^{0.5}} F_p^{0.5} \nu^{0.05} = \frac{1.53}{62.4^{0.5}} 27^{0.5}(1.0)$$

$$= 1.01$$

Referring to Fig. 14-55, the intersection of the capacity parameter and the flow parameter lines gives a pressure drop of 0.38 inches $H_2O$/ft packing.

Using the Robbins method, $G_f = 986 F_s(F_{pd}/20)^{0.5} = 986(1.53)(24/20)^{0.5} = 1653$. $L_f = L\ (62.4/\rho_L)(F_{pd}/20)^{0.5}\ \mu^{0.1} = 9000\ (1.0)(1.095)(1.0) = 9859$. $L_f/G_f = 5.96$.

From Fig. 14-58, pressure drop = 0.40 in. $H_2O$/ft packing.

## PACKING EFFICIENCY

**HETP vs. Fundamental Mass Transfer** The two-film model gives the following transfer unit relationship:

$$H_{OG} = H_G + \lambda H_L \tag{14-152}$$

where $H_{OG}$ = height of an overall transfer unit, gas concentration basis, m
$H_G$ = height of a gas-phase transfer unit, m
$H_L$ = height of a liquid-phase transfer unit, m
$\lambda = m/(L_M/G_M)$ = slope of equilibrium line/slope of operating line

In design practice, a less rigorous parameter, HETP, is used to express packing efficiency. The HETP is the height of packed bed required to achieve a theoretical stage. The terms $H_{OG}$ and HETP may be related under certain conditions:

$$\text{HETP} = H_{OG}\left[\frac{\ln \lambda}{(\lambda - 1)}\right] \tag{14-153}$$

and since

$$Z_p = (H_{OG})(N_{OG}) = (\text{HETP})(N_t) \tag{14-154}$$

$$N_{OG} = N_t[\ln \lambda/(\lambda - 1)] \tag{14-155}$$

Equations (14-153) and (14-155) have been developed for binary mixture separations and hold for cases where the operating line and equilibrium line are straight. Thus, when there is curvature, the equations should be used for sections of the column where linearity can be assumed. When the equilibrium line and operating line have the same slope, HETP = $H_{OG}$ and $N_{OG} = N_t$ (theoretical stages).

An alternative parameter popular in Europe is the NTSM (number of theoretical stages per meter) which is simply the reciprocal of the HETP.

**Factors Affecting HETP: An Overview** Generally, packing efficiency increases (HETP decreases) when the following occur.

- Packing surface area per unit volume increases. Efficiency increases as the particle size decreases (random packing, Fig. 14-59) or as the channel size narrows (structured packing, Fig. 14-60).
- The packing surface is better distributed around a random packing element.
- Y structured packings (45° inclination) give better efficiencies than X structured packings (60° inclination to the horizontal) of the same surface areas (Fig. 14-60).
- For constant *L/V* operation in the preloading regime, generally liquid and vapor loads have little effect on random and most corrugated sheet structured packings HETP (Figs. 14-59 and 14-60). HETP increases with loadings in some wire-mesh structured packing.
- Liquid and vapor are well distributed. Both liquid and vapor maldistribution have a major detrimental effect on packing efficiency.
- Other. These include *L/V* ratio (lambda), pressure, and physical properties. These come into play in some systems and situations, as discussed below.

**HETP Prediction** HETP can be predicted from mass-transfer models, rules of thumb, and data interpolation.

***Mass-Transfer Models*** Development of a reliable mass-transfer model for packing HETP prediction has been inhibited by a lack of understanding of the complex two-phase flow that prevails in packings, by the shortage of commercial-scale efficiency data for the newer packings, and by difficulty in quantifying the surface generation in modern packings. Bennett and Ludwig (*Chem. Eng. Prog.*, p. 72, April 1994) point out that the abundant air-water data cannot be reliably used for assessing real system mass-transfer resistance due to variations in turbulence, transport properties, and interfacial areas. More important, the success and reliability of rules of thumb for predicting packing efficiency made it difficult for mass-transfer models to compete.

For random packings, the Bravo and Fair correlation [*Ind. Eng. Chem. Proc. Des. Dev.* **21,** 162 (1982)] has been one of the most popular theoretical correlations. It was shown (e.g., McDougall, *Chem SA*, p. 255, October 1985) to be better than other theoretical correlations, yet produced large discrepancies when compared to test data [Shariat and Kunesh, *Ind. Eng. Chem. Res.* **34**(4), 1273 (1995)]. For structured packings, the Bravo, Fair, and Rocha correlation [*Chem. Eng. Progr.* **86**(1), 19 (1990); *Ind. Eng. Chem. Res.* **35,** 1660 (1996)] is one of the most popular theoretical correlations. This correlation is based on the two-film theory. Interfacial areas are calculated from the packing geometry and an empirical wetting parameter.

Alternate popular theoretical correlations for random packings, structured packings, or both (e.g., Billet and Schultes, "Beitrage zur Verfahrens-und Umwelttechnik," p. 88, Ruhr Universitat, Bochum, Germany, 1991) are also available.

***Rules of Thumb*** Since in most circumstances packing HETP is sensitive to only few variables, and due to the unreliability of even the best mass-transfer model, it has been the author's experience that rules of thumb for HETP are more accurate and more reliable than mass-transfer models. A similar conclusion was reached by Porter and Jenkins (*IChemE Symp. Ser.* **56,** Summary paper, London, 1979).

The majority of published random packing rules of thumb closely agree with one another. They are based on second- and third-generation random packings and should not be applied to the obsolete first-generation packings. Porter and Jenkins's (loc. cit.), Frank's (*Chem. Eng.*, p. 40, March 14, 1977), Harrison and France's (*Chem. Eng.*, p. 121, April 1989), Chen's (*Chem. Eng.*, p. 40, March 5, 1984), and Walas' (*Chem. Eng.*, p. 75, March 16, 1987) general rules of thumb are practically the same, have been successfully tested against an extensive data bank, and are slightly conservative, and therefore suitable for design.

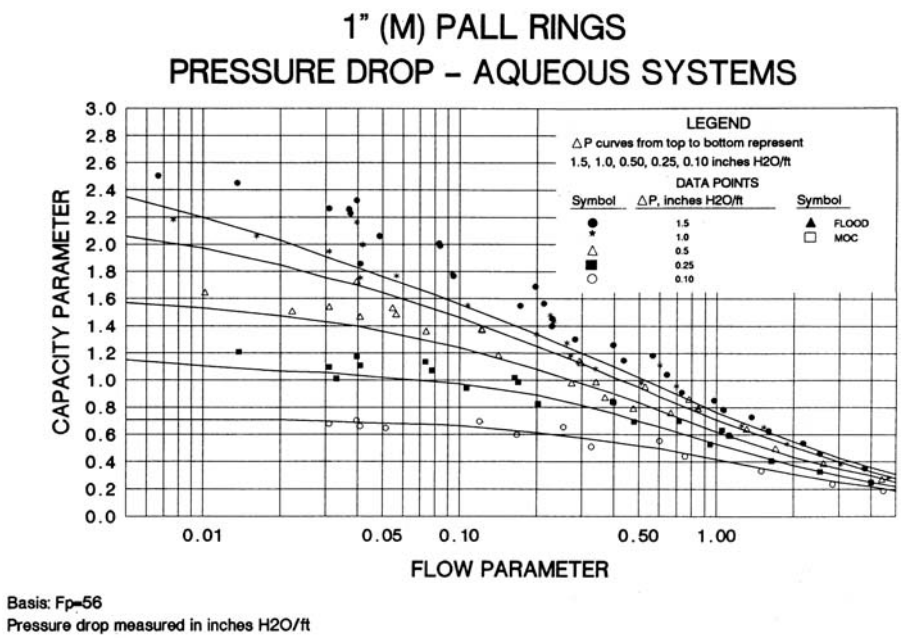
For small-diameter columns, the rules of thumb presented by Frank (loc. cit.), Ludwig (*Applied Process Design for Chemical and Petrochemical Plants*, vol. 2, 2d ed., Gulf Publishing, Houston, Tex., 1979), and Vital et al. [*Hydrocarbon Processing*, **63**(12), 75 (1984)] are identical. The author believes that for small columns, the more conservative value predicted from either the Porter and Jenkins or the Frank-Ludwig-Vital rule should be selected for design. Summarizing:

$$\text{HETP} = 18D_P \tag{14-156a}$$

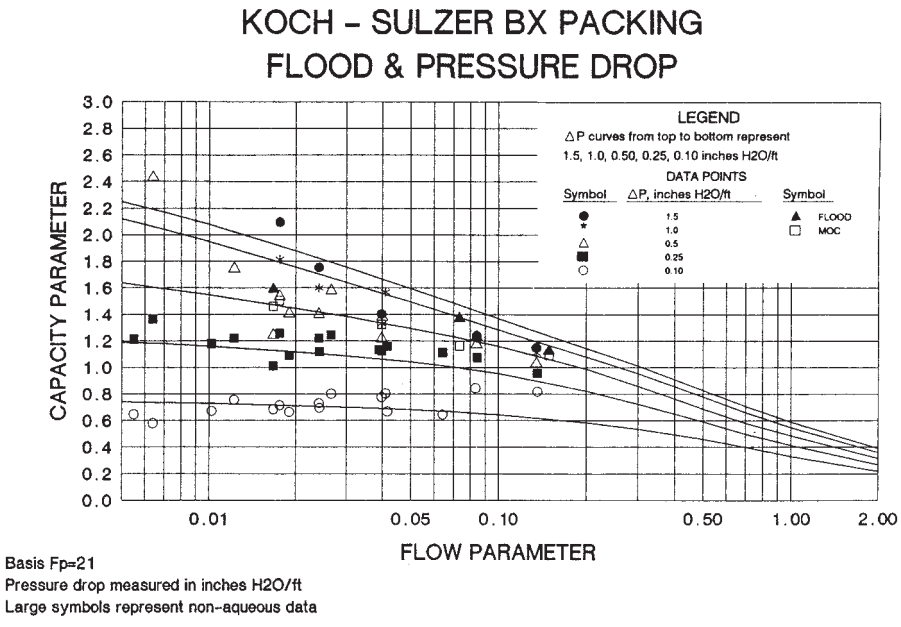
$$\text{HETP} > D_T \qquad \text{for } D_T < 0.67 \text{ m} \tag{14-156b}$$

where $D_P$ and $D_T$ are the packing and tower diameters, *m*, respectively, and the HETP is in meters. In high-vacuum columns (<100 mbar), and when $\lambda = mG_M/L_M$ is outside the range of 0.5 to 2.0, the above rules may be optimistic (see below).

The above rules of thumb were based on experience with Pall rings. The packing diameter may be difficult to establish for some of the modern packings, especially those of saddle or flat shape. For these,



(a)



(b)

**FIG. 14-57** Superimposing experimental pressure-drop data for a given packing generates a GPDC interpolation chart for this packing. (*a*) A random packing; chart is based on Eckert's GPDC, Fig. 14-55. (*b*) A structured packing; chart is based on Kister and Gill's GPDC (SP), Fig. 14-56. *(From Kister, H. Z.,* Distillation Design, *copyright © McGraw-Hill, 1992; used with permission.)*

Kister and Larson (in Schweitzer, *Handbook of Separation Techniques for Chemical Engineers,* 3d ed., McGraw-Hill, 1997) extended Eq. (14-156*a*) by expressing the packing diameter in terms of the more fundamental surface area per unit volume $a_P$, $m^2/m^3$. For Pall rings, it can be shown that

$$a_P = 5.2/D_P \tag{14-157}$$

and Eq. (14-156*a*) becomes

$$\text{HETP} = 93/a_P \tag{14-158}$$

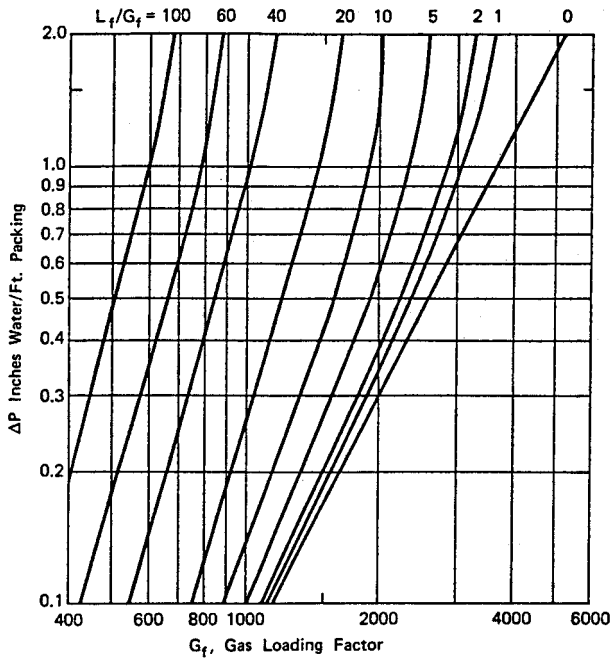


**FIG. 14-58** The Robbins generalized pressure-drop correlation. (*From L. A. Robbins.* Chem Eng. Progr., *May 1991. p. 87, reprinted courtesy of the American Institute of Chemical Engineers.*)

Harrison and France (loc. cit.) presented the only published rule of thumb for structured packings efficiency as a function of packing crimp. Kister and Larson reexpressed it in terms of the surface area per unit volume to accommodate a wider range of packing geometries. The final expression is

$$\text{HETP} = 100C_{XY}/a_p + 0.10 \qquad (14\text{-}159)$$

Specific surface areas are listed in Tables 14-13 and 14-14.

The above rules of thumb apply to organic and hydrocarbon systems, whose surface tensions are relatively low ($\sigma < 25$ mN/m). For higher surface tensions, the liquid does not adhere well to the packing surfaces (*underwetting*), causing higher HETPs. In a water-rich system ($\sigma = 70$ mN/m or so) HETPs obtained from Eqs. (14-156), (14-158), and (14-159) need to be doubled. For intermediate surface tension systems (some amines and glycols, whose surface tension at column conditions is 40 to 50 mN/m), HETPs obtained from Eqs. (14-156), (14-158), and (14-159) need to be multiplied by 1.5.

For random packings, Eqs. (14-156) and (14-158) apply for packings of 25-mm diameter and larger. For smaller packings, use of the $a_p$ at 25-mm often gives a slightly conservative HETP estimate. For structured packing, $C_{XY}$ in Eq. (14-159) reflects the effect of the inclination angle (*Fig. 14-60*), $C\Xi\Psi = 1$ for Y-type, S-type, or high-capacity packings, and $C_{XY} = 1.45$ for the larger ($<300$ m$^2$/m$^3$) X-type packings. There are insufficient data to determine $C_{XY}$ for high specific area X-type packings, but Fig. 14-60 suggests it is somewhat lower than 1.45.

Compared to experimental data, the above rules of thumb are slightly conservative. Since packing data are usually measured with perfect distribution, a slight conservative bias is necessary to extend

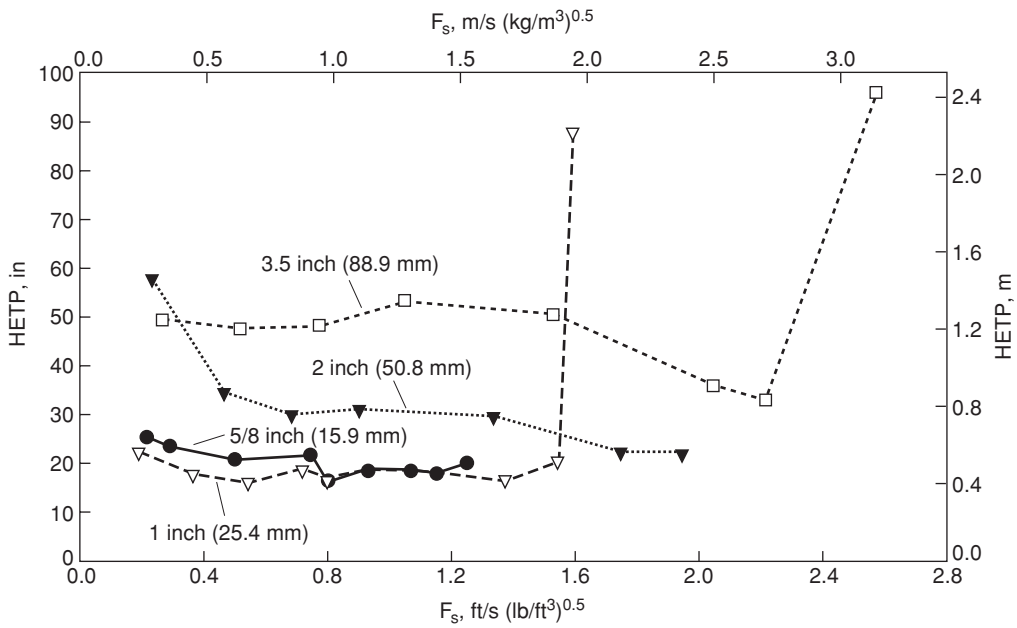

**FIG. 14-59** HETP values for four sizes of metal pall rings, vacuum operation. Cyclohexane/*n*-heptane system, total reflux, 35 kPa (5.0 psia). Column diameter = 1.2 m (4.0 ft). Bed height = 3.7 m (12 ft). Distributor = tubed drip pan, 100 streams/m$^2$. [*Adapted from Shariat and Kunesh,* Ind. Eng. Chem. Res., ***34,*** *1273 (1995). Reproduced with permission. **FIG. 14-60** Effect of structured packing surface areas, loads, and inclination angle on packing efficiency. Efficiency expressed as number of theoretical stages per meter, the reciprocal of HETP. Sulzer data, chlorobenzene–ethylbenzene, 100 mbar, at total reflux; 250-mm-diameter test column. (*Reprinted courtesy of Sulzer Chemtech.*)

these data to the good, yet imperfect, distributors used in the real world. For poor distributors, the above rules of thumb will usually predict well below the HETPs measured in the field.

Lockett (*Chem. Eng. Progr.,* p. 60, January 1998) simplified the fundamental Bravo-Fair-Rocha correlation [*Ind. Eng. Chem. Res.* **35,** p. 1660 (1996)] to derive an alternative rule of thumb for structured packing efficiency. This rule of thumb predicts HETPs under perfect distribution conditions. Lockett recommends caution when applying this rule of thumb for aqueous systems as it does not predict the effects of underwetting (below).

***Service-Oriented Rules of Thumb*** Strigle (*Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) proposed a multitude of rules of thumb as a function of the service, column pressure, and physical properties. These rules are based on the extensive experience of Strigle and the Norton Company (now merged with Koch-Glitsch LP).

***Data Interpolation*** Interpolation of experimental HETP data is the most reliable means of obtaining design HETP values. This is hardly surprising in an area where our understanding of the theory is so poor that rules of thumb can do better than theoretical models. The author believes that it is best to derive HETP from experimental data, and to check it against a rule of thumb.

Eckert [*Chem. Eng. Progr.* **59**(5), 76 (1963)], Chen (*Chem. Eng.* p. 40, March 5, 1984), and Vital et al. [*Hydroc. Proc.* **63**(12), 75 (1984)] tabulated experimental HETP data for various random packings. Kister (*Distillation Design,* McGraw-Hill, 1992) extended these tabulations and included published HETP data and a detailed procedure for interpolating such HETP data. A prerequisite to any interpolation of packing data is thorough familiarity with the factors that affect HETP. Overlooking any of the factors listed can easily lead to poor interpolation and grossly incorrect design. In particular, it is imperative to recognize that the quality of distribution in pilot towers is generally superior to the quality of distribution in commercial towers.

**Underwetting** Laboratory- and pilot-scale distillation experiments with systems that exhibit large differences in surface tension along the column such as methanol-water showed a sharp drop in efficiency at the high-surface-tension end of the column [Ponter et al., *Trans. Instn. Chem. Engineers [London],* **45,** T345 (1967)]. There appeared to be a critical methanol composition below which performance deteriorated rapidly. The poor performance at the low-methanol-concentration end appeared independent of the type and size of packing. Visual observations with disk columns attributed these effects to underwetting.

Underwetting is a packing surface phenomenon, which breaks up liquid film. The tendency of the liquid film to break (the degree of wetting) is expressed by the contact angle (Fig. 14-61). A contact angle of 0° indicates perfect wetting; an angle of 180° indicates no wetting. Mersmann and Deixler [*Chem. Ing. Tech.* **58**(1), 19 (1986)] provide a preliminary chart for estimating contact angles. The contact angle depends on both the surface and the liquid and is a strong function of composition. In systems with large surface tension gradients, both contact angles and minimum wetting rates may vary rapidly with changes of composition or surface tension. Extensive studies by Ponter et al. [loc. cit.; also, Ponter and Au-Yeung, *Chem. Ing. Tech.*, **56**(9), 701 (1984)] showed that

- Underwetting is most significant in aqueous-organic systems, and tends to occur at the high-surface-tension (aqueous) end of the composition range. Liquid viscosity may also have an effect.
- Underwetting may be alleviated by changing the material and surface roughness of the packing.
- In systems susceptible to underwetting, column efficiency can sometimes (but not always) be improved by the addition of small amounts of surfactants.

**Effect of Lambda** Most packed-column efficiency testing has been at total reflux. Some tests for both random and structured packings [Billet, "Packed Towers Analysis and Design," Ruhr University, Bochum, Germany, 1989; Meier, Hunkeler, and Stocker, *IChemE Symp. Ser.* **56,** 3.3/1 (1979); Eckert and Walter, *Hydroc. Proc.* **43**(2), 107 (1964)] suggest that efficiencies at finite reflux are similar to those at total reflux when lambda ($\lambda = mG_M/L_M$, which is the ratio of the slope of the equilibrium curve to the slope of the operating line) ranges between 0.5 and 2.0. This range is typical for most distillation systems.

Koshy and Rukovena [*Hydroc. Proc.*, **65**(5), 64 (1986)], experimenting with methanol-water and water-DMF using #25 IMTP packing in a pilot-scale column, observed a sharp efficiency drop when the group $\lambda$ was greater than 2 or lower than 0.5. The efficiency loss escalated as $\lambda$ deviated more from this range. Koshy and Rukovena recognized that surface tension gradients and underwetting may have influenced some of their findings, but argue that the lambda effect is the major cause for the efficiency differences observed in their tests. High-relative-volatility systems are those most likely to be affected by $\lambda$, because at low volatility, $\lambda$ ranges from 0.5 to 2. Strigle (loc. cit.) quantified the lambda effect on HETP using the following equation:

$$\text{Actual HETP/standard HETP} = 1 + 0.278[\text{ABS}(\ln \lambda)^3] \quad (14\text{-}160)$$

For $0.5 < \lambda < 2$, Eq. (14-160) gives a ratio of less than 1.1; that is, it has a little influence on HETP.

**Pressure** Generally, pressure has little effect on HETP of both random and structured packing, at least above 100 mbar abs. At deep vacuum (<100 mbar), there are data to suggest that efficiency decreases as pressure is lowered for random packings [Zelvinski, Titov, and Shalygin, *Khim Tekhnol. Topl. Masel.* **12**(10) (1966)], but most of these data can also be explained by poor wetting or maldistribution.

At high pressures (>15 to 20 bar), structured packing efficiency diminishes as pressure is raised (Fitz, Shariat, and Spiegel, Paper presented at the AIChE Spring National Meeting, Houston, Tex., March 1995). Zuiderweg and Nutter [*IChemE Symp.* **128,** A481 (1992)] report the same phenomenon, but to a much smaller extent, also in random packings. They explain the efficiency reduction at higher pressure by vapor backmixing. Nooijen et al. [*IChemE Symp. Ser.* **142,** 885 (1997)] concur, bringing a supporting case study in which high-pressure distillation efficiency improved by splitting a packed bed.

With structured packings (only) FRI's high-pressure (10 to 30 bar; flow parameters >0.25) distillation tests measured maxima, termed *humps* in the HETP vs. load plot, typically at 65 to 90 percent of flood [Fitz, Shariat, and Kunesh, *IChemE Symp. Ser.* **142,** 829 (1997); Cai et al., *Trans IChemE* **81,** Part A, p. 85 (2003)]. These humps (Fig. 14-62) were not observed with lower pressure distillation (flow parameters <0.2) and appeared to intensify with higher pressure. The humps did not always occur; some tests at different distributor positioning and with larger packing showed no humps. Zuiderweg et al. [*IChemE Symp. Ser.* **142,** 865 (1997); *Trans. IChemE* **81,** Part A, p. 85 (January 2003)] and Nooijen et al. [*IChemE Symp. Ser.* **142,** 885 (1997)] explain the humps by two-phase backmixing. At the high liquid loads in high-pressure distillation, flow unevenness prematurely floods some of the packing channels, carrying vapor bubbles downward and recirculating liquid upward.

**Physical Properties** Data presented by a number of workers [e.g., Vital, Grossel, and Olsen, *Hydroc. Proc.* **63**(12), 75 (1984)] suggest that, generally, random packing HETP is relatively insensitive to system properties for nonaqueous systems. A survey of data in Chapter

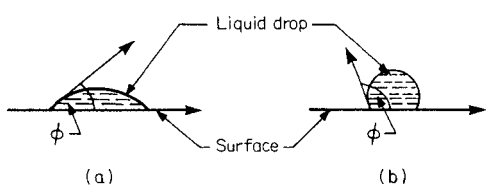

**FIG. 14-61** Contact angles. (*a*) Acute, good wetting. (*b*) Obtuse, poor wetting.

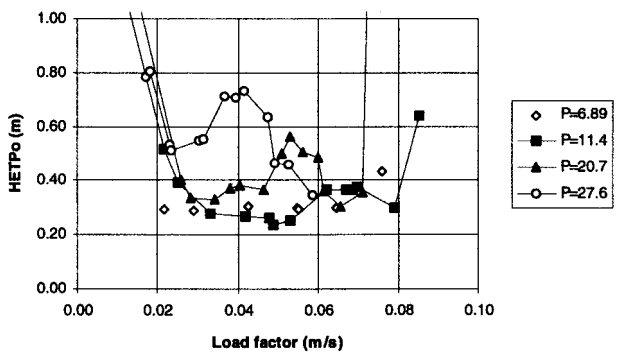

**FIG. 14-62** $HETP_o$ data as measured in the FRI column for the $iC_4/nC_4$ system at different pressures (bara), showing efficiency humps. (*From J. L. Nooijen, K. A. Kusters, and J. J. B. Pek,* IChemE Symp. Ser. ***142,*** *p. 885, 1997. Reprinted courtesy of IChemE.*)

11 of Kister's *Distillation Design* (McGraw-Hill, New York, 1992) leads to a similar conclusion for structured packings. For water-rich systems, packing HETPs tend to be much higher than for nonaqueous systems due to their high lambda or surface underwetting, as discussed above. High hydrogen concentrations (>30 percent or so in the gas) have also led to low packing efficiencies (Kister et al., *Proc. 4th Ethylene Producers Conference,* AIChE, New Orleans, La., p. 283, 1992), possibly due to the fast-moving hydrogen molecule dragging heavier molecules with it as it diffuses from a liquid film into the vapor.

**Errors in VLE** These affect packing HETP in the same way as they affect tray efficiency. The discussions and derivation earlier in this subsection apply equally to tray and packed towers.

**Comparison of Various Packing Efficiencies for Absorption and Stripping** In past editions of this handbook, extensive data on absorption/stripping systems were given. Emphasis was given to the following systems:

| | |
|---|---|
| Ammonia-air-water | Liquid and gas phases contributing; chemical reaction contributing |
| Air-water | Gas phase controlling |
| Sulfur dioxide-air-water | Liquid and gas phase controlling |
| Carbon dioxide-air-water | Liquid phase controlling |

The reader may refer to the data in the 5th edition. For the current work, emphasis will be given to one absorption system, carbon dioxide-air-caustic.

***Carbon Dioxide-Air-Caustic System*** The vendors of packings have adopted this system as a "standard" for comparing the performance of different packing types and sizes for absorption/stripping. For tests, air containing 1.0 mol % $CO_2$ is passed countercurrently to a circulating stream of sodium hydroxide solution. The initial concentration of NaOH in water is 1.0 N (4.0 wt %), and as the circulating NaOH is converted to sodium carbonate it is necessary to make a mass-transfer correction because of reduced mass-transfer rate in the liquid phase. The procedure has been described by Eckert et al. [*Ind. Eng. Chem.*, **59**(2), 41 (1967); *Chem. Eng. Progr.*, **54**(1), 790 (1958)]. An overall coefficient is measured using gas-phase ($CO_2$) concentrations:

$$K_{OG}a_e = \frac{\text{moles } CO_2 \text{ absorbed}}{\text{time-bed volume-partial pressure } CO_2 \text{ driving force}} \tag{14-161}$$

The coefficients are usually corrected to a hydroxide conversion of 25 percent at 24°C. For other conversions, Fig. 14-14 may be used. Reported values of $K_{OG}a$ for representative random packings are given in Table 14-15. The effect of liquid rate on the coefficient is shown in Fig. 14-63.

While the carbon dioxide/caustic test method has become accepted, one should use the results with caution. The chemical reaction masks the effect of physical absorption, and the relative values in the table may not hold for other cases, where much of the resistance to mass transfer is in the gas phase. Background on this combination of physical and chemical absorption may be found earlier in the present section, under "Absorption with Chemical Reaction."

**TABLE 14-15 Overall Coefficients for Representative Packings**

| $CO_2$-air-caustic system | | |
|---|---|---|
| | Nominal size, mm | Overall coefficient $K_{OG}a$, kg·moles/(hr·m³·atm) |
| Ceramic raschig rings | 25 | 37.0 |
| | 50 | 26.1 |
| Ceramic Intalox saddles | 25 | 45.1 |
| | 50 | 30.1 |
| Metal pall rings | 25 | 49.6 |
| | 50 | 34.9 |
| Metal Intalox saddles (IMTP®) | 25 | 54.8 |
| | 50 | 39.1 |

NOTE: Basis for reported values: $CO_2$ concentration in inlet gas, 1.0 vol %; 1N NaOH solution in water, 25 percent NaOH conversion; temperature = 24°C; atmospheric pressure: gas rate = 1.264 kg/(s·m²); liquid rate = 6.78 kg/(s·m²).

SOURCE: Strigle, R. L., *Packed Tower Design and Applications,* 2d ed., Gulf Publ. Co., Houston, 1994.

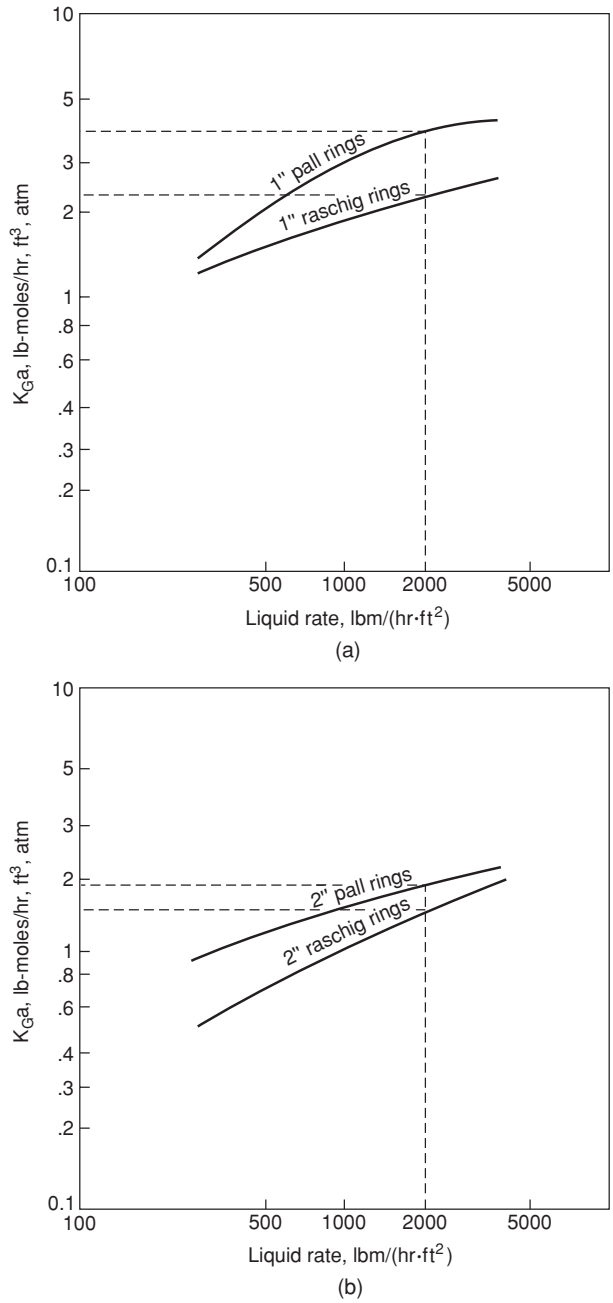

**FIG. 14-63** Overall mass transfer coefficients for carbon dioxide absorbed from air by 1N caustic solution. (*a*) 1-in Pall rings and Raschig rings. (*b*) 2-in Pall rings and Raschig rings. Air rate = 0.61 kg/s·m² (450 lb/hr·ft²). To convert from lb/hr·ft² to kg/s·m², multiply by 0.00136. To convert from lb-moles/hr·ft³ atm to kg-moles/s·m³ atm, multiply by 0.0045. [*Eckert et al.*, Chem. Eng. Progr., ***54****(1), 70 (1958).*]

**Summary** In the preloading regime, packing size, type, and distribution affect HETP. With aqueous-organic systems, HETP may be sensitive to underwetting and composition. A lambda value ($\lambda = mG_M/L_M$) outside the range of 0.5 to 2.0 causes HETP to rise, and so does a high hydrogen concentration. HETP of structured packings may also be affected by pressure (at high pressure), and vapor and liquid loads.

## MALDISTRIBUTION AND ITS EFFECTS ON PACKING EFFICIENCY

**Modeling and Prediction** Maldistribution may drastically reduce packing efficiency. HETP may increase by a factor as high as 2 or 3 due to maldistribution. Shariat and Kunesh [*Ind. Eng. Chem. Res.,* **34**(4), 1273 (1995)] provide a good demonstration.

Early models [Mullins, *Ind. Chem. Mfr.,* **33,** 408 (1957); Manning and Cannon, *Ind. Eng. Chem.* **49**(3), 347 (1957)] expressed the effect of liquid maldistribution on packing efficiency in terms of a simple channeling model. A portion of the liquid bypasses the bed, undergoing negligible mass transfer, and then rejoins and contaminates the rest of the liquid. Huber et al. [*Chem. Ing. Tech.* **39,** 797 (1967); *Chem. Eng. Sci.* **21,** 819 (1966)] and Zuiderweg et al. [*IChemE Symp. Ser.* **104,** A217 (1987)] replaced the simple bypassing by variations in the local *L/V* ratios. The overirrigated parts have a high *L/V* ratio, the underirrigated parts a low *L/V* ratio. Regions with low *L/V* ratios experience pinching, and, therefore, produce poor separation.

Huber et al. (loc. cit.) and Yuan and Spiegel [*Chem. Ing. Tech.* **54,** 774 (1982)] added lateral mixing to the model. Lateral deflection of liquid by the packing particles tends to homogenize the liquid, thus counteracting the channeling and pinching effect.

A third factor is the nonuniformity of the flow profile through the packing. This nonuniformity was observed as far back as 1935 [Baker, Chilton, and Vernon, *Trans. Instn. Chem. Engrs.* **31,** 296 (1935)] and was first modeled by Cihla and Schmidt [*Coll. Czech. Chem. Commun.,* **22,** 896 (1957)]. Hoek (Ph.D. Thesis, The University of Delft, The Netherlands, 1983) combined all three factors into a single model, leading to the zone-stage model below.

***The Zone-Stage Model*** Zuiderweg et al. [*IChemE Symp. Ser.* **104,** A217, A233 (1987)] extended Hoek's work combining the effects of local *L/V* ratio, lateral mixing, and flow profile into a model describing the effect of liquid maldistribution on packing efficiency. This work was performed at Fractionation Research Inc. (FRI) and at The University of Delft in The Netherlands. The model postulates that, in the absence of maldistribution, there is a "basic" (or "true" or "inherent") HETP which is a function of the packing and the system only. This HETP can be inferred from data for small towers, in which lateral mixing is strong enough to offset any pinching. For a given initial liquid distribution, the model uses a diffusion-type equation to characterize the splitting and recombining of liquid streams in the horizontal and vertical directions. The mass transfer is then calculated by integrating the liquid flow distribution at each elevation and the basic HETP. Kunesh et al. successfully applied the model to predict measured effects of maldistribution on packing efficiency. However, this model is difficult to use and has not gained industrywide acceptance.

***Empirical Prediction*** Moore and Rukovena [*Chemical Plants and Processing* (European edition), p. 11, August 1987] proposed the empirical correlation in Fig. 14-64 for efficiency loss due to liquid maldistribution in packed towers containing Pall® rings or Metal Intalox® packing. This correlation was shown to work well for several case studies (Fig. 14-64), is simple to use, and is valuable, at least as a preliminary guide.

To quantify the quality of liquid irrigation, the correlation uses the distribution quality rating index. Typical indexes are 10 to 70 percent for most standard commercial distributors, 75 to 90 percent for intermediate-quality distributors, and over 90 percent for high-performance distributors. Moore and Rukovena present a method for calculating a distribution-quality rating index from distributor geometry. Their method is described in detail in their paper as well as in Kister's book (*Distillation Operation,* McGraw-Hill, New York, 1990).

***Maximum Liquid Maldistribution Fraction*** $\mathbf{f}_{max.}$ To characterize the sensitivity of packed beds to maldistribution, Lockett and Billingham (*Trans. IChemE.* **80,** Part A, p. 373, May 2002; *Trans. IChemE.* **81,** Part A, p. 134, January 2003) modeled maldistribution as two parallel columns, one receiving more liquid $(1 + f)L$, the other receiving less $(1 - f)L$. The vapor was assumed equally split (Fig. 14-65)

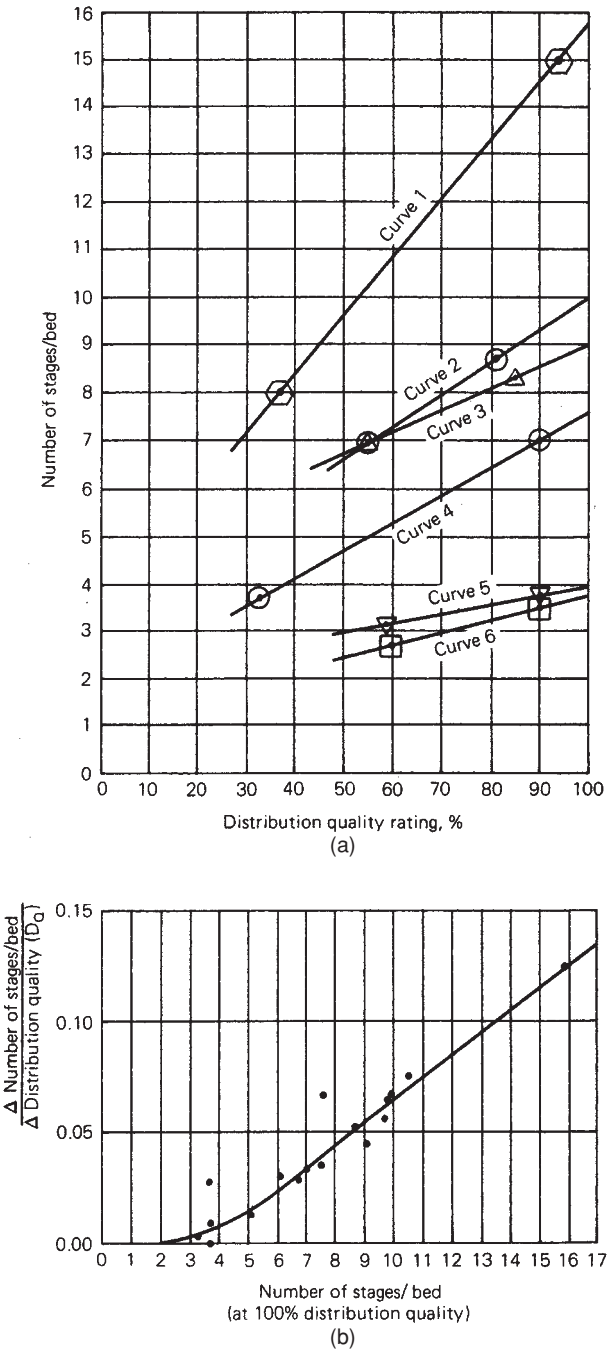

**FIG. 14-64** Effect of irrigation quality on packing efficiency. (*a*) Case histories demonstrating efficiency enhancement with higher distribution quality rating. (*b*) Correlation of the effect of irrigation quality on packing efficiency. (*From F. Moore and F. Rukovena,* Chemical Plants and Processing, *Europe edition, Aug. 1987; reprinted courtesy of* Chemical Plants and Processing.)

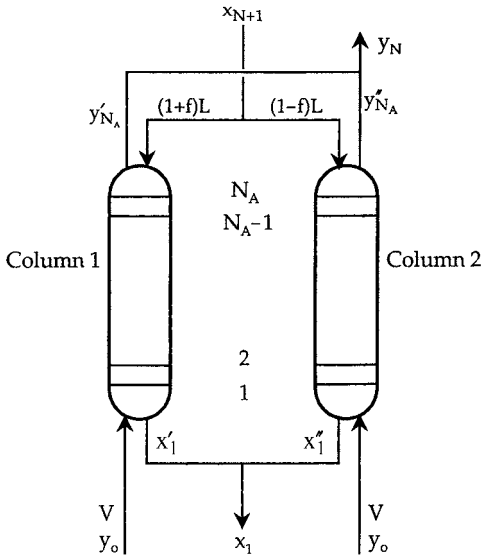

**FIG. 14-65** Parallel-columns model. (*From Lockett and Billingham,* Trans. IChemE ***80,*** *Part A, p. 373, May 2002; reprinted courtesy of IChemE.*)

without lateral mixing. Because of the different *L/V* ratios, the overall separation is less than is obtained at uniform distribution. A typical calculated result (Fig. 14-66) shows the effective number of stages from the combined two-column system decreasing as the maldistribution fraction *f* increases. Figure 14-66*a* shows that the decrease is minimal in short beds (e.g., 10 theoretical stages) or when the maldistribution fraction is small. Figure 14-66*a* shows that there is a limiting fraction $f_{max}$ which characterizes the maximum maldistribution that still permits achieving the required separation. Physically, $f_{max}$ represents the maldistribution fraction at which one of the two parallel columns in the model becomes pinched. Figure 14-66*b* highlights the steep drop in packing efficiency upon the onset of this pinch. Billingham and Lockett derived the following equation for $f_{max}$ in a binary system:

$$f_{max} = \frac{y_{N+1} - y_N}{y_N - y_o} + \frac{x_1 - x_o}{x_{N+1} - x_o} - \left(\frac{y_{N+1} - y_N}{y_N - y_o}\right)\left(\frac{x_1 - x_o}{x_{N+1} - x_o}\right) \quad (14\text{-}162)$$

This equation can be used to calculate $f_{max}$ directly without the need for a parallel column model. Billingham and Lockett show that the various terms in Eq. (14-162) can be readily calculated from the output of a steady-state computer simulation. Multicomponent systems are represented as binary mixtures, either by lumping components together to form a binary mixture of pseudolight and pseudoheavy components, or by normalizing the mole fractions of the two key components. Once $f_{max}$ is calculated, Billingham and Lockett propose the following guidelines:

- $f_{max} < 0.05$, extremely sensitive to maldistribution. The required separation will probably not be achieved.
- $0.05 < f_{max} < 0.10$, sensitive to maldistribution, but separation can probably be achieved.
- $0.10 < f_{max} < 0.20$, not particularly sensitive to maldistribution.
- $f_{max} > 0.20$ insensitive to maldistribution.

Figure 14-66*b* shows that shortening the bed can increase $f_{max}$. Relative volatility and *L/V* ratio also affect $f_{max}$. The bed length and *L/V* ratio can often be adjusted to render the bed less sensitive to maldistribution.

**Implications of Maldistribution to Packing Design Practice** These are discussed at length with extensive literature citation in Kister's book *Distillation Operation,* McGraw-Hill, New York, 1990. Below are the highlights:

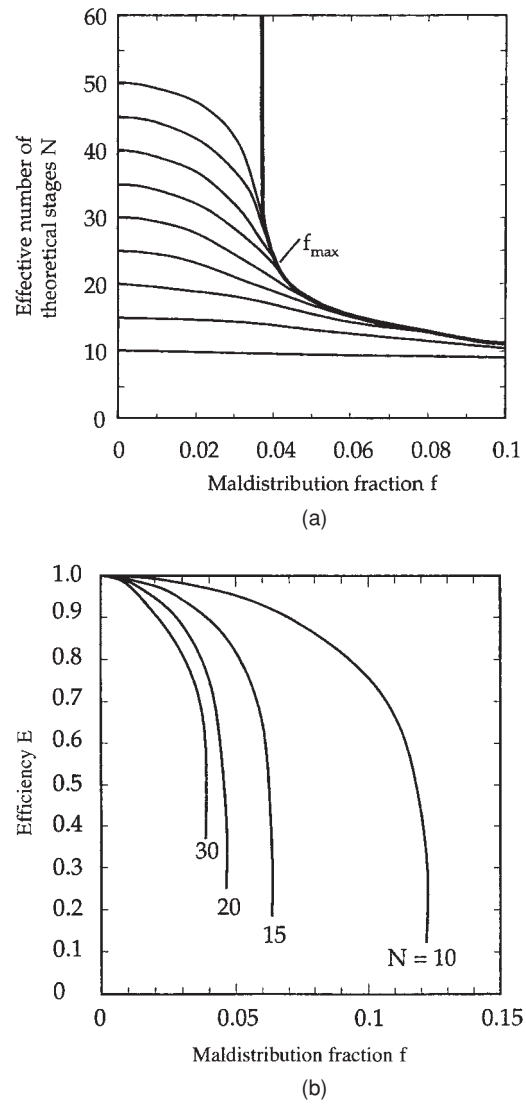

**FIG. 14-66** Loss of efficiency due to maldistribution as a function of maldistribution fraction *f* and the number of stages per bed for a given case study. (*a*) $f_{max}$ and reduction in number of stages. (*b*) Showing larger efficiency loss at higher number of stages per bed and higher *f*. The steep drops indicate pinching associated with $f_{max}$. (*From Lockett and Billingham,* Trans. IChemE ***80,*** *Part A, p. 373, May 2002; reprinted courtesy of IChemE.*)

1. Three factors appear to set the effect of maldistribution on efficiency:

*a. Pinching.* Regional changes in *L/V* ratio cause regional composition pinches.

*b. Lateral mixing.* Packing particles deflect both liquid and vapor laterally. This promotes mixing of vapor and liquid and counteracts the pinching effect.

*c. Liquid nonuniformity.* Liquid flows unevenly through the packing and tends to concentrate at the wall.

2. At small tower-to-packing diameter ratios ($D_T/D_p < 10$), the lateral mixing cancels out the pinching effect, and a greater degree of maldistribution can be tolerated without a serious efficiency loss. At high ratios ($D_T/D_p > 40$), the lateral mixing becomes too small to offset

the pinching effect. The effects of maldistribution on efficiency are therefore most severe in large-diameter columns and small-diameter packings.

A good design practice is to seek a packing size that gives a $D_T/D_p$ between 10 and 40. This is often impractical, and higher ratios are common. When $D_T/D_p$ exceeds 100, avoiding efficiency loss due to maldistribution is difficult. Either ratios exceeding 100 should be avoided, or a special allowance should be made for loss of efficiency due to maldistribution.

3. Wall flow effects become large when $D_T/D_p$ falls below about 10. Packing diameter should be selected such that $D_T/D_p$ exceeds 10.

4. Columns containing less than five theoretical stages per bed are relatively insensitive to liquid maldistribution. With 10 or more stages per bed, efficiency can be extremely sensitive to maldistribution (Strigle, *Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) (Fig. 14-66). Beds consisting of small packings or structured packings, which develop more theoretical stages per bed, are therefore more sensitive to maldistribution than equal-depth beds of larger packings. This is clearly demonstrated by FRI's experiments [Shariat and Kunesh, *Ind. Eng. Chem. Res.* **34**(4), 1273 (1995)]. Lockett and Billingham (*Trans. IChemE,* vol. 81, Part A, p. 131, January 2003) concur with these comments when their procedure (above) indicates high sensitivity to maldistribution, but allow a higher number of stages per bed when the sensitivity is low.

5. Maldistribution tends to be a greater problem at low liquid flow rates than at high liquid flow rates [Zuiderweg, Hoek, and Lahm, *I. ChemE Symp. Ser.* **104,** A217 (1987)]. The tendency to pinch and to spread unevenly is generally higher at the lower liquid flow rates.

6. A packed column has reasonable tolerance for a uniform or smooth variation in liquid distribution and for a variation that is totally random (*small-scale maldistribution*). The impact of discontinuities or zonal flow (*large-scale maldistribution*) is much more severe [Zuiderweg et al., loc. cit.; Kunesh, *Chem. Eng.,* p. 101, Dec. 7, 1987; Kunesh, Lahm, and Yanagi, *Ind. Eng. Chem. Res.* **26**(9), 1845 (1987)]. This is so because the local pinching of small-scale maldistribution is evened out by the lateral mixing, and therefore causes few ill effects. In contrast, the lateral mixing either is powerless to rectify a large-scale maldistribution or takes considerable bed length to do so (meanwhile, efficiency is lost).

Figure 14-67 shows HETPs measured in tests that simulate various types of maldistribution in FRI's 1.2-m column containing a 3.6-m bed of 1-in Pall® rings. The $y$ axis is the ratio of measured HETP in the maldistribution tests to the HETP obtained with an excellent distributor. Analogous measurements with structured packing were reported by Fitz, King, and Kunesh [*Trans. IChemE* **77,** Part A, p. 482 (1999)]. Generally, the response of the structured packings resembled that of the Pall® rings, except as noted below.

Figure 14-67*a* shows virtually no loss of efficiency when a distributor uniformly tilts, such that the ratio of highest to lowest flow is 1.25 (i.e., a "1.25 tilt"). In contrast, an 11 percent chordal blank of a level distributor causes packing HETP to rise by 50 percent.

Figure 14-67*b* compares continuous tilts with ratios of highest to lowest flow of 1.25 and 1.5 to a situation where one-half of the distributor passes 25 percent more liquid than the other half. The latter ("zonal") situation causes a much greater rise in HETP than a "uniform" maldistribution with twice as much variation from maximum to minimum.

Figure 14-67*c* shows results of tests in which flows from individual distributor drip points were varied in a gaussian pattern (maximum/mean = 2). When the pattern was randomly assigned, there was no efficiency loss. When the variations above the mean were assigned to a "high zone," and those below the mean to a "low zone," HETP rose by about 20 percent. With structured packing, both random and zonal maldistribution caused about the same loss of efficiency at the same degree of maldistribution.

7. A packed bed appears to have a "natural distribution," which is an inherent and stable property of the packings. An initial distribution which is better than natural will rapidly degrade to it, and one that is worse will finally achieve it, but sometimes at a slow rate. If the rate is extremely slow, recovery from a maldistributed pattern may not be observed in practice (Zuiderweg et al., loc. cit.). Even though the

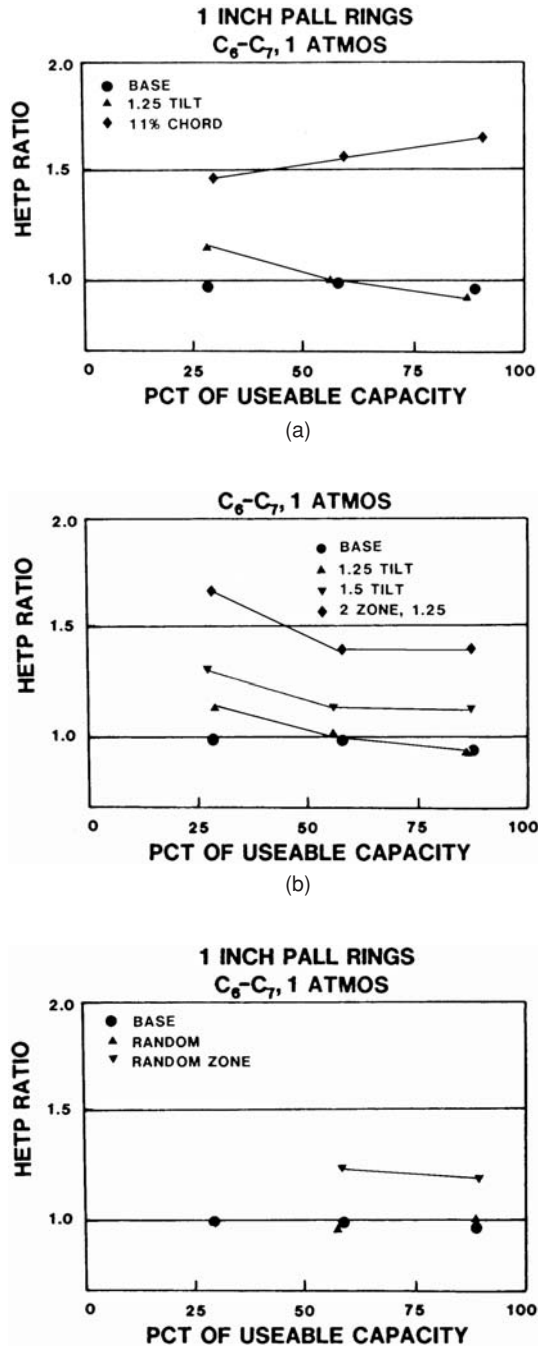

**FIG. 14-67** Comparing the effects of "small-scale" and "large-scale" maldistribution on packing HETP. (*a*) Comparing the effect of a simulated continuous tilt (max/min flow ratio = 1.25) with the simulated effect of blanking a chordal area equal to 11 percent of the tower area. (*b*) Comparing the effects of simulated continuous tilts (max/min flow ratios of 1.25 and 1.5) with the effects of a situation where one-half of the distributor passes 25 percent more liquid to the other half. (*c*) Comparing the effects of random maldistribution with those of zonal maldistribution. (*Reprinted with permission from J. G. Kunesh, L. Lahm, and T. Yahagi,* Ind. Eng. Chem. Res., **26,** *p. 1845; copyright © 1987, American Chemical Society.*)

volumetric distribution improves along the bed, the concentration profile could have already been damaged, and pinching occurs (Bonilla, *Chem. Eng. Prog.,* p. 47, March 1993).

8. Liquid maldistribution lowers packing turndown. The 2-in Pall rings curve in Fig. 14-59 shows HETP rise upon reaching the distributor turndown limit.

9. The major source of gas maldistribution is undersized gas inlet and reboiler return nozzles, leading to the entry of high-velocity gas jets into the tower. These jets persist through low-pressure-drop devices such as packings. Installing gas distributors and improving gas distributor designs, even inlet baffles, have alleviated many of these problems. Vapor distribution is most troublesome in large-diameter columns. Strigle (*Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994) recommends considering a gas distributing device whenever the gas nozzle *F*-factor ($F_N = u_N \rho_G^{0.5}$) exceeds 27 m/s $(kg/m^3)^{0.5}$, or the kinetic energy of the inlet gas exceeds 8 times the pressure drop through the first foot of packing, or the pressure drop through the bed is less than 0.65 mbar/m. Gas maldistribution is best tackled at the source by paying attention to the gas inlet arrangements.

10. A poor initial liquid maldistribution may cause gas maldistribution in the loading region, i.e., at high gas rates [Stoter, Olujic, and de Graauw, *IChemE Symp. Ser.* **128,** A201 (1992); Kouri and Sohlo, *IChemE Symp. Ser.* **104,** B193 (1987)]. At worst, initial liquid maldistribution may induce local flooding, which would channel the gas. The segregation tends to persist down the bed. Outside the loading region, the influence of the liquid flow on gas maldistribution is small or negligible. Similarly, in high-gas-velocity situations, the liquid distribution pattern in the bottom structured packing layers is significantly influenced by a strongly maldistributed inlet gas flow [Olujic et al., *Chem. Eng. and Processing,* **43,** 465 (2004)]. Duss [*IChemE Symp. Ser.* **152,** 418 (2006)] suggests that high liquid loads such as those experienced in high-pressure distillation also increase the susceptibility to gas maldistribution.

11. The effect of gas maldistribution on packing performance is riddled with unexplained mysteries. FRI's (Cai, Paper presented at the AIChE Annual Meeting, Reno, Nev., 2001) commercial-scale tests show little effect of gas maldistribution on both random and structured packing efficiencies. Cai et al. (*Trans IChemE* **81,** Part A, p. 85, 2003) distillation tests in a 1.2-m-diameter tower showed that blocking the central 50 percent or the chordal 30 percent of the tower cross-sectional area beneath a 1.7-m-tall bed of 250 $m^2/m^3$ structured packing had no effect on packing efficiency, pressure drop, or capacity. The blocking did not permit gas passage but allowed collection of the descending liquid. Simulator tests with similar blocking with packing heights ranging from 0.8 to 2.4 m (Olujic et al., *Chemical Engineering and Processing,* **43,** p. 465, 2004; *Distillation 2003: Topical Conference Proceedings,* AIChE Spring National Meeting, New Orleans, La., AIChE, p. 567, 2003) differed, showing that a 50 percent chordal blank raised pressure drop, gave a poorer gas pattern, and prematurely loaded the packing. They explain the difference by the ability of liquid to drain undisturbed from the gas in the blocked segment in the FRI tests. Olujic et al. found that while gas maldistribution generated by collectors and by central blockage of 50 percent of the cross-sectional areas was smoothed after two to three layers of structured packing, a chordal blockage of 30 to 50 percent of cross-sectional area generated maldistribution that penetrated deeply into the bed.

12. Computational fluid dynamics (CFD) has been demonstrated effective for analyzing the effects of gas inlet geometry on gas maldistribution in packed beds. Using CFD, Wehrli et al. (*Trans. IChemE* **81,** Part A, p. 116, January 2003) found that a very simple device such as the V-baffle (Fig. 14-70) gives much better distribution than a bare nozzle, while a more sophisticated vane device such as a Schoepentoeter (Fig. 14-71*c*) is even better. Implications of the gas inlet geometry to gas distribution in refinery vacuum towers was studied by Vaidyanathan et al. (Distillation 2001, Topical Conference Proceedings, AIChE Spring National Meeting, Houston, Tex., p. 287, April 22–26, 2001); Paladino et al. (Distillation 2003: Topical Conference Proceedings, AIChE Spring National Meeting, New Orleans, La., p. 241, 2003); Torres et al. (ibid., p. 284); Waintraub et al. (Distillation 2005: Topical Conference Proceedings, AIChE Spring National Meeting, Atlanta, Ga., p. 79, 2005); and Wehrli et al. (*IChemE* Symp. Ser 152, London, 2006). Vaidyanathan et al. and Torres et al. examined the effect of the geometry of a chimney tray (e.g., Fig. 14-72) above the inlet on gas distribution and liquid entrainment. Paladino et al. demonstrated that the presence of liquid in the feed affects the gas velocity profile, and must be accounted for in modeling. Paladino et al. and Waintraub et al. used their two-fluid model to study the velocity distributions and entrainment generated by different designs of vapor horns (e.g., Fig. 14-71). Wehrli et al. produced pilot-scale data simulating a vacuum tower inlet, which can be used in CFD model validation. Ali et al. (*Trans. IChemE,* vol. 81, Part A, p. 108, January 2003) found that the gas velocity profile obtained using a commercial CFD package compared well to those measured in a 1.4-m simulator equipped with structured packing together with commercial distributors and collectors. Their CFD model effectively pointed them to a collector design that minimizes gas maldistribution.

## PACKED-TOWER SCALE-UP

**Diameter** For random packings there are many reports [Billet, *Distillation Engineering,* Chem Publishing Co., New York, 1979; Chen, *Chem. Eng.,* p. 40, March 5, 1984; Zuiderweg, Hoek, and Lahm, *IChemE. Symp. Ser.* **104,** A217 (1987)] of an increase in HETP with column diameter. Billet and Mackowiak's (Billet, Packed Column Analysis and Design, Ruhr University, Bochum, Germany, 1989) scale-up chart for Pall® rings implies that efficiency decreases as column diameter increases.

Practically all sources explain the increase of HETP with column diameter in terms of enhanced maldistribution or issues with the scale-up procedure. Lab-scale and pilot columns seldom operate at column-to-packing diameter ratios ($D_T/D_p$) larger than 20; under these conditions, lateral mixing effectively offsets loss of efficiency due to maldistribution pinch. In contrast, industrial-scale columns usually operate at $D_T/D_p$ ratios of 30 to 100; under these conditions, lateral mixing is far less effective for offsetting maldistribution pinch.

To increase $D_T/D_p$, it may appear attractive to perform the bench-scale tests using a smaller packing size than will be used in the prototype. Deibele, Goedecke, and Schoenmaker [*IChemE Symp. Ser.* **142,** 1021 (1997)], Goedecke and Alig (Paper presented at the AIChE Spring National Meeting, Atlanta, Ga., April 1994), and Gann et al. [*Chem. Ing. Tech.,* **64**(1), 6 (1992)] studied the feasibility of scaling up from 50- to 75-mm-diameter packed columns directly to industrial columns. Deibele et al. and Gann et al. provide an extensive list of factors that can affect this scale-up, including test mixture, packing pretreatment, column structure, packing installation, snug fit at the wall, column insulation and heat losses, vacuum tightness, measurement and control, liquid distribution, reflux subcooling, prewetting, sampling, analysis, adjusting the number of stages to avoid pinches and analysis issues, evaluation procedure, and more. Data from laboratory columns can be particularly sensitive to some of these factors. Goedecke and Alig show that for wire-mesh structured packing, bench-scale efficiency tends to be better than large-column efficiency, while for corrugated-sheets structured packing, the converse occurs, possibly due to excessive wall flow. For some packings, variation of efficiency with loads at bench scale completely differs from its variation in larger columns. For one structured packing, Kuhni Rombopak 9M, there was little load effect and there was good consistency between data obtained from different sources—at least for one test mixture. Deibele et al. present an excellent set of practical guidelines to improve scale-up reliability. So, it appears that great caution is required for packing data scale-up from bench-scale columns.

**Height** Experimental data for random packings show that HETP slightly increases with bed depth [Billet, Distillation Engineering, Chemical Publishing Co., New York, 1979; "Packed Tower Analysis and Design," Ruhr University, Bochum, Germany, 1989; Eckert and Walter, *Hydrocarbon Processing,* **43**(2), 107 (1964)].

For structured packing, some tests with Mellapak 250Y [Meier, Hunkeler, and Stöcker, *IChemE Symp. Ser.* **56,** p. 3, 3/1 (1979)] showed no effect of bed height on packing efficiency, while others (Cai et al., *Trans IChemE,* vol. 81, Part A, p. 89, January 2003) did show a significant effect.

The effect of bed depth on packing HETP is attributed to liquid maldistribution. Zuiderweg et al. [*IChemE. Symp. Ser.* **104,** A217 (1987)] suggest that the uneven irrigation generates an uneven concentration profile and localized pinching near the bottom of the beds. The tests by Martin, Bravo, and Fair (Paper presented at the National AIChE Meeting, New Orleans, La., 1988) confirm that the problem area is near the bottom. According to the zone-stage and Lockett and Billingham models (above), as well as the empirical correlation by Moore and Rukovena (Fig. 14-64), the more stages per bed, the greater is the rise in HETP with bed depth. The presence and extent of maldistribution play an important role in determining the bed-depth effect.

As the bed depth increases, end effects (i.e., mass transfer in the region of liquid introduction and in the region where liquid drips from the packing supports) become less important. Such end effects tend to lower the HETP observed in short columns, such as pilot-plant columns.

In summary, bed depth may significantly influence HETP. This adds uncertainty to scale-up. Shallow test beds should be avoided. Most investigators use beds at least 1.5 m tall, and often more than 3 m tall. The FRI sampling technique (below) can detect maldistribution along the bed height.

**Loadings** For many random and corrugated-sheet structured packings, HETP is independent of vapor and liquid loadings (Figs. 14-59 and 14-60). For wire-mesh and some corrugated-sheet structured packings, HETP changes with gas and liquid loads.

Wu and Chen [*IChemE Symp. Ser.* **104,** B225 (1987)] recommend pilot testing over the entire range between the expected minimum and maximum operating rates, and taking the highest measured HETP as the basis for scale-up. The author concurs. With structured packings, the load effect may be due to liquid rather than gas loads, and the pilot tests should cover the range of liquid loads (i.e., m/s based on column cross section) that is expected in the prototype.

**Wetting** For operation at low liquid loads, the onset of minimum wetting can adversely affect scale-up, particularly with random packings and aqueous systems. Scale-up reliability at low liquid loads can be improved by pilot-testing at the composition range expected in the prototype, and by using identical packing materials and surface treatment in the pilot tests and in the prototype.

**Underwetting** At the aqueous end of aqueous-organic columns, underwetting is important. Rapid changes of concentration profiles and physical properties in organic-water separations complicate scale-up [Eiden and Kaiser, *IChemE Symp. Ser.* **142,** 757 (1997)]. Near the onset of underwetting, HETP becomes strongly dependent on composition, packing material and surface roughness, and the presence of surfactants. Scale-up reliability can be enhanced by pilot-testing at the composition range expected in the prototype, and by using identical packing material and surface treatment in the pilot tests and in the prototype.

**Preflooding** For one structured packing test with an aqueous system, Billet ("Packed Column Analysis and Design," Ruhr University, Bochum, Germany, 1989) measured higher efficiency for a preflooded bed compared with a non-preflooded bed. Presumably, the preflooding improved either wetting or distribution. Billet recommends preflooding the packing, both in the prototype and in the pilot column, to ensure maximum efficiency.

**Sampling** Fractionation Research Inc. (FRI) developed a sampling technique that eliminates the influence of "end effects" and detects a maldistributed composition profile. This technique [Silvey and Keller, *IChemE Symp. Ser.* **32,** p. 4:18 (1969)] samples the bed at frequent intervals, typically every 0.6 m or so. HETP is determined from a plot of these interbed samples rather than from the top and bottom compositions.

It is imperative that the interbed samplers catch representative samples, which are an average through the bed cross section. Caution is required when the liquid is highly aerated and turbulent (e.g., above 1300 kPa psia or above 1 m/min). The author highly recommends the FRI sampling technique for all other conditions.

**Aging** Billet (loc. cit.) showed that for some plastic packings in aqueous systems, the efficiency after one week's operation was almost double the efficiency of new packings. Little further change was observed after one week. Billet explains the phenomenon by improved wetting. He recommends that data for plastic packings should only be used for scale-up after being in operation for an adequately long period.

## DISTRIBUTORS

**Liquid Distributors** A liquid distributor (or redistributor) should be used in any location in a packed column where an external liquid stream is introduced. Liquid redistributors are also used between packed beds to avoid excessive bed lengths that may impair packing efficiency or mechanical strength. It is best to have the packing supplier also supply the distributor, with the user critically reviewing the design. The user must provide the supplier with concise information about the plugging, corrosive, and foaming tendencies of the service as well as the range of liquid flow rates that it needs to handle and the physical properties of the liquid.

Olsson (*Chem. Eng. Progr.,* p. 57, October 1999) discussed the key for successful distributor design and operation. He states that it is critical to correctly evaluate the fouling potential of the service and design for it (e.g., preventing small holes, filtering the feed, etc.); to avoid gas entry into liquid distributors (e.g., no flashing feed into a liquid distributor); to systematically check the irrigation pattern using a method such as the circle analysis of Moore and Rukovena [*Chem. Plants and Process* (European ed.), p. 11, August 1987; described in detail in Kister's *Distillation Operation,* McGraw-Hill, New York, 1990]; to water-test any liquid distributor (major suppliers have dedicated test stands that are available for those purposes at cost); to ensure correct entry of a feed into a liquid distributor; and to thoroughly inspect a distributor. Kister [*Trans. IChemE.* vol. 81, Part A, p. 5 (January 2003)] found that between 80 and 90 percent of the distributor failures reported in the literature in the last 50 years could have been prevented if users and suppliers had followed Olsson's measures.

A minimum of 40 irrigation points per square meter has been recommended, with 60 to 100 per square meter being ideal [Strigle, *Packed Tower Design and Applications,* 2d ed., Gulf Publishing, Houston, Tex., 1994; Kister, *Distillation Operation,* McGraw-Hill, New York, 1990; Norton Company (now Koch-Glitsch LP), *Packed Column Internals,* Bulletin TA-80R, 1974]. Commercial-scale tests with both random and structured packings showed no improvement in packing efficiency by increasing the irrigation point density above 40 per square meter [Fitz, King, and Kunesh, *Trans. IChemE* **77,** Part A, p. 482 (1999)]. So going to larger numbers of irrigation points per square meter provides little improvement while leading to smaller holes which increases the plugging tendency. In orifice-type distributors, which are the most common type, the head-flow relationship is given by the orifice equation

$$Q = 3.96 \times 10^{-4} K_D n_D d_h^2 h^{0.5} \qquad (14\text{-}163)$$

where $Q$ is the liquid flow rate, $m^3/h$; $K_D$ is the orifice discharge coefficient, with a recommended value of 0.707 (Chen, *Chem. Eng.,* p. 40, March 5, 1984); $n_D$ is the number of holes; $d_h$ is the hole diameter, mm; and $h$ is the liquid head, mm. Equation (14-163) shows that at a given $Q$, increasing $n$ leads to either smaller $d$ or smaller $h$.

Figures 14-68 and 14-69 show common distributor types used for distillation and absorption. An excellent detailed discussion of the types of distributors and their pros and cons was given by Bonilla (*Chem. Eng. Progr.,* p. 47, March 1993). The *perforated pipe* (or *ladder pipe*) distributor (Fig. 14-68*a*) has holes on the underside of the pipes. It is inexpensive, provides a large open area for vapor flow, and does not rely on gravity. On the debit side, it is typically designed for high velocity heads, 500 to 1000 mm of water, which is 5 to 10 times more than gravity distributors, requiring [per Eq. (14-163)] either fewer irrigation points or the use of plugging-prone smaller holes. The high hole velocities make it prone to corrosion and erosion. These disadvantages make it relatively unpopular. A gravity variation of this distributor uses a liquid drum above the distributor that gravity-feeds it.

*Spray* distributors (Fig. 14-68*b*) are pipe headers with spray nozzles fitted on the underside. The spray nozzles are typically wide-angle (often 120°) full-cone. Spray distributors are unpopular in distillation but are common in heat transfer, washing and scrubbing services

(especially in refinery towers), and in small-diameter towers where a single spray nozzle can be used. They are inexpensive and offer a large open area for vapor flow and a robustness for handling of fouling fluids when correctly designed, and the sprays themselves contribute to mass and heat transfer. On the debit side, the spray cones often generate regions of over- and underirrigation, the sprays may not be homogeneous, the spray nozzles are prone to corrosion, erosion, and damage. With highly subcooled liquids, the spray angle may collapse when pushed at high pressure drops (above 100 to 150 kPa) (Fractionation Research Inc., "A Spray Collapse Study," motion picture 919, Stillwater, Okla., 1985). The design and spray pattern are highly empirical. Sprays also generate significant entrainment to the section above [Trompiz and Fair, *Ind. Eng. Chem, Res.*, **39**(6), 1797 (2000)].

*Orifice pan* distributors (Fig. 14-69*a*) and *orifice tunnel* distributors (Fig. 14-69*b*) have floor holes for liquid flow and circular (Fig. 14-69*a*) or rectangular (Fig. 14-69*b*) risers for vapor passages. When they are used as redistributors, a hat is installed above each riser to prevent liquid from the bed above from dripping into the risers. Unlike the ladder pipe and spray distributors that operate by pressure drop, orifice distributors operate by gravity, and therefore use a much smaller liquid head, typically 100 to 150 mm at maximum rates. Using Eq. (14-163), the lower head translates to either more distributions points ($n_D$), which helps irrigation quality, or larger hole diameters, which resists plugging. However, the low liquid velocities, large residence times, and open pans (or troughs) make them more prone to plugging than the pressure distributors. A good hole pattern and avoidance of oversized risers are essential. Orifice distributors are self-collecting, a unique advantage for redistributors. Orifice distributors are one of the most popular types and are favored whenever the liquid loads are high enough to afford hole diameters large enough to resist plugging (>12 mm).

*Orifice trough* (or *orifice channel*) distributors (Fig. 14-69*c–f*) are some of the most popular types. The trough construction does away with the multitude of joints in the orifice pans, making them far more leak-resistant, a major advantage in large towers and low-liquid-rate applications. Liquid from a central parting box (Fig. 14-69*c*, *e*) or middle channel (Fig. 14-69*d*) is metered into each trough. The troughs can have floor holes, but elevating the holes above the floor (Fig. 14-69*c–g*) is preferred as it enhances plugging resistance. Tubes (Fig. 14-69*c*, *d*, *f*) or baffles (Fig. 14-69*e*) direct the liquid issuing from the elevated holes downward onto the packings. Orifice trough distributors are not self-collecting. When used for redistribution, they require a liquid collector to be installed above them.

Turndown of orifice distributors is constrained to about 2 : 1 by Eq. (14-163). For example, a 100-mm liquid head at the design drops to 25 mm when the liquid rate is halved. Lower heads give poor irrigation and high sensitivity to levelness. Turndown is often enhanced by using two rows of side tubes (in the Fig. 14-69*c* type) or of side holes (in the Fig. 14-69*d* or *e* types). *Perforated drip tubes* (as in Fig. 14-69*d*) are popular in either orifice trough or orifice pan distributors. The lower, smaller hole is active at low liquid rates, with the larger upper hole becoming active at higher liquid rates. Use of perforated drip tubes is not recommended when the vapor dew point is much higher than the liquid bubble point, because liquid may boil in the tubes, causing dryout underneath [Kister, Stupin, and Oude Lenferink, *IChemE. Symp. Ser.* **152,** p. 409, London (2006)].

A popular type of the orifice trough distributor is the *splash plate* distributor (Fig. 14-69*e*). The splash plates spread the issuing liquid over their lengths, making it possible to reduce the number of irrigation points. This is a special advantage with small liquid rates, as fewer irrigation points (at a given head) translate to larger, more fouling-resistant

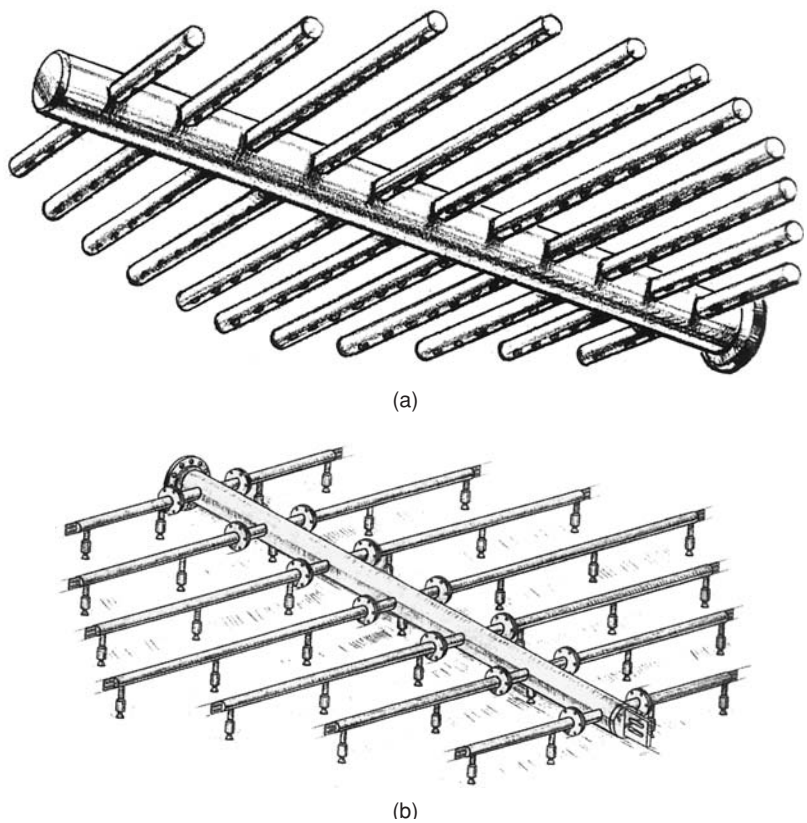

**FIG. 14-68** Pressure liquid distributors. (*a*) Ladder pipe. (*b*) Spray. (*Courtesy of Koch-Glitsch LP.*)

hole diameters [Eq. (14-163)]. Lack of the drip tubes eliminates the possible in-tube boiling issue (above).

*Multistage* orifice trough distributors (Fig. 14-69*f*) also attempt to provide good irrigation at low liquid rates without resorting to plugging-prone small holes. The primary stage uses fewer irrigation points. Liquid from the primary stage is further split at the secondary stage. The secondary stage is of small size, so leveling and small flow variations are not of great concern. The secondary stage may use the same or a different liquid splitting principle as the primary stage. Even short layers of structured packings have been used as a secondary distribution stage.

*Notched trough* distributors (Fig. 14-69*g*) consist of parallel troughs with side V notches. This distributor obeys the triangular notch equation instead of the orifice equation, which makes the flow proportional to $h^{2.5}$ [instead of $h^{0.5}$ in Eq. (14-163)]. This high power renders the distributor highly sensitive to out-of-levelness and hydraulic gradients and makes it difficult to incorporate a large number of distribution points. Since the liquid issues sideways, it is difficult to predict where the liquid will hit the packings. Baffles are sometimes used to direct the liquid downward. Overall, the quality of distribution is inferior to that of orifice distributors, making notched-trough distributors unpopular. Their strength is their insensitivity to fouling and corrosive environments and their ability to handle high liquid rates at good turndown.

With any trough distributor, and especially those with V notches, excessive hydraulic gradients must be avoided. This is often achieved by using more parting boxes.

The hydraulic gradient is highest where the liquid enters the troughs, approaching zero at the end of the trough. The hydraulic gradient (between entry point and trough end) can be calculated from [Moore and Rukovena, *Chemical Plants and Processing* (European ed.), p. 11, August 1987]

**Flashing Feed and Vapor Distributors** When the feed or reflux is a flashing feed, the vapor must be separated out of the liquid before the liquid enters a liquid distributor. At low velocities (only), this can be achieved by a *bare nozzle* (Fig. 14-70*a*). A *V baffle* (Fig. 14-70*b*) is sometimes installed as a primitive flashing feed or vapor distributor.

For better vapor-liquid separation and distribution, with smaller-diameter towers (<1.5 m), a *flash chamber* (Fig. 14-70*c*) separates the liquid from the vapor, with the collected liquid descending via downpipes to a liquid distributor below. The flash chamber can be peripheral (Fig. 14-70*c*) or central. In larger towers, *gallery distributors* (Fig. 14-70*d*) are preferred. The flashing feed enters the peripheral section of the upper plate (the gallery) where vapor disengages and flows up, with liquid descending through holes (Fig. 14-70*d*) or down pipes onto the liquid distributor below. Alternatively, an external knockout pot is sometimes used to give separate vapor and liquid feeds.

The *vapor horn* (Fig. 14-71*a*) is unique for high-velocity feeds in which vapor is the continuous phase with liquid present as suspended drops in the feed vapor. This is common when the feed makes up the bulk of the vapor traffic in the tower section above. Typical examples are feeds to refinery vacuum and crude towers and rich solution feeds to hot carbonate regenerators. A tangential helical baffle or vapor horn, covered at the top, open at the bottom, and spiraling downward, is used at the feed entry. This baffle forces the vapor to follow the contour of the vessel as it expands and decreases in velocity. Liquid droplets, due to their higher mass, tend to collide with the tower wall, which deflects them downward, thus reducing upward entrainment. Large forces, generated by hurricane-force winds and vapor flashing, are absorbed by the entire tower wall rather than by a small area. A wear plate is required at the tower wall. Some designs have vane openings on the inside wall.

Alternatively, multivane triangular diffusers (Fig. 14-71*b*, *c*) such as the Schoepentoeter have been successful for high-velocity vapor-rich feeds. These are used with radial (as distinct from tangential) nozzles. The vanes knock out the liquid and direct it downward while the vapor expands to the tower diameter.

Pilot-scale tests by Fan et al. [*IChemE Symp. Ser.* **142,** 899 (1997)] compared vapor distribution and entrainment from sparger, vapor horns, and multivane triangular diffusers. Vapor horns gave the best overall performance considering vapor distribution, entrainment, and pressure drop, with multivane distributors doing well too. The designs of the inlets compared, however, were not optimized so the comparison could have reflected deviations from optimum rather than real differences between the devices.

Low-velocity vapor-only feeds often enter via bare nozzles or V baffles (above). At higher velocities, perforated vapor spargers are used. At high velocities, vapor horns and Schoepentoeters are often preferred. Alternatively or additionally, a vapor distributor may be mounted above the feed. The vapor distributor is a chimney tray (Fig. 14-72) where liquid is collected on the deck and flows via downcomers or is drawn out while vapor passes through the chimneys. To be effective as a vapor distributor, the pressure drop through the chimneys needs to be high enough to counter the maldistributed vapor. It was recommended to make the pressure drop through the chimneys at least equal to the velocity head at the tower inlet nozzle (Strigle, *Random Packings and Packed Towers,* Gulf Publishing, Houston, Tex., 1987), with common pressure drops ranging from 25 to 200 mm water.

## OTHER PACKING CONSIDERATIONS

**Liquid Holdup** Liquid holdup is the liquid present in the void spaces of the packing. Reasonable liquid holdup is necessary for good mass transfer and efficient tower operation, but beyond that, it should be kept low. High holdup increases tower pressure drop, the weight of the packing, the support load at the bottom of the packing and tower, and the tower drainage time. Most important, when distilling thermally unstable materials, excessive holdup raises product degradation and fouling, and with hazardous chemicals, increases undesirable inventories.

The effect of liquid and gas rates on the operating holdup is shown in Figs. 14-73 and 14-74. In the preloading regime, holdup is essentially independent of gas velocity, but is a strong function of liquid flow rate and packing size. Smaller packings and high liquid rates tend to have greater holdup.

Holdup can be estimated by using Buchanan's correlation [*Ind. Eng. Chem. Fund.* **6,** 400 (1967)], as recommended in previous editions of this handbook. More recent correlations by Billet and Schultes [*IChemE. Symp. Ser.* **104,** A159 (1987)], by Maćkowiak

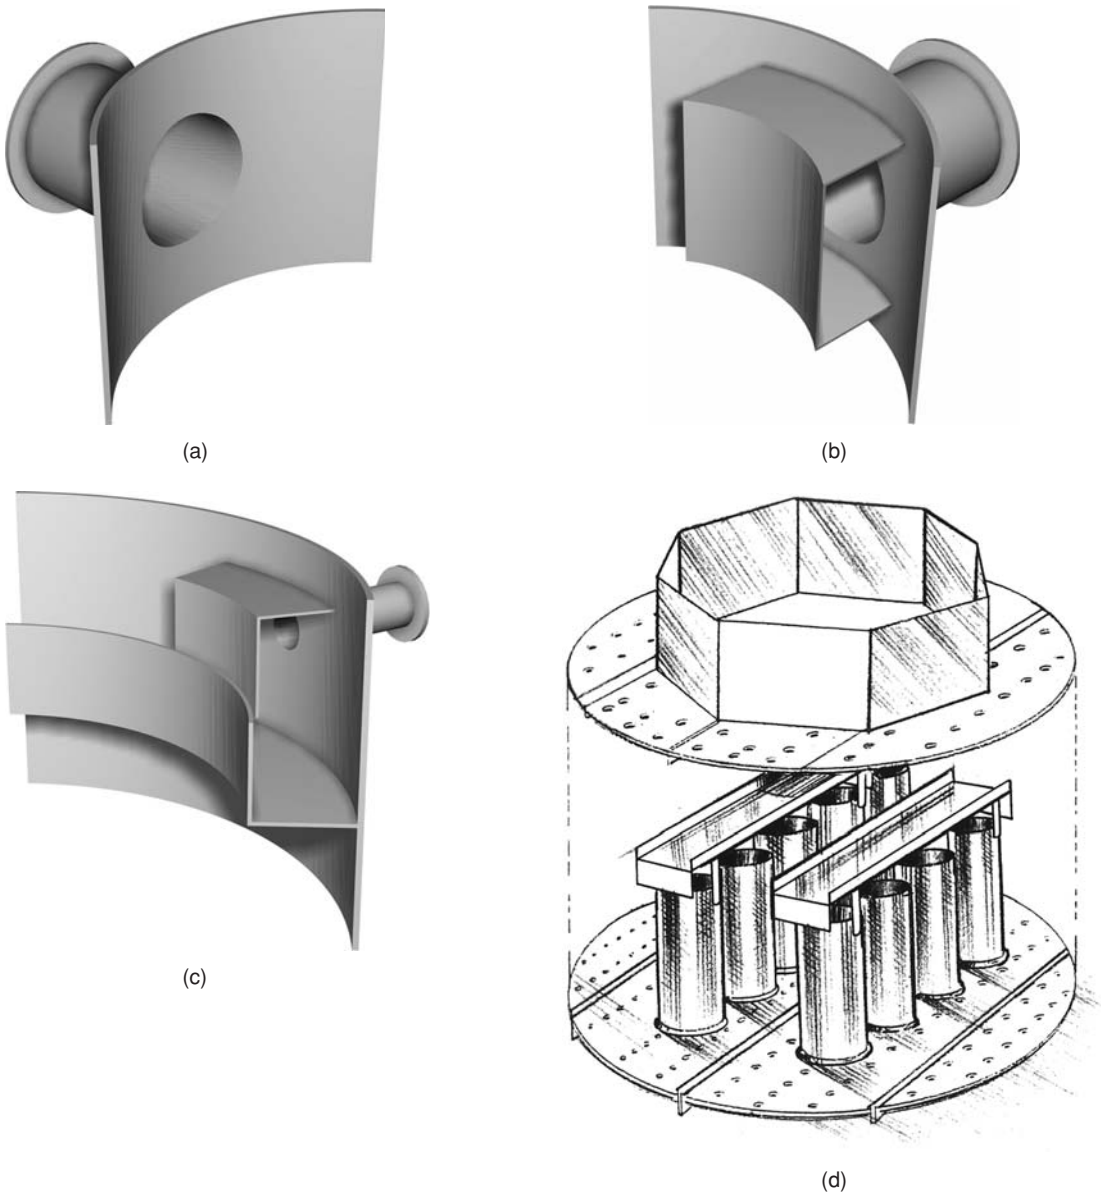

**FIG. 14-70** Flashing feed and vapor distributors. (*a*) Bare nozzle. (*b*) Rounded V baffle. (*c*) Peripheral flash box—the box extends right around the tower wall, with the collected liquid descending via downpipes to a liquid distributor below. (*d*) Gallery distributor—the feed enters the gallery area (upper plate). *(Parts a–c, courtesy of Sulzer Chemtech; part d, courtesy of Koch-Glitsch LP.)*

("Fluiddynamik von Kolonnen mit Modernen Füllkörpern und Packungen für Gas/Flüssigkeitssysteme, Otto Salle Verlag, Frankfurt am Main, and Verlag Sauerländer, Aarau, 1991), and by Mersmann and Deixler [*Chem. Ing. Tech.* **58**(1), 19 (1986)] apply to second- and third-generation random packings as well as to some structured packings.

Stichlmair and Fair (*Distillation Principles and Practice,* Wiley-VCH, New York, 1998) show that liquid holdup is primarily a function of the liquid Froude number, specific surface area of the packing, and physical properties. They recommend the correction by Engel, Stichlmair, and Geipel [*Ind. Eng. Chem. Symp. Ser.* **142,** 939 (1997)].

$$h_{Lo} = 0.93\left(\frac{U_L^2 a_p}{g}\right)^{1/6}\left(\frac{\mu_L^2 a_p^3}{\rho_L^2 g}\right)^{1/10}\left(\frac{\sigma a_p^2}{1000\rho_L g}\right)^{1/8} \quad (14\text{-}165)$$

where $h_{Lo}$ = liquid holdup, fractional
$U_L$ = liquid superficial velocity, m/s
$a_p$ = packing specific surface area, $m^2/m^3$
$g$ = acceleration due to gravity, m/s
$\mu_L$ = liquid viscosity, kg/(m·s)
$\sigma$ = surface tension, mN/m

The Engel, Stichlmair, and Geipel correlation applies only in the preloading regime. The packing geometry is represented in the

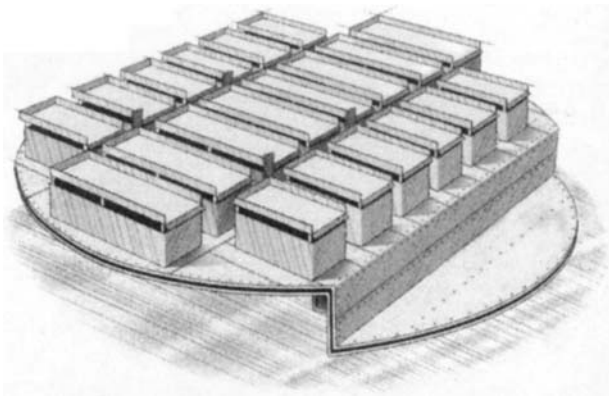

**FIG. 14-72** Chimney tray vapor distributor. *(Reprinted courtesy of Koch-Glitsch LP.)*

correlation solely by the readily available specific surface area (Tables 14-13 and 14-14).

**Minimum Wetting Rate** The minimum wetting rate (MWR) is the lower stability limit of packings. Below this liquid load the liquid film on the packing surfaces breaks up and dewetting occurs. The area available for mass transfer diminishes, and efficiency drops.

Schmidt [*IChemE Symp. Ser.* **56,** 3.1/1 (1979)] described the MWR in terms of a force balance at a dry patch along the path of a falling liquid film. While the gravity and viscous forces resist dewetting, the surface tension and vapor shear forces tend to dewet the falling film. The MWR therefore rises with an increase in surface tension and liquid density, and with a decrease in liquid viscosity. Large packing sizes and poor surface wetting characteristics also contribute to higher MWR.

Schmidt presented a fundamental correlation to predict minimum wetting for Raschig and Pall® rings. More popular have been the Glitsch rules of thumb [Table 14-16; Glitsch, Inc. (now Koch Glitsch), Bulletin 345, Dallas, Tex., 1986] for CMR® random packings with packing surface areas around 200 $m^2/m^3$. To extend these rules to other random packings, Kister (*Distillation Design*, McGraw-Hill, New York, 1992) applied Schmidt's model to give

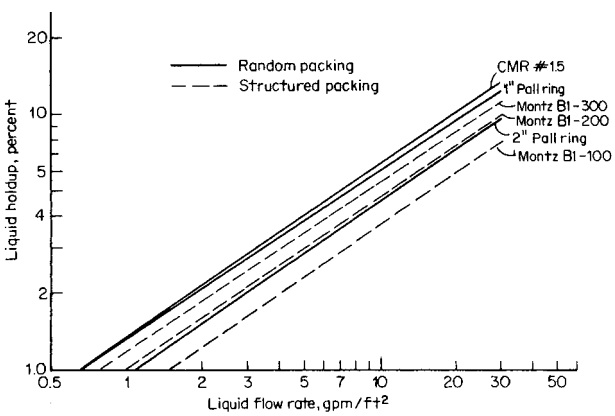

**FIG. 14-73** Liquid holdup, air-water data by Billet ("Packed Column Design and Analysis," Ruhr University, Bochum, Germany), preloading regime. *(From Kister, H. Z.,* Distillation Design, *copyright © by McGraw-Hill; reprinted with permission.)*

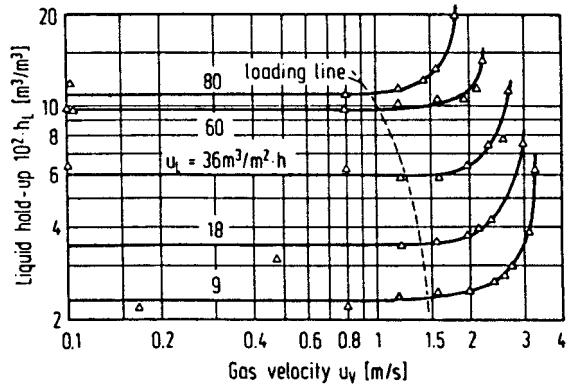

**FIG. 14-74** Effect of liquid and gas rates on the operating holdup of modern random packings (25-mm NorPac®). [*From R. Billet and M. Schultes,* IChemE Symp. Ser. ***104,*** *p. A159, 1987. Reprinted courtesy of the Institution of Chemical Engineers (UK).*]

$$Q_{MW} \approx (Q_{MW} \text{ from Table 14-16}) \times (200/a_p)^{0.5} \qquad (14\text{-}166)$$

The Glitsch brochure did not state the surface tension bases of Table 14-16. The author believes that they conservatively apply to organic and hydrocarbon systems ($\sigma$ <25 mN/m). For water ($\sigma$ = 70 mN/m) the author believes that double the values from Table 14-16 is reasonable.

Some surface treatments of the packing (e.g., oxidizing, sandblasting, etching) can substantially reduce the MWR. Chuang and Miller [*Can. J. Chem. Eng.* **66**(6), 377 (1988)] tested a metallic random packing with an aqueous system at low liquid rates (about 0.4 $m^3/hm^2$). They used two alternative techniques for oxidizing the packing surfaces. The packings oxidized with the more effective technique gave a column efficiency twice as high as those oxidized by the others.

Superior wetting characteristics characterize structured packings. Satisfactory performance was reported down to 0.25 and 0.12 $m^3/hm^2$ in corrugated-sheet and wire-mesh metal structured packings, respectively. FRI's commercial-scale tests (Fitz and Kunesh, Paper presented at the AIChE Annual Meeting, Chicago, Nov. 1996) demonstrated good efficiencies down to 0.5 $m^3/hm^2$ (no lower limit reached) with good liquid and vapor distribution.

**Two Liquid Phases** Two liquid phases often occur in heterogeneous distillation, in steam stripping, and in solvent recovery. Harrison (*Chem. Eng. Progr.,* p. 80, November 1990) and Meier et al. [*IChemE Symp. Ser.* **152,** 267 (2006)] saw no reason to expect unusual capacity or pressure drop limitations due to the presence of the second liquid phase, suggesting that standard correlations for these should apply.

In contrast, both expressed uncertainty in predicting packing efficiency. Harrison presented two case studies: In one, adding water to two water-insoluble organics had no effect on HETP; in another, a key

**TABLE 14-16 Glitsch's Rule of Thumb for Minimum Wetting**

Basis: CMR with $a_p$ > 150 $m^2/m^3$

| Material | Minimum wetting rate, $m^3/(m^2 \cdot h)$ |
|---|---|
| Unglazed ceramic (chemical stoneware) | 0.5 |
| Oxidized metal (carbon steel, copper) | 0.7 |
| Surface-treated metal (etched stainless steel) | 1.0 |
| Glazed ceramic | 2.0 |
| Glass | 2.5 |
| Bright metal (stainless steel, tantalum, other alloys) | 3.0 |
| PVC-CPVC | 3.5 |
| Polypropylene | 4.0 |
| Fluoropolymers (PTFE type) | 5.0 |

component was soluble in both liquid phases, and HETP was about 50 percent above normal. Harrison argued that a second liquid phase leads to lower efficiency only when it impairs diffusion of the key species. On this basis, Harrison expects efficiency loss also when an "inert" liquid or vapor represents a large fraction of the liquid or vapor phase. Meier et al. recommend obtaining efficiencies by scaling up laboratory-scale data using a similar type of packing.

Both Harrison and Meier et al. emphasize adequately distributing each liquid phase to the packing. Harrison noted that a well-designed ladder pipe distributor can maintain high velocities and low residence times that provide good mixing. With trough distributors that separate the phases and then distribute each to the packing, a light-to-heavy phase maldistribution may occur, especially when the phase ratio and separation vary. Meier et al. noted the existence of a cloudy two-liquid layer between the clear light and heavy liquid and recommend an additional middle distribution point for this layer. They also noticed that phase separation unevenness can have a large influence on the phase ratio irrigated to the packing.

**High Viscosity and Surface Tension** Bravo (Paper presented at the AIChE Spring National Meeting, Houston, Tex., 1995) studied a system that had 425-cP viscosity, 350 mN/m surface tension, and a high foaming tendency. He found that efficiencies were liquid-phase-controlled and could be estimated from theoretical HTU models. Capacity was less than predicted by conventional methods which do not account for the high viscosity. Design equations for orifice distributors extended well to the system once the orifice coefficient was calculated as a function of the low Reynolds number and the surface tension head was taken into account.

# OTHER TOPICS FOR DISTILLATION AND GAS ABSORPTION EQUIPMENT

## COMPARING TRAYS AND PACKINGS

Most separations can be performed either with trays or with packings. The factors below represent economic pros and cons that favor each and may be overridden. For instance, column complexity is a factor favoring trays, but gas plant demethanizers that often use one or more interreboilers are traditionally packed.

### Factors Favoring Packings

*Vacuum systems.* Packing pressure drop is much lower than that of trays because the packing open area approaches the tower cross-sectional area, while the tray's open area is only 8 to 15 percent of the tower cross-sectional area. Also, the tray liquid head, which incurs substantial pressure drop (typically about 50 mm of the liquid per tray), is absent in packing. Typically, tray pressure drop is of the order of 10 mbar per theoretical stage, compared to 3 to 4 mbar per theoretical stage with random packings and about one-half of that with structured packings.

Consider a vacuum column with 10 theoretical stages, operating at 70-mbar top pressure. The bottom pressure will be 170 mbar with trays, but only 90 to 110 mbar with packings. The packed tower will have a much better relative volatility in the lower parts, thus reducing reflux and reboil requirements and bottom temperature. These translate to less product degradation, greater capacity, and smaller energy consumption, giving packings a major advantage.

*Lower-pressure-drop applications.* When the gas is moved by a fan through the tower, or when the tower is in the suction of a compressor, the smaller packing pressure drop is often a controlling consideration. This is particularly true for towers operating close to atmospheric pressure. Here excessive pressure drop in the tower increases the size of the fan or compressor (new plant), bottlenecks them (existing plant), and largely increases power consumption. Due to the compression ratio, pressure drop at the compressor discharge is far less important and seldom a controlling consideration.

*Revamps.* The pressure drop advantage is invaluable in vacuum column revamps, can be translated to a capacity gain, an energy gain, a separation improvement, or various combinations of these benefits. Likewise, for towers in the suction of compressors, replacing trays by packings reduces the compression ratio and helps debottleneck the compressor.

Packings also offer an easy tradeoff between capacity and separation. In the loaded sections of the tower, larger packings can overcome capacity bottlenecks at the expense of loss in separation. The separation loss can often be regained by retrofitting with smaller packings in sections of the tower that are not highly loaded. In tray towers, changing tray spacing gives similar results, but is more difficult to do.

*Foaming (and emulsion).* The low gas and liquid velocities in packing suppress foam formation. The large open area of the larger random packing promotes foam dispersal. Both attributes make random packing excellent for handling foams. In many cases recurrent foaming was alleviated by replacing trays by random packing, especially when tray downcomers were poorly designed.

Switching from trays to structured packing can aggravate foaming. While the low gas and liquid velocities help, the solid walls restrict lateral movement of foams and give support to the foams.

*Small-diameter columns.* Columns with diameter less than 1 m (3 ft) are difficult to access from inside to install and maintain the trays. "Cartridge" trays or an oversized diameter are often used. Either option is expensive. Cartridge trays also run into problems with sealing to the tower wall and matching tower to tray hardware [Sands, *Chem. Eng.*, p. 86 (April 2006)]. Packing is normally a cheaper and more desirable alternative.

*Corrosive systems.* The practical range of packing materials is wider. Ceramic and plastic packings are cheap and effective. Trays can be manufactured in nonmetals, but packing is usually a cheaper and more desirable alternative.

*Low liquid holdup.* Packings have lower liquid holdup than do trays. This is often advantageous for reducing polymerization, degradation, or the inventory of hazardous materials.

*Batch distillation.* Because of the smaller liquid holdup of packing, a higher percentage of the liquid can be recovered as top product.

### Factors Favoring Trays

*Solids.* Trays handle solids much more easily than packing. Both gas and liquid velocities on trays are often an order of magnitude higher than through packing, providing a sweeping action that keeps tray openings clear. Solids tend to accumulate in packing voids. There are fewer locations on trays where solids can be deposited. Plugging in liquid distributors has been a common trouble spot. Cleaning trays is much easier than cleaning packings.

Not all trays are fouling-resistant. Floats on moving valve trays tend to "stick" to deposits on the tray deck. Fouling-resistant trays have large sieve holes or large fixed valves, and these should be used when plugging and fouling are the primary considerations.

There is much that can be done to alleviate plugging with random packing. Large, open packing with minimal pockets offers good plugging resistance. Distributors that resist plugging have large holes (> 13-mm diameter). Such large holes are readily applied with high liquid flow rates, but often not practical for small liquid flow rates.

*Maldistribution.* The sensitivity of packing to liquid and gas maldistribution has been a common cause of failures in packed towers. Maldistribution issues are most severe in large-diameter towers, long beds, small liquid flow rates, and smaller packing. Structured packing is generally more prone to maldistribution than random packing. While good distributor design, water testing, and inspection can eliminate most maldistribution issues, it only takes a few small details that fall through the cracks to turn success into failure. Due to maldistribution, there are far more failures experienced

with packing than in trays, and it takes more trials "to get it right" than with trays. This makes trays more robust.

*Complex towers.* Interreboilers, intercondensers, cooling coils, and side drawoffs are more easily incorporated in trays than in packed towers. In packed towers, every complexity requires additional distribution and/or liquid collection equipment.

*Feed composition variation.* One way of allowing for design uncertainties and feedstock variation is by installing alternate feed points. In packed towers, every alternate feed point requires expensive distribution equipment.

*Performance prediction.* Due to their sensitivity to maldistribution there is greater uncertainty in predicting packed column performance.

*Chemical reaction, absorption.* Here the much higher liquid holdup on trays provides greater residence time for absorption or chemical reaction than does packing.

*Turndown.* Moving valve and bubble-cap trays normally give better turndown than packings. Unless very expensive distributors are used, packed tower turndown is usually limited by distributor turndown.

*Weight.* Tray towers usually weigh less than packed towers, saving on the cost of foundations, supports, and column shell.

**Trays vs. Random Packings** The following factors generally favor trays compared to random packings, but not compared to structured packings.

*Low liquid rates.* With the aid of serrated weirs, splash baffles, reverse-flow trays, and bubble-cap trays, low liquid rates can be handled better in trays. Random packings suffer from liquid dewetting and maldistribution sensitivity at low liquid rates.

*Process surges.* Random packings are usually more troublesome than trays in services prone to process surges (e.g., those caused by slugs of water entering a hot oil tower, relief valve lifting, compressor surges, or instability of liquid seal loops). Structured packings are usually less troublesome than trays in such services.

**Trays vs. Structured Packings** The following factors generally favor trays compared to structured packings, but not compared to random packings.

*Packing fires.* The thin sheets of structured packing (typically 0.1 mm) poorly dissipate heat away from hot spots. Also, cleaning, cooling, and washing can be difficult, especially when distributors or packing plug up. Many incidents of packing fires during turnarounds (while towers with structured packings were open to atmosphere) have been reported. Most of these fires were initiated by pyrophoric deposits, hot work (e.g., welding) above the packing, opening the tower while hot organics were still present, and packing metallurgy that was not fire-resistant. Detailed discussion can be found in Fractionation Research Inc. (FRI) Design Practices Committee, "Causes and Prevention of Packing Fires," *Chem. Eng.,* July 2007.

*Materials of construction.* Due to the thin sheets of structured packings, their materials of construction need to have better resistance to oxidation or corrosion. For a service in which carbon steel is usually satisfactory with trays, stainless steel is usually required with structured packings.

*Column wall inspection.* Due to their snug fit, structured packings are easily damaged during removal. This makes it difficult to inspect the column wall (e.g., for corrosion).

*Washing and purging.* Thorough removal of residual liquid, wash water, air, or process gas trapped in structured packings at startup and shutdown is more difficult than with trays. Inadequate removal of these fluids may be hazardous.

*High liquid rates.* Multipass trays effectively lower the liquid load "seen" by each part of the tray. A similar trick cannot be applied with packings. The capacity of structured packings tends to rapidly fall off at high liquid rates.

**Capacity and Efficiency Comparison** Kister et al. [*Chem. Eng. Progr.,* **90**(2), 23 (1994)] reported a study of the relative capacity and efficiency of conventional trays, modern random packings, and conventional structured packings. They found that, for each device optimally designed for the design requirements, a rough guide could be developed on the basis of flow parameter $L/G\ (\rho_G/\rho_L)^{0.5}$ (abcissa in Figs. 14-31, 14-55, and 14-56) and the following tentative conclusions could be drawn:

***Flow Parameter 0.02–0.1***

1. Trays and random packings have much the same efficiency and capacity.
2. Structured packing efficiency is about 1.5 times that of trays or random packing.
3. At a parameter of 0.02, the structured packing has a 1.3–1.4 capacity advantage over random packing and trays. This advantage disappears as the parameter approaches 0.1.

***Flow Parameter 0.1–0.3***

1. Trays and random packings have about the same efficiency and capacity.
2. Structured packing has about the same capacity as trays and random packings.
3. The efficiency advantage of structured packing over random packings and trays decreases from 1.5 to 1.2 as the parameter increases from 0.1 to 0.3.

***Flow Parameter 0.3–0.5***

1. The loss of capacity of structured packing is greatest in this range.
2. The random packing appears to have the highest capacity and efficiency with conventional trays just slightly behind. Structured packing has the least capacity and efficiency.

Experience indicates that use of structured packings has capacity/efficiency disadvantages in the higher-pressure (higher-flow-parameter) region.

Zuiderweg and Nutter [*IChemE Symp. Ser.* **128,** A481 (1992)] explain the loss of capacity/efficiency by a large degree of backmixing and vapor recycle at high flow parameters, promoted by the solid walls of the corrugated packing layers.

## SYSTEM LIMIT: THE ULTIMATE CAPACITY OF FRACTIONATORS

Liquid drops of various sizes form in the gas-liquid contact zones of tray or packed towers. Small drops are easily entrained upward, but their volume is usually too small to initiate excessive liquid accumulation (flooding). When the gas velocity is high enough to initiate a massive carryover of the larger drops to the tray above, or upward in a packed bed, liquid accumulation (entrainment flooding) takes place. This flood can be alleviated by increasing the tray spacing or using more hole areas on trays or by using larger, more open packings.

Upon further increase of gas velocity, a limit is reached when the superficial gas velocity in the gas-liquid contact zone exceeds the settling velocity of large liquid drops. At gas velocities higher than this, ascending gas lifts and carries over much of the tray or packing liquid, causing the tower to flood. This flood is termed *system limit* or *ultimate capacity*. This flood cannot be debottlenecked by improving packing size or shape, tray hole area, or tray spacing. The system limit gas velocity is a function only of physical properties and liquid flow rate. Once this limit is reached, the liquid will be blown upward. This is analogous to spraying water against a strong wind and getting drenched (Yangai, *Chem.* Eng., p. 120, November 1990). The system limit represents the ultimate capacity of the vast majority of existing trays and packings. In some applications, where very open packings (or trays) are used, such as in refinery vacuum towers, the system limit is the actual capacity limit.

The original work of Souders and Brown [*Ind. Eng. Chem.* **26**(1), 98 (1934), Eq. (14-80)] related the capacity of fractionators due to entrainment flooding to the settling velocity of drops. The concept of system limit was advanced by Fractionation Research Inc. (FRI), whose measurements and model have recently been published (Fitz and Kunesh, Distillation 2001: Proceedings of Topical Conference, AIChE Spring National Meeting, Houston, Tex., 2001; Stupin, FRI Topical Report 34, 1965 available through Special Collection Section, Oklahoma State University Library, Stillwater, Okla.). Figure 14-75 is a plot of FRI system limit data (most derived from tests with dual-flow trays with 29 percent hole area and 1.2- to 2.4-m tray spacing) against liquid superficial velocity for a variety of systems (Stupin, loc. cit.,

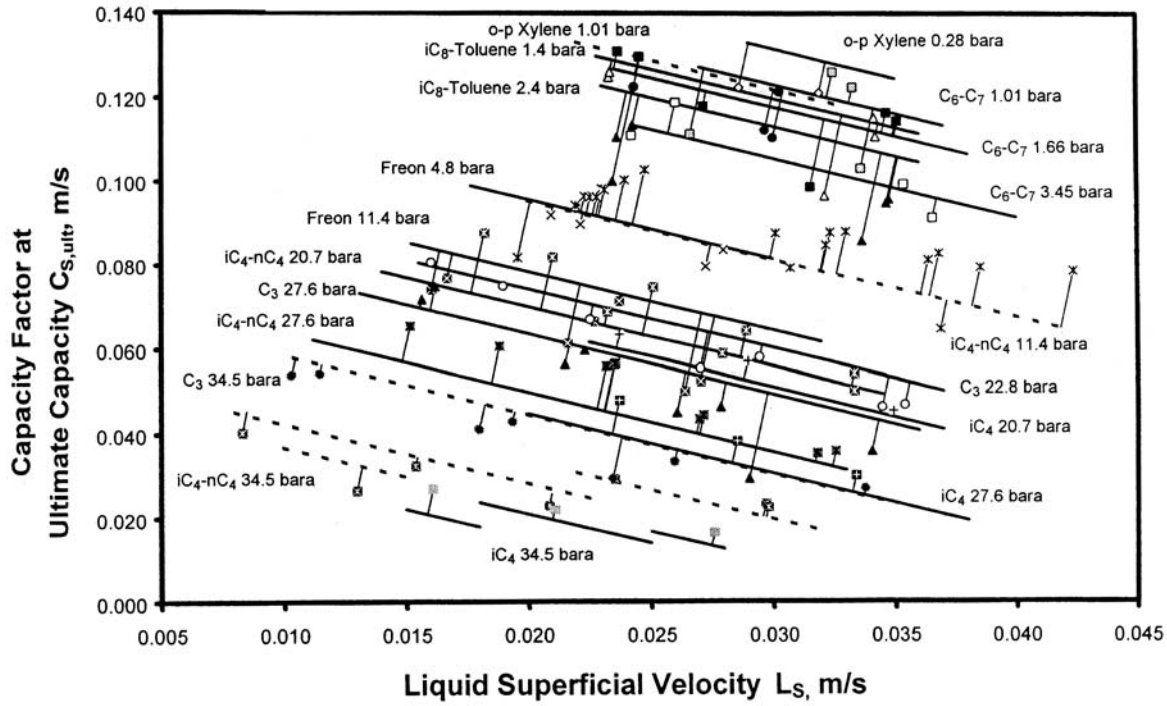

**FIG. 14-75** Effect of liquid rate on ultimate capacity at higher liquid rates. *(From Stupin, W. J., and H. Z. Kister,* Trans. IChemE, *vol. 81, Part A, p. 136, January 2003. Reprinted courtesy of IChemE.)*

1965). The data show a constant-slope linear dependence of the system limit *C*-factor on the liquid load. There was a shortage of data at low liquid loads. Later data (Fig. 14-76) showed that as the liquid load was reduced, the system limit $C_{s,ult}$ stopped increasing and reached a limiting value. Based on this observation, Stupin and Kister [*Trans. IChemE* **81,** Part A, p. 136 (January 2003)] empirically revised the earlier Stupin/FRI correlation to give

$$C_1 = 0.445(1 - F)\left(\frac{\sigma}{\Delta\rho}\right)^{0.25} - 1.4L_S \qquad (14\text{-}167)$$

$$C_2 = 0.356(1 - F)\left(\frac{\sigma}{\Delta\rho}\right)^{0.25} \qquad (14\text{-}168)$$

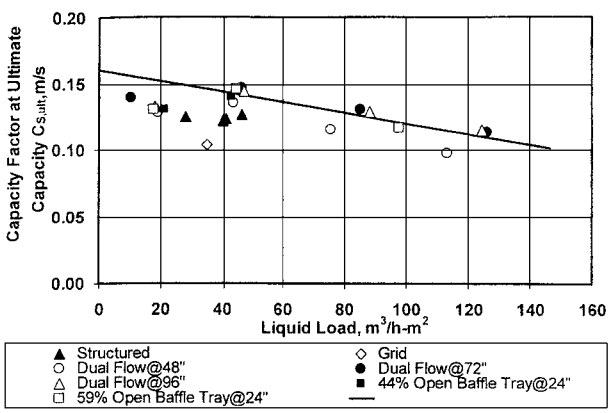

**FIG. 14-76** Comparison of original ultimate capacity correlation to test data, $C_6/C_7$, 1.66 bar. *(From Stupin, W. J., and H. Z. Kister,* Trans. IChemE, *vol. 81, Part A, p. 136, January 2003. Reprinted courtesy of IChemE.)*

$$C_{s,ult} = \text{smaller of } C_1 \text{ and } C_2 \qquad (14\text{-}169)$$

where

$$F = \frac{1}{1 + 1.4(\Delta\rho/\rho_G)^{1/2}} \qquad (14\text{-}170)$$

In Eqs. (14-167) through (14-170), $C_{s,ult}$ is the system limit *C*-factor based on the tower superficial area [see Eq. (14-77) for *C*-factor definition]; $L_S$ is the liquid superficial velocity, m/s; $\sigma$ is the surface tension, mN/m; $\Delta\rho$ is the difference between the liquid and gas densities, $kg/m^3$; and $\rho_G$ is the gas density, $kg/m^3$.

Stupin and Kister (loc. cit.) relate the flattening of the curve in Fig. 14-76 at low liquid loads to the formation of more, smaller, easier-to-entrain liquid drops when the liquid load is lowered beyond the limiting liquid load. It follows that devices that can restrict the formation of smaller drops may be able to approach the system limit capacity predicted by Stupin's original equation [Eq. (14-167)] even at low liquid loads.

The only devices capable of debottlenecking a tray system-limit device are those that introduce a new force that helps disentrain the vapor space. Devices that use centrifugal force (see "Centrifugal Force Deentrainment") are beginning to make inroads into commercial distillation and have achieved capacities as high as 25 percent above the system limit. Even the horizontal vapor push (see "Truncated Downcomers/Forward-Push Trays") can help settle the entrained drops, but to a much lesser extent. It is unknown whether the horizontal push alone can achieve capacities exceeding the system limit.

## WETTED-WALL COLUMNS

Wetted-wall or falling-film columns have found application in mass-transfer problems when high-heat-transfer-rate requirements are concomitant with the absorption process. Large areas of open surface

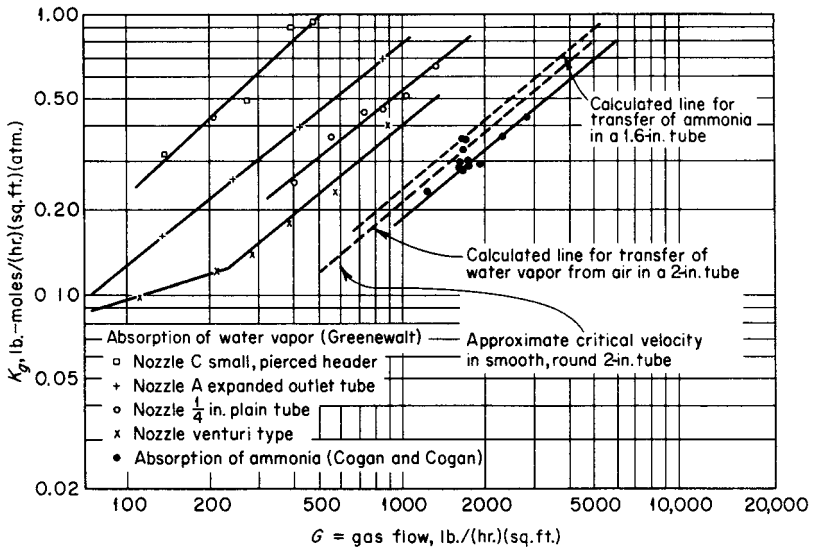

**FIG. 14-77** Mass-transfer rates in wetted-wall columns having turbulence promoters. To convert pound-moles per hour-square foot-atmosphere to kilogram-moles per second-square meter-atmosphere, multiply by 0.00136; to convert pounds per hour-square foot to kilograms per second-square meter, multiply by 0.00136; and to convert inches to millimeters, multiply by 25.4. (Data of Greenewalt and Cogan and Cogan, *Sherwood, and Pigford,* Absorption and Extraction, *2d ed., McGraw-Hill, New York, 1952.*)

are available for heat transfer for a given rate of mass transfer in this type of equipment because of the low mass-transfer rate inherent in wetted-wall equipment. In addition, this type of equipment lends itself to annular-type cooling devices.

Gilliland and Sherwood [*Ind. Eng. Chem.*, **26,** 516 (1934)] found that, for vaporization of pure liquids in air streams for streamline flow,

$$\frac{k_g D_{\text{tube}}}{D_g}\,\frac{P_{BM}}{P} = 0.023 N_{\text{Re}}^{0.83} N_{\text{Sc}}^{0.44} \qquad (14\text{-}171)$$

where $D_g$ = diffusion coefficient, ft²/h
$D_{\text{tube}}$ = inside diameter of tube, ft
$k_g$ = mass-transfer coefficient, gas phase, lb·mol/(h·ft²) (lb·mol/ft³)
$P_{BM}$ = logarithmic mean partial pressure of inert gas, atm
$P$ = total pressure, atm
$N_{\text{Re}}$ = Reynolds number, gas phase
$N_{\text{Sc}}$ = Schmidt number, gas phase

Note that the group on the left side of Eq. (14-171) is dimensionless. When turbulence promoters are used at the inlet-gas section, an improvement in gas mass-transfer coefficient for absorption of water vapor by sulfuric acid was observed by Greenewalt [*Ind. Eng. Chem.*, **18,** 1291 (1926)]. A falling off of the rate of mass transfer below that indicated in Eq. (14-171) was observed by Cogan and Cogan (thesis, Massachusetts Institute of Technology, 1932) when a calming zone preceded the gas inlet in ammonia absorption (Fig. 14-77).

In work with the hydrogen chloride-air-water system, Dobratz, Moore, Barnard, and Meyer [*Chem. Eng. Prog.*, **49,** 611 (1953)] using a cocurrent-flow system found that $K_g \propto G^{1.8}$ (Fig. 14-78) instead of the 0.8 power as indicated by the Gilliland equation. Heat-transfer coefficients were also determined in this study. The radical increase in heat-transfer rate in the range of $G = 30$ kg/(s·m²) [20,000 lb/(h·ft²)] was similar to that observed by Tepe and Mueller [*Chem. Eng. Prog.*, **43,** 267 (1947)] in condensation inside tubes.

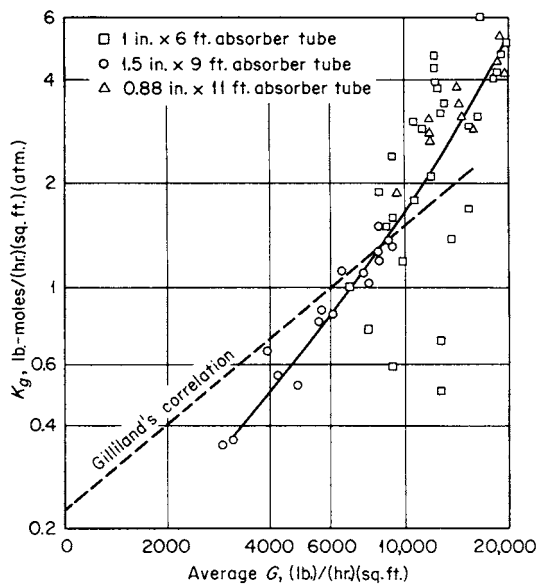

**FIG. 14-78** Mass-transfer coefficients versus average gas velocity—HCl absorption, wetted-wall column. To convert pound-moles per hour-square foot-atmosphere to kilogram-moles per second-square meter-atmosphere, multiply by 0.00136; to convert pounds per hour-square foot to kilograms per second-square meter, multiply by 0.00136; to convert feet to meters, multiply by 0.305; and to convert inches to millimeters, multiply by 25.4. [*Dobratz et al.,* Chem. Eng. Prog., **49,** *611 (1953).*]

Gaylord and Miranda [*Chem. Eng. Prog.*, **53,** 139M (1957)] using a multitube cocurrent-flow falling-film hydrochloric acid absorber for hydrogen chloride absorption found

$$K_g = \frac{1.66(10^{-5})}{M_m^{1.75}} \left( \frac{D_{\text{tube}} G}{\mu} \right) \tag{14.172}$$

where $K_g$ = overall mass-transfer coefficient, (kg·mol)/(s·m²·atm)
$M_m$ = mean molecular weight of gas stream at inlet to tube
$D_{\text{tube}}$ = diameter of tube, m
$G$ = mass velocity of gas at inlet to tube, kg/(s·m²)
$\mu$ = viscosity of gas, Pa·s

Note that the group $D_{tube}G/\mu$ is dimensionless. This relationship also satisfied the data obtained for this system, with a single-tube falling-film unit, by Coull, Bishop, and Gaylor [*Chem. Eng. Prog.*, **45,** 506 (1949)].

The rate of mass transfer in the liquid phase in wetted-wall columns is highly dependent on surface conditions. When laminar-flow conditions prevail without the presence of wave formation, the laminar-penetration theory prevails. When, however, ripples form at the surface, and they may occur at a Reynolds number exceeding 4, a significant rate of surface regeneration develops, resulting in an increase in mass-transfer rate.

If no wave formations are present, analysis of behavior of the liquid-film mass transfer as developed by Hatta and Katori [*J. Soc. Chem. Ind.*, **37,** 280B (1934)] indicates that

$$k_\ell = 0.422 \sqrt{\frac{D_\ell \Gamma}{\rho B_F^2}} \tag{14-173}$$

where $B_F = (3u\Gamma/\rho^2 g)^{1/3}$
$D_l$ = liquid-phase diffusion coefficient, m²/s
$\rho$ = liquid density, kg/m³
$Z$ = length of surface, m
$k_l$ = liquid-film-transfer coefficient, (kg·mol)/[(s·m²)(kg·mol)/m³]
$\Gamma$ = liquid-flow rate, kg/(s·m) based on wetted perimeter
$\mu$ = viscosity of liquid, Pa·s
$g$ = gravity acceleration, 9.81 m/s²

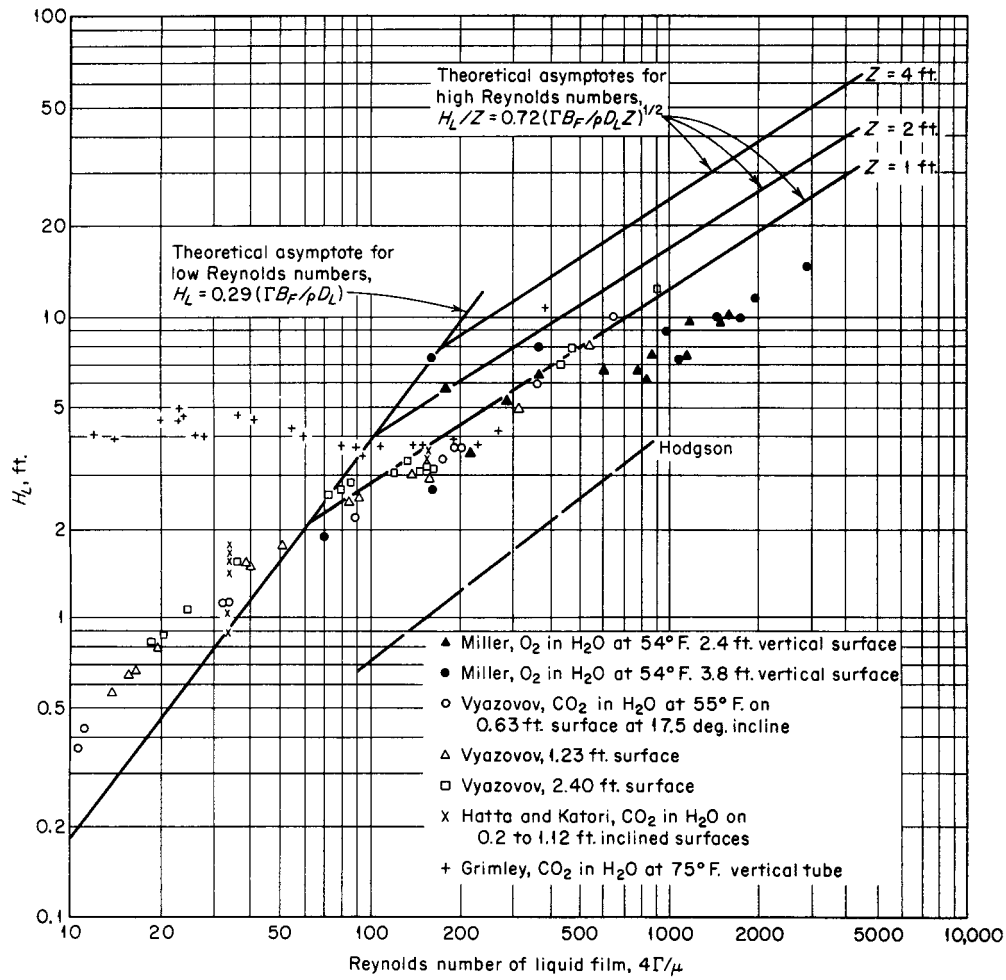

**FIG. 14-79** Liquid-film resistance in absorption of gases in wetted-wall columns. Theoretical lines are calculated for oxygen absorption in water at 55°F. To convert feet to meters, multiply by 0.3048; °C = ⅝ (°F − 32). (*Sherwood and Pigford,* Absorption and Extraction, *2d ed., McGraw-Hill, New York, 1952.*)

When $Z$ is large or $\Gamma/\rho B_F$ is so small that liquid penetration is complete,

$$k_\ell = 11.800\, D_\ell/B_F \tag{14-174}$$

and

$$H_\ell = 0.95\, \Gamma B_F/D_\ell \tag{14-175}$$

A comparison of experimental data for carbon dioxide absorption obtained by Hatta and Katori (op. cit.), Grimley [*Trans. Inst. Chem. Eng.,* **23,** 228 (1945)], and Vyazov [*Zh. Tekh. Fiz.* (U.S.S.R.), **10,** 1519 (1940)] and for absorption of oxygen and hydrogen by Hodgson (S.M. thesis, Massachusetts Institute of Technology, 1949), Henley (B.S. thesis, University of Delaware, 1949), Miller (B.S. thesis, University of Delaware, 1949), and Richards (B.S. thesis, University of Delaware, 1950) was made by Sherwood and Pigford (*Absorption and Extraction,* McGraw-Hill, New York, 1952) and is indicated in Fig. 14-79.

In general, the observed mass-transfer rates are greater than those predicted by theory and may be related to the development of surface rippling, a phenomenon which increases in intensity with increasing liquid path.

Vivian and Peaceman [*Am. Inst. Chem. Eng. J.,* **2,** 437 (1956)] investigated the characteristics of the $CO_2$-$H_2O$ and $Cl_2$-HCl, $H_2O$ system in a wetted-wall column and found that gas rate had no effect on the liquid-phase coefficient at Reynolds numbers below 2200. Beyond this rate, the effect of the resulting rippling was to increase significantly the liquid-phase transfer rate. The authors proposed a behavior relationship based on a dimensional analysis but suggested caution in its application concomitant with the use of this type of relationship. Cognizance was taken by the authors of the effects of column length, one to induce rippling and increase of rate of transfer, one to increase time of exposure which via the penetration theory decreases the average rate of mass transfer in the liquid phase. The equation is

$$\frac{k_\ell h}{D_\ell} = 0.433 \left(\frac{\mu_\ell}{\rho_\ell D_\ell}\right)^{1/2} \left(\frac{\rho_\ell^2 g h^3}{\mu_\ell^2}\right)^{1/6} \left(\frac{4\Gamma}{\mu_\ell}\right)^{0.4} \tag{14-176}$$

where $D_\ell$ = diffusion coefficient of solute in liquid, ft²/h
$g$ = gravity-acceleration constant, $4.17 \times 10^8$ ft/h²
$h$ = length of wetted wall, ft
$k_\ell$ = mass-transfer coefficient, liquid phase, ft/h
$\Gamma$ = mass rate of flow of liquid, lb/(h)(ft of periphery)
$\mu_\ell$ = viscosity of liquid, lb/(ft)(h)
$\rho_\ell$ = density of liquid, lb/ft³

The equation is dimensionless.

The effect of chemical reaction in reducing the effect of variation of the liquid rate on the rate of absorption in the laminar-flow regime was illustrated by the evaluation of the rate of absorption of chlorine in ferrous chloride solutions in a wetted-wall column by Gilliland, Baddour, and White [*Am. Inst. Chem. Eng. J.,* **4,** 323 (1958)].

**Flooding in Wetted-Wall Columns** When gas and liquid are in counterflow in wetted-wall columns, flooding can occur at high gas rates. Methods for calculating this flood are given in "Upper Limit Flooding in Vertical Tubes." In the author's experience, Eq. (14-204) has had an excellent track record for calculating flooding in these columns.

## COLUMN COSTS

Estimation of column costs for preliminary process evaluations requires consideration not only of the basic type of internals but also of their effect on overall system cost. For a distillation system, for example, the overall system can include the vessel (column), attendant structures, supports, and foundations; auxiliaries such as reboiler, condenser, feed heater, and control instruments; and connecting piping. The choice of internals influences all these costs, but other factors influence them as well. A complete optimization of the system requires a full-process simulation model that can cover all pertinent variables influencing economics.

**Cost of Internals** Installed costs of trays may be estimated from Fig. 14-80, with corrections for tray material taken from Table 14-17. For two-pass trays the cost is 15 to 20 percent higher. Approximate costs of random packing materials may be obtained from Table 14-18, but it should be recognized that, because of competition, there can be significant variations in these costs from vendor to vendor. Also, packings sold in very large quantities carry discounts. In 1995, costs of structured packings, made from sheet metal, averaged $90 to $110 per cubic foot, but the need for special distributors and redistributors can double the cost of structured-packings on a volumetric basis. Note

**TABLE 14-17 Relative Fabricated Cost for Metals Used in Tray-Tower Construction***

| Materials of construction | Relative cost per ft² of tray area (based on carbon steel = 1) |
|---|---|
| Sheet-metal trays | |
| Steel | 1 |
| 4–6% chrome—½ moly alloy steel | 2.1 |
| 11–13% chrome type 410 alloy steel | 2.6 |
| Red brass | 3 |
| Stainless steel type 304 | 4.2 |
| Stainless steel type 347 | 5.1 |
| Monel | 7.0 |
| Stainless steel type 316 | 5.5 |
| Inconel | 8.2 |
| Cast-iron trays | 2.8 |

*Peters and Timmerhaus, *Plant Design and Economics for Chemical Engineers,* 4th ed., McGraw-Hill, New York, 1991. To convert cost per square foot to cost per square meter, multiply by 10.76.

**TABLE 14-18 Costs of Random Packings, Uninstalled, January 1990**

Prices in dollars per ft³, 100 ft³ orders, f.o.b. manufacturing plant

| | Size, in, $/ft³ | | | |
|---|---|---|---|---|
| | 1 | 1½ | 2 | 3 |
| Raschig rings | | | | |
| Chemical porcelain | 12.8 | 10.3 | 9.4 | 7.8 |
| Carbon steel | 36.5 | 23.9 | 20.5 | 16.8 |
| Stainless steel | 155 | 117 | 87.8 | — |
| Carbon | 52 | 46.2 | 33.9 | 31.0 |
| Intalox saddles | | | | |
| Chemical stoneware | 17.6 | 13.0 | 11.8 | 10.7 |
| Chemical porcelain | 18.8 | 14.1 | 12.9 | 11.8 |
| Polypropylene | 21.2 | — | 13.1 | 7.0 |
| Berl saddles | | | | |
| Chemical stoneware | 27.0 | 21.0 | — | — |
| Chemical porcelain | 33.5 | 21.5 | 15.6 | — |
| Pall rings | | | | |
| Carbon steel | 29.3 | 19.9 | 18.2 | — |
| Stainless steel | 131 | 99.0 | 86.2 | — |
| Polypropylene | 21.2 | 14.4 | 13.1 | |

Peters and Timmerhaus, *Plant Design and Economics for Chemical Engineers,* 4th ed., McGraw-Hill, New York, 1991. To convert cubic feet to cubic meters, multiply by 0.0283; to convert inches to millimeters, multiply by 25.4; and to convert dollars per cubic foot to dollars per cubic meter, multiply by 35.3.

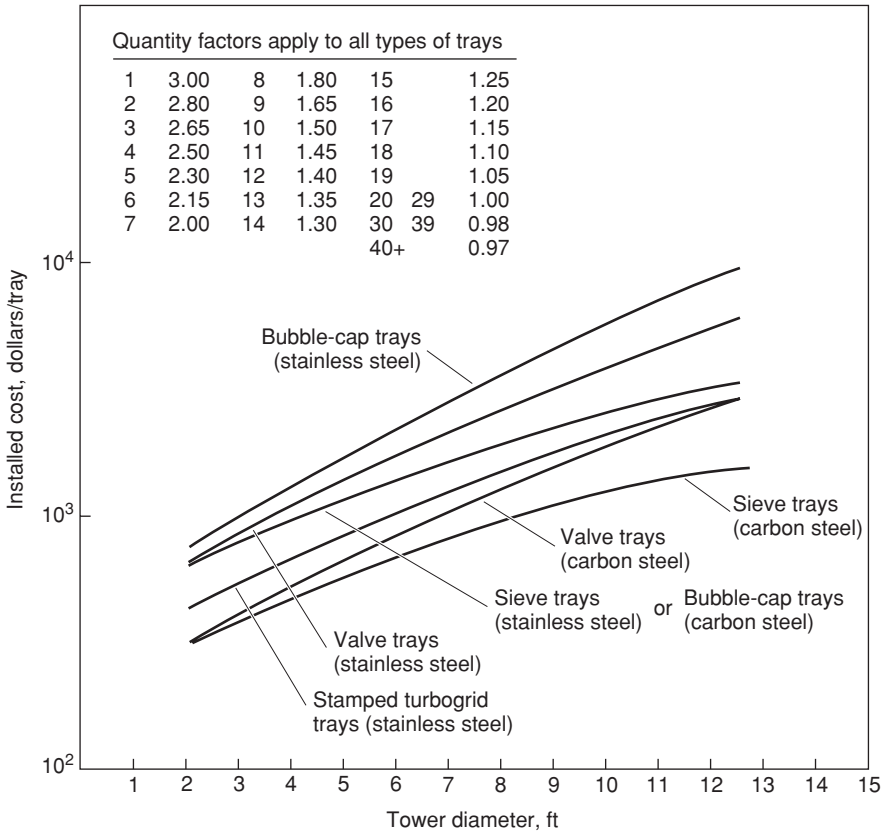

**FIG. 14-80** Cost of trays. Price includes tray deck, valves, bubble caps, risers, downcomers, and structural-steel parts. The stainless steel designated is type 410 (*Peters and Timmerhaus,* Plant Design and Economics for Chemical Engineers, *4th ed., McGraw-Hill, New York, 1991*).

that for Fig. 14-80 and Table 14-17, the effective cost date is January 1990, with the Marshall and Swift cost index being taken as 904.

As indicated above, packed column internals include liquid distributors, packing support plates, redistributors (as needed), and holddown plates (to prevent movement of packing under flow conditions). Costs of these internals for columns with random packing are given in Fig. 14-81, based on early 1976 prices, and a Marshall and Swift cost index of 460.

**Cost of Column** The cost of the vessel, including heads, skirt, nozzles, and ladderways, is usually estimated on the basis of weight. Figure 14-82 provides early 1990 cost data for the shell and heads, and Fig. 14-83 provides 1990 cost data for connections. For very approximate estimates of complete columns, including internals, Fig. 14-84 may be used. As for Figs. 14-82 and 14-83, the cost index is 904.

# PHASE DISPERSION

**General References:** For an overall discussion of gas-liquid breakup processes, see Brodkey, *The Phenomena of Fluid Motions,* Addison-Wesley, Reading, Massachusetts, 1967. For a discussion of atomization devices and how they work, see Masters, *Spray Drying Handbook,* 5th ed., Wiley, New York, 1991; and Lefebvre, *Atomization and Sprays,* Hemisphere, New York, 1989. A beautifully illustrated older source is Dombrowski and Munday, *Biochemical and Biological Engineering Science,* vol. 2, Academic Press, London, 1968, pp. 209–320. Steinmeyer [*Chem. Engr. Prog.*, **91**(7), 72–80 (1995)] built on Hinze's work with turbulence and showed that several atomization processes follow the common theme of breakup of large droplets due to turbulence in the gas phase. Turbulence in turn correlates with power dissipation per unit mass. In the text below, correlations referring to *power/mass* are taken from this source. For a survey on fog formation, see Amelin, *Theory of Fog Formation,* Israel Program for Scientific Translations, Jerusalem, 1967.

## BASICS OF INTERFACIAL CONTACTORS

**Steady-State Systems: Bubbles and Droplets** Bubbles are made by injecting vapor below the liquid surface. In contrast, droplets are commonly made by atomizing nozzles that inject liquid into a vapor. Bubble and droplet systems are fundamentally different, mainly because of the enormous difference in density of the injected phase. There are situations where each is preferred. Bubble systems tend to have much higher interfacial area as shown by Example 16 contrasted with Examples 14 and 15. Because of their higher area, bubble systems will usually give a closer approach to equilibrium.

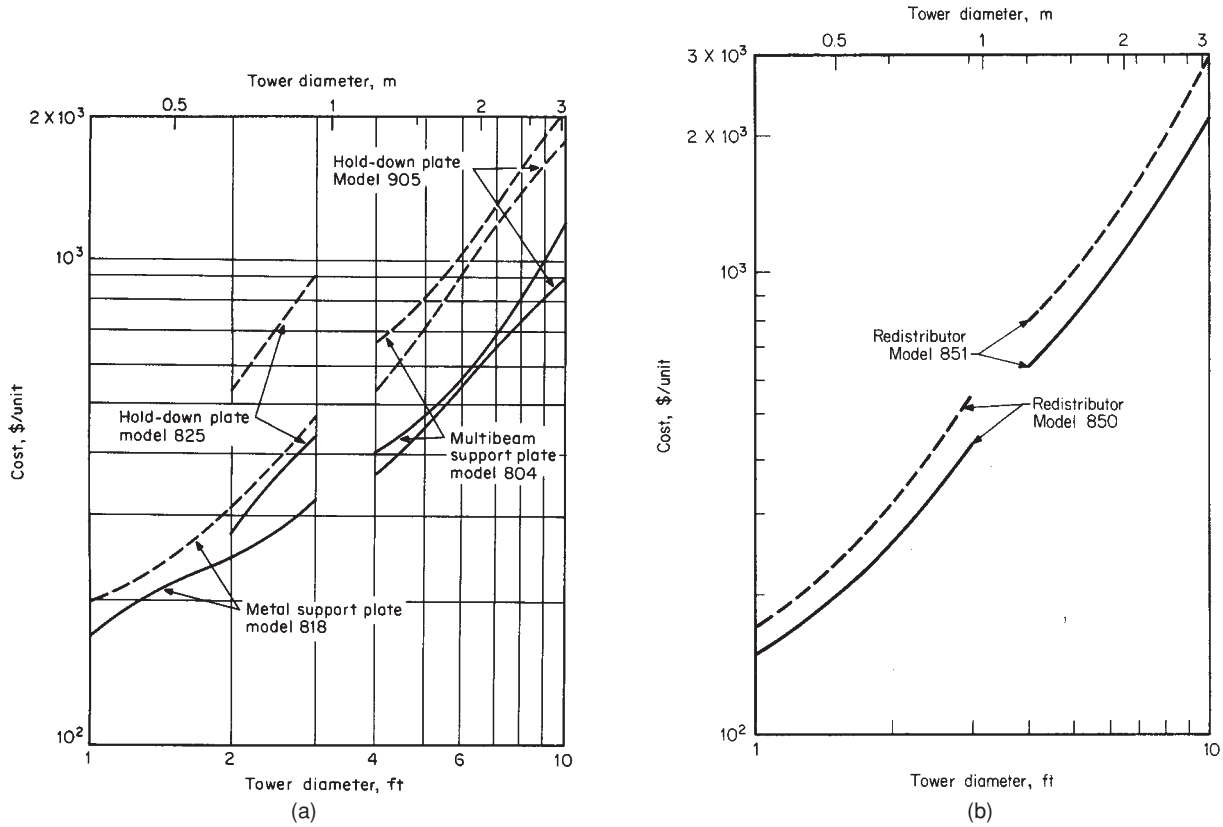

**FIG. 14-81** Cost of internal devices for columns containing random packings. (*a*) Holddown plates and support plates. (*b*) Redistributors. [*Pikulik and Diaz,* Chem. Eng., ***84****(21), 106 (Oct. 10, 1977).*]

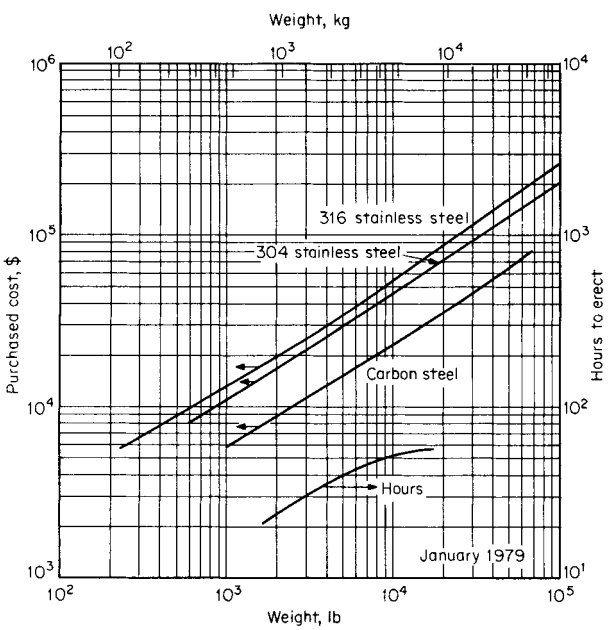

**FIG. 14-82** Fabricated costs and installation time of towers. Costs are for shell with two heads and skirt, but without trays, packing, or connections. (*Peters and Timmerhaus,* Plant Design and Economics for Chemical Engineers, *4th ed., McGraw-Hill, New York, 1991.*)

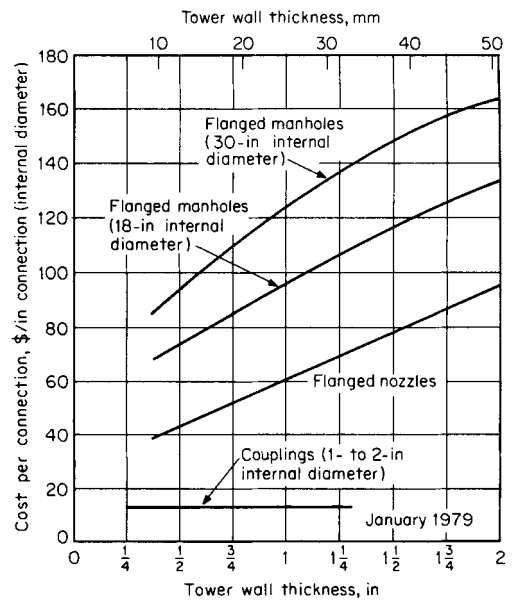

**FIG. 14-83** Approximate installed cost of steel-tower connections. Values apply to 2070-kPa connections. Multiply costs by 0.9 for 1035-kPa (150-lb) connections and by 1.2 for 4140-kPa (600-lb) connections. To convert inches to millimeters, multiply by 25.4; to convert dollars per inch to dollars per centimeter, multiply by 0.394. (*Peters and Timmerhaus,* Plant Design and Economics for Chemical Engineers, *4th ed., New York, McGraw-Hill, 1991.*)

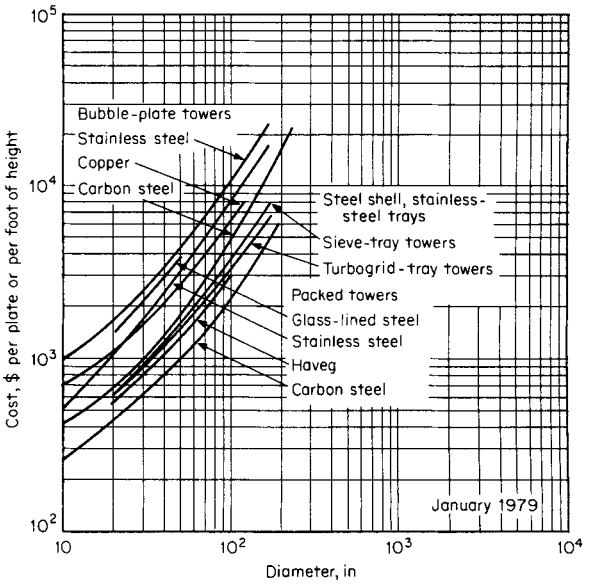

**FIG. 14-84** Cost of towers including installation and auxiliaries. To convert inches to millimeters, multiply by 25.4; to convert feet to meters, multiply by 0.305; and to convert dollars per foot to dollars per meter, multiply by 3.28. (*Peters and Timmerhaus,* Plant Design and Economics for Chemical Engineers, *4th ed., McGraw-Hill, New York, 1991.*)

However, droplet systems can enable much higher energy input (via gas phase pressure drop in cocurrent systems) and, as a result, dominate applications where a quick quench is needed. See Examples 21 and 22. Conversely, droplet systems can also be designed for very low pressure drop which is advantageous in applications such as vacuum condensers.

**Unstable Systems: Froths and Hollow Cone Atomizing Nozzles** We usually think of interfacial contact as a steady-state system of raining droplets or rising bubbles, but some of the most efficient interfacial contactors take advantage of unstable interfacial geometry. The most common is the distillation tray which operates with a wild mix of bubbles, jets, films, and droplets. The mix is often described as *froth.* Gas pressure drop provides the energy to create the froth.

A variant on the froth contact is the reverse jet contactor (Example 22), which can be considered as an upside-down distillation tray, operated above the flooding velocity in cocurrent flow of gas and liquid. It is limited to one stage.

An entirely different unstable contactor involves the thin expanding liquid film produced by a hollow cone spray nozzle. Because of fresh surface and the thinness of the film, this can give very high transfer for liquid-limited systems. Two applications are direct contact condensation and removal of volatile components from a high-boiling residual liquid.

**Surface Tension Makes Liquid Sheets and Liquid Columns Unstable** Surface tension is the energy required to make an increment of interfacial surface. A sheet or column of liquid has more surface than a sphere, hence surface tension converts sheets and columns to droplets. See Fig. 14-86.

There are many different atomizers, but the underlying principle of all is the same—to first generate a flat sheet or a liquid column. Liquid sheets and columns are unstable, a small surface disturbance on either will propagate, and the liquid will reshape itself into droplets. The key property in controlling this process is surface tension. Surface tension gets a high exponent in all the atomization correlations.

**Little Droplets and Bubbles vs. Big Droplets and Bubbles—Coalescence vs. Breakup** When big drops are subjected to shear forces, as in falling rain, the droplets are distorted; and if the distortions are great enough, the big droplets break into little ones. This is why raindrops never exceed a certain size. A variant on this is breakup in highly turbulent systems such as in high-velocity quench systems or pneumatic nozzles. Here the droplets are distorted by the energy of the turbulent eddies.

But little droplets and bubbles have more surface per unit of liquid than big ones. Hence little droplets tend to coalesce into big ones, and will grow in size if given enough quiet time.

While the primary difficulty is estimating the interfacial area due to the unstable interface, a secondary problem is that freshly made, unstable surface gives higher transfer than older, more stable surface.

**Empirical Design Tempered by Operating Data** The net of these is that interfacial area is difficult to predict and interfacial contactors are difficult to design.

*Prediction methods are given below but should always be tempered by operating experience.*

## INTERFACIAL AREA—IMPACT OF DROPLET OR BUBBLE SIZE

Transfer is aided by increased interfacial area. Interfacial area per unit volume $a_D$ of a single droplet or bubble is inversely proportional to the diameter of the droplet or bubble $D$.

$$a_D = 6/D \tag{14-177}$$

To estimate the total interfacial area in a given volume, the $a_d$ value is multiplied by the fractional holdup of dispersed phase in the total volume.

$$a = a_D(\Phi_D) \tag{14-178}$$

where $a$ = interfacial area/volume and $\Phi_D$ = fraction of volume in dispersed phase = holdup. Fractional holdup in a continuous process depends on the velocities of the two phases, as if they were flowing by themselves.

$\Phi_D$ = (dispersed phase volume)/(volume of dispersed and continuous phases)

***Example 14: Interfacial Area for Droplets/Gas in Cocurrent Flow*** For equal mass flow of gas and liquid and with gas density 0.001 of liquid density, the gas velocity in cocurrent flow will be 1000 times the liquid velocity. This sets $\Phi_D$.

$$\Phi_D = 1/(1 + 1000) = 0.00099$$

If the droplets are 500 μm in diameter, Eqs. (14-177) and (14-178) give

$$a = (6/0.0005)(0.00099) = 12 \text{ m}^2/\text{m}^3$$

If the droplets are 100 μm in diameter, Eqs. (14-177) and (14-178) give

$$a = (6/0.0001)(0.00099) = 60 \text{ m}^2/\text{m}^3$$

***Example 15: Interfacial Area for Droplets Falling in a Vessel*** Droplet systems rarely exceed a $\Phi_D$ value of 0.01. At this low level, $\Phi_D$ in a low-velocity countercurrent contactor can be approximated by Eq. (14-179).

$$\Phi_D = U_L/(U_t - U_G) \tag{14-179}$$

where $U_L$ = liquid superficial velocity
$U_t$ = terminal velocity of droplet
$U_G$ = gas superficial velocity

With a gas superficial velocity of 1.5 m/s, for equal mass flow of gas and liquid, with gas density 0.001 of liquid density, and with 500-μm-diameter droplets falling at a terminal settling of 2.5 m/s, Eq. (14-179) gives a fractional holdup of liquid of

$$\Phi_D = (0.001)1.5/(2.5 - 1.5) = 0.0015$$

Equations (14-177) and (14-178) then give

$$a = (6/0.0005)(0.0015) = 18 \text{ m}^2/\text{m}^3$$

***Example 16: Interfacial Area for Bubbles Rising in a Vessel*** For bubble systems (gases dispersed in liquids) fractional holdup can approach 0.5 as shown by Fig. 14-104. However, before reaching this holdup, the bubble systems shift to an unstable mix of bubbles and vapor jets. Hence an exact

comparison to Example 14 isn't possible because at the 1.5 m/s velocity of Example 14, the system becomes a froth. But at about one-fifth the velocity of Example 14, an estimate of interfacial area is possible.

If the bubble size is 10,000 μm and fractional holdup is 0.4, Eqs. (14-177) and (14-178) give an interfacial area of

$$a = (6/0.01)(0.4) = 240 \text{ m}^2/\text{m}^3$$

Measured interfacial area in distillation trays is consistent with this high value.

Note the much higher interfacial area than in the droplet systems of Examples 14 and 15. The higher interfacial area when the gas is dispersed explains why bubbling and froth systems often give better performance than droplet systems. The big difference in interfacial area stems from the much larger volume per unit of mass of gas, i.e., lower density of the gas than the liquid.

## RATE MEASURES, TRANSFER UNITS, APPROACH TO EQUILIBRIUM, AND BYPASSING

**What Controls Mass/Heat Transfer: Liquid or Gas Transfer or Bypassing** Either gas side or liquid side of the interface can be controlling.

**Liquid-Controlled** In fractionation systems with high viscosity or component relative volatility that greatly exceeds 1, the liquid side will be controlling. This is clearly illustrated by Fig. 14-47 which shows a sharp decline in efficiency with either a rise in liquid viscosity or a rise in *component relative volatility*.

Note that *high component relative volatility* means the same thing as *sparingly soluble*. Oxygen dissolving in a fermentation reactor is an example of a system being liquid-controlled due to a *sparingly soluble gas*. Another application that is liquid-controlled is the removal of *high relative volatility components* out of residual oil.

Still another case where liquid controls is in condensing a pure vapor, as in Example 23, or absorbing a pure gas, as in Example 24.

**Gas-Controlled** The gas side dominates in gas cooling applications. An example is the quenching of a furnace effluent with a vaporizing liquid. In this application the liquid is nearly uniform in temperature. Restated, the reduction in driving force across the liquid side of the interface is unimportant.

Other applications that are gas-side-controlled include removal of a component such as $NH_3$ from a gas by using an acidic liquid, or removing a component such as $SO_2$ from a gas with a basic liquid. See Examples 19 through 22.

**Bypassing-Controlled** Trayed or packed columns operate with countercurrent flow and can achieve many equilibrium stages in series by good distribution of gas and liquid, and careful control of details. Other devices such as sprays are vulnerable to bypassing and are limited to one equilibrium stage.

**Rate Measures for Interfacial Processes** Terminology used for reporting rate data can be confusing. Normally rate data are reported on a volumetric basis with transfer rate and effective area combined. For example, $k_L$a denotes mass-transfer data per unit volume. The $L$ subscript means it is referenced to the molar concentration difference between the interface and the bulk liquid. This is commonly used on data involving a sparingly soluble (high relative volatility) component. Note that the lowercase $k$ means the data deal only with the resistance in the liquid phase.

Less commonly, data are given as $k_G a$. The $G$ subscript means it is referenced to the molar concentration difference between the interface and the gas. This might be used for data on absorbing a gas such as $NH_3$ by a highly acidic liquid. Note that $k_G a$ only deals with the resistance in the gas phase.

When one is dealing with direct contact heat transfer, the corresponding terms are $h_L a$ and $h_G a$. Here the driving force is the temperature difference. The $L$ subscript means that we are dealing with a liquid-limited process such as condensing a pure liquid. How to convert $k_L a$ data to an $h_L a$ value is illustrated by Example 23.

There are ways to combine the liquid and gas resistance to get an overall transfer rate such as $K_G a$ (as denoted by the uppercase $K$). However, data are rarely reported in this form.

**Approach to Equilibrium** Although rate measures such as $k_G a$ and $h_G a$ are often cited in the literature, they are often not as useful to designers as the simpler concept of approach to equilibrium. *Approach to equilibrium* compares the transfer between liquid and gas phases to the best possible that could be achieved in a single backmixed equilibrium stage.

Approach to equilibrium is easy to understand and easy to apply. Examples 17 through 23 illustrate its use.

***Example 17: Approach to Equilibrium—Perfectly Mixed, Complete Exchange*** This would be approximated by a very long pipeline contactor where an acidic aqueous stream is injected to cool the gas and remove $NH_3$.

If the adiabatic saturation temperature of the gas is 70°C, at the exit of the contactor, the gas would be cooled to 70°C.

Similarly, at the exit of the contactor, the $NH_3$ in the gas would be zero, regardless of the initial concentration.

***Example 18: Approach to Equilibrium—Complete Exchange but with 10 Percent Gas Bypassing*** A spray column is used, and an acidic liquid rains down on the gas of Example 17. If the initial $NH_3$ is 1000 ppm and 10 percent of the gas bypasses, the $NH_3$ in the exit gas would be

$$0.1(1000) = 100 \text{ ppm}$$

Similarly, if the gas enters at 120°C, at the exit we would find 10 percent of the differential above the adiabatic saturation temperature. For an adiabatic saturation temperature of 70°C, the exit gas temperature would be

$$70 + 0.1(120 - 70) = 75°\text{C}$$

**Approach to Equilibrium—Finite Contactor with No Bypassing** When there is no bypassing, the measure that sets the approach is the ratio of change to driving force. This ratio is called the *number of transfer units* $N_G$. It is dimensionless. For heat-transfer applications, it can be envisioned as a conventional heat exchanger where a vaporizing liquid cools a gas:

$$\text{No. of gas-phase transfer units} = \frac{T_{G,\text{out}} - T_{G,\text{in}}}{(T_G - T_L)_{\text{av}}} = N_G \qquad (14\text{-}180)$$

Where $T_G$ = gas temperature and $T_L$ = liquid temperature. The number of transfer units $N_G$ can also be calculated as the capability for change divided by the thermal capacitance of the flowing streams.

$$N_G = \frac{(\text{system volume})(h_G a)}{(\text{volumetric flow rate})\rho_G c_G}$$

$$= \frac{(\text{gas contact time})(h_G a)}{\rho_G c_G} \qquad (14\text{-}181)$$

where $a$ = interfacial area per unit volume
$h_G$ = heat-transfer coefficient from interface to gas
$\rho_G$ = gas density
$c_G$ = gas specific heat

Note that in the above, performance and properties all refer to the gas, which is appropriate when dealing with a gas-limited transfer process.

This leads to a way to estimate the approach to equilibrium.

$$E = 1 - e^{-N_G} \qquad (14\text{-}182)$$

where $E$ = "approach to equilibrium" fractional removal of $NH_3$ or fractional approach to adiabatic liquid temperature
$N_G$ = number of transfer units calculated relative to gas flow

***Example 19: Finite Exchange, No Bypassing, Short Contactor*** A short cocurrent horizontal pipeline contactor gives 86 percent removal of $NH_3$. There is no bypassing because of the highly turbulent gas flow and injection of liquid into the center of the pipe. What would we expect the exit gas temperature to be?

Equation (14-182) says that the backcalculated $N_G$ is 2:

$$N_G = -\ln(1 - 0.86) = 2$$

For diffusing gases of similar molecular weight, the properties that control heat transfer follow the same rules as those that control mass transfer. As a result, the $NH_3$ scrubbing and gas cooling processes achieve similar approaches to equilibrium.

For an entry temperature of 120°C and an adiabatic saturation temperature of 70°C, the expected outlet temperature would be

$$70 + (1 - 0.86)(120 - 70) = 77°C$$

This looks like a powerful concept, but its value is limited due to uncertainty in estimating $h_G a$. Both $h_G$ and $a$ are difficult to estimate due to dependence on power dissipation as discussed below. The primary value of the $N_G$ concept is in estimating an expected change from baseline data as in the comparison of Example 19 with Example 20.

***Example 20: A Contactor That Is Twice as Long, No Bypassing*** If we double the length of the pipeline contactor, double the effective contact area, and double the number of transfer units to 4, what do we expect for performance?

For $N_G = 4$,

$$E = 1 - e^{-4} = 0.982$$

The $NH_3$ in the exit gas would be expected to drop to

$$(1 - 0.982)(1000) = 18 \text{ ppm}$$

and the expected outlet temperature would be

$$70 + (1 - 0.982)(120 - 70) = 70.9°C$$

If we double the length again, we increase the number of transfer units to 8 and achieve an approach of

$$E = 1 - e^{-8} = 0.9997$$

The outlet temperature would be

$$70 + (1 - 0.9997)(120 - 70) = 70.015°C$$

Similarly the $NH_3$ in the exit gas would be

$$(1 - 0.9997)(1000) = 0.3 \text{ ppm}$$

Note that this approximates the exit condition of Example 17.

**Transfer Coefficient—Impact of Droplet Size** The transfer coefficients increase as the size of droplets decreases. This is so because the transfer process is easier if it only has to move mass or heat a shorter distance (i.e., as the bubble or droplet gets smaller).

In the limiting case of quiescent small bubbles or droplets, the transfer coefficients vary inversely with average bubble or droplet diameter. For example, in heat transfer from a droplet interface to a gas, the minimum value is

$$h_{G,\min} = \text{heat transfer coefficient from interface to gas} = 2k_G/D \tag{14-183}$$

where $k_G$ = gas thermal conductivity and
$D$ = droplet diameter.

## IMPORTANCE OF TURBULENCE

The designer usually has control over the size of a droplet. As discussed below, several of the correlations show that droplet diameter varies with turbulent energy dissipation. For example, Eqs. (14-190) and (14-201) suggest that in droplet systems

$$D \propto \{1/(\text{gas velocity})\}^{1.2}$$

and hence from Eq. (14-178)

$$a \propto 1/D \propto (\text{gas velocity})^{1.2} \tag{14-184}$$

However, just looking at the impact of velocity on droplet size underestimates the velocity impact because turbulence gives higher transfer than Eq. (14-183) predicts. Transfer coefficients increase as the mixing adjacent to the surface increases. This mixing depends on the energy dissipated into the phases. To a first approximation this transfer from droplets increases with local power dissipation raised to the 0.2 power.

$$h_{G,\text{turbulent}} \propto (\text{power dissipated})^{0.2}$$

and since power dissipation per unit volume increases with (velocity)$^3$,

$$h_{G,\text{turbulent}} \propto (\text{velocity})^{0.6} \tag{14-185}$$

The combined effect on interfacial area and on the transfer coefficient is that the effective transfer increases greatly with gas velocity. From Eqs. (14-178) and (14-185)

$$h_G a_{\text{turbulent}} \propto (\text{velocity})^{1.8} \tag{14-186}$$

For quenching operations, this means that even though residence time is cut as gas velocity goes up, the effective approach to equilibrium increases. Since the volume for a given length of pipe falls with (velocity)$^{-1}$, the expected number of transfer units $N_G$ in a given length of pipe increases with (velocity)$^{0.8}$.

$$N_{G,\text{turbulent}} \propto (h_G a_{\text{turbulent}})(\text{volume}) \propto (\text{velocity})^{0.8} \tag{14-187}$$

See Example 21.

## EXAMPLES OF CONTACTORS

**High-Velocity Pipeline Contactors** High-velocity cocurrent flow can give more power input than any other approach. This is critical when extremely high rates of reaction quenching are needed.

***Example 21: Doubling the Velocity in a Horizontal Pipeline Contactor—Impact on Effective Heat Transfer*** Velocity in pipeline quench systems often exceeds 62 m/s (200 ft/s). Note that this is far above the flooding velocity in distillation packing, distillation trays, or gas-sparged reactors. There are few data available to validate performance even though liquid injection into high-velocity gas streams has been historically used in quenching reactor effluent systems. However, the designer knows the directional impact of parameters as given by Eq. (14-187).

For example, if a 10-ft length of pipe gives a 90 percent approach to equilibrium in a quench operation, Eq. (14-182) says that the backcalculated $N_G$ is 2.303:

$$N_G - \ln(1 - 0.9) = 2.303$$

Equation (14-187) says if we double velocity but retain the same length, we would expect an increase of $N_G$ to 4.0.

$$N_G = 2.303(2)^{0.8} = 4$$

and

$$E = 1 - e^{-4} = 0.982$$

Restated, the approach to equilibrium rises from 90 percent to greater than 98 percent even though the contact time is cut in half.

**Vertical Reverse Jet Contactor** A surprisingly effective modification of the liquid injection quench concept is to inject the liquid countercurrent *upward* into a gas flowing *downward*, with the gas velocity at some multiple of the flooding velocity defined by Eq. (14-203). The reverse jet contactor can be envisioned as an upside-down distillation tray. For large gas volumes, multiple injection nozzles are used. One advantage of this configuration is that it minimizes the chance of liquid or gas bypassing. Another advantage is that it operates in the froth region which generates greater area per unit volume than the higher-velocity cocurrent pipeline quench.

The concept was first outlined in U.S. Patent 3,803,805 (1974) and was amplified in U.S. Patent 6,339,169 (2002). The 1974 patent presents data which clarify that the key power input is from the gas stream.

A more recent article discusses use of the reverse jet in refinery offgas scrubbing for removal of both $SO_2$ and small particles [*Hydrocarbon*

*Processing*, **84,**(9), 99–106 (2005)]. This article cites downward gas velocities in the range of 10 to 37 m/s and notes gas pressure drop in the range of 6 to 20 in of water. Removals of $SO_2$ and fine particles were both close to 99 percent. The froth produced by the contactor reverses direction, flows down, and is largely disengaged in a vessel mounted below.

***Example 22: The Reverse Jet Contactor, U.S. Patent 6,339,169*** This patent deals with rapid cooling and removal of $NH_3$ from gas exiting an acrylonitrile reactor. Liquid is injected upward. The claims suggest downward-flowing gas velocity is between 20 and 25 m/s.

Gas cooling is reported to be largely complete in 0.1 s. $NH_3$ removal at the exit of the contactor is reported to be greater than 99 percent. The gas is cooled by water vaporizing from the injected liquid, with total water circulated being in the range of 100 times that evaporated.

Since the gas cooling and $NH_3$ scrubbing move in parallel, they would be expected to achieve nearly the same approach to equilibrium as long as the pH of all the liquid stays below a key threshold. The great excess of liquid enables this.

The key is high froth interfacial area per unit volume.

**Simple Spray Towers** The other extreme to the pipeline and reverse jet contactors is an open vessel where spray is injected down into upflowing gas to form a rain of liquid. The advantage of simple spray towers is that they give low gas pressure drop and also tend to be nonfouling.

Even though gas velocity is well below flooding velocity, the finer droplets of the spray will be entrained. Note the wide spectrum of particle sizes shown by Fig. 14-88.

However, as shown by Examples 23 and 24, they can be extremely effective in liquid-limited systems.

**Bypassing Limits Spray Tower Performance in Gas Cooling** As shown by Example 18, only modest performance is achieved in gas-limited systems. The modest efficiency is due to gas bypassing. Tall spray towers are not effective countercurrent devices. Even with nominally falling droplets, there is a great deal of backmixing because there is no stabilizing pressure drop as there would be in a column filled with packing or trays. A packet of droplets weighs more than a gas-filled space. The result is that the volume that is filled with the most droplets moves down relative to all other volumes. Similarly the gas volume that has fewest droplets moves up more quickly than other volumes. This generates bypassing of liquid and gas. The flows are driven by the rain of droplets themselves. Anything less than perfect distribution of liquid and gas will induce a dodging action between the flowing streams. Most designers limit expectations for spray contactors to some fraction of a single equilibrium stage regardless of height.

One approach that has been employed to get better distribution in spray systems is to mount a single large-capacity nozzle in the center of the vessel with radial discharge of large droplets. The droplets are discharged with enough velocity to penetrate to the vessel walls.

**Spray Towers in Liquid-Limited Systems—Hollow Cone Atomizing Nozzles** If we follow an element of liquid leaving a hollow cone hydraulic spray nozzle, the sequence is a rapidly thinning cone followed by wave development, followed by shedding of ligaments, followed by breakage of the ligaments into droplets. See Fig. 14-86. The sequence gives high transfer for liquid-limited systems. This results from the thin sheet of the hollow cone as well as the creation of fresh surface in the breakup process.

**Devolatilizers** Devolatilization systems are liquid-limited due to the combination of high liquid viscosity and removal of a component with high relative volatility. Simpson and Lynn [*AIChE J.*, **23** (5), 666–673 (1977)] reported oxygen stripping from water at 98 percent complete, in less than 1 ft of contact. The concept has been employed for residual devolatilization in refineries.

**Spray Towers as Direct Contact Condensers** Similarly spray contactors can be highly effective for direct contact condensers, which are also liquid-limited. The high transfer rate in the initial formation of sprays is the key. Kunesh [*Ind. Engr. Chem. Res.*, **32,** 2387–2389 (1993)] reported a 97 percent approach to equilibrium in a hydrocarbon system in the 6-in space below the discharge of a row of hollow cone spray nozzles.

Other results on heat transfer in a large spray condenser are given by Waintraub et al. ("Removing Packings from Heat Transfer Sections of Vacuum Towers," AIChE 2005 Spring National Meeting, Proceedings of Topical Conference, April 10, 2005, Atlanta, p. 79). The paper highlights the importance of good gas and liquid distribution.

**Converting Liquid Mass-Transfer Data to Direct Contact Heat Transfer** Liquid-limited performance measures are much more commonly given for mass-transfer than for heat transfer. Often mass-transfer data are reported as $k_La$ with units of $h^{-1}$. This can be converted to $h_La$ with units of Btu/(h·°F·ft$^3$) by Eq. (14-188).

$$h_La = 187(k_La)\,(c_L)\,(\rho_L)\,(\mu_L/T)^{0.5} \qquad (14\text{-}188)$$

where $\mu_L$ = liquid, cP
$T$ = temperature, °R
$\rho_L$ = liquid density, lb/ft$^3$
$c_L$ = liquid specific heat, Btu/(lb·°F)

Calculation of transfer units for heat transfer is relatively simple. For a liquid

$$N_L = \frac{(\text{liquid contact time})(h_La)}{\rho_L c_L} \qquad (14\text{-}189)$$

where $\rho_L$ = liquid density and $c_L$ = liquid specific heat. [See parallel gas expression, Eq. (14-181).]

Unlike gases, the liquid properties that control mass and heat transfer differ greatly. The key term is diffusivity which for liquids drops with viscosity.

The resulting values for $h_La$ and $N_L$ can be surprisingly large when a pure vapor such as steam is condensed. See Example 23.

***Example 23: Estimating Direct Contact Condensing Performance Based on $k_La$ Mass-Transfer Data*** If an aqueous system at 560°R gives a $k_La$ of 60 $h^{-1}$, what does Eq. (14-188) predict for $h_La$ in a direct contact steam condenser?

For an aqueous system

$$\mu_L = 1 \text{ cP}$$

$$\rho_L = 62 \text{ lb/ft}^3$$

$$c_L = 1 \text{ Btu/(lb·°F)}$$

and Eq. (14-189) predicts

$$h_La = 187(60)(1)(62)(1/560)^{0.5} = 29{,}400 \text{ Btu/(h·°F·ft}^3\text{)}$$

When a pure gas such as HCl is absorbed by low viscosity liquid such as water, simple spray systems can also be highly effective. See Example 24.

***Example 24: HCl Vent Absorber*** (Kister, *Distillation Troubleshooting*, Wiley, 2006, p. 95.) A 6-in-diameter, 8-ft-tall packed bed was giving major problems due to failure of the packing support. Water was the scrubbing fluid.

The liquid distributors were replaced with carefully positioned spray nozzles, and the packing was removed. HCl in the vent was removed to a level one-fortieth of the original design.

## LIQUID-IN-GAS DISPERSIONS

**Liquid Breakup into Droplets** There are four basic mechanisms for breakup of liquid into droplets:

- Droplets in a field of high turbulence (i.e., high power dissipation per unit mass)
- Simple jets at low velocity
- Expanding sheets of liquid at relatively low velocity
- Droplets in a steady field of high relative velocity

These mechanisms coexist, and the one that gives the smallest drop size will control. The four mechanisms follow distinctly different velocity dependencies:

1. *Breakup in a highly turbulent field* (1/velocity)$^{1.2}$. This appears to be the dominant breakup process in distillation trays in the spray regime, pneumatic atomizers, and high-velocity pipeline contactors.
2. *Breakup of a low-velocity liquid jet* (1/velocity)$^0$. This governs in special applications like prilling towers and is often an intermediate step in liquid breakup processes.
3. *Breakup of a sheet of liquid* (1/velocity)$^{0.67}$. This governs drop size in most hydraulic spray nozzles.

4. *Single-droplet breakup at very high velocicty* (1/velocity)$^2$. This governs drop size in free fall as well as breakup when droplets impinge on solid surfaces.

**Droplet Breakup—High Turbulence** This is the dominant breakup mechanism for many process applications. Breakup results from local variations in turbulent pressure that distort the droplet shape. Hinze [*Am. Inst. Chem. Eng. J.*, **1,** 289–295 (1953)] applied turbulence theory to obtain the form of Eq. (14-190) and took liquid-liquid data to define the coefficient:

$$D_{max} = 0.725(\sigma/\rho_G)^{0.6}/E^{0.4} \qquad (14\text{-}190)$$

where $E$ = (power dissipated)/mass — length$^2$/time$^3$
$\sigma$ = surface tension — mass/time$^2$
$\rho_G$ = gas density — mass/length$^3$

Note that $D_{max}$ comes out with units of length. Since $E$ typically varies with (gas velocity)$^3$, this results in drop size dependence with (1/velocity)$^{1.2}$.

The theoretical requirement for use of Eq. (14-190) is that the microscale of turbulence $<<D_{max}$. This is satisfied in most gas systems. For example, in three cases,

| | (microscale of turbulence)/$D_{max}$ |
|---|---|
| distillation tray in spray regime | 0.007 |
| pipeline @ 40 m/s and atmospheric pressure | 0.012 |
| two-fluid atomizer using 100 m/s air | 0.03 |

Many applications involve a three-step process with high velocity first tearing wave crests away from liquid sheets, followed by breakup of ligaments into large droplets, followed by breakup of the large droplets. The prediction of final droplet size based on *power/mass* works surprisingly well, as shown by Eqs. (14-198),(14-201), (14-202), and (14-203).

**Liquid-Column Breakup** Because of increased pressure at points of reduced diameter, the liquid column is inherently unstable. As a result, it breaks into small drops with no external energy input. Ideally, it forms a series of uniform drops with the size of the drops set by the fastest-growing wave. This yields a dominant droplet diameter about 1.9 times the initial diameter of the jet as shown by Fig. 14-85. As shown, the actual breakup is quite close to prediction, although smaller satellite drops are also formed. The prime advantage of this type of breakup is the greater uniformity of drop size.

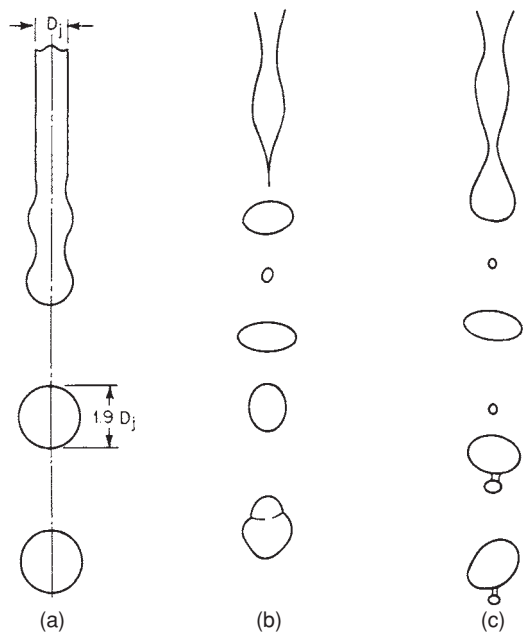

**FIG. 14-85** (*a*) Idealized jet breakup suggesting uniform drop diameter and no satellites. (*b*) and (*c*) Actual breakup of a water jet as shown by high-speed photographs. [*From W. R. Marshall,* "Atomization and Spray Drying," *Chem. Eng. Prog. Monogr. Ser., no. 2 (1954).*]

For high-viscosity liquids, the drops are larger, as shown by Eq. (14-191):

$$D = 1.9D_j\left[1 + \frac{3\mu_\ell}{(\sigma\rho_\ell D_j)^{1/2}}\right] \qquad (14\text{-}191)$$

where $D$ = diameter of droplet
$D_j$ = diameter of jet
$\mu_\ell$ = viscosity of liquid
$\rho_\ell$ = density of liquid
$\sigma$ = surface tension of liquid

These units are dimensionally consistent; any set of consistent units can be used.

As the velocity of the jet is increased, the breakup process changes and ultimately becomes a mix of various competing effects, such as the capture of small drops by bigger ones in the slowing jet and the "turbulent breakup" of the bigger drops. The high-velocity jet is occasionally used in process applications because of the very narrow spray angle (5–20°) and the high penetration into a gas it can give. The focused stream also aids erosion of a surface.

**Liquid-Sheet Breakup** The basic principle of most hydraulic atomizers is to form a thin sheet that breaks via a variety of mechanisms to form ligaments of liquid which in turn yield chains of droplets. See Fig. 14-86.

For a typical nozzle, the drop size varies with 1/(pressure drop)$^{1/3}$. When (velocity)$^2$ is substituted for pressure drop, droplet size is seen to vary with (velocity)$^{-2/3}$.

**Isolated Droplet Breakup—in a Velocity Field** Much effort has focused on defining the conditions under which an isolated drop will break in a velocity field. The criterion for the largest stable drop size is the ratio of aerodynamic forces to surface-tension forces defined by the Weber number, $N_{We}$ (dimensionless):

$$N_{We\ crit} = \text{constant} = [\rho_G\ (\text{velocity})^2(D_{max})/(\sigma)] \qquad (14\text{-}192)$$

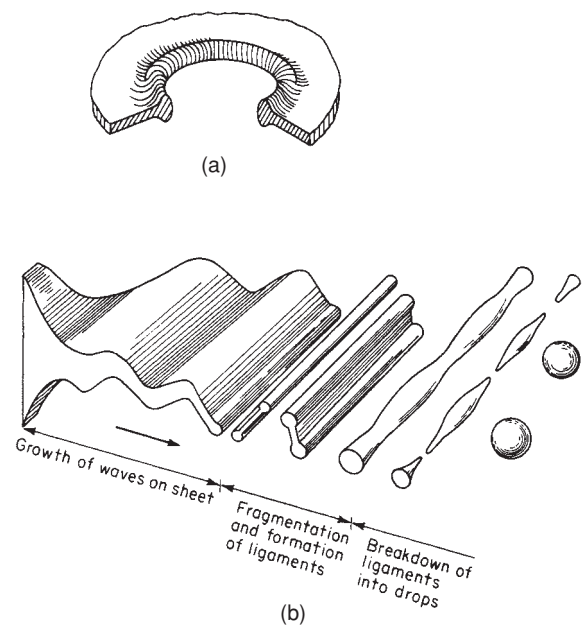

**FIG. 14-86** Sheet breakup. (*a*) By perforation. [*After Fraser et al.,* Am. Inst. Chem. Eng. J., ***8***(5), 672 (1962).] (*b*) By sinusoidal wave growth. [*After Dombrowski and Johns,* Chem. Eng. Sci., ***18,*** *203 (1963).*]

$N_{We\ crit}$ for low-viscosity fluids commonly ranges from 10 to 20, with the larger value for a free-fall condition and the smaller for a sudden acceleration. High liquid viscosity also increases $N_{We\ crit}$.

Droplet breakup via impingement appears to follow a similar relationship, but much less data is available. This type of breakup can result from impingement on equipment walls or compressor blades. In general, there is less tendency to shatter on wetted surfaces.

**Droplet Size Distribution** Instead of the single droplet size implied by the discussion above, a spectrum of droplet sizes is produced. The most common ways to characterize this spectrum are:

- *Volume median* (*mass median*) $D_{vm}$. This has no fundamental meaning but is easy to determine since it is at the midpoint of a cumulative-volume plot.
- *Sauter mean* $D_{32}$. This has the same ratio of surface to volume as the total drop population. It is typically 70 to 90 percent of $D_{vm}$. It is frequently used in transport processes and is used here to characterize drop size.
- *Maximum* $D_{max}$. This is the largest-sized particle in the population. It is typically 3 to 4 times $D_{32}$ in turbulent breakup processes, per Walzel [*International Chemical Engineering,* **33,** 46, (1993)]. It is the size directly calculated from the power/mass relationship. $D_{32}$ is estimated from $D_{max}$ by

$$D_{32} = 0.3 \cdot D_{max} \tag{14-193}$$

and $D_{vm}$ is estimated from it by

$$D_{vm} = 0.4 \cdot D_{max} \tag{14-194}$$

However, any average drop size is fictitious, and none is completely satisfactory. For example, there is no way in which the high surface and transfer coefficients in small drops can be made available to the larger drops. Hence, a process calculation based on a given droplet size describes only what happens to that size and gives at best an approximation to the total mass.

There are a variety of ways to describe the droplet population. Figures 14-88 and 14-90 illustrate one of the most common methods, the plot of cumulative volume against droplet size on log-normal graph paper. This satisfies the restraint of not extrapolating to a negative drop size. Its other advantages are that it is easy to plot, the results are easy to visualize, and it yields a nearly straight line at lower drop sizes.

Cumulative volume over the range of 1 to 50 percent can also be shown to vary approximately as $D^2$. This is equivalent to finding that the number of droplets of a given size is inversely proportional to the droplet area or the surface energy of the droplet.

**Atomizers** The common need to disperse a liquid into a gas has spawned a large variety of mechanical devices. The different designs emphasize different advantages such as freedom from plugging, pattern of spray, small droplet size, uniformity of spray, high turndown ratio, and low power consumption.

As shown in Table 14-19, most atomizers fall into three categories:

1. Pressure nozzles (hydraulic)
2. Two-fluid nozzles (pneumatic)
3. Rotary devices (spinning cups, disks, or vaned wheels)

These share certain features such as relatively low efficiency and low cost relative to most process equipment. The energy required to produce the increase in area is typically less than 0.1 percent of the total energy consumption. This is because atomization is a secondary process resulting from high interfacial shear or turbulence. As droplet sizes decrease, this efficiency drops lower.

Other types are available that use sonic energy (from gas streams), ultrasonic energy (electronic), and electrostatic energy, but they are less commonly used in process industries. See Table 14-19 for a summary of the advantages/disadvantages of the different type units. An expanded discussion is given by Masters [*Spray Drying Handbook,* Wiley, New York (1991)].

Special requirements such as size uniformity in prilling towers can dictate still other approaches to dispersion. Here plates are drilled with many holes to develop nearly uniform columns.

Commonly, the most important feature of a nozzle is the size of droplet it produces. Since the heat or mass transfer that a given dispersion can produce is often proportional to $(1/D_d)^2$, fine drops are usually favored. On the other extreme, drops that are too fine will not settle, and a concern is the amount of liquid that will be entrained from a given spray operation. For example, if sprays are used to contact atmospheric air flowing at 1.5 m/s, drops smaller than 350 mm [terminal velocity = 1.5 m/s (4.92 ft/s)] will be entrained. Even for the relative coarse spray of the hollow-cone nozzle shown in Fig. 14-88, 7.5 percent of the total liquid mass will be entrained.

**Hydraulic (Pressure) Nozzles** Manufacturers' data such as shown by Fig. 14-88 are available for most nozzles for the air-water system. In Fig. 14-88, note the much coarser solid-cone spray. The coarseness results from the less uniform discharge.

**Effect of Physical Properties on Drop Size** Because of the extreme variety of available geometries, no attempt to encompass this variable is made here. The suggested predictive route starts with air-water droplet size data from the manufacturer at the chosen flow rate. This drop size is then corrected by Eq. (14-195) for different viscosity and surface tension:

$$\frac{D_{vm,\,system}}{D_{vm,\,water}} = \left(\frac{\sigma_{system}}{73}\right)^{0.25} \left(\frac{\mu_\ell}{1.0}\right)^{0.25} \tag{14-195}$$

where $D_{vm}$ = volume median droplet diameter
$\sigma$ = surface tension, mN/m (dyn/cm)
$\mu_\ell$ = liquid viscosity, mPa·s (cP)

The exponential dependencies in Eq. (14-195) represent averages of values reported by a number of studies with particular weight given to Lefebvre ([*Atomization and Sprays,* Hemisphere, New York (1989)]. Since viscosity can vary over a much broader range than surface tension, it has much more leverage on drop size. For example, it is common to find an oil with 1000 times the viscosity of water, while most liquids fall within a factor of 3 of its surface tension. Liquid density is generally even closer to that of water, and since the data are not clear that a liquid density correction is needed, none is shown in Eq. (14-195). Vapor density also has an impact on dropsize but the impact is complex, involving conflicts of a number of effects, and vapor density is commonly omitted in atomizer dropsize correlations.

**Effect of Pressure Drop and Nozzle Size** For a nozzle with a developed pattern, the average drop size can be estimated to fall with rising $\Delta P$ (pressure drop) by Eq. (14-196):

$$\frac{D_1}{D_2} = \left(\frac{\Delta P_2}{\Delta P_1}\right)^{1/3} \tag{14-196}$$

For similar nozzles and constant $\Delta P$, the drop size will increase with nozzle size as indicated by Eq. (14-197):

$$\frac{D_1}{D_2} = \left(\frac{\text{orifice diameter}_1}{\text{orifice diameter}_2}\right)^{1/2} \tag{14-197}$$

Once again, these relationships are averages of a number of reported values and are intended as rough guides.

The normal operating regime is well below turbulent breakup velocity. However the data of Kennedy [*J. of Engineering for Gas Turbines and Power,* **108,** 191 (1986)] at very high pressure drop in large nozzles shows a shift to a higher dependence on pressure drop. This data suggests that turbulent droplet breakup can also be governing with hydraulic spray nozzles, although this is unusual.

**Spray Angle** A shift to a smaller-angle nozzle gives slightly larger drops for a given type of nozzle because of the reduced tendency of the sheet to thin. Dietrich [*Proc. 1st Int. Conf. Liq. Atomization Spray Systems,* Tokyo (1978)] shows the following:

| Angle | 25° | 50° | 65° | 80° | 95° |
|---|---|---|---|---|---|
| $D_{vm}$, μm | 1459 | 1226 | 988 | 808 | 771 |

In calculating the impact point of spray, one should recognize that the spray angle closes in as the spray moves away from the nozzle. This is caused by loss of momentum of the spray to the gas.

**TABLE 14-19 Atomizer Summary**

| Types of atomizer | Design features | Advantages | Disadvantages |
|---|---|---|---|
| Pressure. | Flow $\alpha(\Delta P/\rho_\ell)^{1/2}$. Only source of energy is from fluid being atomized. | Simplicity and low cost. | Limited tolerance for solids; uncertain spray with high-viscosity liquids; susceptible to erosion. Need for special designs (e.g., bypass) to achieve turndown. |
| 1. Hollow cone. | Liquid leaves as conical sheet as a result of centrifugal motion of liquid. Air core extends into nozzle. | High atomization efficiency. | Concentrated spray pattern at cone boundaries. |
| *a.* Whirl chamber (see Fig. 14-87*a*). | Centrifugal motion developed by tangential inlet in chamber upstream of orifice. | Minimum opportunity for plugging. | |
| *b.* Grooved core. | Centrifugal motion developed by inserts in chamber. | Smaller spray angle than 1*a* and ability to handle flows smaller than 1*a*. | |
| 2. Solid cone (see Fig. 14-87*b*). | Similar to hollow cone but with insert to provide even distribution. | More uniform spatial pattern than hollow cone. | Coarser drops for comparable flows and pressure drops. Failure to yield same pattern with different fluids. |
| 3. Fan (flat) spray. | Liquid leaves as a flat sheet or flattened ellipse. | Flat pattern is useful for coating surfaces and for injection into streams. | Small clearances. |
| *a.* Oval or rectangular orifice (see Fig. 14-87*c*). Numerous variants on cavity and groove exist. | Combination of cavity and orifice produces two streams that impinge within the nozzle. | | |
| *b.* Deflector (see Fig. 14-87*d*). | Liquid from plain circular orifice impinges on curved deflector. | Minimal plugging. | Coarser drops. |
| *c.* Impinging jets (see Fig. 14-87*e*). | Two jets collide outside nozzle and produce a sheet perpendicular to their plane. | Different liquids are isolated until they mix outside of orifice. Can produce a flat circular sheet when jets impinge at 180°. | Extreme care needed to align jets. |
| 4. Nozzles with wider range of turndown. | | | |
| *a.* Spill (bypass) (see Fig. 14-87*f*). | A portion of the liquid is recirculated after going through the swirl chamber. | Achieves uniform hollow cone atomization pattern with very high turndown (50:1). | Waste of energy in bypass stream. Added piping for spill flow. |
| *b.* Poppet (see Fig. 14-87*g*). | Conical sheet is developed by flow between orifice and poppet. Increased pressure causes poppet to move out and increase flow area. | Simplest control over broad range. | Difficult to maintain proper clearances. |
| Two-fluid (see Fig. 14-87*h*). | Gas impinges coaxially and supplies energy for breakup. | High velocities can be achieved at lower pressures because the gas is the high-velocity stream. Liquid-flow passages can be large, and hence plugging can be minimized. | Because gas is also accelerated, efficiency is inherently lower than pressure nozzles. |
| Sonic. | Gas generates an intense sound field into which liquid is directed. | Similar to two-fluid but with greater tolerance for solids. | Similar to two-fluid. |
| Rotary wheels (see Fig. 14-87*i*) disks, and cups. | Liquid is fed to a rotating surface and spreads in a uniform film. Flat disks, disks with vanes, and bowl-shaped cups are used. Liquid is thrown out at 90° to the axis. | The velocity that determines drop size is independent of flow. Hence these can handle a wide range of rates. They can also tolerate very viscous materials as well as slurries. Can achieve very high capacity in a single unit; does not require a high-pressure pump. | Mechanical complexity of rotating equipment. Radial discharge. |
| Ultrasound. | Liquid is fed over a surface vibrating at a frequency > 20 kHz. | Fine atomization, small size, and low injection velocity. | Low flow rate and need for ultrasound generator. |

At some low flow, pressure nozzles do not develop their normal pattern but tend to approach solid streams. The required flow to achieve the normal pattern increases with viscosity.

**Two-Fluid (Pneumatic) Atomizers** This general category includes such diverse applications as venturi atomizers and reactor-effluent quench systems in addition to two-fluid spray nozzles. Depending on the manner in which the two fluids meet, several of the breakup mechanisms may be applicable, but the final one is high-level turbulent rupture.

As shown by Table 14-20, empirical correlations for two-fluid atomization show dependence on high gas velocity to supply atomizing energy, usually to a power dependence close to that for turbulent breakup. In addition, the correlations show a dependence on the ratio of gas to liquid and system dimension.

Further differences from hydraulic nozzles (controlled by sheet and ligament breakup) are the stronger increase in drop size with increasing surface tension and decreasing gas density.

The similarity of these dependencies to Eq. (14-190) led to a reformulation with two added terms that arise naturally from the theory of power dissipation per unit mass. The result is Eq. (14-198) which is labeled *power/mass* in Table 14-20.

$$D_{32} = 0.29\left(\frac{\sigma}{\rho_G}\right)^{0.6}(1/\text{velocity})^{1.2}\left(1 + \frac{L}{G}\right)^{0.4}\left(D_{\text{nozzle}}\right)^{0.4} \quad (14\text{-}198)$$

where $\sigma$ = surface tension
$\rho_G$ = gas density
$L/G$ = mass ratio of liquid flow to gas flow
$D_{\text{nozzle}}$ = diameter of the air discharge

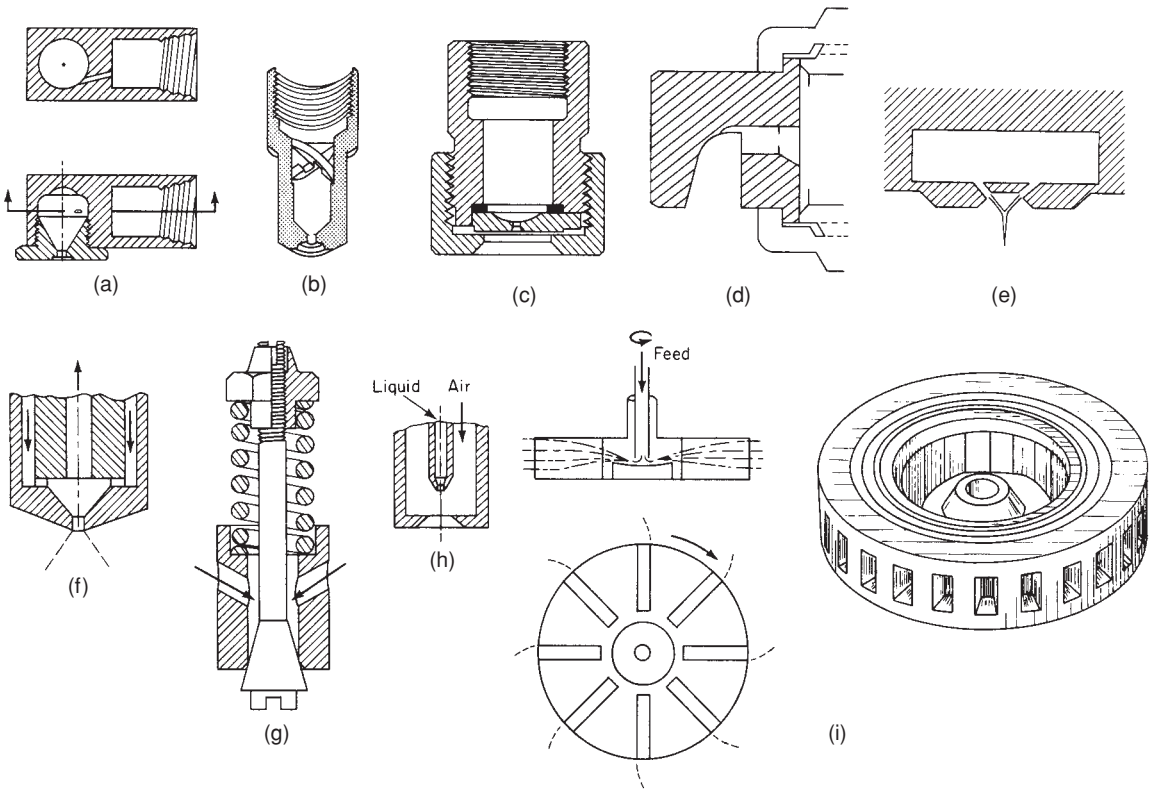

**FIG. 14-87** Charactersitic spray nozzles. (*a*) Whirl-chamber hollow cone. (*b*) Solid cone. (*c*) Oval-orifice fan. (*d*) Deflector jet. (*e*) Impinging jet. (*f*) Bypass. (*g*) Poppet. (*h*) Two-fluid. (*i*) Vaned rotating wheel.

This is remarkably similar to the empirical two-fluid atomizer relationships of El-Shanawany and Lefebvre [*J. Energy,* **4,** 184 (1980)] and Jasuja [*Trans. Am. Soc. Mech. Engr.*, **103,** 514 (1981)]. For example, El-Shanawany and Lefebvre give a relationship for a prefilming atomizer:

$$D_{32} = 0.0711(\sigma/\rho_G)^{0.6}(1/\text{velocity})^{1.2}(1 + L/G)(D_{\text{nozzle}})^{0.4}(\rho_L/\rho_G)^{0.1} + 0.015[(\mu_L)^2/(\sigma \times \rho_L)]^{0.5}(D_{\text{nozzle}})^{0.5}(1 + L/G) \quad (14\text{-}199)$$

where $\mu_L$ is liquid viscosity.

According to Jasuja,

$$D_{32} = 0.17(\sigma/\rho_G)^{0.45}(1/\text{velocity})^{0.9}(1 + L/G)^{0.5}(D_{\text{nozzle}})^{0.55} + \text{viscosity term} \quad (14\text{-}200)$$

[Eqs. (14-198), (14-199), and (14-200) are dimensionally consistent; any set of consistent units on the right-hand side yields the droplet size in units of length on the left-hand side.]

The second, additive term carrying the viscosity impact in Eq. (14-199) is small at viscosities around 1 cP but can become controlling as viscosity increases. For example, for air at atmospheric pressure atomizing water, with nozzle conditions

$$D_{\text{nozzle}} = 0.076 \text{ m (3 in)}$$
$$\text{velocity} = 100 \text{ m/s (328 ft/s)}$$
$$L/G = 1$$

El-Shanaway measured 70 μm and his Eq. (14-199) predicted 76 μm. The *power/mass* correlation [Eq. (14-198)] predicts 102 μm. The agreement between both correlations and the measurement is much better than normally achieved.

**Rotary Atomizers** For rotating wheels, vaneless disks, and cups, there are three regimes of operation. At low rates, the liquid is shed directly as drops from the rim. At intermediate rates, the liquid leaves the rim as threads; and at the highest rate, the liquid extends from the edge as a thin sheet that breaks down similarly to a fan or hollow-cone spray nozzle. As noted in Table 14-19, rotary devices have many unique advantages such as the ability to handle high viscosity and slurries and produce small droplets without high pressures. The prime applications are in spray drying. See Masters [*Spray Drying Handbook,* Wiley, New York (1991)] for more details.

**Pipeline Contactors** The correlation for droplet diameter based on power/mass is similar to that for two-fluid nozzles. The dimensionless correlation is

$$D_{32} = 0.8(\sigma/\rho_G)^{0.6}(1/\text{velocity})^{1.2}(D_{\text{pipe}})^{0.4} \quad (14\text{-}201)$$

(The relation is dimensionally consistent; any set of consistent units on the right-hand side yields the droplet size in units of length on the left-hand side.)

The relationship is similar to the empirical correlation of Tatterson, Dallman, and Hanratty [*Am. Inst. Chem. Eng. J.*, **23**(1), 68 (1977)]

$$D_{32} \sim \left(\frac{\sigma}{\rho_G}\right)^{0.5}(1/\text{velocity})^{1}(D_{\text{pipe}})^{0.5}$$

Predictions from Eq. (14-201) align well with the Tatterson data. For example, for a velocity of 43 m/s (140 ft/s) in a 0.05-m (1.8-inch) equivalent diameter channel, Eq. (14-201) predicts $D_{32}$ of 490 microns, compared to the measured 460 to 480 microns.

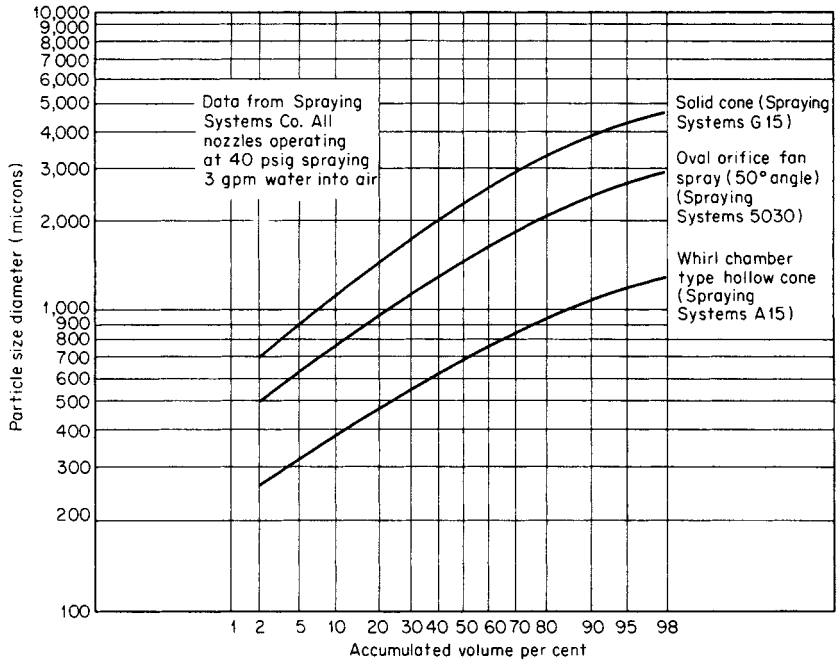

**FIG. 14-88** Droplet-size distribution for three different types of nozzles. To convert pounds per square inch gauge to kilopascals, multiply by 6.89; to convert gallons per minute to cubic meters per hour, multiply by 0.227. (*Spraying Systems Inc.*)

**Entrainment due to Gas Bubbling/Jetting through a Liquid** Entrainment generally limits the capacity of distillation trays and is commonly a concern in vaporizers and evaporators. Fortunately, it is readily controllable by simple inertial entrainment capture devices such as wire mesh pads in gravity separators.

In distillation towers, entrainment lowers the tray efficiency, and 1 pound of entrainment per 10 pounds of liquid is sometimes taken as the limit for acceptable performance. However, the impact of entrainment on distillation efficiency depends on the relative volatility of the component being considered. Entrainment has a minor impact on close separations when the difference between vapor and liquid concentration is small, but this factor can be dominant for systems where the liquid concentration is much higher than the vapor in equilibrium with it (i.e., when a component of the liquid has a very low volatility, as in an absorber).

As shown by Fig. 14-90, entrainment droplet sizes span a broad range. The reason for the much larger drop sizes of the upper curve is the short disengaging space. For this curve, over 99 percent of the entrainment has a terminal velocity greater than the vapor velocity. For contrast, in the lower curve the terminal velocity of the largest particle reported is the same as the vapor velocity. For the settling velocity to limit the maximum drop size entrained, at least 0.8 m (30 in) disengaging space is usually required. Note that even for the lower curve, less than 10 percent of the entrainment is in drops of less than 50 μm. The coarseness results from the relatively low power dissipation per mass on distillation trays. This means that it is relatively easy to remove by a device such as a wire mesh pad. Over 50 percent is typically captured by the underside of the next higher tray or by a turn in the piping leaving an evaporator. Conversely, though small on a mass basis, the smaller drops are extremely numerous. On a number basis, more than one-half of the drops in the lower curve are under 5 μm. These can serve as nuclei for fog condensation in downstream equipment.

**TABLE 14-20 Exponential Dependence of Drop Size on Different Parameters in Two-Fluid Atomization**

| | Relative velocity | Surface tension | Gas density | $1 + L/G$ | Atomizer dimension |
|---|---|---|---|---|---|
| Jasuja (empirical for small nozzle) | −0.9 | 0.45 | −0.45 | 0.5 | 0.55 |
| El-Shanawany and Lefebvre (empirical for small nozzle) | −1.2 | 0.6 | −0.7 | 1 | 0.40 |
| Tatterson, Dallman, and Hanratty (pipe flow) | −1 | 0.5 | −0.5 | | 0.5 |
| Power/mass | −1.2 | 0.6 | −0.6 | 0.4 | 0.4 |

Entrainment $E$ is inherent in the bubbling process and can stem from a variety of sources, as shown by Fig. 14-89. However, the biggest practical problem is entrainment generated by the kinetic energy of the flowing vapor rather than the bubbling process. As vapor velocity approaches the flooding limit [Eq. (14-168)], the entrainment rises approximately with (velocity)$^8$.

Pinczewski and Fell [*Trans. Inst. Chem Eng.*, **55,** 46 (1977)] show that the velocity at which vapor jets onto the tray sets the droplet size, rather than the superficial tray velocity. The power/mass correlation predicts an average drop size close to that measured by Pinczewski and Fell. Combination of this prediction with the estimated fraction of the droplets entrained gave a relationship for entrainment, Eq. (14-202). The dependence of entrainment with the eighth power of velocity even approximates the observed velocity dependence, as flooding is approached.

$$E = \frac{\text{constant}(\text{velocity})^8(\rho_G)^4}{(A_f)^3(\rho_L - \rho_G)^{2.5}\,\sigma^{1.5}} \qquad (14\text{-}202)$$

(Here $E$ is the mass of entrainment per mass of vapor and $A_f$ is the fractional open area on the tray.)

When flooding is defined as the condition that gives $E$ of 1, the flood velocity is estimated by Eq. (14-203).

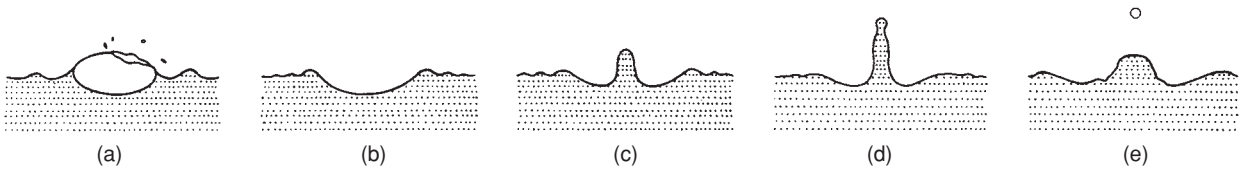

**FIG. 14-89** Mechanism of the burst of an air bubble on the surface of water. [*Newitt, Dombrowski, and Knellman,* Trans. Inst. Chem. Eng., **32,** 244 (*1954*).]

$$U_{\text{flood}} = \frac{1.25(A_f)^{3/8}[g(\rho_L - \rho_G)]^{0.3125}\sigma^{0.1875}}{\rho_G^{0.5}} \qquad (14\text{-}203)$$

The relationship is dimensionally consistent; any set of consistent units on the right-hand side yields velocity units on the left-hand side. It is similar in form to Eq. (14-168) and provides a conceptual framework for understanding the ultimate distillation column capacity concept.

**"Upper Limit" Flooding in Vertical Tubes** If, instead of a gas jet being injected into a liquid as in distillation, the liquid runs down the walls and the gas moves up the center of the tube, higher velocities can be achieved than shown by Eq. (14-168) or (14-203). This application is important in the design of vertical condensers.

Maharudrayya and Jayanti [*AIChE J.,* **48**(2), 212–220 (2002)] show that peak pressure drop in a 25-mm vertical tube occurs at a value close to that predicted by Eq. (14-168) or (14-203). At this velocity about 20 percent of the injected liquid is being entrained out the top of the tube. However, the condition where essentially all liquid was entrained didn't occur until a velocity over twice the value estimated from Eq. (14-168) and Eq. (14-203).

The higher velocities at modest entrainment observed by Maharudrayya and Jayanti were obtained with special smooth entry of gas (and exit of liquid) at the bottom of the tube. Hewitt (*Handbook of Heat Exchanger Design,* pp. 2.3.2-23, 1992) suggests that these values should be derated by at least 35 percent for more typical sharp heat exchanger tube entry. Similar to the smooth entry effect, other data suggest that countercurrent capacity can be increased by providing an extension of the tube below the tube sheet, with the bottom of the extension cut on a steep angle (>60°) to the horizontal. The tapered extension facilitates drainage of liquid.

An extensive data bank correlated by Diehl and Koppany [*Chem. Eng. Prog. Symp. Ser.,* **65,** 77–83 (1965)] also gave higher allowable entry velocities than Eq. (14-168) or (14-203). Diellhl and Koppany's correlation [Eq. (14-204)] is dimensional, and appears to give a much higher dependence on $\sigma$ than the more recent work. However, for many fluids, $\sigma^{0.5}$ is essentially the same as the combination $\sigma^{0.1875}(\rho_l - \rho_g)^{0.3125}$ that appears in Eq. (14-203). Hence Eq. (14-204) gives a similar physical property dependence.

$$U_f = F_1F_2(\sigma/\rho_g)^{0.5} \qquad (14\text{-}204)$$

where $U_f$ = flooding gas velocity, m/s
$F_1 = 1.22$ when $3.2\ d_i/\sigma > 1.0$
$= 1.22\ (3.2\ d_i/\sigma)^{0.4}$ when $3.2\ d_i/\sigma < 1.0$
$F_2 = (G/L)^{0.25}$
$G/L$ = gas-liquid mass ratio
$d_i$ = inside diameter of column, mm
$\sigma$ = surface tension, mN/m (dyn/cm)
$\rho_g$ = gas density, kg/m$^3$

The primary reason for citing Eq. (14-204) is the large successful experience base in practical applications. Note that the reduction in allowable gas velocity for small diameters given by the $F_1$ factor is conceptually the same as the effect of using smaller-diameter packing in distillation. Note also that over the range of $G/L$ between 1 and 0.1, the Maharudrayya and Jayanti data show a similar reduction in allowable gas rate to the $F_2$ factor in Eq. (14-204). The phenomenon behind this is that a thicker liquid film on the tube wall is more easily entrained.

While the limiting phenomenon of upper limit flooding in a vertical pipe is similar to *ultimate capacity* in distillation, there is a distinct difference. *Upper limit* in a vertical pipe applies to a design where a conscious effort should be made to minimize gas-liquid contact. Carried to extremes, it would involve separate tubes for liquid flowing down and vapor going up. In contrast, *ultimate capacity* in a distillation column corresponds to the condition where effective mass transfer disappears due to high entrainment. One could force more vapor up through the contactor, but fractionation would be poor.

**Fog Condensation—The Other Way to Make Little Droplets** For a variety of reasons, a gas or vapor can become supersaturated with a condensable component. Surface tension and mass transfer impose barriers on immediate condensation, so growth of fog particles lags behind what equilibrium predicts. Droplets formed by fog condensation are usually much finer (0.1 to 10 μm) than those formed by mechanical breakup and hence more difficult to collect. Sometimes fog can be a serious problem, as in the atmospheric discharge of a valuable or a hazardous material. More commonly, fog is a curiosity rather than a dominating element in chemical processing.

Fog particles grow because of excess saturation in the gas. Usually this means that the gas is supersaturated (i.e., it is below its dew point). Sometimes, fog can also grow on soluble foreign nuclei at partial pressures below saturation. Increased saturation can occur through a variety of routes:

1. Mixing of two saturated streams at different temperatures. This is commonly seen in the plume from a stack. Since vapor pressure is an exponential function of temperature, the resultant mixture of two saturated streams will be supersaturated at the mixed temperature. Uneven flow patterns and cooling in heat exchangers make this route to supersaturation difficult to prevent.
2. Increased partial pressure due to reaction. An example is the reaction of $SO_3$ and $H_2O$ to yield $H_2SO_4$, which has much lower vapor pressure than its components.
3. Isoentropic expansion (cooling) of a gas, as in a steam nozzle.
4. Cooling of a gas containing a condensable vapor. Here the problem is that the gas cools faster than condensable vapor can be removed by mass transfer.

These mechanisms can be observed in many common situations. For example, fog via mixing can be seen in the discharge of breath on a cold day. Fog via adiabatic expansion can be seen in the low-pressure area over the wing of an airplane landing on a humid summer day; and fog via condensation can be seen in the exhaust from an automobile air conditioner (if you follow closely enough behind another car to pick up the ions or NO molecules needed for nucleation). All of these occur at a very low supersaturation and appear to be keyed to an abundance of foreign nuclei. All of these fogs also quickly dissipate as heat or unsaturated gas is added.

The supersaturation in condensers arises for two reasons. First, the condensable vapor is generally of higher molecular weight than the noncondensable gas. This means that the molecular diffusivity of the vapor will be much less than the thermal diffusivity of the gas. Restated, the ratio of $N_{Sc}/N_{Pr}$ is greater than 1. The result is that a condenser yields more heat-transfer units $dT_g/(T_g - T_i)$ than mass-transfer units $dY_g/(Y_g - Y_i)$. Second, both transfer processes derive their driving force from the temperature difference between the gas $T_g$ and the interface $T_i$. Each incremental decrease in interface temperature

**TABLE 14-21 Simulation of Three Heat Exchangers with Varying Foreign Nuclei**

| | 1 | 2 | 3 |
|---|---|---|---|
| Weight fraction, noncondensable | | | |
| Inlet | 0.51 | 0.42 | 0.02 |
| Outlet | 0.80 | 0.80 | 0.32 |
| Molecular weight | | | |
| Inert | 28 | 29 | 29 |
| Condensable | 86 | 99 | 210 |
| Temperature difference between gas and liquid interface, K | | | |
| Inlet | 14 | 24 | 67 |
| Outlet | 4 | 10 | 4 |
| Percent of liquid that leaves unit as fog | | | |
| Nuclei concentration in inlet particles/cm$^3$ | | | |
| 100 | 0.05 | 1.1 | 2.2 |
| 1,000 | 0.44 | 5.6 | 3.9 |
| 10,000 | 3.2 | 9.8 | 4.9 |
| 100,000 | 9.6 | 11.4 | 5.1 |
| 1,000,000 | 13.3 | 11.6 | |
| 10,000,000 | 14.7 | | |
| ∞ | 14.7 | 11.8 | 5.1 |
| Fog particle size based on 10,000 nuclei/cm$^3$ at inlet, μm | 28 | 25 | 4 |

yields the same relative increase in temperature driving force. However, the interface vapor pressure can only approach the limit of zero. Because of this, for equal molecular and thermal diffusivities a saturated mixture will supersaturate when cooled. The tendency to supersaturate generally increases with increased molecular weight of the condensable, increased temperature differences, and reduced initial superheating. To evaluate whether a given condensing step yields fog requires rigorous treatment of the coupled heat-transfer and mass-transfer processes through the entire condensation. Steinmeyer [*Chem. Eng. Prog.,* **68**(7), 64 (1972)] illustrates this, showing the impact of foreign-nuclei concentration on calculated fog formation. See Table 14-21. Note the relatively large particles generated for cases 1 and 2 for 10,000 foreign nuclei per cm$^3$. These are large enough to be fairly easily collected. There have been very few documented problems with industrial condensers despite the fact that most calculate to generate supersaturation along the condensing path. The explanation appears to be a limited supply of foreign nuclei.

Ryan et al. [*Chem. Eng. Progr.,* **90**(8), 83 (1994)] show that separate mass and heat transfer-rate modeling of an HCl absorber predicts 2 percent fog in the vapor. The impact is equivalent to lowering the stage efficiency to 20 percent.

**Spontaneous (Homogeneous) Nucleation** This process is quite difficult because of the energy barrier associated with creation of the interfacial area. It can be treated as a kinetic process with the rate a very steep function of the supersaturation ratio ($S$ = partial pressure of condensable per vapor pressure at gas temperature). For water, an increase in $S$ from 3.4 to 3.9 causes a 10,000-fold increase in the nucleation rate. As a result, below a critical supersaturation ($S_{crit}$), homogeneous nucleation is slow enough to be ignored. Generally, $S_{crit}$ is defined as that which limits nucleation to one particle produced per cubic centimeter per second. It can be estimated roughly by traditional theory (*Theory of Fog Condensation,* Israel Program for Scientific Translations, Jerusalem, 1967) using the following equation:

$$S_{crit} = \exp\left[0.56\,\frac{M}{\rho_l}\left(\frac{\sigma}{T}\right)^{3/2}\right] \qquad (14\text{-}205)$$

where $\sigma$ = surface tension, mN/m (dyn/cm)
$\rho_l$ = liquid density, g/cm$^3$
$T$ = temperature, K
$M$ = molecular weight of condensable

Table 14-22 shows typical experimental values of $S_{crit}$ taken from the work of Russel [*J. Chem. Phys.,* **50,** 1809 (1969)]. Since the critical supersaturation ratio for homogeneous nucleation is typically greater than 3, it is not often reached in process equipment. However, fog formation is typically found in steam turbines. Gyarmathy [*Proc. Inst. Mech. E., Part A: J. Power and Energy* **219**(A6), 511–521 (2005)] reports fog in the range 3.5 to 5 percent of total steam flow, with average fog diameter in the range of 0.1 to 0.2 μm.

**TABLE 14-22 Experimental Critical Supersaturation Ratios**

| | Temperature, K | $S_{crit}$ |
|---|---|---|
| $H_2O$ | 264 | 4.91 |
| $C_2H_5OH$ | 275 | 2.13 |
| $CH_4OH$ | 264 | 3.55 |
| $C_6H_6$ | 253 | 5.32 |
| $CCl_4$ | 247 | 6.5 |
| $CHCl_3$ | 258 | 3.73 |
| $C_6H_5Cl$ | 250 | 9.5 |

**Growth on Foreign Nuclei** As noted above, foreign nuclei are often present in abundance and permit fog formation at much lower supersaturation. For example,

1. *Solids.* Surveys have shown that air contains thousands of particles per cubic centimeter in the 0.1-μm to 1-μm range suitable for nuclei. The sources range from ocean-generated salt spray to combustion processes. The concentration is highest in large cities and industrial regions. When the foreign nuclei are soluble in the fog, nucleation occurs at $S$ values very close to 1.0. This is the mechanism controlling atmospheric water condensation. Even when not soluble, a foreign particle is an effective nucleus if wet by the liquid. Thus, a 1-μm insoluble particle with zero contact angle requires an $S$ of only 1.001 in order to serve as a condensation site for water.

2. *Ions.* Amelin [*Theory of Fog Condensation,* Israel Program for Scientific Translations, Jerusalem, (1967)] reports that ordinary air contains even higher concentrations of ions. These ions also reduce the required critical supersaturation, but by only about 10 to 20 percent, unless multiple charges are present.

3. *Entrained liquids.* Production of small droplets is inherent in the bubbling process, as shown by Fig. 14-90. Values range from near zero to 10,000/cm$^3$ of vapor, depending on how the vapor breaks through the liquid and on the opportunity for evaporation of the small drops after entrainment.

As a result of these mechanisms, most process streams contain enough foreign nuclei to cause some fogging. While fogging has been reported in only a relatively low percent of process partial condensers, it is rarely looked for and volunteers its presence only when yield losses or pollution is intolerable.

**Dropsize Distribution** Monodisperse (nearly uniform droplet size) fogs can be grown by providing a long retention time for growth. However, industrial fogs usually show a broad distribution, as in Fig. 14-91. Note also that for this set of data, the sizes are several orders of magnitude smaller than those shown earlier for entrainment and atomizers.

The result, as discussed in a later subsection, is a demand for different removal devices for the small particles.

While generally fog formation is a nuisance, it can occasionally be useful because of the high surface area generated by the fine drops. An example is insecticide application.

**Objectives of Gas Dispersion** The dispersion of gas as bubbles in a liquid or in a plastic mass is effected for one of the following purposes: (1) gas-liquid contacting (to promote absorption or stripping, with or without chemical reaction), (2) agitation of the liquid phase, or

(3) foam or froth production. Gas-in-liquid dispersions also may be produced or encountered inadvertently, sometimes undesirably.

***Gas-Liquid Contacting*** Usually this is accomplished with conventional columns or with spray absorbers (see preceding subsection "Liquid-in-Gas Dispersions"). For systems containing solids or tar likely to plug columns, absorptions accomplished by strongly exothermic reactions, or treatments involving a readily soluble gas or a condensable vapor, however, bubble columns or agitated vessels may be used to advantage.

***Agitation*** Agitation by a stream of gas bubbles (often air) rising through a liquid is often employed when the extra expense of mechanical agitation is not justified. Gas spargers may be used for simple blending operations involving a liquid of low volatility or for applications where agitator shaft sealing is difficult.

***Foam Production*** This is important in froth-flotation separations; in the manufacture of cellular elastomers, plastics, and glass; and in certain special applications (e.g., food products, fire extinguishers). Unwanted foam can occur in process columns, in agitated vessels, and in reactors in which a gaseous product is formed; it must be avoided, destroyed, or controlled. Berkman and Egloff (*Emulsions and Foams,* Reinhold, New York, 1941, pp. 112–152) have mentioned that foam is produced only in systems possessing the proper combination of interfacial tension, viscosity, volatility, and concentration of solute or suspended solids. From the standpoint of gas comminution, foam production requires the creation of small bubbles in a liquid capable of sustaining foam.

**Theory of Bubble and Foam Formation** A bubble is a globule of gas or vapor surrounded by a mass or thin film of liquid. By extension, globular voids in a solid are sometimes called bubbles. Foam is a group of bubbles separated from one another by thin films, the aggregation having a finite static life. Although nontechnical dictionaries do not distinguish between foam and froth, a technical distinction is often made. A highly concentrated dispersion of bubbles in a liquid is considered a froth even if its static life is substantially nil (i.e., it must be dynamically maintained). Thus, all foams are also froths, whereas the reverse is not true. The term *lather* implies a froth that is worked up on a solid surface by mechanical agitation; it is seldom used in technical discussions. The thin walls of bubbles comprising a foam are called *laminae* or *lamellae.*

Bubbles in a liquid originate from one of three general sources: (1) They may be formed by desupersaturation of a solution of the gas or by the decomposition of a component in the liquid; (2) They may be introduced directly into the liquid by a bubbler or sparger or by mechanical entrainment; and (3) They may result from the disintegration of larger bubbles already in the liquid.

***Generation*** Spontaneous generation of gas bubbles within a homogeneous liquid is theoretically impossible (Bikerman, *Foams: Theory and Industrial Applications,* Reinhold, New York, 1953, p. 10). The appearance of a bubble requires a gas nucleus as a void in the liquid. The nucleus may be in the form of a small bubble or of a solid carrying adsorbed gas, examples of the latter being dust particles, boiling chips, and a solid wall. A void can result from cavitation, mechanically or acoustically induced. Basu, Warrier, and Dhir [*J. Heat Transfer*, **124**, 717 (2002)] have reviewed boiling nucleation, and Blander and Katz [*AIChE J.,* **21,** 833 (1975)] have thoroughly reviewed bubble nucleation in liquids.

Theory permits the approximation of the maximum size of a bubble that can adhere to a submerged horizontal surface if the contact angle between bubble and solid (angle formed by solid-liquid and liquid-gas interfaces) is known [Wark, *J. Phys. Chem.,* **37,** 623 (1933); Jakob, *Mech. Eng.,* **58,** 643 (1936)]. Because the bubbles that actually rise from a surface are always considerably smaller than those so calculated and inasmuch as the contact angle is seldom known, the theory is not directly useful.

***Formation at a Single Orifice*** The formation of bubbles at an orifice or capillary immersed in a liquid has been the subject of much study, both experimental and theoretical. Kulkarni and Joshi [*Ind. Eng. Chem. Res.*, **44**, 5873 (2005)] have reviewed bubble formation and rise. Bikerman (op. cit., Secs. 3 to 7), Valentin (op. cit., Chap. 2), Jackson (op. cit.), Soo (op. cit., Chap. 3), Fair (op. cit.), Kumer et al. (op. cit.), Clift et al. (op. cit.) and Wilkinson and Van Dierendonck [*Chem. Eng. Sci.,* **49,** 1429 (1994)] have presented reviews and analyses of this subject.

There are three regimes of bubble production (Silberman in *Proceedings of the Fifth Midwestern Conference on Fluid Mechanics,* Univ. of Michigan Press, Ann Arbor, 1957, pp. 263–284): (1) single-bubble, (2) intermediate, and (3) jet.

***Single-Bubble Regime*** Bubbles are produced one at a time, their size being determined primarily by the orifice diameter $d_o$, the interfacial tension of the gas-liquid film $\sigma$, the densities of the liquid $\rho_L$ and gas $\rho_G$, and the gravitational acceleration $g$ according to the relation

$$d_b/d_o = [6\sigma/gd_o^2(\rho_L - \rho_G)]^{1/3} \tag{14-206}$$

where $d_b$ is the bubble diameter.

$$f = Q/(\pi d_b^3/6) = Qg(\rho_L - \rho_G)/(\pi d_o \sigma) \tag{14-207}$$

where $f$ is the frequency of bubble formation and $Q$ is the volumetric rate of gas flow in consistent units.

Equations (14-206) and (14-207) result from a balance of bubble buoyancy against interfacial tension. They include no inertia or viscosity effects. At low bubbling rates (<1/s), these equations are quite satisfactory. Van Krevelen and Hoftijzer [*Chem. Eng. Prog.,* **46,** 29 (1950)], Guyer and Peterhaus [*Helv. Chim. Acta,* **26,** 1099 (1943)] and Wilkinson (op. cit.) report good agreement with Eq. (14-206) for water, transformer oil, ether, and carbon tetrachloride for vertically oriented orifices with $0.004 < D < 0.95$ cm. If the orifice diameter becomes too large, the bubble diameter will be smaller than the orifice diameter, as predicted by Eq. (14-206), and instability results; consequently, stable, stationary bubbles cannot be produced. Kulkarni et al. (op. cit.) have discussed much more detailed models for predicting bubble size; however, the models are very difficult and tedious to use in practice. These more sophisticated models need to be considered if the added accuracy warrants the extra effort.

For bubbles formed in water, the orifice diameter that permits bubbles of about its own size is calculated as 0.66 cm. Davidson and Amick [*AIChE J.,* **2,** 337 (1956)] confirmed this estimate in their observation that stable bubbles in water were formed at a 0.64-cm orifice but could not be formed at a 0.79-cm orifice.

For very thin liquids, Eqs. (14-206) and (14-207) are expected to be valid up to a gas-flow Reynolds number of 200 (Valentin, op. cit., p. 8). For liquid viscosities up to 100 cP, Datta, Napier, and Newitt [*Trans. Inst. Chem. Eng.,* **28,** 14 (1950)] and Siems and Kauffman [*Chem. Eng. Sci.,* **5,** 127 (1956)] have shown that liquid viscosity has very little effect on the bubble volume, but Davidson and Schuler [*Trans. Instn. Chem. Eng.,* **38,** 144 (1960)] and Krishnamurthi et al. [*Ind. Eng. Chem. Fundam.,* **7,** 549 (1968)] have shown that bubble size increases considerably over that predicted by Eq. (14-206) for liquid viscosities above 1000 cP. In fact, Davidson et al. (op. cit.) found that their data agreed very well with a theoretical equation obtained by equating the buoyant force to drag based on Stokes' law and the velocity of the bubble equator at break-off:

$$d_b = \left(\frac{6}{\pi}\right)\left(\frac{4\pi}{3}\right)^{1/4}\left(15 \times \frac{\nu Q}{2g}\right)^{3/4} \tag{14-208}$$

where $\nu$ is the liquid kinematic viscosity and $Q$ is the gas volumetric flow rate. This equation is dimensionally consistent. The relative effect of liquid viscosity can be obtained by comparing the bubble diameters calculated from Eqs. (14-206) and (14-208). If liquid viscosity appears significant, one might want to use the long and tedious method developed by Krishnamurthi et al. (op. cit.) and the review by Kulkarni et al. (op. cit.) that considers both surface-tension forces and viscous-drag forces.

***Intermediate Regime*** This regime extends approximately from a Reynolds number of 200 to one of 2100. As the gas flow through a

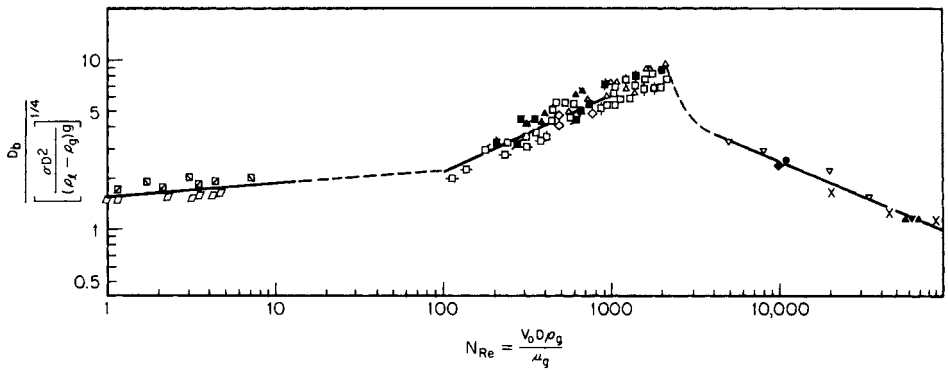

**FIG. 14-92** Bubble-diameter correlation for air sparged into relatively inviscid liquids. $D_b$ = bubble diameter, $D$ = orifice diameter, $V_o$ = gas velocity through sparging orifice, $P$ = fluid density, and μ = fluid viscosity. [*From* Can. J. Chem. Eng., ***54,*** 503 (*1976*).]

submerged orifice increases beyond the limit of the single-bubble regime, the frequency of bubble formation increases more slowly, and the bubbles begin to grow in size. Between the two regimes there may indeed be a range of gas rates over which the bubble size decreases with increasing rate, owing to the establishment of liquid currents that nip the bubbles off prematurely. The net result can be the occurrence of a minimum bubble diameter at some particular gas rate [Mater, *U.S. Bur. Mines Bull.* 260 (1927) and Bikerman, op. cit., p. 4]. At the upper portion of this region, the frequency becomes very nearly constant with respect to gas rate, and the bubble size correspondingly increases with gas rate. The bubble size is affected primarily by (1) orifice diameter, (2) liquid-inertia effects, (3) liquid viscosity, (4) liquid density, and (5) the relationship between the constancy of gas flow and the constancy of pressure at the orifice.

Kumar et al. have done extensive experimental and theoretical work reported in *Ind. Eng. Chem. Fundam.,* **7,** 549 (1968); *Chem. Eng. Sci,* **24,** part 1, 731; part 2, 749; part 3, 1711 (1969) and summarized in *Adv. Chem. Eng.,* **8,** 255 (1970). They, along with other investigators—Swope [*Can. J Chem. Eng.,* **44,** 169 (1972)], Tsuge and Hibino [*J. Chem. Eng. Japan,* **11,** 307 (1972)], Pinczewski [*Chem. Eng. Sci.,* **36,** 405 (1981)], Tsuge and Hibino [*Int. Chem. Eng.,* **21,** 66 (1981)], and Takahashi and Miyahara [ibid., p. 224]—have solved the equations resulting from a force balance on the forming bubble, taking into account buoyancy, surface tension, inertia, and viscous-drag forces for both conditions of constant flow through the orifice and constant pressure in the gas chamber. The design method is complex and tedious and involves the solution of algebraic and differential equations. Although Mersmann [*Ger. Chem. Eng.,* **1,** 1 (1978)] claims that the results of Kumar et al. (loc. cit.) well fit experimental data, Lanauze and Harn [*Chem. Eng. Sci.,* **29,** 1663 (1974)] claim differently:

> Further, it has been shown that the mathematical formulation of Kumar's model, including the condition of detachment, could not adequately describe the experimental situation—Kumar's model has several fundamental weaknesses, the computational simplicity being achieved at the expense of physical reality.

In lieu of careful independent checks of predictive accuracy, the results of the comprehensive theoretical work will not be presented here. Simpler, more easily understood predictive methods, for certain important limiting cases, will be presented. As a check on the accuracy of these simpler methods, it will perhaps be prudent to calculate the bubble diameter from the graphical representation by Mersmann (loc. cit.) of the results of Kumar et al. (loc. cit.) and the review by Kulkarni et al. (op. cit.)

For conditions approaching constant flow through the orifice, a relationship derived by equating the buoyant force to the inertia force of the liquid [Davidson et al., *Trans. Instn. Chem. Engrs.,* **38,** 335 (1960)] (dimensionally consistent),

$$d_b = 1.378 \times \frac{6Q^{6/5}}{\pi g^{3/5}} \tag{14-209}$$

fits experimental data reasonably well. Surface tension and liquid viscosity tend to increase the bubble size—at a low Reynolds number. The effect of surface tension is greater for large orifice diameters. The magnitude of the diameter increase due to high liquid viscosity can be obtained from Eq. (14-208).

For conditions approaching constant pressure at the orifice entrance, which probably simulates most industrial applications, there is no independently verified predictive method. For air at near atmospheric pressure sparged into relatively inviscid liquids (11 ~ 100 cP), the correlation of Kumar et al. [*Can. J. Chem. Eng.,* **54,** 503 (1976)] fits experimental data well. Their correlation is presented here as Fig. 14-92.

Wilkinson et al. (op. cit.) make the following observation about the effect of gas density on bubble size: "The fact that the bubble size decreases slightly for higher gas densities can be explained on the basis of a force balance."

***Jet Regime*** With further rate increases, turbulence occurs at the orifice, and the gas stream approaches the appearance of a continuous jet that breaks up 7.6 to 10.2 cm above the orifice. Actually, the stream consists of large, closely spaced, irregular bubbles with a rapid swirling motion. These bubbles disintegrate into a cloud of smaller ones of random size distribution between 0.025 cm or smaller and about 1.25 cm, with a mean size for air and water of about 0.4 cm (Leibson et al., loc. cit.). According to Wilkinson et al. (op. cit.), jetting begins when

$$N_{We,g} = \frac{\rho_g d_o U_o^2}{\sigma} \le 2 \tag{14-210}$$

There are many contradictory reports about the jet regime, and theory, although helpful (see, for example, Siberman, loc. cit.), is as yet unable to describe the phenomena observed. The correlation of Kumar et al. (Fig. 14-92) is recommended for air-liquid systems.

***Formation at Multiple Orifices*** At high velocities, coalescence of bubbles formed at individual orifices occurs; Helsby and Tuson [*Research* (London), **8,** 270 (1955)], for example, observed the frequent coalescence of bubbles formed in pairs or in quartets at an orifice. Multiple orifices spaced by the order of magnitude of the orifice diameter increase the probability of coalescence, and when the magnitude is small (as in a sintered plate), there is invariably some. The broken lines of Fig. 14-92 presumably represent zones of increased coalescence and relatively less effective dispersion as the gas rate through porous-carbon tubes is increased. Savitskaya [*Kolloidn. Zh.,* **13,** 309 (1951)] found that the average bubble size formed at the

surface of a porous plate was such as to maintain constancy of the product of bubble specific surface and interfacial tension as the latter was varied by addition of a surfactant. Konig et al. [*Ger. Chem. Eng.,* **1,** 199 (1978)] produced bubble sizes varying from 0.5 to 4 mm by the use of two porous-plate spargers and one perforated-plate sparger with superficial gas velocities from 1 to 8 cm/s. The small bubble sizes were stabilized by adding up to 0.5 percent of various alcohols to water.

At high-flow rates through perforated plates such as those that occur in distillation columns, Calderbank and Rennie [*Trans. Instn. Chem. Engrs.,* **40,** T3 (1962)]; Porter et al. [ibid., **45,** T265 (1967)]; Rennie and Evans [*Br. Chem. Eng,* **7,** 498 (1962)]; and Valentin (op. cit., Chap. 3) have investigated and discussed the effect of the flow conditions through the multiple orifices on the froths and foams that occur above perforated plates.

***Entrainment and Mechanical Disintegration*** Gas can be entrained into a liquid by a solid or a stream of liquid falling from the gas phase into the liquid, by surface ripples or waves, and by the vertical swirl of a mass of agitated liquid about the axis of a rotating agitator. Small bubbles probably form near the surface of the liquid and are caught into the path of turbulent eddies, whose velocity exceeds the terminal velocity of the bubbles. The disintegration of a submerged mass of gas takes place by the turbulent tearing of smaller bubbles away from the exterior of the larger mass or by the influence of surface tension on the mass when it is attenuated by inertial or shear forces into a cylindrical or disk form. A fluid cylinder that is greater in length than in circumference is unstable and tends to break spontaneously into two or more spheres. These effects account for the action of fluid attrition and of an agitator in the disintegration of suspended gas. Quantitative correlations for gas entrainment by liquid jets and in agitated vessels will be given later.

***Foams*** Two excellent reviews (Shedlovsky, op. cit.; Lemlich, op. cit.; Herzhaft, op. cit.; and Heller et al., op. cit) covering the literature pertinent to foams have been published. A foam is formed when bubbles rise to the surface of a liquid and persist for a while without coalescence with one another or without rupture into the vapor space. The formation of foam, then, consists simply of the formation, rise, and aggregation of bubbles in a liquid in which foam can exist. The life of foams varies over many magnitudes—from seconds to years—but in general is finite. Maintenance of a foam, therefore, is a dynamic phenomenon.

Gravitational force favors the separation of gas from liquid in a disperse system, causing the bubbles to rise to the liquid surface and the liquid contained in the bubble walls to drain downward to the main body of the liquid. Interfacial tension favors the coalescence and ultimate disappearance of bubbles; indeed, it is the cause of bubble destruction upon the rupture of the laminae.

The viscosity of the liquid in a film opposes the drainage of the film and its displacement by the approach of coalescing bubbles. The higher the viscosity, the slower will be the film-thinning process; furthermore, if viscosity increases as the film grows thinner, the process becomes self-retarding. The viscosity of films appears to be greater than that of the main body of the parent liquid in many cases. Sometimes this is a simple temperature effect, the film being cooler because of evaporation; sometimes it is a concentration effect, with dissolved or fine suspended solids migrating to the interface and producing classical or anomalous increases in viscosity; at yet other times, the effect seems to occur without explanation.

If the liquid laminae of a foam system can be converted to impermeable solid membranes, the film viscosity can be regarded as having become infinite, and the resulting solid foam will be permanent. Likewise, if the laminae are composed of a gingham plastic or a thixotrope, the foam will be permanently stable for bubbles whose buoyancy does not permit exceeding the yield stress. For other nonnewtonian fluids, however, and for all newtonian ones, no matter how viscous, the viscosity can only delay but never prevent foam disappearance. The popular theory, held since the days of Plateau, that foam life is proportional to surface viscosity and inversely proportional to interfacial tension, is not correct, according to Bikerman (op. cit., p. 161), who points out that it is contradicted by experiment.

The idea that foam films drain to a critical thickness at which they spontaneously burst is also rejected by Bikerman. Foam stability, rather, is keyed to the existence of a surface skin of low interfacial tension immediately overlying a solution bulk of higher tension, latent until it is exposed by rupture of the superficial layer [Maragoni, *Nuovo Cimento,* **2** (5–6), 239 (1871)]. Such a phenomenon of surface elasticity, resulting from concentration differences between bulk and surface of the liquid, accounts for the ability of bubbles to be penetrated by missiles without damage. It is conceivable that films below a certain thickness no longer carry any bulk of solution and hence have no capacity to close surface ruptures, thus becoming vulnerable to mechanical damage that will destroy them. The Maragoni phenomenon is consistent also with the observation that neither pure liquids nor saturated solutions will sustain a foam, since neither extreme will allow the necessary differences in concentration between surface and bulk of solution.

The specific ability of certain finely divided, insoluble solids to stabilize foam has long been known [Berkman and Egloff, op. cit., p. 133; and Bikerman, op. cit., Chap. 11]. Bartsch [*Kolloidchem. Beih,* **20,** 1 (1925)] found that the presence of fine galena greatly extended the life of air foam in aqueous isoamyl alcohol, and the finer the solids, the greater the stability. Particles on the order of 50 μm length extended the life from 17 seconds to several hours. This behavior is consistent with theory, which indicates that a solid particle of medium contact angle with the liquid will prevent the coalescence of two bubbles with which it is in simultaneous contact. Quantitative observations of this phenomenon are scanty.

Berkman and Egloff explain that some additives increase the flexibility or toughness of bubble walls, rather than their viscosity, to render them more durable. They cite as illustrations the addition of small quantities of soap to saponin solutions or of glycerin to soap solution to yield much more stable foam. The increased stability with ionic additives is probably due to electrostatic repulsion between charged, nearly parallel surfaces of the liquid film, which acts to retard draining and hence rupture.

### Characteristics of Dispersion

***Properties of Component Phases*** As discussed in the preceding subsection, dispersions of gases in liquids are affected by the viscosity of the liquid, the density of the liquid and of the gas, and the interfacial tension between the two phases. They also may be affected directly by the composition of the liquid phase. Both the formation of bubbles and their behavior during their lifetime are influenced by these quantities as well as by the mechanical aspects of their environment.

Viscosity and density of the component phases can be measured with confidence by conventional methods, as can the interfacial tension between a pure liquid and a gas. The interfacial tension of a system involving a solution or micellar dispersion becomes less satisfactory, because the interfacial free energy depends on the concentration of solute at the interface. Dynamic methods and even some of the so-called static methods involve the creation of new surfaces. Since the establishment of equilibrium between this surface and the solute in the body of the solution requires a finite amount of time, the value measured will be in error if the measurement is made more rapidly than the solute can diffuse to the fresh surface. Eckenfelder and Barnhart (Am. Inst. Chem. Engrs., 42d national meeting, Repr. 30, Atlanta, 1960) found that measurements of the surface tension of sodium lauryl sulfate solutions by maximum bubble pressure were higher than those by DuNuoy tensiometer by 40 to 90 percent, the larger factor corresponding to a concentration of about 100 ppm, and the smaller to a concentration of 2500 ppm of sulfate.

Even if the interfacial tension is measured accurately, there may be doubt about its applicability to the surface of bubbles being rapidly formed in a solution of a surface-active agent, for the bubble surface may not have time to become equilibrated with the solution. Coppock and Meiklejohn [*Trans. Instn. Chem. Engrs.,* **29,** 75 (1951)] reported that bubbles formed in the single-bubble regime at an orifice in a solution of a commercial detergent had a diameter larger than that calculated in terms of the measured surface tension of the solution [Eq. (14-206)]. The disparity is probably a reflection of unequilibrated bubble laminae.

One concerned with the measurement of gas-liquid interfacial tension should consult the useful reviews of methods prepared by Harkins [in Chap. 9 of Weissberger, *Techniques of Organic Chemstry,* 2d ed., vol. 1, part 2, Interscience, New York, 1949), Schwartz and coauthors [*Surface Acttve Agents,* vol. 1, Interscience, New York, 1949, pp. 263–271; *Surface Active Agents and Detergents,* vol. 2, Interscience, New York, 1958, pp. 389–391, 417–418], and by Adamson [*Physical Chemistry of Surfaces,* Interscience, New York, 1960].

***Dispersion Characteristics*** The chief characteristics of gas-in-liquid dispersions, like those of liquid-in-gas suspensions, are heterogeneity and instability. The composition and structure of an unstable dispersion must be observed in the dynamic situation by looking at the mixture, with or without the aid of optical devices, or by photographing it, preferably in nominal steady state; photographs usually are required for quantitative treatment. Stable foams may be examined after the fact of their creation if they are sufficiently robust or if an immobilizing technique such as freezing is employed [Chang et al., *Ind. Eng Chem.,* **48,** 2035 (1956)].

The rate of rise of bubbles has been discussed by Kulkarni, op. cit.; Benfratello, *Energ Elettr.,* **30,** 80 (1953); Haberman and Morton, *Report 802: David W. Taylor Model Basin,* Washington, September 1953; Jackson, loc. cit.; Valentin, op. cit., Chap. 2; Soo, op. cit., Chap. 3; Calderbank, loc. cit., p. CE220; and Levich, op. cit., Chap. 8). A comprehensive and apparently accurate predictive method has been published [Jamialahamadi et al., *Trans ICE,* **72,** part A, 119–122 (1994)]. Small bubbles (below 0.2 mm in diameter) are essentially rigid spheres and rise at terminal velocities that place them clearly in the laminar-flow region; hence their rising velocity may be calculated from Stokes' law. As bubble size increases to about 2 mm, the spherical shape is retained, and the Reynolds number is still sufficiently small (<10) that Stokes' law should be nearly obeyed.

As bubble size increases, two effects set in, however, that alter the velocity. At about $N_{Re} = 100$, a wobble begins that can develop into a helical path if the bubbles are not liberated too closely to one another [Houghton, McLean, and Ritchie, *Chem. Eng. Sci.,* **7,** 40 (1957); and Houghton et al., ibid., p. 111]. Furthermore, for bubbles in the range of 1 mm and larger (until distortion becomes serious) internal circulation can set in [Garner and Hammerton, *Chem. Eng. Sci.,* **3,** (1954); and Haberman and Morton, loc. cit.], and according to theoretical analyses by Hadamard and Rybczynski and given by Levich (op. cit.), the drag coefficient for a low-viscosity dispersed phase and a high-viscosity continuous phase will approach two-thirds of the drag coefficient for rigid spheres, namely $C_D = 16/N_{Re}$. The rise velocity of a circulating bubble or drop will thus be 1.5 times that of a rigid sphere. Redfield and Houghton [*Chem. Eng. Sci.,* **20,** 131 (1965)] have found that $CO_2$ bubbles rising in pure water agree with the theoretical solution for a circulating drop below $N_{Re} = 1$. Many investigators (see Valentin, op. cit.) have found that extremely small quantities of impurities can retard or stop this internal circulation. In this behavior may lie the explanation of the fact that the addition of long-chain fatty acids to water to produce a concentration of $1.5 \times 10^{-4}$ molar markedly reduces the rate of rise of bubbles [Stuke, *Naturwissenschaften,* **39,** 325 (1952)].

Above diameters of about 2 mm, bubbles begin to change to ellipsoids, and above 1 cm they become lens-shaped, according to Davies and Taylor [*Proc. Roy. Soc.* (London), **A200,** 379 (1950)]. The rising velocity in thin liquids for the size range $1 \text{ mm} < D_B < 20 \text{ mm}$ has been reported as 20 to 30 cm/s by Haberman and Morton (op. cit.) and Davenport, Richardson, and Bradshaw [*Chem. Eng. Sci.,* **22,** 1221 (1967)]. Schwerdtieger [ibid., **23,** 937 (1968)] even found the same for argon bubbles rising in mercury. Surface-active agents have no effect on the rise velocity of bubbles larger than 4 mm in thin liquids (Davenport et al., loc. cit.).

Above a Reynolds number of the order of magnitude of 1000, bubbles assume a helmet shape, with a flat bottom (Eckenfelder and Barnhart, loc. cit.; and Leibson et al., loc. cit.). After bubbles become large enough to depart from Stokes' law at their terminal velocity, behavior is generally complicated and erratic, and the reported data scatter considerably. The rise can be slowed, furthermore, by a wall effect if the diameter of the container is not greater than 10 times the diameter of the bubbles, as shown by Uno and Kintner [*AIChE J.,* **2,** 420 (1956); and Collins, *J. Fluid Mech.,* **28**(1), 97 (1967)]. Work has been done to predict the rise velocity of large bubbles [Rippin and Davidson, *Chem. Eng. Sci.,* **22,** 217 (1967); Grace and Harrison, ibid., 1337; Mendelson, *AIChE J.,* **13,** 250 (1967); Cole, ibid.; Lehrer, *J. Chem. Eng. Japan,* **9,** 237 (1976); and Lehrer, *AIChE J.,* **26,** 170 (1980)]. The works of Lehrer present correlations that accurately predict rise velocities for a wide range of system properties. Reviews of the technical literature concerning the rise of single bubbles and drops have been published by Kulkarni et al. (op. cit.) and Clift, Grace, and Weber (*Bubbles, Drops and Particles,* Academic, New York, 1978). Mendelson has used a wave theory to predict the terminal velocity, and Cole has checked the theory with additional data. The other authors listed solved some simplified form of the Navier-Stokes equations. Jamialahmadi et al., loc. cit., have developed a single equation predictive method for bubble rise velocity, which covers the entire range of bubble diameters.

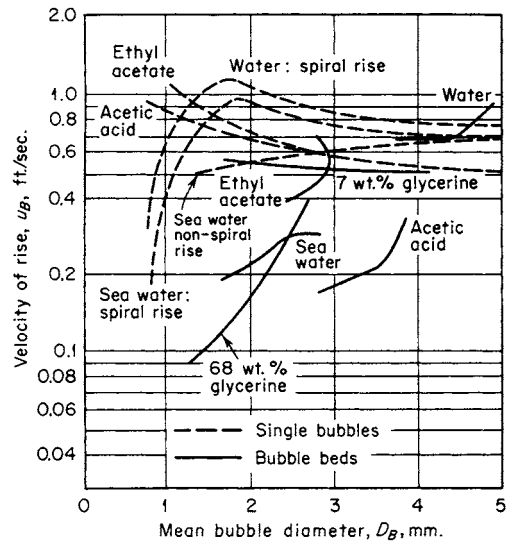

**FIG. 14-93** Velocity of rising bubbles, singly and in clouds. To convert feet per second to meters per second, multiply by 0.305. [*From* Chem. Eng. Sci., **7,** *48 (1957).*]

When bubbles are produced in clouds, as by a porous disperser, their behavior during rising is further complicated by interaction among themselves. In addition to the tendency for small bubbles to coalesce and large ones to disintegrate, there are two additional opposing influences on the rate of rise of bubbles of any particular size: (1) A "chimney effect" can develop in which a massive current upward appears at the axis of the bubble stream, leading to increased net bubble velocity; and (2) the proximity of the bubbles to one another can result in a hindered-settling condition, leading to reduced average bubble velocity. Figure 14-93 shows the data of Houghton et al. (op. cit.) for clouds of bubbles compared with their single-bubble data for pure water and seawater and of Peebles and Garber [*Chem. Eng. Progr.,* **49,** 88 (1953)] for acetic acid and ethyl acetate. The bubble clouds were produced with a sintered-glass plate of mean pore size (inferred from air wet-permeability data) of 81 μm.

The difference between the curves for pure water and seawater again illustrates the significance of small concentrations of solute with respect to bubble behavior. In commercial bubble columns and agitated vessels coalescence and breakup are so rapid and violent that the rise velocity of a single bubble is meaningless. The average rise velocity can, however, be readily calculated from holdup correlations that will be given later.

The quantitative examination of bubble systems is aided by the use of proper illumination and photography. The formation of bubbles at single sources often is sufficiently periodic to be stopped by stroboscopic light. Clouds of rising bubbles are more difficult to assess and

require careful technique. Satisfactory photographic methods have been developed by Vermenlen, Williams, and Langlois [*Chem. Eng. Progr.,* **51,** 85 (1955)] and by Calderbank [*Trans. Instn. Chem. Engrs.,* **36,** 443 (1958)] and are described by these authors. Calderbank's technique resulted in particularly precise measurements that permitted a good estimation of the surface area of the dispersed bubbles.

**Methods of Gas Dispersion** The problem of dispersing a gas in a liquid may be attacked in several ways: (1) The gas bubbles of the desired size or which grow to the desired size may be introduced directly into the liquid; (2) a volatile liquid may be vaporized by either decreasing the system pressure or increasing its temperature; (3) a chemical reaction may produce a gas; or (4) a massive bubble or stream of gas is disintegrated by fluid shear and/or turbulence in the liquid.

***Spargers: Simple Bubblers*** The simplest method of dispersing gas in a liquid contained in a tank is to introduce the gas through an open-end standpipe, a horizontal perforated pipe, or a perforated plate at the bottom of the tank. At ordinary gassing rates (corresponding to the jet regime), relatively large bubbles will be produced regardless of the size of the orifices.

Perforated-pipe or -plate spargers usually have orifices 3 to 12 mm in diameter. Effective design methods to minimize maldistribution are presented in the fifth edition of this handbook, p. 5–47, 1973, and by Knaebel [*Chem. Eng.,* 116 (Mar. 9, 1981)]. For turbulent flow conditions into the sparger, the following relationship will allow design of a perforated-pipe sparger for a given degree of maldistribution provided $N_h > 5$ and length/diameter <300.

$$d_P = 0.95(N_h C_v)^{1/2} \times \left( \frac{d_h}{\Delta U_h / U_h} \right)^{1/4} \qquad (14\text{-}211)$$

where $d_p$ = pipe diameter, $d_h$ = sparging hole diameter, $N_h$ = number of holes in sparger, $C_v$ = orifice coefficient for sparger hole (see *Chemical Engineers' Handbook,* 5th ed., pp. 5–13, 5–34), $U_h$ = average velocity through sparger holes, $\Delta U_h$ = difference between maximum and minimum velocities through sparger holes, and $\Delta U_h/U_h$ = fractional maldistribution of flow through sparger holes.

Simple spargers are used as agitators for large tanks, principally in the cement and oil industries. Kauffman [*Chem. Metall. Eng.,* **37,** 178–180 (1930)] reported the following air rates for various degrees of agitation in a tank containing 2.7 m (9 ft) of *liquid:*

| Degree of agitation | Air rate, $m^3/(m^2$ tank cross section, min) |
|---|---|
| Moderate | 0.0033 |
| Complete | 0.0066 |
| Violent | 0.016 |

For a liquid depth of 0.9 m (3 ft), Kauffman recommended that the listed rates be doubled.

An air lift consisting of a sparger jetting into a draft tube with ports discharging at several heights has been recommended by Heiser [*Chem. Eng.,* **55**(1), 135 (1948)] for maintaining agitation in a heavy, coarse slurry, the level of which varies widely. The design is illustrated in Fig. 14-94.

The ability of a sparger to blend miscible liquids might be described in terms of a fictitious diffusivity. Siemes did so, reporting that the agitation produced by a stream of bubbles rising in a tube with a superficial velocity of about 8.2 cm/s corresponded to an apparent diffusion coefficient as large as 75 $cm^2/s$ [*Chem. Ing. Tech.,* **29,** 727 (1957)]. The blending rate thus is several orders of magnitude higher than it would be by natural diffusive action. These results are typical of subsequent investigations on back mixing, which will be discussed in more detail later.

Lehrer [*Ind. Eng. Chem. Process Des. Dev.,* **7,** 226 (1968)] conducted liquid-blending tests with air sparging in a 0.61-m-diameter by 0.61-m-tall vessel and found that an air volume equal to about one-half of the vessel volume gave thorough blending of inviscid liquids of equal viscosities. Using an analogy to mechanically agitated vessels in which equal tank turnovers give equal blend times, one would expect this criterion to be applicable to other vessel sizes. Liquids of unequal density would require somewhat more air.

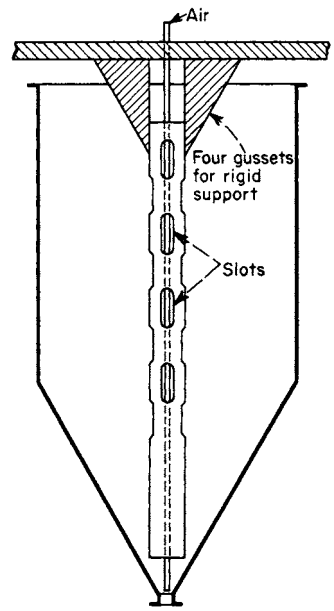

**FIG. 14-94** Slotted air lift for agitation of a variable-level charge. [*From* Chem. Eng., ***55****(1), 135 (1948).*]

Open-end pipes, perforated plates, and ring- or cross-style perforated-pipe spargers are used without mechanical agitation to promote mass transfer, as in chlorinators and biological sewage treatment. In the "quiescent regime" (superficial gas velocity less than 4.57 to 6.1 cm/s [0.15 to 0.2 ft/s]) the previously mentioned spargers are usually operated at orifice Reynolds numbers in excess of 6000 in order to get small bubbles so as to increase the interfacial area and thus increase mass transfer. In the "turbulent regime" (superficial gas velocity greater than 4.57 to 6.1 cm/s), sparger design is not critical because a balance between coalescence and breakup is established very quickly according to Towell et al. [*AIChE Symp. Ser. No. 10,* 97 (1965)]. However, a reasonably uniform orifice distribution over the column cross section is desirable, and according to Fair [*Chem. Eng.,* **74,** 67 (July 3, 1967); 207 (July 17, 1967)] the orifice velocity should be less than 75 to 90 m/s.

***Porous Septa*** In the quiescent regime porous plates, tubes, disks, or other shapes that are made by bonding or sintering together carefully sized particles of carbon, ceramic, polymer, or metal are frequently used for gas dispersion, particularly in foam fractionators. The resulting septa may be used as spargers to produce much smaller bubbles than will result from a simple bubbler. Figure 14-95 shows a comparison of the bubbles emitted by a perforated-pipe sparger [0.16-cm orifices] and a porous carbon septum (120 μm pores). The gas flux through a porous septum is limited on the lower side by the requirement that, for good performance, the whole sparger surface should bubble more or less uniformly, and on the higher side by the onset of serious coalescence at the surface of the septum, resulting in poor dispersion. In the practical range of fluxes, the size of the bubbles produced depends on both the size of pores in the septum and the pressure drop imposed across it, being a direct function of both.

Table 14-23 lists typical grades of porous carbon, silica, alumina, stainless steel (type 316), and polymers commercially available.

Porous media are also manufactured from porcelain, glass, silicon carbide, and a number of metals: Monel, Inconel, nickel, bronze, Hastelloy C, Stellite L-605, gold, platinum, and many types of stainless steel. Two manufacturers of porous septa are Mott (mottcorp.com) and Pall (pall.com). The air permeabilities of Table 14-23 indicate the relative flow resistances of the various grades to homogeneous fluid but may not be used in designing a disperser for submerged

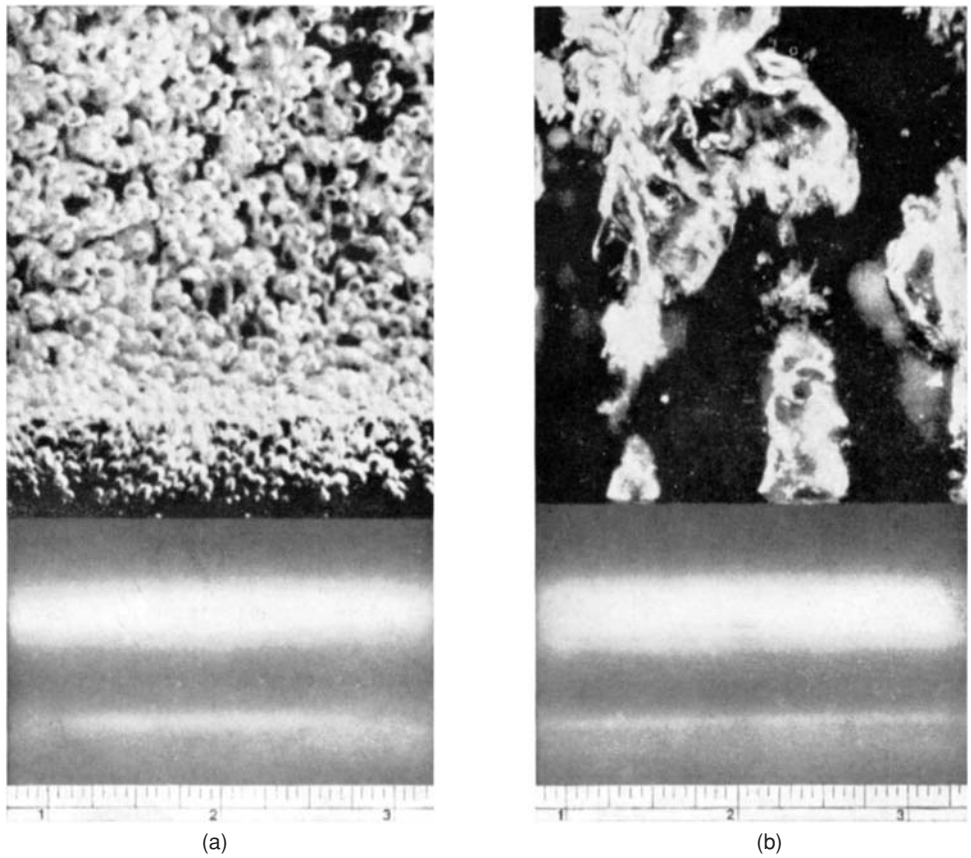

**FIG. 14-95** Comparison of bubbles from a porous septum and from a perforated-pipe sparger. Air in water at 70°F. (*a*) Grade 25 porous-carbon diffuser operating under a pressure differential of 13.7 in of water. (*b*) Karbate pipe perforated with 1/16-in holes on 1-in centers. To convert inches to centimeters, multiply by 2.54; °C = 5⁄9 (°F − 32). (*National Carbon Co.*)

operation, for the resistance of a septum to the flow of gas increases when it is wet. The air permeabilities for water-submerged porous carbon of some of the grades listed in the table are shown in Fig. 14-96. The data were determined with septa 0.625 in thick in water at 70°F. Comparable wet-permeability data for 1-in Alundum plates of two grades of fineness are given in Table 14-24.

The gas rate at which coalescence begins to reduce the effectiveness of dispersion appears to depend not only on the pore size and pore structure of the dispersing medium but also on the liquid properties, liquid depth, agitation, and other features of the sparging environment; coalescence is strongly dependent on the concentration of surfactants capable of forming an electrical double layer and thus produce ionic bubbles, long-chain alcohols in water being excellent examples. For porous-carbon media, the manufacturer suggests that the best dispersion performance will result if the broken-line regions of Fig. 14-96 are avoided. For porous stainless-steel spargers, which extend to a lower pore size than carbon, Micro Metallic Division, Pall Corp., recommends (Release 120A, 1959) a working limit of 8 ft/min (0.044 m/s) to avoid serious coalescence. This agrees with the data reported by Konig et al. (loc. cit.), in which 0.08 m/s was used and bubbles as small as 1 mm were produced from a 5-μm porous sparger.

Slabs of porous material are installed by grouting or welding together to form a diaphragm, usually horizontal. Tubes are prone to produce coalesced gas at rates high enough to cause bubbling from their lower faces, but they have the advantage of being demountable for cleaning or replacement (U.S. Patent 2,328,655). Roe [*Sewage Works J.,* **18,** 878 (1945)] claimed that silicon carbide tubes are superior to horizontal plates, principally because of the wiping action of the liquid circulating past the tube. He reported respective maximum capacities of 2.5 and 1.5 $cm^2/s$ of gas/$cm^2$ of sparger for a horizontal tube and a horizontal plate of the same material (unspecified grade). Mounting a flat-plate porous sparger vertically instead of horizontally seriously reduces the effectiveness of the sparger for three reasons: (1) The gas is distributed over a reduced cross section; (2) at normal rates, the lower portion of the sparger may not operate because of difference in hydrostatic head; and (3) there is a marked tendency for bubbles to coalesce along the sparger surface. Bone (M.S. thesis in chemical engineering, University of Kansas, 1948) found that the oxygen sulfite solution coefficient for a 3.2- by 10-cm rectangular porous carbon sparger was 26 to 41 percent lower for vertical than for horizontal operation of the sparger, the greatest reduction occurring when the long dimension was vertical.

***Precipitation and Generation Methods*** For a thorough understanding of the phenomena involved, bubble nucleation should be considered. A discussion of nucleation phenomena is beyond the scope of this handbook; however, a starting point with recent references is Deng, Lee, and Cheng, *J. Micromech. Microeng.*, **15,** 564 (2005), and Jones, Evans, and Galvin, *Adv. Colloid and Interface Sci.* **80,** 27 (1999).

***Gas Dispersion—Vessel Headspace*** Boerma and Lankester have measured the surface aeration of a nine-bladed disk-type turbine (NOTE: A well-designed pitched-blade turbine will give equal or better performance). In a fully baffled vessel, the optimum depth to obtain maximum gas dispersion was 15 to 50 percent of the impeller diameter.

¶Similar septa made from other metals are available.

In a vessel with baffles extending only halfway to the liquid surface the optimum impeller submergence increased with agitator speed because of the vortex formed. At optimum depth, the following correlation is recommended for larger vessels:

$$Q = 0.00015(N/10)^{2.5}(D/0.1)^{4.5} \qquad (14\text{-}214)$$

with $Q$ in $m^3/s$, $N$ in rps, and $D$ in m. Thus, a typical 3-m-diameter plant-size vessel, with four-blade pitched impeller ($D = 1$ m) operating at 2 rps will give gas dispersion from the headspace into the batch of $Q = 0.00015(2/10)^{2.5}(2/0.1)^{4.5} = 1.9$ $m^3/s$ (4000 $ft^3$/min).

Borema et al. (op. cit.) recommend headspace gas dispersion with partial baffling for fatty oils hydrogenation in stirred reactors: "The hydrogen in the head-space of the closed reactor can again be brought into contact with the liquid by a stirrer under the liquid level, . . ." And Penney in Paul et al. (loc. cit.) says, "partial baffling can be very effective to produce a vortex, which can effectively drawdown gas from the headspace. . . ." However, Middleton et al. in Paul et al. (op. cit) say, "The simplest self-inducer for an agitated vessel is an impeller located near the surface, sometimes with the upper part of the baffles removed so as to encourage the formation of a vortex. This is, however, a sensitive and unstable arrangement. It is better, although probably more expensive, to use a self-inducing impeller system in which gas is drawn down a hollow shaft to the low-pressure region behind the blades of a suitable, often shrouded impeller. . . . Various proprietary designs are available, such as the Ekato gasjet, Prasair AGR and the Frings Friborator. . . ." Figure 14-97 illustrates a gas-inducing hollow shaft/hollow impeller agitator. In many hydrogenation reactors, the impeller just

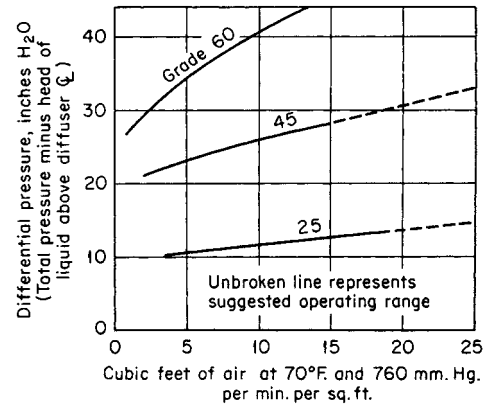

**FIG. 14-96** Pressure drop across porous-carbon diffusers submerged in water at 70°F. To convert feet per minute to meters per second, multiply by 0.0051; to convert inches to millimeters, multiply by 25.4; °C = 5/9 (°F − 32). (*National Carbon Co.*)

underneath the free surface has, without any doubt, performed admirably; consequently, one must consider this fact very carefully before using a self-inducing impeller.

Gas dispersion through the free surface by mechanical aerators is commonplace in aerobic waste-treatment lagoons. Surface aerators are generally of three types: (1) large-diameter flow-speed turbines operating just below the free surface of the liquid, often pontoon-mounted; (2) small-diameter high-speed (normally motor-speed) propellers operating in draft tubes, the units of which are always pontoon-mounted; and (3) hollow-tube turbines (Fig. 14-97). An example of the turbine type is illustrated in Fig. 14-98 and the propeller type is illustrated in Fig. 14-99. There are several other styles of the turbine type; for instance, Mixing Equipment Co., Inc., (www.lightninmixers.com), uses an unshrouded 45° axial-flow turbine [see Dykman and Michel, *Chem. Eng.,* **117** (Mar. 10, 1969)], and Infilco (www.infilcodegremont.com) makes a unit that has a large-diameter vaned disk operating just below the free surface with a smaller-diameter submerged-disk turbine for additional solids suspension.

Aeration injectors, like the one shown in Fig. 14-100 by Penberthy [a division of Houdialle Industries (penberthy-online.com/jet1.asp)], are used to provide mass transfer in gas-liquid applications, and simple impingement aerators (Fig. 14-101) are sometimes used for mass-transfer applications.

**Equipment Selection** Ideally, selection of equipment to produce a gas-in-liquid dispersion should be made on the basis of a complete economic analysis. The design engineer and especially the pilot-plant engineer seldom have sufficient information or time to do a complete economic analysis. In the following discussion, some

**TABLE 14-24 Wet Permeability of Alundum Porous Plates 1 in Thick***

guidelines are given as to what equipment might be feasible and what equipment might prove most economical.

For producing foam for foam-separation processes, perforated-plate or porous-plate spargers are normally used. Mechanical agitators are often not effective in the light foams needed in foam fractionation. Dissolved-air flotation, based on the release of a pressurized flow in which oxygen was dissolved, has been shown to be effective for particulate removal when sparged air failed because the bubbles formed upon precipitation are smaller—down to 80 μm—than bubbles possible with sparging, typically 1000 μm [Grieves and Ettelt, *AIChE J.*, **13,** 1167 (1967)]. Mechanically agitated surface aerators such as the Wemco-Fagergren flotation unit (Fig. 14-102) are used extensively for ore flotation.

To produce foam in batch processes, mechanical agitators are used almost exclusively. The gas can either be introduced through the free surface by the entraining action of the impeller or alternatively sparged beneath the impeller. In such batch operation, the liquid level gradually rises as the foam is generated; thus, squatly impellers such as turbines are rapidly covered with foam and must almost always be sparged from below. Tall impellers such as wire whips (Fig. 14-103) are especially well suited to entrain gas from the vapor space. Intermeshing wire whips are standard kitchen utensils for producing foamed meringues, consisting of air, vegetable oil, and egg whites. For a new application, generally some experimentation with different impellers is necessary in order to get the desired fine final bubble size without getting frothing over initially. For producing foams continually, an aspirating venturi nozzle and restrictions in pipes such as baffles and metal gauzes are generally most economical.

For gas absorption, the equipment possibilities are generally packed columns; plate distillation towers, possibly with mechanical agitation on every plate; deep-bed contactors (bubble columns or sparged lagoons); and mechanically agitated vessels or lagoons. Packed towers and plate distillation columns are discussed elsewhere. Generally these devices are used when a relatively large number of stages (more than two or three) is required to achieve the desired result practically.

The volumetric mass-transfer coefficients and heights of transfer units for bubble columns and packed towers have been compared for absorption of $CO_2$ into water by Houghton et al. [*Chem. Eng. Sci.*, **7,** 26 (1957)]. The bubble column will tolerate much higher vapor velocities, and in the overlapping region (superficial gas velocities of 0.9 to 1.8 cm/s), the bubble column has about three times higher mass-transfer coefficient and about 3 times greater height of transfer unit. The liquid in a bubble column is, for practical purposes, quite well mixed; thus, chemical reactions and component separations requiring significant plug flow of the liquid cannot be effected with bubble columns. Bubble columns and agitated vessels are the ideal equipment for processes in which the fraction of gas absorbed need not be great, possibly the gas can be recycled, and the liquid can or should be well mixed. The gas phase in bubble columns is not nearly so well back-mixed as the liquid, and often plug flow of the gas is a logical assumption, but in agitated vessels the gas phase is also well mixed.

The choice of a bubble column or an agitated vessel depends primarily on the solubility of the gas in the liquid, the corrosiveness of the liquid (often a gas compressor can be made of inexpensive material, whereas a mechanical agitator may have to be made of exotic, expensive materials), and the rate of chemical reaction as compared with the mass-transfer rate. Bubble columns and agitated vessels are seldom used for gas absorption except in chemical reactors. As a general rule, if the overall reaction rate is five times greater than the mass-transfer rate in a simple bubble column, a mechanical agitator will be most economical unless the mechanical agitator would have to be made from considerably more expensive material than the gas compressor.

In bubble columns and simply sparged lagoons, selecting the sparger is a very important consideration. In the turbulent regime (superficial gas velocity greater than 4.6 to 6 cm/s), inexpensive

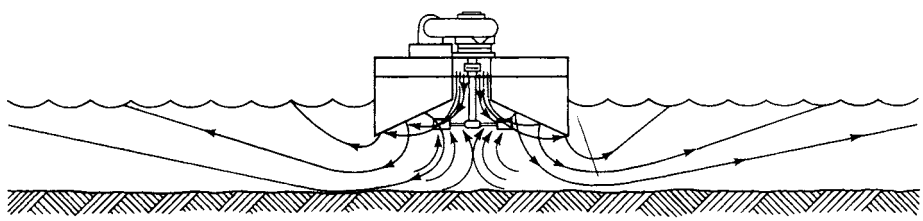

**FIG. 14-98** The Cyclox surface aerator. *(Cleveland Mixer Co.)*

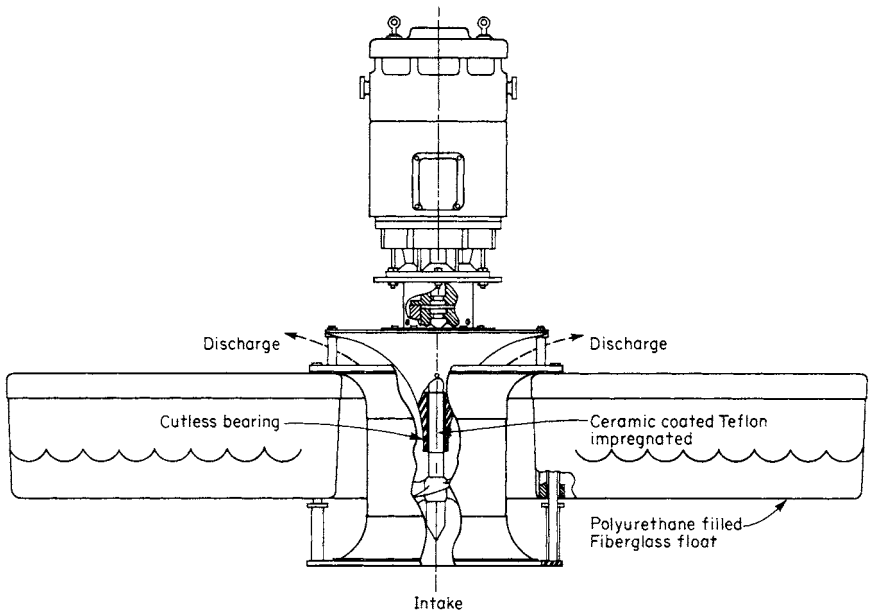

**FIG. 14-99** Propeller-type surface aerator. *(Ashbrook-Simon-Hartley Corp.)*

perforated-pipe spargers should be used. Often the holes must be placed on the pipe bottom in order to make the sparger free-draining during operation. In the quiescent regime, porous septa will often give considerably higher overall mass-transfer coefficients than perforated plates or pipes because of the formation of tiny bubbles that do not coalesce. Chain and coworkers (*First International Symposium on Chemical Microbiology,* World Health Organization, Monograph Ser. 10, Geneva, 1952) claimed that porous disks are about twice as effective as open-pipe and ring spargers for the air oxidation of sodium sulfite. Eckenfelder [*Chem. Eng. Progr.,* **52**(7), 290 (1956)] has compared the oxygen-transfer capabilities of various devices on the basis of the operating power required to absorb a given quantity of $O_2$. The installed cost of the various pieces of equipment probably would not vary sufficiently to warrant being including in an economic analysis. Surface mechanical aerators are not included in this comparison. Of the units compared, it appears that porous tubes give the most efficient power usage. Kalinske (*Adv. Biol. Waste Treatment,* 1963, p. 157) has compared submerged sparged aerators with mechanical surface aerators. He has summarized this comparison in *Water Sewage Works,* **33** (January 1968). He indicates that surface aerators are significantly more efficient than subsurface aeration, both for oxygen absorption and for gas-stripping operations.

Zlokarnik and Mann (paper at Mixing Conf., Rindge, New Hampshire, August 1975) have found the opposite of Kalinske, i.e., subsurface diffusers, subsurface sparged turbines, and surface aerators compare approximately as 4:2:1 respectively in terms of $O_2$ transfer efficiency; however, Zlokarnik [*Adv. Biochem. Eng.,* **11,** 157 (1979)] later indicates that the scale-up correlation used earlier might be somewhat inaccurate. When all available information is considered, it appears that with near-optimum design any of the aeration systems (diffusers, submerged turbines, or surface impellers) should give a transfer efficiency of at least 2.25 kg $O_2$/kWh. Thus, the final selection should probably be made primarily on the basis of operational reliability, maintenance, and capital costs.

**Mass Transfer** Mass transfer in plate and packed gas-liquid contactors has been covered earlier in this subsection. Attention here will be limited to deep-bed contactors (bubble columns and agitated vessels). Theory underlying mass transfer between phases is discussed in Sec. 5 of this handbook.

To design deep-bed contactors for mass-transfer operations, one must have, in general, predictive methods for the following design parameters:

- Flooding (for both columns and agitator impellers)
- Agitator power requirements

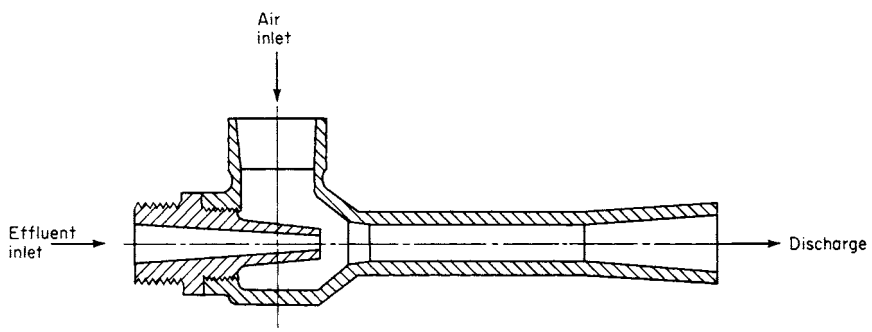

**FIG. 14-100** Aeration ejector. *(Penberthy, a division of Houdaille Industries, Inc.)*

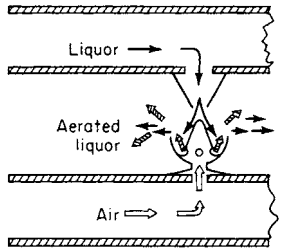

**FIG. 14-101** Impingement aerator.

- Gas-phase and liquid-phase mass-transfer coefficients
- Interfacial area
- Interface resistance
- Mean concentration driving force for mass transfer

In most cases, available methods are incomplete or unreliable, and some supporting experimental work is necessary, followed by scale-up. The methods given here should allow theoretical feasibility studies, help minimize experimentation, and permit a measure of optimization in final design.

***Flooding of Agitator Impellers*** Impeller flooding correlations for six-blade disk (6BD) Rusthon turbines and six-blade disk Smith turbines (Chemineer designation: CD-6) are presented by Bakker, Myers, and Smith [*Chem. Eng.*, **101,** 98 (Dec. 1994)] and a review of impeller flooding. The Bakker et al. (loc. cit.) correlation is

$$Q/ND^3 = C_{FL}N_{Fr}(D/T)^{3.5} \qquad (14\text{-}215)$$

where $C_{FL} = 30$ for a 6BD impeller and $C_{FL} = 70$ for a concave blade CD-6 impeller and $N_{Fr}$ = Froude number = $N^2D/g$; $Q$ = gas flow rate at flooding, $m^3/s$; $N$ = impeller speed, rps; $D$ = impeller diameter, m; and $T$ = tank diameter, m. Note that the CD-6 impeller will handle 70/30 = 2.33 times the gas a 6BD will handle, without flooding, at the same $N$ and $D$; this is the great advantage of the CD-6 along with lower power decrease as the gas flow rate increases.

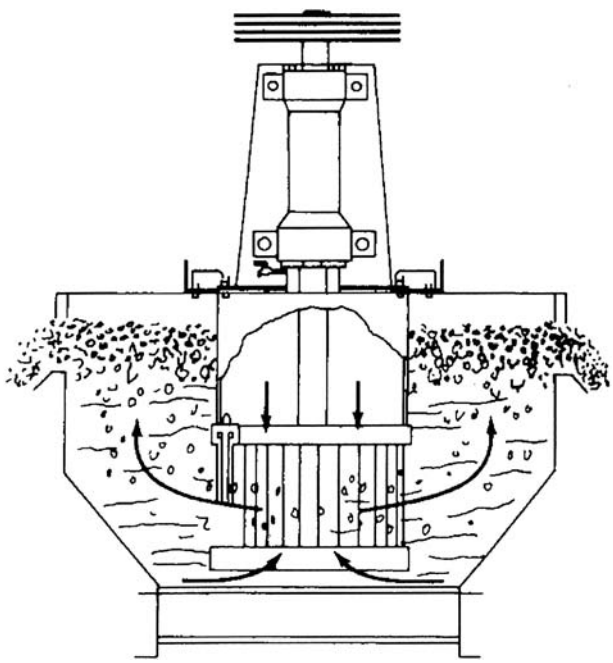

**FIG. 14-102** The Wemco-Fagergren flotation machine. [*From www.tucottbus.de/BTU/Fak4/Aufbtech/pages/pbrr_N 7 Sep2-(elstat-flotat).pdf*].

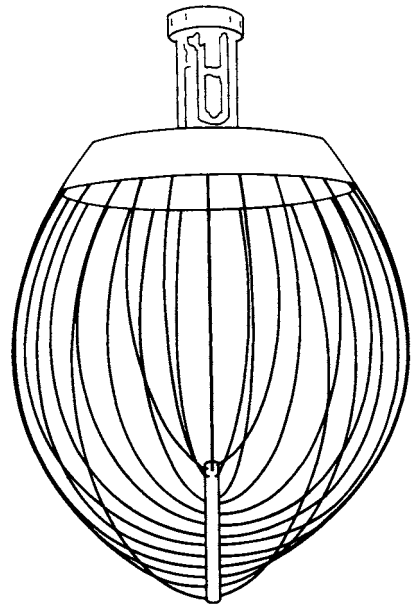

**FIG. 14-103** Wire whip.

***Gassed Impeller Power*** Bakker et al. (op. cit.) have given a gassed power correlation for the 6BD and CD-6 impellers.

$$P_g/P_u = [1 - (b - a\mu)]N_{Fr}^d \tanh(cN_A) \qquad (14\text{-}216a)$$

where $P_g$ = gassed power, W; $P_u$ = ungassed power, W; $N_A = Q/ND^3$; and the constants of Eq. (14-216*a*) are given in Table 14-25.

As mentioned previously, the CD-6 suffers much less power decrease with increased gassing compared to the 6BD. For example, at $N_A = 0.15$, $P_g/P_u = 0.7$ for the CD-6 and 0.5 for the CD-6.

The ungassed power is calculated by

$$P_u = N_p\rho/N^3D^5 \qquad (14\text{-}216b)$$

where the impeller power numbers $N_p$ are given Table 14-25.

Bakker et al. (op. cit.) and Sensel et al. (op. cit.) have given correlations for gas holdup in agitated vessels. The Bakker et al. correlation is

$$\varepsilon = C_\varepsilon = (P_g/V)^A v_{sg}^B \qquad (14\text{-}217)$$

where $C_\varepsilon = 0.16$, $A = 0.33$, $B = 0.67$; $V$ = batch volume, $m^3$; $v_{sg}$ = superficial gas velocity = $Q/[(\pi/4)T^2]$; $T$ = tank diameter, m. Equation (14-217) applies for both 6BD and CD-6.

***Interfacial Area*** This consideration in agitated vessels has been reviewed and summarized by Tatterson (op. cit.). Predictive methods for interfacial area are not presented here because correlations are given for the overall volumetric mass transfer coefficient liquid phase controlling mass transfer.

**TABLE 14-25 Constants in Eq. (14-216) and Impeller Power Numbers**

| Impeller type | $a$ | $b$ | $c$ | $d$ | $N_p$ |
|---|---|---|---|---|---|
| 6BD | 0.72 | 0.72 | 24 | 0.25 | 3.2 |
| CD-6 | 0.12 | 0.44 | 12 | 0.37 | 5.5 |

***Overall Mass-Transfer Coefficient*** In systems with relatively sparing soluble gases, where the gas-phase resistance is negligible, the mass-transfer rate can be determined by using the concept of an overall volumetric mass-transfer coefficient $k_La$ as follows:

$$M_s = k_La(C_s^* - C_{s,b}) \tag{14-218}$$

where $M_s$ = solute molar mass-transfer rate, kg·mol/s; $k_La$ = overall mass-transfer coefficient, 1/s; $C_s^*$ = solute concentration in equilibrium with the liquid phase, kg·mol/s; and $C_{s,b}$ = solute concentration in bulk of liquid.

Bakker et al. (op. cit.) have given a correlation for $k_La$ for aqueous systems in the absence of significant surface active agents.

$$k_La = C_{kLa}(P_g/V)^a v_{sg}^b \tag{14-219}$$

where $C_{kLa} = 0.015$, 1/s; Eq. (14-219) applies for both 6BD and CD-6.

***Interfacial Phenomena*** These can significantly affect overall mass transfer. Deckwer, *Bubble Column Reactors*, Wiley, Hoboken, N.J., 1992, has covered the effect of surfactants on mass transfer in bubble columns. In fermentation reactors, small quantities of surface-active agents (especially antifoaming agents) can drastically reduce overall oxygen transfer (Aiba et al., op. cit., pp. 153, 154), and in aerobic mechanically aerated waste-treatment lagoons, overall oxygen transfer has been found to be from 0.5 to 3 times that for pure water from tests with typical sewage streams (Eckenfelder et al., op. cit., p. 105).

One cannot quantitatively predict the effect of the various interfacial phenomena; thus, these phenomena will not be covered in detail here. The following literature gives a good general review of the effects of interfacial phenomena on mass transfer: Goodridge and Robb, *Ind. Eng. Chem. Fund.*, **4,** 49 (1965); Calderbank, *Chem. Eng. (London),* CE 205 (1967); Gal-Or et al., *Ind. Eng. Chem.*, **61**(2), 22 (1969); Kintner, *Adv. Chem. Eng.*, **4** (1963); Resnick and Gal-Or, op. cit., p. 295; Valentin, loc. cit.; and Elenkov, loc. cit., and *Ind. Eng. Chem. Ann. Rev. Mass Transfer,* **60**(1), 67 (1968); **60**(12), 53 (1968); **62**(2), 41 (1970). In the following outline, the effects of the various interfacial phenomena on the factors that influence overall mass transfer are given. Possible effects of interfacial phenomena are tabulated below:

1. Effect on continuous-phase mass-transfer coefficient
   *a.* Impurities concentrate at interface. Bubble motion produces circumferential surface-tension gradients that act to retard circulation and vibration, thereby decreasing the mass-transfer coefficient.
   *b.* Large concentration gradients and large heat effects (very soluble gases) can cause interfacial turbulence (the Marangoni effect), which increases the mass-transfer coefficient.
2. Effect on interfacial area
   *a.* Impurities will lower static surface tension and give smaller bubbles.
   *b.* Surfactants can electrically charge the bubble surface (produce ionic bubbles) and retard coalescence (soap stabilization of an oil-water emulsion is an excellent example of this phenomenon), thereby increasing the interfacial area.
   *c.* Large concentration gradients and large heat effects can cause bubble breakup.
3. Effect on mean mass-transfer driving force
   *a.* Relatively insoluble impurities concentrate at the interface, giving an interfacial resistance. This phenomenon has been used in retarding evaporation from water reservoirs.
   *b.* The axial concentration variation can be changed by changes in coalescence. The mean driving force for mass transfer is therefore changed.

***Gas Holdup (ε) in Bubble Columns*** With coalescing systems, holdup may be estimated from a correlation by Hughmark [*Ind. Eng Chem. Process Des. Dev.*, **6,** 218–220 (1967)] reproduced here as Fig. 14-104. For noncoalescing systems, with considerably smaller bubbles, ε can be as great as 0.6 at $U_{sg} = 0.05$ m/s, according to Mersmann [*Ger. Chem. Eng.*, **1,** 1 (1978)].

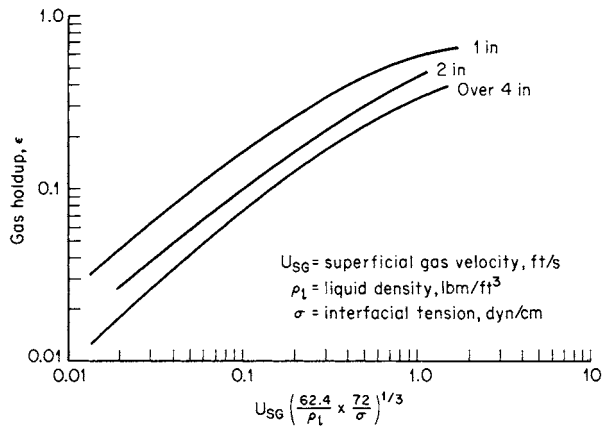

**FIG. 14-104** Gas holdup correlation. [Ind. Eng. Chem. Process Des. Dev., ***6,*** 218 (*1967*).]

It is often helpful to use the relationship between ε and superficial gas velocity ($U_{sg}$) and the rise velocity of a gas bubble relative to the liquid velocity ($U_r + U_L$, with $U_L$ defined as positive upward):

$$\varepsilon = \frac{U_{sg}}{U_r + U_L} \tag{14-220}$$

Rise velocities of bubbles through liquids have been discussed previously.

For a better understanding of the interactions between parameters, it is often helpful to calculate the effective bubble rise velocity $U_r$ from measured valves of ε; for example, the data of Mersmann (loc. cit.) indicated $\varepsilon = 0.6$ for $U_{sg} = 0.05$ m/s, giving $U_r = 0.083$ m/s, which agrees with the data reported in Fig. 14-43 for the rise velocity of bubble clouds. The rise velocity of single bubbles, for $d_b \sim 2$ mm, is about 0.3 m/s, for liquids with viscosities not too different from water. Using this value in Eq. (14-220) and comparing with Fig. 14-104, one finds that at low values of $U_{sg}$, the rise velocity of the bubbles is less than the rise velocity of a single bubble, especially for small-diameter tubes, but that the opposite occurs for large values of $U_{sg}$.

More recent literature regarding generalized correlational efforts for gas holdup is adequately reviewed by Tsuchiya and Nakanishi [*Chem. Eng Sci.*, **47**(13/14), 3347 (1992)] and Sotelo et al. [*Int. Chem. Eng.*, **34**(1), 82–90 (1994)]. Sotelo et al. (op. cit.) have developed a dimensionless correlation for gas holdup that includes the effect of gas and liquid viscosity and density, interfacial tension, and diffuser pore diameter. For systems that deviate significantly from the waterlike liquids for which Fig. 14-104 is applicable, their correlation (the fourth numbered equation in the paper) should be used to obtain a more accurate estimate of gas holdup. Mersmann (op. cit.) and Deckwer et al. (op. cit.) should also be consulted.

Liquid-phase mass-transfer coefficients in bubble columns have been reviewed by Calderbank ("Mixing," loc. cit.), Fair (*Chem. Eng.*, loc. cit.), Mersmann [*Ger. Chem. Eng.* **1,** 1 (1978), *Int. Chem. Eng.*, **32**(3) 397–405 (1991)], Deckwer et al. [*Can. J. Chem. Eng,* **58,** 190 (1980)], Hikita et al. [*Chem. Eng. J.*, **22,** 61 (1981)] and Deckwer and Schumpe [*Chem. Eng. Sci.*, **48**(5), 889–911 (1993)]. The correlation of Ozturk, Schumpe, and Deckwer [*AIChE J.*, **33,** 1473–1480 (1987)] is recommended. Deckwer et al. (op. cit.) have documented the case for using the correlation:

> Ozturk et al. (1987) developed a new correlation on the basis of a modification of the Akita-Yoshida correlation suggested by Nakanoh and Yoshida (1980). In addition, the bubble diameter $d_b$ rather than the column diameter was used as the characteristic length as the column diameter has little influence on $k_La$. The value of $d_b$ was assumed to be approximately constant ($d_b = 0.003$ m). The correlation was obtained by nonlinear regression is as follows:

$$\left(\frac{k_L a\, d_B}{D_L}\right) = 0.62\left[\frac{\mu_L}{(\rho_L D_L)}\right]^{0.5}\left(\frac{g\rho_L d_B^2}{\sigma}\right)^{0.33}\left(\frac{g\rho_L^2 d_B}{\mu_L^2}\right)^{0.29} \times \left[\frac{U_G}{(g d_B)^{0.5}}\right]^{0.68}\left(\frac{\rho_G}{\rho_L}\right)^{0.04} \quad (14\text{-}221)$$

where $k_L a$ = overall mass-transfer coefficient, $d_B$ = bubble diameter = 0.003 m, $D_L$ = diffusivity of gas in liquid, $\rho$ = density, $\mu$ = viscosity, $\sigma$ = interfacial tension, $g$ = gravitational acceleration.

As mentioned earlier, surfactants and ionic solutions significantly affect mass transfer. Normally, surface affects act to retard coalescence and thus increase the mass transfer. For example, Hikata *et al.* [*Chem. Eng. J.*, **22,** 61–69 (1981)] have studied the effect of KCl on mass transfer in water. As KCI concentration increased, the mass transfer increased up to about 35 percent at an ionic strength of 6 gm/l. Other investigators have found similar increases for liquid mixtures.

**Axial Dispersion** Backmixing in bubble columns has been extensively studied. Wiemann and Mewes [*Ind. Eng. Chem. Res.*, **44,** 4959 (2005)] and Wild et al. [*Int. J. Chemical Reactor Eng.*, **1,** R7 (2003)] give a long list of references pertaining to backmixing in bubble columns. An excellent review article by Shah et al. [*AIChE J.*, **24,** 369 (1978)] has summarized the literature prior to 1978. Works by Konig et al. [*Ger. Chem. Eng.*, **1,** 199 (1978)], Lucke et al. [*Trans. Inst. Chem. Eng.*, **58,** 228 (1980)], Riquarts [*Ger. Chem. Eng.*, **4,** 18 (1981)], Mersmann (op. cit.), Deckwer (op. cit.), Yang et al. [*Chem. Eng. Sci.*, **47**(9–11), 2859 (1992)], and Garcia-Calvo and Leton [*Chem. Eng. Sci.*, **49**(21), 3643 (1994)] are particularly useful references.

Axial dispersion occurs in both the liquid and the gas phases. The degree of axial dispersion is affected by vessel diameter, vessel internals, gas superficial velocity, and surface-active agents that retard coalescence. For systems with coalescence-retarding surfactants the initial bubble size produced by the gas sparger is also significant. The gas and liquid physical properties have only a slight effect on the degree of axial dispersion, except that liquid viscosity becomes important as the flow regime becomes laminar. With pure liquids, in the absence of coalescence-inhibiting, surface-active agents, the nature of the sparger has little effect on the axial dispersion, and experimental results are reasonably well correlated by the dispersion model. For the liquid phase the correlation recommended by Deckwer et al. (op. cit.), after the original work by Baird and Rice [*Chem. Eng. J.*, **9,** 171(1975)] is as follows:

$$\frac{E_L}{(DU_G)} = 0.35\left(\frac{gD}{U_G^2}\right)^{1/3} \quad (14\text{-}222)$$

where $E_L$ = liquid-phase axial dispersion coefficient, $U_G$ = superficial velocity of the gas phase, $D$ = vessel diameter, and $g$ = gravitational acceleration.

The recommended correlation for the gas-phase axial-dispersion coefficient is given by Field and Davidson (loc. cit.):

$$E_G = 56.4\, D^{1.33}\left(\frac{U_G}{\varepsilon}\right)^{3.56} \quad (14\text{-}223)$$

where $E_G$ = gas-phase axial-dispersion coefficient, $m^2/s$; $D$ = vessel diameter, m; $U_G$ = superficial gas velocity, m/s; and $\varepsilon$ = fractional gas holdup, volume fraction.

The correlations given in the preceding paragraphs are applicable to vertical cylindrical vessels with pure liquids without coalescence inhibitors. For other vessel geometries such as columns of rectangular cross section, packed columns, and coiled tubes, the work of Shah et al. (loc. cit.) should be consulted. For systems containing coalescence-inhibiting surfactants, axial dispersion can be vastly different from that in systems in which coalescence is negligible. Konig et al. (loc. cit.) have well demonstrated the effects of surfactants and sparger type by conducting tests with weak alcohol solutions using three different porous spargers. With pure water, the sparger—and, consequently, initial bubble size—had little effect on back mixing because coalescence produced a dynamic-equilibrium bubble size not far above the sparger. With surfactants, the average bubble size was smaller than the dynamic-equilibrium bubble size. Small bubbles produced minimal back mixing up to $\varepsilon \approx 0.40$; however, above $\varepsilon \approx 0.40$ backmixing increased very rapidly as $U_G$ increased The rapid increase in back mixing as $\varepsilon$ exceeds 0.40 was postulated to occur indirectly because a bubble carries upward with it a volume of liquid equal to about 70 percent of the bubble volume, and, for $\varepsilon \approx 0.40$, the bubbles carry so much liquid upward that steady, uniform bubble rise can no longer be maintained and an oscillating, slugging flow develops, which produces fluctuating pressure at the gas distributor and the formation of large eddies. The large eddies greatly increase backmixing. For the air alcohol-water system, the minimum bubble size to prevent unsteady conditions was about 1, 1.5, and 2 mm for $U_G$ = 1, 3, and 5 cm/s, respectively. Any smaller bubble size produced increased backmixing. The results of Konig et al. (loc. cit.) clearly indicate that the interaction of surfactants and sparger can be very complex; thus, one should proceed very cautiously in designing systems for which surfactants significantly retard coalescence. Caution is particularly important because surfactants can produce either much more or much less backmixing than surfactant-free systems, depending on the bubble size, which, in turn, depends on the sparger utilized.

# PHASE SEPARATION

Gases and liquids may be intentionally contacted as in absorption and distillation, or a mixture of phases may occur unintentionally as in vapor condensation from inadvertent cooling or liquid entrainment from a film. Regardless of the origin, it is usually desirable or necessary ultimately to separate gas-liquid dispersions. While separation will usually occur naturally, the rate is often economically intolerable and separation processes are employed to accelerate the step.

## GAS-PHASE CONTINUOUS SYSTEMS

Practical separation techniques for liquid particles in gases are discussed. Since gas-borne particulates include both liquid and solid particles, many devices used for dry-dust collection (discussed in Sec. 17 under "Gas-Solids Separation") can be adapted to liquid-particle separation. Also, the basic subject of particle mechanics is covered in Sec. 6. Separation of liquid particulates is frequently desirable in chemical processes such as in countercurrent-stage contacting because liquid entrainment with the gas partially reduces true countercurrency. Separation before entering another process step may be needed to prevent corrosion, to prevent yield loss, or to prevent equipment damage or malfunction. Separation before the atmospheric release of gases may be necessary to prevent environmental problems and for regulatory compliance.

**Definitions: Mist and Spray** Little standardization has been adopted in defining gas-borne liquid particles, and this frequently leads to confusion in the selection, design, and operation of collection equipment. Aerosol applies to suspended particulate, either solid or liquid, which is slow to settle by gravity and to particles from the submicrometer range up to 10 to 20 μm. Mists are fine suspended liquid dispersions usually resulting from condensation and ranging upward in particle size from around 0.1 μm. Spray refers to entrained liquid droplets. The droplets may be entrained from atomizing processes previously discussed under "Liquid-in-Gas Dispersions" in this section. In such instances, size will range from the finest particles produced up to a particle whose terminal settling velocity is equal to the entraining gas velocity if some settling volume is provided. Process spray is often created unintentionally, such as by the condensation of vapors on cold duct walls and its subsequent reentrainment, or from two-phase flow in pipes, gas bubbling through liquids, and entrainment from boiling liquids. Entrainment size distribution from sieve trays has been given by Cheng and Teller [*Am. Inst. Chem. Eng. J.*, **7**(2), 282 (1961)] and evaporator spray by Garner et al. [*Trans. Inst. Chem. Eng.*, **32,** 222 (1954)]. In general, spray can range downward in particle size from 5000 μm. There can be overlapping in size between the coarsest mist particles and the finest spray particles, but some authorities have found it convenient arbitrarily to set a boundary of 10 μm between the two. Actually, considerable overlap exists in the region of 5 to 40 μm. Table 14-26 lists typical ranges of particle size created by different mechanisms. The sizes actually entrained can be influenced by the local gas velocity. Figure 14-105 compares the approximate size range of liquid particles with other particulate material and the approximate applicable size range of collection devices. Figure 17-34 gives an expanded chart by Lapple for solid particles. Mist and fog formation has been discussed previously.

**Gas Sampling** The sampling of gases containing mists and sprays may be necessary to obtain data for collection-device design, in which case particle-size distribution, total mass loading, and gas volume, temperature, pressure, and composition may all be needed. Other reasons for sampling may be to determine equipment performance, measure yield loss, or determine compliance with regulations.

Location of a sample probe in the process stream is critical especially when larger particles must be sampled. Mass loading in one portion of a duct may be severalfold greater than in another portion as affected by flow patterns. Therefore, the stream should be sampled at a number of points. The U.S. Environmental Protection Agency (R-1) has specified 8 points for ducts between 0.3 and 0.6 m (12 and 24 in) and 12 points for larger ducts, provided there are no flow disturbances for eight pipe diameters upstream and two downstream from the sampling point. When only particles smaller than 3 μm are to be sampled, location and number of sample points are less critical since such particles remain reasonably well dispersed by brownian motion. However, some gravity settling of such particles and even gases of high density have been observed in long horizontal breeching. Isokinetic sampling (velocity at the probe inlet is equal to local duct velocity) is required to get a representative sample of particles larger than 3 μm (error is small for 4- to 5-μm particles). Sampling methods and procedures for mass loading have been developed (R-1 through R-8).

**Particle Size Analysis** Many particle-size-analysis methods suitable for dry-dust measurement are unsuitable for liquids because of coalescence and drainage after collection. Measurement of particle sizes in the flowing aerosol stream by using a cascade impactor is one

**TABLE 14-26 Particle Sizes Produced by Various Mechanisms**

| Mechanism or process | Particle-size range, μm |
|---|---|
| Liquid pressure spray nozzle | 100–5000 |
| Gas-atomizing spray nozzle | 1–100 |
| Gas bubbling through liquid or boiling liquid | 20–1000 |
| Condensation processes with fogging | 0.1–30 |
| Annular two-phase flow in pipe or duct | 10–2000 |

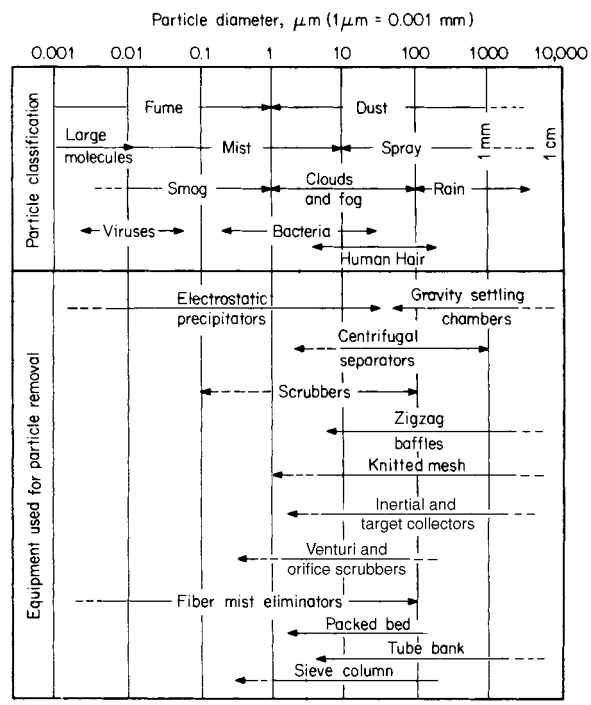

**FIG. 14-105** Particle classification and useful collection equipment versus particle size.

of the better means. The impacting principle has been described by Ranz and Wong [*Ind. Eng. Chem.*, **44,** 1371 (1952)] and Gillespie and Johnstone [*Chem. Eng. Prog.*, **51,** 75F (1955)]. The Andersen, Sierra, and University of Washington impactors may be used if the sampling period is kept short so as not to saturate the collection substrate. An impactor designed specifically for collecting liquids has been described by Brink, Kennedy, and Yu [*Am. Inst. Chem. Eng. Symp. Ser.*, **70**(137), 333 (1974)].

**Collection Mechanisms** Mechanisms which may be used for separating liquid particles from gases are (1) gravity settling, (2) inertial (including centrifugal) impaction, (3) flow-line interception, (4) diffusional (brownian) deposition, (5) electrostatic attraction, (6) thermal precipitation, (7) flux forces (thermophoresis, diffusiophoresis, Stefan flow), and (8) particle agglomeration (nucleation) techniques. Equations and parameters for these mechanisms are given in Table 17-2. Most collection devices rarely operate solely with a single mechanism, although one mechanism may so predominate that it may be referred to, for instance, as an inertial-impaction device.

After collection, liquid particles coalesce and must be drained from the unit, preferably without reentrainment. Calvert (R-12) has studied the mechanism of reentrainment in a number of liquid-particle collectors. Four types of reentrainment were typically observed: (1) transition from separated flow of gas and liquid to a two-phase region of separated-entrained flow, (2) rupture of bubbles, (3) liquid creep on the separator surface, and (4) shattering of liquid droplets and splashing. Generally, reentrainment increased with increasing gas velocity. Unfortunately, in devices collecting primarily by centrifugal and inertial impaction, primary collection efficiency increases with gas velocity; thus overall efficiency may go through a maximum as reentrainment overtakes the incremental increase in efficiency. Prediction of collection efficiency must consider both primary collection and reentrainment.

**Procedures for Design and Selection of Collection Devices** Calvert and coworkers (R-9 to R-12 and R-19) have suggested useful design and selection procedures for particulate-collection devices in which direct impingement and inertial impaction are the most significant mechanisms. The concept is based on the premise that the mass median aerodynamic particle diameter $d_{p50}$ is a significant measure of the difficulty of collection of the liquid particles and that the collection device cut size $d_{pc}$ (defined as the aerodynamic particle diameter collected with 50 percent efficiency) is a significant measure of the capability of the collection device. The aerodynamic diameter for a particle is the diameter of a spherical particle (with an arbitrarily assigned density of 1 g/cm$^3$) which behaves in an air stream in the same fashion as the actual particle. For real spherical particles of diameter $d_p$, the equivalent aerodynamic diameter $d_{pa}$ can be obtained from the equation $d_{pa} = dp(\rho_p C')^{1/2}$, where $\rho_p$ is the apparent particle density (mass/volume) and $C'$ is the Stokes-Cunningham correction factor for the particle size, all in consistent units. If particle diameters are expressed in micrometers, $\rho_p$ can be in grams per cubic centimeter and $C'$ can be approximated by $C' = 1 + A_c(2\lambda/D_p)$, where $A_c$ is a constant dependent upon gas composition, temperature, and pressure ($A_c = 0.88$ for atmospheric air at 20°C) and $\lambda$ is the mean free path of the gas molecules ($\lambda = 0.10$ μm for 20°C atmospheric air). For other temperatures or pressures, or gases other than air, calculations using these more precise equations may be made: $A_c = 1.257 + 0.4 \exp[-1.1\ (d_p/2\lambda)]$ and $\lambda = \mu_g/0.499\rho_g \times \mu_m$ (where $\mu_g$ is the gas viscosity, kg/m·h; $p_g$ is gas density, g/cm$^3$; and $\mu_m$ is the mean molecular speed, m/s. $u_m = [8R_uT/\pi M]^{0.5}$, where $R_u$ is the universal gas constant, 8.315 kJ/kg·mol·K; $T$ is the gas absolute temperature, K; and $M$ is the molar mass or equivalent molecular weight of the gas. ($\pi$ is the usual geometric constant.) For test purposes (air at 25°C and 1 atm), $p_g = 1.183$ kg/m, $\mu_g = 0.0666$ kg/m·h, $\lambda = 0.067$ μm, and $u_m = 467$ m/s. For airborne liquid particles, the assumption of spherical shape is reasonably accurate, and $\rho_p$ is approximately unity for dilute aqueous particles at ambient temperatures. $C'$ is approximately unity at ambient conditions for such particles larger than 1 to 5 μm, so that often the actual liquid particle diameter and the equivalent aerodynamic diameter are identical.

When a distribution of particle sizes which must be collected is present, the actual size distribution must be converted to a mass distribution by aerodynamic size. Frequently the distribution can be represented or approximated by a log-normal distribution (a straight line on a log-log plot of cumulative mass percent of particles versus diameter) which can be characterized by the mass median particle diameter $d_{p50}$ and the standard statistical deviation of particles from the median $\sigma_g$. $\sigma_g$ can be obtained from the log-log plot by $\sigma_g = D_{pa50}/D_{pe}$ at 15.87 percent = $D_{pe}$ at 84.13 percent/$D_{pa50}$.

The grade efficiency $\eta$ of most collectors can be expressed as a function of the aerodynamic particle size in the form of an exponential equation. It is simpler to write the equation in terms of the particle penetration $P_t$ (those particles not collected), where the fractional penetration $P_t = 1 - \eta$, when $\eta$ is the fractional efficiency. The typical collection equation is

$$P_t = e^{(-A_a D_{pa} B)} \tag{14-224}$$

where $A_a$ and $B$ are functions of the collection device. Calvert (R-12) has determined that for many devices in which the primary collection mechanism is direct interception and inertial impaction, such as packed beds, knitted-mesh collectors, zigzag baffles, target collectors such as tube banks, sieve-plate columns, and venturi scrubbers, the value of $B$ is approximately 2.0. For cyclonic collectors, the value of $B$ is approximately 0.67. The overall integrated penetration $\overline{P}_t$ for a device handling a distribution of particle sizes can be obtained by

$$\overline{P}_t = \int_0^W \left(\frac{dW}{W}\right) P_t \tag{14-225}$$

where $(dW/W)$ is the mass of particles in a given narrow size distribution and $P_t$ is the average penetration for that size range. When the particles to be collected are log-normally distributed and the collection device efficiency can be expressed by Eq. (14-224), the required overall integrated collection efficiency $\overline{P}_t$ can be related to the ratio of the device aerodynamic cut size $D_{pc}$ to the mass median aerodynamic particle size $D_{pa50}$. This required ratio for a given distribution and collection is designated $R_{rL}$ and these relationships are illustrated graphically in Fig. 14-106. For the many devices for which $B$ is approximately 2.0, a simplified plot (Fig. 14-107) is obtained. From these figures, by knowing the desired overall collection efficiency and particle distribution, the value of $R_{rL}$ can be read. Substituting the mass median particle diameter gives the aerodynamic cut size

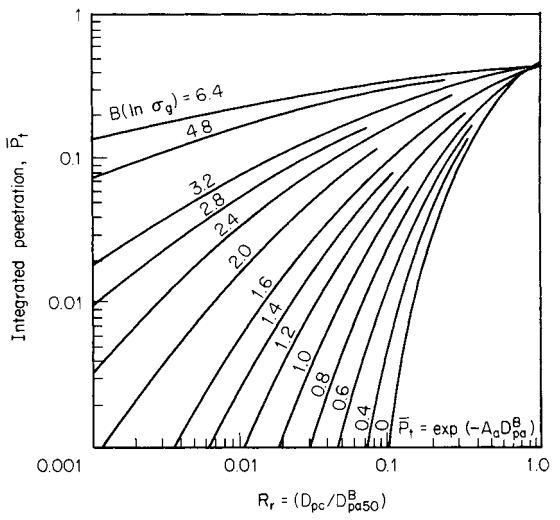

**FIG. 14-106** Overall integrated penetration as a function of particle-size distribution and collector parameters. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

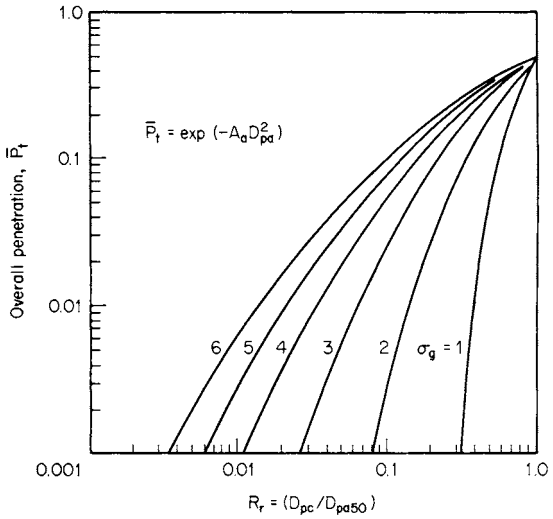

**FIG. 14-107** Overall integrated penetration as a function of particle-size distribution and collector cut diameter when $B = 2$ in Eq. (14-224). (*Calvert, Goldshmid, Leith, and Mehta, NTIS Publ. PB-213016, 213017, 1972.*)

required from the collection device being considered. Therefore, an experimental plot of aerodynamic cut size for each collection device versus operating parameters can be used to determine the device suitability.

### Collection Equipment

***Gravity Settlers*** Gravity can act to remove larger droplets. Settling or disengaging space above aerated or boiling liquids in a tank or spray zone in a tower can be very useful. If gas velocity is kept low, all particles with terminal settling velocities (see Sec. 6) above the gas velocity will eventually settle. Increasing vessel cross section in the settling zone is helpful. Terminal velocities for particles smaller than 50 μm are very low and generally not attractive for particle removal. Laminar flow of gas in long horizontal paths between trays or shelves on which the droplets settle is another effective means of employing gravity. Design equations are given in Sec. 17 under "Gas-Solids Separations." Settler pressure drop is very low, usually being limited to entrance and exit losses.

***Centrifugal Separation*** Centrifugal force can be utilized to enhance particle collection to several hundredfold that of gravity. The design of cyclone separators for dust removal is treated in detail in Sec. 17 under "Gas-Solids Separations," and typical cyclone designs are shown in Fig. 17-43. Dimension ratios for one family of cyclones are given in Fig. 17-36. Cyclones, if carefully designed, can be more efficient on liquids than on solids since liquids coalesce on capture and are easy to drain from the unit. However, some precautions not needed for solid cyclones are necessary to prevent reentrainment.

Tests by Calvert (R-12) show high primary collection efficiency on droplets down to 10 μm and in accordance with the efficiency equations of Leith and Licht [*Am. Inst. Chem. Eng. Symp. Ser.,* 68(126), 196–206 (1972)] for the specific cyclone geometry tested if entrainment is avoided. Typical entrainment points are (1) creep along the gas outlet pipe, (2) entrainment by shearing of the liquid film from the walls, and (3) vortex pickup from accumulated liquid in the bottom (Fig. 14-108*a*). Reentrainment from creep of liquid along the top of the cyclone and down the outlet pipe can be prevented by providing the outlet pipe with a flared conical skirt (Fig. 14-108*b*), which provides a point from which the liquid can drip without being caught in the outlet gas. The skirt should be slightly shorter than the gas outlet pipe but extend below the bottom of the gas inlet. The cyclone inlet gas should not impinge on this skirt. Often the bottom edge of the skirt is V-notched or serrated.

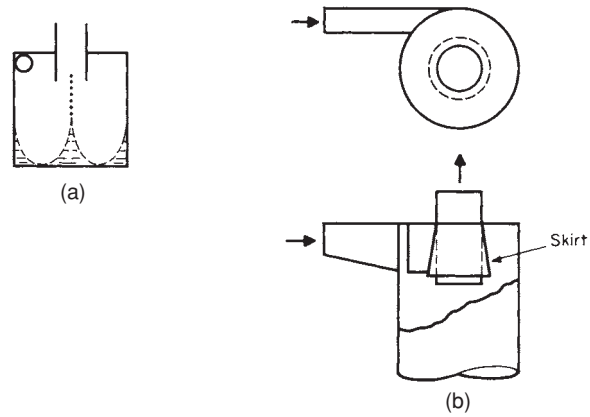

**FIG. 14-108** (*a*) Liquid entrainment from the bottom of a vessel by centrifugal flow. (*Rietema and Verver,* Cyclones in Industry, *Elsevier, Amsterdam, 1961.*) (*b*) Gas-outlet skirt for liquid cyclones. (*Stern et al.,* Cyclone Dust Collectors, *American Petroleum Institute, New York, 1955.*)

Reentrainment is generally reduced by lower inlet gas velocities. Calvert (R-12) reviewed the literature on predicting the onset of entrainment and found that of Chien and Ibele (ASME Pap. 62-WA170) to be the most reliable. Calvert applies their correlation to a liquid Reynolds number on the wall of the cyclone, $N_{\mathrm{Re},L} = 4Q_L/h_i v_L$, where $Q_L$ is the volumetric liquid flow rate, cm$^3$/s; $h_i$ is the cyclone inlet height, cm; and $v_L$ is the kinematic liquid viscosity, cm$^2$/s. He finds that the onset of entrainment occurs at a cyclone inlet gas velocity $V_{ci}$, m/s, in accordance with the relationship in $V_{ci} = 6.516 - 0.2865 \ln N_{\mathrm{Re},L}$.

Reentrainment from the bottom of the cyclone can be prevented in several ways. If a typical long-cone dry cyclone is used and liquid is kept continually drained, vortex entrainment is unlikely. However, a vortex breaker baffle in the outlet is desirable, and perhaps a flat disk on top extending to within 2 to 5 cm (0.8 to 2 in) of the walls may be beneficial. Often liquid cyclones are built without cones and have dished bottoms. The modifications described earlier are definitely needed in such situations. Stern, Caplan, and Bush (*Cyclone Dust Collectors,* American Petroleum Institute, New York, 1955) and Rietema and Verver (in Tengbergen, *Cyclones in Industry,* Elsevier, Amsterdam, 1961, chap. 7) have discussed liquid-collecting cyclones.

As with dust cyclones, no reliable pressure-drop equations exist (see Sec. 17), although many have been published. A part of the problem is that there is no standard cyclone geometry. Calvert (R-12) experimentally obtained $\Delta P = 0.000513\ \rho_g (Q_g/h_i W_i)^2 (2.8 h_i w_i/d_o^2)$, where $\Delta P$ is in cm of water; $\rho_g$ is the gas density, g/cm$^3$; $Q_g$ is the gas volumetric flow rate, cm$^3$/s; $h_i$ and $w_i$ are cyclone inlet height and width respectively, cm; and $d_o$ is the gas outlet diameter, cm. This equation is in the same form as that proposed by Shepherd and Lapple [*Ind. Eng. Chem.,* **31,** 1246 (1940)] but gives only 37 percent as much pressure drop.

Liquid cyclone efficiency can be improved somewhat by introducing a coarse spray of liquid in the cyclone inlet. Large droplets which are easily collected collide with finer particles as they sweep the gas stream in their travel to the wall. (See subsection "Wet Scrubbers" regarding optimum spray size.) Cyclones may also be operated wet to improve their operation on dry dust. Efficiency can be improved through reduction in entrainment losses since the dust particles become trapped in the water film. Collision between droplets and dust particles aids collection, and adequate irrigation can eliminate problems of wall buildup and fouling. The most effective operation is obtained by spraying countercurrently to the gas flow in the cyclone inlet duct at liquid rates of 0.7 to 2.0 L/m$^3$ of gas. There are also many proprietary designs of liquid separators using centrifugal force, some of which are illustrated in Fig. 14-109. Many of these were originally

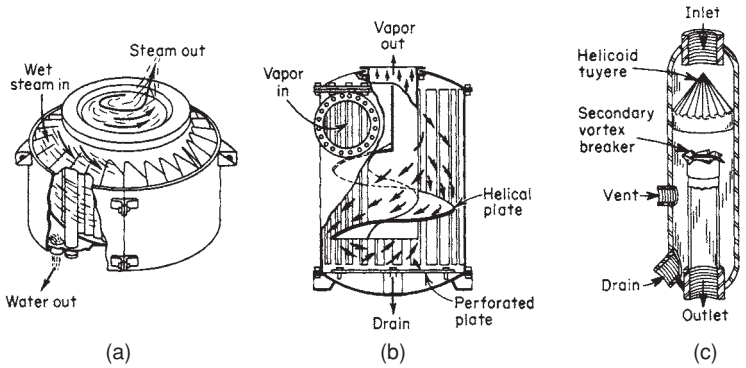

**FIG. 14-109** Typical separators using impingement in addition to centrifugal force. (*a*) Hi-eF purifier. (*V. D. Anderson Co.*) (*b*) Flick separator. (*Wurster & Sanger, Inc.*) (*c*) Type RA line separator. (*Centrifix Corp., Bull. 220.*)

developed as steam separators to remove entrained condensate. In some designs, impingement on swirl baffles aids separation.

***Impingement Separation*** Impingement separation employs direct impact and inertial forces between particles, the gas streamlines, and target bodies to provide capture. The mechanism is discussed in Sec. 17 under "Gas-Solids Separations." With liquids, droplet coalescence occurs on the target surface, and provision must be made for drainage without reentrainment. Calvert (R-12) has studied droplet collection by impingement on targets consisting of banks of tubes, zigzag baffles, and packed and mesh beds. Figure 14-110 illustrates some other types of impingement-separator designs.

In its simplest form, an impingement separator may be nothing more than a target placed in front of a flow channel such as a disk at the end of a tube. To improve collection efficiency, the gas velocity may be increased by forming the end into a nozzle (Fig. 14-110*a*). Particle collection as a function of size may be estimated by using the target-efficiency correlation in Fig. 17-39. Since target efficiency will be low for systems with separation numbers below 5 to 10 (small particles, low gas velocities), the mist will frequently be subjected to a number of targets in series as in Fig. 14-110*c, d,* and *g.*

The overall droplet penetration is the product of penetration for each set of targets in series. Obviously, for a distribution of particle sizes, an integration procedure is required to give overall collection efficiency. This target-efficiency method is suitable for predicting efficiency when the design effectively prevents the bypassing or short-circuiting of targets by the gas stream and provides adequate time to accelerate the liquid droplets to gas velocity. Katz (R-16) investigated a jet and target-plate entrainment separator design and found the pressure drop less than would be expected to supply the kinetic energy both for droplet acceleration and gas friction. An estimate based on his results indicates that the liquid particles on the average were being accelerated to only about 60 percent of the gas velocity. The largest droplets, which are the easiest to collect, will be accelerated less than the smaller particles. This factor has a leveling effect on collection efficiency as a function of particle size so that experimental results on such devices may not show as sharp a decrease in efficiency with particle size as predicted by calculation. Such results indicate that in many cases our lack of predicting ability results, not from imperfections in the theoretical treatment, but from our lack of knowledge of velocity distributions within the system.

Katz (R-16) also studied *wave-plate impingement separators* (Fig. 14-110*b*) made up of 90° formed arcs with an 11.1-mm (0.44-in) radius and a 3.8-mm (0.15-in) clearance between sheets. The pressure drop is a function of system geometry. The pressure drop for Katz's system and collection efficiency for seven waves are shown in Fig. 14-111. Katz used the Souders-Brown expression to define a design velocity for the gas between the waves:

$$U = K\sqrt{\rho_l - \rho_g)/\rho_g} \qquad (14\text{-}226)$$

$K$ is 0.12 to give $U$ in $ms^{-1}$ (0.4 for ft/s), and $\rho_l$ and $\rho_g$ are liquid and gas densities in any consistent set of units. Katz found no change in efficiency at gas velocities from one-half to 3 times that given by the equation.

Calvert (R-12) investigated *zigzag baffles* of a design more like Fig. 14-110*e.* The baffles may have spaces between the changes in direction or be connected as shown. He found close to 100 per collection for water droplets of 10 μm and larger. Some designs had high efficiencies down to 5 or 8 μm. Desirable gas velocities were 2 to 3.5 m/s (6.6 to 11.5 ft/s), with a pressure drop for a six-pass baffle of 2 to 2.5 cm (0.8 to 1.0 in) of water. On the basis of turbulent mixing, an equation was developed for predicting primary collection efficiency as a function of particle size and collector geometry:

$$\eta = 1 - \exp\left[-\frac{u_{te} n W \theta}{57.3 U_g b \tan \theta}\right] \qquad (14\text{-}227)$$

where $\eta$ is the fractional primary collection efficiency; $u_{te}$ is the drop terminal centrifugal velocity in the normal direction, cm/s; $U_g$ is the superficial gas velocity, cm/s; $n$ is the number of rows of baffles or bends; $\theta$ is the angle of inclination of the baffle to the flow path, °; $W$ is the width of the baffle, cm; and $b$ is the spacing between baffles in the same row, cm. For conditions of low Reynolds number ($N_{Re,D} < 0.1$) where Stokes' law applies, Calvert obtains the value for drop terminal centrifugal velocity of $u_{te} = d_p^2 \rho_p a/18 \mu_g$, where $d_p$ and $\rho_p$ are the drop particle diameter, cm, and particle density, g/cm$^3$, respectively; $\mu_g$ is the gas viscosity, P; and $a$ is the acceleration due to centrifugal force. It is defined by the equation $a = 2U_g^2 \sin \theta / W \cos^3 \theta$. For situations in which Stokes' law does not apply, Calvert recommends substitution in the derivation of Eq. (14-227) for $u$ of drag coefficients from drag-coefficient data of Foust et al. (*Principles of Unit Operations,* Toppan Co., Tokyo, 1959).

Calvert found that reentrainment from the baffles was affected by the gas velocity, the liquid-to-gas ratio, and the orientation of the baffles. Horizontal gas flow past vertical baffles provided the best drainage and lowest reentrainment. Safe operating regions with vertical baffles are shown in Fig. 14-112. Horizontal baffles gave the poorest drainage and the highest reentrainment, with inclined baffles intermediate in performance. Equation (14-228), developed by Calvert, predicts pressure drop across zigzag baffles. The indicated summation must be made over the number of rows of baffles present.

$$\Delta P = \sum_{i=1}^{i=n} 1.02 \times 10^{-3} f_D \rho_g \frac{U_g' A_p}{2A_t} \qquad (14\text{-}228)$$

$\Delta P$ is the pressure drop, cm of water; $\rho_g$ is the gas density, g/cm$^3$; $A_p$ is the total projected area of an entire row of baffles in the direction of inlet gas flow, cm$^2$; and $A_t$ is the duct cross-sectional area, cm$^2$. The

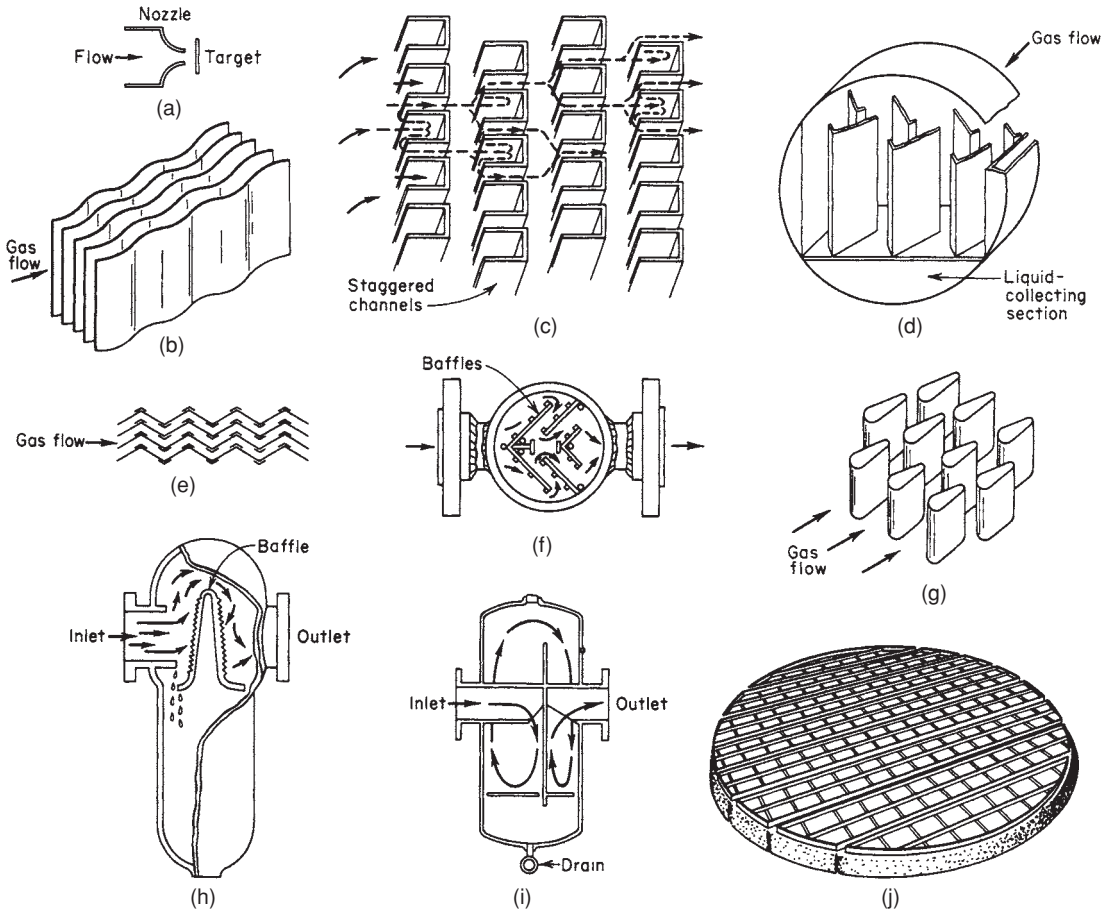

**FIG. 14-110** Typical impingement separators. (*a*) Jet impactor. (*b*) Wave plate. (*c*) Staggered channels. (*Blaw-Knox Food & Chemical Equipment, Inc.*) (*d*) Vane-type mist extractor. (*Union Carbide Corporation*) (*h*) Type E horizontal separator. (*Wright-Austin Co.*) (*i*) PL separator. (*Ingersoll Rand.*) (*j*) Wire-mesh demister. (*Otto H. York Co.*)

value $f_D$ is a drag coefficient for gas flow past inclined flat plates taken from Fig. 14-113, while $U'_g$ is the actual gas velocity, cm/s, which is related to the superficial gas velocity $U_g$ by $U'_g = U_g/\cos\theta$. It must be noted that the angle of incidence $\theta$ for the second and successive rows of baffles is twice the angle of incidence for the first row. Most of Calvert's work was with 30° baffles, but the method correlates well with other data on 45° baffles.

The Karbate line separator (Fig. 14-110*g*) is composed of several layers of teardrop-shaped target rods of Karbate. A design flow constant $K$ in Eq. (14-226) of 0.035 m/s (1.0 ft/s) is recommended by the

manufacturer. Pressure drop is said to be 5½ velocity heads on the basis of the superficial gas velocity. This value would probably increase at high liquid loads. Figure 14-114 gives the manufacturer's reported grade efficiency curve at the design air velocity.

The use of multiple tube banks as a droplet collector has also been studied by Calvert (R-12). He reports that collection efficiency for closely packed tubes follows equations for rectangular jet impaction which can be obtained graphically from Fig. 14-115 by using a dimensional parameter $\beta$ which is based on the tube geometry; $\beta = 2l_i/b$, where $b$ is the open distance between adjacent tubes in the row (orifice width) and $l_i$ is the impaction length (distance between orifice and impingement plane), or approximately the distance between centerlines of successive tube rows. Note that the impaction parameter $K_p$ is plotted to the one-half power in Fig. 14-115 and that the radius of the droplet is used rather than the diameter. Collection efficiency overall for a given size of particle is predicted for the entire tube bank by

$$\eta = 1 - (1 - \eta_b)^N \qquad (14\text{-}229)$$

where $\eta_b$ is the collection efficiency for a given size of particle in one stage of a rectangular jet impactor (Fig. 14-115) and $N$ is the number of stages in the tube bank (equal to one less than the number of rows).

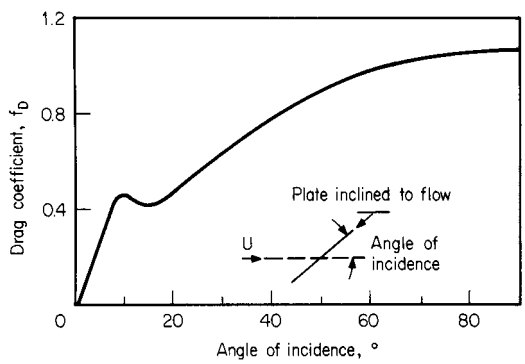

**FIG. 14-113** Drag coefficient for flow past inclined flat plates for use in Eq. (14-228). [*Calvert, Yung, and Leung, NTIS Publ. PB-248050; based on Fage and Johansen,* Proc. R. Soc. (London), *116A, 170 (1927).*]

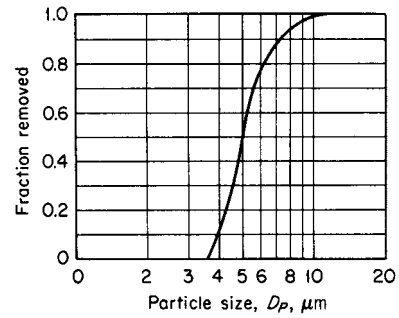

**FIG. 14-114** Collection efficiency of Karbate line separator, based on particles with a specific gravity of 1.0 suspended in atmospheric air with a pressure drop of 2.5 cm water gauge. (*Union Carbide Corporation Cat. Sec. S-6900, 1960.*)

For widely spaced tubes, the target efficiency $\eta_g$ can be calculated from Fig. 17-39 or from the impaction data of Golovin and Putnam [*Ind. Eng. Chem. Fundam.*, **1,** 264 (1962)]. The efficiency of the overall tube banks for a specific particle size can then be calculated from the equation $\eta = 1 - (1 - \eta_i a'/A)^n$, where $a'$ is the cross-sectional area of all tubes in one row, $A$ is the total flow area, and $n$ is the number of rows of tubes.

Calvert reports pressure drop through tube banks to be largely unaffected by liquid loading and indicates that Grimison's correlations in Sec. 6 ("Tube Banks") for gas flow normal to tube banks or data for gas flow through heat-exchanger bundles can be used. However, the following equation is suggested:

$$\Delta P = 8.48 \times 10^{-3} n \rho_g U_g'^2 \qquad (14\text{-}230)$$

where $\Delta P$ is cm of water; $n$ is the number of rows of tubes; $\rho_g$ is the gas density, g/cm³; and $U_g'$ is the actual gas velocity between tubes in a row, cm/s. Calvert did find an increase in pressure drop of about 80 to 85 percent above that predicted by Eq. (14-230) in vertical upflow of gas through tube banks due to liquid holdup at gas velocities above 4 m/s.

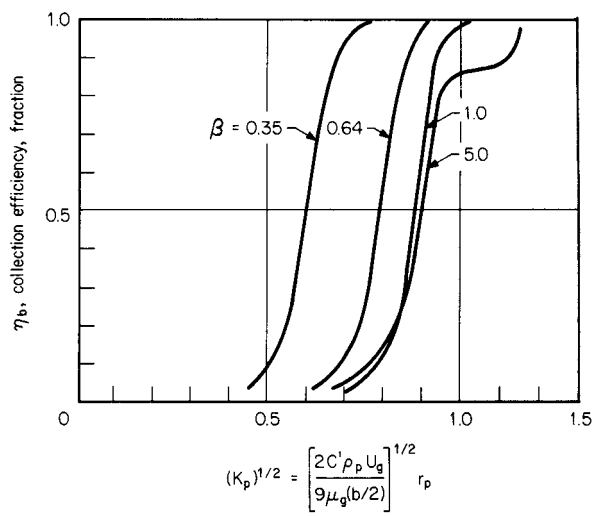

**FIG. 14-115** Experimental collection efficiencies of rectangular impactors. $C'$ is the Stokes-Cunningham correction factor; $\rho_p$, particle density, g/cm³; $U_g$, superficial gas velocity, approaching the impactor openings, cm/s; and $\mu_g$, gas viscosity, P. [*Calvert, Yung, and Leung, NTIS Publ. PB-248050; based on Mercer and Chow,* J. Coll. Interface Sci., **27,** 75 (*1968*).]

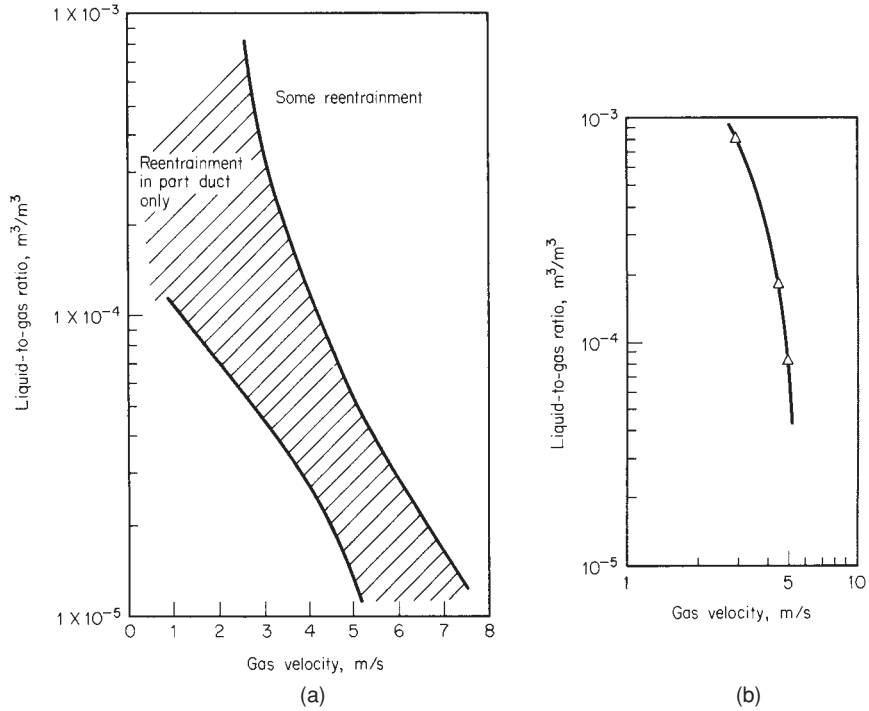

**FIG. 14-116** Experimental results showing effect of gas velocity and liquid load on entrainment from (*a*) vertical tube banks with horizontal gas flow and (*b*) horizontal tube banks with upflow. To convert meters per second to feet per second, multiply by 3.281. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050.*)

The onset of liquid reentrainment from tube banks can be predicted from Fig. 14-116. Reentrainment occurred at much lower velocities in vertical upflow than in horizontal gas flow through vertical tube banks. While the top of the cross-hatched line of Fig. 14-116*a* predicts reentrainment above gas velocities of 3 m/s (9.8 ft/s) at high liquid loading, most of the entrainment settled to the bottom of the duct in 1 to 2 m (3.3 to 6.6 ft), and entrainment did not carry significant distances until the gas velocity exceeded 7 m/s (23 ft/s).

***Packed-Bed Collectors*** Many different materials, including coal, coke, broken solids of various types such as brick, tile, rock, and stone, as well as normal types of tower-packing rings, saddles, and special plastic shapes, have been used over the years in packed beds to remove entrained liquids through impaction and filtration. Separators using natural materials are not available as standard commercial units but are designed for specific applications. Coke boxes were used extensively in the years 1920 to 1940 as sulfuric acid entrainment separators (see *Chemical Engineers' Handbook*, 5th ed., p. 18–87) but have now been largely superseded by more sophisticated and efficient devices.

Jackson and Calvert [*Am. Inst. Chem. Eng. J.*, **12,** 1075 (1966)] studied the collection of fine fuel-oil-mist particles in beds of ½-in glass spheres, Raschig rings, and Berl and Intalox saddles. The mist had a mass median particle diameter of 6 μm and a standard deviation of 2.0. The collection efficiency as a function of particle size and gas velocity in a 355-mm- (14-in-) diameter by 152-mm- (6-in-) thick bed of Intalox saddles is given in Fig. 14-117. This and additional work have been generalized by Calvert (R-12) to predict collection efficiencies of liquid particles in any packed bed. Assumptions in the theoretical development are that the drag force on the drop is given by Stokes' law and that the number of semicircular bends to which the gas is subjected, $\eta_1$, is related to the length of the bed, Z (cm), in the direction of gas flow, the packing diameter, $d_c$ (cm), and the gas-flow channel width, $b$ (cm), such that $\eta_1 = Z/(d_c + b)$. The gas velocity through the channels, $U_{gb}$ (cm/s), is inversely proportional to the bed free volume for gas flow such that $U_{gb} = U_g[1/(\varepsilon - h_b)]$, where $U_g$ is the gas superficial velocity, cm/s, approaching the bed, ε is the bed void fraction, and $h_b$ is the fraction of the total bed volume taken up with liquid which can be obtained from data on liquid holdup in packed beds. The width of the semicircular channels $b$ can be expressed as a fraction $j$ of the diameter of the packing elements, such that $b = jd_c$. These assumptions (as modified by G. E. Goltz, personal communica-

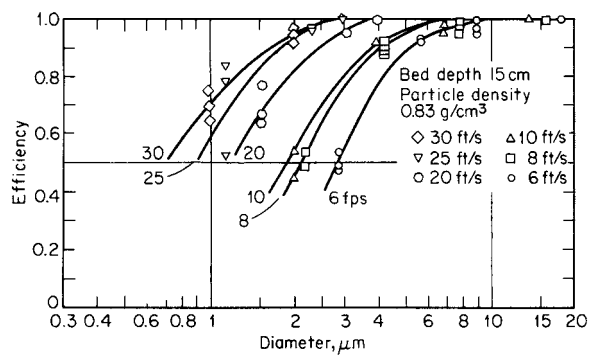

**FIG. 14-117** Experimental collection efficiency. ½-in Intalox saddles. To convert feet per second to meters per second, multiply by 0.3048; to convert centimeters to inches, multiply by 0.394; and to convert grams per cubic centimeter to pounds per cubic foot, multiply by 62.43. [*Jackson and Calvert,* Am. Inst. Chem. Eng. J., ***12,*** *1975 (1968).*]

**TABLE 14-27 Experimental Values for *j*, Channel Width in Packing as a Fraction of Packing Diameter**

| Packing size | | | |
|---|---|---|---|
| cm | in | Type of packing | *j* |
| 1.27 | 0.5 | Berl and Intalox saddles, marbles, Raschig rings | 0.192 |
| 2.54 | 1.0 | Berl and Intalox saddles, pall rings | 0.190 |
| 3.8 | 1.5 | Berl and Intalox saddles, pall rings | 0.165 |
| 7.6–12.7 | 3–5 | Coke | 0.03 |

tion) lead to an equation for predicting the penetration of a given size of liquid particle through a packed bed:

$$P_t = \exp\left[\frac{-\pi}{2(j+j^2)(\varepsilon - h_b)}\left(\frac{Z}{d_c}\right) K_p\right] \qquad (14\text{-}231)$$

where

$$K_p = \frac{\rho_p d_p^2 U_g}{9\mu_g d_c} \qquad (14\text{-}232)$$

Values of $\rho_p$ and $d_p$ are droplet density, g/cm$^3$, and droplet diameter, cm; $\mu_g$ is the gas viscosity, P. All other terms were defined previously. Table 14-27 gives values of $j$ calculated from experimental data of Jackson and Calvert. Values of $j$ for most manufactured packing appear to fall in the range from 0.16 to 0.19. The low value of 0.03 for coke may be due to the porosity of the coke itself.

Calvert (R-12) has tested the correlation in cross-flow packed beds, which tend to give better drainage than countercurrent beds, and has found the effect of gas-flow orientation insignificant. However, the onset of reentrainment was somewhat lower in a bed of 2.5-cm (1.0-in) pall rings with gas upflow [6 m/s (20 ft/s)] than with horizontal cross-flow of gas. The onset of reentrainment was independent of liquid loading (all beds were nonirrigated), and entrainment occurred at values somewhat above the flood point for packed beds as predicted by conventional correlations. In beds with more than 3 cm (1.2 in) of water pressure drop, the experimental drop with both vertical and horizontal gas flow was somewhat less than predicted by generalized packed-bed pressure-drop correlations. However, Calvert recommends these correlations for design as conservative.

Calvert's data indicate that packed beds irrigated only with the collected liquid can have collection efficiencies of 80 to 90 percent on mist particles down to 3 μm but have low efficiency on finer mist particles. Frequently, irrigated packed towers and towers with internals will be used with liquid having a wetting capability for the fine mist which must be collected. Tennessee Valley Authority (TVA) experiments with the collection of 1.0-μm mass median phosphoric acid mist in packed towers have shown that the strength of the circulating phosphoric acid is highly important [see Baskerville, *Am. Inst. Chem. Eng. J.*, **37,** 79 (1941); and p. 18–87, 5th ed. of the *Handbook*]. Hesketh (*J. Air Pollut. Control Assoc.*, **24,** 942 (1974)] has reported up to 50 percent improvement in collection efficiency in venturi scrubbers on fine particles with the addition of only 0.10 percent of a low-foaming nonionic surfactant to the scrubbing liquid, and others have experienced similar results in other gas-liquid-contacting devices. Calvert (R-9 and R-10) has reported on the efficiency of various gas-liquid-contacting devices for fine particles. Figure 14-118 gives the particle aerodynamic cut size for a single-sieve-plate gas scrubber as a function of sieve hole size $d_h$, cm; hole gas velocity $u_h$, m/s; and froth or foam density on the plate $F$, g/cm$^3$. This curve is based on standard air and water properties and wettable (hydrophilic) particles. The cut diameter decreases with an increase in froth density, which must be predicted from correlations for sieve-plate behavior (see Fig. 14-32). Equation (14-231) can be used to calculate generalized design curves for collection in packed columns in the same fashion by finding parameters of packing size, bed length, and gas velocity which give collection efficiencies of 50 percent for various size particles. Figure 14-119 illustrates such a plot for three gas velocities and two sizes of packing.

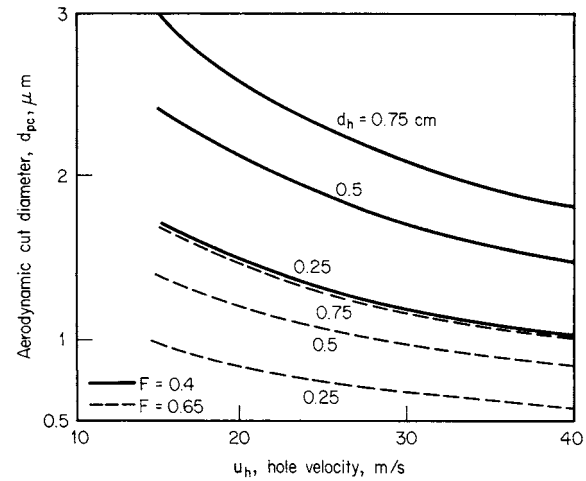

**FIG. 14-118** Aerodynamic cut diameter for a single-sieve-plate scrubber as a function of hole size, hole-gas velocity, and froth density, $F$, g/cm$^3$. To convert meters per second to feet per second, multiply by 3.281; to convert grams per cubic centimeter to pounds per cubic foot, multiply by 62.43. [*Calvert,* J. Air Pollut. Control Assoc., ***24,*** 929 (*1974*).]

***Wire-Mesh Mist Collectors*** Knitted mesh of varying density and voidage is widely used for entrainment separators. Its advantage is close to 100 percent removal of drops larger than 5 μm at superficial gas velocities from about 0.2 ms/s (0.6 ft/s) to 5 m/s (16.4 ft/s), depending somewhat on the design of the mesh. Pressure drop is usually no more than 2.5 cm (1 in) of water. A major disadvantage is the ease with which tars and insoluble solids plug the mesh. The separator can be made to fit vessels of any shape and can be made of any material which can be drawn into a wire. Stainless-steel and plastic fibers are most common, but other metals are sometimes used. Generally three basic types of mesh are used: (1) layers with a crimp in the same direction (each layer is actually a nested double layer); (2) layers with a crimp in

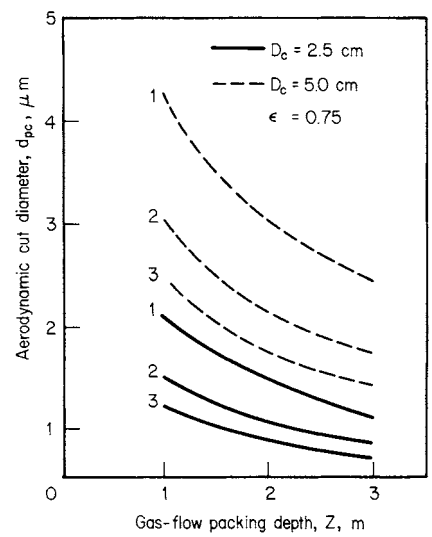

**FIG. 14-119** Aerodynamic cut diameter for a typical packed-bed entrainment separator as a function of packing size, bed depth, and three gas velocities: curve 1–1.5 m/s, curve 2–3.0 m/s, and curve 3–4.5 m/s. To convert meters to feet, multiply by 3.281; to convert centimeters to inches, multiply by 0.394. [*Calvert,* J. Air Pollut. Control Assoc., ***24,*** 929 (*1974*).]

alternate directions, which increases voidage, reduces sheltering and increases target efficiency per layer, and gives a lower pressure drop per unit length; and (3) spiral-wound layers which reduce pressure drop by one-third, but fluid creep may lead to higher entrainment. Some small manufacturers of plastic meshes may offer other weaves claimed to be superior. The filament size can vary from about 0.15 mm (0.006 in) for fine-wire pads to 3.8 mm (0.15 in) for some plastic fibers. Typical pad thickness varies from 100 to 150 mm (4 to 6 in), but occasionally pads up to 300 mm (12 in) thick are used. A typical wire diameter for standard stainless mesh is 0.28 mm (0.011 in), with a finished mesh density of 0.15 g/cm$^3$ (9.4 lb/ft$^3$). A lower mesh density may be produced with standard wire to give 10 to 20 percent higher flow rates.

Figure 14-120 presents an early calculated estimate of mesh efficiency as a fraction of mist-particle size. Experiments by Calvert (R-12) confirm the accuracy of the equation of Bradie and Dickson (*Joint Symp. Proc. Inst. Mech. Eng./Yorkshire Br. Inst. Chem. Eng.*, 1969, pp. 24–25) for primary efficiency in mesh separators:

$$\eta = 1 - \exp(-2/3)\pi a l \eta_i) \qquad (14\text{-}232)$$

where $\eta$ is the overall collection efficiency for a given-size particle; $l$ is the thickness of the mesh, cm, in the direction of gas flow; $a$ is the surface area of the wires per unit volume of mesh pad, cm$^2$/cm$^3$; and $\eta_i$, the target collection efficiency for cylindrical wire, can be calculated from Fig. 17-39 or the impaction data of Golovin and Putnam [*Ind. Eng. Chem.*, **1,** 264 (1962)]. The factor 2/3, introduced by Carpenter and Othmer [*Am. Inst. Chem. Eng. J.*, **1,** 549 (1955)], corrects for the fact that not all the wires are perpendicular to the gas flow and gives the projected perpendicular area. If the specific mesh surface area $a$ is not available, it can be calculated from the mesh void area $\varepsilon$ and the mesh wire diameter $d_w$ in cm, $a = 4(1 - \varepsilon)/d_w$.

York and Poppele (R-17) have stated that factors governing maximum allowable gas velocity through the mesh are (1) gas and liquid density, (2) liquid surface tension, (3) liquid viscosity, (4) specific wire surface area, (5) entering-liquid loading, and (6) suspended-solids content. York (R-18) has proposed application of the Souders-Brown equation [Eq. (14-226)] for correlation of maximum allowable gas velocity with values of $K$ for most cases of 0.1067 m/s to give $U$ in m/s (0.35 for ft/s). When liquid viscosity or inlet loading is high or the liquid is dirty, the value of $K$ must be reduced. Schroeder (M.S. thesis, Newark College of Engineering, 1962) found lower values for $K$ necessary when liquid surface tension is reduced such as by the presence of surfactants in water. Ludwig (*Applied Process Design for Chemical and Petrochemical Plants,* 2d ed., vol. I, Gulf, Houston, 1977, p. 157) recommends reduced $K$ values of (0.061 m/s) under vacuum at an absolute pressure of 6.77 kPa (0.98 lbf/in$^2$) and $K = 0.082$ m/s at 54 kPa (7.83 lbf/in$^2$) absolute. Most manufacturers suggest setting the design velocity at three-fourths of the maximum velocity to allow for surges in gas flow.

York and Poppele (R-17) have suggested that total pressure drop through the mesh is equal to the sum of the mesh dry pressure drop plus an increment due to the presence of liquid. They considered the mesh to be equivalent to numerous small circular channels and used the D'Arcy formula with a modified Reynolds number to correlate friction factor (see Fig. 14-121) for Eq. (14-233) giving dry pressure drop.

$$\Delta P_{\text{dry}} = fla\rho_g U_g^2/981\ \varepsilon^3 \qquad (14\text{-}233)$$

where $\Delta P$ is in cm of water; $f$ is from Fig. (14-121); $\rho_g$ is the gas density, g/cm$^3$; $U_g$ is the superficial gas velocity, cm/s; and $\varepsilon$ is the mesh porosity or void fraction; $l$ and $a$ are as defined in Eq. (14-232). Figure 14-121 gives data of York and Poppele for mesh crimped in the same and alternating directions and also includes the data of Satsangee, of Schuring, and of Bradie and Dickson.

The incremental pressure drop for wet mesh is not available for all operating conditions or for mesh of different styles. The data of York and Poppele for wet-mesh incremental pressure drop, $\Delta P_L$ in cm of water, are shown in Fig. 14-122 or parameters of liquid velocity $L/A$, defined as liquid volumetric flow rate, cm$^3$/min per unit of mesh cross-sectional area in cm$^2$; liquid density $\rho_L$ is in g/cm$^3$.

York generally recommends the installation of the mesh horizontally with upflow of gas as in Fig. 14-110*f;* Calvert (R-12) tested the mesh horizontally with upflow and vertically with horizontal gas flow. He reports better drainage with the mesh vertical and somewhat higher permissible gas velocities without reentrainment, which is contrary to past practice. With horizontal flow through vertical mesh, he found collection efficiency to follow the predictions of Eq. (14-232) up to 4 m/s (13 ft/s) with air and water. Some reentrainment was encountered at higher velocities, but it did not appear serious until velocities exceeded 6.0 m/s (20 ft/s). With vertical upflow of gas, entrainment was encountered at velocities above and below 4.0 m/s (13 ft/s), depending on inlet liquid quantity (see Fig. 14-123). Figure 14-124 illustrates the onset of entrainment from mesh as a function of liquid loading and gas velocity and the safe operating area recommended by Calvert. Measurements of dry pressure drop by Calvert gave values only about one-third of those predicted from Eq. (14-233). He found the pressure drop to be highly affected by liquid load. The pressure drop of wet mesh could be correlated as a function of $U_g^{1.65}$ and parameters of liquid loading $L/A$, as shown in Fig. 14-125.

As indicated previously, mesh efficiency drops rapidly as particles decrease in size below 5 μm. An alternative is to use two mesh pads in series. The first mesh is made of fine wires and is operated beyond the

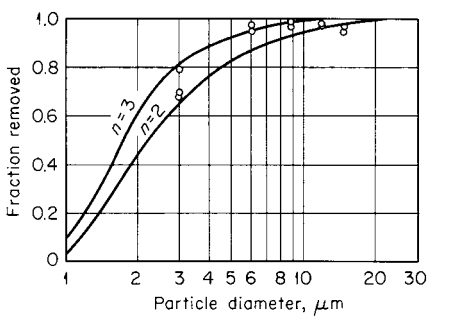

**FIG. 14-120** Collection efficiency of wire-mesh separator; 6-in thickness, 98.6 percent free space, 0.006-in-diameter wire used for experiment points. Curves calculated for target area equal to 2 and 3 times the solids volume of packing. To convert inches to millimeters, multiply by 25.4.

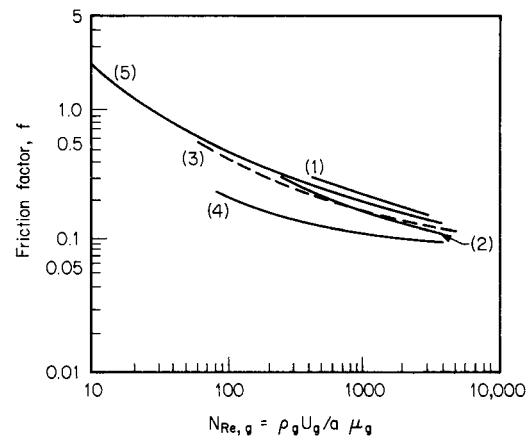

**FIG. 14-121** Value of friction factor $f$ for dry knitted mesh for Eq. (14-233). Values of York and Poppele [Chem. Eng. Prog., ***50,*** *421 (1954)*] are given in curve 1 for mesh crimped in the alternating direction and curve 2 for mesh crimped in the same direction. Data of Bradie and Dickson (*Joint Symp. Proc. Inst. Mech. Eng./Yorkshire Br. Inst. Chem. Eng., 1969, pp. 24–25*) are given in curve 3 for layered mesh and curve 4 for spiral-wound mesh. Curve 5 is data of Satsangee (M.S. thesis, Brooklyn Polytechnic Institute, 1948) and Schurig (D.Ch.E. dissertation, Brooklyn Polytechnic Institute, 1946). (*From Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

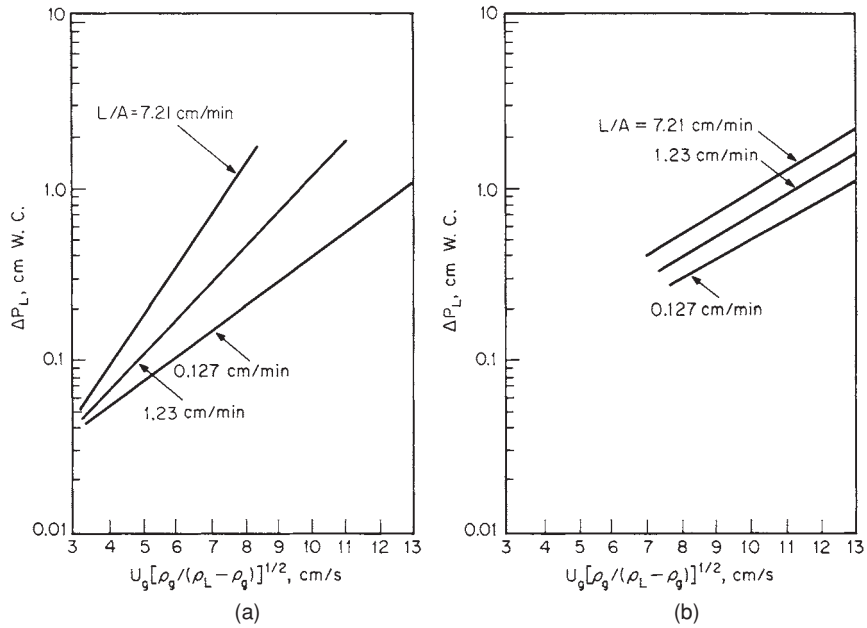

**FIG. 14-122** Incremental pressure drop in knitted mesh due to the presence of liquid (*a*) with the mesh crimps in the same direction and (*b*) with crimps in the alternating direction, based on the data of York and Poppele [Chem. Eng. Prog., ***50,*** 421 (*1954*)]. To convert centimeters per minute to feet per minute, multiply by 0.0328; to convert centimeters per second to feet per second, multiply by 0.0328. (*From Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

flood point. It results in droplet coalescence, and the second mesh, using standard wire and operated below flooding, catches entrainment from the first mesh. Coalescence and flooding in the first mesh may be assisted with water sprays or irrigation. Massey [*Chem. Eng. Prog.*, **53**(5), 114 (1959)] and Coykendall et al. [*J. Air Pollut. Control Assoc.*, **18,** 315 (1968)] have discussed such applications. Calvert (R-12) presents data on the particle size of entrained drops from mesh as a function of gas velocity which can be used for sizing the secondary collector. A major disadvantage of this approach is high pressure drop, which can be in the range from 25 cm (10 in) of water to as high as 85 cm (33 in) of water if the mist is mainly submicrometer.

***Wet Scrubbers*** Scrubbers have not been widely used for the collection of purely liquid particulate, probably because they are generally more complex and expensive than impaction devices of the types previously discussed. Further, scrubbers are no more efficient than the former devices for the same energy consumption. However, scrubbers of the types discussed in Sec. 17 and illustrated in Figs. 17-48 to 17-54 can be used to capture liquid particles efficiently. Their use is primarily indicated when it is desired to accomplish simultaneously another task such as gas absorption or the collection of solid and liquid particulate mixtures.

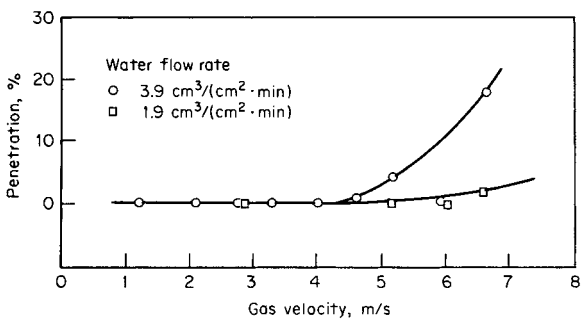

**FIG. 14-123** Experimental data of Calvert with air and water in mesh with vertical upflow, showing the effect of liquid loading on efficiency and reentrainment. To convert meters per second to feet per second, multiply by 3.281; to convert cubic centimeters per square centimeter-minute to cubic feet per square foot-minute, multiply by 0.0328. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

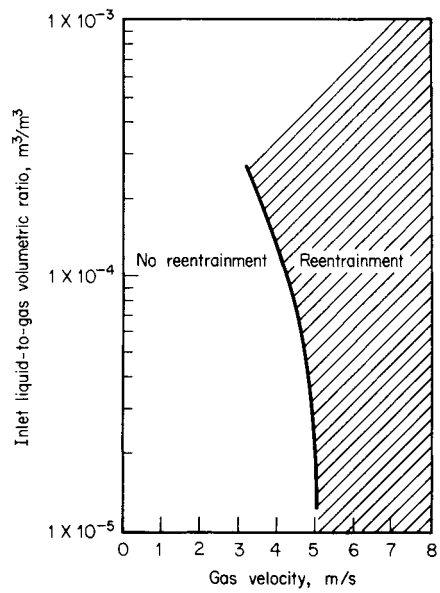

**FIG. 14-124** Effect of gas and liquid rates on onset of mesh reentrainment and safe operating regions. To convert meters per second to feet per second, multiply by 3.281. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

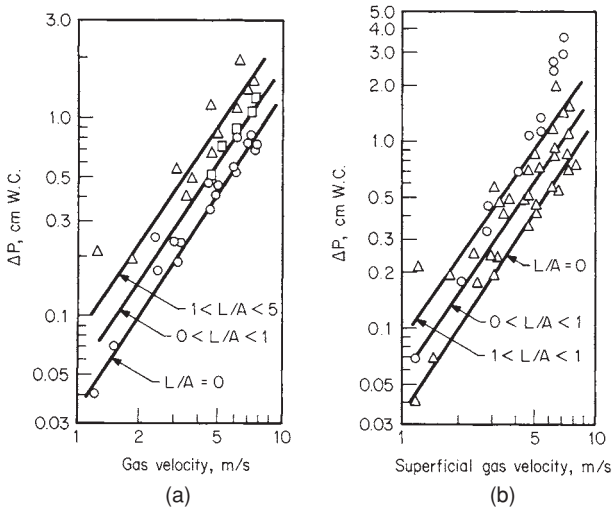

**FIG. 14-125** Experimental pressure measured by Calvert as a function of gas velocity and liquid loading for (*a*) horizontal gas flow through vertical mesh and (*b*) gas upflow through horizontal mesh. Mesh thickness was 10 cm with 2.8-mm wire and void fraction of 98.2 percent, crimped in alternating directions. To convert meters per second to feet per second, multiply by 3.281; to convert centimeters to inches, multiply by 0.394. (*Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*)

Table 20-41 [*Chemical Engineers' Handbook*, 5th ed.)], showing the minimum size of particles collectible in different types of scrubbers at reasonably high efficiencies, is a good selection guide. Cyclonic spray towers can effectively remove liquid particles down to around 2 to 3 μm. Figures 20-112 and 20-113 (*Chemical Engineers' Handbook*, 5th ed.), giving target efficiency between spray drop size and particle size as calculated by Stairmand or Johnstone and Roberts, should be considered in selecting spray atomization for the most efficient tower operation. Figure 14-126 gives calculated particle cut size as a function of tower height (or length) for vertical countercurrent spray towers and for horizontal-gas-flow, vertical-liquid-flow cross-current spray towers with parameters for liquid drop size. These curves are based on physical properties of standard air and water and should be used under conditions in which these are reasonable approximations. Lack of uniform liquid distribution or liquid flowing down the walls can affect the performance, requiring empirical correction factors. Calvert (R-10) suggests that a correction factor of 0.2 be used in small-diameter scrubbers to account for the liquid on the walls, i.e., let $Q_L/Q_g = 0.2\ (Q_L/Q_g)_{actual}$. Many more complicated wet scrubbers employ a combination of sprays or liquid atomization, cyclonic action, baffles, and targets. These combinations are not likely to be more efficient than similar devices previously discussed that operate at equivalent pressure drop. The vast majority of wet scrubbers operate at moderate pressure drop [8 to 15 cm (3 to 6 in) of water or 18 to 30 cm (7 to 12 in) of water] and cannot be expected to have high efficiency on particles smaller than 10 μm or 3 to 5 μm respectively. Fine and submicrometer particles can be captured efficiently only in wet scrubbers having high energy input such as venturi scrubbers, two-phase eductor scrubbers, and flux-force-condensation scrubbers.

***Venturi Scrubbers*** One type of venturi scrubber is illustrated in Fig. 17-48. Venturi scrubbers have been used extensively for collecting fine and submicrometer solid particulate, condensing tars and mists, and mixtures of liquids and solids. To a lesser extent, they have also been used for simultaneous gas absorption, although Lundy [*Ind. Eng. Chem.*, **50,** 293 (1958)] indicates that they are generally limited to three transfer units. They have been used to collect submicrometer chemical incinerator fume and mist as well as sulfuric and phosphoric acid mists. The collection efficiency of a venturi scrubber is highly dependent on the throat velocity or pressure drop, the liquid-to-gas ratio, and the chemical nature of wettability of the particulate. Throat velocities may range from 60 to 150 m/s (200 to 500 ft/s). Liquid injection rates are typically 0.67 to 1.4 $m^3/1000\ m^3$ of gas. A liquid rate of 1.0 $m^3$ per 1000 $m^3$ of gas is usually close to optimum, but liquid rates as high as 2.7 $m^3$ (95 $ft^3$) have been used. Efficiency improves with increased liquid rate but only at the expense of higher pressure drop and energy consumption. Pressure-drop predictions for a given efficiency are hazardous without determining the nature of the particulate and the liquid-to-gas ratio. In general, particles coarser than 1 μm can be collected efficiently with pressure drops of 25 to 50 cm of water. For appreciable collection of submicrometer particles, pressure drops of 75 to 100 cm (30 to 40 in) of water are usually required. When particles are appreciably finer than 0.5 μm, pressure drops of 175 to 250 cm (70 to 100 in) of water have been used.

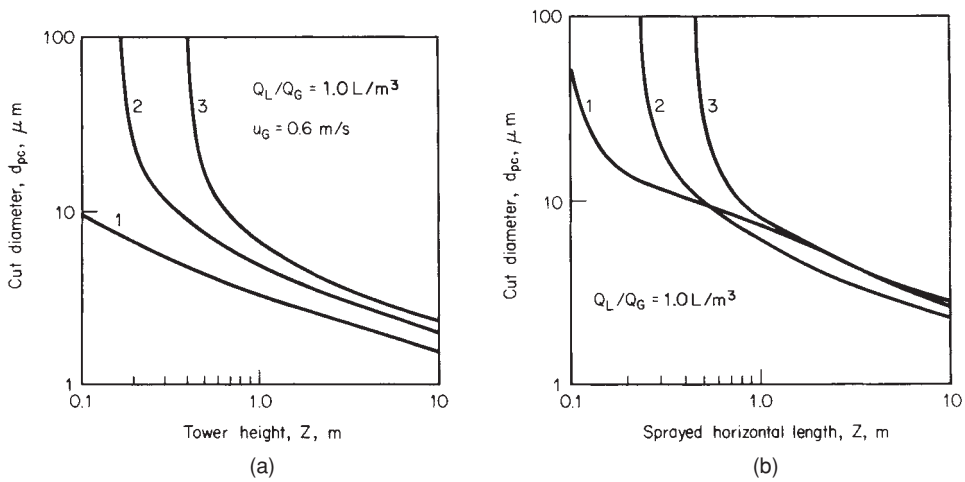

**FIG. 14-126** Predicted spray-tower cut diameter as a function of sprayed length and spray droplet size for (*a*) vertical-countercurrent towers and (*b*) horizontal-cross-flow towers per Calvert [J. Air Pollut. Control Assoc., ***24,*** 929 (*1974*)]. Curve 1 is for 200-μm spray droplets, curve 2 for 500-μm spray, and curve 3 for 1000-μm spray. $Q_L/Q_C$ is the volumetric liquid-to-gas ratio, $L$ liquid/$m^3$ gas, and $u_G$ is the superficial gas velocity in the tower. To convert liters per cubic meter to cubic feet per cubic foot, multiply by $10^{-3}$.

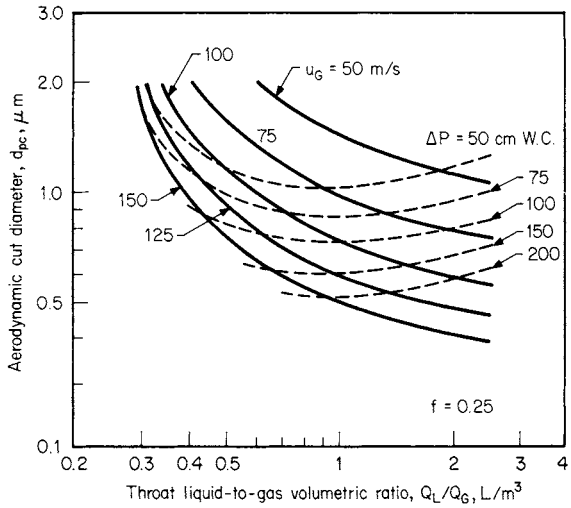

**FIG. 14-127** Prediction of venturi-scrubber cut diameter for hydrophobic particles as functions of operating parameters as measured by Calvert [*Calvert, Goldshmid, Leith, and Mehta, NTIS Publ. PB-213016, 213017, 1972; and Calvert,* J. Air Pollut. Control Assoc., **24,** 929 (*1974*).] $u_G$ is the superficial throat velocity, and $\Delta P$ is the pressure drop from converging to diverging section. To convert meters per second to feet per second, multiply by 3.281; to convert liters per cubic meter to cubic feet per cubic foot, multiply by $10^{-3}$; and to convert centimeters to inches, multiply by 0.394.

One of the problems in predicting efficiency and required pressure drop of a venturi is the chemical nature or wettability of the particulate, which on 0.5-μm-size particles can make up to a threefold difference in required pressure drop for its efficient collection. Calvert (R-9, R-10) has represented this effect by an empirical factor $f$, which is based on the hydrophobic ($f = 0.25$) or hydrophilic ($f = 0.50$) nature of the particles. Figure 14-127 gives the cut diameter of a venturi scrubber as a function of its operating parameters (throat velocity, pressure drop, and liquid-to-gas ratio) for hydrophobic particles. Figure 14-129 compares cut diameter as a function of pressure drop for an otherwise identically operating venturi on hydrophobic and hydrophilic particles. Calvert (R-9) gives equations which can be used for constructing cut-size curves similar to those of Fig. 14-127 for other values of the empirical factor $f$. Most real particles are neither completely hydrophobic nor completely hydrophilic but have $f$ values lying between the two extremes. Phosphoric acid mist, on the basis of data of Brink and Contant [*Ind. Eng. Chem.*, 50, 1157 (1958)] appears to have a value of $f = 0.46$. Unfortunately, no chemical-test methods have yet been devised for determining appropriate $f$ values for a particulate in the laboratory.

Pressure drop in a venturi scrubber is controlled by throat velocity. While some venturis have fixed throats, many are designed with variable louvers to change throat dimensions and control performance for changes in gas flow. Pressure-drop equations have been developed by Calvert (R-13, R-14, R-15), Boll [*Ind. Eng. Chem. Fundam.,* **12,** 40 (1973)], and Hesketh [*J. Air Pollut. Control Assoc.,* **24,** 939 (1974)]. Hollands and Goel [*Ind. Eng. Chem. Fundam.,* **14,** 16 (1975)] have developed a generalized pressure-drop equation.

The Hesketh equation is empirical and is based upon a regression analysis of data from a number of industrial venturi scrubbers:

$$\Delta P = U_{gt}^2 \rho_g A_t^{0.155} L^{0.78}/1270 \qquad (14\text{-}234)$$

where $\Delta P$ is the pressure drop, in of water; $U_{gt}$ is the gas velocity in the throat, ft/s; $\rho_g$ is the gas density, lb/ft$^3$; $A_t$ is the throat area, ft$^2$; and $L$ is the liquid-to-gas ratio, gal/1000 acf.

Calvert (R-15) critiqued the many pressure-drop equations and suggested the following simplified equation as accurate to ±10 percent:

$$\Delta P = \frac{2\rho_\ell U_g^2}{981 g_c}\left(\frac{Q_t}{Q_g}\right)[1 - x^2 + \sqrt{(x^4 - x^2)^{0.5}}] \qquad (14\text{-}235)$$

where

$$x = (3 l_t C_{Di}\rho_g/16 d_l \rho_l) + 1 \qquad (14\text{-}236)$$

$\Delta P$ is the pressure drop, cm of water; $\rho_\ell$ and $\rho_g$ are the density of the scrubbing liquid and gas respectively, g/cm$^3$; $U_g$ is the velocity of the gas at the throat inlet, cm/s; $Q_t/Q_g$ is the volumetric ratio of liquid to gas at the throat inlet, dimensionless; $l_t$ is the length of the throat, cm; $C_{Di}$ is the drag coefficient, dimensionless, for the mean liquid diameter, evaluated at the throat inlet; and $d_l$ is the Sauter mean diameter, cm, for the atomized liquid. The atomized-liquid mean diameter must be evaluated by the Nukiyama and Tanasawa [*Trans. Soc. Mech Eng.* (*Japan*), 4, 5, 6 (1937–1940)] equation:

$$d_\ell = \frac{0.0585}{U_g}\left(\frac{\sigma_\ell}{\rho_\ell}\right)^{0.5} + 0.0597\left[\frac{\mu_\ell}{(\sigma_\ell \rho_\ell)^{0.5}}\right]^{0.45}\left(\frac{Q_\ell}{Q_g}\right)^{1.5} \qquad (14\text{-}237)$$

where $\sigma_\ell$ is the liquid surface tension, dyn/cm; and $\mu_\ell$ is the liquid viscosity; P. The drag coefficient $C_{Di}$ should be evaluated by the Dickinson and Marshall [*Am. Inst. Chem. Eng. J.,* **14,** 541 (1968)] correlation $C_{Di} = 0.22 + (24/N_{Rei})(1 + 0.15\, N_{Rei}^{0.6})$. The Reynolds number, $N_{Rei}$, is evaluated at the throat inlet considerations as $d_\ell G_g/\mu_g$.

All venturi scrubbers must be followed by an entrainment collector for the liquid spray. These collectors are usually centrifugal and will have an additional pressure drop of several centimeters of water, which must be added to that of the venturi itself.

***Other Scrubbers*** A liquid-ejector venturi (Fig. 17-49), in which high-pressure water from a jet induces the flow of gas, has been used to collect mist particles in the 1- to 2-μm range, but submicrometer particles will generally pass through an eductor. Power costs for liquid pumping are high if appreciable motive force must be imparted to the gas because jet-pump efficiency is usually less than 10 percent. Harris [*Chem. Eng. Prog.,* **42**(4), 55 (1966)] has described their application. Two-phase eductors have been considerably more successful on capture of submicrometer mist particles and could be attractive in situations in which large quantities of waste thermal energy are available. However, the equivalent energy consumption is equal to that required for high-energy venturi scrubbers, and such devices are likely to be no more attractive than venturi scrubbers when the thermal energy is priced at its proper value. Sparks [*J. Air Pollut. Control Assoc.,* **24,** 958 (1974)] has discussed steam ejectors giving 99 percent collection of particles 0.3 to 10 μm. Energy requirements were 311,000 J/m$^3$(8.25 Btu/scf). Gardenier [*J. Air Pollut. Control Assoc.,* **24,** 954 (1974)] operated a liquid eductor with high-pressure (6900- to 27,600-kPa) (1000- to 4000-lbf/in$^2$) hot water heated to 200°C (392°F) which flashed into two phases as it issued from the jet. He obtained 95 to 99 percent collection of submicrometer particulate. Figure 14-128 shows the water-to-gas ratio required as a function of particle size to achieve 99 percent collection.

***Effect of Gas Saturation in Scrubbing*** If hot unsaturated gas is introduced into a wet scrubber, spray particles will evaporate to cool and saturate the gas. The evaporating liquid molecules moving away from the target droplets will repel particles which might collide with them. This results in the forces of diffusiophoresis opposing particle collection. Semrau and Witham (Air Pollut. Control Assoc. Prepr. 75-30.1) investigated temperature parameters in wet scrubbing and found a definite decrease in the efficiency of evaporative scrubbers and an enhancement of efficiency when a hot saturated gas is scrubbed with cold water rather than recirculated hot water. Little improvement was experienced in cooling a hot saturated gas below a 50°C dew point.

**Energy Requirements for Inertial-Impaction Efficiency** Semrau [*J. Air Pollut. Control Assoc.,* **13,** 587 (1963)] proposed a "contacting-power" principle which states that the collecting efficiency of a given size of particle is proportional to the power expended and that the smaller the particle, the greater the power required.

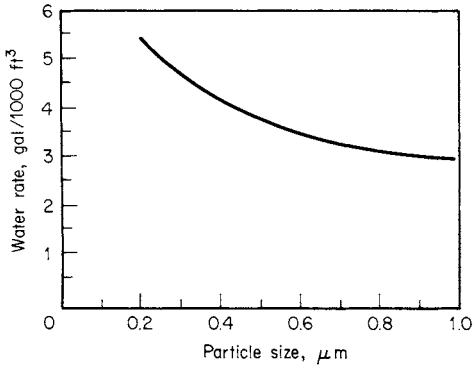

**FIG. 14-128** Superheated high-pressure hot-water requirements for 99 percent collection as a function of particle size in a two-phase eductor jet scrubber. To convert gallons per 1000 cubic feet to cubic meters per 1000 cubic meters, multiply by 0.134. [*Gardenier,* J. Air Pollut. Control Assoc., ***24,*** *954 (1974).*]

Mathematically expressed, $N_T = \propto P_T^{\gamma}$, where $N_T$ is the number of particulate transfer units achieved and $P_T$ is the total energy expended within the collection device, including gas and liquid pressure drop and thermal and mechanical energy added in atomizers. $N_T$ is further defined as $N_T = \ln [1/(1 - \eta)]$, where $\eta$ is the overall fractional collection efficiency. This was intended as a universal principle, but the constants $\propto$ and $\gamma$ have been found to be functions of the chemical nature of the system and the design of the control device. Others have pointed out that the principle is applicable only when the primary collection mechanism is impaction and direct interception. Calvert (R-10, R-12) has found that plotting particle cut size versus pressure drop (or power expended) as in Fig. 14-129 is a more suitable way to develop a generalized energy-requirement curve for impaction

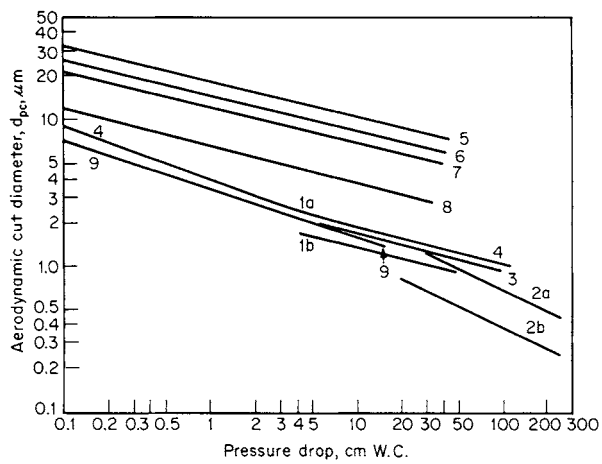

**FIG. 14-129** Typical cut diameter as a function of pressure drop for various liquid-particle collectors. Curves 1*a* and *b* are single-sieve plates with froth density of 0.4 g/cm$^3$; 1*a* has sieve holes of 0.5 cm and 1*b* holes of 0.3 cm. Curves 2*a* and *b* are for a venturi scrubber with hydrophobic particles (2*a*) and hydrophilic particles (2*b*). Curve 3 is an impingement plate, and curve 4 is a packed column with 2.5-cm-diameter packing. Curve 5 is a zigzag baffle collector with six baffles at $\theta = 30°$. Curve 7 is for six rows of staggered tubes with 1-cm spacing between adjacent tube walls in a row. Curve 8 is similar, except that tube-wall spacing in the row is 0.3 cm. Curve 9 is for wire-mesh pads. To convert grams per cubic centimeter to pounds per cubic foot, multiply by 62.43; to convert centimeters to inches, multiply by 0.394. [*Calvert,* J. Air Pollut. Control Assoc., ***24,*** *929 (1974); and Calvert, Yung, and Leung, NTIS Publ. PB-248050, 1975.*]

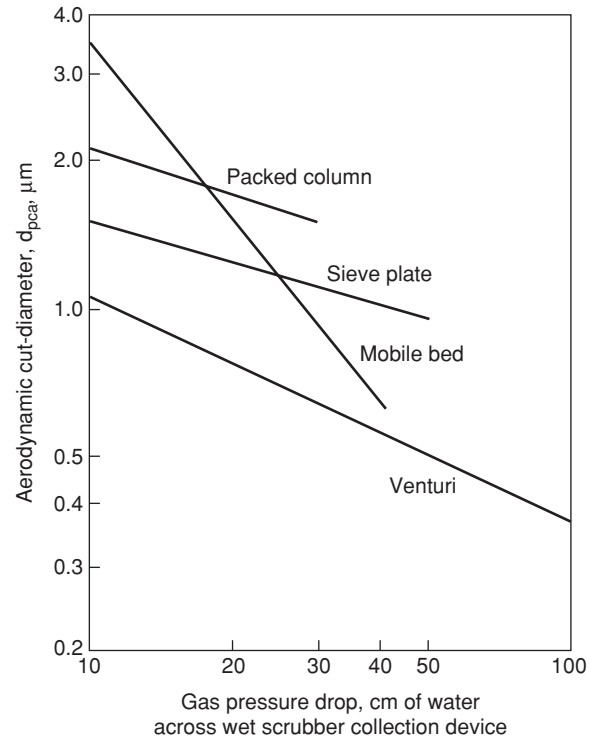

**FIG. 14-130** Calvert's refined particle cut-size/power relationship for particle inertial impaction wet collectors. Ref. (R-19) by permission.

devices. The various curves fall close together and outline an imaginary curve that indicates the magnitude of pressure drop required as particle size decreases bound by the two limits of hydrophilic and hydrophobic particles. By calculating the required cut size for a given collection efficiency, Fig. 14-129 can also be used as a guide to deciding between different collection devices.

Subsequently, Calvert (R-19, p. 228) has combined mathematical modeling with performance tests on a variety of industrial scrubbers and has obtained a refinement of the power-input/cut-size relationship as shown in Fig. 14-130. He considers these relationships sufficiently reliable to use this data as a tool for selection of scrubber type and performance prediction. The power input for this figure is based solely on gas pressure drop across the device.

**Collection of Fine Mists** Inertial-impaction devices previously discussed give high efficiency on particles above 5 μm in size and often reasonable efficiency on particles down to 3 μm in size at moderate pressure drops. However, this mechanism becomes ineffective for particles smaller than 3 μm because of the particle gaslike mobility. Only impaction devices having extremely high energy input such as venturi scrubbers and a flooded mesh pad (the pad interstices really become miniature venturi scrubbers in parallel and in series) can give high collection efficiency on fine particles, defined as 2.5 or 3 μm and smaller, including the submicrometer range. Fine particles are subjected to brownian motion in gases, and diffusional deposition can be employed for their collection. Diffusional deposition becomes highly efficient as particles become smaller, especially below 0.2 to 0.3 μm. Table 14-28 shows typical displacement velocity of particles. Randomly oriented fiber beds having tortuous and narrow gas passages are suitable devices for utilizing this collection mechanism. (The diffusional collection mechanism is discussed in Sec. 17 under "Mechanisms of Dust Collection.") Other collection mechanisms which are efficient for fine particles are electrostatic forces and flux forces such as thermophoresis and diffusiophoresis. Particle growth and nucleation methods are also applicable. Efficient collection of fine particles

**TABLE 14-28 Brownian Movement of Particles***

| Particle diameter, μm | Brownian displacement of particle, μm/s |
|---|---|
| 0.1 | 29.4 |
| 0.25 | 14.2 |
| 0.5 | 8.92 |
| 1.0 | 5.91 |
| 2.5 | 3.58 |
| 5.0 | 2.49 |
| 10.0 | 1.75 |

*Brink, *Can. J. Chem. Eng.*, **41,** 134 (1963). Based on spherical water particles in air at 21°C and 1 atm.

is important because particles in the range of 2.0 to around 0.2 μm are the ones which penetrate and are deposited in the lung most efficiently. Hence, particles in this range constitute the largest health hazard.

**Fiber Mist Eliminators** These devices are produced in various configurations. Generally, randomly oriented glass or polypropylene fibers are densely packed between reinforcing screens, producing fiber beds varying in thickness usually from 25 to 75 mm (1 to 3 in), although thicker beds can be produced. Units with efficiencies as high as 99.9 percent on fine particles have been developed (see *Chemical Engineers' Handbook,* 5th ed., p. 18–88). A combination of mechanisms interacts to provide high overall collection efficiency. Particles larger than 2 to 3 μm are collected on the fibers by inertial impaction and direct interception, while small particles are collected by brownian diffusion. When the device is designed to use this latter mechanism as the primary means, efficiency turndown problems are eliminated as collection efficiency by diffusion increases with residence time. Pressure drop through the beds increases with velocity to the first power since the gas flow is laminar. This leads to design capability trade-offs. As pressure drop is reduced and energy is conserved, capital increases because more filtering area is required for the same efficiency.

Three series of fiber mist eliminators are typically available. A spray-catcher series is designed primarily for essentially 100 percent capture of droplets larger than 3 μm. The high-velocity type is designed to give moderately high efficiency on particles down to 1.0 μm as well. Both of these types are usually produced in the form of flat panels of 25- to 50-mm (1- to 2-in) thickness. The high-efficiency type is illustrated in Fig. 14-131. As mist particles are collected, they coalesce into a liquid film which wets the fibers. Liquid is moved horizontally through the bed by the gas drag force and downward by gravity. It drains down the downstream retaining screen to the bottom of the element and is returned to the process through a liquid seal. Table 14-29 gives typical operating characteristics of the three types of collectors. The application of these devices to sulfuric acid plants and other process gases has been discussed by Brink (see *Chemical Engineers' Handbook,* 5th ed., pp. 18–89, 18–90).

Solid particulates are captured as readily as liquids in fiber beds but can rapidly plug the bed if they are insoluble. Fiber beds have frequently been used for mixtures of liquids and soluble solids and with soluble solids in condensing situations. Sufficient solvent (usually water) is atomized into the gas stream entering the collector to irrigate the fiber elements and dissolve the collected particulate. Such fiber beds have been used to collect fine fumes such as ammonium nitrate and ammonium chloride smokes, and oil mists from compressed air.

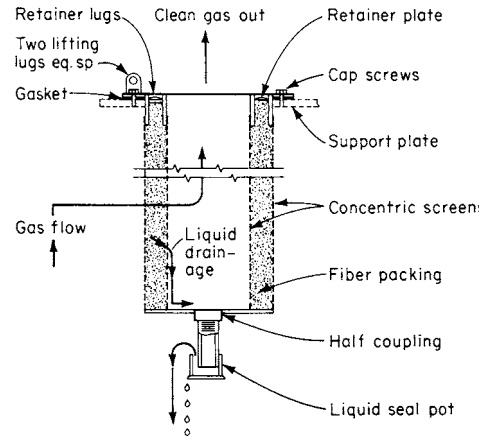

**FIG. 14-131** Monsanto high-efficiency fiber-mist-eliminator element. (*Monsanto Company.*)

**Electrostatic Precipitators** The principles and operation of electrical precipitators are discussed in Sec. 17 under "Gas-Solids Separations." Precipitators are admirably suited to the collection of fine mists and mixtures of mists and solid particulates. Tube-type precipitators have been used for many years for the collection of acid mists and the removal of tar from coke-oven gas. The first practical installation of a precipitator by Cottrell was made on sulfuric acid mist in 1907. Most older installations of precipitators were tube-type rather than plate-type. However, recently two plate-type wet precipitators employing water sprays or overflowing weirs have been introduced by Mikropul Corporation [Bakke, *J. Air Pollut. Control Assoc.,* **25,** 163 (1975)] and by Fluid Ionics. Such precipitators operate on the principle of making all particles conductive when possible, which increases the particle migration velocity and collection efficiency. Under these conditions, particle dielectric strength becomes a much more important variable, and particles with a low dielectric constant such as condensed hydrocarbon mists become much more difficult to collect than water-wettable particles. Bakke (U.S.–U.S.S.R. Joint Work. Group Symp.: Fine Particle Control, San Francisco, 1974) has developed equations for particle charge and relative collection efficiency in wet precipitators that show the effect of dielectric constant. Wet precipitators can also be used to absorb soluble gases simultaneously by adjusting the pH or the chemical composition of the liquid spray. The presence of the electric field appears to enhance absorption. Wet precipitators have found their greatest usefulness to date in handling mixtures of gaseous pollutants and submicrometer particulate (either liquid or solid, or both) such as fumes from aluminum-pot lines, carbon anode baking, fiberglass-fume control, coke-oven and metallurgical operations, chemical incineration, and phosphate-fertilizer operations. Two-stage precipitators are used increasingly for moderate-volume gas streams containing nonconductive liquid mists which will drain from the collecting plates. Their application on hydrocarbon mists has been quite successful, but careful attention must be given to fire and explosion hazards.

**Electrically Augmented Collectors** A new area for enhancing collection efficiency and lowering cost is the combining of electrostatic forces with devices using other collecting mechanisms such as

**TABLE 14-29 Operating Characteristics of Various Types of Fiber Mist Eliminators as Used on Sulfuric Acid Plants***

| | High efficiency | High velocity | Spray catcher |
|---|---|---|---|
| Controlling mechanism for mist collection | Brownian movement | Impaction | Impaction |
| Superficial velocity, m/s | 0.075–0.20 | 2.0–2.5 | 2.0–2.5 |
| Efficiency on particles greater than 3 μm, % | Essentially 100 | Essentially 100 | Essentially 100 |
| Efficiency on particles 3 μm and smaller, % | 95–99+ | 90–98 | 15–30 |
| Pressure drop, cm $H_2O$ | 12–38 | 15–20 | 1.0–2.5 |

impaction and diffusion. Cooper (Air Pollut. Control Assoc. Prepr. 75-02.1) evaluated the magnitude of forces operating between charged and uncharged particles and concluded that electrostatic attraction is the strongest collecting force operating on particles finer than 2 μm. Nielsen and Hill [*Ind. Eng. Chem. Fundam.,* **15,** 149 (1976)] have quantified these relationships, and a number of practical devices have been demonstrated. Pilat and Meyer (NTIS Publ. PB-252653, 1976) have demonstrated up to 99 percent collection of fine particles in a two-stage spray tower in which the inlet particles and water spray are charged with opposite polarity. The principle has been applied to retrofitting existing spray towers to enhance collection.

Klugman and Sheppard (Air Pollut. Control Assoc. Prepr. 75-30.3) have developed an ionizing wet scrubber in which the charged mist particles are collected in a grounded, irrigated cross-flow bed of Tellerette packing. Particles smaller than 1 μm have been collected with 98 percent efficiency by using two units in series. Dembinsky and Vicard (Air Pollut. Control Assoc. Prepr. 78-17.6) have used an electrically augmented low-pressure [5 to 10 cm (2 to 4 in) of water] venturi scrubber to give 95 to 98 percent collection efficiency on submicrometer particles.

**Particle Growth and Nucleation** Fine particles may be subjected to conditions favoring the growth of particles either through condensation or through coalescence. Saturation of a hot gas stream with water, followed by condensation on the particles acting as nuclei when the gas is cooled, can increase particle size and ease of collection. Addition of steam can produce the same results. Scrubbing of the humid gas with a cold liquid can bring diffusiophoresis into play. The introduction of cold liquid drops causes a reduction in water-vapor pressure at the surface of the cold drop. The resulting vapor-pressure gradient causes a hydrodynamic flow toward the drop known as Stefan flow which enhances the movement of mist particles toward the spray drop. If the molecular mass of the diffusing vapor is different from the carrier gas, this density difference also produces a driving force, and the sum of these forces is known as diffusiophoresis. A mathematical description of these forces has been presented by Calvert (R-9) and by Sparks and Pilat [*Atmos. Environ.,* **4,** 651 (1970)]. Thermal differences between the carrier gas and the cold scrubbing droplets can further enhance collection through thermophoresis. Calvert and Jhaseri [*J. Air Pollut. Control Assoc.,* **24,** 946 (1974)]; and NTIS Publ. PB-227307, 1973)] have investigated condensation scrubbing in multiple-sieve plate towers.

Submicrometer droplets can be coagulated through brownian diffusion if given ample time. The introduction of particles 50 to 100 times larger in diameter can enhance coagulation, but the addition of a broad range of particle sizes is discouraged. Increasing turbulence will aid coagulation, so fans to stir the gas or narrow, tortuous passages such as those of a packed bed can be beneficial. Sonic energy can also produce coagulation, especially the production of standing waves in the confines of long, narrow tubes. Addition of water and oil mists can sometimes aid sonic coagulation. Sulfuric acid mist [Danser, *Chem. Eng.,* 57(5), 158 (1950)] and carbon black [Stokes, *Chem. Eng. Prog.,* **46,** 423 (1950)] have been successfully agglomerated with sonic energy. Frequently sonic agglomeration has been unsuccessful because of the high energy requirement. Most sonic generators have very poor energy-transformation efficiency. Wegrzyn et al. (U.S. EPA Publ. EPA-600/7-79-004C, 1979, p. 233) have reviewed acoustic agglomerators. Mednikov (U.S.S.R. Akad. Soc. Moscow, 1963) suggested that the incorporation of sonic agglomeration with electrostatic precipitation could greatly reduce precipitator size.

**Other Collectors** Tarry particulates and other difficult-to-handle liquids have been collected on a dry, expendable phenol formaldehyde-bonded glass-fiber mat (Goldfield, *J. Air Pollut. Control Assoc.,* **20,** 466 (1970)] in roll form which is advanced intermittently into a filter frame. Superficial gas velocities are 2.5 to 3.5 m/s (8.2 to 11.5 ft/s), and pressure drop is typically 41 to 46 cm (16 to 18 in) of water. Collection efficiencies of 99 percent have been obtained on submicrometer particles. Brady [*Chem. Eng. Prog.,* **73**(8), 45 (1977)] has discussed a cleanable modification of this approach in which the gas is passed through a reticulated foam filter that is slowly rotated and solvent-cleaned.

In collecting very fine (mainly submicron) mists of a hazardous nature where one of the collectors previously discussed has been used as the primary one (fiber-mist eliminators of the Brownian diffusion type and electrically augmented collectors are primarily recommended), there is the chance that the effluent concentration may still be too high for atmospheric release when residual concentration must be in the range of 1–2 μm. In such situations, secondary treatment may be needed. Probably removal of the residual mist by adsorption will be in order. See "Adsorption," Sec. 16. Another possibility might be treatment of the remaining gas by membrane separation. A separator having a gas-permeable membrane that is essentially nonliquid-permeable could be useful. However, if the gas-flow volumes are appreciable, the device could be expensive. Most membranes have low capacity (requiring high membrane surface area) to handle high gas-permeation capacity. See "Membrane Separation Processes," Sec. 20.

**Continuous Phase Uncertain** Some situations exist such as in two-phase gas-liquid flow where the volume of the liquid phase may approach being equal to the volume of the vapor phase, and where it may be difficult to be sure which phase is the continuous phase. Svrcek and Monnery [*Chem. Eng. Prog.,* **89**(10), 53–60 (Oct. 1993)] have discussed the design of two-phase separation in a tank with gas-liquid separation in the middle, mist elimination in the top, and entrained gas-bubble removal from the liquid in the bottom. Monnery and Svrcek [*Chem. Eng. Prog.,* **90**(9), 29–40 (Sept. 1994)] have expanded the separation to include multiphase flow, where the components are a vapor and two immiscible liquids and these are also separated in a tank. A design approach for sizing the gas-liquid disengaging space in the vessel is given using a tangential tank inlet nozzle, followed by a wire mesh mist eliminator in the top of the vessel for final separation of entrained mist from the vapor. Design approaches and equations are also given for sizing the lower portion of the vessel for separation of the two immiscible liquid phases by settling and separation of discontinuous liquid droplets from the continuous liquid phase.

## LIQUID-PHASE CONTINUOUS SYSTEMS

Practical separation techniques for gases dispersed in liquids are discussed. Processes and methods for dispersing gas in liquid have been discussed earlier in this section, together with information for predicting the bubble size produced. Gas-in-liquid dispersions are also produced in chemical reactions and electrochemical cells in which a gas is liberated. Such dispersions are likely to be much finer than those produced by the dispersion of a gas. Dispersions may also be unintentionally created in the vaporization of a liquid.

**Types of Gas-in-Liquid Dispersions** Two types of dispersions exist. In one, gas bubbles produce an unstable dispersion which separates readily under the influence of gravity once the mixture has been removed from the influence of the dispersing force. Gas-liquid contacting means such as bubble towers and gas-dispersing agitators are typical examples of equipment producing such dispersions. More difficulties may result in separation when the gas is dispersed in the form of bubbles only a few micrometers in size. An example is the evolution of gas from a liquid in which it has been dissolved or released through chemical reaction such as electrolysis. Coalescence of the dispersed phase can be helpful in such circumstances.

The second type is a stable dispersion, or foam. Separation can be extremely difficult in some cases. A pure two-component system of gas and liquid cannot produce dispersions of the second type. Stable foams can be produced only when an additional substance is adsorbed

**TABLE 14-30 Terminal Velocity of Standard Air Bubbles Rising in Water at 20°C***

at the liquid-surface interface. The substance adsorbed may be in true solution but with a chemical tendency to concentrate in the interface such as that of a surface-active agent, or it may be a finely divided solid which concentrates in the interface because it is only poorly wetted by the liquid. Surfactants and proteins are examples of soluble materials, while dust particles and extraneous dirt including traces of nonmiscible liquids can be examples of poorly wetted materials.

Separation of gases and liquids always involves coalescence, but enhancement of the rate of coalescence may be required only in difficult separations.

**Separation of Unstable Systems** The buoyancy of bubbles suspended in liquid can frequently be depended upon to cause the bubbles to rise to the surface and separate. This is a special case of gravity settling. The mixture is allowed to stand at rest or is moved along a flow path in laminar flow until the bubbles have surfaced. Table 14-30 shows the calculated rate of rise of air bubbles at atmospheric pressure in water at 20°C (68°F) as a function of diameter. It will be observed that the velocity of rise for 10-μm bubbles is very low, so that long separating times would be required for gas which is more finely dispersed.

For liquids other than water, the rise velocity can be approximated from Table 14-30 by multiplying by the liquid's specific gravity and the reciprocal of its viscosity (in centipoises). For bubbles larger than 100 μm, this procedure is erroneous, but the error is less than 15 percent for bubbles up to 1000 μm. More serious is the underlying assumption of Table 14-30 that the bubbles are rigid spheres. Circulation within the bubble causes notable increases in velocity in the range of 100 μm to 1 mm, and the flattening of bubbles 1 cm and larger appreciably decreases their velocity. However, in this latter size range the velocity is so high as to make separation a trivial problem.

In design of separating chambers, static vessels or continuous-flow tanks may be used. Care must be taken to protect the flow from turbulence, which could cause back mixing of partially separated fluids or which could carry unseparated liquids rapidly to the separated-liquid outlet. Vertical baffles to protect rising bubbles from flow currents are sometimes employed. Unseparated fluids should be distributed to the separating region as uniformly and with as little velocity as possible. When the bubble rise velocity is quite low, shallow tanks or flow channels should be used to minimize the residence time required.

Quite low velocity rise of bubbles due either to small bubble size or to high liquid viscosity can cause difficult situations. With low-viscosity liquids, separation-enhancing possibilities in addition to those previously enumerated are to sparge the liquid with large-diameter gas bubbles or to atomize the mixture as a spray into a tower. Large gas bubbles rising rapidly through the liquid collide with small bubbles and aid their coalescence through capture. Atomizing of the continuous phase reduces the distance that small gas bubbles must travel to reach a gas interface. Evacuation of the spray space can also be beneficial in promoting small-bubble growth and especially in promoting gas evolution when the gas has appreciable liquid solubility. Liquid heating will also reduce solubility.

Surfaces in the settling zone for bubble coalescence such as closely spaced vertical or inclined plates or tubes are beneficial. When clean low-viscosity fluids are involved, passage of the undegassed liquid through a tightly packed pad of mesh or fine fibers at low velocity will result in efficient bubble coalescence. Problems have been experienced in degassing a water-based organic solution that has been passed through an electrolytic cell for chemical reaction in which extremely fine bubbles of hydrogen gas are produced in the liquid within the cell. Near-total removal of hydrogen gas from the liquid is needed for process safety. This is extremely difficult to achieve by gravity settling alone because of the fine bubble size and the need for a coalescing surface. Utilization of a fine fiber media is strongly recommended in such situations. A low-forward liquid flow through the media is desireable to provide time for the bubbles to attach themselves to the fiber media through Brownian diffusion. Spielman and Goren [*Ind. Eng. Chem.,* **62**(10), (1970)] reviewed the literature on coalescence with porous media and reported their own experimental results [*Ind. Eng. Chem. Fundam.,* **11**(1), 73 (1972)] on the coalescence of oil-water liquid emulsions. The principles are applicable to a gas-in-liquid system. Glass-fiber mats composed of 3.5-, 6-, or 12-μm diameter fibers, varying in thickness from 1.3 to 3.3 mm, successfully coalesced and separated 1- to 7-μm oil droplets at superficial bed velocities of 0.02 to 1.5 cm/s (0.00067 to 0.049 ft/s).

In the deaeration of high-viscosity fluids such as polymers, the material is flowed in thin sheets along solid surfaces. Vacuum is applied to increase bubble size and hasten separation. The Versator (Cornell Machine Co.) degasses viscous liquids by spreading them into a thin film by centrifugal action as the liquids flow through an evacuated rotating bowl.

**Separation of Foam** Foam is a colloidal system containing relatively large volumes of dispersed gas in a relatively small volume of liquid. Foams are thermodynamically unstable with respect to separation into their components of gas and vapor, and appreciable surface energy is released in the bursting of foam bubbles. Foams are dynamic systems in which a third component produces a surface layer that is different in composition from the bulk of the liquid phase. The stabilizing effect of such components (often present only in trace amounts) can produce foams of troubling persistence in many operations. (Foams which have lasted for years when left undisturbed have been produced.) Bendure [TAPPI, 58(2), 83 (1975)], Keszthelyi [*J. Paint Technol.,* **46**(11), 31 (1974)], Ahmad [*Sep. Sci.* **10,** 649 (1975)], and Shedlovsky ("Foams," *Encyclopedia of Chemical Technology,* 2d ed., Wiley, New York, 1966) have presented concise articles on the characteristics and properties of foams in addition to the general references cited at the beginning of this subsection.

Foams can be a severe problem in chemical-processing steps involving gas-liquid interaction such as distillation, absorption, evaporation, chemical reaction, and particle separation and settling. It can also be a major problem in pulp and paper manufacture, oil-well drilling fluids, production of water-based paints, utilization of lubricants and hydraulic fluids, dyeing and sizing of textiles, operation of steam boilers, fermentation operations, polymerization, wet-process phosphoric acid concentration, adhesive production, and foam control in products such as detergents, waxes, printing inks, instant coffee, and glycol antifreeze.

Foams, as freshly generated, are gas emulsions with spherical bubbles separated by liquid films up to a few millimeters in thickness. They age rapidly by liquid drainage and form polyhedrals in which three bubbles intersect at corners with angles of approximately 120°. During drainage, the lamellae become increasingly thinner, especially in the center (only a few micrometers thickness), and more brittle. This feature indicates that with some foams if a foam layer can be tolerated, it may be self-limiting, as fresh foam is added to the bottom of the layer with drained foam collapsing on the top. (A quick-breaking foam may reach its maximum life cycle in 6 s. A moderately stable foam can persist for 140 s.) During drainage, gas from small foam bubbles, which is at a high pressure, will diffuse into large bubbles so that foam micelles increase with time. As drainage proceeds, weak areas in the lamella may develop. However, the presence of a higher concentration of surfactants in the surface produces a lower surface tension. As the lamella starts to fail, exposing bulk liquid with higher surface tension, the surface is renewed and healed. This is known as the *Marangoni effect.* If drainage can occur faster than Marangoni healing, a hole may develop in the lamella. The forces involved are such that collapse will occur in milliseconds without concern for rupture propagation. However, in very stable foams, electrostatic surface forces (zeta potential) prevent complete drainage and collapse. In

some cases, stable lamella thicknesses of only two molecules have been measured.

Drainage rate is influenced by surface viscosity, which is very temperature-sensitive. At a critical temperature, which is a function of the system, a temperature change of only a few degrees can change a slow-draining foam to a fast-draining foam. This change in drainage rate can be a factor of 100 or more; thus increasing the temperature of foam can cause its destruction. An increase in temperature may also cause liquid evaporation and lamella thinning. As the lamellae become thinner, they become more brittle and fragile. Thus, mechanical deformation or pressure changes, which cause a change in gas-bubble volume, can also cause rupture.

Bendure indicates 10 ways to increase foam stability: (1) increase bulk liquid viscosity, (2) increase surface viscosity, (3) maintain thick walls (higher liquid-to-gas ratio), (4) reduce liquid surface tension, (5) increase surface elasticity, (6) increase surface concentration, (7) reduce surfactant-adsorption rate, (8) prevent liquid evaporation, (9) avoid mechanical stresses, and (10) eliminate foam inhibitors. Obviously, the reverse of each of these actions, when possible, is a way to control and break foam.

**Physical Defoaming Techniques** Typical physical defoaming techniques include mechanical methods for producing foam stress, thermal methods involving heating or cooling, and electrical methods. Combinations of these methods may also be employed, or they may be used in conjunction with chemical defoamers. Some methods are only moderately successful when conditions are present to reform the foam such as breaking foam on the surface of boiling liquids. In some cases it may be desirable to draw the foam off and treat it separately. Foam can always be stopped by removing the energy source creating it, but this is often impractical.

***Thermal Methods*** Heating is often a suitable means of destroying foam. As indicated previously, raising the foam above a critical temperature (which must be determined experimentally) can greatly decrease the surface viscosity of the film and change the foam from a slow-draining to a fast-draining foam. Coupling such heating with a mechanical force such as a revolving paddle to cause foam deformation is frequently successful. Other effects of heating are expansion of the gas in the foam bubbles, which increases strain on the lamella walls as well as requiring their movement and flexing. Evaporation of solvent may occur causing thinning of the walls. At sufficiently high temperatures, desorption or decomposition of stabilizing substances may occur. Placing a high-temperature bank of steam coils at the maximum foam level is one control method. As the foam approaches or touches the coil, it collapses. The designer should consider the fact that the coil will frequently become coated with solute.

Application of radiant heat to a foam surface is also practiced. Depending on the situation, the radiant source may be electric lamps, Glowbar units, or gas-fired radiant burners. Hot gases from burners will enhance film drying of the foam. Heat may also be applied by jetting or spraying hot water on the foam. This is a combination of methods since the jetting produces mechanical shear, and the water itself provides dilution and change in foam-film composition. Newer approaches might include foam heating with the application of focused microwaves. This could be coupled with continuous or intermittent pressure fluctuations to stress lamella walls as the foam ages.

Cooling can also destroy foam if it is carried to the point of freezing since the formation of solvent crystals destroys the foam structure. Less drastic cooling such as spraying a hot foam with cold water may be effective. Cooling will reduce the gas pressure in the foam bubbles and may cause them to shrink. This is coupled with the effects of shear and dilution mentioned earlier. In general, moderate cooling will be less effective than heating since the surface viscosity is being modified in the direction of a more stable foam.

***Mechanical Methods*** Static or rotating breaker bars or slowly revolving paddles are sometimes successful. Their application in conjunction with other methods is frequently better. As indicated in the theory of foams, they will work better if installed at a level at which the foam has had some time to age and drain. A rotating breaker works by deforming the foam, which causes rupture of the lamella walls. Rapidly moving slingers will throw the foam against the vessel wall and may cause impact on other foam outside the envelope of the slinger. In some instances, stationary bars or closely spaced plates will limit the rise of foam. The action here is primarily one of providing surface for coalescence of the foam. Wettability of the surface, whether moving or stationary, is frequently important. Usually a surface not wetted by the liquid is superior, just as is frequently the case of porous media for foam coalescence. However, in both cases there are exceptions for which wettable surfaces are preferred. Shkodin [*Kolloidn. Zh.*, **14,** 213 (1952)] found molasses foam to be destroyed by contact with a wax-coated rod and unaffected by a clean glass rod.

Goldberg and Rubin [*Ind. Eng. Chem. Process Des. Dev.*, **6** 195 (1967)] showed in tests with a disk spinning vertically to the foam layer that most mechanical procedures, whether centrifugation, mixing, or blowing through nozzles, consist basically of the application of shear stress. Subjecting foam to an air-jet impact can also provide a source of drying and evaporation from the film, especially if the air is heated. Other effective means of destroying bubbles are to lower a frame of metal points periodically into the foam or to shower the foam with falling solid particles.

***Pressure and Acoustic Vibrations*** These methods for rupturing foam are really special forms of mechanical treatment. Change in pressure in the vessel containing the foam stresses the lamella walls by expanding or contracting the gas inside the foam bubbles. Oscillation of the vessel pressure subjects the foam to repeated film flexing. Parlow [*Zucker,* 3, 468 (1950)] controlled foam in sugar-sirup evaporators with high-frequency air pulses. It is by no means certain that high-frequency pulsing is necessary in all cases. Lower frequency and higher amplitude could be equally beneficial. Acoustic vibration is a similar phenomenon causing localized pressure oscillation by using sound waves. Impulses at 6 kHz have been found to break froth from coal flotation [Sun, *Min. Eng.*, **3,** 865 (1958)]. Sonntag and Strenge (*Coagulation and Stability of Disperse Systems,* Halsted-Wiley, New York, 1972, p. 121) report foam suppression with high-intensity sound waves (11 kHz, 150 dB) but indicate that the procedure is too expensive for large-scale application. The Sontrifuge (Teknika Inc., a subsidiary of Chemineer, Inc.) is a commercially available low-speed centrifuge employing sonic energy to break the foam. Walsh [*Chem. Process.*, **29,** 91 (1966)], Carlson [*Pap. Trade J.*, **151,** 38 (1967)], and Thorhildsen and Rich [*TAPPI,* **49,** 95A (1966)] have described the unit.

***Electrical Methods*** As colloids, most foams typically have electrical double layers of charged ions which contribute to foam stability. Accordingly, foams can be broken by the influence of an external electric field. While few commercial applications have been developed, Sonntag and Strenge (op. cit., p. 114) indicate that foams can be broken by passage through devices much like electrostatic precipitators for dusts. Devices similar to two-stage precipitators having closely spaced plates of opposite polarity should be especially useful. Sonntag and Strenge, in experiments with liquid-liquid emulsions, indicate that the colloid structure can be broken at a field strength of the order of 8 to $9 \times 10^5$ V/cm.

**Chemical Defoaming Techniques** Sonntag and Strenge (op. cit., p. 111) indicate two chemical methods for foam breaking. One method is causing the stabilizing substances to be desorbed from the interface, such as by displacement with other more surface-active but nonstabilizing compounds. Heat may also cause desorption. The second method is to carry on chemical changes in the adsorption layer, leading to a new structure. Some defoamers may act purely by mechanical means but will be discussed in this subsection since their action is generally considered to be chemical in nature. Often chemical defoamers act in more than one way.

***Chemical Defoamers*** The addition of chemical foam breakers is the most elegant way to break a foam. Effective defoamers cause very rapid disintegration of the foam and frequently need be present only in parts per million. The great diversity of compounds used for defoamers and the many different systems in which they are applied make a brief and orderly discussion of their selection difficult. Compounds needed to break aqueous foams may be different from those needed for aqueous-free systems. The majority of defoamers are insoluble or nonmiscible in the foam continuous phase, but some work best because of their ready solubility. Lichtman (*Defoamers,* 3d ed., Wiley, New York, 1979) has presented a concise summary of the application and use of defoamers. Rubel (*Antifoaming and Defoaming*

**TABLE 14-31 Major Types and Applications of Defoamers**

| Classification | Examples | Applications |
|---|---|---|
| Silicones | Dimethyl silicone, trialkyl and tetraalkyl silanes | Lubricating oils; distillation; fermentation; jam and wine making; food processing |
| Aliphatic acids or esters | Mostly high-molecular-weight compounds; diethyl phthalate; lauric acid | Papermaking; wood-pulp suspensions; water-based paints; food processing |
| Alcohols | Moderate- to high-molecular-weight monohydric and polyhydric alcohols; octyl alcohol; C-12 to C-20 alcohols; lauryl alcohol | Distillation; fermentation; papermaking; glues and adhesives |
| Sulfates or sulfonates | Alkali metal salts of sulfated alcohols, sulfonic acid salts; alkyl-aryl sulfonates; sodium lauryl sulfate | Nonaqueous systems; mixed aqueous and nonaqueous systems; oil-well drilling muds; spent $H_3SO_4$ recovery; deep-fat frying |
| Amines or amides | Alkyl amines (undecyloctyl and diamyl methyl amine); polyamides (acyl derivatives of piperazine) | Boiler foam; sewage foam; fermentation; dye baths |
| Halogenated compounds | Fluochloro hydrocarbons with 5 to 50 C atoms; chlorinated hydrocarbons | Lubrication-oil and grease distillation; vegetable-protein glues |
| Natural products | Vegetable oils; waxes, mineral oils plus their sulfated derivatives (including those of animal oils and fats) | Sugar extraction; glue manufacture; cutting oils |
| Fatty-acid soaps | Alkali, alkaline earth, and other metal soaps; sodium stearate; aluminum stearate | Gear oils; paper stock; paper sizing; glue solutions |
| Inorganic compounds | Monosodium phosphate mixed with boric acid and ethyl carbonate, disodium phosphate; sodium aluminate, bentonite and other solids | Distillation; instant coffee; boiler feedwater; sugar extraction |
| Phosphates | Alkyl-alkalene diphosphates; tributyl phosphate in isopropanol | Petroleum-oil systems; foam control in soap solutions |
| Hydrophobic silica | Finely divided silica in polydimethyl siloxane | Aqueous foaming systems |
| Sulfides or thio derivatives | Metallic derivatives of thio ethers and disulfides, usually mixed with organic phosphite esters; long-chain alkyl thienyl ketones | Lubricating oils; boiler water |

*Agents,* Noyes Data Corp., Park Ridge, N.J., 1972) has reviewed the extensive patent literature on defoamers. Defoamers are also discussed extensively in the general references at the beginning of this subsection.

One useful method of aqueous defoaming is to add a nonfoam stabilizing surfactant which is more surface-active than the stabilizing substance in the foam. Thus a foam stabilized with an ionic surfactant can be broken by the addition of a very surface-active but nonstabilizing silicone oil. The silicone displaces the foam stabilizer from the interface by virtue of its insolubility. However, it does not stabilize the foam because its foam films have poor elasticity and rupture easily.

A major requirement for a defoamer is cost-effectiveness. Accordingly, some useful characteristics are low volatility (to prevent stripping from the system before it is dispersed and does its work), ease of dispersion and strong spreading power, and surface attraction-orientation. Chemical defoamers must also be selected in regard to their possible effect on product quality and their environmental and health suitability. For instance, silicone antifoam agents are effective in textile jet dyeing but reduce the fire retardancy of the fabric. Mineral-oil defoamers in sugar evaporation have been replaced by specifically approved materials. The tendency is no longer to use a single defoamer compound but to use a formulation specially tailored for the application comprising carriers, secondary antifoam agents, emulsifiers, and stabilizing agents in addition to the primary defoamer. Carriers, usually hydrocarbon oils or water, serve as the vehicle to support the release and spread of the primary defoamer. Secondary defoamers may provide a synergistic effect for the primary defoamer or modify its properties such as spreadability or solubility. Emulsifiers may enhance the speed of dispersion, while stabilizing agents may enhance defoamer stability or shelf life.

Hydrophobic silica defoamers work on a basis which may not be chemical at all. They are basically finely divided solid silica particles dispersed in a hydrocarbon or silicone oil which serves as a spreading vehicle. Kulkarni [*Ind. Eng. Chem. Fundam.,* **16,** 472 (1977)] theorizes that this mixture defoams by the penetration of the silica particle into the bubble and the rupture of the wall. Table 14-31 lists major types of defoamers and typical applications.

***Other Chemical Methods*** These methods rely chiefly on destroying the foam stabilizer or neutralizing its effect through methods other than displacement and are applicable when the process will permit changing the chemical environment. Forms stabilized with alkali esters can be broken by acidification since the equivalent free acids do not stabilize foam. Foams containing sulfated and sulfonated ionic detergents can be broken with the addition of fatty-acid soaps and calcium salts. Several theories have been proposed. One suggests that the surfactant is tied up in the foam as double calcium salts of both the sulfonate and the soap. Another suggests that calcium soaps oriented in the film render it inelastic.

Ionic surfactants adsorb at the foam interface and orient with the charged group immersed in the lamellae and their uncharged tails pointed into the gas stream. As the film drains, the charged groups, which repel each other, tend to be moved more closely together. The repulsive force between like charges hinders drainage and stabilizes the film. Addition of a salt or an electrolyte to the foam screens the repulsive effect, permits additional drainage, and can reduce foam stability.

**Foam Prevention** Chemical prevention of foam differs from defoaming only in that compounds or mixtures are added to a stream prior to processing to prevent the formation of foam either during processing or during customer use. Such additives, sometimes distinguished as antifoam agents, are usually in the same chemical class of materials as defoamers. However, they are usually specifically formulated for the application. Typical examples of products formulated with antifoam agents are laundry detergents (to control excess foaming), automotive antifreeze, instant coffee, and jet-aircraft fuel. Foaming in some chemical processes such as distillation or evaporation may be due to trace impurities such as surface-active agents. An alternative to antifoam agents is their removal before processing such as by treatment with activated carbon [Pool, *Chem. Process.,* **21**(9), 56 (1958)].

**Automatic Foam Control** In processing materials when foam can accumulate, it is often desirable to measure the height of the foam layer continuously and to dispense defoamer automatically as required to control the foam. Other corrective action can also be taken automatically. Methods of sensing the foam level have included electrodes in which the electrical circuit is completed when the foam touches the electrode [Nelson, *Ind. Eng. Chem.,* **48,** 2183 (1956); and Browne, U.S. Patent 2,981,693, 1961], floats designed to rise in a foam layer (Carter, U.S. Patent 3,154,577, 1964), and change in power input required to turn a foam-breaking impeller as the foam level rises (Yamashita, U.S. Patent 3,317,435, 1967). Timers to control the duration of defoamer addition have also been used. Browne has suggested automatic addition of defoamer through a porous wick when the foam level reaches the level of the wick. Foam control has also been discussed by Kroll [*Ind. Eng. Chem.,* **48,** 2190 (1956)].

## Nomenclature

A given symbol may represent more than one property. The appropriate meaning should be apparent from the context. The equations given in Sec. 15 reflect the use of the SI or cgs system of units and not ft-lb-s units, unless otherwise noted in the text. The gravitational conversion factor $g_c$ needed to use ft-lb-s units is not included in the equations.

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $a$ | Interfacial area per unit volume | $m^2/m^3$ | $ft^2/ft^3$ |
| $a_p$ | Specific packing surface area (area per unit volume) | $m^2/m^3$ | $ft^2/ft^3$ |
| $a_w$ | Specific wall surface area (area per unit volume) | $m^2/m^3$ | $ft^2/ft^3$ |
| $b_{ij}$ | NRTL model regression parameter (see Table 15-10) | K | K |
| $A$ | Envelope-style downcomer area | $m^2$ | $ft^2$ |
| $A$ | Area between settled layers in a decanter | $m^2$ | $ft^2$ |
| $A_{col}$ | Column cross-sectional area | $m^2$ | $ft^2$ |
| $A_{dow}$ | Area for flow through a downcorner (or upcomer) | $m^2$ | $ft^2$ |
| $A_{ij}/RT$ | van Laar binary interaction parameter | Dimensionless | Dimensionless |
| $A_o$ | Cross-sectional area of a single hole | $m^2$ | $in^2$ |
| $C$ | Concentration (mass or mol per unit volume) | $kg/m^3$ or kgmol/$m^3$ or gmol/L | $lb/ft^3$ or lbmol/$ft^3$ |
| $C_A^i$ | Concentration of component $A$ at the interface | $kg/m^3$ or kgmol/$m^3$ or gmol/L | $lb/ft^3$ or lbmol/$ft^3$ |
| $C^*$ | Concentration at equilibrium | $kg/m^3$ or kgmol/$m^3$ or gmol/L | $lb/ft^3$ or lbmol/$ft^3$ |
| $C_D$ | Drag coefficient | Dimensionless | Dimensionless |
| $C_o$ | Initial concentration | $kg/m^3$ or kgmol/$m^3$ or gmol/L | $lb/ft^3$ or lbmol/$ft^3$ |
| $C_t$ | Concentration at time $t$ | $kg/m^3$ or kgmol/$m^3$ or gmol/L | $lb/ft^3$ or lbmol/$ft^3$ |
| $d$ | Drop diameter | m | in |
| $d_C$ | Critical packing dimension | m | in |
| $d_i$ | Diameter of an individual drop | m | in |
| $d_m$ | Characteristic diameter of media in a packed bed | m | in |
| $d_o$ | Orifice or nozzle diameter | m | in |
| $d_p$ | Sauter mean drop diameter | m | in |
| $d_{32}$ | Sauter mean drop diameter | m | in |
| $D_{col}$ | Column diameter | m | in or ft |
| $D_{eq}$ | Equivalent diameter giving the same area | m | in |
| $D_h$ | Equivalent hydraulic diameter | m | in |
| $\mathcal{D}_i$ | Distribution ratio for a given chemical species including all its forms (unspecified units) | | |
| $D_i$ | Impeller diameter or characteristic mixer diameter | m | in or ft |
| $D_{sm}$ | Static mixer diameter | m | in or ft |
| $D_t$ | Tank diameter | m | ft |
| $\mathcal{D}$ | Molecular diffusion coefficient (diffusivity) | $m^2/s$ | $cm^2/s$ |
| $\mathcal{D}_{AB}$ | Mutual diffusion coefficient for components $A$ and $B$ | $m^2/s$ | $cm^2/s$ |
| $E$ | Mass or mass flow rate of extract phase | kg or kg/s | lb or lb/h |
| $E'$ | Solvent mass or mass flow rate (in the extract phase) | | |
| $E$ | Axial mixing coefficient (eddy diffusivity) | $m^2/s$ | $cm^2/s$ |

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $\mathcal{E}^C$ | Extraction factor for case $C$ [Eq. (15-98)] | Dimensionless | Dimensionless |
| $\mathcal{E}_i$ | Extraction factor for component $i$ | Dimensionless | Dimensionless |
| $\mathcal{E}_s$ | Stripping section extraction factor | Dimensionless | Dimensionless |
| $\mathcal{E}_w$ | Washing section extraction factor | Dimensionless | Dimensionless |
| $f_{da}$ | Fractional downcomer area in Eq. (15-160) | Dimensionless | Dimensionless |
| $f_{ha}$ | Fractional hole area in Eq. (15-159) | Dimensionless | Dimensionless |
| $F$ | Mass or mass flow rate of feed phase | kg or kg/s | lb or lb/h |
| $F$ | Force | N | $lb_f$ |
| $F'$ | Feed mass or mass flow rate (feed solvent only) | kg or kg/s | lb or lb/h |
| $F_R$ | Solute reduction factor (ratio of inlet to outlet concentrations) | Dimensionless | Dimensionless |
| $g$ | Gravitational acceleration | 9.807 $m/s^2$ | 32.17 $ft/s^2$ |
| $G_{ij}$ | NRTL model parameter | Dimensionless | Dimensionless |
| $h$ | Height of coalesced layer at a sieve tray | m | in |
| $h$ | Head loss due to frictional flow | m | in |
| $h$ | Height of dispersion band in batch decanter | m | in |
| $h_i^E$ | Excess enthalpy of mixing | J/gmol | Btu/lbmol or cal/gmol |
| $H$ | Dimensionless group defined by Eq. (15-123) | Dimensionless | Dimensionless |
| $H$ | Dimension of envelope-style downcomer (Fig. 15-39) | m | in or ft |
| $\Delta H$ | Steady-state dispersion band height in a continuously fed decanter | m | in |
| HDU | Height of a dispersion unit | m | in |
| $H_e$ | Height of a transfer unit due to resistance in extract phase | m | in |
| HETS | Height equivalent to a theoretical stage | m | in |
| $H_{or}$ | Height of an overall mass-tranfer unit based on raffinate phase | m | in |
| $H_r$ | Height of a transfer unit due to resistance in raffinate phase | m | in |
| $I$ | Ionic strength in Eq. (15-26) | | |
| $k$ | Individual mass-transfer coefficient | m/s or cm/s | ft/h |
| $k$ | Mass-transfer coefficient (unspecified units) | | |
| $k_m$ | Membrane-side mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_o$ | Overall mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_c$ | Continuous-phase mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_d$ | Dispersed-phase mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_s$ | Setschenow constant | L/gmol | L/gmol |
| $k_s$ | Shell-side mass-transfer coefficient | m/s or cm/s | ft/h |
| $k_t$ | Tube-side mass-transfer coefficient | m/s or cm/s | ft/h |
| $K$ | Partition ratio (unspecified units) | | |
| $K_s'$ | Stripping section partition ratio (in Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |

**Nomenclature** (*Continued*)

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $K'_w$ | Washing section partition ratio (in Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |
| $K'$ | Partition ratio, mass ratio basis (Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |
| $K''$ | Partition ratio, mass fraction basis | Mass fraction/ mass fraction | Mass fraction/ mass fraction |
| $K^o$ | Partition ratio, mole fraction basis | Mole fraction/ mole fraction | Mole fraction/ mole fraction |
| $K^{vol}$ | Partition ratio (volumetric concentration basis) | Ratio of kg/m$^3$ or kgmol/m$^3$ or gmol/L | Ratio of lb/ft$^3$ or lbmol/ft$^3$ |
| $L$ | Downcomer (or upcomer) length | m | in or ft |
| $L_{fp}$ | Length of flow path in Eq. (15-161) | m | in or ft |
| $m$ | Local slope of equilibrium line (unspecified concentration units) | | |
| $m'$ | Local slope of equilibrium line (in Bancroft coordinates) | Mass ratio/ mass ratio | Mass ratio/ mass ratio |
| $m_{dc}$ | Local slope of equilibrium line for dispersed-phase concentration plotted versus continuous-phase concentration | | |
| $m_{er}$ | Local slope of equilibrium line for extract-phase concentration plotted versus raffinate-phase concentration | | |
| $m^{vol}$ | Local slope of equilibrium line (volumetric concentration basis) | Ratio of kg/m$^3$ or kgmol/m$^3$ or gmol/L | Ratio of lb/ft$^3$ or lbmol/ft$^3$ units |
| $M$ | Mass or mass flow rate | kg or kg/s | lb or lb/h |
| MW | Molecular weight | kg/kgmol or g/gmol | lb/lbmol |
| $N$ | Number of theoretical stages | Dimensionless | Dimensionless |
| $N_A$ | Flux of component A (mass or mol/area/unit time) | (kg or kgmol)/ (m$^2$·s) | (lb or lbmol)/ (ft$^2$·s) |
| $N_{holes}$ | Number of holes | Dimensionless | Dimensionless |
| $N_{or}$ | Number of overall mass-transfer units based on the raffinate phase | Dimensionless | Dimensionless |
| $N_s$ | Number of theoretical stages in stripping section | Dimensionless | Dimensionless |
| $N_w$ | Number of theoretical stages in washing section | Dimensionless | Dimensionless |
| $P$ | Pressure | bar or Pa | atm or lb$_f$/in$^2$ |
| $P$ | Dimensionless group defined by Eq. (15-122) | Dimensionless | Dimensionless |
| $P$ | Power | W or kW | HP or ft·lb$_f$/h |
| Pe | Péclet number $Vb/E$, where $V$ is liquid velocity, $E$ is axial mixing coefficient, and $b$ is a characteristic equipment dimension | Dimensionless | Dimensionless |
| $P_{i,extract}$ | Purity of solute $i$ in extract (in wt %) | wt % | wt % |
| $P_{i,feed}$ | Purity of solute $i$ in feed (in wt %) | wt % | wt % |
| $P_o$ | Power number $P/(\rho_m\omega^3 D_i^5)$ | Dimensionless | Dimensionless |
| $\Delta P_{dow}$ | Pressure drop for flow through a downcomer (or upcomer) | bar or Pa | atm or lb$_f$/in$^2$ |
| $\Delta P_o$ | Orifice pressure drop | bar or Pa | atm or lb$_f$/in$^2$ |
| $q$ | MOSCED induction parameter | Dimensionless | Dimensionless |
| $Q$ | Volumetric flow rate | m$^3$/s | ft$^3$/min |
| $R$ | Universal gas constant | 8.31 J·K/ kgmol | 1.99 Btu·°R/ lbmol |
| $R$ | Mass or mass flow rate of raffinate phase | kg or kg/s | lb or lb/h |
| $R_A$ | Rate of mass-transfer (moles per unit time) | kgmol/s | lbmol/h |

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| Re | Reynolds number: for pipe flow, $Vd\rho/\mu$; for an impeller, $\rho_m\omega D_i^2/\mu_m$; for drops, $V_{so}d_p\,\rho_c/\mu_c$; for flow in a packed-bed coalescer, $Vd_m\rho_c/\mu$; for flow through an orifice, $V_o d_o\rho_d/\mu_d$ | Dimensionless | Dimensionless |
| $Re_{Stokes}$ | $\rho_c\,\Delta\rho g d_p^3/18\mu_c^2$ | Dimensionless | Dimensionless |
| $S$ | Mass or mass flow rate of solvent phase | kg or kg/s | lb or lb/h |
| $S$ | Dimension of envelope-style downcomer (Fig. 15-39) | m | ft |
| $S'$ | Solvent mass or mass flow rate (extraction solvent only) | kg or kg/s | lb or lb/h |
| $S'_s$ | Mass flow rate of extraction solvent within stripping section | kg/s | lb/h |
| $S'_w$ | Mass flow rate of extraction solvent within washing section | kg/s | lb/h |
| $S_{i,j}$ | Separation power for separating component $i$ from component $j$ [defined by Eq. (15-105)] | Dimensionless | Dimensionless |
| $S_{tip}$ | Impeller tip speed | m/s | ft/s |
| $t_b$ | Batch mixing time | s or h | min or h |
| $T$ | Temperature (absolute) | K | °R |
| $u_t$ | Stokes' law terminal or settling velocity of a drop | m/s or cm/s | ft/s or ft/min |
| $u_{t\infty}$ | Unhindered settling velocity of a single drop | m/s or cm/s | ft/s or ft/min |
| $v$ | Molar volume | m$^3$/kgmol or cm$^3$/gmol | ft$^3$/lbmol |
| $V$ | Liquid velocity (or volumetric flow per unit area) | m/s | ft/s or ft/min |
| $\mathcal{V}$ | Volume | m$^3$ | ft$^3$ or gal |
| $V_{cf}$ | Continuous-phase flooding velocity | m/s | ft/s or ft/min |
| $V_{cflow}$ | Cross-flow velocity of continuous phase at sieve tray | m/s | ft/s or ft/min |
| $V_{df}$ | Dispersed-phase flooding velocity | m/s | ft/s or ft/min |
| $V_{drop}$ | Average velocity of a dispersed drop | m/s | ft/s or ft/min |
| $V_{ic}$ | Interstitial velocity of continuous phase | m/s | ft/s or ft/min |
| $V_{o,max}$ | Maximum velocity through an orifice or nozzle | m/s | ft/s or ft/min |
| $V_s$ | Slip velocity | m/s | ft/s or ft/min |
| $V_{so}$ | Slip velocity at low dispersed-phase flow rate | m/s | ft/s or ft/min |
| $V_{sm}$ | Static mixer superficial liquid velocity (entrance velocity) | m/s | ft/s or ft/min |
| $W$ | Mass or mass flow rate of wash solvent phase | kg or kg/s | lb or lb/h |
| $W'_s$ | Mass flow rate of wash solvent within stripping section | kg/s | lb/h |
| $W'_w$ | Mass flow rate of wash solvent within washing section | kg/s | lb/h |
| We | Weber number: for an impeller, $\rho_c\omega^2 D_i^3/\sigma$; for flow through an orifice or nozzle, $V_o^2 d_o\rho_d/\sigma$; for a static mixer, $V_{sm}^2 D_{sm}\rho_c/\sigma$ | Dimensionless | Dimensionless |
| $x$ | Mole fraction solute in feed or raffinate | Mole fraction | Mole fraction |
| $X$ | Concentration of solute in feed or raffinate (unspecified units) | | |
| $X''$ | Mass fraction solute in feed or raffinate | Mass fractions | Mass fractions |
| $X'$ | Mass solute/mass feed solvent in feed or raffinate | Mass ratios | Mass ratios |
| $X_f^B$ | Pseudoconcentration of solute in feed for case $B$ [Eq. (15-95)] | Mass ratios | Mass ratios |

**Nomenclature** (*Concluded*)

| Symbol | Definition | SI units | U.S. Customary System units |
|---|---|---|---|
| $X_f^C$ | Pseudoconcentration of solute in feed for case *C* [Eq. (15-97)] | Mass ratios | Mass ratios |
| $X_{i,\text{extract}}$ | Concentration of solute *i* in extract | Mass fraction | Mass fraction |
| $X_{i,\text{feed}}$ | Concentration of solute *i* in feed | Mass fraction | Mass fraction |
| $X_{ij}$ | Concentration of component *i* in the phase richest in *j* | Mass fraction | Mass fraction |
| $y$ | Mole fraction solute in solvent or extract | Mole fraction | Mole fraction |
| $Y$ | Concentration of solute in the solvent or extract (unspecified units) | | |
| $Y'''$ | Mass fraction solute in solvent or extract | Mass fraction | Mass fraction |
| $Y'$ | Mass solute/mass extraction solvent in solvent or extract | Mass ratio | Mass ratio |
| $Y_s^B$ | Pseudoconcentration of solute in solvent for case *B* [Eq. (15-96)] | Mass ratio | Mass ratio |
| $z$ | Dimension or direction of mass transfer | m | in or ft |
| $z$ | Sieve tray spacing | m | in or ft |
| $z$ | Point representing feed composition on a tie line | | |
| $z_i$ | Number of electronic charges on an ion | Dimensionless | Dimensionless |

# INTRODUCTION AND OVERVIEW

Liquid-liquid extraction is a process for separating the components of a liquid (the feed) by contact with a second liquid phase (the solvent). The process takes advantage of differences in the chemical properties of the feed components, such as differences in polarity and hydrophobic/hydrophilic character, to separate them. Stated more precisely, the transfer of components from one phase to the other is driven by a deviation from thermodynamic equilibrium, and the equilibrium state depends on the nature of the interactions between the feed components and the solvent phase. The potential for separating the feed components is determined by differences in these interactions.

A liquid-liquid extraction process produces a solvent-rich stream called the extract that contains a portion of the feed and an extracted-feed stream called the raffinate. A commercial process almost always includes two or more auxiliary operations in addition to the extraction operation itself. These extra operations are needed to treat the extract and raffinate streams for the purposes of isolating a desired product, recovering the solvent for recycle to the extractor, and purging unwanted components from the process. A typical process includes two or more distillation operations in addition to extraction.

Liquid-liquid extraction is used to recover desired components from a crude liquid mixture or to remove unwanted contaminants. In developing a process, the project team must decide what solvent or solvent mixture to use, how to recover solvent from the extract, and how to remove solvent residues from the raffinate. The team must also decide what temperature or range of temperatures should be used for the extraction, what process scheme to employ among many possibilities, and what type of equipment to use for liquid-liquid contacting and phase separation. The variety of commercial equipment options is large and includes stirred tanks and decanters, specialized mixer-settlers, a wide variety of agitated and nonagitated extraction columns or towers, and various types of centrifuges.

Because of the availability of hundreds of commercial solvents and extractants, as well as a wide variety of established process schemes and equipment options, liquid-liquid extraction is a versatile technology with a wide range of commercial applications. It is utilized in the processing of numerous commodity and specialty chemicals including metals and nuclear fuel (hydrometallurgy), petrochemicals, coal and wood-derived chemicals, and complex organics such as pharmaceuticals and agricultural chemicals. Liquid-liquid extraction also is an important operation in industrial wastewater treatment, food processing, and the recovery of biomolecules from fermentation broth.

## HISTORICAL PERSPECTIVE

The art of solvent extraction has been practiced in one form or another since ancient times. It appears that prior to the 19th century solvent extraction was primarily used to isolate desired components such as perfumes and dyes from plant solids and other natural sources [Aftalion, *A History of the International Chemical Industry* (Univ. Penn. Press, 1991); and Taylor, *A History of Industrial Chemistry* (Abelard-Schuman, 1957)]. However, several early applications involving liquid-liquid contacting are described by Blass, Liebel, and Haeberl ["Solvent Extraction—A Historical Review," *International Solvent Extraction Conf. (ISEC) '96 Proceedings* (Univ. of Melbourne, 1996)], including the removal of pigment from oil by using water as the solvent.

The modern practice of liquid-liquid extraction has its roots in the middle to late 19th century when extraction became an important laboratory technique. The partition ratio concept describing how a solute partitions between two liquid phases at equilibrium was introduced by Berthelot and Jungfleisch [*Ann. Chim. Phys.*, **4,** p. 26 (1872)] and further defined by Nernst [*Z. Phys. Chemie,* **8,** p. 110 (1891)]. At about the same time, Gibbs published his theory of phase equilibrium (1876 and 1878). These and other advances were accompanied by a growing chemical industry. An early countercurrent extraction process utilizing ethyl acetate solvent was patented by Goering in 1883 as a method for recovering acetic acid from "pyroligneous acid" produced by pyrolysis of wood [Othmer, p. xiv in *Handbook of Solvent Extraction* (Wiley, 1983; Krieger, 1991)], and Pfleiderer patented a stirred extraction column in 1898 [Blass, Liebl, and Haeberl, *ISEC '96 Proceedings* (Univ. of Melbourne, 1996)].

With the emergence of the chemical engineering profession in the 1890s and early 20th century, additional attention was given to process fundamentals and development of a more quantitative basis for process design. Many of the advances made in the study of distillation and absorption were readily adapted to liquid-liquid extraction, owing to its similarity as another diffusion-based operation. Examples include application of mass-transfer coefficients [Lewis, *Ind. Eng. Chem.*, **8**(9), pp. 825–833 (1916); and Lewis and Whitman, *Ind. Eng. Chem.*, **16**(12), pp. 1215–1220 (1924)], the use of graphical stagewise design methods [McCabe and Thiele, *Ind. Eng. Chem.*, **17**(6), pp. 605–611 (1925); Evans, *Ind. Eng. Chem.*, **26**(8), pp. 860–864 (1934); and Thiele, *Ind. Eng. Chem.*, **27**(4), pp. 392–396 (1935)], the use of theoretical-stage calculations [Kremser, *National Petroleum News*, **22**(21), pp. 43–49 (1930); and Souders and Brown, *Ind. Eng. Chem.* **24**(5), pp. 519–522 (1932)], and the transfer unit concept introduced in the late 1930s by Colburn and others [Colburn, *Ind. Eng. Chem.*, **33**(4), pp. 459–467 (1941)]. Additional background is given by Hampe, Hartland, and Slater [Chap. 2 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994)].

The number of commercial applications continued to grow, and by the 1930s liquid-liquid extraction had replaced various chemical treatment methods for refining mineral oil and coal tar products [Varteressian and Fenske, *Ind. Eng. Chem.*, **28**(8), pp. 928–933 (1936)]. It was also used to recover acetic acid from waste liquors generated in the production of cellulose acetate, and in various nitration and sulfonation processes [Hunter and Nash, *The Industrial Chemist*, **9**(102–104), pp. 245–248, 263–266, 313–316 (1933)]. The article by Hunter and Nash also describes early mixer-settler equipment, mixing jets, and various extraction columns including the spray column, baffle tray column, sieve tray column, and a packed column filled with Raschig rings or coke breeze, the material left behind when coke is burned.

Much of the liquid-liquid extraction technology in practice today was first introduced to industry during a period of vigorous innovation and growth of the chemical industry as a whole from about 1920 to 1970. The advances of this period include development of fractional extraction schemes including work described by Cornish et al., [*Ind. Eng. Chem.*, **26**(4), pp. 397–406 (1934)] and by Thiele [*Ind. Eng. Chem.*, **27**(4), pp. 392–396 (1935)]. A well-known commercial example involving the use of extract reflux is the Udex process for separating aromatic compounds from hydrocarbon mixtures using diethylene glycol, a process developed jointly by The Dow Chemical Company and Universal Oil Products in the 1940s. This period also saw the introduction of many new equipment designs including specialized mixer-settler equipment, mechanically agitated extraction columns, and centrifugal extractors as well as a great increase in the availability of different types of industrial solvents. A variety of alcohols, ketones, esters, and chlorinated hydrocarbons became available in large quantities beginning in the 1930s, as petroleum refiners and chemical companies found ways to manufacture them inexpensively using the byproducts of petroleum refining operations or natural gas. Later, a number of specialty solvents were introduced including sulfolane (tetrahydrothiophene-1,1-dioxane) and NMP (*N*-methyl-2-pyrrolidinone) for improved extraction of aromatics from hydrocarbons. Specialized extractants also were developed including numerous organophosphorous extractants used to recover or purify metals dissolved in aqueous solutions.

The ready availability of numerous solvents and extractants, combined with the tremendous growth of the chemical industry, drove the development and implementation of many new industrial applications. Handbooks of chemical process technology provide a glimpse of some of these [*Riegel's Handbook of Industrial Chemistry*, 10th ed., Kent, ed. (Springer, 2003); *Chemical Processing Handbook*, McKetta, ed. (Dekker, 1993); and Austin, *Shreve's Chemical Process Industries,* 5th ed. (McGraw-Hill, 1984)], but many remain proprietary and are not widely known. The better-known examples include the separation of aromatics from aliphatics, as mentioned above, extraction of phenolic compounds from coal tars and liquors, recovery of ε-caprolactam for production of polyamide-6 (nylon-6), recovery of hydrogen peroxide from oxidized anthraquinone solution, plus many processes involving the washing of crude organic streams with alkaline or acidic solutions and water, and the detoxification of industrial wastewater prior to biotreatment using steam-strippable organic solvents. The pharmaceutical and specialty chemicals industry also began using liquid-liquid extraction in the production of new synthetic drug compounds and other complex organics. In these processes, often involving multiple batch reaction steps, liquid-liquid extraction generally is used for recovery of intermediates or crude products prior to final isolation of a pure product by crystallization. In the inorganic chemical industry, extraction processes were developed for purification of phosphoric acid, purification of copper by removal of arsenic impurities, and recovery of uranium from phosphate-rock leach solutions, among other applications. Extraction processes also were developed for bioprocessing applications, including the recovery of citric acid from broth using trialkylamine extractants, the use of amyl acetate to recover antibiotics from fermentation broth, and the use of water-soluble polymers in aqueous two-phase extraction for purification of proteins.

The use of supercritical or near-supercritical fluids for extraction, a subject area normally set apart from discussions of liquid-liquid extraction, has received a great deal of attention in the R&D community since the 1970s. Some processes were developed many years before then; e.g., the propane deasphalting process used to refine lubricating oils uses propane at near-supercritical conditions, and this technology dates back to the 1930s [McHugh and Krukonis, *Supercritical Fluid Processing*, 2d ed. (Butterworth-Heinemann, 1993)]. In more recent years the use of supercritical fluids has found a number of commercial applications displacing earlier liquid-liquid extraction methods, particularly for recovery of high-value products meant for human consumption including decaffeinated coffee, flavor components from citrus oils, and vitamins from natural sources.

Significant progress continues to be made toward improving extraction technology, including the introduction of new methods to estimate solvent properties and screen candidate solvents and solvent blends, new methods for overall process conceptualization and optimization, and new methods for equipment design. Progress also is being made by applying the technology developed for a particular application in one industry to improve another application in another industry. For example, much can be learned by comparing equipment and practices used in organic chemical production with those used in the inorganic chemical industry (and vice versa), or by comparing practices used in commodity chemical processing with those used in the specialty chemicals industry. And new concepts offering potential for significant improvements continue to be described in the literature. (See "Emerging Developments.")

## USES FOR LIQUID-LIQUID EXTRACTION

For many separation applications, the use of liquid-liquid extraction is an alternative to the various distillation schemes described in Sec. 13, "Distillation." In many of these cases, a distillation process is more economical largely because the extraction process requires extra operations to process the extract and raffinate streams, and these operations usually involve the use of distillation anyway. However, in certain cases the use of liquid-liquid extraction is more cost-effective than using distillation alone because it can be implemented with smaller equipment and/or lower energy consumption. In these cases, differences in chemical or molecular interactions between feed components and the solvent provide a more effective means of accomplishing the desired separation compared to differences in component volatilities.

For example, liquid-liquid extraction may be preferred when the relative volatility of key components is less than 1.3 or so, such that an unusually tall distillation tower is required or the design involves high reflux ratios and high energy consumption. In certain cases, the distillation option may involve addition of a solvent (extractive distillation) or an entrainer (azeotropic distillation) to enhance the relative volatility. Even in these cases, a liquid-liquid extraction process may offer advantages in terms of higher selectivity or lower solvent usage and lower energy consumption, depending upon the application. Extraction may be preferred when the distillation option requires operation at pressures less than about 70 mbar (about 50 mmHg) and an unusually large-diameter distillation tower is required, or when most of the

feed must be taken overhead to isolate a desired bottoms product. Extraction may also be attractive when distillation requires use of high-pressure steam for the reboiler or refrigeration for overheads condensation [Null, *Chem. Eng. Prog.*, **76**(8), pp. 42–49 (August 1980)], or when the desired product is temperature-sensitive and extraction can provide a gentler separation process.

Of course, liquid-liquid extraction also may be a useful option when the components of interest simply cannot be separated by using distillation methods. An example is the use of liquid-liquid extraction employing a steam-strippable solvent to remove nonstrippable, low-volatility contaminants from wastewater [Robbins, *Chem. Eng. Prog.*, **76**(10), pp. 58–61 (1980)]. The same process scheme often provides a cost-effective alternative to direct distillation or stripping of volatile impurities when the relative volatility of the impurity with respect to water is less than about 10 [Robbins, U.S. Patent 4,236,973 (1980); Hwang, Keller, and Olson, *Ind. Eng. Chem. Res.*, **31,** pp. 1753–1759 (1992); and Frank et al., *Ind. Eng. Chem. Res.,* **46**(11), pp. 3774–3786 (2007)].

Liquid-liquid extraction also can be an attractive alternative to separation methods, other than distillation, e.g., as an alternative to crystallization from solution to remove dissolved salts from a crude organic feed, since extraction of the salt content into water eliminates the need to filter solids from the mother liquor, often a difficult or expensive operation. Extraction also may compete with process-scale chromatography, an example being the recovery of hydroxytyrosol (3,4-dihydroxyphenylethanol), an antioxidant food additive, from olive-processing wastewaters [Guzman et al., U.S. Patent 6,849,770 (2005)].

The attractiveness of liquid-liquid extraction for a given application compared to alternative separation technologies often depends upon the concentration of solute in the feed. The recovery of acetic acid from aqueous solutions is a well-known example [Brown, *Chem. Eng. Prog.*, **59**(10), pp. 65–68 (1963)]. In this case, extraction generally is more economical than distillation when handling dilute to moderately concentrated feeds, while distillation is more economical at higher concentrations. In the treatment of water to remove trace amounts of organics, when the concentration of impurities in the feed is greater than about 20 to 50 ppm, liquid-liquid extraction may be more economical than adsorption of the impurities by using carbon beds, because the latter may require frequent and costly replacement of the adsorbent [Robbins, *Chem. Eng. Prog.*, **76**(10), pp. 58–61 (1980)]. At lower concentrations of impurities, adsorption may be the more economical option because the usable lifetime of the carbon bed is longer.

Examples of cost-effective liquid-liquid extraction processes utilizing relatively low-boiling solvents include the recovery of acetic acid from aqueous solutions using ethyl ether or ethyl acetate [King, Chap. 18.5 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983, Krieger, 1991)] and the recovery of phenolic compounds from water by using methyl isobutyl ketone [Greminger et al., *Ind. Eng. Chem. Process Des. Dev.,* **21**(1), pp. 51–54 (1982)]. In these processes, the solvent is recovered from the extract by distillation, and dissolved solvent is removed from the raffinate by steam stripping (Fig. 15-1). The solvent circulates through the process in a closed loop.

One of the largest applications of liquid-liquid extraction in terms of total worldwide production volume involves the extraction of aromatic compounds from hydrocarbon mixtures in petrochemical operations using high-boiling polar solvents. A number of processes have been developed to recover benzene, toluene, and xylene (BTX) as feedstock for chemical manufacturing or to refine motor oils. This general technology is described in detail in "Single-Solvent Fractional Extraction with Extract Reflux" under "Calculation Procedures." A typical flow diagram is shown in Fig. 15-2. Liquid-liquid extraction also may be used to upgrade used motor oil; an extraction process employing a relatively light polar solvent such as *N,N*-dimethylformamide or acetonitrile has been developed to remove polynuclear aromatic and sulfur-containing contaminants [Sherman, Hershberger, and Taylor, U.S. Patent 6,320,090 (2001)]. An alternative process utilizes a blend of methyl ethyl ketone + 2-propanol and small amounts of aqueous KOH [Rincón, Cañizares, and García, *Ind. Eng. Chem. Res.*, **44**(20), pp. 7854–7859 (2005)].

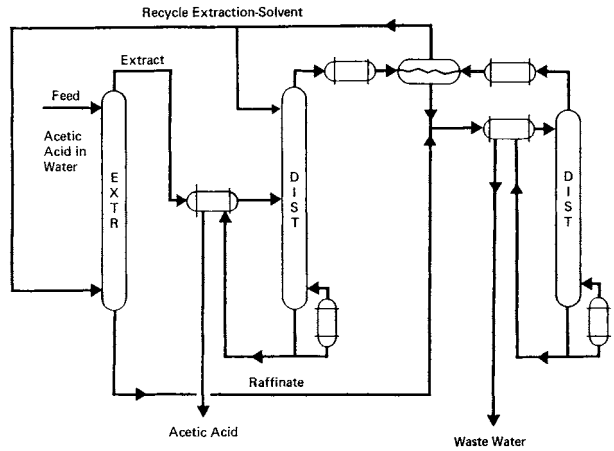

**FIG. 15-1** Typical process for extraction of acetic acid from water.

Extraction also is used to remove $CO_2$, $H_2S$, and other acidic contaminants from liquefied petroleum gases (LPGs) generated during operation of fluid catalytic crackers and cokers in petroleum refineries, and from liquefied natural gas (LNG). The acid gases are extracted from the liquefied hydrocarbons (primarily $C_1$ to $C_3$) by reversible reaction with various amine extractants. Typical amines are methyldiethanolamine (MDEA), diethanolamine (DEA), and monoethanolamine (MEA). In a typical process (Fig. 15-3), the treated hydrocarbon liquid (the raffinate) is washed with water to remove residual amine, and the loaded amine solution (the extract) is regenerated in a stripping tower for recycle back to the extractor [Nielsen et al., *Hydrocarbon Proc.*, **76,** pp. 49–59 (1997)]. The technology is similar to that used to scrub $CO_2$ and $H_2S$ from gas streams [Oyenekan and Rochelle, *Ind. Eng. Chem. Res.*, **45**(8), pp. 2465–2472 (2006); and Jassim and Rochelle, *Ind. Eng. Chem. Res.*, **45**(8), pp. 2457–2464 (2006)], except that the process involves liquid-liquid contacting instead of gas-liquid contacting. Because of this, a common stripper often is used to regenerate solvent from a variety of gas absorbers and liquid-liquid extractors operated within a typical refinery. In certain applications, organic acids such as formic acid are present in low concentrations in the hydrocarbon feed. These contaminants will react with the amine extractant to form heat-stable amine salts that accumulate in the solvent loop over time, requiring periodic purging or regeneration of the solvent solution [Price and Burns, *Hydrocarbon Proc.*, **74,** pp. 140–141 (1995)]. The amine-based extraction process is an alternative to washing with caustic or the use of solid adsorbents.

A typical extraction process used in hydrometallurgical applications is outlined in Fig. 15-4. This technology involves transferring the desired element from the ore leachate liquor, an aqueous acid, into an organic solvent phase containing specialty extractants that form a complex with the metal ion. The organic phase is later contacted with an aqueous solution at a different pH and temperature to regenerate the solvent and transfer the metal into a clean solution from which it can be recovered by electrolysis or another method [Cox, Chap. 1 in *Science and Practice of Liquid-Liquid Extraction*, vol. 2, Thornton, ed. (Oxford, 1992)]. Another process technology utilizes metals complexed with various organophosphorus compounds as recyclable homogeneous catalysts; liquid-liquid extraction is used to transfer the metal complex between the reaction phase and a separate liquid phase after reaction. Different ligands having different polarities are chosen to facilitate the use of various extraction and recycle schemes [Kanel et al., U.S. Patents 6,294,700 (2001) and 6,303,829 (2001)].

Another category of useful liquid-liquid extraction applications involves the recovery of antibiotics and other complex organics from fermentation broth by using a variety of oxygenated organic solvents such as acetates and ketones. Although some of these products are unstable at the required extraction conditions (particularly if pH must

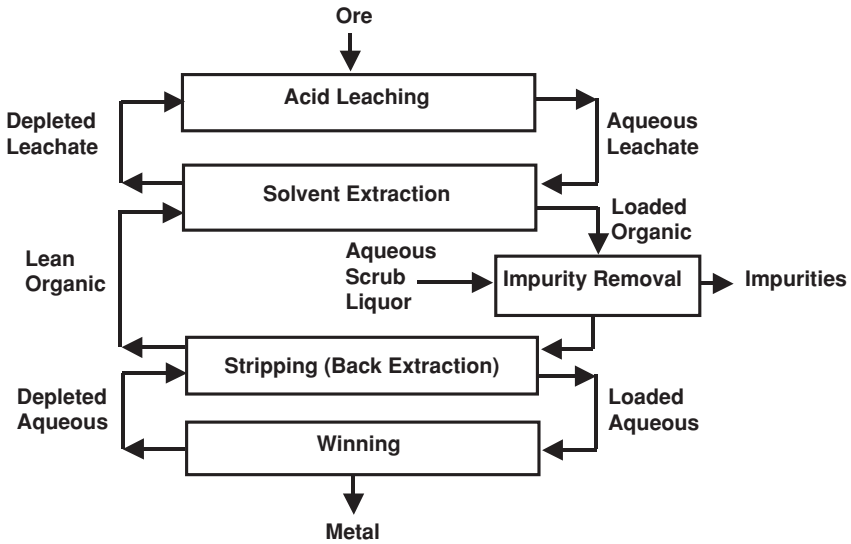

**FIG. 15-4** Example process scheme used in hydrometallurgical applications. [*Taken from Cox, Chap. 1 in* Science and Practice of Liquid-Liquid Extraction, *vol. 2, Thornton, ed. (Oxford, 1992), with permission. Copyright 1992 Oxford University Press.*]

be low for favorable partitioning), short-contact-time centrifugal extractors may be used to minimize exposure. Centrifugal extractors also help overcome problems associated with formation of emulsions between solvent and broth. In a number of applications, the whole broth can be processed without prior removal of solids, a practice that can significantly reduce costs. For detailed information, see "The History of Penicillin Production," Elder, ed., *Chemical Engineering Progress Symposium Series No. 100*, vol. 66, pp. 37–42 (1970); Queener and Swartz, "Penicillins: Biosynthetic and Semisynthetic," in *Secondary Products of Metabolism, Economic Microbiology*, vol. 3, Rose, ed. (Academic, 1979); and Chaung et al., *J. Chinese Inst. Chem. Eng.*, **20**(3), pp. 155–161 (1989). Another well-known commercial application of liquid-liquid extraction in bioprocessing is the Baniel process for the recovery of citric acid from fermentation broth with tertiary amine extractants [Baniel, Blumberg, and Hadju, U.S. Patent 4,275,234 (1980)]. This type of process is discussed in "Reaction-Enhanced Extraction" under "Commercial Process Schemes."

## DEFINITIONS

Extraction terms defined by the International Union of Pure and Applied Chemistry (IUPAC) generally are recommended. [See Rice, Irving, and Leonard, *Pure Appl. Chem.* (IUPAC), **65**(11), pp. 2673–2396 (1993); and J. Inczédy, *Pure Appl. Chem.* (IUPAC), **66**(12), pp. 2501–2512 (1994).] **Liquid-liquid extraction** is a process for separating components dissolved in a liquid feed by contact with a second liquid phase. *Solvent extraction* is a broader term that describes a process for separating the components of any matrix by contact with a liquid, and it includes liquid-solid extraction (leaching) as well as liquid-liquid extraction. The **feed** to a liquid-liquid extraction process is the solution that contains the components to be separated. The major liquid component (or components) in the feed can be referred to as the **feed solvent** or the **carrier solvent.** Minor components in solution often are referred to as **solutes.** The **extraction solvent** is the immiscible or partially miscible liquid added to the process to create a second liquid phase for the purpose of extracting one or more solutes from the feed. It is also called the **separating agent** and may be a mixture of several individual solvents (a **mixed solvent** or a **solvent blend**). The extraction solvent also may be a liquid comprised of an **extractant** dissolved in a liquid **diluent**. In this case, the extractant species is primarily responsible for extraction of solute due to a relatively strong attractive interaction with the desired solute, forming a reversible adduct or molecular complex. The diluent itself does not contribute significantly to the extraction of solute and in this respect is not the same as a true extraction solvent. A **modifier** may be added to the diluent to increase the solubility of the extractant or otherwise enhance the effectiveness of the extractant. The phase leaving a liquid-liquid contactor rich in extraction solvent is called the **extract.** The **raffinate** is the liquid phase left from the feed after it is contacted by the extract phase. The word *raffinate* originally referred to a "refined product"; however, common usage has extended its meaning to describe the feed phase after extraction whether that phase is a product or not.

Industrial liquid-liquid extraction most often involves processing two immiscible or partially miscible liquids in the form of a **dispersion** of droplets of one liquid (the **dispersed phase**) suspended in the other liquid (the **continuous phase**). The dispersion will exhibit a distribution of drop diameters $d_i$ often characterized by the volume to surface area average diameter or **Sauter mean drop diameter.** The term **emulsion** generally refers to a liquid-liquid dispersion with a dispersed-phase mean drop diameter on the order of 1 μm or less.

The tension that exists between two liquid phases is called the **interfacial tension**. It is a measure of the energy or work required to increase the surface area of the liquid-liquid interface, and it affects the size of dispersed drops. Its value, in units of force per unit length or energy per unit area, reflects the compatibility of the two liquids. Systems that have low compatibility (low mutual solubility) exhibit high interfacial tension. Such a system tends to form relatively large dispersed drops and low interfacial area to minimize contact between the phases. Systems that are more compatible (with higher mutual solubility) exhibit lower interfacial tension and more easily form small dispersed droplets.

A **theoretical** or **equilibrium stage** is a device or combination of devices that accomplishes the effect of intimately mixing two liquid phases until equilibrium concentrations are reached, then physically separating the two phases into clear layers. The **partition ratio *K*** is commonly defined for a given solute as the solute concentration in the extract phase divided by that in the raffinate phase after equilibrium is attained in a single stage of contacting. A variety of concentration units are used, so it is important to determine how partition ratios have been defined in the literature for a given application. The term *partition ratio* is preferred, but it also is referred to as the **distribution constant**, **distribution coefficient**, or the ***K*** value. It is a measure of the

thermodynamic potential of a solvent for extracting a given solute and can be a strong function of composition and temperature. In some cases, the partition ratio transitions from a value less than unity to a value greater than unity as a function of solute concentration. A system of this type is called a **solutrope** [Smith, *Ind. Eng. Chem.*, **42**(6), pp. 1206–1209 (1950)]. The term *distribution ratio*, designated by $\mathcal{D}_i$, is used in analytical chemistry to describe the distribution of a species that undergoes chemical reaction or dissociation, in terms of the total concentration of analyte in one phase over that in the other, regardless of its chemical form.

The **extraction factor** $\mathcal{E}$ is a process variable that characterizes the capacity of the extract phase to carry solute relative to the feed phase. Its value largely determines the number of theoretical stages required to transfer solute from the feed to the extract. The extraction factor is analogous to the stripping factor in distillation and is the ratio of the slope of the equilibrium line to the slope of the operating line in a McCabe-Thiele type of stagewise graphical calculation. For a standard extraction process with straight equilibrium and operating lines, $\mathcal{E}$ is constant and equal to the partition ratio for the solute of interest times the ratio of the solvent flow rate to the feed flow rate. The **separation factor** $\alpha_{i,j}$ measures the relative enrichment of solute $i$ in the extract phase, compared to solute $j$, after one theoretical stage of extraction. It is equal to the ratio of $K$ values for components $i$ and $j$ and is used to characterize the **selectivity** a solvent has for a given solute.

A **standard extraction** process is one in which the primary purpose is to transfer solute from the feed phase into the extract phase in a manner analogous to stripping in distillation. **Fractional extraction** refers to a process in which two or more solutes present in the feed are sharply separated from each other, one fraction leaving the extractor in the extract and the other in the raffinate. **Cross-current or cross-flow extraction** (Fig. 15-5) is a series of discrete stages in which the raffinate $R$ from one extraction stage is contacted with additional fresh solvent $S$ in a subsequent stage. **Countercurrent extraction** (Fig. 15-6) is an extraction scheme in which the extraction solvent enters the stage or end of the extraction farthest from where the feed $F$ enters, and the two phases pass each other in countercurrent fashion. The objective is to transfer one or more components from the feed solution $F$ into the extract $E$. Compared to cross-current operation, countercurrent operation generally allows operation with less solvent. When a **staged contactor** is used, the two phases are mixed with droplets of one phase suspended in the other, but the phases are separated before leaving each stage. A **countercurrent cascade** is a process utilizing multiple staged contactors with countercurrent flow of solvent and feed streams from stage to stage. When a **differential contactor** is used, one of the phases can remain dispersed as drops throughout the contactor as the phases pass each other in countercurrent fashion. The dispersed phase is then allowed to coalesce at the end of the device before being discharged. For these types of processes, **mass-transfer units** (or the related **mass-transfer coefficients)** often are used instead of theoretical stages to characterize separation performance. For a given phase, mass-transfer units are

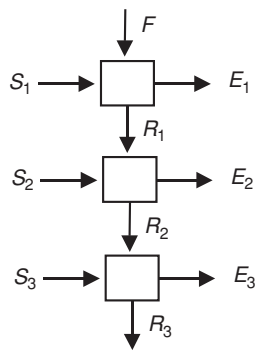

**FIG. 15-5** Cross-current extraction.

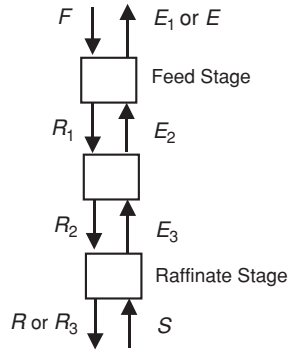

**FIG. 15-6** Standard countercurrent extraction.

defined as the integral of the differential change in solute concentration divided by the deviation from equilibrium, between the limits of inlet and outlet solute concentrations. A single transfer unit represents the change in solute concentration equal to that achieved by a single theoretical stage when the extraction factor is equal to 1.0. It differs from a theoretical stage at other values of the extraction factor.

The term *flooding* generally refers to excessive breakthrough or entrainment of one liquid phase into the discharge stream of the other. The flooding characteristics of an extractor limit its hydraulic capacity. Flooding can be caused by excessive flow rates within the equipment, by **phase inversion** due to accumulation and coalescence of dispersed droplets, or by formation of stable dispersions or emulsions due to the presence of surface-active impurities or excessive agitation. The **flood point** typically refers to the specific total volumetric **throughput** in $(m^3/h)/m^2$ or $gpm/ft^2$ of cross-sectional area (or the equivalent **phase velocity** in m/s or ft/s) at which flooding begins.

## DESIRABLE SOLVENT PROPERTIES

Common industrial solvents generally are single-functionality organic solvents such as ketones, esters, alcohols, linear or branched aliphatic hydrocarbons, aromatic hydrocarbons, and so on; or water, which may be acidic or basic or mixed with water-soluble organic solvents. More complex solvents are sometimes used to obtain specific properties needed for a given application. These include compounds with multiple functional groups such as diols or triols, glycol ethers, and alkanol amines as well as heterocyclic compounds such as pine-derived solvents (terpenes), sulfolane (tetrahydrothiophene-1,1-dioxane), and NMP (*N*-methyl-2-pyrrolidinone). Solvent properties have been summarized in a number of handbooks and databases including those by Cheremisinoff, *Industrial Solvents Handbook*, 2d ed. (Dekker, 2003); Wypych, *Handbook of Solvents* (ChemTech, 2001); Wypych, *Solvents Database*, CD-ROM (ChemTec, 2001); Yaws, *Thermodynamic and Physical Property Data*, 2d ed. (Gulf, 1998); and Flick, *Industrial Solvents Handbook*, 5th ed. (Noyes, 1998). Solvents are sometimes blended to obtain specific properties, another approach to achieving a multifunctional solvent with properties tailored for a given application. Examples are discussed by Escudero, Cabezas, and Coca [*Chem. Eng. Comm.*, **173,** pp. 135–146 (1999)] and by Delden et al. [*Chem. Eng. Technol.*, **29**(10), pp. 1221–1226 (2006)]. As discussed earlier, a solvent also may be a liquid containing a dissolved extractant species, the extractant chosen because it forms a specific attractive interaction with the desired solute.

In terms of desirable properties, no single solvent or solvent blend can be best in every respect. The choice of solvent often is a compromise, and the relative weighting given to the various considerations depends on the given situation. Assessments should take into account long-term sustainability and overall cost of ownership. Normally, the factors considered in choosing a solvent include the following.

1. *Loading capacity.* This property refers to the maximum concentration of solute the extract phase can hold before two liquid phases can no longer coexist or solute precipitates as a separate phase.

If a specialized extractant is used, loading capacity may be determined by the point at which all the extractant in solution is completely occupied by solute and extractant solubility limits capacity. If loading capacity is low, a high solvent-to-feed ratio may be needed even if the partition ratio is high.

2. *Partition ratio* $K_i = Y_i/X_i$. Partition ratios on the order of $K_i = 10$ or higher are desired for an economical process because they allow operation with minimal amounts of solvent (more specifically, with a minimal solvent-to-feed ratio) and production of higher solute concentrations in the extract—unless the solute concentration in the feed already is high and a limitation in the solvent's loading capacity determines the required solvent-to-feed ratio. Since high partition ratios generally allow for low solvent use, smaller and less costly extraction equipment may be used and costs for solvent recovery and recycle are lower. In principle, partition ratios less than $K_i = 1.0$ may be accommodated by using a high solvent-to-feed ratio, but usually at much higher cost.

3. *Solute selectivity*. In certain applications, it is important not only to recover a desired solute from the feed, but also to separate it from other solutes present in the feed and thereby achieve a degree of solute purification. The selectivity of a given solvent for solute *i* compared to solute *j* is characterized by the separation factor $\alpha_{i,j} = K_i/K_j$. Values must be greater than $\alpha_{i,j} = 1.0$ to achieve an increase in solute purity (on a solvent-free basis). When solvent blends are used in a commercial process, often it is because the blend provides higher selectivity, and often at the expense of a somewhat lower partition ratio. The degree of purification that can be achieved also depends on the extraction scheme chosen for the process, the amount of extraction solvent, and the number of stages employed.

4. *Mutual solubility*. Low liquid-liquid mutual solubility between feed and solvent phases is desirable because it reduces the separation requirements for removing solvents from the extract and raffinate streams. Low solubility of extraction solvent in the raffinate phase often results in high relative volatility for stripping the residual solvent in a raffinate stripper, allowing low-cost desolventizing of the raffinate [Hwang, Keller, and Olson, *Ind. Eng. Chem. Res.*, **31**(7), pp. 1753–1759 (1992)]. Low solubility of feed solvent in the extract phase reduces separation requirements for recovering solvent for recycle and producing a purified product solute. In some cases, if the solubility of feed solvent in the extract is high, more than one distillation operation will be required to separate the extract phase. If mutual solubility is nil (as for aliphatic hydrocarbons dissolved in water), the need for stripping or another treatment method may be avoided as long as efficient liquid-liquid phase separation can be accomplished without entrainment of solvent droplets into the raffinate. However, very low mutual solubility normally is achieved at the expense of a lower partition ratio for extracting the desired solute—because a solvent that has very little compatibility with the feed solvent is not likely to be a good extractant for something that is dissolved in the feed solvent—and therefore has some compatibility. Mutual solubility also limits the solvent-to-feed ratios that can be used, since a point can be reached where the solvent stream is so large it dissolves the entire feed stream, or the solvent stream is so small it is dissolved by the feed, and these can be real limitations for systems with high mutual solubility.

5. *Stability*. The solvent should have little tendency to react with the product solute and form unwanted by-products, causing a loss in yield. Also it should not react with feed components or degrade to undesirable contaminants that cause development of undesirable odors or color over time, or cause difficulty achieving desired product purity, or accumulate in the process because they are difficult to purge.

6. *Density difference*. As a general rule, a difference in density between solvent and feed phases on the order of 0.1 to 0.3 g/mL is preferred. A value that is too low makes for poor or slow liquid-liquid phase separation and may require use of a centrifuge. A value that is too high makes it difficult to build high dispersed-droplet population density for good mass transfer; i.e., it is difficult to mix the two phases together and maintain high holdup of the dispersed phase within the extractor—but this depends on the viscosity of the continuous phase.

7. *Viscosity*. Low viscosity is preferred since higher viscosity generally increases mass-transfer resistance and liquid-liquid phase separation difficulty. Sometimes an extraction process is operated at an elevated temperature where viscosity is significantly lower for better mass-transfer performance, even when this results in a lower partition ratio. Low viscosity at ambient temperatures also facilitates transfer of solvent from storage to processing equipment.

8. *Interfacial tension*. Preferred values for interfacial tension between the feed phase and the extraction solvent phase generally are in the range of 5 to 25 dyn/cm (1 dyn/cm is equivalent to $10^{-3}$ N/m). Systems with lower values easily emulsify. For systems with higher values, dispersed droplets tend to coalesce easily, resulting in low interfacial area and poor mass-transfer performance unless mechanical agitation is used.

9. *Recoverability*. The economical recovery of solvent from the extract and raffinate is critical to commercial success. Solvent physical properties should facilitate low-cost options for solvent recovery, recycle, and storage. For example, the use of relatively low-boiling organic solvents with low heats of vaporization generally allows cost-effective use of distillation and stripping for solvent recovery. Solvent properties also should enable low-cost methods for purging impurities from the overall process (lights and/or heavies) that may accumulate over time. One of the challenges often encountered in utilizing a high-boiling solvent or extractant involves accumulation of heavy impurities in the solvent phase and difficulty in removing them from the process. Another consideration is the ease with which solvent residues can be reduced to low levels in final extract or raffinate products, particularly for food-grade products and pharmaceuticals.

10. *Freezing point*. Solvents that are liquids at all anticipated ambient temperatures are desirable since they avoid the need for freeze protection and/or thawing of frozen solvent prior to use. Sometimes an "antifreeze" compound such as water or an aliphatic hydrocarbon can be added to the solvent, or the solvent is supplied as a mixture of related compounds instead of a single pure component—to suppress the freezing point.

11. *Safety*. Solvents with low potential for fire and reactive chemistry hazards are preferred as inherently safe solvents. In all cases, solvents must be used with a full awareness of potential hazards and in a manner consistent with measures needed to avoid hazards. For information on the safe use of solvents and their potential hazards, see Sec. 23, "Safety and Handling of Hazardous Materials." Also see Crowl and Louvar, *Chemical Process Safety: Fundamentals with Applications* (Prentice-Hall, 2001); Yaws, *Handbook of Chemical Compound Data for Process Safety* (Elsevier, 1997); Lees, *Loss Prevention in the Process Industries* (Butterworth, 1996); and *Bretherick's Handbook of Reactive Chemical Hazards*, 6th ed., Urben and Pitt, eds. (Butterworth-Heinemann, 1999).

12. *Industrial hygiene*. Solvents with low mammalian toxicity and good warning properties are desired. Low toxicity and low dermal absorption rate reduce the potential for injury through acute exposure. A thorough review of the medical literature must be conducted to ascertain chronic toxicity issues. Measures needed to avoid unsafe exposures must be incorporated into process designs and implemented in operating procedures. See Goetsch, *Occupational Safety and Health for Technologists, Engineers, and Managers* (Prentice-Hall, 2004).

13. *Environmental requirements*. The solvent must have physical or chemical properties that allow effective control of emissions from vents and other discharge streams. Preferred properties include low aquatic toxicity and low potential for fugitive emissions from leaks or spills. It also is desirable for a solvent to have low photoreactivity in the atmosphere and be biodegradable so it does not persist in the environment. Efficient technologies for capturing solvent vapors from vents and condensing them for recycle include activated carbon adsorption with steam regeneration [Smallwood, *Solvent Recovery Handbook* (McGraw-Hill, 1993), pp. 7–14] and vacuum-swing adsorption [Pezolt et al., *Environmental Prog.*, **16**(1), pp. 16–19 (1997)]. The optimization of a process to increase the efficiency of solvent utilization is a key aspect of waste minimization and reduction of environmental impact. An opportunity may exist to reduce solvent use through application of countercurrent processing and other chemical engineering principles aimed at improving processing efficiencies. For a discussion of environmental issues in

process design, see Allen and Shonnard, *Green Engineering: Environmentally Conscious Design of Chemical Processes* (Prentice-Hall, 2002)]. Also see Sec. 22, "Waste Management."

14. *Multiple uses*. It is desirable to use as the extraction solvent a material that can serve a number of purposes in the manufacturing plant. This avoids the cost of storing and handling multiple solvents. It may be possible to use a single solvent for a number of different extraction processes practiced in the same facility, either in different equipment operated at the same time or by using the same equipment in a series of product campaigns. In other cases, the solvent used for extraction may be one of the raw materials for a reaction carried out in the same facility, or a solvent used in another operation such as a crystallization.

15. *Materials of construction*. It is desirable for a solvent to allow the use of common, relatively inexpensive materials of construction at moderate temperatures and pressures. Material compatability and potential for corrosion are discussed in Sec. 25, "Materials of Construction."

16. *Availability and cost*. The solvent should be readily available at a reasonable cost. Considerations include the initial fill cost, the investment costs associated with maintaining a solvent inventory in the plant (particularly when expensive extractants are used), as well as the cost of makeup solvent.

## COMMERCIAL PROCESS SCHEMES

For the purpose of illustrating process concepts, liquid-liquid extraction schemes typically practiced in industry may be categorized into a number of general types, as discussed below.

**Standard Extraction** Also called simple extraction or single-solvent extraction, standard extraction is by far the most widely practiced type of extraction operation. It can be practiced using single-stage or multistage processing, cross-current or countercurrent flow of solvent, and batch-wise or continuous operation. Figure 15-6 illustrates the contacting stages and liquid streams associated with a typical multistage, countercurrent scheme. Standard extraction is analogous to stripping in distillation because the process involves transferring or stripping components from the feed phase into another phase. Note that the feed ($F$) enters the process where the extract stream ($E$) leaves the process, analogous to feeding the top of a stripping tower. And the raffinate ($R$) leaves where the extraction solvent ($S$) enters. Standard extraction is used to remove contaminants from a crude liquid feed (product purification) or to recover valuable components from the feed (product recovery). Applications can involve very dilute feeds, such as when purifying a liquid product or detoxifying a wastewater stream, or concentrated feeds, such as when recovering a crude product from a reaction mixture. In either case, standard extraction can be used to transfer a high fraction of solute from the feed phase into the extract. Note, however, that transfer of the desired solute or solutes may be accompanied by transfer of unwanted solutes. Because of this, standard extraction normally cannot achieve satisfactory solute purity in the extract stream unless the separation factor for the desired solute with respect to unwanted solutes is at least $\alpha_{i,j} = K_i/K_j = 20$ and usually much higher. This depends on the crude feed purity and the product purity specification. (See "Potential for Solute Purification Using Standard Extraction" under "Process Fundamentals and Basic Calculation Methods.")

**Fractional Extraction** Fractional extraction combines solute recovery with cosolute rejection. In principle, the process can achieve high solute recovery and high solute purity even when the solute separation factor is fairly low, as low as $\alpha_{i,j} = 4$ or so (see "Dual-Solvent Fractional Extraction" under "Calculation Procedures"). Dual-solvent fractional extraction utilizes an extraction solvent ($S$) and a wash solvent ($W$) and includes a stripping section at the raffinate end of the process (for product-solute recovery) and a washing section at the extract end of the process (for cosolute rejection and product purification) (Fig. 15-7). The feed enters the process at an intermediate stage located between the extract and raffinate ends. In this respect, the process is analogous to a middle-fed fractional distillation, although the analogy is not exact since wash solvent is added to the extract end of the process instead of returning a reflux stream. The

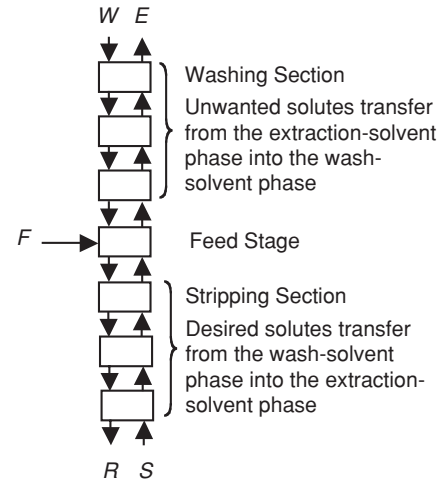

**FIG. 15-7** Dual-solvent fractional extraction without reflux.

desired solutes transfer into the extraction solvent (the extract phase) within the stripping section, and unwanted solutes transfer into the wash solvent (the raffinate phase) within the washing section. Typically, the feed stream consists of feed solutes predissolved in wash solvent or extraction solvent; or, if they are liquids, they may be injected directly into the process. To maximize performance, a fractional extraction process may be operated such that the washing and stripping sections are carried out in different equipment and at different temperatures. The stripping section is sometimes called the extraction section, and the washing section is sometimes called the enriching section, the scrubbing section, or the absorbing section. A dual-solvent fractional extraction process involving reflux to the washing section is shown in Fig. 15-8.

In a special case referred to as single-solvent fractional extraction with extract reflux, the wash solvent is comprised of components that

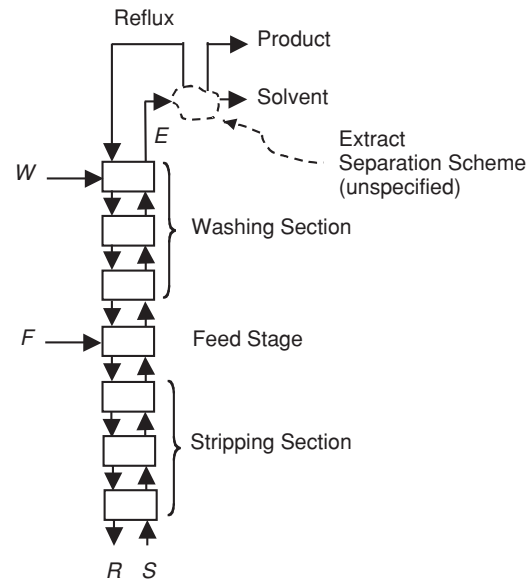

**FIG. 15-8** Process concepts for dual-solvent fractional extraction with extract reflux.

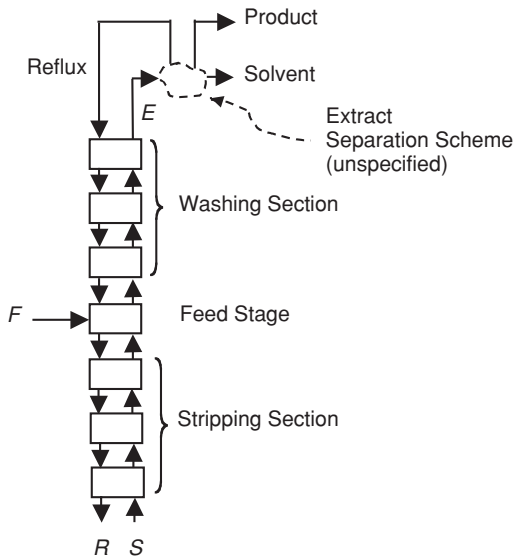

**FIG. 15-9** Process concepts for single-solvent fractional extraction with extract reflux. The process flow sheet shown in Fig. 15-2 is an example of this general process scheme.

enter the overall process with the feed and return as reflux (Fig. 15-9). This is the type of extraction scheme commonly used to recover aromatic components from crude hydrocarbon mixtures using high-boiling polar solvents (as in Fig. 15-2). A reflux stream rich in light aromatics including benzene is refluxed to the washing section to serve as wash solvent. This process scheme is very similar in concept to fractional distillation. It is used only in a very limited number of applications [Stevens and Pratt, Chap. 6, in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992), pp. 379–395]. More detailed discussion is given in "Single-Solvent Fractional Extraction with Extract Reflux" under "Calculation Procedures."

In terms of common practice, fractional extraction operations may be classified into several types: (1) standard extraction augmented by addition of a washing section utilizing a relatively small amount of feed solvent as the wash solvent; (2) full fractionation (less common); and (3) full fractionation with solute reflux (much less common). The first two categories are examples of dual-solvent fractional extraction. The third category can be practiced as dual-solvent or single-solvent fractional extraction.

In the first type of operation, a relatively small amount of feed solvent is added to a short washing section as wash solvent. (The word *short* is used here in an extraction column context, but refers in general to a relatively few theoretical stages.) This approach is useful for systems exhibiting a moderate to high solute separation factor ($\alpha_{i,j} > 20$ or so) and requiring a boost in product-solute purity. An example involves recovery of an organic solute from a dilute brine feed by using a partially miscible organic solvent. In this case, the inorganic salt present in the aqueous feed stream has some solubility in the organic solvent phase because of water that saturates that phase, and the partition ratio for transfer of salt into the organic phase is small (i.e., the partition ratio for transfer of salt into wash water is high). Adding wash water to the extract end of the process has the effect of washing a portion of the soluble salt content out of the organic extract. The reduction in salt content depends on how much wash water is added and how many washing stages or transfer units are used in the design.

The second type of fractional extraction operation involves the use of stripping and washing sections without reflux (Fig. 15-7) to separate a mixture of feed solutes with close $K$ values. In this case, the solute separation factor is low to moderate. Normally, $\alpha_{i,j}$ must be greater than about 4 for a commercially viable process. Scheibel [*Chem. Eng. Prog.*, **44**(9), pp. 681–690 (1948); and **44**(10), pp. 771–782 (1948)] gives several instructive examples of fractional extraction: (1) separation of ortho and para chloronitrobenzenes using heptane and 85% aqueous methanol as solvents ($\alpha_{\text{para,ortho}} \approx 1.6$ to 1.8); (2) separation of ethanol and isopropanol by using water and xylene ($\alpha_{\text{ethanol,isopropanol}} \approx 2$); and (3) separation of ethanol and methyl ethyl ketone (MEK) by using water and kerosene ($\alpha_{\text{ethanol,MEK}} \approx 10$ to 20). The first two applications demonstrate fractional extraction concepts, but a sharp separation is not achieved because the selectivity of the solvent is too low. In these kinds of applications, fractional extraction might be combined with another separation operation to complete the separation. (See "Hybrid Extraction Processes.") In Scheibel's third example, the selectivity is much higher and nearly complete separation is achieved by using a total of about seven theoretical stages. In another example, Venter and Nieuwoudt [*Ind. Eng. Chem. Res.*, **37**(10), pp. 4099–4106 (1998)] describe a dual-solvent extraction process using hexane and aqueous tetraethylene glycol to selectively recover *m*-cresol from coal pyrolysis liquors also containing *o*-toluonitrile. This process has been successfully implemented in industry. The separation factor for *m*-cresol with respect to *o*-toluonitrile varies from 5 to 70 depending upon solvent ratios and the resulting liquid compositions. The authors compare a standard extraction configuration (bringing the feed into the first stage) with a fractional extraction configuration (bringing the feed into the second stage of a seven theoretical-stage process).

Another example of the use of dual-solvent fractional extraction concepts involves the recovery of ε-caprolactam monomer (for nylon-6 production) from a two-liquid-phase reaction mixture containing ammonium sulfate plus smaller amounts of other impurities, using water and benzene as solvents [Simons and Haasen, Chap. 18.4 in *Handbook of Solvent Extraction* (Wiley, 1983; Krieger, 1991)]. In this application, the separation factor for caprolactam with respect to ammonium sulfate is high because the salt greatly favors partitioning into water; however, separation factors with respect to the other impurities are smaller. Alessi et al. [*Chem. Eng. Technol.*, **20,** pp. 445–454 (1997)] describe two process schemes used in industry. These are outlined in Fig. 15-10. The simpler scheme (Fig. 15-10*a*) is a straightforward dual-solvent fractional extraction process that isolates caprolactam (CPL) in a benzene extract stream and ammonium sulfate (AS) in the aqueous raffinate. The feed stage is comprised of mixer M1 and settler S1, and separate extraction columns are used for the washing and stripping sections. In Fig. 15.10*a*, these are denoted by C1 and C2, respectively. Minor impurity components also present in the feed must exit the process in either the extract or the raffinate. The more complex scheme (Fig. 15-10*b*) eliminates addition of benzene to the feed stage and adds a back-extraction section at the extract end of the process (denoted by C4) to extract CPL from the benzene phase leaving the washing section. Also, a separate fractional extractor (denoted as C1 in Fig. 15-10*b*) is added between the original stripping and washing sections to treat the benzene phase leaving the stripping section and recover the CPL content of the CPL-rich aqueous stream leaving the feed stage. In the C1 extractor, the CPL transfers into the benzene stream that ultimately enters the upper washing section, leaving hydrophilic impurities in an aqueous purge stream that exits at the bottom. The resulting process scheme includes two purge streams for rejecting minor impurities: a stream rich in heavy organic impurities leaving the bottom of the benzene distillation tower and the aqueous stream rich in hydrophilic impurities leaving the bottom of the C1 extractor. This sophisticated design separates the feed into four streams instead of just two, allowing separate removal of two impurity fractions to increase the purity of the two main products. The caprolactam is made to transfer into either an aqueous or a benzene-rich stream as desired, by judicious choice of solvent-to-feed ratio at the various sections in the process (perhaps aided by adjustment of temperature).

A dual-solvent fractional extraction process can provide a powerful separation scheme, as indicated by the examples given above, and some authors suggest that fractional extraction is not utilized as much as it could be. In many cases, instead of using full fractional extraction, standard extraction is used to recover solute from a crude feed; and if the solvent-to-feed ratio is less than 1.0, concentrate the solute in a smaller solute-bearing stream. Another operation such as crystallization, adsorption, or process chromatography is then used downstream for solute purification. Perhaps fractional extraction schemes should be evaluated more often as an alternative processing scheme that may have advantages.

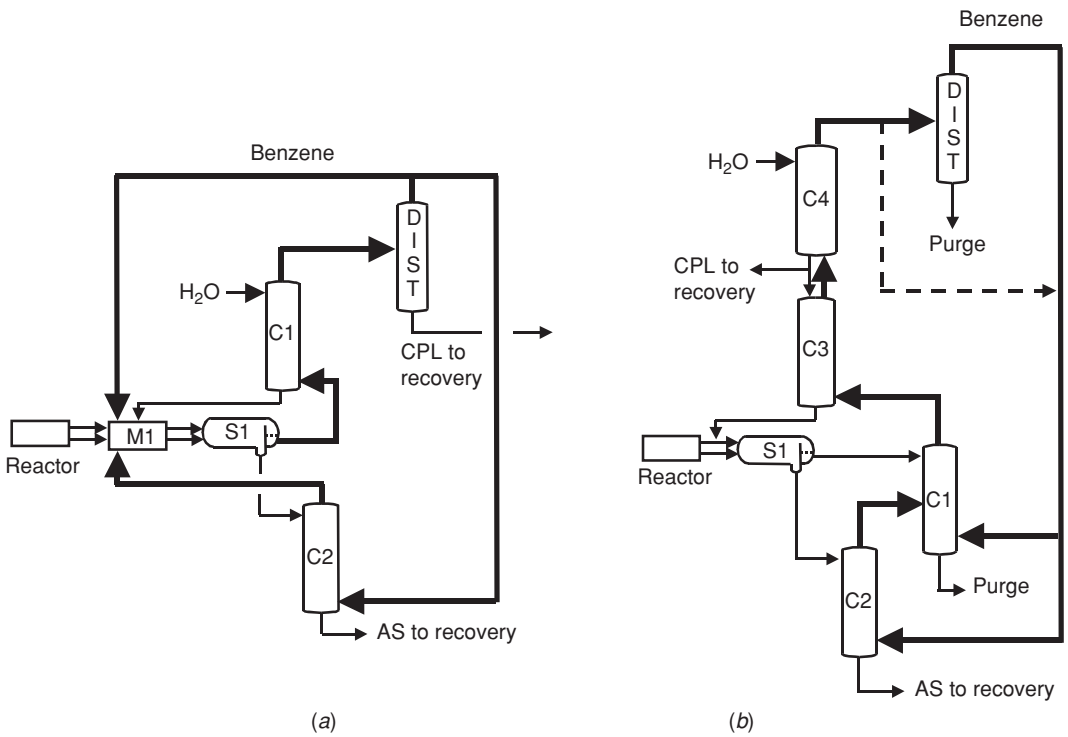

**FIG. 15-10** Two industrial extraction processes for separation of caprolactam (CPL) and ammonium sulfate (AS): (*a*) a simpler fractional extraction scheme; (*b*) a more complex scheme. Heavy lines denote benzene-rich streams; light lines denote aqueous streams. [*Taken from Alessi, Penzo, Slater, and Tessari,* Chem. Eng. Technol., ***20***(7), *pp. 445–454 (1997), with permission. Copyright 1997 Wiley-VCH.*]

The third type of fractional extraction operation involves refluxing a portion of the extract stream back to the extract end (washing section) of the process. As mentioned earlier, this process can be practiced as a dual-solvent process (Fig. 15-8) or as a single-solvent process (Figs. 15-2 and 15-9). However, unlike in distillation, the use of reflux is not common. The reflux consists of a portion of the extract stream from which a significant amount of solvent has been removed. Injection of this solvent-lean, concentrated extract back into the washing section increases the total amount of solute and the amount of raffinate phase present in that section of the extractor. This can boost separation performance by allowing the process to operate at a more favorable location within the phase diagram, resulting in a reduction in the number of theoretical stages or transfer units needed within the washing section. This also allows the process to boost the concentration of solute in the extract phase above that in equilibrium with the feed phase. The increased amount of solute present within the process may require use of extra solvent to avoid approaching the plait point at the feed stage (the composition at which only a single liquid phase can exist at equilibrium). Because of this, utilizing reflux normally involves a tradeoff between a reduction in the number of theoretical stages and an increase in the total liquid traffic within the process equipment, requiring larger-capacity equipment and increasing the cost of solvent recovery and recycle. This tradeoff is discussed by Scheibel with regard to extraction column design [*Ind. Eng. Chem.*, **47**(11), pp. 2290–2293 (1955)]. The potential benefit that can be derived from the use of extract reflux is greatest for applications utilizing solvents with a low solute separation factor and low partition ratios (as in the example illustrated in Fig. 15-2). In these cases, reflux serves to reduce the number of required theoretical stages or transfer units to a practical number on the order of 10 or so, or reduce the solvent-to-feed ratio required for the desired separation.

The fractional extraction schemes described above are typical of those practiced in industry. A related kind of process employs a second solvent in a separate extraction operation to wash the raffinate produced in an upstream extraction operation. This process scheme is particularly useful when the wash solvent is only slightly soluble in the raffinate and can easily be removed. An example is the use of water to remove residual amine solvent from the treated hydrocarbon stream in an acid-gas extraction process (Fig. 15-3).

A potential fourth type of fractional extraction operation involves the use of reflux at both ends of a dual-solvent process, i.e., reflux to the raffinate end of the process (the stripping section) as well as reflux to the extract end of the process (the washing section). The authors are not aware of a commercial application of this kind; however, Scheibel [*Chem. Eng. Prog.*, **62**(9), pp. 76–81 (1966)] discusses such a process scheme in light of several potential flow sheets. In the special case of single-solvent fractional extraction with extract reflux, Skelland [*Ind. Eng. Chem.*, **53**(10), pp. 799–800 (1961)] has pointed out that addition of raffinate reflux is not effective from a strictly thermodynamic point of view as it cannot reduce the required number of theoretical stages in this special case.

**Dissociative Extraction** This process scheme normally involves partitioning of weak organic acids or bases between water and an organic solvent. Whether the solute partitions mainly into one phase or the other depends upon whether it is in its neutral state or its charged ionic state and the ability of each phase to solvate that form of the solute. In general, water interacts much more strongly with the charged species, and the ionic form will strongly favor partitioning into the aqueous phase. The nonionic form generally will favor partitioning into the organic phase.

The $pK_a$ is the pH at which 50 percent of the solute is in the dissociated (ionized) state. It is a function of solute concentration and normally is reported for dilute conditions. For an organic acid (RCOOH) dissolved in aqueous solution, the amount of solute in the dissociated state relative to that in the nondissociated state is $[RCOO^-]/[RCOOH] = 10^{pH-pK_a}$. Extraction of an organic acid out of an organic feed into an aqueous phase is greatly facilitated by operating at a pH

above the acid's $pK_a$ value because the majority of the acid will be deprotonated to yield the dissociated form ($RCOO^-$). On the other hand, partitioning of the organic acid from an aqueous feed into an organic solvent is favored by operating at a pH below its $pK_a$ to ensure most of the acid is in the protonated (nondissociated) form. Another example involves extraction of a weak base, such as a compound with amine functionality ($RNH_2$), out of an organic phase into water at a pH below the $pK_a$. This will protonate or neutralize the majority of the base, yielding the ionized form ($RNH_3^+$) and favoring extraction into water. It follows that extracting an organic base out of an aqueous feed into an organic solvent is favored by operating at a pH above its $pK_a$ since this yields most of the solute in the free base (nonionized) form. For weak bases, $pK_a = 14 - pK_b$, and the relative amount of solute in the dissociated state in the aqueous phase is given by $10^{pK_a - pH}$. In principle, to obtain the maximum partition ratio for an extraction, the pH should be maintained about 2 units from the solute's $pK_a$ value to obtain essentially complete dissociation or nondissociation, as appropriate for the extraction. In a typical continuous application, the pH of the aqueous stream leaving the process is controlled at a constant pH set point by injection of acid or base at the opposite end of the process, and a pH gradient exists within the process. The pH set point may be adjusted to optimize performance. The effect of pH on the partition ratio is discussed in "Effect of pH for Ionizable Organic Solutes" under "Thermodynamic Basis for Liquid-Liquid Extraction." Determination of the optimum pH for extraction of compounds with multiple ionizable groups and thus multiple $pK_a$ values is discussed by Crocker, Wang, and McCauley [*Organic Process Res. Dev.*, **5**(1), pp. 77–79 (2001)].

In fractional dissociative extraction, a sharp separation of feed solutes is achieved by taking advantage of a difference in their $pK_a$ values. If the difference in $pK_a$ is sufficient, controlling pH at a specific value can yield high $K$ values for one solute fraction and very low $K$ values for another fraction, thus allowing a sharp separation. For example, a mixture of two organic bases can be separated by contacting the mixture with an aqueous acid containing less than the stoichiometric amount of acid needed to neutralize (ionize) both bases. The stronger of the two bases reacts with the acid to yield the dissociated form in the aqueous phase, while the other base remains undissociated in a separate organic phase. Buffer compounds may be used to control pH within a desired range for improved separation results [Ma and Jha, *Organic Process Res. Dev.*, **9**(6), pp. 847–852 (2005)]. Buffers are discussed by Perrin and Dempsey [*Buffers for pH and Metal Ion Control* (Chapman and Hall, 1979)]. For additional discussion, see Pratt, Chap. 21 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991), and Anwar, Arif, and Pritchard, *Solvent Ext. Ion Exch.*, **16,** p. 931 (1998).

**pH-Swing Extraction** A pH-swing extraction process utilizes dissociative extraction concepts to recover and purify ionizable organic solutes in a forward- and back-extraction scheme, each extraction operation carried out at a different pH. For example, in the forward extraction, the desired solute may be in its nonionized state so it can be extracted out of a crude aqueous feed into an organic solvent. The extract stream from this operation is then fed to a separate extraction operation where the solute is ionized by readjustment of pH and back-extracted into clean water. This scheme can achieve both high recovery and high purity if the impurity solutes are not ionizable or have $pK_a$ values that differ greatly from those of the desired solute. A pH-swing extraction scheme commonly is used for recovery and purification of antibiotics and other complex organic solutes with some ionizable functionality. The production of high-purity food-grade phosphoric acid from lower-grade acid is another example of a pH-swing process ["Purification of Wet Phosphoric Acid" in *Ullmann's Encyclopedia of Industrial Chemistry*, 6th ed. (VCH, 2002)].

**Reaction-Enhanced Extraction** Reaction-enhanced extraction involves enhancement of the partition ratio for extraction through the use of a reactive extractant that forms a reversible adduct or molecular complex with the desired solute. Normally, the extractant compound is dissolved in a diluent liquid such as kerosene or another high-boiling hydrocarbon. Because reactive extractants form strong specific interactions with the solute molecule, they can provide much higher partition ratios and generally are more selective compared to conventional solvents. Also, when used to recover relatively volatile compounds, extractants may allow significant reduction in the energy required to separate the extract phase by distillation. Extractants are successfully used at very large scales to recover metals in hydrometallurgical processing, among other applications. However, it is important to note that the use of high-boiling extractants can present severe difficulties whenever high-boiling impurities are present. A number of commercial processes have failed because there was no economical option for purging high-boiling contaminants that accumulated in the solvent phase over time, so care must be taken to address this possibility when developing a new application. The advantages and disadvantages of using high-boiling solvents or extractants versus low-boiling solvents are discussed by King in the context of acetic acid recovery [Chap. 18.5 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991)].

Detailed reviews of reactive extractants are given by Cox [Chap. 1 in *Science and Practice of Liquid-Liquid Extraction*, vol. 2 (Oxford, 1992), (pp. 1–27)] and by King [Chap. 15 in *Handbook of Separation Process Technology*, Rousseau, ed. (Wiley, 1987)]. Also see *Solvent Extraction Principles and Practice*, 2d ed., Rydberg et al., eds. (Dekker, 2004). Cox has classified extractants as either acidic, ion-pair-forming or solvating (nonionic) according to the mechanism of solute-solvent interaction in solution. In hydrometallurgical applications involving recovery or purification of metals dissolved in aqueous feed solutions, commercial extractants include acid chelating agents, alkyl amines, and various organophosphorous compounds including trioctylphosphene oxide (TOPO) and tri-*n*-butyl phosphate, plus quaternary ammonium salts. A well-known example is the use of TOPO to remove arsenic impurities from copper electrolyte solutions produced in copper refining operations. Another well-known class of applications involves formation of ion-pair interactions between a carboxylic acid dissolved in an aqueous feed and alkylamine extractants such as trioctylamine dissolved in a hydrocarbon diluent, as discussed by Wennersten [*J. Chem. Technol. Biotechnol.*, **33B**, pp. 85–94 (1983)], by King and others [*Ind. Eng. Chem. Res.*, **29**(7), pp. 1319–1338 (1990); and *Chemtech*, **22,** p. 285 (1992)], and by Schunk and Maurer [*Ind. Eng. Chem. Res.*, **44**(23), pp. 8837–8851 (2005)]. Extractants also may be used to facilitate extraction of other ionizable organic solutes including certain antibiotics [Pai, Doherty, and Malone, *AIChE J.*, **48**(3), pp. 514–526 (2002)]. Sometimes mixing extractants with promoter compounds (called modifiers) provides synergistic effects that dramatically enhance the partition ratio. An example is discussed by Atanassova and Dukov [*Sep. Purif. Technol.*, **40**, pp. 171–176 (2004)]. Also see the discussion of combined physical (hydrogen-bonding) and reaction-enhanced extraction by Lee [*Biotechnol. Prog.*, **22**(3), pp. 731–736 (2006)].

**Extractive Reaction** Extractive reaction combines reaction and separation in the same unit operation for the purpose of facilitating a desired reaction. To avoid confusion, the term *extractive reaction* is recommended for this type of process, while the term *reaction-enhanced extraction* is recommended for a process involving formation of reversible solute-extractant interactions and enhanced partition ratios for the purpose of facilitating a desired separation. The term *reactive extraction* is a more general term commonly used for both types of processes.

In general, extractive reaction involves carrying out a reaction in the presence of two liquid phases and taking advantage of the partitioning of reactants, products, and homogeneous catalyst (if used) between the two phases to improve reaction performance. The classes of reactions that can benefit from an extractive reaction scheme include chemical-equilibrium-limited reactions (such as esterifications, transesterifications, and hydrolysis reactions), where it is important to remove a product or by-product from the reaction zone to drive conversion, and consecutive or sequential reactions (such as nitrations, sulfonations, and alkylations), where the goal may be to produce only the mono- or difunctional product and minimize formation of subsequent addition products. For additional discussion, see Gorissen, *Chem Eng. Sci.*, **58,** pp. 809–814 (2003); Van Brunt and Kanel, Chap. 3, in *Reactive Separation Processes*, S. Kulprathipanja, ed. (Taylor & Francis, 2002), pp. 51–92; and Hanson, "Extractive Reaction Processes," Chap. 22 in *Handbook of Solvent*

*Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991), pp. 615–618.

The manufacture of fatty acid methyl esters (FAME) for use as biodiesel fuel, by transesterification of triglyceride oils and greases [Canakci and Van Gerpen, *ASAE Trans.*, **46**(4), pp. 945–954 (2003)], provides an example of a chemical-equilibrium-limited extractive reaction. Low-grade triglycerides are reacted with methanol to produce FAME plus glycerin as a by-product. Because glycerin is only partially miscible with the feed and the FAME product, it transfers from the reaction zone into a separate glycerin-rich liquid phase, driving further conversion of the triglycerides. In another example, Minotti, Doherty, and Malone [*Ind. Eng. Chem. Res.*, **37**(12), pp. 4748–4755 (1998)] studied the esterification of aqueous acetic acid by reaction with butanol in an extractive reaction process involving extraction of the butyl acetate product into a separate butanol-rich phase. The authors concluded that cocurrent processing is preferred over countercurrent processing in this case. Their general conclusions likely apply to other applications involving extraction of a reaction product out of the reaction phase to drive conversion. The cocurrent scheme is equivalent to a series of two-liquid-phase stirred-tank reactors approaching the performance of a plug-flow reactor. Rohde, Marr, and Siebenhofer [Paper no. 232f, AIChE Annual Meeting, Austin, Tex., Nov. 7–12, 2004] studied the esterification of acetic acid with methanol to produce methyl acetate. Their extractive reaction scheme involves selective transfer of methyl acetate into a high-boiling solvent such as *n*-nonane.

An example of a sequential-reaction extractive reaction is the manufacture of 2,4-dinitrotoluene, an important precursor to 2,4-diaminotoluene and toluene diisocyanate (TDI) polyurethanes. The reaction involves nitration of toluene by using concentrated nitric and sulfuric acids which form a separate phase. Toluene transfers into the acid phase where it reacts with nitronium ion, and the reaction product transfers back into the organic phase. Careful control of liquid-liquid contacting conditions is required to obtain high yield of the desired product and minimize formation of unwanted reaction products. A similar reaction involves nitration of benzene to mononitrobenzene, a precursor to aniline used in the manufacture of many products including methylenediphenylisocyanate (MDI) for polyurethanes [Quadros, Reis, and Baptista, *Ind. Eng. Chem. Res.*, **44**(25), pp. 9414–9421 (2005)].

Another category of extractive reaction involves the extraction of a product solute during microbial fermentation (biological reaction) to avoid microbe inhibition effects, allowing an increase in fermenter productivity. An example involving production of ethanol is discussed by Weilnhammer and Blass [*Chem. Eng. Technol.*, **17,** pp. 365–373 (1994)], and an example involving production of propionic acid is discussed by Gu, Glatz, and Glatz [*Biotechnol. and Bioeng.*, **57**(4), pp. 454–461 (1998)]. Finally, the scrubbing of reactive components from a feed liquid, by irreversible reaction with a treating solution, also may be considered an extractive reaction. An example is removal of acidic components from petroleum liquids by reaction with aqueous NaOH.

**Temperature-Swing Extraction** Temperature-swing processes take advantage of a change in $K$ value with temperature. An extraction example is the commercial process used to recover citric acid from whole fermentation broth by using trioctylamine (TOA) extractant [Baniel et al., U.S. Patent 4,275,234 (1981); Wennersten, *J. Chem. Biotechnol.*, **33B,** pp. 85–94 (1983); and Pazouki and Panda, *Bioprocess Eng.*, **19,** pp. 435–439 (1998)]. This process involves a forward reaction-enhanced extraction carried out at 20 to 30°C in which citric acid transfers from the aqueous phase into the extract phase. Relatively pure citric acid is subsequently recovered by back extraction into clean water at 80 to 100°C, also liberating the TOA extractant for recycle. This temperature-swing process is feasible because partitioning of citric acid into the organic phase is favored at the lower temperature but not at 80 to 100°C.

Partition ratios can be particularly sensitive to temperature when solute-solvent interactions in one or both phases involve specific attractive interactions such as formation of ion-pair bonds (as in trialkyamine–carboxylic acid interactions) or hydrogen bonds, or when mutual solubility between feed and extraction solvent involves hydrogen bonding. An interesting example is the extraction of citric acid from water with 1-butoxy-2-propanol (common name propylene glycol *n*-butyl ether) as solvent (Fig. 15-11). This example illustrates how important it can be when developing and optimizing an extraction operation to understand how $K$ varies with temperature, regardless of whether a temperature-swing process is contemplated. Of course, changes in other properties such as mutual solubility and viscosity also must be considered. For additional discussion, see "Temperature Effect" under "Thermodynamic Basis for Liquid-Liquid Extraction."

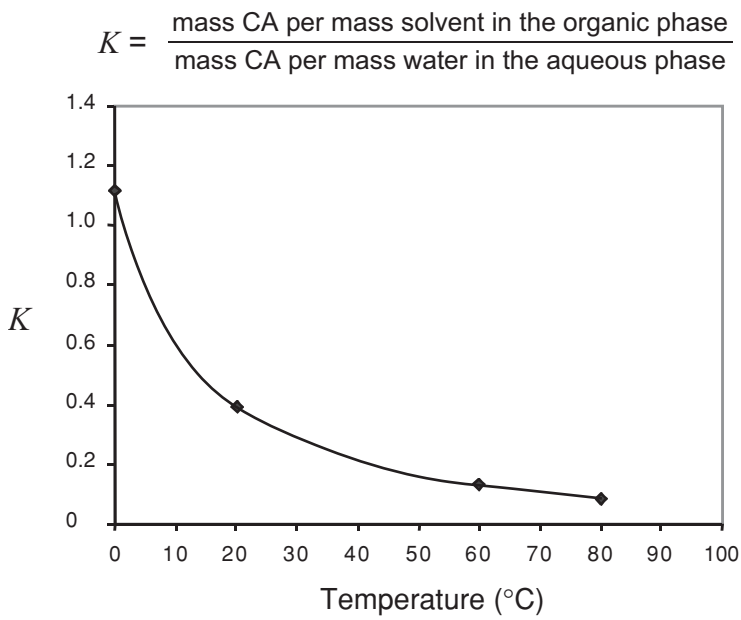

**FIG. 15-11** Partition ratio as a function of temperature for recovery of citric acid (CA) from water using 1-butoxy-2-propanol (propylene glycol *n*-butyl ether). (*Data generated by The Dow Chemical Company.*)

**Reversed Micellar Extraction** This scheme involves use of microscopic water-in-oil micelles formed by surfactants and suspended within a hydrophobic organic solvent to isolate proteins from an aqueous feed. The micelles essentially are microdroplets of water having dimensions on the order of the protein to be isolated. These stabilized water droplets provide a compatible environment for the protein, allowing its recovery from a crude aqueous feed without significant loss of protein activity [Ayala et al., *Biotechnol. and Bioeng.*, **39,** pp. 806–814 (1992); and Bordier, *J. Biolog. Chem.*, **256**(4), pp. 1604–1607 (February 1981)]. Also see the discussion of ultrafiltration membranes for concentrating micelles in "Liquid-Liquid Phase Separation Equipment."

**Aqueous Two-Phase Extraction** Also called aqueous biphasic extraction, this technique generally involves use of two incompatible water-miscible polymers [normally polyethylene glycol (PEG) and dextran, a starch-based polymer], or a water-miscible polymer and a salt (such as PEG and $Na_2SO_4$), to form two immiscible aqueous phases each containing 75+% water. This technology provides mild conditions for recovery of proteins and other biomolecules from broth or other aqueous feeds with minimal loss of activity [Walter and Johansson, eds., *Aqueous Two Phase Systems*, *Methods in Enzymology*, vol. 228 (Academic, 1994); Zaslavsky, *Aqueous Two-Phase Partitioning* (Dekker, 1994); and Blanch and Clark, Chap. 6 in *Biochemical Engineering* (Dekker, 1997) pp. 474–482]. The effect of salts on the liquid-liquid phase equilibrium of polyethylene glycol + water mixtures has been extensively studied [Salabat, *Fluid Phase Equil.*, **187–188,** pp. 489–498 (2001)]. A typical phase diagram, for PEG 6000 + $Na_2SO_4$ + water, is shown in Fig. 15-12. The hydraulic characteristics of the aqueous two-phase system PEG 4000 + $Na_2SO_4$ + water in a countercurrent sieve plate column have been reported by Hamidi et al. [*J. Chem. Technol. Biotechnol.*, **74,** pp. 244–249 (1999)]. Two immiscible aqueous phases also may be formed by using two incompatible salts. An example is the system formed by using the hydrophilic organic salt 1-butyl-3-methylimidazolium chloride and a water-structuring (kosmotropic) salt such as $K_3PO_4$ [Gutowski et al., *J. Am. Chem. Soc.*, **125,** p. 6632 (2003)].

**Hybrid Extraction Processes** Hybrid processes employ an extraction operation in close association with another unit operation. In these processes, the individual unit operations may not be able to achieve all the separation goals, or the use of one or the other operation alone may not be as economical as the hybrid process. Common examples include the following.

***Extraction-distillation*** An example involves the use of extraction to break the methanol + dichloromethane azeotrope. The near-azeotropic overheads from a distillation tower can be fed to an extractor where water is used to extract the methanol content and generate nearly methanol-free dichloromethane (saturated with roughly 2000 ppm water). A related type of extraction-distillation operation involves closely coupling extraction with the distillate or bottoms stream produced by a distillation tower, such that the distillation specification for that stream can be relaxed. For example, this approach has been used to facilitate distillation of aqueous acetic acid to produce acetic acid as a bottoms product, taking a mixture of acidic acid and water overhead [Gualy et al., U.S. Patent 5,492,603 (1996)]. The distillate is sent to an extraction tower to recover the acetic acid content for recycle back to the process. The hybrid process allows operation with lower energy consumption compared to distillation alone, because it allows the distillation tower to operate with a reduced requirement for recovering acetic acid in the bottoms stream, which permits relaxation of the minimum concentration of acetic acid allowed in the distillate. Another type of hybrid process involves combining liquid-liquid extraction with azeotropic or extractive distillation of the extract [Skelland and Tedder, chap. 7, in *Handbook of Separation Process Technology*, Roussean, ed. (Wiley, 1987), pp. 449–453]. The solvent serves both as the extraction solvent for the upstream liquid-liquid extraction operation and as the entrainer for a subsequent azeotropic distillation or as the distillation solvent for a subsequent extractive distillation. (For a detailed discussion of azeotropic and extraction distillation concepts, see Sec. 13, "Distillation.") The solvent-to-feed ratio must be optimized with regard to both the liquid-liquid extraction operation and the downstream distillation operation. An example is the use of ethyl acetate to extract acetic acid from an aqueous feed, followed by azeotropic distillation of the extract to produce a dry acetic acid bottoms product and an ethyl acetate + water overheads stream. In this example, ethyl acetate serves as the extraction solvent in the extractor and as the entrainer for removing water overhead in the distillation tower. Examples involving extractive distillation and high-boiling solvents can be seen in the various processes used to recover aromatics from aliphatic hydrocarbons, as described by Mueller et al., in *Ullmann's Encyclopedia of Industrial Chemistry*, 5th ed., vol. B3, Gerhartz, ed. (VCH, 1988), pp. 6-34 to 6-43.

***Extraction-crystallization*** Extraction often is used in association with a crystallization operation. In the pharmaceutical and specialty chemical industries, extraction is used to recover a product compound (or remove impurities) from a crude reaction mixture, with subsequent crystallization of the product from the extract (or from the preextracted reaction mixture). In many of these applications, the product needs to be delivered as a pure crystalline solid, so crystallization is a necessary

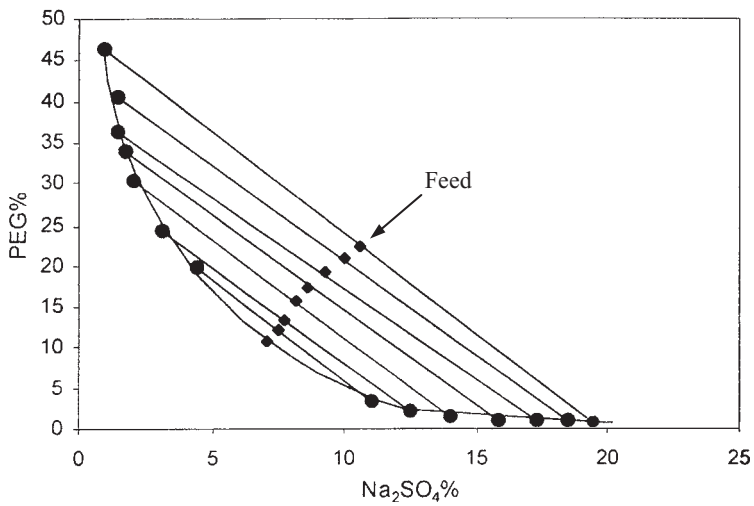

**FIG. 15-12** Equilibrium phase diagram for PEG 6000 + $Na_2SO_4$ + water at 25°C. [*Reprinted from Salabat*, Fluid Phase Equil., ***187–188,*** *pp. 489–498 (2001), with permission. Copyright 2001 Elsevier B. V.*]

operation. (For a detailed discussion of crystallization operations, see Sec. 18, "Liquid-Solid Operations and Equipment.") The desired solute can sometimes be crystallized directly from the reaction mixture with sufficient purity and yield, thus avoiding the cost of the extraction operation; however, direct crystallization generally is more difficult because of higher impurity concentrations. In cases where direct crystallization is feasible, deciding whether to use extraction prior to crystallization or crystallization alone involves consideration of a number of tradeoffs and ultimately depends on the relative robustness and economics of each approach [Anderson, *Organic Process Res. Dev.*, **8**(2), pp. 260–265 (2004)]. A well-known example of extraction-crystallization is the recovery of penicillin from fermentation broth by using a pH-swing forward and back extraction scheme followed by final purification using crystallization [Queener and Swartz, "Penicillins: Biosynthetic and Semisynthetic," in *Secondary Products of Metabolism, Economic Microbiology*, vol. 3, Rose, ed. (Academic, 1979)]. Extraction is used for solute recovery and initial purification, followed by crystallization for final purification and isolation as a crystalline solid. Another category of extraction-crystallization processes involves use of extraction to recover solute from the spent mother liquor leaving a crystallization operation. In yet another example, Maeda et al., [*Ind. Eng. Chem. Res.*, **38**(6), pp. 2428–2433 (1999)] describe a crystallization-extraction hybrid process for separating fatty acids (lauric and myristic acids). In comparing these process options, the potential uses of extraction should include efficient countercurrent processing schemes, since these may significantly reduce solvent usage and cost.

***Neutralization-extraction*** A common example of neutralization-extraction involves neutralization of residual acidity (or basicity) in a crude organic feed by injection of an aqueous base (or aqueous acid) combined with washing the resulting salts into water. The neutralization and washing operations may be combined within a single extraction column as illustrated in Fig. 15-13. Also see the discussion by Koolen [*Design of Simple and Robust Process Plants* (Wiley-VCH, 2001), pp. 159–161].

***Reaction-extraction*** This technique involves chemical modification of solutes in solution in order to more easily extract them in a subsequent extraction operation. Applications generally involve modification of impurity compounds to facilitate purification of a desired product. An example is the oxygenation of sulfur-containing aromatic impurities present in fuel oil by using $H_2O_2$ and acetic acid, followed by liquid-liquid extraction into an aqueous acetonitrile solution [Shiraishi and Hirai, *Energy and Fuels*, **18**(1), pp. 37–40 (2004); and Shiraishi et al., *Ind. Eng. Chem. Res.*, **41**, pp. 4362–4375 (2002)]. Another example involves esterification of aromatic alcohol impurities to facilitate their separation from apolar hydrocarbons by using an aqueous extractant solution [Kuzmanovid et al., *Ind. Eng. Chem. Res.*, **43**(23), pp. 7572–7580 (2004)].

***Reverse osmosis-extraction*** In certain applications, reverse osmosis (RO) or nanofiltration membranes may be used to reduce the volume of an aqueous stream and increase the solute concentration, in order to reduce the size of downstream extraction and solvent recovery equipment. Wytcherley, Gentry, and Gualy [U.S. Patents 5,492,625 (1996) and 5,624,566 (1997)] describe such a process for carboxylic acid solutes. Water is forced through the membrane when the operating pressure drop exceeds the natural osmotic pressure difference generated by the concentration gradient:

$$\text{Flux} = \frac{\mathcal{P}}{\lambda_m}(\Delta P - \Delta\pi) \qquad (15\text{-}1)$$

where $\mathcal{P}$ is a permeability coefficient for water, $\lambda_m$ is the membrane thickness, $\Delta P$ is the operating pressure drop, and $\Delta\pi$ is the osmotic pressure gradient, a function of solute concentration on each side of the membrane. Normally the solute also will permeate the membrane to a small extent. The maximum possible concentration of solute in the concentrate is limited by that corresponding to an osmotic pressure of about 70 bar (about 1000 psig), since this is the maximum pressure rating of commercially available membrane modules (typical). For acetic acid, this maximum concentration is about 25 wt %. Depending upon whether the particular organic permeate of interest can swell or degrade the membrane material, the concentration achieved in practice may need to be reduced below this osmotic-pressure limit to avoid excessive membrane deterioration. In general, a membrane preconcentrator is considered for feeds containing on the order of 3 wt % solute or less. In these cases, a moderate membrane operating pressure may be used, and the preconcentrator can provide a large reduction in the volume of feed entering the extraction process. In these processes, the stream entering the membrane module normally must be carefully prefiltered to avoid fouling the membrane. The general application of RO and nanofiltration membranes is described in Sec. 20, "Alternative Separation Processes." The modeling of mass transfer through RO membranes, with an emphasis on cases involving solute-membrane interactions, is discussed by Mehdizadeh, Molaiee-Nejad, and Chong [*J. Membrane Sci.*, **267,** pp. 27–40 (2005)].

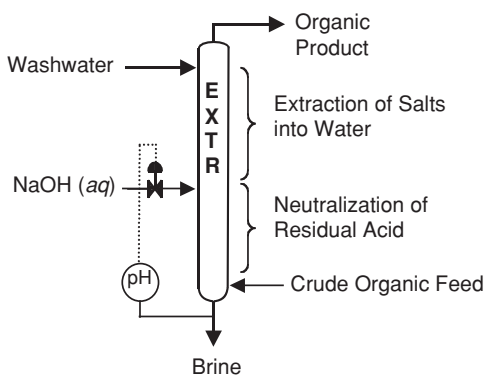

**FIG. 15-13** Example of neutralization-extraction hybrid process implemented in an extraction column.

**Liquid-Solid Extraction (Leaching)** Extraction of solubles from porous solids is a form of solvent extraction that has much in common with liquid-liquid extraction [Prabhudesai, "Leaching," Sec. 5.1 in *Handbook of Separation Techniques for Chemical Engineers*, Schweitzer, ed., pp. 5-3 to 5-31 (McGraw-Hill, 1997)]. The main differences come from the need to handle solids and the fact that mass transfer of soluble components out of porous solids generally is much slower than mass transfer between liquids. Because of this, different types of contacting equipment operating at longer residence times often are required. Washing of nonporous solids is a related operation that generally exhibits faster mass-transfer rates compared to leaching. On the other hand, purification of nonporous solids or crystals by removal of impurities that reside within the bulk solid phase often is not economical or even feasible by using these methods, because the rate of mass transfer of impurities through the bulk solid is extremely slow. Liquid-solid extraction is covered in Sec. 18, "Liquid-Solid Operations and Equipment."

**Liquid-Liquid Partitioning of Fine Solids** This process involves separation of small-particle solids suspended in a feed liquid, by contact with a second liquid phase. Robbins describes such a process for removing ash from pulverized coal [U.S. Patent 4,575,418 (1986)]. The process involves slurrying pulverized coal fines into a hydrocarbon liquid and contacting the resulting slurry with water. The coal slurry is cleaned by preferential transfer of ash particles into the aqueous phase. The process takes advantage of differences in surface-wetting properties to separate the different types of solid particles present in the feed.

**Supercritical Fluid Extraction** This process generally involves the use of $CO_2$ or light hydrocarbons to extract components from liquids or porous solids [Brunner, *Gas Extraction: An Introduction to Fundamentals of Supercritical Fluids and the Application to Separation Processes* (Springer-Verlag, 1995); Brunner, ed., *Supercritical Fluids as Solvents and Reaction Media* (Elsevier, 2004); and McHugh and Krukonis, *Supercritical Fluid Extraction*, 2d ed. (Butterworth-Heinemann, 1993)]. Supercritical fluid extraction differs from liquid-liquid or liquid-solid extraction in that the operation is carried out at high-pressure, supercritical (or near-supercritical) conditions where the extraction fluid exhibits

physical and transport properties that are inbetween those of liquid and vapor phases (intermediate density, viscosity, and solute diffusivity). Most applications involve the use of $CO_2$ (critical pressure = 73.8 bar at 31°C) or propane (critical pressure = 42.5 bar at 97°C). Other supercritical fluids and their critical-point properties are discussed by Poling, Prausnitz, and O'Connell [*The Properties of Gas and Liquids*, 5th ed. (McGraw-Hill, 2001)].

Supercritical $CO_2$ extraction often is considered for extracting high-value soluble components from natural materials or for purifying low-volume specialty chemicals. For products derived from natural materials, this can involve initial processing of solids followed by further processing of the crude liquid extract. Applications include decaffeination of coffee and recovery of active ingredients from plant- and animal-derived feeds including recovery of flavor components and vitamins from natural oils. An example is the use of supercritical $CO_2$ fractional extraction to remove terpenes from cold-pressed bergamot oil [Kondo et al., *Ind. Eng. Chem. Res.*, **39**(12), pp. 4745–4748 (2000)]. A nonfood example involves the removal of unreacted dodecanol from nonionic surfactant mixtures and fractionation of the surfactant mixture based on polymer chain length [Eckert et al., *Ind. Eng. Chem. Res.*, **31**(4), pp. 1105–1110 (1992)]. In these applications, process advantages may be obtained because solvent residues are easily removed or are nontoxic, the process can be operated at mild temperatures that avoid product degradation, the product is easily recovered from the extract fluid, or the solute separation factor and product purity can be adjusted by making small changes in the operating temperature and pressure. Although the loading capacity of supercritical $CO_2$ typically is low, addition of cosolvents such as methanol, ethanol, or tributylphosphate can dramatically boost capacity and enhance selectivity [Brennecke and Eckert, *AIChE J.*, **35**(9), pp. 1409–1427 (1989)].

For processing liquid feeds, some supercritical fluid extraction processes utilize packed columns, in which the liquid feed phase wets the packing and flows through the column in film flow, with the supercritical fluid forming the continuous phase. In other applications, sieve trays give improved performance [Seibert and Moosberg, *Sep. Sci. Technol.*, **23,** p. 2049 (1988)]. In a number of these applications, concentrated solute is added back to the column as reflux to boost separation power (a form of single-solvent fractional extraction). Supercritical fluid extraction requires high-pressure equipment and may involve a high-pressure compressor. These requirements add considerable capital and operating costs. In certain cases, pumps can be used instead of compressors, to bring down the cost. The separators are run slightly below the critical point at slightly elevated pressure and reduced temperature to ensure the material is in the liquid state so it can be pumped. As a rule, supercritical fluid extraction is considerably more expensive than liquid-liquid extraction, so when the required separation can be accomplished by using a liquid solvent, liquid-liquid extraction often is more cost-effective.

Although most commercial applications of supercritical fluid extraction involve processing of high-value, low-volume products, a notable exception is the propane deasphalting process used to refine lubricating oils. This is a large-scale, commodity chemical process dating back to the 1930s. In this process and more recent versions, lube oils are extracted into propane at near-supercritical conditions. The extract phase is depressurized or cooled in stages to isolate various fractions. Compared to operation at lower pressures, operation at near-supercritical conditions minimizes the required pressure or temperature change—so the process is more efficient. For further discussion of supercritical fluid separation processes, see Sec. 20, "Alternative Separation Processes," Gironi and Maschietti, *Chem. Eng. Sci.*, **61,** pp. 5114–5126 (2006), and Fernandes et al., *AIChE J.*, **53**(4), pp. 825–837 (2007).

## KEY CONSIDERATIONS IN THE DESIGN OF AN EXTRACTION OPERATION

Successful approaches to designing an extraction process begin with an appreciation of the fundamentals (basic phase equilibrium and mass-transfer principles) and generally rely on both experimental studies and mathematical models or simulations to define the commercial technology. Small-scale experiments using representative feed usually are needed to accurately quantify physical properties and phase equilibrium. Additionally, it is common practice in industry to perform miniplant or pilot-plant tests to accurately characterize the mass-transfer capabilities of the required equipment as a function of throughput [Robbins, *Chem. Eng. Prog.*, **75**(9), pp. 45–48 (1979)]. In many cases, mass-transfer resistance changes with increasing scale of operation, so an ability to accurately scale up the data also is needed. The required scale-up know-how often comes from experience operating commercial equipment of various sizes or from running pilot-scale equipment of sufficient size to develop and validate a scale-up correlation. Mathematical models are used as a framework for planning and analyzing the experiments, for correlating the data, and for estimating performance at untested conditions by extrapolation. Increasingly, designers and researchers are utilizing computational fluid dynamics (CFD) software or other simulation tools as an aid to scale-up.

Typical steps in the work process for designing and implementing an extraction operation include the following:

1. Outline the design basis including specification of feed composition, required solute recovery or removal, product purity, and production rate.
2. Search the published literature (including patents) for information relevant to the application.
3. For dilute feeds, consider options for preconcentrating the feed to reduce the volumes of feed and solvent that must be handled by the extraction operation. Consider evaporation or distillation of a high-volatility feed solvent or the use of reverse osmosis membranes to concentrate aqueous feeds. (See "Hybrid Extraction Processes" under "Commercial Process Schemes.")
4. Generate a list of candidate solvents based on chemical knowledge and experience. Consider solvents similar to those used in analogous applications. Use one or more of the methods described in "Solvent Screening Methods" to identify additional candidates. Include consideration of solvent blends and extractants.
5. Estimate key physical properties and review desirable solvent properties. Give careful consideration to safety, industrial hygiene, and environmental requirements. Use this preliminary information to trim the list of candidate solvents to a manageable size. (See "Desirable Solvent Properties.")
6. Measure partition ratios for selected solvents at representative conditions.
7. Evaluate the potential for trace chemistry under extraction and solvent recovery conditions to determine whether solutes and candidate solvents are likely to degrade or react to produce unwanted impurities. For example, it is well known that pencillin G easily degrades at commercial extraction conditions, and short contact time is required for good results. Also under certain conditions acetate solvents may hydrolyze to form alcohols, certain alcohols and ethers can form peroxides, sulfur-containing solvents may degrade at elevated regeneration temperatures to form acids, chlorinated solvents may hydrolyze at elevated temperatures to form trace HCl with severe corrosion implications, and so on. In other cases, leakage of air into the process may cause formation of trace oxidation products. Understanding the potential for trace chemistry, the fate of potential impurities (i.e., where they go in the process), their possible effects on the process (including impact on product purity and interfacial tension) and devising means to avoid or successfully deal with impurities often are critical to a successful process design. Laboratory tests designed to probe the stability of feed and solvent mixtures may be needed.
8. Characterize mass-transfer difficulty in terms of the required number of theoretical stages or transfer units as a function of the solvent-to-feed ratio. Keep in mind that there will be a limit to the number of theoretical stages that can be achieved. For most cost-effective extraction operations, this limit will be in the range of 3 to 10 theoretical stages, although some can achieve more, depending upon the chemical system, type of equipment, and flow rate (throughput).
9. Estimate the cost of the proposed extraction operation relative to alternative separation technologies, such as extractive distillation, adsorption, and crystallization. Explore other options if they appear less expensive or offer other advantages.
10. If technical and economic feasibility looks good, determine accurate values of physical properties and phase equilibria, particularly liquid densities, mutual solubilities (miscibility), viscosities, interfacial tension, and $K$ values (at feed, extract, and raffinate ends of the

proposed process), as well as data needed to evaluate solvent recycle options. Search available literature and databases. Assess data quality and generate additional data as needed. Develop the appropriate data correlations. Finalize the choice of solvent.

11. Outline an overall process flow sheet and material balance including solvent recovery and recycle. This should be done with the aid of process simulation software. [See Seider, Seader, and Lewin, *Product and Process Design Principles: Synthesis, Analysis, and Evaluation*, 2d ed. (Wiley, 2004); and Turton et al., *Analysis, Synthesis, and Design of Chemical Processes*, 2d ed. (Prentice-Hall, 2002)]. In the flow sheet include methods needed for controlling emissions and managing wastes. Carefully consider the possibility that impurities may accumulate in the recycled solvent, and devise methods for purging these impurities, if needed.

12. In some cases, especially with multiple solutes and complex phase equilibria, it may be useful to perform laboratory batch experiments to simulate a continuous, countercurrent, multistage process. These experiments can be used to test/verify calculation results and determine the correct distribution of components. For additional information, see Treybal, Chap. 9 in *Liquid Extraction*, 2d ed. (McGraw-Hill, 1963), pp. 359–393, and Baird and Lo, Chap. 17.1 in *Handbook of Solvent Extraction* (Wiley, 1983; Krieger, 1991).

13. Identify useful equipment options for liquid-liquid contacting and liquid-liquid phase separation, estimate approximate equipment size, and outline preliminary design specifications. (See "Extractor Selection" under "Liquid-Liquid Extraction Equipment.") Where appropriate, consult with equipment vendors. Using small-scale experiments, determine whether sludgelike materials are likely to accumulate at the liquid-liquid interface (called formation of a rag layer). If so, it will be important to identify equipment options that can tolerate accumulation of a rag layer and allow the rag to be drained or otherwise purged periodically.

14. For the most promising equipment option, run miniplant or pilot-plant tests over a range of operating conditions. Utilize representative feed including all anticipated impurities, since even small concentrations of surface-active components can dramatically affect interfacial behavior. Whenever possible, the miniplant tests should be conducted by using actual material from the manufacturing plant, and should include solvent recycle to evaluate the effects of impurity accumulation or possible solvent degradation. Run the miniplant long enough that the solvent encounters numerous cycles so that recycle effects can be seen. If difficulties arise, consider alternative solvents.

15. Analyze miniplant data and update the preliminary design. Carefully evaluate loss of solvent to the raffinate, and devise methods to minimize losses as needed. Consult equipment vendors or other specialists regarding recommended scale-up methods.

16. Specify the final material balance for the overall process and carry out detailed equipment design calculations. Try to add some flexibility (depending on the cost) to allow for some adjustment of the process equipment during operation—to compensate for uncertainties in the design.

17. Install and start up the equipment in the manufacturing plant.

18. Troubleshoot and improve the operation as needed. Once a unit is operational, carefully measure the material balance and characterize mass-transfer performance. If performance does not meet expectations, look for defects in the equipment installation. If none are found, revisit the scale-up methodology and its assumptions.

## LABORATORY PRACTICES

An equilibrium or theoretical stage in liquid-liquid extraction, as defined earlier, is routinely utilized in laboratory procedures. A feed solution is contacted with a solvent to remove one or more of the solutes from the feed. This can be carried out in a separating funnel or, preferably, in an agitated vessel that can produce droplets about 1 mm in diameter. After agitation has stopped and the phases separate, the two clear liquid layers are isolated by decantation. The partition ratio can then be determined directly by measuring the concentration of solute in the extract and raffinate layers. (Additional discussion is given in "Liquid-Liquid Equilibrium Experimental Methods" under "Thermodynamic Basis for Liquid-Liquid Extraction.") When an appropriate analytical method is available only for the feed phase, the partition ratio can be determined by measuring the solute concentration in the feed and raffinate phases and calculating the partition ratio from the material balance. When the initial concentration of solute in the extraction solvent is zero (before extraction), the partition ratio expressed in terms of mass fractions is given by

$$K'' = \frac{Y''_e}{X''_r} = \frac{M_r}{M_e}\left(\frac{M_f}{M_r}\frac{X''_f}{X''_r} - 1\right) \tag{15-2}$$

where $K''$ = mass fraction solute in extract divided by that in raffinate
$M_f$ = total mass of feed added to vial
$M_s$ = total mass of extraction solvent before extraction
$M_r$ = mass of raffinate phase after extraction
$M_e$ = mass of extract phase after extraction
$X''_f$ = mass fraction solute in feed prior to extraction
$X''_r$ = mass fraction solute in raffinate, at equilibrium
$Y''_e$ = mass fraction solute in extract, at equilibrium

For systems with low mutual solubility between phases, $K'' \approx (M_f/M_s)(X''_f/X''_r - 1)$. An actual analysis of solute concentration in the extract and raffinate is preferred in order to understand how well the material balance closes (a check of solute accountability).

After a single stage of liquid-liquid contact, the phase remaining from the feed solution (the raffinate) can be contacted with another quantity of fresh extraction solvent. This cross-current (or cross-flow) extraction scheme is an excellent laboratory procedure because the extract and raffinate phases can be analyzed after each stage to generate equilibrium data for a range of solute concentrations. Also, the feasibility of solute removal to low levels can be demonstrated (or shown to be problematic because of the presence of "extractable" and "nonextractable" forms of a given species). The number of cross-current treatments needed for a given separation, assuming a constant $K$ value, can be estimated from

$$N = \frac{\ln\left(\dfrac{X_{\text{in}} - Y_{\text{in}}/K}{X_{\text{out}} - Y_{\text{in}}/K}\right)}{\ln(KS^*/F + 1)} \tag{15-3}$$

where $F$ is the amount of feed, the feed and solvent are presaturated, and equal amounts of solvent (denoted by $S^*$) are used for each treatment [Treybal, *Liquid Extraction*, 2d ed. (McGraw-Hill, 1963), pp. 209–216]. The total amount of solvent is $N \times S^*$. The variable $Y_{\text{in}}$ is the concentration of solute in the fresh solvent, normally equal to zero. Equation (15-3) is written in a general form without specifying the units, since any consistent system of units may be used. (See "Process Fundamentals and Basic Calculation Methods.")

A cross-current scheme, although convenient for laboratory practice, is not generally economically attractive for large commercial processes because solvent usage is high and the solute concentration in the combined extract is low. A number of batchwise countercurrent laboratory techniques have been developed and can be used to demonstrate countercurrent performance. (See item 12 in the previous subsection, "Key Considerations in the Design of an Extraction Operation.") Several equipment vendors also make available continuously fed laboratory-scale extraction equipment. Examples include small-scale mixer-settler extraction batteries offered by Rousselet-Robatel, Normag, MEAB, and Schott/QVF. Small-diameter extraction columns also may be used, such as the $\frac{3}{8}$-in- (16-mm-) diameter reciprocating-plate agitated column offered by Koch Modular Process Systems, and a 60-mm-diameter rotary-impeller agitated column offered by Kühni. Static mixers also may be useful for mixer-settler studies in the laboratory [Benz et al., *Chem. Eng. Technol.*, **24**(1), pp. 11–17 (2001)].

For additional discussion of laboratory techniques, see "Liquid-Liquid Equilibrium Experimental Methods" as well as "High-Throughput Experimental Methods" under "Solvent-Screening Methods."

## ACTIVITY COEFFICIENTS AND THE PARTITION RATIO

Two phases are at equilibrium when the total Gibbs energy for the system is at a minimum. This criterion can be restated as follows: Two nonreacting phases are at equilibrium when the chemical potential of each distributed component is the same in each phase; i.e., for equilibrium between two phases I and II containing $n$ components

$$\mu_i^{\mathrm{I}} = \mu_i^{\mathrm{II}} \qquad i = 1, 2, \ldots, n \tag{15-4}$$

For two phases at the same temperature and pressure, Eq. (15-4) can be expressed in terms of mole fractions and activity coefficients, giving

$$y_i \gamma_i^{\mathrm{I}} = x_i \gamma_i^{\mathrm{II}} \qquad i = 1, 2, \ldots, n \tag{15-5}$$

where $y_i$ and $x_i$ represent mole fractions of component $i$ in phases I and II, respectively. The equilibrium partition ratio, in units of mole fraction, is then given by

$$K_i^o = \frac{y_i}{x_i} = \frac{\gamma_i^{\text{raffinate}}}{\gamma_i^{\text{extract}}} \tag{15-6}$$

where $y_i$ is the mole fraction in the extract phase and $x_i$ is the mole fraction in the raffinate. Note that, in general, activity coefficients and $K_i^\circ$ are functions of temperature and composition. For ionic compounds that dissociate in solution, the species that form and the extent of dissociation in each phase also must be taken into account. Similarly, for extractions involving adduct formation or other chemical reactions, the reaction stoichiometry is an important factor. For discussion of these special cases, see Choppin, Chap. 3, and Rydberg et al., Chap. 4, in *Solvent Extraction Principles and Practice*, 2d ed., Rydberg et al., eds. (Dekker, 2004).

The activity coefficient for a given solute is a measure of the nonideality of solute-solvent interactions in solution. In this context, the solvent is either the feed solvent or the extraction solvent depending on which phase is considered, and the composition of the "solvent" includes all components present in that phase. For an ideal solution, activity coefficients are unity. For solute-solvent interactions that are repulsive relative to solvent-solvent interactions, $\gamma_i$ is greater than 1. This is said to correspond to a positive deviation from ideal solution behavior. For attractive interactions, $\gamma_i$ is less than 1.0, corresponding to a negative deviation. Activity coefficients often are reported for binary pairs in the limit of very dilute conditions (infinite dilution) since this represents the interaction of solute completely surrounded by solvent molecules, and this normally gives the largest value of the activity coefficient (denoted as $\gamma_i^\infty$). Normally, useful approximations of the activity coefficients at more concentrated conditions can be obtained by extrapolation from infinite dilution using an appropriate activity coefficient correlation equation. (See Sec. 4, "Thermodynamics.") Extrapolation in the reverse direction, i.e., from finite concentration to infinite dilution, often does not provide reliable results.

In units of mass fraction, the partition ratio for a nonreacting/nondissociating solute is given by

$$K_i'' \text{ (mass frac. basis)} = \frac{Y_i''}{X_i''} = K_i^o \text{ (mole frac. basis)} \times \left[ \frac{y_i(\mathrm{MW}_i - \mathrm{MW}_{\text{raffinate}}) + \mathrm{MW}_{\text{raffinate}}}{x_i(\mathrm{MW}_i - \mathrm{MW}_{\text{extract}}) + \mathrm{MW}_{\text{extract}}} \right] \tag{15-7}$$

Here, the notation MW refers to the molecular weight of solute $i$ and the effective average molecular weights of the extract and raffinate phases, as indicated by the subscripts. For dilute systems, $K_i'' \approx K_i^o (\mathrm{MW}_{\text{raffinate}}/\mathrm{MW}_{\text{extract}})$. For theoretical stage or transfer unit calculations, often it is useful to express the partition ratio in terms of mass ratio coordinates introduced by Bancroft [*Phys. Rev.*, **3**(1), pp. 21–33; **3**(2), pp. 114–136; and **3**(3), pp. 193–209 (1895)]:

$$K_i' = \frac{Y_i'}{X_i'} = \frac{M_{\text{solute}}/M_{\text{extraction solvent}} \text{ in extract phase}}{M_{\text{solute}}/M_{\text{feed solvent}} \text{ in raffinate phase}} \tag{15-8}$$

Partition ratios also may be expressed on a volumetric basis. In that case,

$$K_i^{\text{vol}} \text{ (mass/vol. basis)} = K_i'' \frac{\rho_{\text{extract}}}{\rho_{\text{raffinate}}} \tag{15-9}$$

$$K_i^{\text{vol}} \text{ (mole/vol. basis)} = K_i^o \left( \frac{\rho_{\text{extract}}}{\rho_{\text{raffinate}}} \right) \left( \frac{\mathrm{MW}_{\text{raffinate}}}{\mathrm{MW}_{\text{extract}}} \right) \tag{15-10}$$

**Extraction Factor** The extraction factor is defined by

$$\mathcal{E}_i = m_i \frac{S}{F} \tag{15-11}$$

where $m_i = dY_i/dX_i$, the slope of the equilibrium line, and $F$ and $S$ are the flow rates of the feed phase and the extraction-solvent phase, respectively. On a McCabe-Thiele type of diagram, $\mathcal{E}$ is the slope of the equilibrium line divided by the slope of the operating line $F/S$. (See "McCabe-Thiele Type of Graphical Method" under "Process Fundamentals and Basic Calculation Methods.") For dilute systems with straight equilibrium lines, the slope of the equilibrium line is equal to the partition ratio $m_i = K_i$.

To illustrate the significance of the extraction factor, consider an application where $K_i$, $S$, and $F$ are constant (or nearly so) and the extraction solvent entering the process contains no solute. When $\mathcal{E}_i = 1$, the extract stream has just enough capacity to carry all the solute present in the feed:

$$SY_{i,\text{extract}} = FX_{i,\text{feed}} \qquad \text{at } \mathcal{E}_i = 1 \text{ and equilibrium conditions} \tag{15-12}$$

At $\mathcal{E}_i < 1.0$, the extract's capacity to carry solute is less than this amount, and the maximum fraction that can be extracted $\theta_i$ is numerically equal to the extraction factor:

$$(\theta_i)_{\max} = \mathcal{E}_i \qquad \text{when } \mathcal{E}_i < 1.0 \tag{15-13}$$

At $\mathcal{E}_i > 1.0$, the extract phase has more than sufficient carrying capacity (in principle), and the actual amount extracted depends on the extraction scheme, number of contacting stages, and mass-transfer resistance. Even a solute for which $m_i < 1.0$ (or $K_i < 1.0$) can, in principle, be extracted to a very high degree—by adjusting $S/F$ so that $\mathcal{E}_i > 1$.

Thus, the extraction factor characterizes the relative capacity of the extract phase to carry solute present in the feed phase. Its value is a major factor determining the required number of theoretical stages or transfer units. (For further discussion, see "The Extraction Factor and

General Performance Trends.") In general, the value of the extraction factor can vary at each point along the equilibrium curve, although in many cases it is nearly constant. Many commercial extraction processes are designed to operate with an average or overall extraction factor in the range of 1.3 to 5. Exceptions include applications where the partition ratio is very large and the solvent-to-feed ratio is set by hydraulic considerations.

Because the extraction factor is a dimensionless variable, its value should be independent of the units used in Eq. (15-11), as long as they are consistently applied. Engineering calculations often are carried out by using mole fraction, mass fraction, or mass ratio units (Bancroft coordinates). The flow rates $S$ and $F$ then need to be expressed in terms of total molar flow rates, total mass flow rates, or solute-free mass flow rates, respectively. In the design of extraction equipment, volume-based units often are used. Then the appropriate concentration units are mass or mole per unit volume, and flow rates are expressed in terms of the volumetric flow rate of each phase.

**Separation Factor** The separation factor in extraction is analogous to relative volatility in distillation. It is a dimensionless factor that measures the relative enrichment of a given component in the extract phase after one theoretical stage of extraction. For cosolutes $i$ and $j$,

$$\alpha_{i,j} = \frac{(Y_i/Y_j)_{\text{extract}}}{(X_i/X_j)_{\text{raffinate}}} = \frac{(Y_i)_{\text{extract}}/(X_i)_{\text{raffinate}}}{(Y_j)_{\text{extract}}/(X_j)_{\text{raffinate}}} = \frac{K_i}{K_j} \qquad (15\text{-}14)$$

The enrichment of solute $i$ with respect to solute $j$ can be further increased with the use of multiple contacting stages. The solute separation factor $\alpha_{i,j}$ is used to characterize the selectivity a solvent has for extracting a desired solute from a feed containing other solutes. It can be calculated by using any consistent units. As in distillation, $\alpha_{i,j}$ must be greater than 1.0 to achieve an increase in product-solute purity (on a solvent-free basis). In practice, if solute purity is an important requirement of a given application, $\alpha_{i,j}$ must be greater than 20 for standard extraction (at least) and greater than about 4 for fractional extraction, in order to have sufficient separation power. (See "Potential for Solute Purification Using Standard Extraction" in "Process Fundamentals and Basic Calculation Methods" and "Dual-Solvent Fractional Extraction" in "Calculation Procedures.")

The separation factor also can be evaluated for solute $i$ with respect to the feed solvent denoted as component $f$. The value of $\alpha_{i,f}$ must be greater than 1.0 if the proposed separation is to be feasible, i.e., in order to be able to enrich solute $i$ in a separate extract phase. Note that the feed may still be separated if $\alpha_{i,f} < 1.0$, but this would have to involve concentrating solute $i$ in the feed phase by preferential transfer of component $f$ into the extract phase. Although $\alpha_{i,f} > 1.0$ represents a minimum theoretical requirement for enriching solute $i$ in a separate extract phase, most commercial extraction processes operate with values of $\alpha_{i,f}$ on the order of 20 or higher. There are exceptions to this rule, such as the Udex process and similar processes involving extraction of aromatics from aliphatic hydrocarbons. In these applications, $\alpha_{i,f}$ can be as low as 10 and sometimes even lower. Applications such as these involve particularly difficult design challenges because of low solute partition ratios and high mutual solubility between phases. (For more detailed discussion of these kinds of systems, see "Single Solvent Fractional Extraction with Extract Reflux" in "Fractional Extraction Calculations.")

**Minimum and Maximum Solvent-to-Feed Ratios** Normally, it is possible to quickly estimate the physical constraints on solvent usage for a standard extraction application in terms of minimum and maximum solvent-to-feed ratios. As discussed above, the minimum theoretical amount of solvent needed to transfer a high fraction of solute $i$ is the amount corresponding to $\mathcal{E}_i = 1$. In practice, the minimum practical extraction factor is about 1.3, because at lower values the required number of theoretical stages increases dramatically. This gives a minimum solvent-to-feed ratio for a practical process equal to

$$\left(\frac{S}{F}\right)_{\min} \approx \frac{1.3}{K_i} \qquad (15\text{-}15)$$

Note that this minimum is achievable only if a sufficient number of contacting stages or transfer units can be used. (For additional discussion, see "The Extraction Factor and General Performance Trends.") It is also achievable only if the amount of solvent added to the feed is greater than the solubility limit in the feed phase (including solute); otherwise, only one liquid phase can exist. In certain cases involving fairly high mutual solubilities, this can be an important consideration when running a process using minimal solvent—because if the process operates close to the solubility limit, an upset in the solvent-to-feed ratio may cause the solvent phase to disappear.

The maximum possible solvent-to-feed ratio is obtained when the amount of extraction solvent is so large that it dissolves the feed phase. Assuming the feed entering the process does not contain extraction solvent,

$$\left(\frac{S}{F}\right)_{\max} = \frac{1}{1 - Y_s^{\text{SAT}}} \qquad (15\text{-}16)$$

where $Y_s^{\text{SAT}}$ denotes the concentration of extraction solvent in the extract phase at equilibrium after contact with the feed phase. The denominator in Eq. (15-16) represents the solubility limit on the solvent-rich side of the miscibility envelope, including the effect of the presence of solute on solubility. Normally, the solubility limits are easily measured in small-scale experiments by adding solvent until the solvent phase appears (representing the feed-rich side of the miscibility envelope) and continuing to add solvent until the feed phase disappears (the solvent-rich side). For dilute feeds containing less than about 1% solute, reasonable estimates often can be obtained by using mutual solubility data for the feed solvent + extraction solvent binary pair.

If an application proves to be technically feasible, the choice of solvent-to-feed ratio is determined by identifying the most cost-effective ratio between the minimum and maximum limits. For most applications, the maximum solvent-to-feed ratio will be much larger than the ratio chosen for the commercial process; however, the maximum ratio can be a real constraint when dealing with applications exhibiting high mutual solubility, especially for systems that involve high solute concentrations. Additional discussion is given by Seader and Henley [Chap. 8 in *Separations Process Principles* (Wiley, 1998)]. Solvent ratios are further constrained for a fractional extraction scheme, as discussed in "Fractional Extraction Calculations."

**Temperature Effect** The effect of temperature on the value of the partition ratio can vary greatly from one system to another. This depends on how the activity coefficients of the components in each phase are affected by changes in temperature, including any effects due to changes in mutual solubility with temperature. For a given phase, the Gibbs-Helmholtz equation indicates that

$$\left[\frac{\partial \ln \gamma_i^{\infty}}{\partial(1/T)}\right]_{P,x} = \frac{h_i^{E,\infty}}{R} \qquad (15\text{-}17)$$

where $\gamma_i^{\infty}$ is the activity coefficient for solute $i$ at infinite dilution and $h_i^E$ is the partial molar excess enthalpy of mixing relative to ideal solution behavior [Atik et al., *J. Chem. Eng. Data*, **49**(5), pp. 1429–1432 (2004); and Sherman et al., *J. Phys. Chem.*, **99,** pp. 11239–11247 (1995)].

Systems with specific interactions between solute and solvent, such as hydrogen bonds or ion-pair bonds, often are particularly sensitive to changes in temperature because the specific interactions are strongly temperature-dependent. In general, hydrogen bonding and ion-pair formation are disrupted by increasing temperature (increasing molecular motion), and this can dominate the overall temperature dependence of the partition ratio. An example of a temperature-sensitive hydrogen bonding system is toluene + diethylamine + water [Morello and Beckmann, *Ind. Eng. Chem.*, **42,** pp. 1079–1087 (1950)]. The partition ratio for transfer of diethylamine from water into toluene increases with increasing temperature (on a weight percent basis, $K = 0.7$ at 20°C and $K = 2.8$ at 58°C). For further discussion of the temperature dependence of $K$ for this type of system, see Frank et al., *Ind. Eng. Chem. Res.*, **46**(11), pp. 3774–3786 (2007). An example of a temperature-sensitive system involving ion-pair formation is the commercial process used to recover citric acid from fermentation broth using trioctylamine (TOA) extractant [Pazouki and Panda, *Bioprocess*

*Engineering*, **19,** pp. 435–439 (1998)]. In this case, the partition ratio for transfer of citric acid into the TOA phase decreases with increasing temperature. Temperature-sensitive ion-pair interactions in the extract phase are disrupted with increasing temperature, and this appears to dominate the temperature sensitivity of the partition ratio, not the interactions between citric acid and water in the aqueous raffinate phase [Canari and Eyal, *Ind. Eng. Chem. Res.,* **43,** pp. 7608–7617 (2004)]. Also see the discussion of "Temperature-Swing Extraction" in "Commercial Extraction Schemes."

**Salting-out and Salting-in Effects for Nonionic Solutes** It is well known that the presence of an inorganic salt can significantly affect the solubility of a nonionic (nonelectrolyte) organic solute dissolved in water. In most cases the inorganic salt reduces the organic solute's solubility (salting-out effect). Here, the salt increases the organic solute's activity coefficient in the aqueous solution. As a result, certain solutes that are not easily extracted from water may be quite easily extracted from brine, depending upon the type of solute and the salt. In principle, the deliberate addition of a salt to an aqueous feed is an option for enhancing partition ratios and reducing the mutual solubility of the two liquid phases; however, this approach complicates the overall process and normally is not cost-effective. Difficulties include the added complexity and costs associated with recovery and recycle of the salt in the overall process, or disposal of the brine after extraction and the need to purchase makeup salt. The potential use of NaCl to enhance the extraction of ethanol from fermentation broth is discussed by Gomis et al. [*Ind. Eng. Chem. Res*., **37**(2), pp. 599–603 (1998)].

When an aqueous feed contains a salt, the effect of the dissolved salt on the partition ratio for a given organic solute may be estimated by using an expression introduced by Setschenow [*Z. Phys. Chem*., **4,** pp. 117–128 (1889)] and commonly written in the form

$$\log \frac{\gamma_{i,\text{brine}}}{\gamma_{i,\text{water}}} = k_s C_{\text{salt}} \tag{15-18}$$

where $C_{\text{salt}}$ is the concentration of salt in the aqueous phase in units of gmol/L and $k_s$ is the Setschenow constant. Equation (15-18) generally is valid for dilute organic solute concentrations and low to moderate salt concentrations. In many cases, the salt has no appreciable effect on the activity coefficient in the organic phase since the salt solubility in that phase is low or negligible. Then

$$\log \frac{K_{i,\text{brine}}}{K_{i,\text{water}}} \approx \log \frac{\gamma_{i,\text{brine}}}{\gamma_{i,\text{water}}} = k_s C_{\text{salt}} \tag{15-19}$$

for extraction from the aqueous phase into an organic phase. For aromatic solutes dissolved in NaCl brine at room temperature, typical values of $k_s$ fall within the range of 0.2 to 0.3 L/gmol. In general, $k_s$ is found to vary with salt composition (i.e., with the type of salt) and increase with increasing organic-solute molar volume. Kojima and Davis [*Int. J. Pharm*., **20**(1–2), pp. 203–207 (1984)] showed that partition ratio data for extraction of phenol dissolved in NaCl brine (at low concentration) using $CCl_4$ solvent is well fit by a Setschenow equation for salt concentrations up to 4 gmol/L (about 20 wt % NaCl). Experimental values and methods for estimating Setschenow constants are discussed by Ni and Yalkowski [*Int. J. Pharm*., **254**(2), pp. 167–172 (2003)] and by Xie, Shiu, and MacKay [*Marine Environ. Res*. **44,** pp. 429–444 (1997)].

In special cases, salts with large ions (such as tetramethylammonium chloride and sodium toluene sulfonate) may cause a "salting in" or "hydrotropic" effect where by the salt increases the solubility of an organic solute in water, apparently by disordering the structure of associated water molecules in solution [Sugunan and Thomas, *J. Chem. Eng. Data*., **38**(4), pp. 520–521 (1993)]. Agrawal and Gaikar [*Sep. Technol*., **2,** pp. 79–84 (1992)] discuss the use of hydrotropic salts to facilitate extraction processes. For additional discussion, see Ruckenstein and Shulgin, *Ind. Eng. Chem. Res*., **41**(18), pp. 4674–4680 (2002); and Akia and Feyzi, *AIChE J*., **52**(1), pp. 333–341 (2006).

**Effect of pH for Ionizable Organic Solutes** The distribution of weak acids and bases between organic and aqueous phases is dramatically affected by the pH of the aqueous phase relative to the $pK_a$ of the solute. As discussed earlier, the $pK_a$ is the pH at which 50 percent of the solute is in the ionized state. (See "Dissociative Extraction" in "Commercial Extraction Schemes.") For a weak organic acid (RCOOH) that dissociates into $RCOO^-$ and $H^+$, the overall partition ratio for extraction into an organic phase depends upon the extent of dissociation such that

$$K_{\text{weak acid}} = K_{\text{nonionized}} \div \left(1 + \frac{[\text{RCOO}^-]_{aq}}{[\text{RCOOH}]_{aq}}\right) \tag{15-20}$$

where $K_{\text{weak acid}} = [\text{RCOOH}]_{\text{org}} / ([\text{RCOO}^-]_{aq} + [\text{RCOOH}]_{aq})$ is the partition ratio for both ionized and nonionized forms of the acid, and $K_{\text{nonionized}} = [\text{RCOOH}]_{\text{org}}/[\text{RCOOH}]_{aq}$ is the partition ratio for the nonionized form alone [Treybal, *Liquid Extraction*, 2d ed. (McGraw-Hill, 1963), pp. 38–40]. Equation (15-20) can be rewritten in terms of the $pK_a$ for a weak acid or weak base:

$$K_{\text{weak acid}} = K_{\text{nonionized}} \div (1 + 10^{\text{pH}-pK_a}) \tag{15-21}$$

and

$$K_{\text{weak base}} = K_{\text{nonionized}} \div (1 + 10^{pK_a-\text{pH}}) \tag{15-22}$$

For weak bases, $pK_a = 14 - pK_b$. Appropriate values for $K_{\text{nonionized}}$ may be obtained by measuring the partition ratio at sufficiently low pH (for acids) or high pH (for bases) to ensure the solute is in its nonionized form (normally at a pH at least 2 units from the $pK_a$ value). In Eqs. (15-21) and (15-22), it is assumed that concentrations are dilute, that dissociation occurs only in the aqueous phase, and that the acid does not associate (dimerize) in the organic phase. The effect of pH on the partition ratio for extraction of penicillin G, a complex organic containing a carboxylic acid group, is illustrated in Fig. 15-14. For a discussion of the effect of pH on the extraction of carboxylic acids with teritiary amines, see Yang, White, and Hsu, *Ind. Eng. Chem. Res.*, **30**(6), pp. 1335–1342 (1991). Another example is discussed by Greminger et al., [*Ind. Eng. Chem. Process Des. Dev.*, **21**(1), pp. 51–54 (1982)]; they present partition ratio data for various phenolic compounds as a function of pH.

For compounds with multiple ionizable groups, such as amino acids, the effect of pH on partitioning behavior is more complex. Amino acids are zwitterionic (dipolar) molecules with two or three ionizable groups; the $pK_a$ values corresponding to RCOOH acid groups generally are between 2 and 3, and $pK_a$ values for $RNH_3^+$ amino groups generally are between 9 and 10. Amino acid partitioning is discussed by Schügerl [*Solvent Extraction in Biotechnology* (Springer-Verlag, 1994); Chap. 21 in *Biotechnology*, 2d ed., vol. 3, Stephanopoulos, ed. (VCH, 1993)]; and by Gude, Meuwissen, van der Wielen, and Luyben [*Ind. Eng. Chem. Res*., **35,** pp. 4700–4712

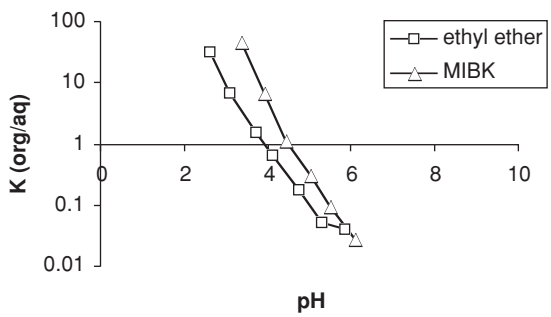

**FIG. 15-14** The effect of pH on the partition ratio for extraction of penicillin G ($pK_a$ = 2.75) from broth using an oxygenated organic solvent. The partition ratio is expressed in units of grams per/liter in the organic phase over that in the aqueous phase. [*Data from R. L. Feder, M.S. thesis (Polytechnic Institute of Brooklyn, 1947).*]

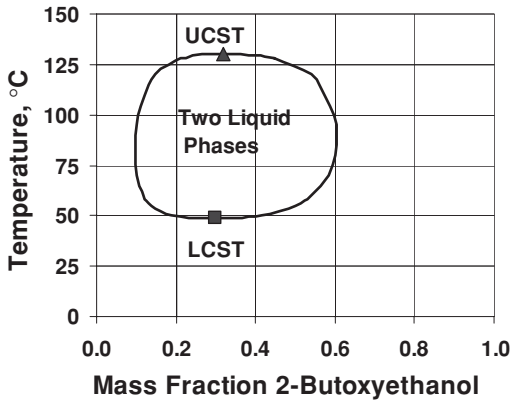

**FIG. 15-15** Temperature-composition diagram for water + 2-butoxyethanol (ethylene glycol *n*-butyl ether). [*Reprinted from Christensen, Donate, Frank, LaTulip, and Wilson,* J. Chem. Eng. Data, ***50****(3), pp. 869–877 (2005), with permission. Copyright 2005 American Chemical Society.*]

(1996)]. The aqueous solubility of amino acids as a function of pH is discussed by Fuchs et al., *Ind. Eng. Chem. Res.*, **45**(19), pp. 6578–6584 (2006). Solution pH also has a strong effect on the solubility of proteins (complex polyaminoacids) in aqueous solution; solubility is lowest at the pH corresponding to the protein's isoelectric point (the pH at which all negative charges are balanced by all positive charges and the protein has zero net charge) [van Holde, Johnson, and Ho, *Principles of Physical Biochemistry* (Prentice-Hall, 1998)]. Partition ratios for partitioning of proteins in two-aqueous-phase systems depend upon many factors and are difficult to predict [Zaslavsky, *Aqueous Two-Phase Partitioning* (Dekker, 1994); and Kelley and Hatton, Chap. 22, "Protein Purification by Liquid-Liquid Extraction," in *Biotechnology*, 2d ed., vol. 3, Stephanopoulos, ed. (VCH, 1993)].

For general discussions of organic acid and base ionic equilibria, see Butler, *Ionic Equilibrium: Solubility and pH Calculations* (Wiley, 1998); and March, *Advanced Organic Chemistry: Reactions, Mechanisms, and Structure*, 5th ed., Chap. 8 (Wiley, 2000). The dissociation of inorganic salts is discussed in the book edited by Perrin [*Ionization Constants of Inorganic Acids and Bases in Aqueous Solution*, vol. 29 (Franklin, 1982)]. Compilations of $pK_a$ values are given in several handbooks [Jencks and Regenstein, "Ionization Constants of Acids and Bases," in *Handbook of Biochemistry and Molecular Biology; Physical and Chemical Data*, vol. 1, 3d ed., Fasman, ed. (CRC Press, 1976), pp. 305–351; and *CRC Handbook of Chemistry and Physics*, 84th ed., Lide, ed. (CRC Press, 2003–2004)]. Also see Perrin, Dempsey, and Serjeant, $pK_a$ *Prediction for Organic Acids and Bases* (Chapman and Hall, 1981).

## PHASE DIAGRAMS

Phase diagrams are used to display liquid-liquid equilibrium data across a wide composition range. Consider the binary system of water + 2-butoxyethanol (common name ethylene glycol *n*-butyl ether) plotted in Fig. 15-15. This system exhibits both an upper critical solution temperature (UCST), also called the upper consolute temperature, and a lower critical solution temperature (LCST), or lower consolute temperature. The mixture is only partially miscible at temperatures between 48°C (the LCST) and 130°C (the UCST). Most mixtures tend to become more soluble in each other as the temperature increases; i.e., they exhibit UCST behavior. The presence of a LCST in the phase diagram is less common. Mixtures that exhibit LCST behavior include hydrogen-bonding mixtures such as an amine, a ketone, or an etheric alcohol plus water. Numerous water + glycol ether mixtures behave in this way [Christensen et al., *J. Chem. Eng. Data*, **50**(3), pp. 869–877 (2005)]. For these systems, hydrogen bonding leads to complete miscibility below the LCST. As temperature increases, hydrogen bonding is disrupted by increasing thermal (kinetic) energy, and hydrophobic interactions begin to dominate, leading to partial miscibility at temperatures above the LCST. The ethylene glycol + triethylamine system shown in Fig. 15-16 is another example.

Most of the ternary or pseudoternary systems used in extraction are of two types: one binary pair has limited miscibility (termed a type I system), or two binary pairs have limited miscibility (a type II system). The water + acetic acid + methyl isobutyl ketone (MIBK) system

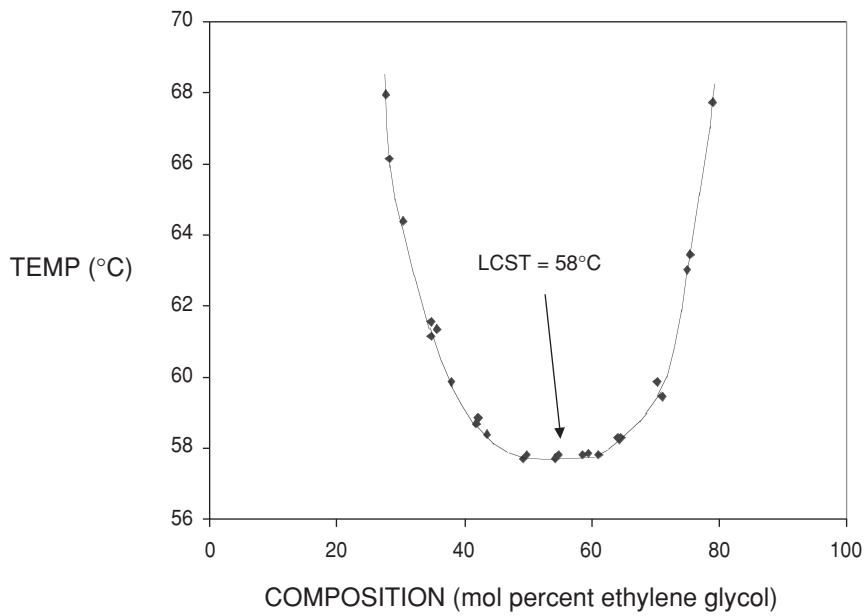

**FIG. 15-16** Temperature-composition diagram for ethylene glycol + triethylamine. [*Data taken from Sorenson and Arlt,* Liquid-Liquid Equilibrium Data Collection, *DECHEMA, Binary Systems, vol. V*, pt. 1, 1979.]

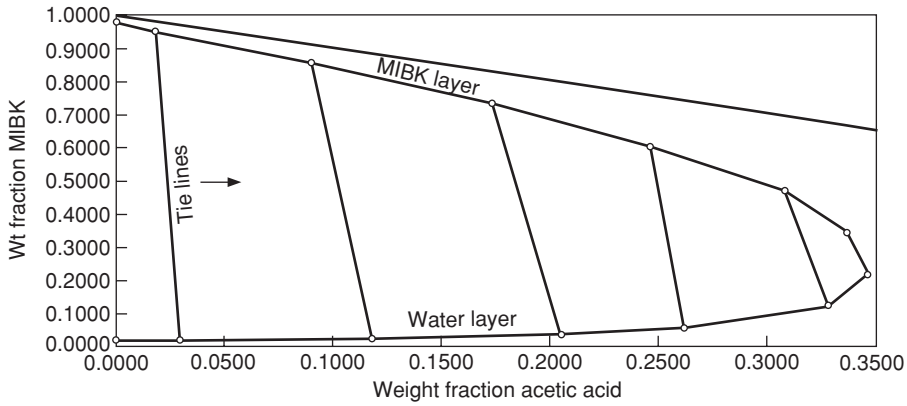

**FIG. 15-17** Water + acetic acid + methyl isobutyl ketone at 25°C, a type I system.

shown in Fig. 15-17 is a type I system where only one of the binary pairs, water + MIBK, exhibits partial misciblity. The heptane + toluene + sulfolane system is another example of a type I system. In this case, only the heptane + sulfolane binary is partially miscible (Fig. 15-18). For a type II system, the solute has limited solubility in one of the liquids. An example of a type II system is MIBK + phenol + water (Fig. 15-19), where MIBK + water and phenol + water are only partially miscible. Some systems form more complicated phase diagrams. For example, the system water + dodecane + 2-butoxyethanol can form three liquid phases in equilibrium at 25°C [Lin and Chen, *J. Chem. Eng. Data*, **47**(4), pp. 992–996 (2002)]. Complex systems such as this rarely are encountered in extraction applications; however, Shen, Chang, and Liu [*Sep. Purif. Technol.*, **49**(3), pp. 217–222 (2006)] describe a single-stage, three-liquid-phase extraction process for transferring phenol and *p*-nitrophenol from wastewater in separate phases. In this process, the three-phase system consists of ethylene oxide–propylene oxide copolymer + ammonium sulfate + water + an oxygenated organic solvent such as butyl acetate or 2-octanol.

For ternary systems, a three-dimensional plot is required to represent the effects of both composition and temperature on the phase behavior. Normally, ternary phase data are plotted on isothermal, two-dimensional triangular diagrams. These can be right-triangle plots, as in Fig. 15-17, or equilateral-triangle plots, as in Figs. 15-18 and 15-19. In Fig. 15-18, the line delineating the region where two liquid phases form is called the binodal locus. The lines connecting equilibrium compositions for each phase are called tie lines, as illustrated by lines *ab* and *cd*. The tie lines converge on the plait point, the point on the bimodal locus where both liquid phases attain the same composition and the tie line length goes to zero. To calculate the relative amounts of the liquid phases, the lever rule is used. For the total feed composition *z*, the fraction of phase 1 with the composition *e* is equal to the ratio of the lengths of the line segments given by *fz/ez* in Fig. 15-18. Data often are plotted on a mass fraction basis when differences in the molecular weights of the components are large, since plotting the phase diagram on a mole basis tends to compress the data into a small region and details are hidden by the scale. This often is the case for systems involving water, for example.

An extraction application normally involves more than three components, including the key solute, the feed solvent, and extraction solvent (or solvent blend), plus impurity solutes. Usually, the minor impurity components do not have a major impact on the phase equilibrium. Phase equilibrium data for multicomponent systems may be represented by using an appropriate activity coefficient correlation. (See "Data Correlation Equations.") However, for many dilute and moderately concentrated feeds, process design calculations are carried out as if the system were a ternary system comprised only of a single solute plus the feed solvent and extraction solvent (a pseudoternary). Partition ratios are determined for major and minor solutes by using a representative feed, and solute transfer calculations are carried out using solute *K* values as if they were completely independent of one another. This approach often is satisfactory, but its validity should be checked with a few key experiments. For industrial mixtures containing numerous impurities, a mass fraction or mass ratio basis often is used to avoid

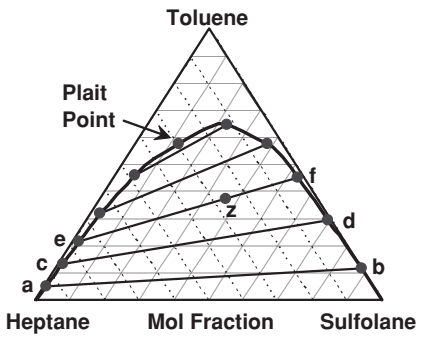

**FIG. 15-18** Heptane + toluene + sulfolane at 25°C, a type I system. [*Data taken from De Fre and Verhoeye,* J. Appl. Chem. Biotechnol., **26,** *pp. 1-19 (1976).*]

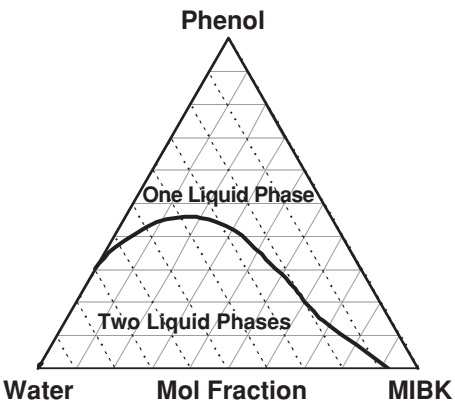

**FIG. 15-19** Methyl isobutyl ketone + phenol + water at 30°C, a type II system. [*Data taken from Narashimhan, Reddy, and Chari,* J. Chem. Eng. Data, **7,** *p. 457 (1962).*]

difficulties accounting for impurities of unknown structure and molecular weight.

## LIQUID-LIQUID EQUILIBRIUM EXPERIMENTAL METHODS

**General References:** Raal, Chap. 3, "Liquid-Liquid Equilibrium Measurements," in *Vapor-Liquid Equilibria Measurements and Calculations* (Taylor & Francis, 1998); Newsham, Chap. 1 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992); and Novak, Matous, and Pick, *Liquid-Liquid Equilibria, Studies in Modern Thermodynamics Series*, vol. 7, pp. 266–282 (Elsevier, 1987).

Three general types of experimental methods commonly are used to generate liquid-liquid equilibrium data: (1) titration with visual observation of liquid clarity or turbidity; (2) visual observation of clarity or turbidity for known compositions as a function of temperature; and (3) direct analysis of equilibrated liquids typically using GC or LC methods. In the titration method, one compound is slowly titrated into a known mass of the second compound during mixing. The titration is terminated when the mixture becomes cloudy, indicating that a second liquid phase has formed. A tie line may be determined by titrating the second compound into the first at the same temperature. This method is reasonably accurate for binary systems composed of pure materials. It also may be applied to ternaries by titrating the third component into a solution of the first and second components, at least to some extent. This method also requires the least time to perform. Since the method is visual, a trace impurity in the "titrant" that is less soluble in the second compound may cause cloudiness at a lower concentration than if pure materials were used. This method has poor precision for sparingly soluble systems. Normally, it is used at ambient temperature and pressure for systems that do not pose a significant health risk to the operator.

In the second method, several mixtures of known composition are formulated and placed in glass vials or ampoules. These are placed in a bath or oven and heated or cooled until two phases become one, or vice versa. In this way, the phase boundaries of a binary system may be determined. Again, impurities in the starting materials may affect the results, and this method does not work well for sparingly soluble systems or for systems that develop significant pressure.

To obtain tie-line data for systems that involve three or more significant components, or for systems that cannot be handled in open containers, both phases must be sampled and analyzed. This generally requires the greatest effort but gives the most accurate results and can be used over the widest range of solubilities, temperatures, and pressures. This method also may be used on multicomponent systems, which are more likely to be encountered in an industrial process. For this method, an appropriate glass vessel or autoclave is selected, based on the temperature, pressure, and compounds in the mixture. It is best to either place the vessel in an oven or submerge it in a bath to ensure there are no cold or hot spots. The mixture is introduced, thermostatted, and thoroughly mixed, and the phases are allowed to separate fully. Samples are then carefully withdrawn through lines that have the minimum dead volume feasible. The sampling should be done isothermally; otherwise the collected sample may not be exactly the same as what was in the equilibrated vessel. Adding a carefully chosen, nonreactive diluent to the sample container will prevent phase splitting, and this can be an important step to ensure accuracy in the subsequent sample workup and analysis. Take sufficient purges and at least three samples from each phase. Use the appropriate analytical method and analyze a calibration standard along with the samples. Try to minimize the time between sampling and analysis.

Rydberg and others describe automated equipment for generating tie line data, including an apparatus called AKUFVE offered by MEAB [Rydberg et al., Chap. 4 in *Solvent Extraction Principles and Practice*, 2d ed., Rydberg et al., eds. (Dekker, 2004), pp. 193–197]. The AKUFVE apparatus employs a stirred cell, a centrifuge for phase separation, and online instrumentation for rapid generation of data. As an alternative, Kuzmanović et al. [*J. Chem. Eng. Data*, **48,** pp. 1237–1244 (2003)] describe a fully automated workstation for rapid measurement of liquid-liquid equilibrium using robotics for automated sampling.

## DATA CORRELATION EQUATIONS

**Tie Line Correlations** Useful correlations of ternary data may be obtained by using the methods of Hand [*J. Phys. Chem.*, **34**(9), pp. 1961–2000 (1930)] and Othmer and Tobias [*Ind. Eng. Chem.*, **34**(6), pp. 693–696 (1942)]. Hand showed that plotting the equilibrium line in terms of mass ratio units on a log-log scale often gave a straight line. This relationship commonly is expressed as

$$\log \frac{X_{23}}{X_{33}} = a + b \log \frac{X_{21}}{X_{11}} \tag{15-23}$$

where $X_{ij}$ represents the mass fraction of component $i$ dissolved in the phase richest in component $j$, and $a$ and $b$ are empirical constants. Subscript 2 denotes the solute, while subscripts 1 and 3 denote feed solvent and extraction solvent, respectively. An equivalent expression can be written by using the Bancroft coordinate notation introduced earlier: $Y' = cX'^{b}$, where $c = 10^{a}$. Othmer and Tobias proposed a similar correlation:

$$\log \frac{1 - X_{33}}{X_{33}} = d + e \log \frac{1 - X_{11}}{X_{11}} \tag{15-24}$$

where $d$ and $e$ are constants. Equations (15-23) and (15-24) may be used to check the consistency of tie line data, as discussed by Awwad et al. [*J. Chem. Eng. Data*, **50**(3), pp. 788–791 (2005)] and by Kirbaslar et al. [*Braz. J. Chem. Eng.*, **17**(2), pp. 191–197 (2000)].

A particularly useful diagram is obtained by plotting the solute equilibrium line on log-log scales as $X_{23}/X_{33}$ versus $X_{21}/X_{11}$ [from Eq. (15-23)] along with a second plot consisting of $X_{23}/X_{33}$ versus $X_{23}/X_{13}$ and $X_{21}/X_{31}$ versus $X_{21}/X_{11}$. This second plot is termed the limiting solubility curve. The plait point may easily be found from the intersection of the solute equilibrium line with this curve, as shown by Treybal, Weber, and Daley [*Ind. Eng. Chem.*, **38**(8), pp. 817–821 (1946)]. This type of diagram also is helpful for interpolation and limited extrapolation when equilibrium data are scarce. An example diagram is shown in Fig. 15-20 for the water + acetic acid + methyl isobutyl ketone (MIBK) system. For additional discussion of various

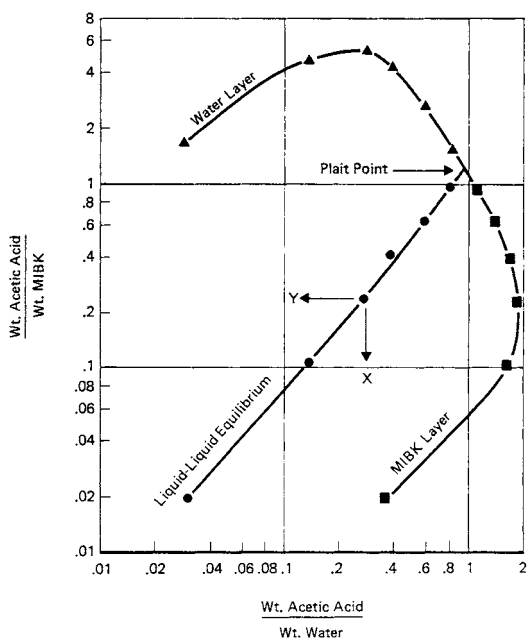

**FIG. 15-20** Hand-type ternary diagram for water + acetic acid + MIBK at 25°C.

correlation methods, see Laddha and Degaleesan, *Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978), Chap. 2.

**Thermodynamic Models** The thermodynamic theories and equations used to model phase equilibria are reviewed in Sec. 4, "Thermodynamics." These equations provide a framework for data that can help minimize the required number of experiments. An accurate liquid-liquid equilibrium (LLE) model is particularly useful for applications involving concentrated feeds where partition ratios and mutual solubility between phases are significant functions of solute concentration. Sometimes it is difficult to model LLE behavior across the entire composition range with a high degree of accuracy, depending upon the chemical system. In that case, it is best to focus on the composition range specific to the particular application at hand—to ensure the model accurately represents the data in that region of the phase diagram for accurate design calculations. Such a model can be a powerful tool for extractor design or when used with process simulation software to conceptualize, evaluate, and optimize process options. However, whether a complete LLE model is needed will depend upon the application. For dilute applications where partition ratios do not vary much with composition, it may be satisfactory to characterize equilibrium in terms of a simple Hand-type correlation or in terms of partition ratios measured over the range of anticipated feed and raffinate compositions and fit to an empirical equation. Also, when partition ratios are always very large, on the order of 100 or larger, as can occur when washing salts from an organic phase into water, a continuous extractor is likely to operate far from equilibrium. In this case, a precise equilibrium model may not be needed because the extraction factor always is very large and solute diffusion rates dominate performance. (See "Rate-Based Calculations" under "Process Fundamentals and Basic Calculation Methods.")

LLE models for nonionic systems generally are developed by using either the NRTL or UNIQUAC correlation equations. These equations can be used to predict or correlate multicomponent mixtures using only binary parameters. The NRTL equations [Renon and Prausnitz, *AIChE J.*, **14**(1), pp. 135–144 (1968)] have the form

$$\ln \gamma_i = \frac{\sum_j \tau_{ji} G_{ji} x_j}{\sum_j G_{ji} x_j} + \sum_k \frac{G_{ji} x_j}{\sum_k G_{kj} x_k} \left( \tau_{ij} - \frac{\sum_k \tau_{kj} G_{kj} x_k}{\sum_k G_{kj} x_k} \right) \qquad (15\text{-}25)$$

where $\tau_{ij}$ and $G_{ij} = \exp(-\alpha_{ij}\tau_{ij})$ are model parameters. The UNIQUAC equations [Abrams and Prausnitz, *AIChE J.*, **21**(1), pp. 116–128 (1975)] are somewhat more complex. (See Sec. 4, "Thermodynamics.") Most commercial simulation software packages include these models and allow regression of data to determine model parameters. One should refer to the process simulator's operating manual for specific details. Not all simulation software will use exactly the same equation format and parameter definitions, so parameters reported in the literature may not be appropriate for direct input to the program but need to be converted to the appropriate form. In theory, activity coefficient data from binary or ternary vapor-liquid equilibria can be used for calculating liquid-liquid equilibria. While this may provide a reasonable starting point, in practice at least some of the binary parameters will need to be determined from liquid-liquid tie line data to obtain an accurate model [Lafyatis et al., *Ind. Eng. Chem. Res.*, **28**(5), pp. 585–590 (1989)]. Detailed discussion of the application and use of NRTL and UNIQUAC is given by Walas [*Phase Equilibria in Chemical Engineering* (Butterworth-Heinemann, 1985)]. The application of NRTL in the design of a liquid-liquid extraction process is discussed by van Grieken et al. [*Ind. Eng. Chem. Res.*, **44**(21), pp. 8106–8112 (2005)], by Venter and Nieuwoudt [*Ind. Eng. Chem. Res.*, 37(10), pp. 4099–4106 (1998)], and by Coto et al. [*Chem. Eng. Sci.*, **61,** pp. 8028–8039 (2006)]. The use of the NRTL model also is discussed in Example 5 under "Single-Solvent Fractional Extraction with Extract Reflux" in "Calculation Procedures." The application of UNIQUAC is discussed by Anderson and Prausnitz [*Ind. Eng. Chem. Process Des. Dev.*, **17**(4), pp. 561–567 (1978)].

Although the NRTL or UNIQUAC equations generally are recommended for nonionic systems, a number of alternative approaches have been introduced. Some include explicit terms for association of molecules in solution, and these may have advantages depending upon the application. An example is the statistical associating fluid theory (SAFT) equation of state introduced by Chapman et al. [*Ind. Eng. Chem. Res.*, **29**(8), pp. 1709–1721 (1990)]. SAFT approximates molecules as chains of spheres and uses statistical mechanics to calculate the energy of the mixture [Müller and Gubbins, *Ind. Eng. Chem. Res*, **40**(10), pp. 2193–2211 (2001)]. Yu and Chen discuss the application of SAFT to correlate data for 41 binary and 8 ternary liquid-liquid systems [*Fluid Phase Equilibria*, **94,** pp. 149–165 (1994)]. Note that at present not all commercial simulation software packages include SAFT as an option; or if it is included, the association term may be left out. The SAFT equation often is used to correlate LLE data for polymer-solvent systems [Jog et al., *Ind. Eng. Chem. Res.*, **41**(5), pp. 887–891 (2002)]. In another approach, Asprion, Hasse, and Maurer [*Fluid Phase Equil.*, **205,** pp. 195–214 (2003)] discuss the addition of chemical theory association terms to the UNIQUAC model and other phase equilibrium models in general. With this approach, molecular association is treated as a reversible chemical reaction, and parameter values for the association terms may be determined from spectroscopic data. Another activity coefficient correlation called COSMO-SPACE is presented as an alternative to UNIQUAC [Klamt, Krooshof, and Taylor, *AIChE J.*, **48**(10), pp. 2332–2349 (2002)].

Other methods are used to describe the behavior of ionic species (electrolytes). The activity coefficient of an ion in solution may be expressed in terms of modified Debye-Hückel theory. A common expression suitable for low concentrations has the form

$$\log \gamma_i = \frac{-a z_i^2 I^{1/2}}{1 + I^{1/2}} + b z_i^2 I \qquad (15\text{-}26)$$

where $I$ is ionic strength, $z_i$ is the number of electronic charges, and $a$ and $b$ are parameters that depend upon temperature. Ionic strength is defined in terms of the ion molal concentration. Equation (15-26) represents the activity coefficient for a single ion. For a compound MX that dissociates into $M^+$ and $X^-$ in solution, the mean ionic activity coefficient is given by $\gamma^{\pm} = (\gamma^+\gamma^-)^{1/2}$. Activity coefficients for most electrolytes dissolved in water are less than unity because of the strong attractive interaction between water and a charged species, but this can vary depending upon the organic character of the ion and its concentration. For more detailed discussions focusing on extraction, see Marcus, Chap. 2, and Grenthe and Wanner, Chap. 6, in *Solvent Extraction Principles and Practice*, 2d ed., Rydberg et al., eds. (Dekker, 2004). For general discussions, see *Activity Coefficients in Electrolyte Solutions*, 2d ed., Pitzer, ed. (CRC Press, 1991); Zemaitis et al., *Handbook of Aqueous Electrolyte Thermodynamics* (DIPPR, AIChE, 1986); and Robinson and Stokes, *Electrolyte Solutions* (Butterworths, 1959). The concepts of molecular association have been applied to modeling electrolyte solutions with good success [Stokes and Robinson, *J. Soln. Chem.* **2,** p. 173 (1973)].

Modeling phase equilibria for mixed-solvent electrolyte systems including nonionic organic compounds is discussed by Polka, Li, and Gmehling [*Fluid Phase Equil.*, **94,** pp. 115–127 (1994)]; Li, Lin, and Gmehling [*Ind. Eng. Chem. Res.*, **44**(5), pp. 1602–1609 (2005)]; and Wang et al. [*Fluid Phase Equil.*, **222–223,** pp. 11–17 (2004)]. Another computer program is discussed by Baes et al. [*Sep. Sci. Technol.*, **25,** p. 1675 (1990)]. Ahlem, Abdeslam-Hassen, and Mossaab [*Chem. Eng. Technol.*, **24**(12), pp. 1273–1280 (2001)] discuss two approaches to modeling metal ion extraction for purification of phosphoric acid.

**Data Quality** Normally, it is not possible to evaluate LLE data for thermodynamic consistency [Sorenson and Arlt, *Liquid-Liquid Equilibrium Data Collection*, Binary Systems, vol. V, pt. 1 (DECHEMA, 1979), p. 12]. The thermodynamic consistency test for VLE data involves calculating an independently measured variable from the others (usually the vapor composition from the temperature, pressure, and liquid composition) and comparing the measurement with the calculated value. Since LLE data are only very weakly affected by change in pressure, this method is not feasible for LLE. However, if the data were produced by equilibration and analysis of both phases, then at least the data can be checked to determine how well the material balance closes. This can be done by plotting the total

**TABLE 15-1 Selected Partition Ratio Data**

Partition ratios are listed in units of weight percent solute in the extract divided by weight percent solute in the raffinate, generally for the lowest solute concentrations given in the cited reference. The partition ratio tends to be greatest at low solute concentrations. Consult the original references for more information about a specific system.

| Solute | Feed solvent | Extraction solvent | Temp. (°C) | *K* (wt % basis) | Reference |
|---|---|---|---|---|---|
| Ethanol | Cyclohexane | Ethanolamine | 25 | 2.79 | 1 |
| Acetone | Ethylene glycol | Amyl acetate | 31 | 1.84 | 2 |

feed composition used in the experiments along with the measured tie line compositions on a ternary diagram. The feed composition should lie on the tie line. For very low solute concentrations, this plot may be unrevealing. Alternatively, a plot of $Y_i''/Z_i''$ versus $X_i''/Z_i''$ (where $Y_i''$ is the mass fraction of component $i$ in the extract phase, $X_i''$ is the mass fraction of component $i$ in the raffinate phase, and $Z_i''$ is the mass fraction of component $i$ in the total feed) should give a straight line that passes through the point (1, 1). The tie line data also may be checked for consistency by plotting the data in the form of a Hand plot or Othmer-Tobias plot, as described in "Tie Line Correlations," and looking for outliers. Another approach is to plot the partition ratio as a function of solute concentration and look for data points that deviate significantly from otherwise smooth trends. If the NRTL equation is used, refit all the binary data sets by using the same value for model parameter $\alpha$. A value of 0.3 is recommended by Walas [*Phase Equilibria in Chemical Engineering* (Butterworth-Heinemann, 1985), p. 203] for nonaqueous systems, and a higher value of 0.4 is recommended for aqueous systems. Sorensen and Arlt [*Chemistry Data Series: Liquid-Liquid Equilibrium Data Collection*, Vol. V, pt. 1 (DECHEMA, 1979), p. 14] use a value of 0.2 for all their work. The particular value chosen appears to be less important than using the same value for all binaries of the same type (aqueous or nonaqueous). Try for a reasonable fit of the overall data, but be sure to focus on achieving a good fit of the data in the region most relevant to the application at hand.

### TABLE OF SELECTED PARTITION RATIO DATA

Table 15-1 summarizes typical partition ratio data for selected systems.

### PHASE EQUILIBRIUM DATA SOURCES

A comprehensive collection of phase equilibrium data (including vapor-liquid, liquid-liquid, and solid-liquid data) is maintained by a group headed by Prof. Juergen Gmehling at the University of Oldenburg, Germany. This collection, known as the Dortmund Data Bank, includes LLE measurements as well as NRTL and UNIQUAC fitted parameters. The data bank also includes a compilation of infinite-dilution activity coefficients. The LLE collection is available as a series of books [Sorensen and Arlt, *Chemistry Data Series: Liquid-Liquid Equilibrium Data Collection*, *Binary Systems*, vol. V, pts. 1–4 (DECHEMA, 1979–1980)], as a proprietary database including retrieval and modeling software, and online by subscription. There also is a new online database offered by FIZ-Berlin Infotherm. Other sources of thermodynamic data include the IUPAC Solubility Data Series published by Oxford University Press, and compilations prepared by the Thermodynamics Research Center (TRC) in Boulder, Colo., a part of the Physical and Chemical Properties Division of the National Institute of Standards and Technology. An older but still useful data collection is that of Stephens and Stephens [*Solubilities of Inorganic and Organic Compounds*, vol. 1, pts. 1 and 2 (Pergamon, 1960)]. Also, a database of activity coefficients is included in the supporting information submitted with the article by Lazzaroni et al. [*Ind. Eng. Chem. Res.*, **44**(11), pp. 4075–4083 (2005)] and available from the publisher. A listing of the original sources is included. Additional sources of data are discussed by Skrzecz [*Pure Appl. Chem.* (IUPAC), **69**(5), pp. 943–950 (1997)].

### RECOMMENDED MODEL SYSTEMS

To facilitate the study and comparison of various types of extraction equipment, Bart et al. [Chap. 3 in Godfrey and Slater, *Liquid-Liquid Extraction Equipment* (Wiley, 1994)] recommend several model systems. These include (1) water + acetone + toluene (high interfacial tension); (2) water + acetone + butyl acetate (moderate interfacial tension); and (3) water + succinic acid + *n*-butanol (low interfacial tension). All have solute partition ratios near $K = 1.0$. Misek, Berger, and Schröter [*Standard Test Systems for Liquid Extraction* (The Instn. of Chemical Engineers, 1985)] summarize phase equilibrium, viscosities, densities, diffusion coefficients, and interfacial tensions for these systems. Note that methyl isobutyl ketone + acetic acid + water was replaced with the water + acetone + butyl acetate system because of concerns over acetic acid dimerization and Marangoni instabilities. (See "Liquid-Liquid Dispersion Fundamentals.") For test systems with a partition ratio near $K = 10$, Bart et al. recommend (1) water + methyl isopropyl ketone + toluene (high interfacial tension) and (2) water + methyl isopropyl ketone + butyl acetate (medium interfacial tension) and give references to data sources. Bart et al. also recommend a number of systems involving reactive extractants.

## SOLVENT SCREENING METHODS

A variety of methods may be used to estimate solvent properties as an aid to identifying useful solvents for a new application. Many of these methods focus on thermodynamic properties; a favorable partition ratio and low mutual solubility often are necessary for an economical extraction process, so ranking candidates according to thermodynamic properties provides a useful initial screen of the more promising candidates. Keep in mind, however, that other factors also must be taken into account when selecting a solvent, as discussed in "Desirable Solvent Properties" under "Introduction and Overview." When using the following methods, also note that the level of uncertainty may be fairly high. The uncertainty depends upon how closely the chemical system of interest resembles the systems used to develop the method.

### USE OF ACTIVITY COEFFICIENTS AND RELATED DATA

Compilations of infinite-dilution activity coefficients, when available for the solute of interest, may be used to rank candidate solvents. Partition ratios at finite concentrations can be estimated from these data by extrapolation from infinite dilution using a suitable correlation equation such as NRTL [Eq. (15-25)]. Examples of these kinds of calculations are given by Walas [*Phase Equilibria in Chemical Engineering* (Butterworth-Heinemann, 1985)]. Most activity coefficients available in the literature are for small organic molecules and are derived from vapor-liquid equilibrium measurements or azeotropic composition data.

Partition ratios at infinite dilution can be calculated directly from the ratio of infinite-dilution activity coefficients for solute dissolved in the extraction solvent and in the feed solution, often providing a reasonable estimate of the partition ratio for dilute concentrations. Infinite-dilution activity coefficients often are reported in terms of a van Laar binary interaction parameter [Smallwood, *Solvent Recovery Handbook* (McGraw-Hill, 1993)] such that

$$\ln \gamma_{ij}^{\infty} = \frac{A_{i,j}}{RT} \tag{15-27}$$

$$K_i^o = \frac{\gamma_i^{\infty}}{\gamma_i^{*,\infty}} = \frac{\exp(A^{ij}/RT)}{\exp(A^{*i,j}/RT)} \tag{15-28}$$

where $^*$ denotes the extraction solvent phase. For example, the partition ratio for transferring acetone from water into benzene at 25°C and dilute conditions may be estimated as follows: For acetone dissolved in benzene $A_{ij}/RT = 2.47$, and for acetone dissolved in water $A_{ij}/RT = 2.29$. Then $K_i^o = e^{2.29}/e^{0.47} = 9.87/1.6 = 6.17$ (mol/mol) $\equiv 1.4$ (wt/wt). Briggs and Comings [*Ind. Eng. Chem.*, **35**(4), pp. 411–417 (1943)] report experimental values that range between 1.06 and 1.39 (wt/wt).

For screening candidate solvents, comparing the magnitude of the activity coefficient for the solute of interest dissolved in the solvent phase often is a good way to rank solvents, since a smaller value of $\gamma_{i,\text{solvent}}$ indicates a higher $K$ value. Solubility data available for a given solute dissolved in a range of solvents also can be used to rank solvents, since higher solubility in a candidate solvent indicates a more attractive interaction (a lower activity coefficient) and therefore a higher partition ratio.

### ROBBINS' CHART OF SOLUTE-SOLVENT INTERACTIONS

When available data are not sufficient (the most common situation), Robbins' chart of functional group interactions (Table 15-2) is a useful

**TABLE 15-2 Robbins' Chart of Solute-Solvent Interactions***

| Solute class | | Solvent class | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |
| | H donor groups | | | | | | | | | | | | |
| 1 | Phenol | 0 | 0 | – | 0 | – | – | – | – | – | – | + | + |
| 2 | Acid, thiol | 0 | 0 | – | 0 | – | – | 0 | 0 | 0 | 0 | + | + |
| 3 | Alcohol, water | – | – | 0 | + | + | 0 | – | – | + | + | + | + |
| 4 | Active H on multihalogen paraffin | 0 | 0 | + | 0 | – | – | – | – | – | – | 0 | + |
| | H acceptor groups | | | | | | | | | | | | |
| 5 | Ketone, amide with no H on N, sulfone, phosphine oxide | – | – | + | – | 0 | + | + | + | + | + | + | + |
| 6 | Tertiary amine | – | – | 0 | – | + | 0 | + | + | 0 | + | 0 | 0 |
| 7 | Secondary amine | – | 0 | – | – | + | + | 0 | 0 | 0 | 0 | 0 | + |
| 8 | Primary amine, ammonia, amide with 2H on N | – | 0 | – | – | + | + | 0 | 0 | + | + | + | + |
| 9 | Ether, oxide, sulfoxide | – | 0 | + | – | + | 0 | 0 | + | 0 | + | 0 | + |
| 10 | Ester, aldehyde, carbonate, phosphate, nitrate, nitrite, nitrile, intramolecular bonding, e.g., *o*-nitrophenol | – | 0 | + | – | + | + | 0 | + | + | 0 | + | + |
| 11 | Aromatic, olefin, halogen aromatic, multihalogen paraffin without active H, monohalogen paraffin | + | + | + | 0 | + | 0 | 0 | + | 0 | + | 0 | 0 |
| | Non-H-bonding groups | | | | | | | | | | | | |
| 12 | Paraffin, carbon disulfide | + | + | + | + | + | 0 | + | + | + | + | 0 | 0 |

*From Robbins, *Chem. Eng. Prog.*, **76**(10), pp. 58–61 (1980), by permission. Copyright 1980 AIChE.

guide to ranking general classes of solvents. It is based on an evaluation of hydrogen bonding and electron donor-acceptor interactions for 900 binary systems [Robbins, *Chem. Eng. Prog.*, **76** (10), pp. 58–61 (1980)]. The chart includes 12 general classes of functional groups, divided into three main types: hydrogen-bond donors, hydrogen-bond acceptors, and non-hydrogen-bonding groups. Compounds representative of each class include (1) phenol, (2) acetic acid, (3) pentanol, (4) dichloromethane, (5) methyl isobutyl ketone, (6) triethylamine, (7) diethylamine, (8) *n*-propylamine, (9) ethyl ether, (10) ethyl acetate, (11) toluene, and (12) hexane. Robbins' chart is applicable to any process where liquid-phase activity coefficients are important, including liquid-liquid extraction, extractive distillation, azeotropic distillation, and crystallization from solution. The activity coefficient in the liquid phase is common to all these separation processes.

Robbins' chart predicts positive, negative, or zero deviations from ideal behavior for functional group interactions. For example, consider an application involving extraction of acetone from water into chloroform solvent. Acetone contains a ketone carbonyl group which is a hydrogen acceptor and a member of solute class 5 according to Table 15-2. Chloroform contains a hydrogen donor group (solvent class 4). The solute class 5 and solvent class 4 interaction in Table 15-2 is shown to give a negative deviation from ideal behavior. This indicates an attractive interaction which enhances the liquid-liquid partition ratio. Other classes of solvents shown in Table 15-2 that yield a negative deviation with a ketone (class 5) are classes 1 and 2 (phenolics and acids). Other ketones (solvent class 5) are shown to be compatible with acetone (solute class 5) and tend to give activity coefficients near 1.0, that is, nearly ideal behavior. The solvent classes 6 through 12 tend to provide repulsive interactions between these groups and acetone, and so they are not likely to exhibit partition ratios for ketones as high as the other solvent groups do.

Most of the classes in Table 15-2 are self-explanatory, but some can use additional definition. Class 4 includes halogenated solvents that have highly active hydrogens as described by Ewell, Harrison, and Berg [*Ind. Eng. Chem.*, **36**(10), pp. 871–875 (1944)]. These are molecules that have two or three halogen atoms on the same carbon as a hydrogen atom, such as dichloromethane, trichloromethane, 1,1-dichloroethane, and 1,1,2,2-tetrachloroethane. Class 4 also includes molecules that have one halogen on the same carbon atom as a hydrogen atom and one or more halogen atoms on an adjacent carbon atom, such as 1,2-dichloroethane and 1,1,2-trichloroethane. Apparently, the halogens interact intramolecularly to leave the hydrogen atom highly active. Monohalogen paraffins such as methyl chloride and ethyl chloride are in class 11 along with multihalogen paraffins and olefins without active hydrogen, such as carbon tetrachloride and perchloroethylene. Chlorinated benzenes are also in class 11 because they do not have halogens on the same carbon as a hydrogen atom. Intramolecular bonding on aromatics is another fascinating interaction which gives a net result that behaves much as does an ester group, class 10. Examples of this include *o*-nitrophenol and *o*-hydroxybenzaldehyde (salicylaldehyde). The intramolecular hydrogen bonding is so strong between the hydrogen donor group (phenol) and the hydrogen acceptor group (nitrate or aldehyde) that the molecule acts as an ester. One result is its low solubility in hot water. By contrast, the *para* derivative is highly soluble in hot water.

## ACTIVITY COEFFICIENT PREDICTION METHODS

Robbins' chart provides a useful qualitative indication of interactions between classes of molecules but does not give quantitative differences within each class. For this, a number of methods are available. Many have been implemented in commercial and university-supported software packages. Perhaps the most widely used of these is the UNIFAC group contribution method [Fredenslund et al., *Ind. Eng. Chem. Proc. Des. Dev.*, **16**(4), pp. 450–462 (1977); and Wittig et al., *Ind. Eng. Chem. Res.*, **42**(1), pp. 183–188 (2003). Also see Jakob et al., *Ind. Eng. Chem. Res.*, **45,** pp. 7924–7933 (2006)]. The use of UNIFAC for estimating LLE is discussed by Gupte and Danner [*Ind. Eng. Chem. Res.*, **26**(10), pp. 2036–2042 (1987)] and by Hooper, Michel, and Prausnitz [*Ind. Eng. Chem. Res.*, **27**(11), pp. 2182–2187 (1988)]. Vakili-Nezhand, Modarress, and Mansoori [*Chem. Eng. Technol.*, **22**(10), pp. 847–852 (1999)] discuss its use for representing a complex feed containing a large number of components for which available LLE data are incomplete.

UNIFAC calculates activity coefficients in two parts:

$$\ln \gamma_i = \ln \gamma_i^C + \ln \gamma_i^R \tag{15-29}$$

The combinatorial part $\ln \gamma_i^C$ is calculated from pure-component properties. The residual part $\ln \gamma_i^R$ is calculated by using binary interaction parameters for solute-solvent group pairs determined by fitting phase equilibrium data. Both parts are based on the UNIQUAC set

of equations. With this approach, a molecule is treated as an assembly of various groups of atoms. Compounds for which phase equilibrium already has been measured are used to regress constants for these different groups. These constants are then used in a correlation to predict properties for a new molecule. There are several UNIFAC parameter sets available. It is important to use a consistent set of parameters since the different parameter databases are not necessarily compatible.

A number of methods based on regular solution theory also are available. Only pure-component parameters are needed to make estimates, so they may be applied when UNIFAC group-interaction parameters are not available. The Hansen solubility parameter model divides the Hildebrand solubility parameter into three parts to obtain parameters $\delta_d$, $\delta_p$, and $\delta_h$ accounting for nonpolar (dispersion), polar, and hydrogen-bonding effects [Hansen, *J. Paint Technol.*, **39,** pp. 104–117 (1967)]. An activity coefficient may be estimated by using an equation of the form

$$\ln \gamma_i = \frac{v_i}{RT}\left\{\left(\overline{\delta}_d - \delta_d^i\right)^2 + 0.25\left[\left(\overline{\delta}_p - \delta_p^i\right)^2 + \left(\overline{\delta}_h - \delta_h^i\right)^2\right]\right\} \quad (15\text{-}30)$$

where $\overline{\delta}$ is the solubility parameter for the mixture, $\delta^i$ is the solubility parameter for component $i$, $v$ is molar volume, $R$ is the universal gas constant, and $T$ is absolute temperature [Frank, Downey, and Gupta, *Chem. Eng. Prog.*, **95**(12), pp. 41–61 (1999)]. The Hansen model has been used for many years to screen solvents and facilitate development of product formulations. Hansen parameters have been determined for more than 500 solvents [Hansen, *Hansen Solubility Parameters: A User's Handbook* (CRC, 2000); and *CRC Handbook of Solubility Parameters and Other Cohesion Parameters*, 2d ed., Barton, ed. (CRC, 1991)].

MOSCED, another modified regular solution model, utilizes two parameters to represent hydrogen bonding: one for proton donor capability (acidity) and one for proton acceptor capability (basicity) [Thomas and Eckert, *Ind. Eng. Chem. Proc. Des. Dev.*, **23**(2), pp. 194–209 (1984)]. This provides a more realistic representation of hydrogen bonding that allows more accurate modeling of a wider range of solvents, and unlike the Hansen model, MOSCED can predict negative deviations from ideal solution (activity coefficients less than 1.0). MOSCED calculates infinite-dilution activity coefficients by using an equation of the general form

$$\ln \gamma_{2,1}^{\infty} = \frac{v_2}{RT}\left[(\lambda_1 - \lambda_2)^2 + \frac{q_1^2 q_2^2 (\tau_1 - \tau_2)^2}{\psi_1} + \frac{(\alpha_1 - \alpha_2)(\beta_1 - \beta_2)}{\xi_1}\right] \quad (15\text{-}31)$$

There are five adjustable parameters per molecule: $\lambda$, the dispersion parameter; $q$, the induction parameter; $\tau$, the polarity parameter; $\alpha$, the hydrogen-bond acidity parameter; and $\beta$, the hydrogen-bond basicity parameter. The induction parameter $q$ often is set to a value of 1.0, yielding a four-parameter model. The terms $\psi_1$ and $\xi_1$ are asymmetry factors calculated from the other parameters. A database of parameter values for 150 compounds, determined by regression of phase equilibrium data, is given by Lazzaroni et al. [*Ind. Eng. Chem. Res.*, **44**(11), pp. 4075–4083 (2005)]. An application of MOSCED in the study of liquid-liquid extraction is described by Escudero, Cabezas, and Coca [*Chem. Eng. Comm.*, **173,** pp. 135–146 (1999)]. Also see Frank et al., *Ind. Eng. Chem. Res.*, **46,** pp. 4621–4625 (2007).

Another method for estimating activity coefficients is described by Chen and Song [*Ind. Eng. Chem. Res.*, **43**(26), pp. 8354–8362 (2004); **44**(23), pp. 8909–8921 (2005)]. This method involves regression of a small data set in a manner similar to the way the Hansen and MOSCED models typically are used. The model is based on a modified NRTL framework called NRTL-SAC (for segment activity coefficient) that utilizes only pure-component parameters to represent polar, hydrophobic, and hydrophilic segments of a molecule. An electrolyte parameter may be added to characterize ion-ion and ion-molecule interactions attributed to ionized segments of species in solution. The resulting model may be used to estimate activity coefficients and related properties for mixtures of nonionic organics plus electrolytes in aqueous and nonaqueous solvents.

A method developed by Meyer and Maurer [*Ind. Eng. Chem. Res.*, **34**(1), pp. 373–381 (1995)] uses the linear solvation energy relationships (LSER) model [Taft et al., *Nature,* **313,** p. 384 (1985); and Taft et al., *J. Pharma Sci.*, **74**, pp. 807–814 (1985)] to estimate infinite-dilution partition ratios for solute distributed between water and an organic solvent. The model uses 36 generalized parameters and four solvatochromic parameters to characterize a given solute. The solvatochromic parameters are $\alpha$ (acidity), $\beta$ (basicity), $\pi$ (polarity), and $\delta$ (polarizability). Another method utilizing LSER concepts is the SPACE model for estimating infinite-dilution activity coefficients [Hait et al., *Ind. Eng. Chem. Res.*, **32**(11), pp. 2905–2914 (1993)]. Also see Abraham, Ibrahim, and Zissimos, J. Chromatography, **1037,** pp. 29–47 (2004).

The thermodynamic methods described above glean information from available data to make estimates for other systems. As an alternative approach, quantum chemistry calculations and molecular simulation methods are finding more and more use in engineering applications [Gupta and Olson, *Ind. Eng. Chem. Res.*, **42**(25), pp. 6359–6374 (2003); and Chen and Mathias, *AIChE J.*, **48**(2), pp. 194–200 (2002)]. These methods minimize the need for data; however, the computational effort and specialized expertise required to use them generally are higher, and the accuracy of the results may not be known. An important method gaining increasing application in the chemical industry is the conductorlike screening model (COSMO) introduced by Klamt and colleagues [Klamt, *J. Phys. Chem.* **99,** p. 2224 (1995); Klamt and Eckert, *Fluid Phase Equil.*, **172,** pp. 43–72 (2000); Eckert and Klamt, *AIChE J.*, **48**(2), pp. 369–385 (2002); and Klamt, *From Quantum Chemistry to Fluid Phase Thermodynamics and Drug Design* (Elsevier, 2005)]. Also see Grensemann and Gmehling, *Ind. Eng. Chem. Res.*, **44**(5), pp. 1610–1624 (2005). This method utilizes computational quantum mechanics to calculate a two-dimensional electron density profile to characterize a given molecule. This profile is then used to estimate phase equilibrium using statistical mechanics and solvation theory. The Klamt model is called COSMO-RS (for realistic solvation). A similar model is COSMO-SAC (segment activity coefficient) published by Lin and Sandler [*Ind. Eng. Chem. Res.*, **41**(5), pp. 899–913, 2332 (2002)]. Databases of electron density profiles (sigma profiles) are available from a number of vendors and universities. For example, a sigma-profile database of more than 1000 molecules is available from the Virginia Polytechnic Institute and State University [Mullins et al., *Ind. Eng. Chem. Res.*, **45**(12), pp. 4389–4415 (2006)]. Once determined, the profiles allow convenient calculation of phase equilibria using available software. An application of COSMOS-RS to predict liquid-liquid equilibria is discussed by Banerjee et al. [*Ind. Eng. Chem. Res.*, **46**(4), pp. 1292–1304 (2007)].

## METHODS USED TO ASSESS LIQUID-LIQUID MISCIBILITY

In evaluating potential solvents, it is important to determine whether a given candidate will exhibit sufficiently limited miscibility with the feed liquid. Mutual solubility data for organic-solvent + water mixtures often are listed somewhere in the literature and can be obtained through a literature search. (See "Phase Equilibrium Data Sources" under "Thermodynamic Basis for Liquid-Liquid Extraction.") However, data often are not available for pairs of organic solvents and for multicomponent mixtures showing the effect of dissolved solutes. In these cases, estimates can provide useful guidance. Note, however, that the available estimation methods normally provide limited accuracy, so it is best to measure these properties for the more promising candidates.

Phase splitting behavior can be inferred from activity coefficients. In general, partial miscibility will not occur whenever the infinite-dilution activity coefficients of the components in solution are less than 7. This is a reliable rule but it depends upon the quality of the activity coefficient data or estimates. If $\gamma^{\infty}$ for any one of the components is greater than 7, then partial miscibility may occur at some finite composition. The criterion $\gamma_i^{\infty} > 7$ often is cited as a general rule indicating a partially miscible system, but there are many exceptions. For detailed discussion, see Prausnitz, Lichtenthaler, and Gomez de Azevedo, *Molecular Thermodynamics of Fluid-Phase Equilibria*, 3d ed. (Prentice-Hall, 1999). Solubility parameters also can be used to assess miscibility [*Handbook of Solubility Parameters and Other Cohesion Parameters,* 2d ed., Barton, ed. (CRC, 1991)].

As a complementary alternative, Godfrey's data-based method [*CHEMTECH*, **2**(6), pp. 359–363 (1972)] provides a quick way of qualitatively assessing whether an organic-solvent pair of interest is likely to

exhibit partial miscibility at near-ambient temperatures. Godfrey assigned miscibility numbers to approximately 400 organic solvents (Table 15-3) by observing their miscibility in a series of 31 standard solvents (Table 15-4). He then showed that the general miscibility behavior of a given solvent pair can be predicted by comparing their miscibility numbers. Godfrey's rules, slightly modified, are summarized below:

1. If $\Delta \le 12$, where $\Delta$ is the difference in miscibility numbers, the solvents are likely to be miscible in all proportions at 25°C.

2. If $13 \le \Delta \le 15$, the solvents may be only partially miscible with an upper critical solution temperature (UCST) between 25 and 50°C. This is a borderline case. If the binary mixture is miscible, then adding a relatively small amount of water likely will induce phase splitting.

3. If $\Delta = 16$, the solvents are likely to exhibit a UCST between 25 and 75°C.

4. If $\Delta \ge 17$, the solvents are likely to exhibit a UCST above 75°C.

About 15 percent of the solvents in Table 15-3 have dual miscibility numbers $A$ and $B$ because the appropriate difference in miscibility numbers depends upon which end of the hydrophobic-lipophilic scale is being considered. If one of the solvents has dual miscibility numbers $A$ and $B$ and the other has a single miscibility number $C$, then $\Delta$ should be calculated as follows:

5. If $C > B$, then the solvent having miscibility number $C$ is somewhat more lipophilic than the solvent having numbers $A$ and $B$. At this end of the lipophilicity scale, the number $A$ characterizes the solvent's miscibility behavior. Apply rules 1 through 3 above, using $\Delta = C - A$.

6. If $C < A$, then the solvent having miscibility number $C$ is somewhat less lipophilic than the solvent with numbers $A$ and $B$. At this end of the lipophilicity scale, the number $B$ characterizes the solvent's miscibility behavior. Apply rules 1 through 3, using $\Delta = B - C$.

7. If $A \le C \le B$, then evaluate $\Delta = C - A$ and $\Delta = B - C$ and use the larger of the $\Delta$ values in applying rules 1 through 3. Such a mixture is likely to be miscible in all proportions at 25°C.

8. If both members of a solvent pair have dual miscibility numbers, then the pair is likely to be miscible in all proportions at 25°C.

If a compound of interest is not listed in Table 15-3 or 15-4, a compound of the same type or class may help to gauge its miscibility behavior. In cases where Godfrey's rules indicate that partial miscibility is likely, whether phase splitting actually occurs depends upon the composition of the mixture and the temperature. The composition may be close to but still outside the two-liquid-phase region on a temperature-composition diagram.

Godfrey's method is a useful guide for compounds that exhibit behavior similar to the 31 standard solvents used to define miscibility numbers. The method deals with the common situation in which a mixture exhibits a UCST; i.e. solubility tends to increase with

**TABLE 15-4 Godfrey Standard Solvents**

| Miscibility Number | Solvent | |

increasing temperature. Exceptions to Godfrey's rules include binary mixtures that form unusually strong hydrogen-bonding interactions. Normally, mixtures of this type are completely miscible, or they exhibit a lower critical solution temperature (LCST). Examples include ethylene glycol + triethylamine (Fig. 15-16) and glycerin + ethylbenzylamine (UCST = 280°C and LCST = 49°C) [Sorenson and Arlt, *Liquid-Liquid Equilibrium Data Collection*, vol. V, pt. 1 (DECHEMA, 1979)]. As mentioned earlier, it is not unusual for mixtures of water and amines or water and glycol ethers to exhibit LCST behavior. (See "Phase Diagrams" under "Thermodynamic Basis for Liquid-Liquid Extraction.") This is a reason why Godfrey's method does not include water.

Sometimes the mutual solubility of a solvent pair of interest can easily be decreased by adding a third component. For example, it is common practice to add water to a solvent system containing a water-miscible organic solvent (the polar phase) and a hydrophobic organic solvent (the nonpolar phase). A typical example is the solvent system (methanol + water) + dichloromethane. An anhydrous mixture of methanol and dichloromethane is completely miscible, but adding water causes phase splitting. Adjusting the amount of water added to the polar phase also may be used to alter the $K$ values for the extraction, density difference, and interfacial tension. Table 15-5 lists some common examples of solvent systems of this type. These systems are common candidates for fractional extractions.

## COMPUTER-AIDED MOLECULAR DESIGN

Many specialized computer programs have been written specifically to identify candidate solvents with properties that best match those needed for a particular application—by weighing various considerations of the kind outlined in "Desired Solvent Properties" in addition to the partition ratio. These Computer-Aided Molecular Design (CAMD) programs generally utilize a group contribution method such as UNIFAC, or a group contribution Hansen parameter model, as the means for estimating phase equilibrium, plus methods for estimating physical properties and other relevant factors. The goal is to determine the optimal solvent structure that best meets the specified set of performance factors [Brignole, Botini, and Gani, *Fluid Phase Equil.*, **29,** pp. 125–132 (1986); and Joback and Stephanopoulos, *Proc. FOCAPD*, **11,** p. 631 (1989)]. Recent studies that include reviews of previous work are given by Papadopoulos and Linke [*AIChE J.*, **52**(3), pp. 1057–1070 (2006)]; Karunanithi, Achenie, and Gani [*Ind. Eng. Chem. Res.*, **44**(13), pp. 4785–4797 (2005)]; Cismondi and Brignole [*Ind. Eng. Chem. Res.*, **43**(3), pp. 784–790 (2004)]; and Giovanoglou et al. [*AIChE J.*, **49**(12), pp. 3095–3109 (2003)]. A variety of creative search strategies have been employed including use of stochastic algorithms to account for uncertainty [Kim and Diwekar, *Ind. Eng. Chem. Res.*, **41**(5), pp. 1285–1296 (2002)], the use of quantum chemisty methods for property estimation [Lehnamm and Maranas, *Ind. Eng. Chem. Res.*, **43**(13), pp. 3419–3432 (2004)], and the application of a genetic theory of evolution (survival of the fittest) [Nieuwoudt, Paper No.

233a, AIChE National Meeting, Austin, Tex. (2004); and Van Dyk and Nieuwoudt, *Ind. Eng. Chem. Res.*, **39**(5), pp. 1423–1429 (2000)]. Similar programs have been written to facilitate identification of alternative solvents or solvent blends as replacements for a given solvent, by attempting to identify compounds that match the physical properties of the solvent the user wishes to replace. An example is the PARIS II program developed by the U.S. Environmental Protection Agency [Cabezas, Harten, and Green, *Chem. Eng. Magazine*, pp. 107–109 (March 2000)].

### HIGH-THROUGHPUT EXPERIMENTAL METHODS

In addition to the methods described above, it may be useful to devise a rapid experimental method for screening solvents and extraction conditions. High-throughput methods are designed to measure a key property and automatically carry out tens or hundreds of experiments in a short time. An example involves automation of liquid-liquid extraction using a 96-well sample plate and a robotic liquid-handling workstation in conjunction with automated liquid chromatography for analysis [Peng et al., *Anal. Chem.*, **72**(2), pp. 261–266 (2000)]. The authors developed this method to purify libraries of compounds for accelerated discovery of active compounds (such as new pharmaceuticals); however, the same approach may prove useful for screening solvents for a particular extraction application. Another paper describes a high throughput screening method for rapid optimization of aqueous two-phase extraction applications [Bensch et al., *Chem. Eng. Sci.*, **62,** pp. 2011–2021 (2007)]. For a review of high-throughput methods in general, see Murray, *Principles and Practice of High Throughput Screening* (Blackwell, 2005). The automated methods described in "Liquid-Liquid Equilibrium Experimental Methods" under "Thermodynamic Basis for Liquid-Liquid Extraction" also may be useful for screening solvents.

## LIQUID DENSITY, VISCOSITY, AND INTERFACIAL TENSION

**General References:** See Sec. 2, "Prediction and Correlation of Physical Properties," and Rosen, *Surfactants and Interfacial Phenomena*, 3d ed. (Wiley, 2004); Hartland, *Surface and Interfacial Phenomena* (Dekker, 2004); and Poling, Prausnitz, and O'Connell, *The Properties of Gases and Liquids*, 5th ed. (McGraw-Hill, 2000).

The utility of liquid-liquid extraction as a separation tool depends upon both phase equilibria and transport properties. The most important physical properties that influence transport properties are liquid-liquid interfacial tension, liquid density, and viscosity. These properties influence solute diffusion and the formation and coalescence of drops, and so are critical factors affecting the performance of liquid-liquid contactors and phase separators.

### DENSITY AND VISCOSITY

Many handbooks, including this one, contain an extensive compilation of liquid density data. These same sources often include liquid viscosity data, although fewer experimental data may be available for a particular compound. Available data compilations include those by Wypych, *Handbook of Solvents* (ChemTech, 2001); Wypych, *Solvents Database*, CD-ROM (ChemTec, 2001); Yaws, *Thermodynamic and Physical Property Data*, 2d ed. (Gulf, 1998); and Flick, *Industrial Solvents Handbook*, 5th ed. (Noyes, 1998). In addition, viscosity data for $C_1$–$C_{28}$ organic compounds have been compiled by Yaws in *Handbook of Viscosity*, vols. 1–3 (Elsevier, 1994). Density and viscosity data also are available from the Thermodynamics Research Center at the National Institute of Standards and Technology (Boulder, Colo.) and from the DIPPR physical property databank of AIChE.

Methods for estimating density and viscosity are reviewed in Sec. 2, "Prediction and Correlation of Physical Properties," and in the book by Poling, Prausnitz, and O'Connell, *The Properties of Gases and Liquids*, 5th ed. (McGraw-Hill, 2000). However, it is best to measure density and viscosity in the laboratory whenever possible. The methods used to measure viscosity are described in numerous books including *Measurement of Transport Properties of Fluids*, vol. 3, Wakeham, Nagashima, and Sengers, eds. (Blackwell, 1991); and Leblanc, Secco, and Kostic, "Viscosity Measurement," Chap. 30 in *Measurement, Instrumentation, and Sensors Handbook*, Webster, ed. (CRC Press, 1999). A new instrument introduced by the Anton Paar Company utilizes Stabinger's methods for simultaneous measurement of viscosity and density [American Society for Testing and Materials, ASTM D7042-04 (2005)].

### INTERFACIAL TENSION

Typical values of interfacial tension are listed in Tables 15-6 and 15-7. Refer to the references listed in these tables for the full data sets and for data on other mixtures. Table 15-6 shows typical values for organic + water binary mixtures. Table 15-7 shows the strong effect of the addition of a third component. Also, Treybal's classic plot of interfacial tension versus mutual solubility is given in Fig. 15-21. This information can be helpful in assessing whether interfacial tension is likely to be low, moderate, or high for a new application. However, for design purposes, interfacial tension should be measured by using representative feed and solvent because even small amounts of surface-active impurities can significantly impact the result.

Methods used to measure interfacial tension are reviewed by Drelich, Fang, and White ["Measurement of Interfacial Tension in Fluid-Fluid Systems," in *Encyclopedia of Surface and Colloid Science* (Dekker, 2003), pp. 3152–3156]. Also see Megias-Alguacil, Fischer, and Windhab, *Chem. Eng. Sci.*, **61,** pp. 1386–1394 (2006). One class of methods derives interfacial tension values from measurement of the shape, contact angle, or volume of a drop suspended in a second liquid. These methods include the pendant drop method (a drop of heavy liquid hangs from a vertically mounted capillary tube immersed

**TABLE 15-6 Typical Interfacial Tensions for Different Classes of Organic + Water Binary Mixtures at 20 to 25°C**

| Class of organic compounds | Interfacial tension, dyn/cm |
|---|---|
| Alkanes ($C_5$–$C_{12}$) | 45–53 |
| Halogenated alkanes ($C_1$–$C_4$) | 30–40 |
| Halogenated aromatics (single ring) | 35–40 |
| Aromatics (single ring) | 30–40 |
| Mononitro aromatics (single ring) | 25–28 |
| Ethers ($C_4$–$C_6$) | 10–30 |
| Esters ($C_4$–$C_6$) | 10–20 |
| Ketones ($C_4$–$C_8$) | 5–15 |
| Organic acids ($C_5$–$C_{12}$) | 3–15 |
| Aniline | 6–7 |
| Alcohols ($C_4$–$C_8$) | 2–8 |

in the light liquid), the sessile drop method (a drop of heavy liquid lies on a plate immersed in the light liquid), and the spinning drop method (a drop of one liquid is suspended in a rotating tube filled with the second liquid). The sessile drop method is particularly useful for following the change in interfacial tension when surfactants or macromolecules accumulate at the surface of the drop. The spinning drop method is well suited to measuring low interfacial tensions. Another class of methods derives interfacial tension values from measurement of the force required to detach a ring of wire (Du Noüy's method), or a plate of glass or platinum foil (the Wilhelmy method), from the liquid-liquid interface. The ring or plate must be extremely clean. For the commonly used ring-pull method, the wire is usually flamed before the experiment and must be kept very horizontal and located exactly at the interface of the two liquids.

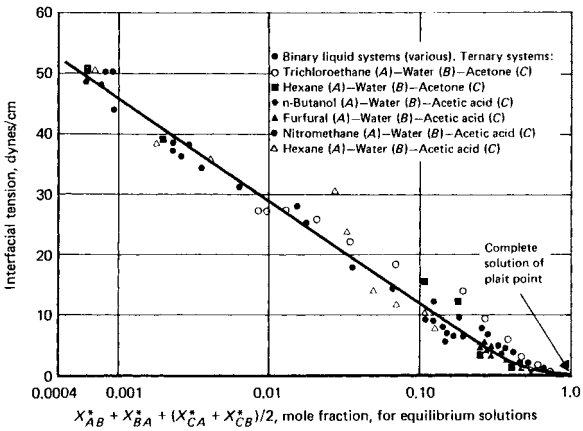

**FIG. 15-21** Correlation of interfacial tension with mutual solubility for binary and ternary two-liquid-phase mixtures. [*Reprinted from Treybal,* Liquid Extraction, *2d ed. (McGraw-Hill, 1963). Copyright 1963 McGraw-Hill, Inc.*]

For an initial assessment, an approximate value for the interfacial tension may be obtained, at least in principle, from knowledge of the maximum size of drops that can persist in a dispersion at equilibrium and without agitation. For example, if it is possible to determine drop size from a photograph of the dispersion of interest at quiescent conditions, then an estimate of interfacial tension may be obtained from the balance between interfacial tension and buoyancy forces

$$\sigma \approx d_{\max}^2 \Delta\rho g \tag{15-32}$$

where $d_{\max}$ is the maximum drop diameter. Antonov's rule also may be used to obtain an approximate value. This rule states that interfacial tension between two liquids is approximately equal to the difference in their liquid-air surface tensions measured at the same conditions. For an organic + water system,

$$\sigma \approx |\sigma_{w(o)} - \sigma_{o(w)}| \tag{15-33}$$

where $\sigma_{w(o)}$ represents the surface tension of the water saturated with the organic and $\sigma_{o(w)}$ represents the surface tension of organic saturated with water.

Measurements of interfacial tension are not always feasible, and calculation methods are sometimes used. The results are least reliable for interfacial tensions below about 10 dyn/cm ($10^{-2}$ N/m). A commonly used empirical correlation of interfacial tension and mutual solubilities is given by Donahue and Bartell [*J. Phys. Chem.*, **56,** pp. 480–484 (1952)]:

$$\sigma = -3.33 - 7.21 \ln (x_1'' + x_2') \tag{15-34}$$

where $\sigma$ = interfacial tension, dyn/cm ($10^{-3}$ N/m)
$x_1''$ = mole fraction solubility of organic in aqueous phase
$x_2'$ = mole fraction solubility of water in organic phase

Treybal [*Liquid Extraction*, 2d ed. (McGraw-Hill, 1963)] modified Eq. (15-36) to expand its application to ternary systems:

$$\sigma = -5.0 - 7.355 \ln [x_1'' + x_2' + 0.5(x_3' + x_3'')] \tag{15-35}$$

where $\sigma$ = interfacial tension, dyn/cm ($10^{-3}$ N/m)
$x_3''$ = mole fraction solute in aqueous phase
$x_3'$ = mole fraction solute in organic phase

The results are plotted in Fig. 15-21. More recently, Fu, Li, and Wang [*Chem. Eng. Sci.*, **41**(10), pp. 2673–2679 (1986)] derived a relationship for ternary mixtures:

$$\sigma = \frac{0.914RT\chi}{(A_o \exp \chi)(x_1''q_1 + x_2'q_2 + x_{3r}q_3)} \tag{15-36}$$

$$\chi = -\ln (x_1'' + x_2' + x_{3r}) \tag{15-37}$$

where $\sigma$ = interfacial tension, dyn/cm ($10^{-3}$ N/m)
$R$ = ideal gas law constant
$T$ = absolute temperature
$x_1''$ = solubility of extract phase in raffinate phase (mole fraction)
$x_2'$ = solubility of raffinate phase in extract phase (mole fraction)
$x_{3r}$ = mole fraction of solute 3 in bulk phase richest in solute 3
$A_o$ = van der Waals area of standard segment ($2.5 \times 10^9$ cm$^2$/mol)
$q_i$ = van der Waals surface area ratio, usually calculated from UNIQUAC

## HOLDUP, SAUTER MEAN DIAMETER, AND INTERFACIAL AREA

Most liquid-liquid extractors are designed to generate drops of one liquid suspended in the other rather than liquid films. The volume fraction of the dispersed phase (or holdup) within the extractor is defined as

$$\phi_d = \frac{\text{volume of dispersed phase}}{\text{total contacting volume}} \tag{15-38}$$

where the total contacting volume is the volume within the extractor minus the volume of any internals such as impellers, packing, or trays. A distribution of drop sizes will be present. The Sauter mean drop diameter $d_{32}$ represents a volume to surface-area average diameter

$$d_{32} = \frac{\sum_{i=1}^{n} N_i d_i^3}{\sum_{i=1}^{n} N_i d_i^2} \tag{15-39}$$

where $N_i$ is the number of drops with diameter $d_i$. The Sauter mean diameter often is used in the analysis and modeling of extractor performance because it is directly related to holdup and interfacial area (assuming spherical drops). It is calculated from the total dispersed volume divided by total interfacial area, and often it is expressed in the form

$$d_{32} = \frac{6\varepsilon\phi_d}{a} \tag{15-40}$$

where $a$ is interfacial area per unit volume and $\varepsilon$ is the void fraction within the extractor, i.e., the fraction of internal volume not occupied by any packing, trays, and so on. In the remainder of Sec. 15, the Sauter mean diameter is denoted simply by $d_p$.

Much less is known about the actual distribution of drop sizes existing within liquid-liquid extractors, particularly at high holdup and as a function of agitation intensity (if agitation is used) and location within the extractor. For a review, see Kumar and Hartland, Chap. 17 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994). Experimental methods used to measure drop size distribution include the use of a high-speed video camera [Ribeiro, et al., *Chem. Eng. J.*, **97,** pp. 173–182 (2004)], real-time optical measurements [Ritter and Kraume, *Chem. Eng. Technol.*, **23**(7), pp. 579–581 (2000)], and phase-Doppler anemometry [Lohner, Bauckhage, and Schombacher, *Chem. Eng. Technol.*, **21**(4), pp. 337–341 (1998); and Willie, Langer, and Werner, *Chem. Eng. Technol.*, **24**(5), pp. 475–479 (2001)].

## FACTORS AFFECTING WHICH PHASE IS DISPERSED

Consider mixing a batch of two liquid phases in a stirred tank. The minority phase generally will be the dispersed phase whenever the ratio of minority to majority volume fractions, or phase ratio, is less than about 0.5 (equivalent to a dispersed-phase volume fraction or holdup less than 0.33). For phase ratios between 0.5 and about 2, a region called the ambivalent range, the phase that becomes dispersed is determined in large part by the protocol used to create the dispersion. For example, pouring liquid A into a stirred tank already containing liquid B will tend to create a dispersion of A suspended in B, as long as agitation is maintained. When more of the dispersed-phase material is added to the system, the population density of dispersed drops will increase and eventually reach a point where the drops are so close together that they rapidly coalesce and the phases become inverted, i.e., the formerly dispersed phase becomes the continuous phase. In the ambivalent range, a sudden increase in the agitation intensity also can trigger phase inversion by increasing the number of drop-to-drop collisions. Once phase inversion occurs, it is not easily reversed because the new condition corresponds to a more stable configuration.

This phase behavior may be roughly correlated in terms of light and heavy phase properties including relative density and viscosity as follows:

$$\chi = \frac{\phi_L}{\phi_H}\left(\frac{\rho_L\mu_H}{\rho_H\mu_L}\right)^{0.3} = \frac{\phi_L}{1-\phi_L}\left(\frac{\rho_L\mu_H}{\rho_H\mu_L}\right)^{0.3} \tag{15-41}$$

where $\chi < 0.3$ light phase always dispersed
$\chi = 0.3 - 0.5$ light phase probably dispersed
$\chi = 0.5 - 2.0$ either phase can be dispersed, and phase inversion may occur
$\chi = 2.0 - 3.3$ heavy phase probably dispersed
$\chi > 3.3$ heavy phase always dispersed

The symbol $\phi$ denotes the volume fraction of light ($L$) and heavy ($H$) phases existing within the vessel. Equation (15-41) is taken from the expression recommended by Hooper [Sec. 1.11 in *Handbook of*

*Separation Techniques for Chemical Engineers*, 3d ed., Schweitzer, ed. (McGraw-Hill, 1997)] and Jacobs and Penney [Chap. 3 in *Handbook of Separation Process Technology*, Rousseau, ed. (Wiley, 1987)] for design of continuous decanters. It is based on the dispersed-phase data of Selker and Sleicher [*Can. J. Chem. Eng.*, **43,** pp. 298–301 (1965)].

Equation (15-41) should apply to continuously fed extraction columns and other continuous extractors as well as batch vessels. The equation is expressed here in terms of volume fractions $\phi_L/\phi_H$ existing within the vessel, not volumetric flow rates of each phase entering the vessel $Q_L/Q_H$. The ratio of volume fractions within a continuously fed vessel can be very different from $Q_L/Q_H$—primarily because buoyancy allows the dispersed-phase drops to travel rapidly through the continuous phase relative to the dispersed-phase superficial velocity. For example, a continuously fed extraction column can be designed to operate with either phase being the dispersed phase, with the main liquid-liquid interface controlled at the top of the column (for a light-phase dispersed system) or at the bottom (for a heavy-phase dispersed system). As the dispersed-to-continuous phase ratio within the column is increased, through either changes in operating variables or changes in the design of the internals, a point may be reached where the population density or holdup of dispersed drops is too large and phase inversion occurs. In the absence of stabilizing surfactants, the point of phase inversion should correspond roughly to the same general phase-ratio rules given in Eq. (15-41), with the exact conditions at which phase inversion occurs depending upon agitation intensity (if used) and the geometry of any internals (baffles, packing, trays, and so on). Certain extractors such as sieve-tray columns often are designed to disperse the majority flowing phase. In extreme cases, the ratio $Q_d/Q_c$ (where $d$ and $c$ represent dispersed and continuous phases) may be as high as 50, and the continuous phase may be nearly stagnant with a superficial velocity as low as 0.02 cm/s; yet the phase ratio within the extractor can be controlled within the guidelines needed to avoid phase inversion [approximated by Eq. (15-41)].

The stability of a dispersion also can be affected by the presence of fine solids or gas bubbles as well as surfactants. For additional discussion of factors affecting which phase is dispersed, see Norato, Tsouris, and Tavlarides, *Can. J. Chem. Eng.*, **76,** pp. 486–494 (1998); and Pacek et al., *AIChE J.*, **40**(12), pp. 1940–1949 (1994). For a given application, the precise conditions that lead to phase inversion must be determined by experiment. For organic + water dispersions, experimental determination may be facilitated by measuring the conductivity of the mixture, since conductivity normally will be significantly higher when water is in the continuous phase [Gilchrist, et al., *Chem. Eng. Sci.*, **44**(10), pp. 2381–2384 (1989)]. Another method involves monitoring the dynamics of phase inversion by using a stereo microscope and video camera [Pacek et al., *AIChE J.*, **40**(12), pp. 1940–1949 (1994)].

## SIZE OF DISPERSED DROPS

In nonagitated (static) extractors, drops are formed by flow through small holes in sieve plates or inlet distributor pipes. The maximum size of drops issuing from the holes is determined not by the hole size but primarily by the balance between buoyancy and interfacial tension forces acting on the stream or jet emerging from the hole. Neglecting any viscosity effects (i.e., assuming low dispersed-phase viscosity), the maximum drop size is proportional to the square root of interfacial tension $\sigma$ divided by density difference $\Delta\rho$:

$$d_{\max} = \text{const}\sqrt{\frac{\sigma}{\Delta\rho\, g}} \quad \text{for static extractors} \qquad (15\text{-}42)$$

The proportionality constant typically is close to unity [Seibert and Fair, *Ind. Eng. Chem. Res.*, **27**(3), pp. 470–481 (1988)]. Note that Eq. (15-42) indicates the maximum stable drop diameter and not the Sauter mean diameter (although the two are proportionally related and may be close in value). Smaller drops may be formed at the distributor due to jetting of the inlet liquid through the distributor holes or by mechanical pulsation of the liquid inside the distributor [Koch and Vogelpohl, *Chem. Eng. Technol.*, **24**(12), pp. 1245–1248 (2001)]. In static extractors, hydrodynamic stresses within the main body of the extractor away from the distributor are small and normally not sufficient to cause significant drop breakage as drops flow through the extractor, although small drops may collide and coalesce into larger drops. Some authors report a small amount of drop breakage in packed columns due to collisions with packing materials [Mao, Godfrey, and Slater, *Chem. Eng. Technol.*, **18,** pp. 33–40 (1995)]. Additional discussion is given in "Static Extraction Columns" under "Liquid-Liquid Extraction Equipment."

In agitated extractors, drop size is determined by the equilibrium established between drop breakage and coalescence rates occurring within the extractor. Breakage is due to turbulent stresses caused by the agitator, so it is mainly confined to the vicinity of the agitator. Drop coalescence, however, can happen anywhere in the vessel where drops can come into close proximity with one another. Dispersed drops will begin to break into smaller droplets when turbulent stresses exceed the stabilizing forces of interfacial tension and liquid viscosity. Kolmogorov [*Dokl. Akad. Nauk*, **66,** pp. 825–828 (1949)] and Hinze [*AIChE J.*, **1**(3), pp. 289–295 (1955)] developed expressions for the maximum size of drops in an agitated liquid-liquid dispersion. Their results can be expressed as follows:

$$d_{\max} = (\text{const})\,\sigma^{3/5}\rho_c^{-1/5}\left(\frac{P}{\mathcal{V}}\right)^{-2/5} \quad \text{for agitated extractors} \qquad (15\text{-}43)$$

where $P/\mathcal{V}$ is the rate of mechanical energy dissipation (or power $P$) input to the dispersion per unit volume $\mathcal{V}$. Equation (15-43) assumes dispersed-phase holdup is low. It also assumes viscous forces that resist breakage can be neglected, a valid assumption for water and typical low- to moderate-viscosity organic solvents. Wang and Calabrese discuss how to determine when viscous resistance to breakage becomes important and show that this depends upon interfacial tension as well as dispersed-phase viscosity [Wang and Calabrese, *AIChE J.*, **32**(4), pp. 667–676 (1986)]. Equation (15-43) can be restated as

$$\frac{d_{\max}}{D_i} \propto \text{We}^{-3/5} \qquad (15\text{-}44)$$

where We is a dimensionless Weber number (disruptive shear stress/cohesive interfacial tension) and $D_i$ is a characteristic diameter. For applications involving the use of rotating impellers, $D_i$ is the impeller diameter and the appropriate Weber number is $\text{We} = \rho_c\omega^2 D_i^3/\sigma$, where $\omega$ is the impeller speed (in rotations per unit time). For static mixers, $D_i = D_{sm}$ and $\text{We} = \rho_c V_{sm}^2 D_{sm}/\sigma$, where $D_{sm}$ is the static mixer pipe diameter and $V_{sm}$ is the superficial liquid velocity (entrance velocity). A variety of drop size models derived for various mixers and operating conditions have been tabulated by Leng and Calabrese [Chap. 12 in *Handbook of Industrial Mixing*, Paul, Atiemo-Obeng, and Kresta, eds. (Wiley, 2004), pp. 669–675]. Also see Naseef, Soultan, and Stamatoudis, *Chem. Eng. Technol.*, **29**(5), pp. 583–587 (2006).

Equation (15-44) represents a limiting operating regime where the rate of drop breakage dominates performance and the coalescence rate can be neglected. Drop coalescence requires that two drops collide, and the coalescence rate increases with increasing holdup since there is greater opportunity for drop-drop collisions. For agitated systems with fast coalescence at high holdup, i.e., when drop coalescence dominates, drop size appears best correlated by an expression of the form $d_p/D \propto \text{We}^{-n}$, where $n$ varies between 0.35 and 0.45 [Pacek, Man, and Nienow, *Chem. Eng. Sci.*, **53**(11), pp. 2005–2011 (1998); and Kraume, Gabler, and Schulze, *Chem. Eng. Technol.*, **27**(3), pp. 330–334 (2004)]. This is similar to the theoretical expression derived by Shinnar [*J. Fluid Mech.*, **10**, p. 259 (1961)].

When two drops first come into contact in the process of coalescing, a film of continuous phase becomes trapped between them. The film is compressed at the point of encounter until it drains away and the two drops can merge. Decreasing the viscosity of the continuous phase, by heating or by addition of a low-viscosity diluent, may promote drop coalescence by increasing the rate of film drainage. Surface-active impurities or surfactants, when present, also can affect the coalescence rate, by accumulating at the surface of the drop. Surfactants tend to stabilize the film and reduce coalescence rates. Fine

solid particles that are wetted by the continuous phase tend to slow film drainage, also reducing the rate of drop coalescence.

A number of semiempirical drop size data correlations have been developed for different types of extractors (static and agitated) including a term for holdup. See Kumar and Hartland, *Ind. Eng. Chem. Res.*, **35**(8), pp. 2682–2695 (1996); and Kumar and Hartland, Chap. 17 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994). These equations predict a characteristic drop size. They do not provide information about the drop size distribution or the minimum drop size. For discussion of minimum drop size, see Zhou and Kresta, *Chem. Eng. Sci.*, **53**(11), pp. 2063–2079 (1998).

## STABILITY OF LIQUID-LIQUID DISPERSIONS

In designing a liquid-liquid extraction process, normally the goal is to generate an unstable dispersion that provides reasonably high interfacial area for good mass transfer during extraction and yet is easily broken to allow rapid liquid-liquid phase separation after extraction. Given enough time, most dispersions will break on standing. Often this process occurs in two distinct periods. The first is a relatively short initial period or primary break during which an interface forms between two liquid layers, one or both of which remain cloudy or turbid. This is followed by a longer period or secondary break during which the liquid layers become clarified. During the primary break, the larger drops migrate to the interface where they accumulate and begin to coalesce. If the coalescence rate is relatively slow compared to the rate at which drops rise or fall to the interface, then a layer of coalescing drops or *dispersion band* will form at the interface. The initial interface can form within a few minutes or less for drop sizes on the order of 100 to 1000 μm (0.1 to 1 mm), as in a water + toluene system, for example. When the drop size distribution in the feed dispersion is wide, smaller droplets remain suspended in one or both phases. Longer residence times are then required to break this secondary dispersion. In extreme cases, the secondary dispersion can take days or even longer to break.

When a dispersion requires a long time to break, the presence of surfactantlike impurities may be a contributing factor. Surfactants are molecules with a hydrophobic end (such as a long hydrocarbon chain) and a hydrophilic end (such as an ionic group or oxygen-containing short chain). Surfactants stabilize droplets by forming an adsorbed film at the interface and by introducing electrical repulsions between drops [Tcholakova, Denkov, and Danner, *Langmuir*, **20**(18), pp. 7444–7458 (2004)]. Both effects can interfere with drop coalescence. Surfactants also decrease the interfacial tension of the system. As more surfactant is introduced into a solution, the concentration of free surfactant molecules in the bulk liquid increases and reaches a plateau called the critical micelle concentration. At this point, any excess molecules begin forming aggregates with other surfactant molecules at the interface of the two liquids to minimize interaction with the continuous phase. The dispersed phase is then trapped inside the micelles. As more surfactant is added to the mixture, more micelles can form and in most cases the droplets become smaller to maximize interfacial area. In theory, the maximum volume fraction of the dispersed phase should be limited to 0.74 due to the close packing density of spheres; but in practice much higher values are possible when the micelles change to other structures of different geometries such as a mix of small drops among larger ones and nonspherical shapes.

Emulsions are broken by changing conditions to promote drop coalescence, either by disrupting the film formed at the interface between adjacent drops or by interfering with the electrical forces that stabilize the drops. Water droplets are usually positively charged while oil droplets are negatively charged. Physical techniques used to break emulsions include heating (including application of microwave radiation), freezing and thawing, adsorption of surface-active compounds, filtration of fine particles that stabilize films between drops, and application of an electric field. Heating can be particularly effective for nonionic surfactants, since heating disrupts hydrogen bonding interactions that contribute to micelle stability. Chemical techniques include adding a salt to alter the charges around drops, changing the pH of the system, and adding a deemulsifier compound (or even another type of surfactant) to interact with and alter the surfactant layer. Ionic surfactants are particularly sensitive to change in pH. Additives include bases and acids, aluminum or ferric salts, chelating agents, charged polymers (polyamines or polyacrylates), polyalcohols, silicone oils, various fatty acid esters and fatty alcohols, as well as adsorbents such as clay and lime. For further discussion, see Rajaković and Skala, *Sep. Purif. Technol.*, **49**(2), pp. 192–196 (2006); and Alther, *Chem. Eng. Magazine*, **104**(3) pp. 82–88 (1998). Chemical additives need to be used in sufficiently small concentrations so as not to interfere with other operations in the overall process or product quality. General information is available in Schramm, *Emulsions, Foams, and Suspensions* (Wiley-VCH, 2005); Becher, *Emulsions: Theory and Practice*, 3d ed. (American Chemical Society, 2001); and Binks, *Modern Aspects of Emulsion Science* (Royal Society of Chemical 1998).

## EFFECT OF SOLID-SURFACE WETTABILITY

The stability of a dispersion also may depend upon the surface properties of the container or equipment used to process the dispersion, since the walls of the vessel, or more importantly, the surfaces of any internal structures, may promote drop coalescence. In a liquid-liquid extractor or a liquid-liquid phase separator, the wetting of a solid surface by a liquid is a function of the interfacial tensions of both the liquid-solid and the liquid-liquid interfaces. For dispersed drops with low liquid-solid interfacial tension, the drops tend to spread out into films when in contact with the solid surface. In general, an aqueous liquid will tend to wet a metal or ceramic surface better than an organic liquid will, and an organic liquid will tend to wet a polymer surface better than an aqueous liquid will. However, there are many exceptions. Strigle [*Packed Tower Design and Applications*, 2d ed., Chap. 11 (Gulf, 1994)] indicates that for packed extractors, metal packings may be wetted by either an aqueous or an organic solvent depending upon the initial exposure of the metal surface (whether the unit is started up filled with the aqueous phase or the organic phase). In general, however, metals tend to be preferentially wetted by an aqueous phase. Also, it is not uncommon for materials of construction to acquire different surface properties after aging in service, since the solid surface can change due to adsorption of impurities, corrosion, or fouling. This aging effect often is observed for polymer materials. Small-scale lab tests are recommended to determine these wetting effects. For detailed discussion of wettability and its characterization, see *Contact Angle, Wettability, and Adhesion*, vols. 1–3, Mittal, ed. (VSP, 1993–); or *Wettability*, Berg, ed. (Dekker, 1993).

In liquid-liquid extraction equipment, the internals generally should be preferentially wetted by the continuous phase—in order to maintain dispersed-phase drops with a high population density (high holdup). If the dispersed phase preferentially wets the internals, then drops may coalescence on contact with these surfaces, and this can result in loss of interfacial area for mass transfer and even in the formation of rivulets that flow along the internals. In an agitated extractor, this tendency may be mitigated somewhat, if needed, by increasing the agitation intensity.

## MARANGONI INSTABILITIES

Numerous studies have shown that mass transfer of solute from one phase to the other can alter the behavior of a liquid-liquid dispersion—because of interfacial tension gradients that form along the surface of a dispersed drop. For example, see Sawistowski and Goltz, *Trans. Inst. Chem. Engrs.*, **41,** p. 174 (1963); Bakker, van Buytenen, and Beek, *Chem Eng. Sci.*, **21**(11), pp. 1039–1046 (1966); Ruckenstein and Berbente, *Chem. Eng. Sci.*, **25**(3), pp. 475–482 (1970); Lode and Heideger, *Chem. Eng. Sci.*, **25**(6), pp. 1081–1090 (1970); and Takeuchi and Numata, *Int. Chem. Eng.*, **17**(3), p. 468 (1977). These interfacial tension gradients can induce interfacial turbulence and circulation within drops. These effects, known as Marangoni instabilities, have been shown to enhance mass-transfer rates in certain cases.

The direction of mass transfer also can have a significant effect upon drop-drop coalescence and the resulting drop size. Seibert and

Fair [*Ind. Eng. Chem. Res.*, **27**(3), pp. 470–481 (1988)] showed that mass transfer out of the drop will promote coalescence. Larger drop sizes were observed when transferring solute into the continuous phase (interfacial tension was increasing as the drop traveled through the extractor). Kumar and Hartland [*Ind. Eng. Chem. Res.*, **35**(8), pp. 2682–2695 (1996)] suggest that transfer of solute from the dispersed to the continuous phase ($d \rightarrow c$) tends to produce larger drops because the concentration of transferring solute in the draining film between two approaching drops is higher than that in the surrounding continuous liquid. This accelerates drainage, thus promoting drop coalescence. For mass transfer in the opposite direction ($c \rightarrow d$), smaller drops tend to form because the solute concentration in the draining film between drops is relatively low. The magnitude of these effects depends upon system properties, the surface activity of the transferring solute, and the degree of mass transfer. Unless the solute is unusually surface-active, the effect will be small. For more information, see Gourdon, Casamatta, and Muratet, Chap. 7 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994); Perez de Oritz, Chap. 3, "Marangoni Phenomena," in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992); and Grahn, *Chem. Eng. Sci.*, **61,** pp. 3586–3592 (2006).

## PROCESS FUNDAMENTALS AND BASIC CALCULATION METHODS

**General References:** See Sec. 5, "Mass Transfer," as well as Wankat, *Separation Process Engineering*, 2d ed. (Prentice-Hall, 2006); Seader and Henley, *Separation Process Principles* (Wiley, 1998); Godfrey and Slater, *Liquid-Liquid Extraction Equipment* (Wiley, 1994); Thornton, ed., *Science and Practice of Liquid-Liquid Extraction*, vol. 1 (Oxford, 1992); Wankat, *Equilibrium Staged Separations* (Prentice-Hall, 1988); Kirwin, Chap. 2 in *Handbook of Separation Process Technology*, Rousseau, ed. (Wiley, 1987); Skelland and Tedder, Chap. 7 in *Handbook of Separation Process Technology,* Rousseau, ed. (Wiley, 1987); Lo, Baird, and Hanson, eds., *Handbook of Solvent Extraction* (Wiley, 1983; Krieger, 1991); King, *Separation Processes*, 2d ed. (McGraw-Hill, 1980); Brian, *Staged Cascades in Chemical Processing* (Prentice-Hall, 1972); Geankoplis, *Mass Transport Phenomena* (Holt, Rinehart and Winston, 1972); and Treybal, *Liquid Extraction*, 2d ed. (McGraw-Hill, 1963).

The fundamental mechanisms for solute mass transfer in liquid-liquid extraction involve molecular diffusion driven by a deviation from equilibrium. When a liquid feed is contacted with a liquid solvent, solute transfers from the interior of the feed phase across a liquid-liquid interface into the interior of the solvent phase. Transfer of solute will continue until the solute's chemical potential is the same in both phases and equilibrium is achieved.

The calculation methods used to quantify extraction processes generally involve either the calculation of theoretical stages, with application of an operating efficiency to reflect mass-transfer resistance, or calculations based on consideration of mass-transfer rates using expressions related in some way to molecular diffusion. Theoretical-stage calculations commonly are used to characterize separation difficulty regardless of the type of extractor to be used. They are also used for extractor design purposes, although for this purpose they generally should be reserved for single-stage contactors or mixer-settler cascades involving discrete stages, or for other equipment where discrete contacting zones exist, such as in a sieve-tray column. The appropriate stage efficiency reflects how closely an actual contacting stage approaches equilibrium, and is a function of operating variables that affect drop size, population density, and contact time.

The development and application of rate-based models for analysis and design of extraction processes are becoming more common. For example, Jain, Sen, and Chopra [*ISEC '02 Proceedings*, **2,** pp. 1265–1270 (2002)] recently described a rate-based model for a lube oil extraction process. Rate-based models most often are applied to differential-type contactors that lack discrete contacting stages, to staged contactors with low stage efficiencies, or to processes with extraction factors greater than about 3, indicating a mass-transfer-limited operating regime. Differential-type contactors operating at extraction factors less than 3 also can be adequately modeled with theoretical stages since these contactors operate reasonably close to equilibrium. With either approach, appropriate values for model parameters typically are determined by fitting data generated by using laboratory or pilot-plant experiments, or by analysis of the performance of large-scale commercial units. In certain cases, parameter values have been correlated as a function of physical properties and operating conditions for specific types of equipment using model systems. The reliability of the resulting correlations is generally limited to applications very similar to those used to develop the correlations. Also, most calculation methods have been developed for continuous steady-state operation. The dynamic modeling of extraction processes is discussed elsewhere [Mohanty, *Rev. Chem. Eng.*, **16**(3), p. 199 (2000); Weinstein, Semiat, and Lewin, *Chem. Eng. Sci.*, **53**(2), pp. 325–339 (1998); and Steiner and Hartland, Chap. 7 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983, Krieger, 1991)].

The calculation methods used for designing extraction operations are analogous in many respects to methods used to design absorbers and strippers in vapor-liquid and gas-liquid contacting such as those described by Ortiz-Del Castillo, et al. [*Ind. Eng. Chem. Res.*, **39**(3), pp. 731–739 (2000)] and by Kohl ["Absorption and Stripping," Chap. 6 in *Handbook of Separation Process Technology* (Wiley-Interscience, 1987)]. Unlike in stripping and absorption, however, liquid-liquid extraction always deals with highly nonideal systems; otherwise, only one liquid phase would exist. This nonideality contributes to difficulties in modeling and predicting phase equilibrium, liquid-liquid phase behavior (hydraulics), and thus mass transfer. Also, the mass-transfer efficiency of an extractor generally is much less than that observed in distillation, stripping, or absorption equipment. For example, an overall sieve tray efficiency of 70 percent is common in distillation, but it is rare when a sieve tray extractor achieves an overall efficiency greater than 30 percent. The difference arises in part because generation of interfacial area, normally by dispersing drops of one phase in the other, generally is more difficult in liquid-liquid contactors. Unlike in distillation, formation of liquid films often is purposely avoided; generation of dispersed droplets provides greater interfacial area for mass transfer per unit volume of extractor. (Film formation may be important in extraction applications involving centrifugal contactors or baffle tray extractors, but this is not generally the case.) In certain cases, mass-transfer rates also may be slower compared to those of gas-liquid contactors because the second phase is a liquid instead of a gas, and transport properties in that phase are less favorable. Although mass-transfer efficiency generally is lower, the specific throughput of liquid-liquid extraction equipment (in kilograms of feed processed per hour per unit volume) can be higher than is typical of vapor-liquid contactors, simply because liquids are much denser than vapors.

### THEORETICAL (EQUILIBRIUM) STAGE CALCULATIONS

Calculating the number of theoretical stages is a convenient method used by process designers to evaluate separation difficulty and assess the compromise between the required equipment size (column height or the number of actual stages) and the ratio of solvent rate to feed rate required to achieve the desired separation. In any mass-transfer process, there can be an infinite number of combinations of flow rates, number of stages, and degrees of solute transfer. The optimum is governed by economic considerations. The cost of using a high solvent rate with relatively few stages should be carefully compared with the cost of using taller extraction equipment (or more equipment) capable of achieving more theoretical stages at a reduced solvent rate and operating cost. While the operating cost of an extractor is generally quite low, the operating cost for a solvent recovery distillation tower can be quite high. Another common objective for calculating the number of countercurrent theoretical stages is to evaluate

the performance of liquid-liquid extraction test equipment in a pilot plant or to evaluate production equipment in an industrial plant. As mentioned earlier, most liquid-liquid extraction equipment in common use can be designed to achieve the equivalent of 1 to 8 theoretical countercurrent stages, with some designed to achieve 10 to 12 stages.

**McCabe-Thiele Type of Graphical Method** Graphical methods may be used to determine theoretical stages for a ternary system (solute plus feed solvent and extraction solvent) or for a pseudo-ternary with the focus placed on a key solute of interest. Although developed long ago, graphical methods are still valuable today because they help visualize the problem, clearly illustrating pinch points and other design issues not readily apparent by using other techniques. Even with computer simulations, often it is useful to plot the results for a key solute as an aid to analyzing the design. This section briefly reviews the commonly used McCabe-Thiele type of graphical method. More detailed discussions of this and other graphical methods are available elsewhere. For example, see Seibert, "Extraction and Leaching," Chap. 14 in *Chemical Process Equipment: Selection and Design*, 2d ed., Couperet et al., eds. (Elsevier, 2005); Wankat, *Separation Process Engineering* (Prentice-Hall, 2006); and King, *Separation Processes*, 2d ed. (McGraw-Hill, 1980), among others.

In distillation calculations, the McCabe-Thiele graphical method assumes constant molar vapor and liquid flow rates and allows convenient stepwise calculation with straight operating lines and a curved equilibrium line. A similar concept can be achieved in liquid-liquid extraction by using Bancroft coordinates and expressing flow rates on a solute-free basis, i.e., a constant flow rate of feed solvent $F'$ and a constant flow rate of extraction solvent $S'$ through the extractor [Evans, *Ind. Eng. Chem.*, **26**(8), pp. 860–864 (1934)]. The solute concentrations are then given as the mass ratio of solute to feed solvent $X'$ and the mass ratio of solute to extraction solvent $Y'$. These concentrations and coordinates give a straight operating line on an $X'$-$Y'$ diagram for stages 2 through $r-1$ in Fig. 15-22. The ratio of solute-free extraction solvent to solute-free feed solvent will be constant within the extractor except at the outer stages where unsaturated feed and extraction solvent enter the process. Equilibrium data using these mass ratios have been shown to follow straight-line segments on a log-log plot (see Fig. 15-20), and they will be approximately linear over some composition range on an $X'$-$Y'$ plot. When expressed in terms of Bancroft coordinates, the equilibrium line typically will curve upward at high solute concentrations, as shown in Fig. 15-23.

To illustrate the McCabe-Thiele method, consider the simplified case where feed and extraction solvents are immiscible; i.e., mutual solubility is nil. Then the rate of feed solvent alone in the feed stream

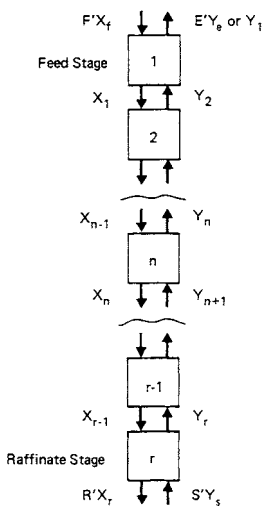

**FIG. 15-22** Countercurrent extraction cascade.

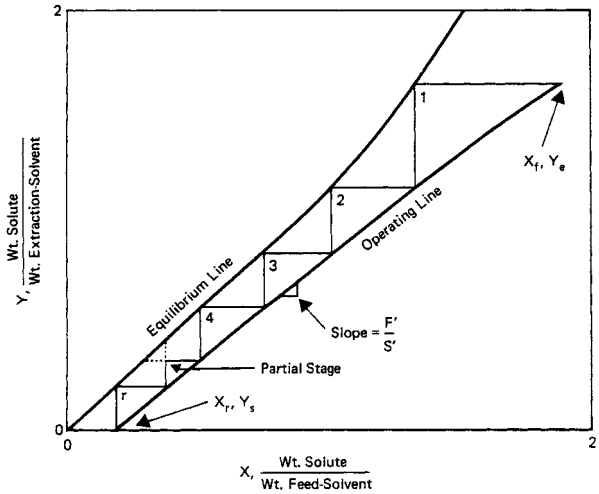

**FIG. 15-23** McCabe-Thiele type of graphical stage calculation using Bancroft coordinates.

$F'$ is the same as the rate of feed solvent alone in the raffinate stream $R'$. In like manner, the rate of extraction solvent alone is the same in the entering stream $S'$ as in the leaving extract stream $E'$. The ratio of extraction-solvent to feed-solvent flow rates is therefore $S'/F' = E'/R'$. A material balance can be written around the feed end of the extractor down to any stage $n$ (as shown in Fig. 15-22) and then rearranged to a McCabe-Thiele type of operating line with a slope of $F'/S'$:

$$Y'_{n+1} = \frac{F'}{S'} X'_n + \frac{E'Y'_e - F'X'_f}{S'} \tag{15-45}$$

Similarly, the same operating line can be derived from a material balance around the raffinate end of the extractor up to stage $n$:

$$Y'_n = \frac{F'}{S'} X'_{n-1} + \frac{S'Y'_s - R'X'_r}{S'} \tag{15-46}$$

The overall extractor material balance is given by

$$Y'_e = \frac{F'X'_f + S'Y'_s - R'X'_r}{E'} \tag{15-47}$$

The endpoints of the operating line on an $X'$-$Y'$ plot (Fig. 15-23) are the points $(X'_r, Y'_s)$ and $(X'_f, Y'_e)$ where $X'$ and $Y'$ are the mass ratios for solute in the feed phase and extract phase, respectively, and subscripts $f$, $r$, $s$, and $e$ denote the feed, raffinate, entering extraction solvent, and leaving extract streams. The number of theoretical stages can then be stepped off graphically as illustrated in Fig. 15-23.

**Kremser-Souders-Brown Theoretical Stage Equation** The Kremser-Souders-Brown (KSB) equation [Kremser, *Natl. Petrol. News*, **22**(21), pp. 43–49 (1930); and Souders and Brown, *Ind. Eng. Chem.*, **24**(5), pp. 519–522 (1932)] provides a way of calculating performance equivalent to that of a McCabe-Thiele type of graphical calculation with straight equilibrium and operating lines. In terms of Bancroft coordinates, the KSB equation may be written

$$N = \frac{\ln\left[\left(\dfrac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)\left(1 - \dfrac{1}{\mathcal{E}}\right) + \dfrac{1}{\mathcal{E}}\right]}{\ln \mathcal{E}} \qquad \mathcal{E} = m' \frac{S'}{F'}, \ \mathcal{E} \neq 1 \tag{15-48}$$

where $N$ = number of theoretical stages
$X'_f$ = mass ratio solute to feed solvent in feed entering process (Bancroft coordinates)

$X'_r$ = mass ratio solute to feed solvent in raffinate leaving process
$Y'_s$ = mass ratio solute to extraction solvent in extraction solvent entering process
$\mathcal{E}$ = extraction factor
$m'$ = $dY'/dX'$, local slope of equilibrium line in Bancroft coordinates
$S'$ = mass flow rate of extraction solvent (solute-free basis)
$F'$ = mass flow rate of feed solvent (solute-free units)

Solutions to Eq. (15-48) are shown graphically in Fig. 15-24. The concentration of solute in the extract leaving the process $Y'_e$ is determined from the material balance, as in Eq. (15-47). (Note that other systems of units also may be used in these equations, as long as they are consistently applied.)

Rearranging Eq. (15-48) yields another common form of the KSB equation:

$$\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} = \frac{\mathcal{E}^N - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \mathcal{E} \neq 1 \tag{15-49}$$

Equations (15-48) and (15-49) can be used whenever $\mathcal{E} > 1$ or $\mathcal{E} < 1$. They cannot be used when $\mathcal{E}$ is exactly equal to unity because this would involve division by zero. When $\mathcal{E} = 1$, the number of theoretical stages is given by

$$N = \frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} - 1 \qquad \text{for } \mathcal{E} = 1 \tag{15-50}$$

Equation (15-50) may be rewritten

$$\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} = N + 1 \qquad \text{for } \mathcal{E} = 1 \tag{15-51}$$

In the special case where $\mathcal{E} < 1$, the *maximum* performance potential is represented by

$$\left(\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)_{\max} \approx \frac{1}{1 - \mathcal{E}} \qquad \text{for } \mathcal{E} < 1 \text{ and large } N \tag{15-52}$$

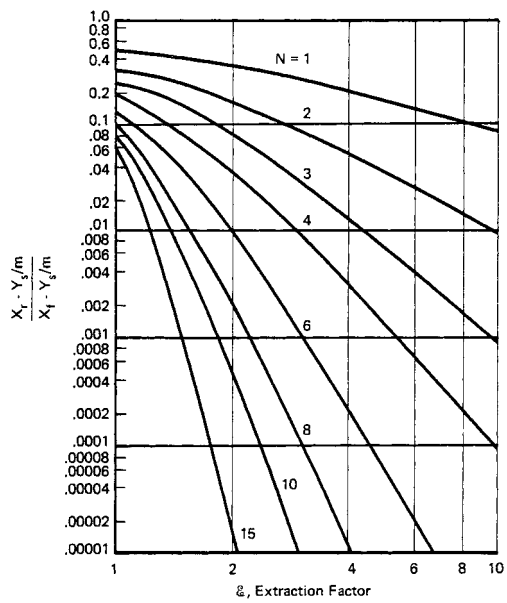

**FIG. 15-24** Graphical solutions to the KSB equation [(Eq. 15-48)].

Equation (15-52) reflects the fact that the carrying capacity of the extract stream limits performance at $\mathcal{E} = < 1$, as noted in earlier discussions.

In general, Eqs. (15-48) through (15-52) (and Fig. 15-24) are valid for any concentration range in which equilibrium can be represented by a linear relationship $Y = mX + b$ (written here in general form for any system of units). For applications that involve dilute feeds, the section of the equilibrium line of interest is a straight line that extends through the origin where $Y_i = 0$ at $X_i = 0$. In this case, $b = 0$ and the slope of the equilibrium line is equal to the partition ratio ($m = K$). The KSB equation also may be used to represent a linear segment of the equilibrium curve at higher solute concentrations. In this case, the linear segment is represented by a straight line that does not extend through the origin, and $m$ is the local slope of the equilibrium line, so $b \neq 0$ and $m \neq K$. Furthermore, a series of KSB equations may be used to model a highly curved equilibrium line by dividing the analysis into linear segments and matching concentrations where the segments meet. For equilibrium lines with moderate curvature, an approximate average slope of the equilibrium line may be obtained from the geometric mean of the slopes at low and high solute concentrations:

$$m_{\text{average}} \approx m_{\text{geometric mean}} = \sqrt{m_{\text{low}} m_{\text{high}}} \tag{15-53}$$

As noted above, other systems of units such as mass fraction and total mass flow rates or mole fraction and total molar flow rates also may be used with the KSB equation; however, Bancroft coordinates and solute-free mass flow rates are recommended because then the operating line must be linear, and this normally extends the concentration range over which the KSB analysis may be used. It is important to check whether equilibrium can be adequately represented by a straight line over the concentration range of interest. The application of the KSB equation is discussed in "Shortcut Calculations" under "Calculation Procedures." Additional discussion is given by Wankat [*Equilibrium Staged Separations* (Prentice-Hall, 1988)] and by King [*Separation Processes*, 2d ed. (McGraw-Hill, 1980)]. To facilitate use of the KSB equation in computer calculations where the singularity around $\mathcal{E} = 1$ can present difficulties, Shenoy and Fraser have proposed an alternative form of the equation [*Chem. Eng. Sci.*, **58**(22) pp. 5121-5124 (2003)].

**Stage Efficiency** For a multistage process, the overall stage efficiency is simply the number of theoretical stages divided by the number of actual stages times 100:

$$\xi_o\,(\%) = \frac{\text{theoretical stages}}{\text{actual stages}} \times 100 \tag{15-54}$$

The fundamental stage efficiency is referred to as the Murphree stage efficiency $\xi_m$. The Murphree efficiency based on the dispersed phase is defined as

$$\xi_{md} = \frac{C_{d,n+1} - C_{d,n}}{C_{d,n+1} - C^*_d} \tag{15-55}$$

where $C_{d,n+1}$ = concentration of solute $i$ in dispersed phase at stage $n + 1$
$C_{d,n}$ = concentration of solute $i$ in dispersed phase at stage $n$
$C^*_d$ = concentration of solute $i$ in dispersed phase, at equilibrium

The overall stage efficiency is related to the Murphree stage efficiency and the extraction factor ($\mathcal{E}$):

$$\xi_o(\%) = \frac{\ln\,[1 + \xi_{md}(\mathcal{E} - 1)]}{\ln\,\mathcal{E}} \times 100 \tag{15-56}$$

For applications involving extraction of multiple solutes, sometimes the extraction rate and mass-transfer efficiency for each solute are significantly different. In these cases, individual efficiencies will need to be determined for each solute.

Stage efficiencies normally are determined by running miniplant tests to measure performance as a function of process variables such as feed rates, operating temperature, physical properties, impurities,

and agitation (if used). A number of data correlations have been developed for various types of mixing equipment. In principle, these can be used in the estimation of mass-transfer rates and stage efficiencies, but in practice reliable design generally requires generation of miniplant data and application of mixing scale-up methods. (See "Mixer-Settler Equipment" under "Liquid-Liquid Extraction Equipment.")

The overall efficiency of an extraction column also can be expressed as the height equivalent to a theoretical stage (HETS). This is simply the total contacting height $Z_t$ divided by the number of theoretical stages achieved.

$$\text{HETS} = \frac{Z_t}{N} \tag{15-57}$$

The HETS often is used to compare staged contactors with differential contactors.

## RATE-BASED CALCULATIONS

This section reviews the basics of the mass-transfer coefficient and mass-transfer unit approaches to modeling extraction performance. These methods have been used for many years and continue to provide a useful basis for the design of extractors and extraction processes. Additional discussions of these and other rate-based methods are given in the books edited by Godfrey and Slater [*Liquid-Liquid Extraction Equipment* (Wiley, 1994)] and by Thornton [*Science and Practice of Liquid-Liquid Extraction*, vol. 1 (Oxford, 1992)]. For discussions of more mechanistic methods that include characterization of drop breakage and coalescence rates, drop size distributions, and drop population balances, see Leng and Calabrese, Chap. 12 in *Handbook of Industrial Mixing*, Paul, Atiemo-Obeng, and Kresta, eds. (Wiley, 2004); Goodson and Kraft, *Chem. Eng. Sci.*, **59,** pp. 3865–3881 (2004); Attarakih, Bart, and Faqir, *Chem. Eng. Sci.*, **61,** pp. 113–123 (2006); and Schmidt et al., *Chem. Eng. Sci.*, **61,** pp. 246–256 (2006). These methods are the subject of current research. Also see the discussion of general approaches to analyzing dispersed-phase systems given by Ramkrishna, Sathyagal, and Narsimhan [*AIChE J.*, **41**(1), pp. 35–44 (1995)]. For discussions of the effect of contaminants on mass-transfer rates, see Saien et al., *Ind. Eng. Chem. Res.,* **45**(4), pp. 1434–1440 (2006); and Dehkordi et al., *Ind. Eng. Chem. Res.*, **46**(5), pp. 1563–1571 (2007).

**Solute Diffusion and Mass-Transfer Coefficients** For a binary system consisting of components *A* and *B*, the overall rate of mass transfer of component *A* with respect to a fixed coordinate is the sum of the rates due to diffusion and bulk flow:

$$N_A = -\mathcal{D}_{AB}\frac{\partial C_A}{\partial z} + N_A\frac{C_A}{C} \tag{15-58}$$

where $N_A$ = flux for component *A* (moles per unit area per unit time)
$\mathcal{D}_{AB}$ = mutual diffusion coefficient of *A* into *B* (area/unit time)
$z$ = dimension or direction of mass transfer (length)
$C$ = total concentration of *A* and *B* (mass or mole per unit volume)
$C_A$ = concentration of *A* (mass or mole per unit volume)

Equation (15-58) is written for steady-state unidirectional diffusion in a quiescent liquid, assuming that the net transfer of component *B* is negligible. For transfer of component *A* across an interface or film between two liquids, it may be rewritten in the form

$$N_A = \frac{\mathcal{D}_{AB}}{\Delta z(1-x_A)_m}(C_A - C_A^i) \tag{15-59}$$

where $(1-x_A)_m$ = mean mole fraction of component *B*
$C_A^i$ = concentration of component *A* at interface
$C_A$ = concentration of component *A* in bulk

For steady-state counter diffusion where $N_A + N_B = 0$, the flux equation simplifies to

$$N_A = \frac{\mathcal{D}_{AB}}{\Delta z}(C_A - C_A^i) \tag{15-60}$$

The flux also may be written in terms of an individual mass-transfer coefficient *k*

$$N_A = k(C_A - C_A^i) \tag{15-61}$$

where

$$k = \frac{\mathcal{D}_{AB}}{\Delta z(1-x_A)_m} \tag{15-62}$$

In Eqs. (15-58) to (15-62), the flux is expressed in terms of mass or moles per unit area per unit time, and the concentration driving force is defined in terms of mass or moles per unit volume. The units of the mass-transfer coefficients are then length per unit time. Other definitions of the flux and resulting mass-transfer coefficients also are used. When mass-transfer coefficients are used, it is important to understand their definition and how they were determined; they need to be used in the same way in any subsequent calculations. Additional discussion of mass- transfer coefficients and mass-transfer rate is given in Sec. 5. Also see Laddha and Degaleesan, *Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978), Chap. 3; Skelland, *Diffusional Mass Transfer* (Krieger, 1985); Skelland and Tedder, Chap. 7 in *Handbook of Separation Process Technology,* Rousseau, ed. (Wiley, 1987); Curtiss and Bird, *Ind. Eng. Chem. Res.*, **38**(7), pp. 2515–2522 (1999); and Bird, Stewart, and Lightfoot, *Transport Phenomena*, 2d ed. (Wiley, 2002). Available correlations of molecular diffusion coefficients (diffusivities) are discussed in Sec. 5 and in Poling, Prausnitz, and O'Connell, *The Properties of Gases and Liquids*, 5th ed. (McGraw-Hill, 2000). The prediction of diffusion coefficients is discussed by Bosse and Bart, *Ind. Eng. Chem. Res.*, **45**(5), pp. 1822–1828 (2006).

**Mass-Transfer Rate and Overall Mass-Transfer Coefficients** In transferring from one phase to the other, a solute must overcome certain resistances: (1) movement from the bulk of the raffinate phase to the interface; (2) movement across the interface; and (3) movement from the interface to the bulk of the extract phase, as illustrated in Fig. 15-25. The two-film theory first used to model this process [Lewis and Whitman, *Ind. Eng. Chem.*, **16,** pp. 1215–1220 (1924)] assumes that motion in the two phases is negligible near the interface such that the entire resistance to transfer is contained within two laminar films on each side of the interface, and mass transfer occurs by molecular diffusion through these films. The theory further invokes the following simplifying assumptions: (1) The rate of mass transfer within each phase is proportional to the difference in concentration in the bulk liquid and the interface; (2) mass-transfer resistance across the interface itself is negligible, and the phases are in equilibrium at the interface; and (3) steady-state diffusion occurs with negligible holdup of diffusing solute at the interface. Within a liquid-liquid extractor, the rate of steady-state mass transfer between the dispersed phase and the continuous phase (mass or moles per unit time per unit volume of extractor) is then expressed as

$$R_A = \frac{dC}{dt} = k_d a(C_{d,i} - C_d) = k_c a(C_c - C_{c,i}) \tag{15-63}$$

where $C_i$ = concentration at interface (mass or moles per unit volume)
$C$ = concentration in bulk liquid (mass or moles per unit volume)
$k_c$ = continuous-phase mass-transfer coefficient (length per unit time)
$k_d$ = dispersed-phase film mass-transfer coefficient (length per unit time)
$a$ = interfacial area for mass transfer per unit volume of extractor (length$^{-1}$)

Subscripts *d* and *c* denote the dispersed and continuous phases. The concentrations at the interface normally are not known, so the rate expression is written in terms of equilibrium concentrations assuming that the rate is proportional to the deviation from equilibrium:

$$R_A = \frac{dC}{dt} = k_{od} a(C_d^* - C_d) = k_{oc} a(C_c - C_c^*) \tag{15-64}$$

where the superscript * denotes equilibrium, and $k_{oc}$ is an overall mass-transfer coefficient given by

$$\frac{1}{k_{oc}} = \underbrace{\frac{1}{k_c}}_{\text{Continuous phase resistance}} + \underbrace{\frac{1}{m_{dc}^{\text{vol}}\, k_d}}_{\text{Dispersed phase resistance}} \tag{15-65}$$

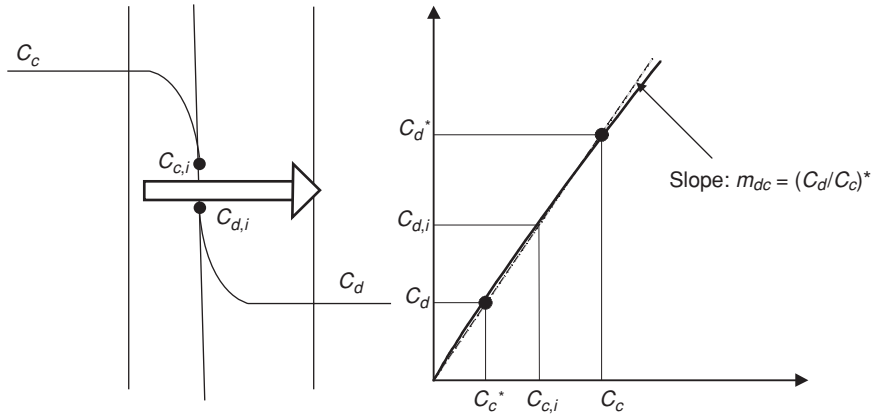

**FIG. 15-25** Two-film mass transfer.

Similarly, the overall mass-transfer coefficient based on the dispersed phase is given by

$$\frac{1}{k_{od}} = \underbrace{\frac{1}{k_d}}_{\text{Dispersed phase resistance}} + \underbrace{\frac{m_{dc}^{\text{vol}}}{k_c}}_{\text{Continuous phase resistance}} \tag{15-66}$$

Assuming mass-transfer coefficients are constant over the range of conditions of interest, Eq. (15-64) may be integrated to give

$$\frac{C_c - C_c^*}{C_{c,\text{initial}} - C_c^*} = \exp(-k_{oc}a\theta) \approx \frac{C_c}{C_{c,\text{initial}}} \tag{15-67}$$

where $\theta$ is the contact time.

In Eqs. (15-65) and (15-66), $m_{dc}^{\text{vol}} = dC_d/dC_c$ is the local slope of the equilibrium line, with the equilibrium concentration of solute in the dispersed phase plotted on the ordinate ($y$ axis), and the equilibrium concentration of solute in the continuous phase plotted on the abscissa ($x$ axis). Note that $m_{dc}^{\text{vol}}$ is expressed on a volumetric basis (denoted by superscript *vol*), i.e., in terms of mass or mole per unit volume, because of the way the mass-transfer coefficients are defined. The mass-transfer coefficients will not necessarily be the same for each solute being extracted, so depending upon the application, mass-transfer coefficients may need to be determined for a range of different solutes. As noted earlier, other systems of units also may be used as long as they are consistently applied.

The mass-transfer coefficient in each film is expected to depend upon molecular diffusivity, and this behavior often is represented by a power-law function $k \propto \mathcal{D}^n$. For two-film theory, $n = 1$ as discussed above [(Eq. (15-62)]. Subsequent theories introduced by Higbie [*Trans. AIChE*, **31,** p. 365 (1935)] and by Dankwerts [*Ind. Eng. Chem.*, **43,** pp. 1460–1467 (1951)] allow for surface renewal or penetration of the stagnant film. These theories indicate a 0.5 power-law relationship. Numerous models have been developed since then where $0.5 < n < 1.0$; the results depend upon such things as whether the dispersed drop is treated as a rigid sphere, as a sphere with internal circulation, or as oscillating drops. These theories are discussed by Skelland ["Interphase Mass Transfer," Chap. 2 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992)].

In the design of extraction equipment with complex flows, mass-transfer coefficients are determined by experiment and then correlated as a function of molecular diffusivity and system properties. The available theories provide an approximate framework for the data. The correlation constants vary depending upon the type of equipment and operating conditions. In most cases, the dominant mass-transfer resistance resides in the feed (raffinate) phase, since the slope of the equilibrium line usually is greater than unity. In that case, the overall mass-transfer coefficient based on the raffinate phase may be written

$$\frac{1}{k_{or}} = \frac{1}{k_r} + \frac{1}{m_{er}^{\text{vol}} k_e} \approx \frac{1}{k_r} \quad \text{for large } m_{er}^{\text{vol}} \tag{15-68}$$

where $m_{er}^{\text{vol}}$ is defined by the usual convention in terms of concentration in the extract phase over that in the raffinate phase, $m_{er}^{\text{vol}} = dC_{i,\text{extract}}/dC_{i,\text{raffinate}}$. This approximation is particularly useful when the extraction solvent is significantly less viscous than the feed liquid, so the solute diffusivity and mass-transfer coefficient in the extract phase are relatively large.

**Mass-Transfer Units** The mass-transfer unit concept follows directly from mass-transfer coefficients. The choice of one or the other as a basis for analyzing a given application often is one of preference. Colburn [*Ind. Eng. Chem.*, **33**(4), pp. 450–467 (1941)] provides an early review of the relationship between the height of a transfer unit and volumetric mass-transfer coefficients ($k_{or}a$). From a differential material balance and application of the flux equations, the required contacting height of an extraction column is related to the height of a transfer unit and the number of transfer units

$$Z_t = \left(\frac{V_r}{k_{or}a}\right)\int_{X_{\text{out}}}^{X_{\text{in}}} \frac{dX}{X - X^*} = H_{or} \times N_{or} \tag{15-69}$$

where $V_r$ is the velocity of the raffinate phase, $a$ is the interfacial area per unit volume, and the superscript * denotes the equilibrium concentration. The transfer unit model has proved to be a convenient framework for characterizing mass-transfer performance.

Thus, mass-transfer units are defined as the integral of the differential change in solute concentration divided by the deviation from equilibrium, between the limits of inlet and outlet solute concentrations:

$$N_{or} = \int_{X_{\text{out}}}^{X_{\text{in}}} \frac{dX}{X - X^*} \tag{15-70}$$

When the equilibrium and operating lines are linear, the solution to Eq. (15-70) can be expressed as

$$N_{or} = \frac{\ln\left[\left(\dfrac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)\left(1 - \dfrac{1}{\mathcal{E}}\right) + \dfrac{1}{\mathcal{E}}\right]}{1 - \dfrac{1}{\mathcal{E}}} \qquad \mathcal{E} = m'\frac{S'}{F'},\ \mathcal{E} \neq 1 \tag{15-71}$$

where $N_{or}$ is the number of overall mass-transfer units based on the raffinate phase. The units are the same as those used previously for the KSB equation [(Eq. 15-48)]. Rearranging Eq. (15-71) gives

$$\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} = \frac{\exp\,[N_{or}(1 - 1/\mathcal{E})] - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad (15\text{-}72)$$

Note that Eq. (15-71) is the same as the KSB equation except in the denominator. Comparing these equations shows that the number of overall raffinate phase transfer units is related to the number of theoretical stages by

$$N_{or} = N \times \frac{\ln \mathcal{E}}{1 - 1/\mathcal{E}} \qquad (15\text{-}73)$$

The difference becomes pronounced when values of the extraction factor are high. When $\mathcal{E} = 1$, the number of mass-transfer units and number of theoretical stages are the same:

$$N_{or} = N = \frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'} - 1 \qquad \text{for } \mathcal{E} = 1 \qquad (15\text{-}74)$$

As with the KSB equation, in the special case where $\mathcal{E} < 1$, the maximum performance potential is represented by

$$\left(\frac{X'_f - Y'_s/m'}{X'_r - Y'_s/m'}\right)_{\max} \approx \frac{1}{1 - \mathcal{E}} \qquad \text{for } \mathcal{E} < 1 \text{ and large } N_{or} \qquad (15\text{-}75)$$

Equation (15-71) often is referred to as the Colburn equation. Although commonly used to represent the performance of a differential contactor, it models any steady-state, diffusion-controlled processes with straight equilibrium and operating lines. As with the KSB equation, the operating line is straight even when solute concentration changes significantly as long as Bancroft coordinates are used, and both the KSB and Colburn equations can be used to model applications involving a highly curved equilibrium line by dividing the analysis into linear segments. With these approaches, these equations often can be used for applications involving high concentrations of solute.

Solutions to the Colburn equation are shown graphically in Fig. 15-26. Note the contrast to the KSB equation solutions shown in Fig. 15-24. The KSB equations are best used to model countercurrent contact devices where the separation is primarily governed by equilibrium limitations, such as extractors involving discrete stages with high stage efficiencies. The Colburn equation, on the other hand, better represents the performance of a diffusion rate-controlled contactor because performance approaches a definite limit as the extraction factor increases beyond $\mathcal{E}$ = 10 or so, corresponding to a diffusion rate limitation where addition of extra solvent has little or no effect. Note that in Eq. (15-71) the extraction factor always appears as $1/\mathcal{E}$, and this is how a finite diffusion rate is taken into account. The KSB equation can be misleading in this regard because it predicts continued improvement as the extraction factor increases without limit. Rate-based models most often are utilized for applications with no discrete stages; however, even staged equipment may be modeled best by the number of mass-transfer units when the extraction factor is higher than about 3, especially when stage efficiencies are low.

The height of an overall mass-transfer unit based on raffinate phase compositions $H_{or}$ is the total contacting height $Z_t$ divided by the number of transfer units achieved by the column.

$$H_{or} = \frac{Z_t}{N_{or}} \qquad (15\text{-}76)$$

The value of $H_{or}$ is the sum of contributions from the resistance to mass transfer in the raffinate phase ($H_r$) plus resistance to mass transfer in the extract phase ($H_e$) divided by the extraction factor $\mathcal{E}$:

$$H_{or} = H_r + \frac{H_e}{\mathcal{E}} \qquad (15\text{-}77)$$

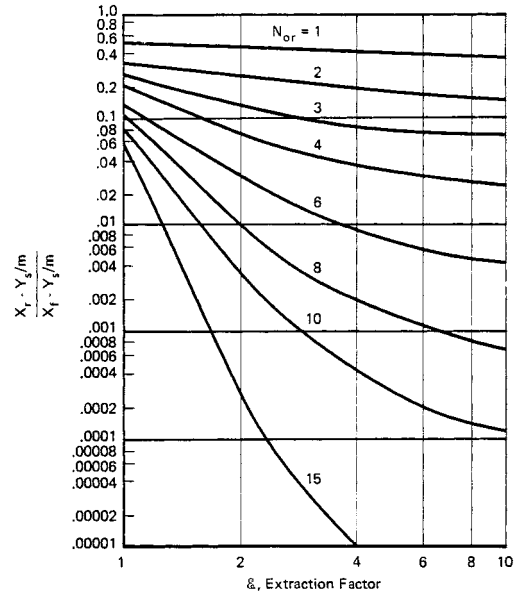

**FIG. 15-26** Graphical solutions to the Colburn equation [Eq. (15-71)].

The individual transfer unit heights are given by

$$H_r = \frac{Q_r}{A_{\text{col}} k_r a} \qquad (15\text{-}78)$$

$$H_e = \frac{Q_e}{A_{\text{col}} k_e a} \qquad (15\text{-}79)$$

where $Q$ = volumetric flow rate
$A_{\text{col}}$ = column cross-sectional area
$k$ = film mass-transfer coefficient (length per unit time)
$a$ = interfacial mass-transfer area per unit volume of extractor

and subscripts $r$ and $e$ denote the raffinate and extract phases, respectively. As discussed earlier, the main resistance to mass transfer generally resides in the feed (raffinate) phase.

The lumped parameter $H_{or}$ often is employed for design of extraction columns. Its value reflects the efficiency of the differential contactor; higher contacting efficiency is reflected in a lower value of $H_{or}$. It deals directly with the ultimate design criterion, the height of the column, and reliable values often can be obtained from miniplant experiments and experience with commercial units. For processes with discrete contacting stages, mass-transfer efficiency may be expressed as the number of transfer units achieved per actual stage. For applications involving transfer of multiple solutes, the value of $H_{or}$ or $N_{or}$ per actual stage may differ for each solute, as discussed earlier with regard to stage efficiencies and mass-transfer coefficients.

## EXTRACTION FACTOR AND GENERAL PERFORMANCE TRENDS

Because of their simplicity, the KSB equation [Eq. (15-48)] and Colburn equation [Eq. (15-71)] are useful for illustrating a number of general trends in mass-transfer performance, in particular, helping to show how the extraction factor is related to process performance for different process configurations. For illustration, consider a dilute system involving immiscible liquids and zero solute concentration in the entering extraction solvent. The resulting expressions that follow are written in a general form without regard to a specific set of units.

For a single-stage batch process or a continuous extraction process that achieves one theoretical stage, the solute reduction factor is given by

$$F_R = \frac{X_{\text{in}}}{X_{\text{out}}} = \frac{\mathcal{E} - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \text{for } N = 1 \tag{15-80}$$

The required solvent-to-feed ratio is then approximated by

$$\frac{S}{F} = \frac{F_R - 1}{K} \qquad \text{for } N = 1 \tag{15-81}$$

After extraction, the concentration of solute in the extract, no matter what the extraction configuration, is given by

$$Y_{\text{out}} = \frac{X_{\text{in}}}{S/F}\left(1 - \frac{1}{F_R}\right) \qquad \text{for } Y_{\text{in}} = 0 \tag{15-82}$$

Equation (15-82) follows from Eq. (15-47).

If the performance of a single-stage extraction is not adequate, repeated cross-current extractions can be carried out to increase solute recovery or removal. For this configuration, the reduction factor is given by

$$F_R = \left(1 + \frac{\mathcal{E}}{N}\right)^{\xi_o N} \qquad \text{for cross-current operation} \tag{15-83}$$

where $N$ is the number of repeated extractions or stages employing equal amounts of solvent, $\xi_o$ is overall stage efficiency, and the extraction factor is expressed in terms of the total amount of solvent used by the process. Although high solute recoveries can be obtained by using cross-current processing, the required solvent usage will be high, as indicated by

$$\frac{S}{F} = \frac{N}{K}\left(F_R^{1/\xi_o N} - 1\right) \qquad \text{for cross-current-operation} \tag{15-84}$$

where $S$ is the total amount of solvent. The concentration of solute in the combined extract will be low, as calculated by using Eq. (15-82). Comparing the results of Eqs. (15-80) and (15-81) with Eqs. (15-83) and (15-84) will show that multistage cross-current extraction yields improved performance relative to using single-stage extraction with the same total amount of solvent, but at the cost of additional contacting steps.

Compared to single-stage or cross-current processing, multistage, countercurrent processing allows a significant reduction in solvent use or an increase in separation performance. For this type of process, the reduction factor is approximated by

$$F_R = \frac{\mathcal{E}^{\xi_o N} - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \text{for countercurrent operation} \tag{15-85}$$

Inspection of Eqs. (15-80) and (15-85) will show how the addition of countercurrent stages magnifies the effect of the extraction factor on performance. Note that Eq. (15-85) predicts that performance will continue to improve as the value of $\mathcal{E}$ increases, approaching $F_R = \mathcal{E}^{\xi_o N}$ at high values of $\mathcal{E}$. However, stage efficiency must remain high, and this likely will require a change in some operating variable such as residence time per stage.

Multistage countercurrent processing may be practiced batchwise as well as in a continuous cascade. A batchwise countercurrent operation involves first treating a batch with extract solution as the extract leaves the process, and the last treatment is carried out by using fresh solvent as it enters the process (as in Figs. 15-6 and 15-22). A multistage, countercurrent process with discrete contacting stages (practiced either batchwise or using a continuous cascade) is well suited to applications with fairly slow rates of mass transfer because liquid-liquid contacting is carried out stagewise in separate vessels or compartments, and long residence times can be designed into each stage.

For a countercurrent extraction column with no discrete stages (or for processes operated within a diffusion-controlled regime far from equilibrium), performance is well modeled by the Colburn equation, where

$$F_R = \frac{\exp\left[N_{or}(1 - 1/\mathcal{E})\right] - 1/\mathcal{E}}{1 - 1/\mathcal{E}} \qquad \text{for countercurrent operation} \tag{15-86}$$

and

$$Z_t = N_{or} \times H_{or} \tag{15-87}$$

Extraction columns are most attractive for applications with fairly fast mass transfer because residence time in the column is limited. Performance becomes mass-transfer-limited at high values of $\mathcal{E}$, approaching $F_R = \exp N_{or}$. At this point, a significant increase in performance can be achieved only by adding transfer units (column height).

With countercurrent processing, carried out using either a multistage cascade or an extraction column, the required solvent-to-feed ratio generally can be reduced by adding more and more stages or transfer units. As discussed in "Minimum and Maximum Solvent-to-Feed Ratios," the minimum practical solvent-to-feed ratio is approximated by

$$\left(\frac{S}{F}\right)_{\min} \approx \frac{1.3}{K} \qquad \text{for countercurrent processing} \tag{15-88}$$

Below this value, the required number of stages or transfer units increases rapidly. At $\mathcal{E} = 1$, the number of theoretical stages and number of transfer units are equal, and

$$F_R = N + 1 = N_{or} + 1 \qquad \text{for } \mathcal{E} = 1 \tag{15-89}$$

For $\mathcal{E} < 1$, the fraction of solute removed from the feed $\theta_i$ will approach a value equal to the extraction factor. In this case,

$$(F_R)_{\max} = \frac{1}{1 - \mathcal{E}} \qquad \text{for } \mathcal{E} < 1 \tag{15-90}$$

## POTENTIAL FOR SOLUTE PURIFICATION USING STANDARD EXTRACTION

As noted earlier, the ability of a standard extraction process to isolate a desired solute from other solutes is limited. This can be illustrated by using the KSB equation [Eq. (15-48)] to calculate solute transfer for a dilute feed containing a desired solute $i$ and an impurity solute $j$. On a solvent-free basis, the purity of solute $i$ in the feed is given by

$$P_{i,\text{feed}}\,(\text{in units of wt \%}) = 100\left(\frac{X''_{i,\text{feed}}}{X''_{i,\text{feed}} + X''_{j,\text{feed}}}\right) \tag{15-91}$$

Similarly, the purity of solute $i$ in the extract is given by

$$P_{i,\text{extract}}(\text{wt \%}) = 100\left(\frac{\theta_i X''_{i,\text{feed}}}{\theta_i X''_{i,\text{feed}} + \theta_j X''_{j,\text{feed}}}\right) \tag{15-92}$$

where $\theta_i$ is the fraction of solute extracted from the feed into the extract. By using the KSB equation to estimate $\theta$ for solutes $i$ and $j$, the following expression is derived:

$$P_{i,\,\text{extract}}\,(\text{wt \%}) = \frac{100}{1 + \left(\dfrac{\theta_j}{\theta_i}\right)\left(\dfrac{X''_{j,\,\text{feed}}}{X''_{i,\,\text{feed}}}\right)}$$

$$= \frac{100}{1 + \left(\dfrac{\mathcal{E}_j^N - 1}{\mathcal{E}_i^N - 1}\right)\left(\dfrac{\mathcal{E}_i^N - 1/\mathcal{E}_i}{\mathcal{E}_j^N - 1/\mathcal{E}_j}\right)\left(\dfrac{X''_{j,\,\text{feed}}}{X''_{i,\,\text{feed}}}\right)} \qquad \text{for } \mathcal{E} \neq 1.0 \tag{15-93}$$

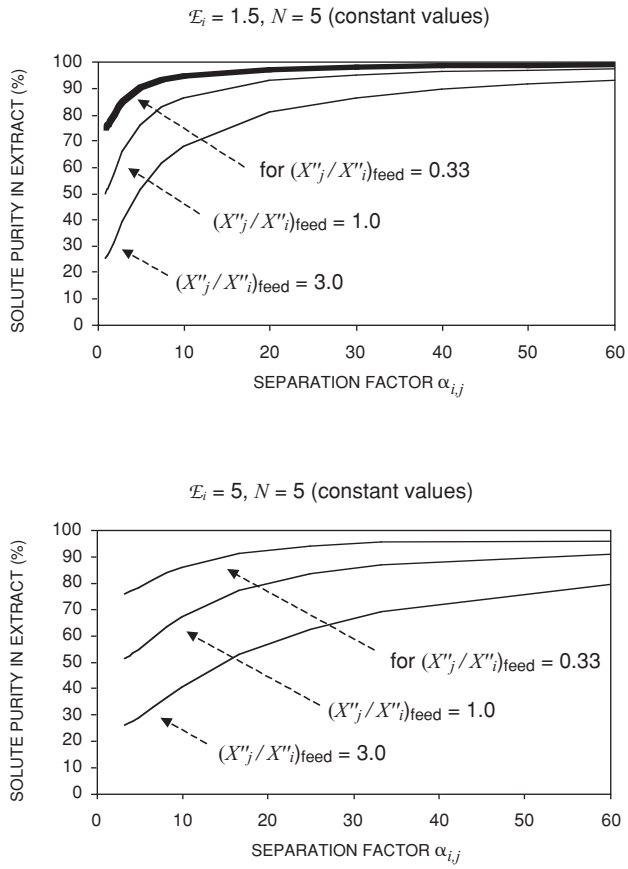

**FIG. 15-27** Approximate purity of solute $i$ in the extract ($P_{i,extract}$) versus separation factor $\alpha_{i,j}$ for standard extraction involving dilute feeds containing solutes $i$ and $j$. Results obtained by using Eq. (15-93). Concentrations are in mass fraction ($X''$).

Equation (15-93) assumes that no solute enters the process with the extraction solvent and that $\mathcal{E}_i$ and $\mathcal{E}_j$ are constant. An alternative expression can be written in terms of transfer units; however, the calculated results are essentially the same as a function of the number of stages or the number of transfer units—because the models assume that both solute $i$ and solute $j$ experience the same mass-transfer resistance. Example results obtained by using Eq. (15-93) are shown in Fig. 15-27. Note that performance is not uniquely determined by a given value of $\alpha_{i,j} = K_i/K_j = \mathcal{E}_i/\mathcal{E}_j$, but depends upon the absolute value of $\mathcal{E}_i$, as well. In principle, the purity of solute $i$ in the extract will approach a maximum value as the number of stages or transfer units approaches infinity:

$$\text{Maximum } P_{i,\text{extract}}(\%) = 100 \div \left[1 + \frac{1}{\alpha_{i,j}}\left(\frac{X''_{j,\text{feed}}}{X''_{i,\text{feed}}}\right)\right] \quad \text{in limit as } N \to \infty \tag{15-94}$$

Of course, this theoretical maximum can never be attained in practice. Equation (15-94) follows from Eq. (15-93), noting that $\theta_j/\theta_i = 1/\alpha_{ij}$ for $N \to \infty$ as discussed by Brian [*Staged Cascades in Chemical Processing* (Prentice-Hall, 1972), p. 50]. As noted earlier, the ability to purify a desired solute is greatly enhanced by using fractional extraction (see "Fractional Extraction Calculations").

# CALCULATION PROCEDURES

## SHORTCUT CALCULATIONS

Shortcut calculations can be quite useful to the process designer or run-plant engineer; they may be used to outline process requirements (stream and equipment sizes) early in a design project, to check the output of a process simulation program for reasonableness, to help analyze or troubleshoot a unit operating in the manufacturing plant or pilot plant, or to help explain performance trends and relationships between key process variables. In some applications involving dilute or even moderately concentrated feeds, they also may be used to specify the final design of an extraction process. In carrying out such calculations, Robbins [Sec. 1.9 in *Handbook of Separation Techniques for Chemical Engineers*, Schweitzer, ed. (McGraw-Hill, 1997)] indicates that most liquid-liquid extraction systems can be treated as having immiscible solvents (case *A*), partially miscible solvents with a low solute concentration in the extract (case *B*), or partially miscible solvents with a high solute concentration in the extract (case *C*). These cases are illustrated in Examples 1 through 3 below.

***Example 1: Shortcut Calculation, Case A*** Consider a 100-kg/h feed stream containing 20 wt % acetic acid in water that is to be extracted with 200 kg/h of recycle MIBK that contains 0.1 wt % acetic acid and 0.01 wt % water. The aqueous raffinate is to be extracted down to 1% acetic acid. How many theoretical stages will be required and what will the extract composition be? The equilibrium data for this system are listed in Table 15-8 (in units of weight percent). The corresponding Hand plot is shown in Fig. 15-20. The Hand correlation (in mass ratio units) can be expressed as $Y' = 0.930(X')^{1.10}$, for $X'$ between 0.03 and 0.25.

Assuming immiscible solvents, we have

$$F' = 100(1 - 0.2) = 80 \text{ kg water/h}$$

$$X'_f = \frac{0.2}{0.8} = 0.25 \text{ kg acetic acid/kg water}$$

$$X'_r = \frac{0.01}{0.99} = 0.01 \text{ kg acetic acid/kg water}$$

$$S' = 200(1 - 0.001) = 199.8 \text{ kg MIBK/h}$$

$$Y'_s = \frac{0.2}{199.8} = 0.001 \text{ kg acetic acid/kg MIBK}$$

If we assume $R' = F'$ and $E' = S'$, we can calculate $Y'_e$ from Eq. (15-47):

$$Y'_e = \frac{80(0.25) + 199.8(0.001) - 80(0.01)}{199.8} = 0.097 \frac{\text{kg acetic acid}}{\text{kg MIBK}}$$

Calculate $X'_1 = (0.097/0.930)^{1/1.10} = 0.128$. Then

$$m' = \frac{dY'}{dX'} = (0.930)(1.10)(X')^{0.1} \quad \text{for } X' \text{ between 0.03 and 0.25}$$

$$m'_1 = 0.833 \quad \text{at } X' = 0.128$$

$$m'_r = \frac{dY'}{dX'} = K' = 0.656 \quad \text{for } X' \text{ below 0.03}$$

$$K'_s = 0.656 \quad \text{at } Y'_s = 0.001$$

$$\mathcal{E} = \sqrt{m'_1 m'_r}\ \frac{S'}{F'} = \frac{0.739(199.8)}{80} = 1.85$$

And $N$ is determined from Fig. 15-24 and Eq. (15-48).

$$N = \frac{\ln\left[\left(\frac{0.25 - 0.001/0.656}{0.01 - 0.001/0.656}\right)\left(1 - \frac{1}{1.85}\right) + \frac{1}{1.85}\right]}{\ln 1.85} = 4.3 \text{ theoretical stages}$$

This result is very close to that obtained by using a McCabe-Thiele diagram (Fig. 15-23). From solubility data at $Y' = 0.1039$ kg acetic acid/kg MIBK (given in Table 15-8), the extract layer contains 5.4/85.7 = 0.0630 kg water/kg MIBK, and $Y''_e = (0.097)/(1 + 0.097 + 0.063) = 0.084$ mass fraction acetic acid in the extract.

For cases *B* and *C*, Robbins developed the concept of pseudosolute concentrations for the feed and solvent streams entering the extractor that will allow the KSB equations to be used. In case *B* the solvents are partially miscible, and the miscibility is nearly constant through the extractor. This frequently occurs when all solute concentrations are relatively low. The feed stream is assumed to dissolve extraction solvent only in the feed stage and to retain the same amount throughout the extractor. Likewise, the extraction solvent is assumed to dissolve feed solvent only in the raffinate stage. With these assumptions the primary extraction solvent rate moving through the extractor is assumed to be $S'$, and the primary feed solvent rate is assumed to be $F'$. The extract rate $E'$ is less than $S'$, and the raffinate rate $R'$ is less than $F'$ because of solvent mutual solubilities.

The slope of the operating line is $F'/S'$, just as in Eqs. (15-45) and (15-46), but only stages 2 through $r - 1$ will fall directly on the operating line. And $X'_1$ must be on the equilibrium line in equilibrium with $Y'_e$ by definition. One can also calculate a pseudofeed concentration $X'^B_f$ that will fall on the operating line at $Y'_{n+1} = Y'_e$ as follows:

$$X'^B_f = X'_f + \frac{S' - E'}{F'} Y'_e \tag{15-95}$$

Likewise, one knows that $Y'_r$ will be on the equilibrium line with $X'_r$. One can therefore calculate a pseudoconcentration of solute in the inlet extraction solvent $Y'^B_s$ that will fall on the operating line where $X'_{n-1} = X'_r$, as follows:

$$Y'^B_s = Y'_s + \frac{F' - R'}{S'} X'_r \tag{15-96}$$

For case *B*, the pseudo inlet concentration $X'^B_f$ can be used in the KSB equation with the actual value of $X'_r$ and $\mathcal{E} = m'S'/F'$ to calculate rapidly the number of theoretical stages required. The graphical stepwise method illustrated in Fig. 15-23 also can be used. The operating line will go through points $(X'_r, Y'^B_s)$ and $(X'^B_f, Y'_e)$ with a slope of $F'/S'$.

***Example 2: Shortcut Calculation, Case B*** Let us solve the problem in Example 1 by assuming case *B*. The solute (acetic acid) concentration is low enough in the extract that we may assume that the mutual solubilities of the solvents remain nearly constant. The material balance can be calculated by an iterative method.

From equilibrium data (Table 15-8) the extraction solvent (MIBK) loss in the raffinate will be about 0.016/0.984 = 0.0163 kg MIBK/kg water, and the feed solvent (water) loss in the extract will be about 5.4/85.7 = 0.0630 kg water/kg MIBK.

First iteration: Assume $R' = F' = 80$ kg water/h. Then extraction solvent in raffinate = (0.0163)(80) = 1.30 kg MIBK/h. Estimate $E' = 199.8 - 1.3 = 198.5$ kg MIBK/h. Then feed solvent in extract = (0.063)(198.5) = 12.5 kg water/h.

Second iteration: Calculate $R' = 80 - (0.063)(198.7) = 67.5$ kg water/h. And $E' = 199.8 - (0.0163)(67.5) = 198.7$ kg MIBK/h.

Third iteration: Converge $R' = 80 - (0.063)(198.7) = 67.5$ kg water/h. And $Y'_e$ is calculated from the overall extractor material balance [(Eq. (15-47)]:

$$Y'_e = \frac{(80)(0.25) + (199.8)(0.001) - (67.5)(0.01)}{198.7} = 0.0983 \frac{\text{kg acetic acid}}{\text{kg MIBK}}$$

$$Y_e = \frac{0.0983}{1 + 0.0983 + 0.0630} = 0.0846 \text{ mass fraction acetic acid in extract}$$

From the Hand correlation of equilibrium data,

$$Y'_e = 0.930(X')^{1.10} \quad \text{for } X' \text{ between 0.03 and 0.25}$$

The raffinate composition leaving the feed (first stage) is

$$X'_1 = \left(\frac{0.0983}{0.930}\right)^{1/1.10} = 0.130$$

$$m'_1 = \frac{dY}{dX} = (0.930)(1.10)(X')^{0.1}$$

**TABLE 15-8 Water + Acetic Acid + Methyl Isobutyl Ketone Equilibrium Data at 25°C**

| Weight percent in raffinate | | | $X'$ | Weight percent in extract | | | $Y'$ |
|---|---|---|---|---|---|---|---|
| Water | Acetic acid | MIBK | Acetic acid | Water | Acetic acid | MIBK | Acetic acid |
| 98.45 | 0 | 1.55 | 0 | 2.12 | 0 | 97.88 | 0 |
| 95.46 | 2.85 | 1.7 | 0.0299 | 2.80 | 1.87 | 95.33 | 0.0196 |
| 85.8 | 11.7 | 2.5 | 0.1364 | 5.4 | 8.9 | 85.7 | 0.1039 |

SOURCE: Sherwood, Evans, and Longcor, *Ind. Eng. Chem.*, **31**(9), pp. 1144–1150 (1939).

$$m'_r = \frac{dY}{dX} = K' = 0.656$$

$$m'_1 = 0.834 \qquad \text{at } X'_1 = 0.13$$

$$m'_r = 0.656 \qquad \text{at } X'_r = 0.01$$

$$K'_s = 0.656 \qquad \text{at } Y'_s = 0.001$$

$$\mathcal{E} = \sqrt{m'_1\, m'_r}\ \frac{S'}{F'} = \frac{(0.740)(199.8)}{80} = 1.85$$

And $X_f^B$ is calculated from Eq. (15-95)

$$X_f^B = 0.25 + \frac{(199.8 - 198.7)(0.0983)}{80} = 0.251$$

and $Y_s^B$ from Eq. (15-96):

$$Y_s^B = 0.001 + \frac{(80 - 67.5)(0.01)}{199.8} = 0.0016$$

Now $N$ is determined from Fig. 15-24, Eq. (15-48), or the McCabe-Thiele type of plot (Fig. 15-23). For case $B$,

$$N = \frac{\ln\left[\left(\dfrac{0.251 - 0.0016/0.656}{0.01 - 0.0016/0.656}\right)\left(1 - \dfrac{1}{1.85}\right) + \dfrac{1}{1.85}\right]}{\ln 1.85} = 4.5 \text{ theoretical stages}$$

A less frequent situation, case $C$, can occur when the solute concentration in the extract is so high that a large amount of feed solvent is dissolved in the extract stream in the "feed stage" but a relatively small amount of feed solvent (say one-tenth as much) is dissolved by the extract stream in the "raffinate stage." The feed stream is assumed to dissolve the extraction solvent only in the feed stage just as in case $B$. But the extract stream is assumed to dissolve a large amount of feed solvent leaving the feed stage and a negligible amount leaving the raffinate stage. With these assumptions the primary feed solvent rate is assumed to be $R'$, so the slope of the operating line for case $C$ is $R'/S'$. Again the extract rate $E'$ is less than $S'$, and the raffinate rate $R'$ is less than $F'$.

The pseudofeed concentration for case $C$, $X_f^C$, can be calculated from

$$X_f^C = \frac{F'}{R'} X'_f + \frac{S' - E'}{R'} Y'_e \tag{15-97}$$

For case $C$, the value of $Y'_s$ will fall on the operating line, and the extraction factor is given by

$$\mathcal{E}^C = \frac{m'S'}{R'} \tag{15-98}$$

On an $X'$-$Y'$ diagram for case $C$, the operating line will go through points $(X'_r, Y'_s)$ and $(X_f^C, Y'_e)$ with a slope of $R'/S'$ similar to Fig. 15-23. When the KSB equation is used for case $C$, use the pseudofeed concentration $X_f^C$ from Eq. (15-97) and the extraction factor $\mathcal{E}^C$ from Eq. (15-98). The raffinate concentration $X'_r$ and inlet solvent concentration $Y'_s$ are used without modification. For more detailed discussion, see Robbins, Sec. 1.9 in *Handbook of Separation Techniques for Chemical Engineers*, Schweitzer, ed. (McGraw-Hill, 1997).

***Example 3: Number of Transfer Units*** Let us calculate the number of transfer units required to achieve the separation in Example 1. The solution to the problem is the same as in Example 1 except that the denominator is changed. From Eq. (15-73):

$$N_{or} = 4.5 \frac{\ln 1.85}{1 - 1/1.85} = 6.0 \text{ transfers units}$$

## COMPUTER-AIDED CALCULATIONS (SIMULATIONS)

A number of process simulation programs such as Aspen Plus® from Aspen Technology, HYSYS® from Honeywell, ChemCAD® from Chemstations, and PRO/II® from SimSci Esscor, among others, can facilitate rigorous calculation of the number of theoretical stages required by a given application, provided an accurate liquid-liquid equilibrium model is employed. At the time of this writing, commercially available simulation packages do not include rate-based programs specifically designed for extraction process simulation; however, the equivalent number of transfer units at each stage can be calculated from knowledge of the extraction factor by using Eq. (15-73). Process simulation programs are particularly useful for concentrated systems that exhibit highly nonlinear equilibrium and operating lines, significant change in extract and raffinate flow rates within the process due to transfer of solute from one phase to the other, significant changes in the mutual solubility of the two phases as solute concentration changes, or nonisothermal operation. They also facilitate convenient calculation for complex extraction configurations such as fractional extraction with extract reflux as well as calculations involving more than three components (more than one solute). They can also facilitate process optimization by allowing rapid evaluation of numerous design cases. These programs do not provide information about mass-transfer performance in terms of stage efficiencies or extraction column height requirements, or information about the throughput and flooding characteristics of the equipment; these factors must be determined separately by using other methods. The use of simulation software to analyze extraction processes is illustrated in Examples 4 and 5.

In using simulation software, it is important to keep in mind that the quality of the results is highly dependent upon the quality of the liquid-liquid equilibrium (LLE) model programmed into the simulation. In most cases, an experimentally validated model will be needed because UNIFAC and other estimation methods are not sufficiently accurate. It also is important to recognize, as mentioned in earlier discussions, that binary interaction parameters determined by regression of vapor-liquid equilibrium (VLE) data cannot be relied upon to accurately model the LLE behavior for the same system. On the other hand, a set of binary interaction parameters that model LLE behavior properly often will provide a reasonable VLE fit for the same system—because pure-component vapor pressures often dominate the calculation of VLE.

Commercially available simulation programs often are used in a fashion similar to the classic graphical methods. When separation of specific solutes is important, the design of a new process generally focuses on determining the optimum solvent rates and number of theoretical stages needed to comply with the separation specifications according to relative $K$ values for solutes of interest. Calculations often are made by focusing on a "soluble" key solute with a relatively high $K$ value, and an "insoluble" key solute, expressing the design specification in terms of the maximum concentration of soluble key left in the raffinate and the maximum concentration of insoluble key contaminating the extract (analogous to light and heavy key components in distillation design). Then solutes with $K$ values higher than that of the soluble key will go out with the extract to a greater extent, and solutes with $K$ values less than that of the insoluble key will go out with the raffinate. If the desired separation is not feasible using a standard extraction scheme, then fractional extraction schemes should be evaluated.

For rating an existing extractor, the designer must make an estimate of the number of theoretical stages the unit can deliver and then determine the concentrations of key solutes in extract and raffinate streams as a function of the solvent-to-feed ratio, keeping in mind the fact that the number of theoretical stages a unit can deliver can vary depending upon operating conditions.

The use of process simulation software for process design is discussed by Seider, Seader, and Lewin [*Product and Process Design Principles: Synthesis, Analysis, and Evaluation*, 2d ed. (Wiley, 2004)] and by Turton et al. [*Analysis, Synthesis, and Design of Chemical Processes*, 2d ed. (Prentice-Hall, 2002)]. Various computational procedures for extraction simulation are discussed by Steiner [Chap. 6 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994)]. In addition, a number of authors have developed specialized methods of analysis. For example, Sanpui, Singh, and Khanna [*AIChE J.*, **50**(2), pp. 368–381 (2004)] outline a computer-based approach to rate-based, nonisothermal modeling of extraction processes. Harjo,

Ng, and Wibowo [*Ind. Eng. Chem. Res.*, **43**(14), pp. 3566–3576 (2004)] describe methods for visualization of high-dimensional liquid-liquid equilibrium phase diagrams as an aid to process conceptualization. Since in general it is not economically feasible to generate precise phase equilibrium data for the entire multicomponent phase diagram, this methodology can help focus the design effort by identifying specific composition regions where the design analysis will be particularly sensitive to uncertainties in the equilibrium behavior. The method of Minotti, Doherty, and Malone [*Ind. Eng. Chem. Res.*, **35**(8), pp. 2672–2681 (1996)] facilitates a feasibility analysis of potential solvents and process options by locating fixed points or pinches in the composition profiles determined by equilibrium and operating constraints. Marcilla et al. [*Ind. Eng. Chem., Res.*, **38**(8), pp. 3083–3095 (1999)] developed a method involving correlation of tie lines to calculate equilibrium compositions at each stage without iterations. To optimize the design and operating parameters of an extraction cascade, Reyes-Labarta and Grossmann [*AIChE J.*, **47**(10), pp. 2243–2252 (2001)] have proposed a calculation framework that employs nonlinear programming techniques to systematically evaluate a wide range of potential process configurations and interconnections. Focusing on another aspect of process design, Ravi and Rao [*Ind. Eng. Chem. Res.*, **44**(26), pp. 10016–10020 (2005)] provide an analysis of the phase rule (number of degrees of freedom) for liquid-liquid extraction processes. For discussion of reactive extraction process conceptualization methods, see Samant and Ng, *AIChE J.*, **44**(12), pp. 2689–2702 (1998); and Gorissen, *Chem. Eng. Sci.*, **58,** pp. 809–814 (2003).

***Example 4: Extraction of Phenol from Wastewater*** The amount of 350 gpm (79.5 $m^3/h$) of wastewater from a coke oven plant contains an average of 700 ppm phenol by weight that needs to be reduced to 1 ppm or less to meet environmental requirements [Karr and Ramanujam, *St. Louis AIChE Symp.* (March 19, 1987)]. The wastewater comes from the bottom of an ammonia stripping tower at 105°C and is to be extracted at 1.7 atm with recycle methylisobutyl ketone (MIBK) containing 5 ppm phenol. The extraction will be carried out by using a reciprocating-plate extractor (Karr column). How many theoretical stages will be required in the extractor at a solvent-to-feed ratio of 1:15, and what is the resulting extract composition?

The Aspen Plus® process simulation program is used in this example, but it should be recognized that any of a number of process simulation programs such as mentioned above may be used for this purpose. In Aspen Plus, the EXTRACT liquid-liquid extraction unit-operation block is used to model the phenol wastewater extraction. As is typical in process simulation programs, the EXTRACT block is fundamentally a rating calculation rather than a design calculation, so the determination of the required number of stages for the separation cannot be made directly. In addition, since the EXTRACT block can only handle integral numbers of theoretical stages, the fractional number of required theoretical stages must be determined by an interpolation method.

The partition ratio for transfer of phenol from water into MIBK at 105°C is $K'' = 34$ on a mass fraction basis [Greminger et al., *Ind. Eng. Chem. Process Des. Dev.*, **21**(1), pp. 51–54 (1982)]. Because the partition ratio is so high, a fairly low solvent-to-feed ratio of 1:15 can be used and still give an extraction factor of about 2. In the EXTRACT block, a property option is available that allows the user to specify liquid-liquid $K$ value correlations (designated as "KLL Correlation" in Aspen Plus) for the components involved in the extraction rather than a complete set of binary interaction parameters to define the liquid-liquid equilibria. In this example, it is time-consuming to regress a set of liquid-liquid binary interaction parameters that results in representative partition ratios, so the option of simply specifying $K$ values directly is highly recommended. Because phenol will be relatively dilute in both the raffinate and extract phases, appropriate liquid-liquid $K$ values for distribution of water and MIBK between phases at 105°C can be estimated from water-MIBK liquid-liquid equilibrium data [Rehak et al., *Collect. Czech Chem. Commun.*, **65,** pp. 1471–1486 (2000)] to yield $K''_{water} = 0.0532$ and $K''_{MIBK} = 53.8$ (mass fraction basis). It is important in Aspen Plus to specify $K$ values for all the components in the extractor in order to properly model the liquid-liquid equilibria with this approach.

The temperatures and compositions of the wastewater and solvent feed streams, as well as the wastewater feed flow rate, are specified in the problem statement. The solvent flow rate is specified as one-fifteenth of the wastewater flow rate as described above. In the EXTRACT block, the number of stages will be manually varied from 2 to 10 to observe the effect on the raffinate and extract concentrations, and it will be specified as operating adiabatically at 1.7 atm. Water is specified as the key component in the first liquid phase, and MIBK is specified as the key component in the second liquid phase. The rest of the block parameters (convergence, report, and miscellaneous block options) are allowed to remain at their default values.

The raffinate and extract concentrations resulting from successive simulation runs for 2 through 10 theoretical stages are given in Table 15-9, and the raffinate phenol concentrations are presented graphically in Fig. 15-28. Examining the results, we can see that the number of theoretical stages required to achieve the 1 ppm phenol discharge limitation falls somewhere between 7 and 8. In addition, we can see from Fig. 15-28 that the dependence of raffinate phenol concentration on number of stages yields nearly a straight line on a semilog plot. As a result, performing a linear interpolation of the log of the raffinate concentration between 7 and 8 stages yields the number of stages required to achieve 1 ppm phenol in the raffinate:

$$N = 7 + (8 - 7)\left(\frac{\log 1.47 - \log 1}{\log 1.47 - \log 0.707}\right) = 7.53 \text{ theoretical stages}$$

From examining the extract phenol concentrations in Table 15-9, it is clear that for 5 or more stages, they varied little with number of stages, as is expected since nearly all the phenol contained in the wastewater feed was extracted in stages 1 through 4. As a result, the extract will contain 1.3 wt % phenol, 5.2% water, and 93.5% MIBK.

The simulation results can be checked by using a shortcut calculation—to provide confidence that the simulation is delivering a reasonable result. The KSB equation [Eq. (15-48)] can be used for this purpose with values taken from the problem specification and estimates of the phenol $K'$ value (in Bancroft coordinates). Since phenol is always quite dilute in both the extract and raffinate phases, its $K'$ value can be calculated from the component mass fraction $K''$ values according to the following approximation:

$$K'_{PhOH} \cong K''_{PhOH}\left[\frac{K_{MIBK} - 1}{K_{MIBK}(1 - K_{H_2O})}\right] = 34\left[\frac{53.8 - 1}{53.8(1 - 0.0532)}\right] = 35.24$$

This value compares favorably with the value of 35.28 calculated directly from phenol mass ratios taken from extractor internal profile data in the simulation output. The extraction factor [Eq. (15-11)] is then calculated with the dilute system approximation that $m_{PhOH} \cong K_{PhOH}$ and solute-free water and MIBK feed rates of 159,841 and 10,668 lb/h taken from the simulation output:

$$\mathcal{E}_{PhOH} = m_{PhOH}\frac{S}{F} \cong K''_{PhOH}\frac{S''}{F''} = K'_{PhOH}\frac{S'}{F'} = 35.24 \times \frac{10{,}668}{159{,}841} = 2.35$$

It is interesting to note that this value of the extraction factor, 2.35, is the same as those calculated on mole fraction, mass fraction, and Bancroft coordinate bases from extractor internal profile data in the simulation, a confirmation that the extraction factor is indeed independent of units as long as consistent values of $m$, $S$, and $F$ are used. By substituting the above values into Eq. (15-48) along

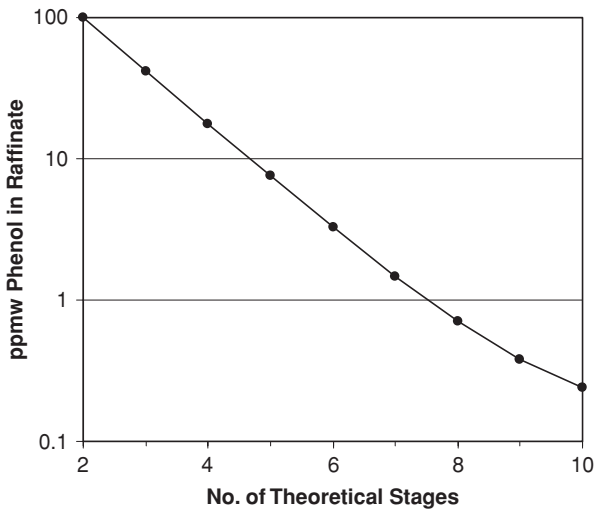

**FIG. 15-28** Simulation results showing phenol concentration in the raffinate versus number of theoretical stages (Example 4).

with concentrations taken from the problem statement and Table 15-9, the required number of stages is estimated as

$$N \approx \frac{\ln\left[\dfrac{0.0007/0.9993 - (0.000005)/(0.999995)/35.24}{0.000001/0.9824 - (0.000005)/(0.999995)/35.24}\,(1 - 1/2.35) + 1/2.35\right]}{\ln 2.35}$$

$$= 7.18 \text{ theoretical stages}$$

The simulation result of 7.53 theoretical stages is close to this shortcut estimate, indicating that the simulation is indeed delivering reasonable results.

## FRACTIONAL EXTRACTION CALCULATIONS

**Dual-Solvent Fractional Extraction** As discussed in "Commercial Process Schemes," under "Introduction and Overview," fractional extraction often may be viewed as combining product purification with product recovery by adding a washing section to the stripping section of a standard extraction process. In the stripping section, the mass transfer we focus on is the transfer of the product solute from the wash solvent into the extraction solvent. If we assume dilute conditions and use shortcut calculations for illustration, the extraction factor is given by

$$\mathcal{E}_s = K'_s \frac{S'_s}{W'_s} \tag{15-99}$$

where $\mathcal{E}_s$ = stripping section extraction factor (dimensionless)
$K'_s$ = stripping section partition ratio, defined as equilibrium concentration of product solute in extraction solvent divided by that in wash solvent (Bancroft coordinates)
$S'_s$ = mass flow rate of extraction solvent within stripping section (solute-free basis)
$W'_s$ = mass flow rate of wash solvent in stripping section (solute-free basis)

The change in the concentration of product dissolved in the wash solvent, within the stripping section, can be calculated by using the KSB equation

$$\left(\frac{X'_{\text{out}}}{X'_{\text{in}}}\right)_{\text{product}} \approx \frac{1 - 1/\mathcal{E}_s}{(\mathcal{E}_s)^{N_s} - 1/\mathcal{E}_s} \tag{15-100}$$

where $N_s$ = number of theoretical stages in stripping section
$X'_{\text{in}}$ = concentration of product solute in wash solvent at inlet to stripping section (feed stage)
$X'_{\text{out}}$ = concentration of product solute in wash solvent at outlet from stripping section (raffinate end of overall process)

In the washing section, we focus on transfer of impurity solute from the extraction solvent into the wash solvent. A washing extraction factor can be defined as

$$\mathcal{E}_w = \frac{1}{K'_w}\frac{W'_w}{S'_w} \tag{15-101}$$

where $\mathcal{E}_w$ = washing section extraction factor (dimensionless)
$K'_w$ = washing section partition ratio (equilibrium concentration of impurity solute in extraction solvent divided by that in wash solvent, in Bancroft coordinates)
$S'_w$ = mass flow rate of extraction solvent within washing section (solute-free basis)
$W'_w$ = mass flow rate of wash solvent in washing section (solute-free basis)

Then the change in the concentration of impurity solute dissolved in the extraction solvent, within the washing section, is given by

$$\left(\frac{Y'_{\text{out}}}{Y'_{\text{in}}}\right)_{\text{impurities}} \approx \frac{1 - 1/\mathcal{E}_w}{(\mathcal{E}_w)^{N_w} - 1/\mathcal{E}_w} \tag{15-102}$$

where $N_w$ = number of theoretical stages in washing section
$Y'_{\text{in}}$ = concentration of impurity solute in extraction solvent at inlet to washing section (feed stage)
$Y'_{\text{out}}$ = concentration of impurity solute in extraction solvent at outlet from washing section (extract end of overall process)

The ratio of extraction solvent to wash solvent in each section will be different if either solvent enters the process with the feed. Note that both $K'_s$ and $K'_w$ are defined as the ratio of the appropriate solute concentration in the *extraction* solvent to that in the *wash* solvent.

The shortcut calculations outlined above illustrate the general considerations involved in analyzing a fractional extraction process. The analysis requires locating the feed stage and matching the calculations for each section with the material balance at the feed stage, an iterative procedure. Buford and Brinkley [*AIChE J.*, **6**(3), pp. 446–450 (1960)] discuss application of the KSB equation to fractional extraction calculations including the use of reflux. Transfer unit calculations also may be used. When equilibrium and operating lines are not linear, more sophisticated calculations will be needed to take this into account. Commercially available simulation software or other computer programs often are used to carry out this procedure (see "Computer-Aided Calculations"). Note that with dual-solvent fractional extraction, solute concentrations always are highest at the feed stage. This can lead to undesired behavior such as tendencies toward emulsion formation or even formation of a single liquid phase at the plait point. The minimum amounts of solvent needed to avoid these effects can be determined in laboratory tests.

Early in a project, it may be useful to consider a simplified case in which the ratio of extraction solvent to wash solvent is constant and the same in the stripping and washing sections (i.e., the amount of solvent entering with the feed is negligible) and the extraction factors for each section are equal. For this special case, termed a *symmetric separation*, the extraction factors are

$$\mathcal{E}_s = \mathcal{E}_w = \sqrt{\alpha_{i,j}} \tag{15-103}$$

and the ratio of extraction solvent to wash solvent is given by

$$\frac{S}{W} \approx \frac{1}{\sqrt{K_s K_w}} \approx \frac{1}{\sqrt{\alpha_{i,j}}\,K_w} = \frac{\sqrt{\alpha_{i,j}}}{K_s} \tag{15-104}$$

Using these relationships, we find the number of stages required for the stripping and washing sections will be about the same and the total number of stages required likely will be close to the minimum number—assuming symmetric separation requirements. The effects of the separation factor and the number of stages on the separation performance can be estimated by using expressions given by Brian [*Staged Cascades in Chemical Processing* (Prentice-Hall, 1972)]. For a process containing two solutes $i$ and $j$, with the feed entering at the middle stage, it follows from Brian's analysis that

$$S_{i,j} = \frac{Y_i}{X_i}\,\frac{1 - X_i}{1 - Y_i} \approx \alpha_{i,j}^{(N+1)/2} \tag{15-105}$$

where $S_{i,j}$ is termed the *separation power* of the process. Equation (15-105) is derived by assuming that the ratio of extract phase to raffinate phase within the process is constant, and that $\alpha_{i,j}$ is constant. Interestingly, Eq. (15-105) is very similar in its general form to the equation obtained by using the Fenske equation to calculate fractional distillation performance for a binary feed, assuming that the required number of theoretical stages is twice the minimum number obtained at total reflux. (See Sec. 13, "Distillation.")

For a proposed symmetric separation, Eqs. (15-104) and (15-105) can be used to gauge the required flow rates, number of theoretical stages, and separation factor. For example, consider a hypothetical application with the goal of transferring 99 percent of a key solute $i$ into the extract and 99 percent of an impurity solute $j$ into the raffinate. For illustration, let $K_i = 2.0$ and $K_j = 0.5$, so $\alpha_{i,j} = 4$. From Eq. (15-104), the extraction solvent to wash solvent ratio should be about $S/W = 1.0$ for a symmetric separation. The number of theoretical stages is estimated by using Eq. (15-105): $S_{i,j} = 99 \times 99 = 9801$ gives $N \approx 12$ total stages for $\alpha_{i,j} = 4$. When one is evaluating candidate solvent pairs for a proposed fractional extraction process, a useful first step is to measure the equilibrium $K$ values for product and impurity solutes and then assess process feasibility by using Eqs. (15-104) and (15-105). This can provide a quick way of assessing whether the measured separation factor is sufficiently large to achieve the separation goals, using a reasonable number of stages.

**Single-Solvent Fractional Extraction with Extract Reflux** As discussed earlier, single-solvent fractional extraction with extract reflux is widely practiced in the petrochemical industry to separate aromatics from crude hydrocarbon feeds. For example, a variety of extraction processes utilizing different high-boiling, polar solvents are used to separate benzene, toluene, and xylene (BTX) from aliphatic hydrocarbons and naphthenes (cycloalkanes), although processes involving extractive distillation are displacing some of the older extraction processes, depending upon the application. A typical hydrocarbon feed is a distillation cut containing mostly $C_5$ to $C_9$ components. Commercial extraction processes include the Udex process (employing diethylene and/or triethylene glycol), the AROSOLVAN process (employing *N*-methyl-2-pyrrolidone), and the Sulfolane process (employing tetrahydrothiophene-1,1-dioxane), among others. Although the flow diagrams for these processes differ, they all involve use of a liquid-liquid extractor followed by a top-fed extract stripper or extractive distillation tower. A number of different processing schemes are used to isolate the aromatics and recycle the heavy solvent. For detailed discussion, see Chaps. 18.1 to 18.3 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991); Mueller et al., *Ullmann's Encyclopedia of Industrial Chemistry*, 5th ed., vol. B3, Gerhartz, ed. (VCH, 1988), pp. 6-34 to 6-43; Gaile et al., *Chem. Technol. Fuels Oils*, **40**(3), pp. 131–136, and **40**(4), pp. 215–221 (2004); and Schneider, *Chem. Eng. Prog.*, **100**(7), pp. 34–39 (2004).

Consider a process scheme involving a liquid-liquid extractor followed by a top-fed extract stripper (as illustrated in Fig. 15-2). In the extractor, the feed is contacted with the polar solvent to transfer aromatics into the solvent phase. Some nonaromatics (NAs) also transfer into the solvent. In the stripper, low-boiling NAs plus some aromatics are stripped out of the extract. The overheads stream also contains some high-boiling NAs because their low solubility in the polar solvent boosts their relative volatility in the stripper. In this respect, the stripper may be thought of as an extractive distillation tower with the high-boiling polar solvent serving as the extractive distillation solvent. The stripper overheads are then condensed and returned to the bottom of the extractor as extract reflux. As the backwash of extract reflux passes up through the extractor, the aromatics and a portion of the low-boiling NAs transfer back into the solvent phase, preferentially displacing high-boiling NAs from the extract phase because of their lower solubilities in the polar solvent. Without extract reflux, the concentration of higher-boiling NAs in the extract phase would be significantly higher, and they would be difficult to completely remove in the stripper in spite of their low solubilities in the polar solvent. In this manner, low-boiling aromatics and NAs tend to build up in the extract reflux loop to provide a sort of barrier that minimizes entry of higher-boiling NAs into the extract phase.

The use of simulation software to analyze this type of process is illustrated in Example 5, which considers a simplified ternary system for illustration. The simulation of an actual aromatics extraction process is more complex and can exhibit considerable difficulty converging on a solution; however, Example 5 illustrates the basic considerations involved in carrying out the calculations. For more detailed discussion of process simulation and optimization methods, see Seider, Seader, and Lewin, *Product and Process Design Principles: Synthesis, Analysis, and Evaluation*, 2d ed. (Wiley, 2004); and Turton et al., *Analysis, Synthesis, and Design of Chemical Processes*, 2d ed. (Prentice-Hall, 2002).

***Example 5: Simplified Sulfolane Process—Extraction of Toluene from n-Heptane*** The amount of 40 metric tons (t) per hour (t/h) of distilled catalytic reformate from petroleum refining, containing 50% by weight aromatics, is to be extracted with recovered sulfolane containing 0.4 vol % aromatics in a 10-stage column contactor operating nearly adiabatically at 3 bar (gauge pressure). The extract will be fed to a 10-stage top-fed extract/paraffin stripper operating at 1 bar gauge to recover 98 percent of the aromatics with no more than 500 ppm by weight of nonaromatics. The catalytic reformate at 90°C is fed into the extractor at three stages up from the bottom, and the recovered sulfolane leaving the bottom of a solvent recovery tower at 185°C is cross-exchanged with the extract stream leaving the bottom of the extractor before being fed to the top of the extractor at 105°C. Extract reflux is returned from the paraffin stripper's condenser to the bottom of the extractor with subcooling to 105°C.

1. What solvent flow and stripper reboiler duty are required to achieve the performance specifications, and what are the extract reflux rate and composition?

2. If the required aromatics recovery is increased to 99 percent, what is the effect on solvent flow and stripper reboiler duty?

In real-world commercial catalytic reformate streams, a wide range of aromatic and nonaromatic hydrocarbons must be considered, and the liquid-liquid extraction and distillation simulation becomes quite complicated. In addition, real-world applications of sulfolane extraction normally add a few percent of water to the sulfolane to reduce its pure-component freezing point of 27 to 28°C during shipping and storage [Kosters, Chap. 18.2.3 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991)]. Also, in many processes, steam is injected into the bottom of the solvent recovery tower to help strip the aromatics (i.e., the tower is both steam-stripped and reboiled). This also allows operation of the recovery tower at higher pressures without incurring (excessive) solvent thermal degradation. In a real-world process, water also may be used to wash the raffinate to recover solvent. To simplify the problem for this example, however, we model the aromatics as toluene and the NAs as *n*-heptane, consider only sulfolane as the extraction solvent, and do not include water in the calculations—to reduce the problem to a simple ternary system for illustration.

As in Example 4, the EXTRACT block in the Aspen Plus process simulation program (version 12.1) is used to model this problem, but any of a number of process simulation programs such as mentioned earlier may be used for this purpose. The first task is to obtain an accurate fit of the liquid-liquid equilibrium (LLE) data with an appropriate model, realizing that liquid-liquid extraction simulations are very sensitive to the quality of the LLE data fit. The NRTL liquid activity-coefficient model [Eq. (15-27)] is utilized for this purpose since it can represent a wide range of LLE systems accurately. The regression of the NRTL binary interaction parameters is performed with the Aspen Plus Data Regression System (DRS) to ensure that the resulting parameters are consistent with the form of the NRTL model equations used within Aspen Plus.

Since the extractor operates nearly isothermally only slightly above and below 100°C, the 100°C data of De Fre and Verhoeye [*J. Appl. Chem. Biotechnol.*, **26,** pp. 1–19 (1976)] are used as the basis for the toluene + *n*-heptane + sulfolane LLE. Because of the liquid-liquid miscibility gap for the *n*-heptane + sulfolane binary, the NRTL $\alpha_{ij}$ parameter for this pair is given a value of 0.2. The NRTL

**TABLE 15-10 NRTL Binary Interaction Parameters for Example 5**

| Component $i$ | Component $j$ | $b_{ij}$, K |
|---|---|---|
| $n$-Heptane | Toluene | 23.2040 |
| Toluene | $n$-Heptane | –34.3180 |
| Toluene | Sulfolane | 238.952 |
| Sulfolane | Toluene | 203.243 |
| $n$-Heptane | Sulfolane | 1476.41 |
| Sulfolane | $n$-Heptane | 719.006 |

$\tau_{ij} = b_{ij}/T$ (K); $\alpha_{ij} = 0.2$ for $n$-heptane + sulfolane; $\alpha_{ij} = 0.3$ for toluene + sulfolane and for $n$-heptane + sulfolane. Aspen Plus regression parameters $a_{ij}$, $d_{ij}$, $e_{ij}$, and $f_{ij}$ are set to zero; $c_{ij} = \alpha_{ij}$; $\tau_{ii} = 0$; and $G_{ii} = 1$.

$\alpha_{ij}$ parameters for toluene + sulfolane and $n$-heptane + toluene are allowed to remain at the default value of 0.3 because of their low levels of nonideality. The temperature dependence of $\alpha_{ij}$ is set to zero (Aspen Plus parameter $d_{ij} = 0$). In Aspen Plus, the $\tau_{ij}$ parameter may be regressed as a function of temperature by using the expression $\tau_{ij} = a_{ij} + b_{ij}/T + e_{ij} \ln T + f_{ij}T$. In this example, all the regression parameters are set to zero except $b_{ij}$. The component activity coefficients are chosen as the objective function for the regression to obtain a fit that models the liquid-liquid $K$ values closely, generally found to be within 5 to 10 percent in this case. The resulting $b_{ij}$ binary parameters given in Table 15-10 are then entered into the properties section of the Aspen Plus flow sheet simulation. Pure-component properties were taken from the standard Aspen Plus pure-component databases supplied with the program.

The major unit operations in the sulfolane process usually include an extractor, paraffin stripper, solvent recovery tower, raffinate wash tower, solvent regenerator, and numerous heat exchangers; but for the purposes of this example, the simulation includes only the extractor, paraffin stripper, and extract/recovered solvent cross-exchanger—the portion of the flow sheet shown in Fig. 15-2 outlined by dotted lines. It should be recognized that the exclusion of the solvent recovery tower ignores the highly interactive behavior of the extractor, stripper, and recovery tower; but this is done here to simplify the analysis for the purposes of illustration. Note that the stripper's condenser is modeled as a separate Aspen Plus HEATER block rather than being included in the stripper block, because the Aspen Plus RADFRAC multistage distillation block used to model the stripper requires some distillate reflux if a condenser is included within the block, and generally none is required for the top-fed stripper in the sulfolane process. As a result, the stripper RADFRAC block is specified with no condenser. Also note that in the sulfolane process, the sulfolane solvent enters the top of the extractor since it is denser than the catalytic reformate feed stream.

The 40,000 kg/h of catalytic reformate fed to stage 7 (counting from the top according to the convention in the EXTRACT block) is modeled as 50/50 $n$-heptane/toluene on a mass basis, and the residual aromatic content of the recovered sulfolane fed to the top of the extractor is 0.4 vol % toluene as given in the problem statement. As an initial guess, the sulfolane rate to the extractor was set at 120,000 kg/h or a solvent-to-feed ratio of 3.0 since depending on the feedstock, solvent-to-feed ratios can range from about 2.0 to 4.0 (Huggins, "Sulfolane Extraction of Aromatics," Paper 67C, AIChE Spring National Meeting, Houston, March 1997). In the EXTRACT block, sulfolane must be specified as the key component in the first liquid phase, and $n$-heptane must be specified as the key component in the second liquid phase, since the EXTRACT block requires that the first liquid be the one exiting the bottom of the extractor. A constant-temperature profile of 105°C in the extractor is entered as an initial estimate. The rest of the block parameters (convergence, report, and miscellaneous block options) are allowed to remain at their default values.

The paraffin stripper RADFRAC block is specified with feed to the first of 10 stages, a reboiler but no condenser, a 1-bar gauge top pressure, no internal pressure drop, and a molar boil-up ratio (boil-up rate/bottoms rate) of 0.2 as an initial guess. An internal RADFRAC design specification is entered to vary the boil-up ratio from 0.10 to 0.30 to achieve a mass purity of 500 ppm $n$-heptane in the stripper bottoms on a sulfolane solvent-free basis. To aid RADFRAC convergence, the standard algorithm was changed to Petroleum/Wide-boiling (Sum-Rates) because of the large volatility difference between the hydrocarbons and the sulfolane solvent.

A separate flow sheet Design Spec block (termed a *controller* block in some other simulators) is entered to vary the solvent feed rate to the extractor to achieve the required 98 percent toluene recovery. In addition, the extract reflux stream is called out as the flow sheet tear stream in a Wegstein convergence block to provide proper block sequencing in the simulation. (This is a numerical technique used to accelerate convergence to a solution.) Since the EXTRACT block will not execute with a zero extract reflux flow to the bottom of the extractor, an initial guess is required for that stream: 10,000 kg/h of 50/50 by weight $n$-heptane/toluene at 100°C is chosen.

During simulation execution, we found that reflux tear stream convergence with the default Wegstein parameters is very oscillatory, with no convergence even with maximum iterations raised to 200. As a result, significant damping needs to be provided in the convergence block. We raised the bounds of the Wegstein $q$ acceleration parameter to be between 0.75 and 1.0 for nearly full damping, after which flow sheet convergence was achieved in less than 50 iterations of every reflux tear stream loop. We also found that good initial guesses and bounds on variables needed to be set to keep the simulation from converging to an aberrant solution that was not physically valid.

With these modifications, the result is that 125,500 kg/h of sulfolane feed to the extractor is required to recover 98 percent of the toluene in the simplified reformate feed. The stage-by-stage mass fraction profile in the extractor is given in Table 15-11, from which we can see that there is very little change in concentration in either phase from the feed stage downward. This is so because in our simplified example we have only a single NA hydrocarbon component ($n$-heptane) to deal with, so the benefit of a backwash section in the extractor below the feed is not apparent. In a real-world profile, however, concentrations of higher-boiling NAs would decrease from the feed point to the bottom of the extractor. Also given in Table 15-11 are stage-by-stage $K''$ values, the separation factor (toluene with respect to $n$-heptane), and the extraction factor profiles in

| Wt. fraction sulfolane | 0.85736 | 0.00759 | 0.01547 | 0.91225 |
| Total flow, kg/h | 247,592 | 20,344 | 15,155 | 232,437 |
| Temperature, °C | 98.9 | 103.9 | 105.0 | 215.9 |

the extractor. From these we can see that the separation factor for toluene with respect to *n*-heptane varies from about 6 at the bottom of the extractor to 12 at the top, and that the extraction factor is about 2 above the feed and about 6 below the feed. These separation factors are somewhat higher than the value of 4 or so normally seen in real-world aromatic extraction cases; this, too, is an artifact of the simplified ternary system used to model the sulfolane process.

Another result of the simulation is that a molar boil-up ratio of 0.180 is required in the stripper to achieve the bottoms mass purity of 500 ppm *n*-heptane considering only the hydrocarbons (solvent-free basis). This boil-up ratio corresponds to a reboiler duty of 3695 kW, or roughly 6700 kg/h of 12-bar gauge steam, and results in 12,914 kg/h of extract reflux for an extractor reflux-to-feed ratio of 0.323. Compositions and rates of the extract, raffinate, reflux, and stripper bottoms streams are given in Table 15-12.

To determine the solvent flow and other conditions required to achieve 99 percent toluene recovery, we merely need to change the specification of the recovery Design Spec block from 98 to 99 percent and reconverge the simulation. With this change and an additional 180 total reflux tear stream iterations, the result is that 212,800 kg/h of sulfolane feed to the extractor is required, 1.7 times the amount needed for 98 percent toluene recovery. A molar boil-up ratio of 0.158 is required in the stripper to maintain the bottoms mass purity of 500 ppm *n*-heptane on a solvent-free basis, even lower than that for the 98 percent recovery case. Likewise, only a slightly higher extract reflux rate is required, 15,155 kg/h, for an extractor reflux-to-feed ratio of 0.379. However, this boil-up ratio corresponds to a reboiler duty of 7191 kW, or roughly 13,100 kg/h of 12-bar gauge steam, about 95 percent higher than for the 98 percent recovery case. The much higher stripper reboiler duty required for 99 percent recovery results from the significantly greater sulfolane feed rate, indicating that the sizes of the extractor and stripper as well as the energy consumption would need to be significantly greater for that increased recovery, probably making it uneconomical in most applications with a 10-stage extractor and stripper. Compositions and rates of the extract, raffinate, reflux, and stripper bottoms streams for the 99 percent recovery case are also given in Table 15-12.

# LIQUID-LIQUID EXTRACTION EQUIPMENT

## EXTRACTOR SELECTION

The common types of commercially available extraction equipment and their general features are outlined in Table 15-13. The choice of extractor type depends upon many factors including the required number of theoretical stages or transfer units, required residence time (due to slow or fast extraction kinetics or limited solute stability), required production rate, tolerance to fouling, ease of cleaning, availability of the required materials of construction, as well as the ability to handle high or low interfacial tension, high or low density difference, and high or low viscosities. Other factors that influence the choice of extractor include familiarity and tradition (the preferences among designers and operating companies often differ), confidence in scale-up, height constraints, and, of course, the relative capital and operating costs. The flexibility of the extractor to adjust to changes in feed properties also can be an important consideration. For example, compared to a static extractor, a mechanically agitated extractor typically provides a greater turndown ratio (ability to handle a wider range of flow rates), and agitation intensity can be adjusted in the field as needed to accommodate changes in the feed over time. Other factors that may be important include the ability to operate under pressure, to handle corrosive, highly toxic, or flammable materials, and to meet maintenance requirements, among many other possible considerations. Experience with applications similar to the current application and the use of pilot-plant testing play important roles in equipment selection. Pilot testing can address critical issues including demonstration of separation capabilities and equipment scale-up. The simplest extractor design that can meet the process requirements generally will be selected over other competing designs.

Figure 15-29 outlines the decision process recommended by Robbins [Sec. 1.9 in *Handbook of Separation Techniques for Chemical Engineers*, 3d ed., Schweitzer, ed. (McGraw-Hill, 1997)]. As an aid to decision making, Robbins recommends characterizing the feed by measuring a flooding curve using a 1-in-diameter reciprocating-plate (Karr column) miniplant extractor. This is a plot of maximum specific throughput (very close to flooding) versus agitation intensity in the Karr column. The position of the resulting curve may be used to identify the type of extractor best suited for commercial development, as illustrated in Fig. 15-30. The flooding curve results reflect the liquid-liquid dispersion behavior of the system, and so they can point to options most in line with those properties. The test typically requires 40 to 200 L of feed materials (10 to 50 gal).

A number of equipment selection guides have been published. Pratt and Hanson [Chap. 16 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991)] provide a detailed comparison chart for 20 equipment types considering 14 characteristics. Pratt and Stevens [Chap. 8 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992)] modified the Pratt and Hanson selection guide to include solvent volatility and flammability design parameters. Stichlmair [*Chem. Ing. Tech.*, **52**(3) pp. 253–255 (1980)] and Holmes, Karr, and Cusack (AIChE

**TABLE 15-13 Common Liquid-Liquid Extraction Equipment and Applications**

| Type of extractor | General features | Fields of industrial application |
|---|---|---|
| Static extraction columns<br>Spray column<br>Baffle column<br>Packed column (random and structured packing)<br>Sieve tray column | Deliver low to medium mass-transfer efficiency, simple construction (no internal moving parts), low capital cost, low operating and maintenance costs, best suited to systems with low to moderate interfacial tension, can handle high production rates | Petrochemical<br>Chemical<br>Food |
| Mixer-settlers<br>Stirred-vessels with integral or external settling zones | Can deliver high stage efficiencies with long residence time, can handle high-viscosity liquids, can be adjusted in the field (good flexibility), with proper mixer-settler design can handle systems with low to high interfacial tension, can handle very high production rates | Petrochemical<br>Nuclear<br>Fertilizer<br>Metallurgical |
| Rotary-agitated columns<br>Rotary disc contactor (RDC)<br>Asymmetric rotating disc (ARD) contactor<br>Oldshue-Rushton column<br>Scheibel column<br>Kühni column | Can deliver moderate to high efficiency (many theoretical stages possible in a single column), moderate capital cost, low operating cost, can be adjusted in the field (good flexibility), suited to low to moderate viscosity (up to several hundred centipoise), well suited to systems with moderate to high interfacial tension, can handle moderate production rates | Petrochemical<br>Chemical<br>Pharmaceutical<br>Metallurgical<br>Fertilizer<br>Food |
| Reciprocating-plate column<br>Karr column | Can deliver moderate to high efficiency (many theoretical stages possible in a single column), moderate capital cost, low operating cost, can be adjusted in the field (good flexibility), well suited to systems with low to moderate interfacial tension including mixtures with emulsifying tendencies, can handle moderate production rates | Petrochemical<br>Chemical<br>Pharmaceutical<br>Metallurgical<br>Food |
| Pulsed columns<br>Packed column<br>Sieve tray column | No internal moving parts, can deliver moderate to high efficiency, can handle moderate production rates, well suited to highly corrosive or toxic feeds requiring a hermetically sealed system | Nuclear<br>Petrochemical<br>Metallurgical |
| Centrifugal extractors | Allow short contact time for unstable solutes, minimal space requirements (minimal footprint and height), can handle systems with low density difference or tendency to easily emulsify | Petrochemical<br>Chemical<br>Pharmaceutical<br>Nuclear |

Summer National Meeting, August 1987) compared performance characteristics of various equipment designs in the form of a Stichlmair plot. This is a plot of typical mass-transfer efficiency versus characteristic specific throughput (for combined feed and solvent flows) for various types of extractors. Figure 15-31 represents typical performance data generated by using various small-diameter (2- to 6-in, equal to 5- to 15-cm) extractors. This type of plot is intended for use in comparing the relative performance of different extractor types and can be very helpful in this regard. It should not be used for design purposes.

Volumetric efficiency is another characteristic used to compare the different types of extractors. It can be expressed as the product of specific throughput (including feed and extraction solvent) in total volumetric flow rate per unit area (or a characteristic liquid velocity) times the number of theoretical stages achieved per unit length of extractor. It has the units of stages per unit time, or simply reciprocal time ($h^{-1}$). Thus, volumetric efficiency is inversely proportional to the volume of the column needed to perform a given separation. The Karr reciprocating-plate extractor provides relatively high volumetric efficiency, as it has both a high capacity per unit area and a high number of stages per meter. The Scheibel rotary-impeller column also can provide a high number of stages per meter, but the column throughput typically is less than that of a Karr column, so volumetric efficiency is less. Thus, for a given separation a Scheibel column might be somewhat shorter than a Karr column, but it will need to have a larger diameter to process the same flow rate of feed and extraction solvent. The sieve plate extractor generally exhibits moderate to high throughput, but the number of stages per meter typically is low. The Graesser raining-bucket contactor exhibits low to moderate throughput, but is reported to have a high separating capability in certain applications.

The ability of an extractor to tolerate the presence of surface-active impurities also may be an important factor in choosing the most appropriate design. Karr, Holmes, and Cusack [*Solvent Extraction and Ion Exchange*, **8**(30), pp. 515–528 (1990)] investigated the performance of small-diameter agitated columns and found that the performance of a rotating-disk contactor (RDC) declined faster on addition of trace surface-active impurities compared to the Karr or Scheibel column. The test results indicate that care should be taken when comparing pilot tests of different types of extractors when the data were generated by using high-purity materials. The presence of surface-active impurities can lower column capacity by 20+ percent and efficiency by as much as 60 percent.

Production capacity also may be a deciding factor, since some extractors are available only in small to moderate sizes suitable for low to moderate production rates, as in specialty chemical manufacturing, while others are available in very large sizes designed to handle the very high production rates needed in the petroleum and petrochemical industries. An estimate of relative production rates (feed plus solvent) for selected extractors is given in Table 15-14. Note that the numbers are intended to represent approximate maximum values for a rough comparison. The actual values likely will vary depending upon the particular application. Keep in mind that the relative mass-transfer performance of the various designs is not represented in Table 15-14, and that very large-diameter columns are limited as to how tall they can be built.

## HYDRODYNAMICS OF COLUMN EXTRACTORS

**Flooding Phenomena** The hydraulic capacity of a countercurrent extractor is constrained by breakthrough of one liquid phase into the discharge stream of the other, a condition called *flooding*. The point at which an extractor floods is a function of the design of the internals (as this affects the pressure drop and holdup characteristics of the extractor), the solvent-to-feed ratio and physical properties (as

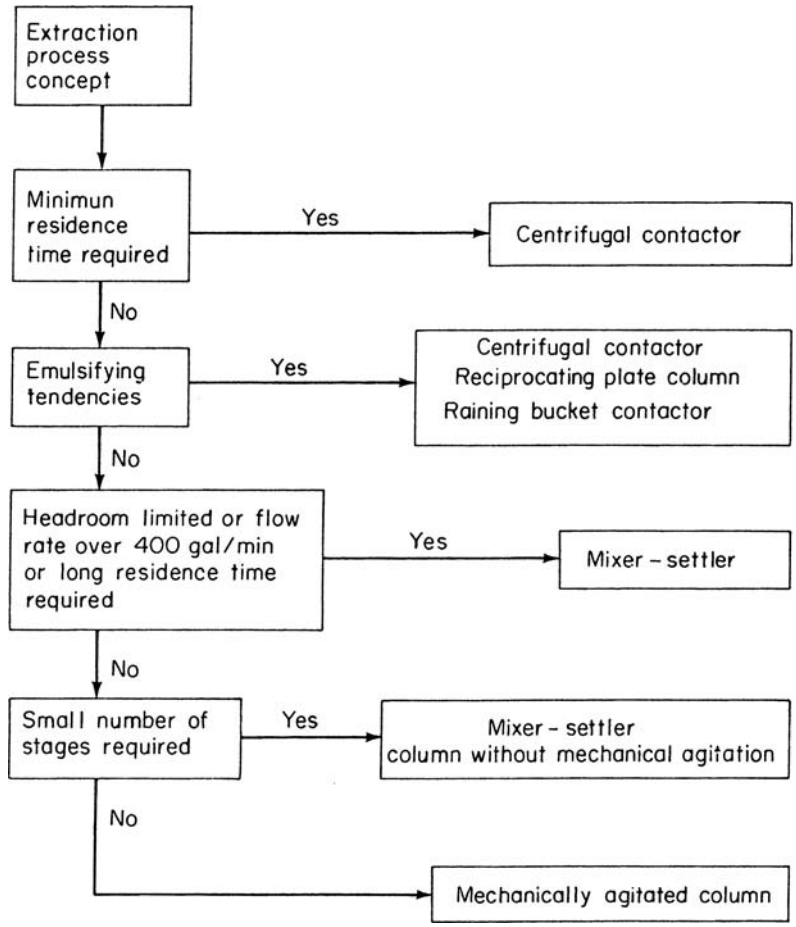

**FIG. 15-29** Decision guide for extractor selection. [*Reprinted from Robbins, Sec. 1.9 in* Handbook of Separation Techniques for Chemical Engineers, *3d ed., Schweitzer, ed. (McGraw-Hill, 1997), with permission. Copyright 1997 McGraw-Hill, Inc.*]

this affects the liquid-liquid dispersion behavior), the agitation intensity (if agitation is used), and the specific throughput. The latter often is expressed in terms of the volumetric flow rate per cross-sectional area; or, equivalently, in terms of liquid velocity. A plot of the maximum throughput that can be sustained just prior to flooding versus a key operating variable is called a flooding curve. Ideally, extractors are designed to operate near flooding to maximize productivity. In practice, however, many new column extractors are designed to operate at 40 to 60 percent of the predicted flood point because of uncertainties in the design, process impurity uncertainties, and to allow for future capacity increases. This practice varies from one type of extractor to another and one designer to another. In a static extraction column, countercurrent flow of the two liquid phases is maintained by virtue of the difference in their densities and the pressure drop through the equipment. Only one of the liquids may be pumped through the equipment at any desired flow rate or velocity; the maximum velocity of the other phase is then fixed by the flood point. If an attempt is made to exceed this hydraulic limit, the extractor will flood.

In extraction equipment, flooding may occur through a variety of mechanisms [Seibert, Bravo, and Fair, *ISEC '02 Proc.*, **2,** pp. 1328–1333 (2002)]:

1. Excessive flow rates of either dispersed-phase or continuous-phase, or high agitation intensity, cause dispersed-phase holdup or population density to exceed the volumetric capacity of the equipment.
2. Excessively high continuous-phase flow rate causes excessive entrainment of dispersed phase into the continuous-phase outlet.
3. Inadequate drop coalescence causes formation of dispersion bands or layers of uncoalesced drops that entrap continuous phase between them. The continuous phase can then be entrained into the wrong outlet.
4. Operation at a high ratio of dispersed phase to continuous phase results in phase inversion. (See "Liquid-Liquid Dispersion Fundamentals.")
5. Operating too close to the liquid-liquid phase boundary causes complete miscibility during an upset. A slight change in solvent or feed rates or an increase in solute concentration in the feed can potentially cause formation of a single phase.
6. In sieve tray columns, excessive orifice and/or downcomer pressure drop within the extractor causes formation of large coalesced layers that back up and overflow the trays.
7. Poor interface control allows the main liquid-liquid interface to leave the extractor. This may result from inadequate size of interface flow control valves, or operation with internals that provide inverse control responses such as those observed with sieve tray extractors. (See "Process-Control Considerations.")
8. Mechanical problems such as plugging of internals or outlet flow control valves can develop.

**Accounting for Axial Mixing** Differential-type column extractors are subject to axial (longitudinal) mixing, also called axial dispersion

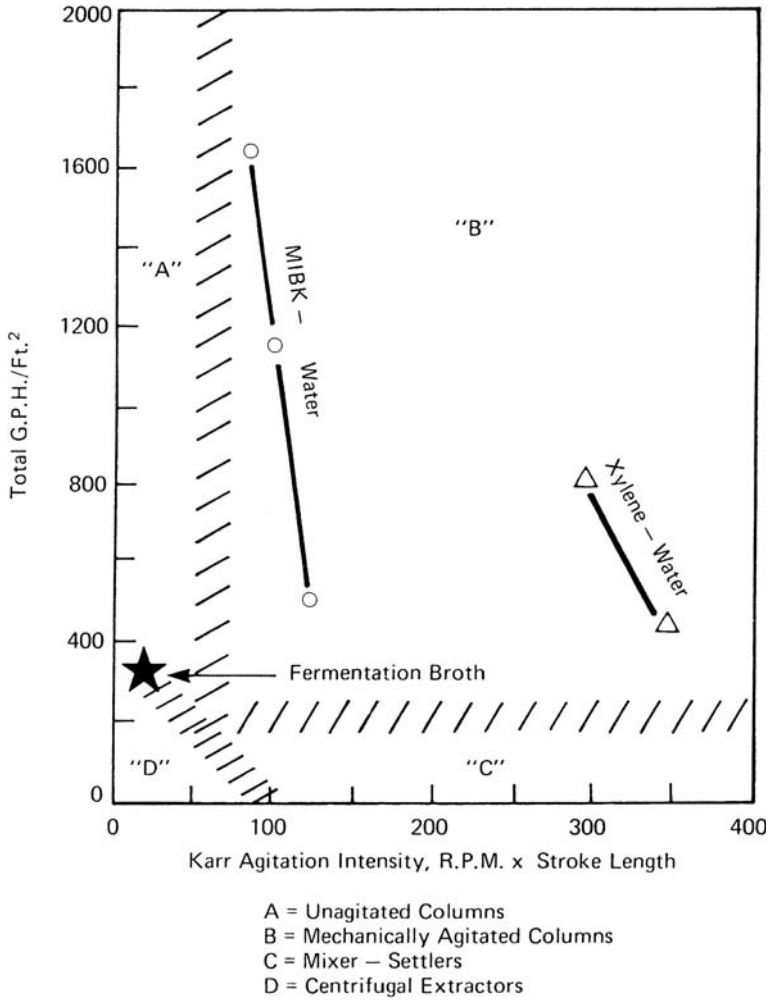

**FIG. 15-30** Typical Karr column flooding characteristics. Example flooding data are shown for two applications involving MIBK + water and xylene + water (flooding occurs to the right of the indicated flooding curve). A data point for extraction of a fermentation broth is indicated by the star. Results will vary depending upon process variables including solute concentration, the presence of other solutes, and temperature. [*Reprinted from Robbins, Sec. 1.9 in* Handbook of Separation Techniques for Chemical Engineers, *3d ed., Schweitzer, ed. (McGraw-Hill, 1997), with permission. Copyright 1997 McGraw-Hill, Inc.*]

and generally referred to as backmixing. This condition refers to a departure from uniform plug flow of the swarm of dispersed drops as drops rise or fall in the column, as well as any departure from plug flow of continuous phase in the opposite direction. As a result of axial mixing, the elements of the dispersed phase and the continuous phase exhibit a distribution of residence times within the equipment, and this decreases the effective or overall concentration driving force in the contactor. Because of this effect, the actual column must be taller than simple application of an ideal, plug flow model would indicate. When one is approaching the design of a contactor, factors that may contribute to axial mixing should be considered so that measures might be taken to reduce their effects. This may involve design of baffles to help direct the liquid traffic within the column. Also, if the transfer of solute occurs such that the continuous phase is significantly denser at the top of an extraction column than at the bottom, this may encourage circulation of continuous phase, and it may be advisable to switch the phase that is dispersed. For more information on this effect, see Holmes, Karr, and Baird, *AIChE J.*, **37**(3), pp. 360–366 (1991); and Aravamudan and Baird, *AIChE J.*, **42**(8), pp. 2128–2140 (1996).

Axial mixing effects commonly are taken into account by using a diffusion analogy and an axial mixing coefficient $E$, also called the longitudinal dispersion coefficient or eddy diffusivity, to account for the spreading of the concentration profiles. At steady state, the conservation equation has the general form

$$E\frac{\partial^2 C}{\partial z^2} + V\frac{\partial C}{\partial z} + k_o a(C - C^*) = 0 \qquad (15\text{-}106)$$

where $V$ is phase velocity, $k_o$ is an overall mass-transfer coefficient, $C$ is solute concentration (mass or moles per unit volume), and the superscript asterisk denotes equilibrium. By using Eq. (15-106) as a foundation, the required height of extractor may be calculated from a simplified plug flow model plus application of a correction factor expressed as a function of $E$ or a Péclet number Pe = $Vb/E$, where $b$ is a characteristic equipment

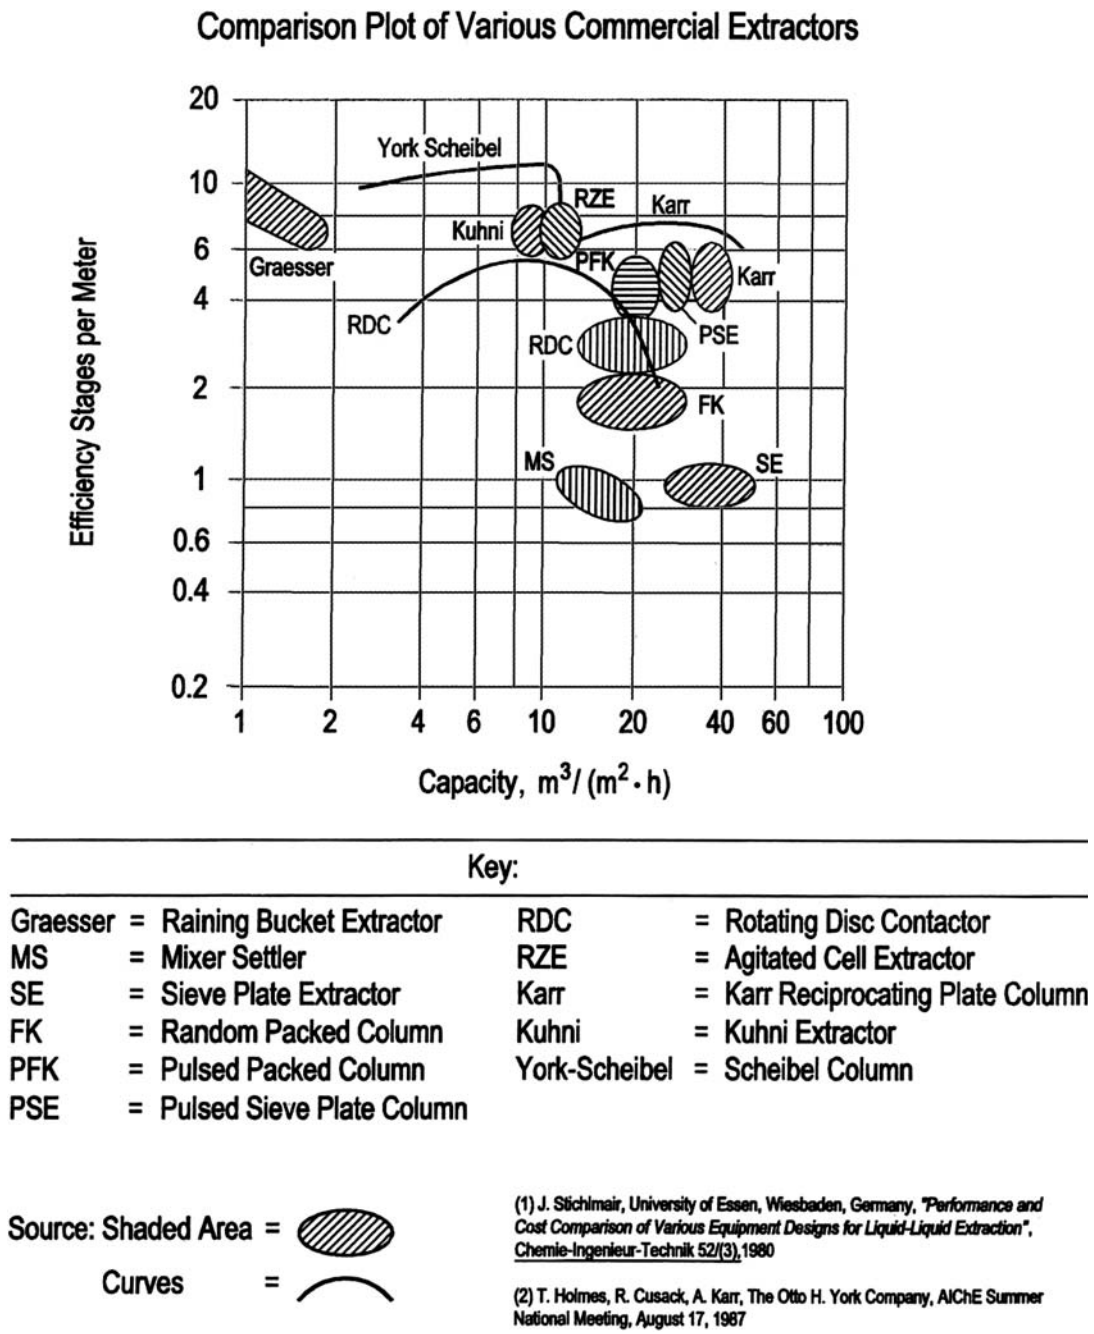

**FIG. 15-31** Modified Stichlmair chart. (*Courtesy of Koch Modular Process Systems.*)

dimension. The required values of $E$ must be determined by experiment. A variety of models and data correlations have been developed for various types of column extractors. For detailed discussion, see Sleicher, *AIChE J.*, **5**(2), pp. 145–149 (1959); Vermeulen et al., *Chem. Eng. Prog.*, **62**(9), pp. 95–102 (1966); and Li and Zeigler, *Ind. Eng. Chem.*, **59**(3), pp. 30–36 (1967). Also see the detailed discussions in Laddha and Degaleesan, *Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978); Pratt and Baird, Chap. 6 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991); and *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994). The method used by Becker [*Chem. Eng. Technol.* **26**(1), pp. 35–41 (2003)] is discussed in "Static Extraction Columns."

Computational fluid dynamics (CFD) simulations are beginning to be developed for certain types of extractors to better understand flow patterns in column extractors. The simulation of two-liquid-phase flows around complex internals is an active research area. For an example of this approach, see the discussion of CFD calculations for a

**TABLE 15-14 Estimated Maximum Production Rate for Selected Extractors**

| Extractor type | Maximum[a] specific throughput | | Maximum[b] diameter (typical) | Estimated maximum production rate | |
|---|---|---|---|---|---|
| | $m^3/h/m^2$ | $gal/h/ft^2$ | m | $m^3/h$ | gal/min |
| Mixer-settler[c] | 30 | 750 | 10 | ~2,400 | 10,000 |
| Baffle tray column | 60 | 1,500 | 5 | ~1,200 | 5,200 |
| Sieve plate column | 50 | 1,200 | 5 | ~1,000 | 4,300 |
| Packed column | 50 | 1,200 | 5 | ~1,000 | 4,300 |
| Spray column[d] | 70 | 1,700 | 4 | ~900 | 4,000 |
| Rotating disk contactor | 35 | 850 | 4 | ~450 | 1,900 |
| Kühni rotating-impeller column[e] | 40 | 1,000 | 3 | ~280 | 1,200 |
| Karr reciprocating-plate column | 40 | 1,000 | 3 | ~280 | 1,200 |
| Scheibel rotating-impeller column | 25 | 600 | 3 | ~200 | 800 |
| Graesser raining-bucket contactor | 10 | 250 | 3 | ~70 | 300 |

[a] Typical maximum value for dispersed + continuous phase flow rates. The actual value for a given application will depend upon physical properties and may be much lower.
[b] Typical value. Larger diameters may be possible.
[c] Throughput and equivalent diameter are based on mixer-settler footprint.
[d] Larger diameters possible but not recommended due to severe backmixing.
[e] Higher throughput may be achieved by increasing the column open area.

rotating-disk contactor by Modes and Bart [*Chem. Eng. Technol.*, **24**(12), pp. 1242–1244 (2001)].

**Liquid Distributors and Dispersers** It should be recognized that the performance of a column extractor can be significantly affected by how uniformly the feed and solvent inlet streams are distributed to the cross section of the column. The requirements for distribution and redistribution vary depending upon the type of column internals (packing, trays, agitators, or baffles) and the impact of the internals on the flow of dispersed and continuous phases within the column. Important considerations in specifying a distributor include the number of holes and the hole pattern (geometric layout), hole size, number of downcomers or upcomers (if used) and their placement, the maximum to minimum flow rates the design can handle (turndown ratio), and resistance to fouling. Various types of liquid distributors are available, including sieve tray dispersers and ladder-type pipe distributors designed to give uniform distribution of drops across the column cross section. (See "Packed Columns" and "Sieve Tray Columns" under "Liquid-Liquid Extraction Equipment" for more information about these. The height of the coalesced layer on a disperser plate may be calculated by using the method described in "Sieve Tray Columns.") Ring-type distributors also are used, primarily for agitated extractors. Equipment vendors should be consulted for additional information.

Typical hole sizes for distributors and dispersers are between 0.05 in (1.3 mm) and 0.25 in (6.4 mm). Small holes should be avoided in applications where the potential for plugging or fouling of the holes is a concern. For plate dispersers, the holes should be spaced no closer than about 3 hole diameters to avoid coalescence of drops emerging from adjacent holes. Design velocities for liquid exiting the holes generally are in the range of 0.5 to 1.0 ft/s (15 to 30 cm/s). Several methods have been proposed for more precisely specifying the design velocities. For detailed discussion, see Kumar and Hartland, Chap. 17 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994), pp. 631–635; Ruff, *Chem. Ing. Tech.*, **50**(6), pp. 441–443 (1978); and Laddha and Degaleesan, *Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978), Chap. 11, pp. 307–310. These methods are relevant for the design of distributors/dispersers used in all types of column extractors. The liquid should issue from the hole as a jet that breaks up into drops. The jet should yield a drop size distribution that provides good interfacial area, with an average drop size smaller than the maximum given by $d_{max} = [\sigma/(\Delta\rho g)]^{0.5}$, but without creating small secondary drops that cause entrainment problems or formation of an emulsion. (See "Size of Dispersed Drops" in "Liquid-Liquid Dispersion Fundamentals.") As a general guideline, the maximum recommended design velocity corresponds to a Weber number of about 12:

$$V_{o,\max} \approx \left(\frac{12\sigma}{d_o \rho_d}\right)^{1/2} \tag{15-107}$$

The minimum Weber number that ensures jetting in all the holes is about 2. It is common practice to specify a Weber number between 8 and 12 for a new design. For a detailed discussion of fundamentals, see Homma et al., *Chem. Eng. Sci.*, **61,** pp. 3986–3996 (2006).

It is well established that the dispersed phase must issue cleanly from the holes. This requires that the material of the pipe or disperser plate be preferentially wetted by the continuous phase (requiring the use of plastics or plastic-coated trays in some instances), or that the dispersed phase issue from nozzles projecting beyond the surface. For plate dispersers, these may be formed by punching the holes and leaving the burr in place [Mayfield and Church, *Ind. Eng. Chem.*, **44**(9), pp. 2253–2260 (1952)]. Once the design velocity is set, the number of holes is given by

$$N_{\text{holes}} = \frac{Q_d}{A_o V_o} \tag{15-108}$$

where $Q_d$ is the total volumetric flow rate of dispersed phase and $A_o$ is the cross-sectional area of a single hole.

## STATIC EXTRACTION COLUMNS

**Common Features and Design Concepts** Static extractors include spray-type, packed, and trayed columns often used in the petrochemical industries (Fig. 15-32). They offer the advantages of (1) availability in large diameters for very high production rates, (2) simple operation with no moving parts and associated seals, (3) requirement for control of only one operating interface, and (4) relatively small required footprint compared to mixer-settler equipment. Their primary disadvantage is low mass-transfer efficiency compared to that of mechanically agitated extractors. This usually limits applications to those involving low viscosities (less than about 5 cP), low to moderate interfacial tensions (typically 3 to 20 dyn/cm equal to 0.003 to 0.02 N/m), and no more than three to five equilibrium stages. Although the spray column is the least efficient static extractor in terms of mass-transfer performance, due to considerable backmixing effects, it finds

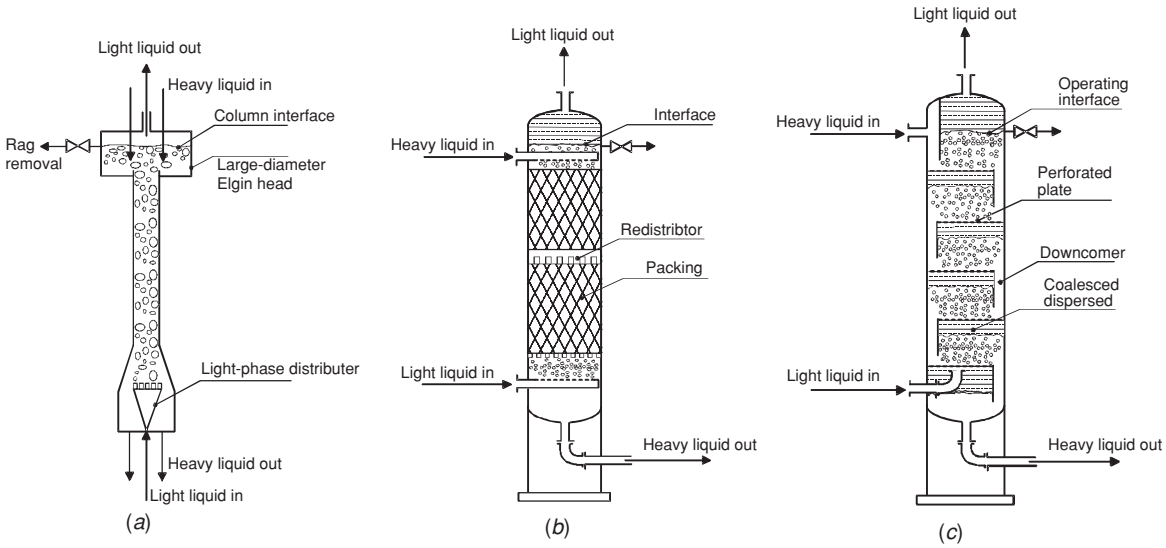

**FIG. 15-32** Schematic of common static extractors. (*a*) Spray column. (*b*) Packed column. (*c*) Sieve tray column.

use in processing feeds that would easily foul other equipment. Packed and trayed column designs provide improved mass-transfer performance by limiting backmixing.

An understanding of the general hydraulics of a static contactor is necessary for estimating the diameter and height of the column, as this affects both capacity and mass-transfer efficiency. Accurate evaluations of characteristic drop diameter, dispersed-phase holdup, slip velocity, and flooding velocities usually are necessary. Fortunately, the relative simplicity of these devices facilitates their analysis and the approaches taken to modeling performance.

***Choice of Dispersed Phase*** In general, formation of dispersed drops is preferred over formation of films or rivulets in order to maximize contact area and mass transfer. Static extractors generally are designed with the majority phase dispersed in order to maximize interfacial area needed for mass transfer; i.e., the phase with the greatest flow rate entering the column generally is dispersed. The choice of dispersed phase also depends upon the relative viscosity of the two phases. If one phase is particularly viscous, it may be necessary to disperse that phase.

***Drop Size and Dispersed-Phase Holdup*** Various models used to estimate the size of dispersed drops in static extractors are listed in Table 15-15. Also see "Size of Dispersed Drops" under "Liquid-Liquid Dispersion Fundamentals." Measurements of dispersed-phase holdup within a column-type extractor often are made by stopping all flows in and out of the extractor and measuring the change in the main interface level. This technique can be prone to significant experimental error as a result of end effects, static holdup present in small laboratory packings, inaccurate measurement of the baseline interface level, and holdup variations within a column as flooding conditions are approached. Examples of models for prediction of holdup are provided in Table 15-16. Additional models are given in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994). In general, an implicit calculation of the dispersed-phase holdup is usually encountered. One must be very careful in evaluating the roots of these equations, especially in the region of high dispersed-phase holdup ($\phi_d > 0.2$).

***Interfacial Area*** The mass-transfer efficiency of most extraction devices is proportional to the area available for mass transfer (neglecting any axial mixing effects). As discussed in "Liquid-Liquid Dispersion Fundamentals," for the general case where the dispersed phase travels through the column as drops, an average liquid-liquid interfacial area can be calculated from the Sauter mean drop diameter and dispersed-phase holdup:

$$a = \frac{6\varepsilon\phi_d}{d_p} \tag{15-109}$$

In most cases, the drop size distribution is not known.

***Drop Velocity and Slip Velocity*** The hydraulic characteristics of a static extractor depend upon drop diameter, liquid velocities, and physical properties. The average velocity of a dispersed-phase drop ($V_{\text{drop}}$) and the interstitial velocity of the continuous phase $V_{ic}$ are given by

$$V_{\text{drop}} = \frac{V_d}{\varepsilon\phi_d} \tag{15-110}$$

$$V_{ic} = \frac{V_c}{\varepsilon(1-\phi_d)} \tag{15-111}$$

where $V_d$ = superficial velocity of dispersed phase
$V_c$ = superficial velocity of continuous phase
$\phi_d$ = fraction of void volume occupied by dispersed phase
$\varepsilon$ = void fraction of column ($\varepsilon = 1.0$ for sprays and sieve trays)

The relative velocity between the counterflowing phases is referred to as the slip velocity and defined by

$$V_s = V_{\text{drop}} + V_{ic} = \frac{V_d}{\varepsilon\phi_d} + \frac{V_c}{\varepsilon(1-\phi_d)} \tag{15-112}$$

The slip velocity of a dispersed-phase drop of diameter $d_p$ can be estimated from a balance of gravitational, buoyancy, and frictional forces:

$$F_{\text{buoyancy}} - F_{\text{gravity}} - F_{\text{drag}} = 0 \tag{15-113}$$

$$F_{\text{buoyancy}} = \rho_c\left(\frac{\pi}{6}d_p^3\right)g \tag{15-114}$$

$$F_{\text{gravity}} = \rho_d\left(\frac{\pi}{6}d_p^3\right)g \tag{15-115}$$

$$F_{\text{drag}} = \frac{1}{2}C_D\rho_c\left(\frac{\pi}{4}d_p^2\right)V_{so}^2 \tag{15-116}$$

**TABLE 15-15 Example Drop Diameter Models for Static Extractors**

| Example | Eq. | Comments | Ref. |
|---|---|---|---|
| $d_p = 1.15\eta\sqrt{\frac{\sigma}{\Delta\rho\, g}}$, $\eta = 1.0$ for no mass transfer and $c \to d$, $\eta = 1.4$ for $d \to c$ | 1 | Spray, packing, and sieve tray | 1 |
| $d_p = 0.12 D_h\, We_c^{-0.5}\, Re_c^{0.15}$, developed with no mass transfer, $We_c$ and $Re_c$ are calculated based on slip velocity | 2 | SMV structured packing | 2 |
| $d_p = C_p\sqrt{\frac{\sigma}{\Delta\rho\, g}}$, $C_p = 1$ for $\rho_d < \rho_c$, $C_p = 0.8$ for $\rho_d > \rho_c$ developed with no mass transfer | 3 | Packing | 3 |
| $d_p = 1.09\sqrt{\frac{\sigma}{\Delta\rho\, g}}\left(1 + 700\frac{V_c\mu_c}{\sigma}\right)$, developed with no mass transfer | 4 | Packing | 4 |
| $d_p = 0.74 C_\psi\sqrt{\frac{\sigma}{\Delta\rho\, g}}\left(\frac{\Delta\rho\,\rho_d\sigma}{\rho_w^2\sigma_w}\right)^{-0.12}$, $C_\psi = 1$ for no mass transfer, $C_\psi = 0.84$ for $c \to d$, $C_\psi = 1.23$ for $d \to c$ | 5 | Packing | 5 |
| $d_p = \frac{C_\psi}{\frac{1}{(6d_o\sigma/\Delta\rho g)^{1/3}} + \frac{1}{2.04(12\sigma/\rho_d V_o^2)}}$ $C_\psi = 1.0$ for $c \to d$ and no mass transfer, $C_\psi = 1.06$ for $d \to c$ | 6 | Spray nozzles | 5 |
| $d_p = d_o E\ddot{o}_o^{-0.35}\left[0.80 + \exp\left(-2.73\times10^{-2}\frac{We_o}{E\ddot{o}_o}\right)\right]$ $E\ddot{o}_o = \frac{d_o^2\Delta\rho g}{\sigma}$, $We_o = \frac{\rho_d d_o V_o^2}{\sigma}$ | 7 | Perforated plate | 6 |

Refer to the original articles for details.

where $V_{so}$ is defined as the characteristic slip velocity obtained at low dispersed-phase flow rate. Rearranging Eqs. (15-113) to (15-116) gives

$$V_{so} = \sqrt{\frac{4\Delta\rho\, g d_p}{3\rho_c C_D}} \tag{15-117}$$

The slip velocity at higher holdup often is estimated from $V_s \approx V_{so}(1 - \phi_d)$.

Equation (15-117) provides the basis for various methods used to predict the characteristic slip velocity. For additional discussion, see Míšek, Chap. 5 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994). Equation (15-117) can be difficult to use for design because of difficulty estimating the drag coefficient $C_D$ and difficulty accounting for packing resistance or drop-drop interactions. The drag coefficient can be affected by internal circulation within the drop. For good mass transfer, it is most desirable to have circulating drops traveling through a relatively nonviscous continuous phase. Particular care should be taken in utilizing models developed primarily from studies involving small laboratory packings, because the packing resistance is particularly significant in that case. Also many studies do not include low-interfacial-tension systems, even though most applications of static extractors involve low to moderate interfacial tension. Also note that surface-active impurities can reduce the characteristic drop velocity [Garner and Skelland, *Ind. Eng. Chem.*, **48**(1), pp. 51–58 (1956); and Skelland and Caenepeel, *AIChE J.*, **18**(6), pp. 1154–1163 (1972)], which is another reason to approach these models with care.

The following method is recommended for calculating slip velocity in static extractors at low dispersed-phase holdup:

$$\text{If } Re_{Stokes} = \frac{\rho_c\Delta\rho\, g d_p^3}{18\mu_c^2} < 2, \quad \text{then } V_{so} = \frac{\Delta\rho\, g d_p^2}{18\mu_c} \quad \text{(Stokes' law)} \tag{15-118}$$

For $Re_{Stokes} > 2$, Seibert and coworkers [Seibert and Fair, *Ind. Eng. Chem. Res.*, **27**(3), pp. 470–481 (1988); and Seibert, Reeves, and Fair [*Ind. Eng. Chem. Res.*, **29**(9), pp. 1901–1907 (1990)] recommend the model of Grace, Wairegi, and Nguyen [*Trans. Inst. Chem. Eng.*, **54**, p. 167 (1976)]. In this case, the characteristic slip velocity may be calculated from

$$V_{so} = \frac{Re\,\mu_c}{d_p\rho_c} \tag{15-119}$$

**TABLE 15-16 Example Hold-up Models for Static Extractors**

| Example | Eq. | Comments | Ref. |
|---|---|---|---|
| $\phi_d = \dfrac{V_d[\cos(\pi\zeta/4)]^{-2}}{\varepsilon[V_{so}\exp(-6\phi_d/\pi) - V_c/\varepsilon(1-\phi_d)]}, \quad \zeta = \dfrac{a_p d_p}{2}$ | 1 | Spray, packing, and sieve tray<br>$V_{so}$ is calculated by the method of Grace et al. (1976), Eqs. (15-118) to (15-123). | 1 |
| $\dfrac{V_d}{\phi_d} + \dfrac{V_c}{1-\phi_d} = \dfrac{4c_p}{3}\sqrt{\dfrac{d_p \Delta\rho g}{C_D \rho_c}}$ | 2 | SMV structured packing. Drag coefficient, $C_D$ is calculated by assuming a drop is a rigid sphere. Parameter $c_p$ depends upon drop-drop and drop-packing interactions. | 2 |

where Re is obtained from the correlation:

$$\frac{\mathrm{Re}}{P^{0.149}} = 0.94H^{0.757} - 0.857 \qquad H \le 59.3 \qquad (15\text{-}120)$$

$$\frac{\mathrm{Re}}{P^{0.149}} = 3.42H^{0.441} - 0.857 \qquad H > 59.3 \qquad (15\text{-}121)$$

And $P$ and $H$ are dimensionless groups defined by

$$P = \frac{\rho_c^2\sigma^3}{\mu_c^4 g\Delta\rho} \qquad (15\text{-}122)$$

$$H = \left(\frac{4d_p^2 g\Delta\rho}{3\sigma}\right)\left(\frac{\mu_w}{\mu_c}\right)^{0.14} P^{0.149} \qquad (15\text{-}123)$$

and $\mu_w$ is a reference viscosity equal to 0.9 cP ($9 \times 10^{-4}$ Pa·s). For discussion of methods to correct slip velocity to account for the effect of high dispersed-phase holdup, see Augier, Masbernat, and Guiraud, *AIChE J*., **49**(9), pp. 2300–2316 (2003).

***Flooding Velocity*** Maximum flow through a countercurrent extractor is limited by the flooding velocity. See "Hydrodynamics of Column Extractors" for a general discussion of flooding mechanisms. Because of the many possible causes of flooding, published data and models should be viewed with some caution. In addition, models developed from laboratory data can lead to problems when used for design of commercial-scale columns. For example, in packed columns a column diameter/packing diameter ratio of at least 8 is recommended to avoid channeling due to wall effects. This means that laboratory studies must utilize small packings with high specific packing surface areas (packing area/contacting volume). The high packing area will provide significant resistance to drop flow, greater than that encountered in large columns containing large commercial packings. In addition, many of the published laboratory data on flooding velocities were generated by using moderate to high-interfacial-tension systems. In this case, the packing surface area resistance controls the flooding mechanism.

Several correlations of flooding velocity have the general form

$$V_{cf} \propto C_1\frac{C_2}{a_p^n} \qquad 0 < n < 1 \qquad (15\text{-}124)$$

where $V_{cf}$ is the continuous-phase velocity at which flooding occurs, $a_p$ is the specific packing surface area, and $C_1$ and $C_2$ are empirical constants that depend upon the specific type of packing, fluid physical properties, and flow ratio. While these types of models have excellent reported fits of data, they were primarily developed by using laboratory-scale packings. Furthermore, in the limit as the packing surface area approaches zero, the predicted flooding velocity becomes infinite, an unrealistic result. Care should be taken when extrapolating such models to a larger packing size.

Seibert, Reeves, and Fair [*Ind. Eng. Chem. Res.*, **29**(9), pp. 1901–1907 (1990)] proposed a more mechanistically consistent flooding model that is derived by assuming a tightly packed arrangement of drops at flooding and yields

$$\frac{1}{V_{cf}} = C_1 + \frac{C_2}{C_3 \cos^2(C_4 a_p)} \tag{15-125}$$

where parameters $C_1$, $C_2$, $C_3$, and $C_4$ are functions of the system properties and flow ratio. An advantage of this flooding model is that as the packing surface area approaches zero, a finite flooding velocity is calculated since the cos 0 = 1. In the absence of packing, Eq. (15-125) can be rewritten to predict flooding in a spray column and the ultimate capacity of a tray column. Examples of published flooding models for static extractors are given in Table 15-17. Unfortunately, very few flooding data are available for columns greater than 30 cm (12 in) in diameter. Also, many of the available flooding data have been obtained in the absence of mass transfer. With this in mind, for new designs it is recommended that flow velocities be limited to no more than 50 percent of the calculated flooding values. The final design should be refined in miniplant or pilot-plant tests using actual feed materials.

***Drop Coalescence Rate*** The rate of drop coalescence often is assumed to be rapid (not rate-limiting) in the design of static extractors. However, this is not necessarily the case, particularly during operation at high dispersed-phase holdup and high flow ratios of dispersed phase to continuous phase. Under these conditions, a large number of drops flow through a nearly stagnant continuous phase, and these drops must coalesce at the main operating interface located at the top or bottom of the column. Seibert, Bravo, and Fair [*ISEC '02 Proc.* **2,** pp. 1328–1333 (2002)] report that problems with coalescence are most likely when the

superficial dispersed-phase velocity $V_{df}$ is greater than about 12 percent of the characteristic slip velocity given by Eqs. (15-118) to (15-123). For these systems, miniplant tests normally are needed to understand the rate of coalescence. If coalescence is slow, design rates will need to be reduced below those predicted by assuming rapid coalescence.

For slowly coalescing systems, placement of coalescing material within the column at the main interface may significantly improve performance. The height of the uncoalesced layer located at the main operating interface may be reduced by adding a high-surface-area mesh type of coalescer that is wetted by the dispersed phase. If plugging is a concern, a more open (lower-surface-area) structured packing may be preferred. It also may be useful to add a separate liquid-liquid phase separator outside the extractor to clarify the extract or raffinate streams. See "Liquid-Liquid Phase Separation Equipment."

***Mass-Transfer Coefficients*** As described in "Rate-Based Calculations," the overall mass-transfer coefficient may be written as

$$\frac{1}{k_{od}} = \frac{1}{k_d} + \frac{m_{dc}^{\text{vol}}}{k_c} \tag{15-126}$$

where the slope of the equilibrium line $m_{dc}^{\text{vol}}$ is expressed in volumetric concentration units. The dispersed-phase and continuous-phase film coefficients $k_d$ and $k_c$ generally are functions of convection and turbulence effects, as well as molecular diffusion coefficients and the thicknesses of stagnant films at the interface between drops and the continuous phase. Examples of mass-transfer coefficient models for static extractors are given in Table 15-18. For additional discussion of

film coefficient models, see *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994).

***Axial Mixing*** See "Accounting for Axial Mixing" under "Liquid-Liquid Extraction Equipment." Many approaches have been developed. Becker recommends the concept of the height of a dispersion unit (HDU) to correct the height of a transfer unit for axial mixing in a static contactor [Becker, *Chem. Eng. Technol.*, **26**(1), pp. 35–41 (2003); *Chem. Ing. Tech.*, **74,** pp. 59–66 (2002); and Becker and Seibert, *Chem. Ing. Tech.*, **72,** pp. 359–364 (2000)]:

$$H_{or}|_{\text{axial}} = H_{or}|_{\text{plug}} + \text{HDU}_o \tag{15-127}$$

where

$$\text{HDU}_o = \left( p_0 + \frac{0.8}{Z_t} \frac{\mathcal{E} \ln \mathcal{E}}{\mathcal{E} - 1} \right)^{-1} \tag{15-128}$$

$$p_0 = \frac{0.1Z_t/H^*_{or} + 1}{0.1Z_t/H^*_{or} + p_1/p_2} \cdot p_1 \tag{15-129}$$

$$\frac{1}{p_1} = \frac{1}{\mathcal{E}} \text{HDU}_r + \text{HDU}_e \qquad \frac{1}{p_2} = \text{HDU}_r + \frac{1}{\mathcal{E}} \text{HDU}_e \tag{15-130}$$

For a given phase,

$$\text{HDU} = \frac{E}{V} \tag{15-131}$$

In these equations, the superscript * denotes the plug flow overall height of a transfer unit, subscript $r$ denotes the raffinate phase, subscript $e$ denotes the extract phase, and $Z_t$ is the contacting height. For $\mathcal{E} = 1$, the equations reduce to

$$\text{HDU}_o = \left( \frac{1}{\text{HDU}_r + \text{HDU}_e} + \frac{0.8}{Z_t} \right)^{-1} \tag{15-132}$$

The axial mixing coefficient is correlated by

$$\frac{E_c \rho_c}{\mu_c} = (C_1 \text{Re}_c^a + C_2 \text{Re}_d^b) \left( \frac{D_{\text{col}}}{100} \right)^c \tag{15-133}$$

$D_{\text{col}}$ = column diameter, cm

where

$$\text{Re}_c = \frac{V_{ic} \rho_c}{\mu_c (a_p + a_w)} \tag{15-134}$$

$$a_w = \frac{4}{D_{\text{col}}} \tag{15-135}$$

$$\text{Re}_d = \frac{V_s d_p \rho_c}{\mu_c} \tag{15-136}$$

In Eq. (15-135), $a_w$ is the specific wall surface ($cm^2/cm^3$) and $a_p$ is the specific packing surface ($cm^2/cm^3$). This term is dropped for a spray column ($C_1 = 0$). The model coefficients are summarized in Table 15-19. Most of the axial mixing data available in the literature are for the continuous phase; dispersed-phase axial mixing data are rare. Becker recommends assuming $\text{HDU}_d = \text{HDU}_c$ when dispersed-phase data are not available. Becker presents a parity plot (Fig. 15-33) based on small- and large-scale data for packed and spray columns.

**Spray Columns** The spray column is one of the simplest and oldest types of equipment used to contact two liquid phases in countercurrent flow. Normally it consists of an empty vertical vessel with a distributor located at one end. The distributor disperses one of the liquids into drops. These drops then rise or fall against the flow of the continuous phase, collecting at the other end of the column and finally coalescing to form a layer of clear liquid that is withdrawn from the column. Because spray columns often are used when solids are present, phases often are dispersed through pipe distributors with large holes oriented in the direction of flow. In cases where the ratio of volumetric flow rates entering the column is far from unity, the liquid entering the extractor at the smaller rate generally should be dispersed to avoid excessive backmixing. Sometimes liquid distributors are used at each end to disperse both phases, with the main liquid-liquid interface located in the middle of the column (Fig. 15-34). See "Liquid Distributors and Dispersers" under "Liquid-Liquid Extraction Equipment."

Spray columns are inexpensive and easy to operate and provide high volumetric throughput. However, because the continuous phase flows freely through the column, backmixing effects generally are severe. As a result, spray columns rarely achieve more than one theoretical stage. Spray columns may be used when only one theoretical stage is required or when solid precipitation is prevalent and no other contacting device can be used because of plugging. Spray columns also are used for direct heat transfer between large immiscible liquid streams.

***Drop Size, Holdup, and Interfacial Area*** Drop size is estimated by using one of the models listed in Table 15-15, and holdup is estimated from expressions given in Table 15-16. Interfacial area is then calculated by using Eq. (15-109).

***Flooding*** Several empirical and mechanistic flooding models have been reported. These have been reviewed by Kumar and Hartland [Chap. 17 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994), pp. 680–686]. Seibert, Reeves, and Fair [*Ind. Eng. Chem. Res.*, **29**(9), pp. 1901–1907 (1990)] propose an alternative model:

$$V_{cf} = \frac{0.178 V_{so}}{1 + 0.925(V_{df}/V_{cf})} \tag{15-137}$$

where $V_{so}$ is the characteristic slip velocity determined by using Eqs. (15-118) to (15-123).

***Mass-Transfer Efficiency*** As mentioned earlier, spray columns rarely develop more than one theoretical stage due to axial mixing within the column. Nevertheless, it is necessary to determine the column height that will give this theoretical stage. Cavers [Chap. 10 in

**TABLE 15-19 Correlation Constants for the Becker Axial Mixing Model***

| | No. of data points | $C_1$ | $a$ | $C_2$ | $B$ | $c$ | Average relative error, % |

*Becker, *Chem. Eng. Technol.*, **24**(12), pp. 1242–1244 (2001).

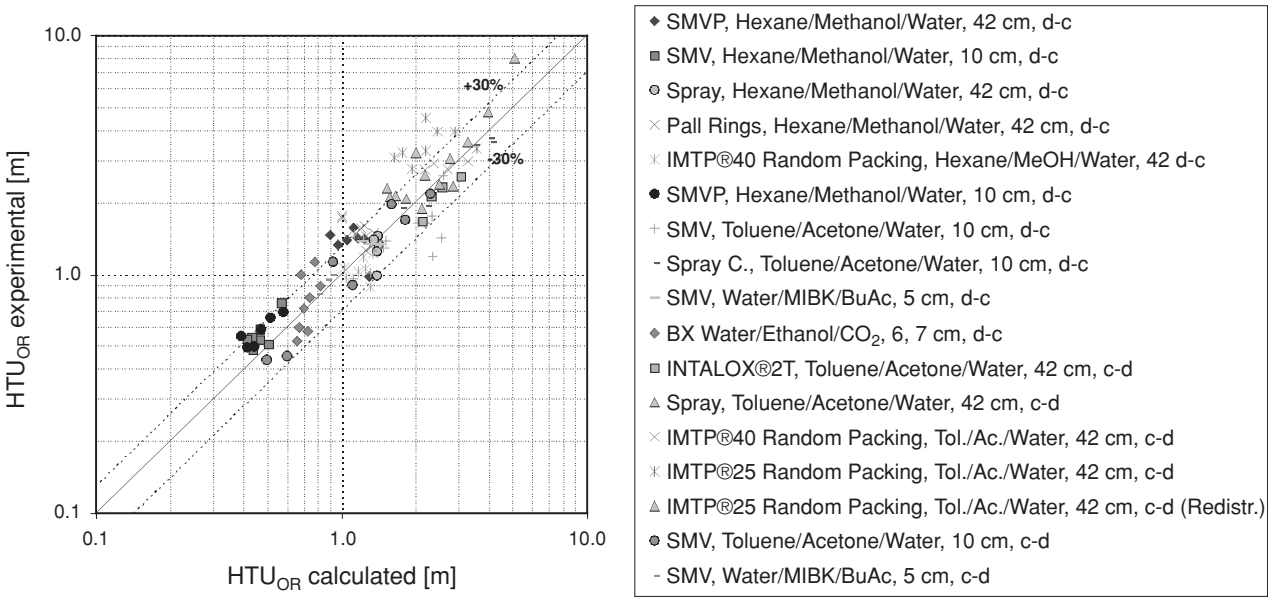

**FIG. 15-33** Parity plot comparing spray and packed column results incorporating axial mixing model. [*Reprinted from Becker,* Chemie Ing. Technik, ***74****(1–2), pp. 59–66 (2002). Copyright 2002 Wiley-VCH.*]

*Handbook of Solvent Extraction,* Lo, Baird, and Hanson, eds, (Wiley, 1983; Krieger, 1991)] recommends the following equation from Laddha and Degaleesan [*Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978), p. 233] to estimate the overall volumetric mass-transfer coefficient:

$$k_{oc}a = m_{dc}^{\text{vol}}\, k_{od}a = 0.08 \times \frac{\phi_d(1-\phi_d)(g^3\Delta\rho^3/\sigma\rho_c^2)^{1/4}}{(\mu_c/\rho_c\mathcal{D}_c)^{1/2} + (1/m_{dc})(\mu_d/\rho_d D_d)^{1/2}} \quad (15\text{-}138)$$

Here $\mathcal{D}_c$ and $\mathcal{D}_d$ are the solute disffusion coefficients in the continuous and dispersed phases, respectively. The height of a transfer unit can then be estimated from

$$H_{oc} = \frac{V_c}{k_{oc}a} \quad (15\text{-}139)$$

where $H_{oc}$ is the height of an overall transfer unit based on the continuous phase and $V_c$ is the superficial velocity of the continuous phase. Equation (15-138) provides only a rough approximation.

**Packed Columns** Packing is used in a column extractor to reduce axial mixing (backmixing). Packing also affects interfacial area and mass transfer through its impact on the holdup and flow path of dispersed drops. For reviews of packed-column extractor design, see Strigle, *Packed Tower Design and Applications*, 2d ed., Chap. 11 (Gulf, 1994); and Stevens, Chap. 8 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994).

The packings used for liquid-liquid extraction are essentially the same as those used in distillation and absorption service, although the distributors and dispersers and many of the associated internals are not the same. Various commercially available packings offered by Koch-Glitsch and Sulzer Chemtech for liquid-liquid extraction service are listed in Table 15-20. Other manufacturers of packings include Raschig, Montz, Lantec, and Jaeger Products. It is a good idea to consult a variety of vendors before making a selection. Illustrations of various types of packings are given in Sec. 14, "Equipment for Distillation, Gas Absorption, Phase Dispersion, and Phase Separation."

Packings are classified as either random or structured. Random packings may be wet-loaded into a column by filling the column with liquid and slowly adding the packing at the liquid surface so the packing pieces gently fall to the surface of the forming bed (typical of ceramic packings); or they may be dry-loaded by transferring them into an empty column through a chute or fabric sock (typical of metal or plastic packings). The familiar ring and saddle packings such as Raschig rings, Berl saddles, Intalox saddles, and Lessing rings are examples of ceramic packings. The more modern metal and plastic random packings such as Pall rings, Hy-Pak®, and IMTP® packings are ring or saddle shapes with internal fingers and slots in the wall. These packings are more open and provide greater access to the interior surfaces for improved capacity and mass-transfer performance. Structured packings are modular assemblies placed inside the column in a specific arrangement. Many are in the form of woven wire mesh or crimped sheets arranged in layers at specific angles. For packing made from sheets, it is not clear whether surface treatments such as perforations and embossing are important in liquid-liquid extraction, so a number of smooth-surface structured packings are marketed for extraction applications. For best performance, the packing should be preferentially wetted by the continuous phase. (See "Effect of Solid-Surface Wettability" under "Liquid-Liquid Dispersion Fundamentals.") Many older packed extractors are being refurbished with newer packings and internals to achieve higher throughput and better separation performance. As with any packing and the associated internals, installation procedures recommended by the packing vendor need to be carefully followed to ensure the packing performs as designed. In addition to mass-transfer performance and throughput, another important consideration when choosing metal packing is the packing material and wall thickness relative to corrosion rates. The packing should have sufficient wall thickness for a reasonable service life.

***Liquid Distribution*** Good initial distribution of the dispersed phase is very important for good performance. Strigle [*Packed Tower Design and Applications*, 2d ed., Chap. 11 (Gulf, 1994)] describes typical packed-column internals for liquid-liquid contacting. When the light phase is dispersed, a combination liquid disperser/packing support is preferred because a separate support plate can adversely affect the flow of dispersed drops. An example of a disperser plate is shown in Fig. 15-35. A ladder-type pipe distributor commonly is used to distribute the dispersed-phase feed to the initial disperser plate. Other

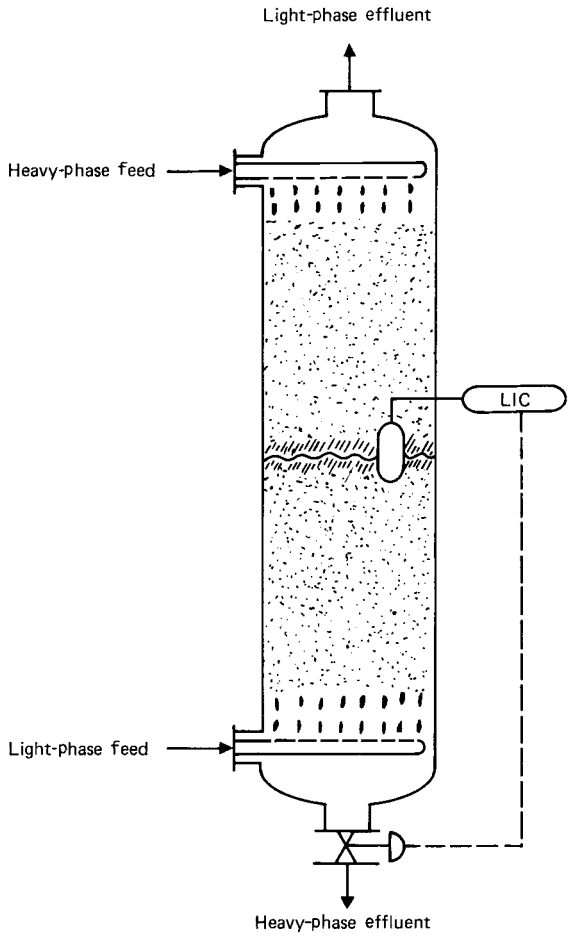

**FIG. 15-34** Spray column with both phases dispersed.

distributor designs also are available. Koch and Vogelpohl [*Chem. Eng. Technol.*, **24**(7), pp. 695–698 (2001); and *Chem. Eng. Technol.*, **24**(8), pp. 795–798 (2001)] discuss a sieve plate distributor design that includes a predistributor plate. Many of the concepts concerning geometric uniformity for liquid distribution in packed gas-liquid contactors [Perry, Nutter, and Hale, *Chem. Eng. Prog.*, **86**(1), pp. 30–35 (1990)] are relevant to liquid-liquid contactors as well. See "Liquid Distributors and Dispersers" under "Liquid-Liquid Extraction Equipment."

***Redistribution*** Seibert, Reeves, and Fair [*Ind. Eng. Chem. Res.*, **29**(9), pp. 1901–1907 (1990)] and Nemunaitis et al. [*Chem. Eng. Prog.*, **67**(11), p. 60 (1971)] report data showing little benefit from a packed height greater than 10 ft (3 m) and recommend redistributing the dispersed phase about every 5 to 10 ft (1.5 to 3 m) to generate new droplets and constrain backmixing. A random packed column often is designed with a redistributor placed between two or more packed sections. Structured packings sometimes are installed with a dual-flow perforated plate (with no downcomer) between elements, without coalescence of dispersed drops.

***Minimum Packing Size and Drop Size*** For a given application there will be a minimum packing size or dimension below which random packing is too small for good extraction performance [Lewis, Jones, and Pratt, *Trans. Inst. Chem. Eng.*, **29,** pp. 126–148 (1951); Gayler and Pratt, *Trans. Inst. Chem. Eng.*, **31,** pp. 69–77 (1953); and Laddha and Degaleesan, *Transport Phenomena in Liquid Extraction*

*Typical value for standard wall thickness. Values will vary depending upon thickness.

†SMV structured packings also are available with horizontal dual-flow perforated plates installed between elements (typically designated SMVP packing). These plates generally reduce backmixing and improve mass-transfer performance at the expense of a reduction in the open cross-sectional area and somewhat reduced capacity.

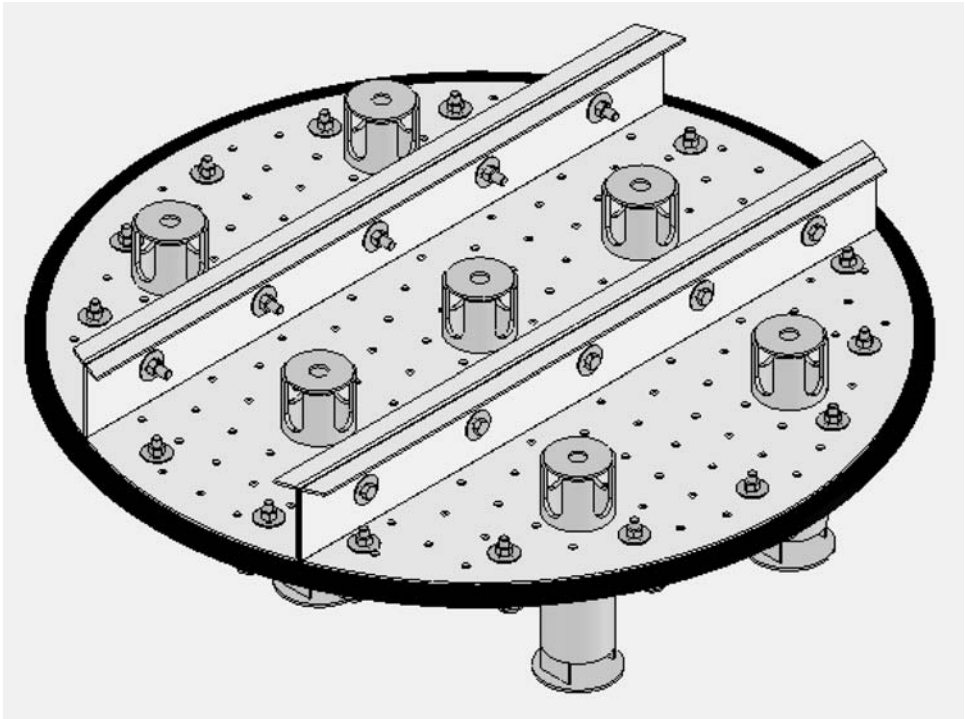

**FIG. 15-35** Example of disperser plate (Sulzer Chemtech model VSX). (*Courtesy of Sulzer Chemtech.*)

(McGraw-Hill, 1978), Chap. 10, pp. 288–289]. The critical packing dimension is given by

$$d_C = 2.4\sqrt{\frac{\sigma}{\Delta\rho g}} \tag{15-140}$$

In many cases, the minimum random packing size is about 0.5 in (1.3 cm). A similar effect may be seen with short-crimp-height structured sheet packings that might act as a parallel-plate type of coalescer. For packings smaller than the critical size, the packing acts to promote growth of dispersed drops somewhat as a packed-bed coalescer as drops flow through the spaces between the packing elements. (For a discussion of packed-bed coalescers, see "Coalescers" under "Liquid-Liquid Phase Separation Equipment.") For packing sizes larger than $d_C$, the characteristic drop diameter is independent of packing size and may be estimated by using the models listed in Table 15-15. The choice of packing size above $d_C$ generally involves a tradeoff; throughput increases with increasing packing size, while mass-transfer performance may decrease with increasing packing size due to an increase in backmixing effects. Typical random packings for commercial-scale columns are in the range of $\frac{3}{4}$ to 2 in (or about 2 to 5 cm). For small columns, the packing should be no larger than one-eighth the column diameter to avoid channeling at the wall. This effectively restricts the size of laboratory extractors packed with random packings to no less than 4 in (10 cm) in diameter if they are intended to generate directly scalable data.

***Holdup and Interfacial Area*** The dispersed-phase holdup in a packed-column extractor may be placed into two categories: (1) a small portion that is held in the column for extended periods (essentially permanent) and (2) a larger portion that is free to move through the packing. This is the portion that participates in transfer of solute between phases. The total is $\phi_d$ which here refers to the volume of dispersed phase expressed as a fraction of the void space in the packed section. Pratt and coworkers [*Trans. Inst. Chem. Eng.*, **29,** pp. 89–109, 110–125, 126–148 (1951); **31,** pp. 57–68, 69–77, 78–93 (1953)] developed relationships between dispersed-phase velocity and holdup for packed columns. For standard commercial packings of 0.5 in (1.27 cm) and larger, they found that $\phi_d$ varies linearly with $V_d$ up to values of $\phi_d = 0.10$ (for low values of $V_d$). With further increase of $V_d$, $\phi_d$ increases sharply up to a "lower transition point" resembling loading in gas-liquid contact. At still higher values of $V_d$ an upper transition point occurs, the drops of dispersed phase tend to coalesce, and $V_d$ can increase without a corresponding increase in $\phi_d$. This regime ends in flooding. Below the upper transition point, Pratt and coworkers calculated dispersed-phase holdup from the expression

$$\frac{V_d}{\phi_d} + \frac{V_c}{1-\phi_d} = \varepsilon V_{so}\,(1-\phi_d) \tag{15-141}$$

where $V_{so}$ is the characteristic slip velocity at low dispersed-phase flow rate. The slip velocity may be estimated by using Eqs. (15-118) to (15-123) or alternative methods listed in Table 15-16. (See the related discussion in "Common Features and Design Concepts.") Interfacial area is calculated from Eq. (15-109).

***Flooding*** Numerous methods have been proposed for correlating flooding velocities in packed extractors as a function of the packing specific surface area and void volume. Most were developed by using the older-style packings such as Raschig rings and Berl saddles. For example, the well-known flooding correlation $(\sigma/\rho_c)^{0.2}(\mu_c/\Delta\rho)(a_p/\varepsilon)^{1.5}$ versus $(V_c^{1/2} + V_d^{1/2})^2\rho_c/(a_p\mu_c)$, developed by Crawford and Wilke [*Chem. Eng. Prog.*, **47**(8), pp. 423–431 (1951)], is plotted in Fig. 15-36. This is a dimensional correlation developed by using U.S. Customary System units, so the following units must be used: viscosity in lb/ft/h (equal to 2.42 times the value in cP), density in lb/ft$^3$, interfacial tension in dyn/cm, specific packing surface area in ft$^2$/ft$^3$, and velocities in ft/h based on total column cross section. Nemunaitis et al. [*Chem. Eng. Prog.*, **67**(11),

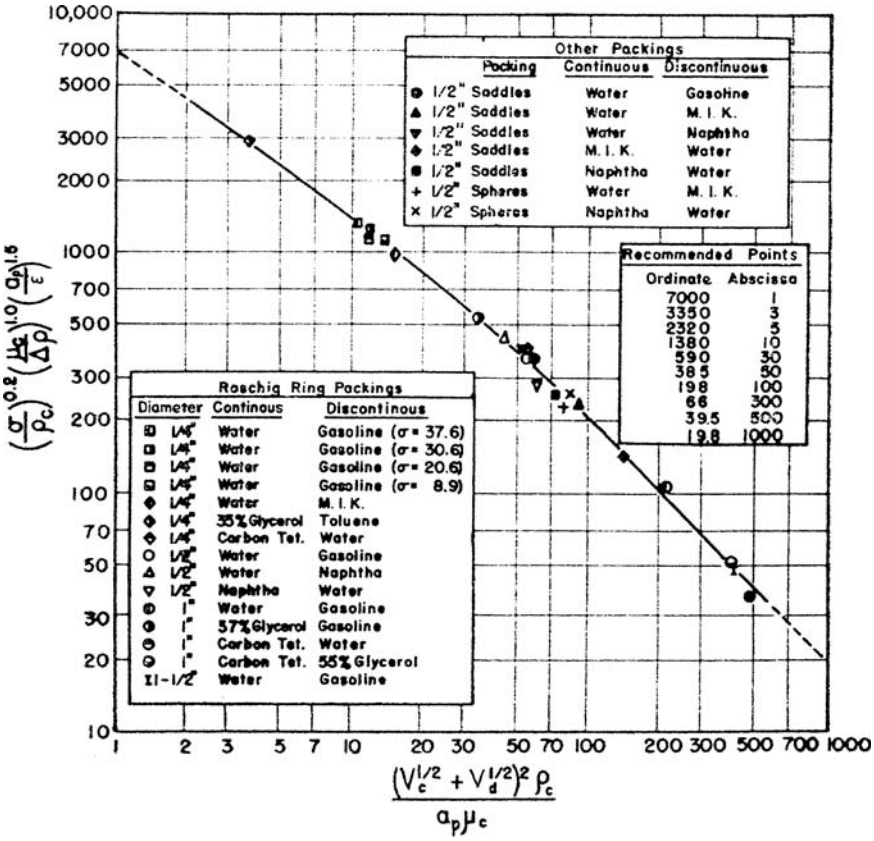

**FIG. 15-36** Crawford-Wilke correlation for flooding in packed columns. Use only the units given in the text. [*Reprinted from Crawford and Wilke*, Chem. Eng. Prog., ***47****(8), pp. 423–431 (1951), with permission.*]

pp. 60–67 (1971)] modified the Crawford-Wilke correlation to include packing factors for specific types of packings (including Raschig rings, Intalox® saddles, and Pall rings). Another correlation that uses packing factors is given by Sakiadis and Johnson [*Ind. Eng. Chem.*, **46**(6), pp. 1229–1239 (1954)]:

$$1 + 0.835\left(\frac{\rho_C}{\rho_D}\right)^{1/4}\left(\frac{V_{cf}}{V_{df}}\right)^{1/2} = C_p\left[\frac{V_{cf}^2 a_p}{g\varepsilon^3}\left(\frac{\rho_C}{\Delta\rho}\right)\sigma^{1/4}\mu_C^{1/4}\right]^{-1/4} \quad (15\text{-}142)$$

where
$$C_p = 0.87\frac{\varepsilon^{0.0068}}{a_p^{0.048}} \quad \text{for nonribbed Raschig rings} \quad (15\text{-}143)$$

$$C_p = 1.2\frac{\varepsilon^{0.78}}{a_p^{0.0351}} \quad \text{for Berl saddles} \quad (15\text{-}144)$$

$$C_p = 1.02\frac{\varepsilon^{0.0068}}{a_p^{0.048}} \quad \text{for Lessing rings} \quad (15\text{-}145)$$

In Eqs. (15-142) to (15-145), the units are as follows: viscosity in cP, interfacial tension in dyn/cm, and specific packing surface area in $ft^2/ft^3$. Other correlation methods are listed in Table 15-17. The generalized flooding model of Seibert, Reeves, and Fair [*Ind. Eng. Chem. Res.*, **29**(9), pp. 1901–1907 (1990)] was developed by using data for several types of packing and a range of operating scales, including data from a larger-scale column (42.5-cm inner diameter) using more modern packings: No. 25 IMTP® and No. 40 IMTP® random packings and Intalox® Structured Packing 2T. It has the form

$$V_{cf} = \frac{0.178\varepsilon V_{so}}{1 + 0.925(V_{df}/V_{cf})\{1/[\cos(\pi\zeta/4)]^2\}} \quad (15\text{-}146)$$

$$\zeta = \frac{a_p d_p}{2} \quad (15\text{-}147)$$

where $\zeta$ is a dimensionless tortuosity factor. The quantity $V_{so}$ is calculated by using Eqs. (15-118) to (15-123).

These correlations may be used to estimate extractor capacity for various types and sizes of packings; however, the results must be used with care due to considerable uncertainties in the calculation. This is particularly true when data for the packing of interest were not included in the data used to develop the correlation equation, and this is generally the case for the more modern packings. Nemunaitis et al. [*Chem. Eng. Prog.*, **67**(11), pp. 60–67 (1971)] recommend designing for only 20 percent of the flood point calculated by using the Crawford-Wilke correlation (or their modified version). Because of this level of uncertainty, it is recommended that some experimental data be generated for a new design. In this regard, the flooding correlations may be used to scale up the pilot plant data to a larger packing size needed for the commercial-scale unit—by calculating the expected percentage change in capacity. This extrapolation approach also may be taken to estimate the improvement that might be achieved by retrofitting an existing commercial unit with a new packing. But again, the results should be used with caution, and consultation with packing vendors is recommended.

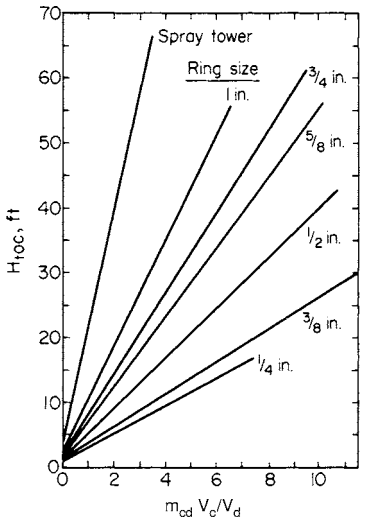

**FIG. 15-37** Extraction of diethylamine from water into toluene (dispersed) in columns packed with unglazed porcelain Raschig rings. To convert feet to meters, multiply by 0.3048; to convert inches to centimeters, multiply by 2.54. [*Reprinted from Leibson and Beckman,* Chem. Eng. Prog., ***49,*** *p. 405 (1953), with permission.*]

***Pressure Drop*** In general, the pressure drop through a packed extractor is due to the hydrostatic head pressure. The resistance to flow caused by the packing itself normally is negligible because typical packings are large, and flooding velocities are much lower than those that would be needed to develop significant $\Delta P$ from resistance to flow between the packing elements. In some applications, solids may accumulate in the region of the packing support over time, and this may cause added pressure drop and premature flooding. For additional discussion, see Laddha and Degaleesan, *Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978), Chap. 10, pp. 271–273.

***Mass Transfer*** Figure 15-37 plots the height of an overall transfer unit based on the raffinate phase $H_{or}$ versus the extraction factor $\mathcal{E}$ for a series of Raschig rings of different sizes. The data are for transfer of diethylamine from water into toluene, where toluene is the dispersed phase. The data are typical in that mass-transfer performance is shown to improve ($H_{or}$ decreases) as the size of the packing decreases. At the same time, the pressure drop must increase and hydraulic capacity decrease, so the design problem involves finding the economic optimum for the given production rate. The system water + ethylenamine + toluene is a high-interfacial-tension system, so the $H_{or}$ data in Fig. 15-37 are expected to be somewhat high compared to those in systems with lower interfacial tension due to larger drop size in a nonagitated extractor. Note that most extractor designs will involve extraction factors in the range of $\mathcal{E} = 1.3$ to 2.

Table 15-21 lists typical mass-transfer performance of various packing sizes, as given by Strigle [*Packed Tower Design and Applications*, 2d ed., Chap. 11 (Gulf, 1994)]. Strigles' table is based on experience

**TABLE 15-21 Typical Packed Extractor Performance According to Strigle***

| | Required bed depth for modern random packings, ft (m) | | |
|---|---|---|---|
| Transfer units per bed | Nominal packing size of 1 in (2.5 cm) | Nominal packing size of 1.5 in (3.8 cm) | Nominal packing size of 2 in (5 cm) |
| 1.5 | 4.4 (1.3) | 5.3 (1.6) | 6.2 (1.9) |
| 2.0 | 7.2 (2.2) | 8.6 (2.6) | 10.1 (3.1) |
| 2.5 | 9.9 (3.0) | 11.9 (3.6) | 14.0 (4.3) |

*Taken from Strigle, Chap. 11 in *Packed Tower Design and Applications*, 2d ed. (Gulf, 1994), with permission. Copyright 1994 Gulf Publishing Company. The numbers represent typical performance achieved with good liquid distribution.

with organic aqueous systems and the use of metal slotted-ring or ceramic saddle packings, using high-performance dispersion plates for liquid distribution and redistribution between packed sections.

Figure 15-37 and Table 15-21 provide only general guidelines. To estimate mass-transfer rates in packed towers, the calculation procedure outlined by Seibert, Reeves, and Fair [*Ind. Eng. Chem. Res.*, **29**(9), pp. 1901–1907 (1990)] and corrected for axial mixing [as in Eqs. (15-127) to (15-136)] is recommended. The overall mass-transfer coefficient is obtained by using Eq. (15-126). The predictive method of Handlos and Baron [*AIChE J.*, **3**(1), pp. 127–136 (1957)] allows calculation of the dipersed-phase coefficient:

$$k_d = \frac{0.00375 V_s}{1 + \mu_d/\mu_c} \qquad \text{when } \Phi = \frac{(\mu_d/\rho_d \mathcal{D}_d)^{1/2}}{1 + \mu_d/\mu_d} < 6 \tag{15-148}$$

For $\Phi > 6$, the method given by Laddha and Degaleesan [*Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978)] is recommended:

$$k_d = 0.023 V_s \left( \frac{\mu_d}{\rho_d \mathcal{D}_d} \right)^{-1/2} \tag{15-149}$$

The continuous-phase coefficient may be calculated from

$$\frac{k_c d_p}{\mathcal{D}_c} = 0.698 \left( \frac{\mu_c}{\rho_c \mathcal{D}_c} \right)^{2/5} \left( \frac{d_p V_s \rho_c}{\mu_c} \right)^{1/2} (1 - \phi_d) \tag{15-150}$$

where $V_s$ is the slip velocity of the dispersed drop [Seibert and Fair, *Ind. Eng. Chem. Res.*, **27**(3), pp. 470–481 (1988)]. While this calculation procedure can provide useful estimates, it does not replace the need for good pilot tests for any new design. Table 15-22 lists selected sources of data for mass transfer in packed columns.

**Sieve Tray Columns** A schematic diagram of the most common design of sieve tray column (also called a sieve plate or perforated-plate column) is shown in Fig. 15-32*c*. The light liquid is shown as the dispersed phase. The liquid flows up through the perforations of each tray and is thereby dispersed into drops that rise up through the continuous phase. The continuous liquid flows horizontally across each tray and passes to the tray beneath through the downcomer. For dispersing the heavy phase, the same design may be used, but turned upside down. The trays serve to eliminate (or at least greatly reduce) the vertical recirculation of continuous phase. Mass-transfer rates may be enhanced by the repeated coalescence and redispersion into droplets of the dispersed phase at each tray, although in general the overall efficiency of a sieve tray is fairly low, on the order of 15 to 30 percent. The higher efficiencies generally are achieved for systems with low to moderate interfacial tension. As discussed earlier, the liquid entering the column at the larger volumetric flow rate generally should be dispersed to obtain satisfactory interfacial area for mass transfer. Example mass-transfer data are plotted in Fig. 15-38 for low values of $\mathcal{E}$. The advantage gained by dispersing the liquid flowing at the larger rate, which results in lower values on the $x$ axis of Fig. 15-38 and consequently lower transfer unit heights, is clear.

***Liquid Distribution*** Good initial distribution is not as essential in a sieve tray extractor as it is in a packed extractor, since the trays provide redistribution. While the same distributors used in packed columns are applicable, simpler devices also are used. Capped pipes with holes drilled uniformly have been found to be adequate in many cases.

***Drop Size, Holdup, and Interfacial Area*** Drop size is estimated by using one of the models listed in Table 15-15, and holdup is estimated from expressions given in Table 15-16. Interfacial area is then calculated by using Eq. (15-109).

***Sieve Tray Design*** Perforations usually are in the range of 0.125 to 0.25 in (0.32 to 0.64 cm) in diameter, set 0.5 to 0.75 in (1.27 to 1.81 cm) apart, on square or triangular pitch. There appears to be relatively little effect of hole size on the mass-transfer rate, except that with systems of high interfacial tension, smaller holes will produce somewhat better mass transfer. The entire hole area is normally set at 15 to 25 percent of the column cross section, although adjustments may be needed. The velocity through the holes should be such that drops do not form slowly at the holes, but rather the

**TABLE 15-22 Mass-Transfer Data for Packed Columns**

| System | Column diameter, in | Packing | Ref. |

dispersed phase streams through the openings as a jet that breaks up into drops at a slight distance from the tray. It is common practice to set the velocity of liquid exiting the holes to correspond to a Weber number between 8 and 12. This normally gives velocities in the range of 0.5 to 1.0 ft/s (15 to 30 cm/s). The same general guidelines used to specify hole size and velocities for plate dispersers apply to sieve tray design. See Eqs. (15-107) and (15-108) and the related discussions in "Liquid Distributors and Dispersers" under "Liquid-Liquid Extraction Equipment."

The velocity of the continuous phase in the downcomer (or upcomer) $V_{dow}$, which sets the downcomer cross-sectional area, should be set at a value lower than the terminal velocity of some arbitrarily small droplet of dispersed phase, say, $\frac{1}{32}$ or $\frac{1}{16}$ in (0.08 or 0.16 cm) in diameter; otherwise, recirculation of entrained dispersed phase around a tray will result in flooding. The terminal velocity of these small drops can be calculated by using Stokes' law: $u_t = (gd_p^2 \Delta\rho)/18\mu_c$. Downcomer area typically is in the range of 5 to 20 percent of the total cross-sectional area, depending upon the ratio of continuous- to dispersed-phase volumetric flow rates. The downcomers should extend beyond the accumulated layer of dispersed phase on the tray, and the tray area directly opposite downcomers should be kept free of perforations.

The spacing between trays should be sufficient that (1) the "streamers" of dispersed liquid from the holes break up into drops before coalescing into the layer of liquid on the next tray; (2) the cross-flow velocity of continuous-phase liquid does not cause excessive entrainment of the dispersed phase; and (3) the column may be entered through handholes or manholes in the sides for inspection and cleaning. For systems that accumulate an interface rag, provision may be made for periodic withdrawal of the rag through the side of the column between trays. For large columns, tray spacing between 18 and 24 in (45 and 60 cm) is generally recommended.

The height of the coalesced layer at each tray is given by

$$h = \frac{\Delta P_o + \Delta P_{\text{dow}} - \phi_d g \Delta\rho L}{(1-\phi_d) g \Delta\rho} \tag{15-151}$$

where $L$ is the downcomer length. Equation (15-151) is a slightly simplified form of the expression given by Mewes and Kunkel [*Ger. Chem. Eng.*, **1,** pp. 111–115 (1978)]. In most cases holdup is low, and Eq. (15-151) reduces to $h = (\Delta P_o + \Delta P_{\text{dow}})/(g\Delta\rho)$. The orifice pressure drop $\Delta P_o$ may be calculated by using the model of Pilhofer and Goedl [*Chem. Eng. Tech.*, **49,** p. 431 (1977)]:

$$\Delta P_o = \frac{1}{2}\left(1 - \frac{0.71}{\log \text{Re}}\right)^{-2} \rho_d V_o^2 + 3.2\left(\frac{d_o^2 g \Delta\rho}{\sigma}\right)^{0.2} \frac{\sigma}{d_o} \tag{15-152}$$

where $V_o$ is the velocity through the orifice, $d_o$ is the orifice diameter, and $\text{Re} = V_o d_o \rho_d / \mu_d$. The pressure drop through the downcomer $\Delta P_{\text{dow}}$ includes losses due to (1) friction in the downcomer, which should be negligible; (2) contraction and expansion upon entering and leaving the downcomer; and (3) two abrupt changes in direction. These losses total 4.5 velocity heads:

$$\Delta P_{\text{dow}} = \frac{4.5 V_{\text{dow}}^2 \rho_c}{2} \tag{15-153}$$

For large columns, the design should be specified such that the height of the coalesced layer is at least 1 in (2.5 cm) to ensure all the holes are adequately covered, and one should allow for the trays to be slightly out of level. On the other hand, the height of the coalesced layer should not be too large, since this is unproductive column height that unnecessarily increases the total column height requirement. A typical design value is about 2 in (5 cm).

Envelope-style segmental downcomers (Fig. 15-39) often are used in commercial-scale sieve tray extractors instead of circular or pipe-style downcomers. The area of an envelope downcomer is given by

$$A = \frac{H}{6S}(3H^2 + 4S^2) \tag{15-154}$$

The distance $S$ is determined from the column diameter. The distance $H$ is obtained from

$$S = \left[8H\left(\frac{D_{\text{col}}}{2} - \frac{H}{2}\right)\right]^{1/2} \tag{15-155}$$

The diameter of a circular downcomer with equivalent area is given by

$$D_{\text{eq}} = \sqrt{\frac{4}{\pi}A} \tag{15-156}$$

***Sieve Tray Capacity at Flooding*** The capacity of a sieve tray is determined by hydraulic mechanisms involved in flooding and is not completely understood, especially for larger-diameter columns. Three studies using larger equipment have been reported by Oloidi, Jeffreys, and Mumford [*Inst. Chem. Eng. Symp. Ser.*, **103,** pp. 117–132 (1987)]; Seibert and Fair [*Ind. Eng. Chem.*, **32,** pp. 2213–2219 (1993)]; and Eldridge and Fair [*Ind. Eng. Chem.*, **38,** pp. 218–222 (1999)]. An example of sieve tray flooding data is illustrated in Fig. 15-40.

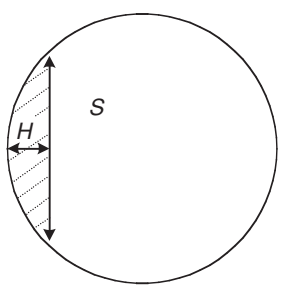

**FIG. 15-39** Dimensions of an envelope-style segmental downcomer or upcomer (shaded area).

The sieve tray capacity and efficiency are strongly influenced by the height of the coalesced layer. If the height of this layer grows to the outlet of the downcomer, a sharp reduction in efficiency will result since the mass-transfer height will be significantly reduced. In this case, the downcomer area and/or total perforated area should be increased. A flooding model based on the height of the coalesced layer is given by Seibert and Fair [*Ind. Eng. Chem. Res.*, **32**(10), pp. 2213–2219 (1993)]

$$V_{cf} = \left[\frac{L - A}{B(V_{df}/V_{cf})^2 + C}\right]^{0.5} \tag{15-157}$$

$$A = \frac{6\sigma}{d_{vs}\,\Delta\rho g} \tag{15-158}$$

$$B = \frac{1.11\rho_d}{g\,\Delta\rho f_{ha}^2} \tag{15-159}$$

$$C = \frac{2.7\rho_c}{2g\,\Delta\rho f_{da}^2} \tag{15-160}$$

where $L$ is the downcomer length, $f_{ha}$ is the fractional hole area, and $f_{da}$ is the fractional downcomer area.

***High Cross-flow of the Continuous Phase*** Miniplant tests of sieve tray extractors are often performed prior to the final design of a commercial-scale column. The design often is scaled up based on superficial velocities of the dispersed and continuous phases calculated from the volumetric flow rates and the column cross-sectional area. However, in scaling up one must be careful about the cross-flow velocity ($V_{c\text{flow}}$) of the continuous phase. A value may be estimated from

$$V_{c\text{flow}} \approx \frac{L_{fp}}{z - h} V_c \tag{15-161}$$

where $L_{fp}$ is the length of flow path, $z$ is the tray spacing, $h$ is the height of coalesced layer, and $V_c$ is the superficial continuous-phase velocity. The magnitude of the cross-flow velocity of the continuous phase can be much geater than that studied in the miniplant. Multiple downcomers or upcomers reduce the flow path length and can be utilized in new designs to reduce cross-flow velocity. Large-diameter multiple downcomer (or upcomer) trays have been reported to provide 10 to 15 percent greater capacity relative to the single-pass tray. Seibert, Bravo, and Fair [*ISEC '02 Proc.*, **2,** pp. 1328–1333 (2002)] propose a model for correcting the sieve tray capacity for high cross-flow velocity.

***Mass-Transfer Data*** Mass-transfer data are available from the sources listed in Table 15-23. Mass-transfer performance can be expressed in terms of the number of transfer units per actual tray, or in terms of overall heights of transfer units for a given column configuration, as in Fig. 15-38. The system of Fig. 15-38 is one of high interfacial tension, so the heights of transfer units are expected to be relatively large. For systems of low interfacial tension, mass-transfer performance is likely to be much improved. Since sieve trays resemble and basically behave in the manner of stages, performance also can be expressed in terms of a stage efficiency, either as an overall $\xi_o$ for the entire tower or, more satisfactorily, as a Murphree efficiency for each tray.

***Tray Efficiency*** The overall efficiencies of sieve trays typically are between 10 and 30 percent. One of the earliest models for predicting the overall tray efficiency was an empirical one reported by Treybal [*Liquid Extraction*, 2d ed. (McGraw-Hill, 1963)]. Krishna, Murty, and Rao [*Ind. Eng. Chem. Process Des. Dev.*, **7**(2),

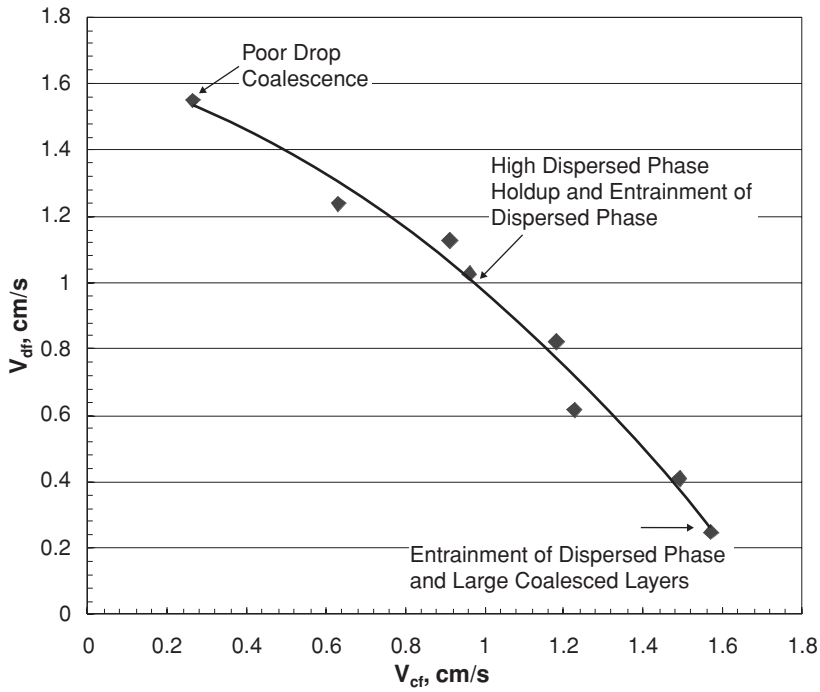

**FIG. 15-40** Sieve tray flooding data. System: toluene (dispersed) + water (continuous). Tray spacing = 30.5 cm. Column diameter = 42.8 cm. [*Taken from Seibert, Bravo, and Fair,* ISEC '02 Proc., ***2,*** *pp. 1328–1333 (2002), with permission. Copyright 2002 South African Institute of Mining and Metallurgy.*]

pp. 166–172 (1968)] modified the Treybal model to account for hole diameter:

$$\xi_o = 0.21\left(\frac{z^{0.5}}{\sigma d_o^{0.35}}\right)\left(\frac{V_d}{V_c}\right)^{0.42} \tag{15-162}$$

where $z$ is the tray spacing, cm; $d_o$ is the hole diameter, cm; and $\sigma$ is interfacial tension, dyn/cm. Seibert and Fair [*Ind. Eng. Chem.*, **32**(10), pp. 2213–2219 (1993)] recommend calculating the local Murphree stage efficiency based on the dispersed phase, assuming a log mean driving force and negligible mass-transfer contribution from drop formation:

$$\xi_{md} = 1 - \exp\left[-\frac{6k_{od}\phi_d(z-h)}{d_p V_d}\right] \tag{15-163}$$

The overall tray efficiency may then be estimated by using

$$\xi_o = \frac{\ln\left[1+\xi_{md}(\mathcal{E}-1)\right]}{\ln \mathcal{E}} \tag{15-164}$$

$$\mathcal{E} = m_{dc}^{\text{vol}}\frac{V_d}{V_c} \tag{15-165}$$

Equation (15-163) assumes plug flow of the rising or falling drop population and complete mixing of the continuous phase on the tray. Also see Eldridge and Fair, *Ind. Eng. Chem. Res.*, **38,** pp. 218–222 (1999); Rocha et al., *Ind. Eng. Chem. Res.*, **28**(12), pp. 1873–1878 (1989); and Rocha, Cárdenas, and García, *Ind. Eng. Chem. Res.*, **28**(12), pp. 1879–1883 (1989).

**Baffle Tray Columns** Baffle tray columns are similar to spray columns except that baffles are added to reduce backmixing. The baffles usually are slightly sloped to drain any solids that might settle out in the column and are designed to provide a high open area. Lemieux [*Hydrocarbon Proc.*, **62**(9), pp. 106–111 (1983)] and Fair [*Hydrocarbon Proc.*, **72**(5), pp. 75–79 (1993)] report on the performance and design of these columns for gas-liquid contacting. Treybal [*Liquid Extraction*, 2d ed. (McGraw-Hill, 1963)] provides a brief but valuable description of a baffle tray extractor. Although no design equations or performance data are provided, Treybal indicates that commercial tray spacings should be in the range of 10 to 15 cm (4 to 6 in). Treybal also provides an interesting illustration of a baffle tray extractor in operation (Fig. 15-41). This figure shows multiple trays with a very short spacing, with the dispersed light phase moving as a layer of liquid under each tray.

Because baffle tray performance data are not widely available, the results of a pilot-scale study (Seibert, Lewis, and Fair, Paper No. 112a, AIChE National Meeting, Indianapolis, 2002) are summarized in Figs. 15-42 to 15-47. The study was carried out using a 4.0-in-(10.2-cm-) diameter column set up with 5 to 30 trays. The trays were arranged in a side-to-side horizontal arrangement, as indicated in Fig. 15-41*a*. The data were generated by using the toluene (dispersed) + acetone + water (continuous) and butanol (dispersed) + succinic acid + water (continuous) systems. The effects of changes in baffle spacing and tray overlap (expressed as the percentage of total tray area covered by the next tray above or below) were measured for transfer of solute from the organic to the aqueous phase.

***Hydraulic Capacity*** The capacity of the baffle trays at flooding was found to depend strongly on system properties, as shown in Fig. 15-42. The butanol system with its lower interfacial tension provided a much lower capacity relative to the toluene system with its higher interfacial tension. The capacity was found to be independent of tray spacing, as shown in Fig. 15-43. However, capacity was strongly affected by the degree of tray overlap, as shown in Figs. 15-44 and 15-45. See Seibert, Lewis, and Fair (Paper No. 112a, AIChE National Meeting, Indianapolis, 2002) for discussion of a proposed flooding model.

**TABLE 15-23 Mass-Transfer Data for Sieve Tray Columns**

| System | Column diameter, in | Tray spacing, in | Ref. |
|---|---|---|---|
| Benzene–acetic acid–water | 1.97 | 3.9–6.3 | 25 |
| | 1.97 | 3.2–6.3 | 24 |
| | 2.2 | 2.8–6.3 | 23 |

***Baffle Tray Efficiency*** Baffle tray mass-transfer efficiency was observed to depend strongly on the tray spacing and system properties, as shown in Figs. 15-46 and 15-47. In these studies, a tray spacing of about 10 cm provided a minimum HETS. The data indicate that the performance of baffle trays relative to sieve trays depends upon the interfacial tension of the system. For the high-interfacial-tension system (Fig. 15-46), the baffle tray performance (in terms of capacity and mass transfer) is relatively low compared to that of a sieve tray. However, for the low-interfacial-tension system (Fig. 15-47), performance was somewhat better using 62 percent tray overlap.

## AGITATED EXTRACTION COLUMNS

In certain applications, the mass-transfer efficiency of a static extraction column is quite low, especially for systems with moderate to high interfacial tension. In these cases, efficiency may be improved by mechanically agitating the liquid-liquid dispersion within the column to better control drop size and population density (dispersed-phase holdup). Many different types of mechanically agitated extraction columns have been proposed. The more common types include various rotary-impeller columns, the reciprocating-plate column, and the rotating-disk contactor (RDC). The following is a brief review. For more detailed discussion, see *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994); *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992); and *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991).

**Rotating-Impeller Columns** A number of different rotating-impeller column extractors have been proposed and built over the years. Only the Scheibel and Kühni designs are reviewed here. For information about the Oldshue-Rushton design, see the previous edition of this handbook. Also see Oldshue, Chap. 13.4 in *Handbook of*

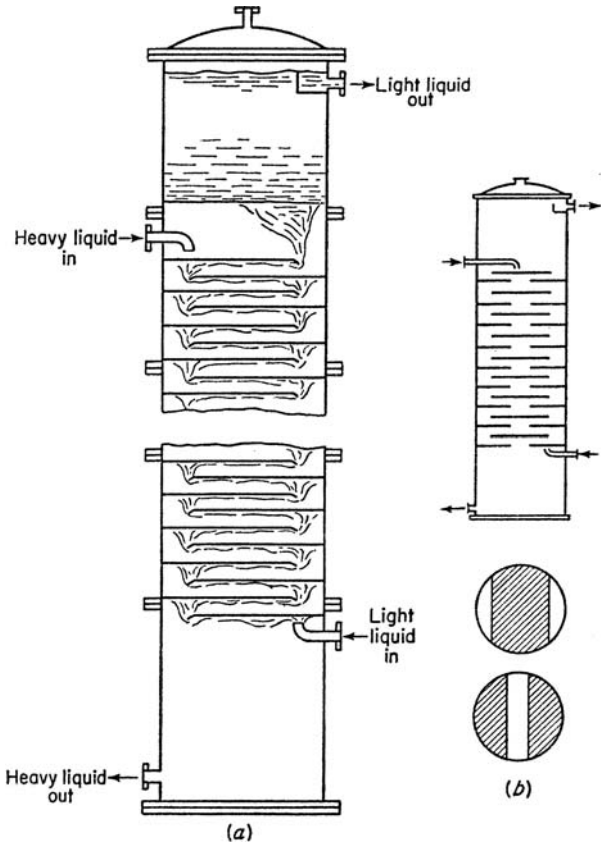

**FIG. 15-41** Baffle towers. (*a*) Side-to-side flow at each tray. (*b*) Center-to-center flow (disk-and-doughnut style). (*c*) Center-to-side flow. [*Reprinted from Treybal,* Liquid Extraction *(McGraw-Hill, 1963), with permission. Copyright 1963 McGraw-Hill, Inc.*]

*Solvent Extraction,* Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991).

***Scheibel Extraction Column*** The original Scheibel column design consisted of a series of knitted-wire-mesh packed sections placed within a vertical column, with a centrally located impeller between each section and no baffles [Scheibel and Karr, *Ind. Eng. Chem.,* **42**(6) pp. 1048–1057 (1950)]. A second-generation Sheibel design [*AIChE J.,* **2**(1), pp. 74–78 (1956); U.S. Patent 2,850,362 (1958)] added flat partitions or baffles to the ends of each packed section, and the impellers were surrounded by stationary shroud baffles to direct the flow of droplets discharged from the impeller tips. The new baffling arrangement improved efficiency, allowing design of larger-diameter columns with less power input and decreased height per theoretical stage. A third design by Scheibel [U.S. Patent 3,389,970 (1968)] eliminated the wire-mesh packing and retained the use of baffles and shrouded impellers (Fig. 15-48). The packed sections were replaced by agitated sections. This design was developed because the wire-mesh packed sections were prone to fouling (plugging) and difficult to clean. A Scheibel extractor of this type is very well suited to handling mixtures with high interfacial tension and can be designed with a large number of stages. It is not as well suited for systems that tend to emulsify easily owing to the high shear rate generated by a rotating impeller. Because of its internal baffling, which controls the mixing patterns on the stages, the Scheibel column has proved to be one of the more efficient extractors in terms of height of a theoretical stage; this makes it well suited to applications that require a large number of stages or are located indoors with headroom restrictions. Holmes, Karr, and Cusack [*Solvent Extraction and Ion Exchange,* **8**(3), pp. 515–528 (1990)] have published results comparing the efficiency of the Scheibel column to that of other extractors using the system toluene + acetone + water. For additional discussion, see Scheibel, Chap. 13.3 in *Handbook of Solvent Extraction,* Lo, Baird, and Hansen, eds. (Wiley, 1983; Kreiger, 1991). A related column design called the AP column consists of alternating sections of Scheibel-type agitators and structured packing [Cusack, Glatz, and Holmes, *Proc. ESEC'99, Soc. Chem. Ind.,* p. 427 (2001)]. The high open area of the packing allows for higher capacity while the agitation provides increased efficiency.

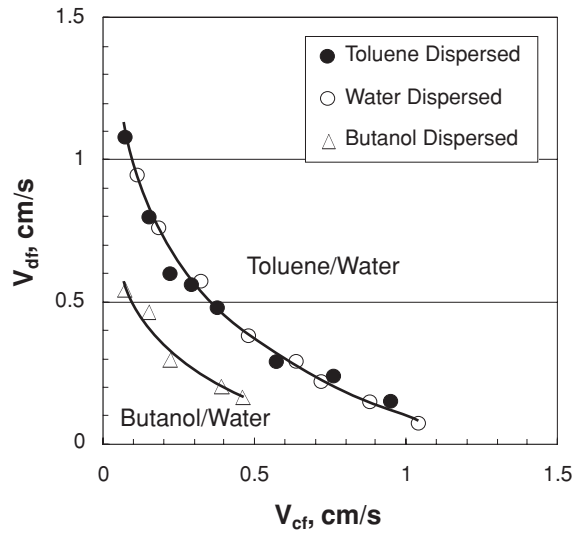

**FIG. 15-42** Capacity characteristics of a baffle tray extractor. Tray overlap = 62 percent. Column diameter = 10.2 cm. [*Taken from Seibert, Lewis, and Fair, Paper No. 112a, AIChE National Meeting, Indianapolis (November 2002), with permission. Copyright 2002 AIChE.*]

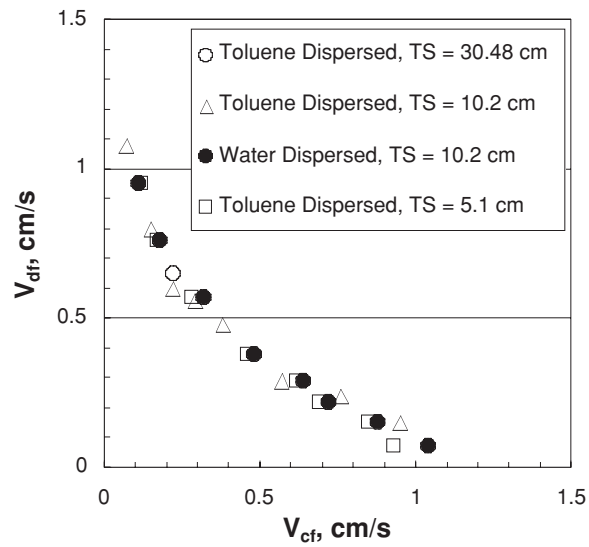

**FIG. 15-43** Effect of tray spacing on baffle tray capacity. [*Taken from Seibert, Lewis, and Fair, Paper No. 112a, AIChE National Meeting, Indianapolis (November 2002), with permission. Copyright 2002 AIChE.*]

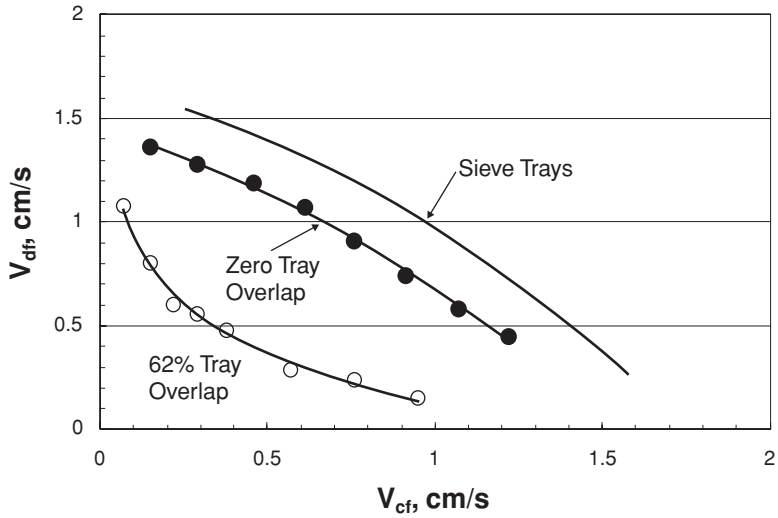

**FIG. 15-44** Effect of tray overlap on baffle tray capacity. System: toluene (*d*) + acetone + water (*c*). [*Taken from Seibert, Lewis, and Fair, Paper No. 112a, AIChE National Meeting, Indianapolis (November 2002), with permission. Copyright 2002 AIChE.*]

As with most agitated extractors, the final design of a Scheibel column typically involves scale-up of data generated in a miniplant or pilot-plant test. The column vendor should be consulted for specific information. The key scale-up guidelines are as follows: (1) $D_t(2)/D_t(1) = [Q(2)/Q(1)]^{0.4}$; (2) $Z_t(2)/Z_t(1) = [D_t(2)/D_t(1)]^{0.70}$; (3) stage efficiency is the same for the pilot and full scale; and (4) power per unit volume is the same for each scale [Cusack and Karr, *Chem. Eng. Magazine*, pp. 112–119 (1991)]. Industrial columns up to 10 ft (3 m) in diameter and containing 90 actual stages have been designed using the following general procedures and a 3-in (75-mm) pilot column:

1. Pilot tests usually are conducted in 3-in (75-mm-) diameter columns. The column should contain a sufficient number of stages to complete the extraction. This may require several iterations on column height.

2. The column is run over a range of throughputs $V_d + V_c$ and agitation speeds. At each condition, the concentrations of solute in extract and raffinate streams are measured after steady-state operation has been achieved (usually after 3 to 5 turnovers of column volume). At each throughput, the flood point is determined by increasing the agitation until flooding is induced. A minimum of three throughput ranges are examined in this manner. Mass-transfer performance is measured at several agitation speeds up to the flood point.

3. From the above mass-transfer and flooding data, the combination of specific throughput and agitation speed that gives the optimum economic performance for the required separation can be determined. This information is used to specify the specific throughput value [gal/(h·ft$^3$) or m$^3$/(h·m$^3$)] and agitation speed (rpm) for the commercial design. However, unlike the RDC and Karr columns, for

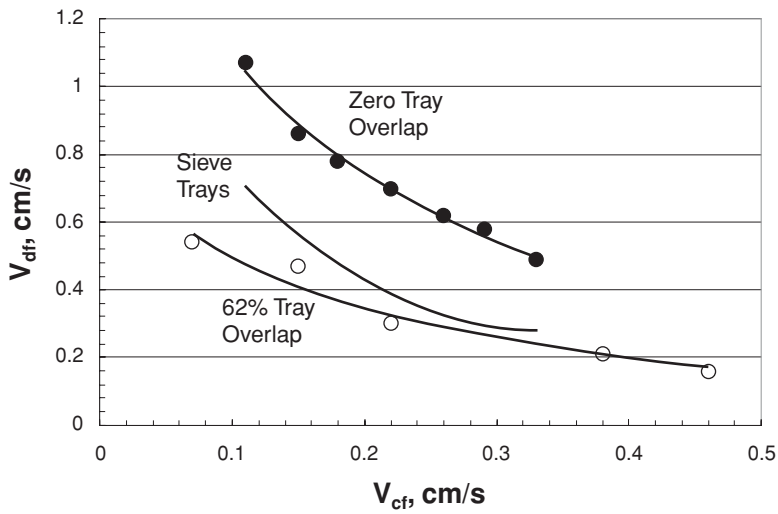

**FIG. 15-45** Effect of tray overlap on baffle tray capacity. System: *n*-Butanol (*d*) + succinic acid + water (*c*). [*Taken from Seibert, Lewis, and Fair, Paper No. 112a, AIChE National Meeting, Indianapolis (November 2002), with permission. Copyright 2002 AIChE.*]

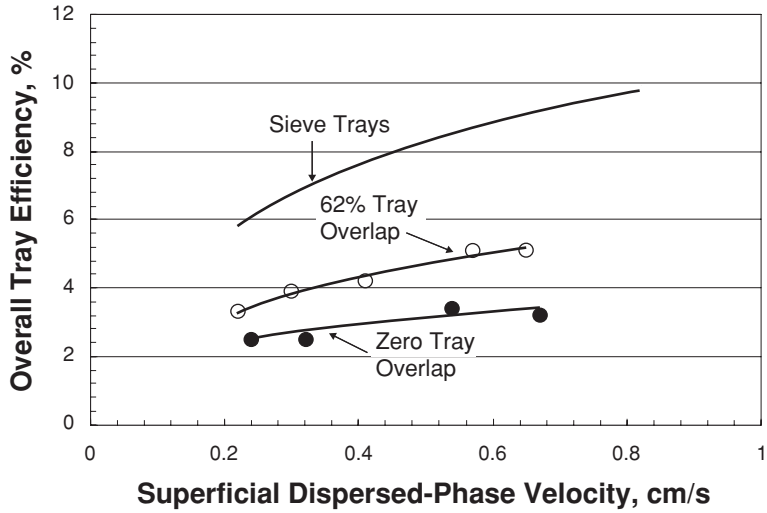

**FIG. 15-46** Effect of tray overlap on baffle tray efficiency. System: toluene (*d*) + acetone + water (*c*). Tray spacing = 10.2 cm. [*Taken from Seibert, Lewis, and Fair, Paper No. 112a, AIChE National Meeting, Indianapolis (November 2002), with permission. Copyright 2002 AIChE.*]

which the specific throughput of the scaled-up version is the same as that of the pilot column, it is a characteristic of the Scheibel column that the throughput of the scaled-up column is on the order of 3 to 5 times greater than that achieved on the 3-in-diameter pilot column. The limited throughput of the 3-in column is due to its restrictive geometry; these restrictions are removed in the scaled-up columns.

4. Once the column diameter is determined, the stage geometry can be fixed. The geometry of a stage is a complex function of the column diameter. In the 3-in pilot column, the stage height-to-diameter ratio is on the order of 1:3. On a 10-ft- (3-m-) diameter column, it is on the order of 1:8. The recommended ratio of height to diameter is $Z_t(2)/Z_t(1) = [D_t(2)/D_t(1)]^{0.70}$.

5. The principle of the Scheibel column scale-up procedure is to maintain the same stage efficiency. Therefore, the scaled-up column will have the same number of actual stages as the pilot column. The only difference is that the stages will be taller, to take into account the effect of axial mixing. With the agitator dimensions determined, the speed is then calculated to give the same power input per unit of throughput. Scheibel found that power input can be correlated by

$$P = 1.85\rho\omega^3 D_i^5 \tag{15-166}$$

where $P$ is the power input per mixing stage, $D_i$ is the impeller diameter, $\rho$ is the average liquid density, and $\omega$ is the impeller speed (rotations per unit time).

***Kühni Column*** Like the Scheibel column, the Kühni column uses shrouded (closed) turbine impellers as mixing elements on a central shaft (Fig. 15-49). Perforated partitions or stator plates extend

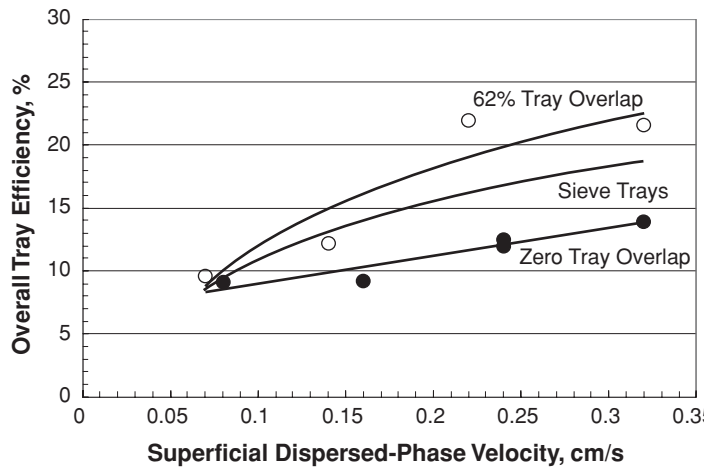

**FIG. 15-47** Effect of tray overlap on baffle tray efficiency. System: *n*-butanol + succinic acid + water. Tray spacing = 10.2 cm. [*Taken from Seibert, Lewis, and Fair, Paper No. 112a, AIChE National Meeting, Indianapolis (November 2002), with permission. Copyright 2002 AIChE.*]

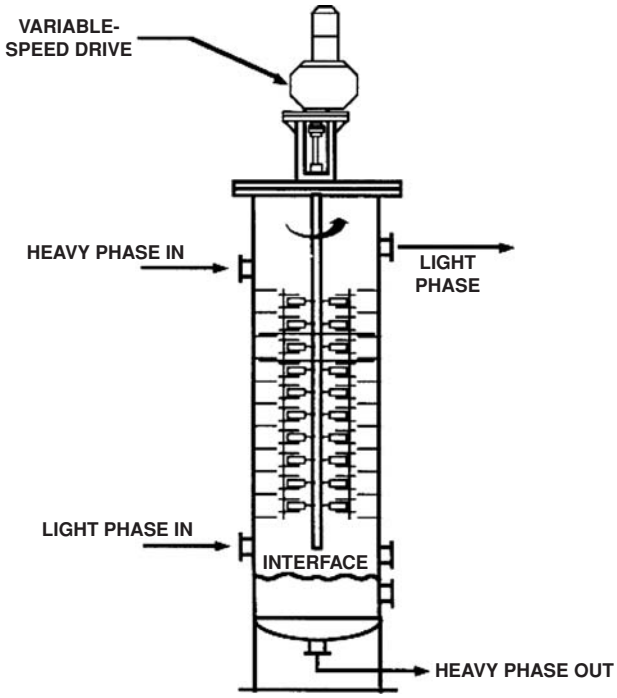

**FIG. 15-48** Scheibel column extractor (third-generation design). (*Courtesy of Koch Modular Process Systems.*)

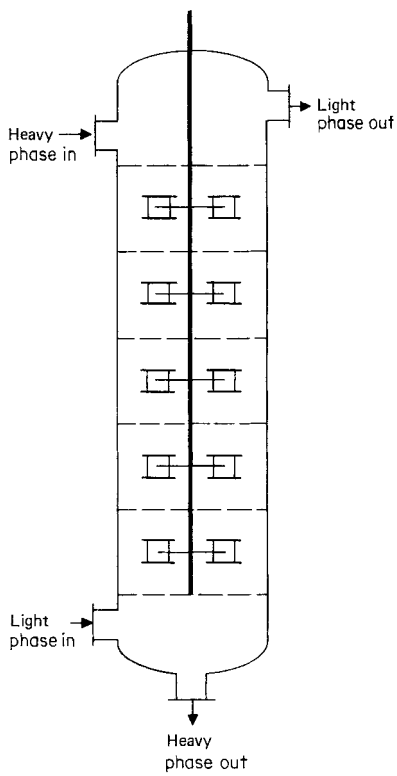

**FIG. 15-49** Kühni column extractor.

over the vessel cross section to separate the extraction stages and reduce backmixing between stages. The fractional free-flow area between compartments can be adjusted by changing the free area around the rotor shaft and/or the perforations in the stator plate. As the free-flow area increases, throughput increases at the expense of increased axial mixing of the continuous phase and reduced mass-transfer performance. Throughput typically varies from 30 $m^3/(h \cdot m^2)$ [750 $gal/(h \cdot ft^2)$] to significantly higher values depending upon the specific design factors chosen to meet the requirements of a given application.

Mögli and Bühlmann [Chap. 13.5 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991)] outline general considerations for specifying a commercial design from pilot data. The column vendor should be consulted for specific information. The scale-up procedures are based upon hydrodynamic and geometric similarity between the pilot-scale and plant-scale designs. Individual stage geometry (impeller size and free area of the stator plate) may be tailored for each stage, especially in cases where physical properties vary significantly along the column length. Mögli and Bühlmann suggest design options to maintain a somewhat uniform interfacial area along the column to minimize the impacts of axial mixing. Pratt and Stevens [*Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992), [Chap. 8, p. 541] provide recommended scale-up factors for a Kühni column as follows: $D_i/D_t$ = 0.33 to 0.5, compartment height = 0.2 to $0.3D_t$, and the fractional free area of the stator plates = 0.2 to 0.4. The minimum recommended diameter for the pilot column is 60 mm (2.4 in) for specifying columns up to 1 m in diameter and 150 mm (6 in) for specifying larger-diameter columns.

A stagewise computational procedure is proposed by Kumar and Hartland [*Ind. Eng. Chem. Res.*, **38**(3), pp. 1040–1056 (1999)] for design of a Kühni column. The procedure considers backflow of the continuous phase, with an attempt to estimate average drop size, drop size distribution, dispersed-phase holdup, flooding velocities, mass-transfer coefficients, and axial mixing. A design example for extraction of aniline from water is presented. This approach to design can be very useful for initial estimates, but as with all agitated extractors, some pilot testing is recommended for a final commercial design. Also see the discussion by Gomes et al. [*Ind. Eng. Chem. Res.*, **43**(4), pp. 1061–1070 (2004)].

**Reciprocating-Plate Columns** Another approach to agitating a dispersion within an extraction column is the use of reciprocating plates. This generally results in a more uniform drop size distribution because the shear forces are more evenly distributed over the entire cross section of the column. Reciprocating-plate extractors have a wide turndown range and are well suited to systems with moderate interfacial tension. They often can handle systems exhibiting a tendency to emulsify, and because of their high open-area design, they can handle slurries of solids, some containing as much as 30 percent solids by weight. Several types of reciprocating-plate extractors have been designed; design differences generally involve differences in the plate open area and plate spacing as well as the inclusion or omission of static baffles or downcomers. For detailed discussion of these designs, see Lo and Procházka, Chap. 12 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991); and Baird et al., Chap. 11 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994).

The Karr reciprocating-plate column (Fig. 15-50) is a popular example. It uses dual-flow plates with 50 to 60 percent open area and has no downcomers [Karr, *AIChE J.*, **5**(4), pp. 446–452 (1959); Karr and Lo, *Chem. Eng. Prog.*, **72**(11), pp. 68–70 (1976); and Karr, *AIChE J.*, **31**(4), pp. 690–692 (1985)]. Because of the high open area, a Karr column may be operated with relatively high throughput compared to other types of agitated columns, up to about 1000 $gal/(h \cdot ft^2)$ [40 $m^3/(h \cdot m^2)$] depending upon the application. The plates are mounted on a central shaft that moves up and down through a stroke length of up to 2 in (5 cm). As the diameter of the column increases, the HETS achieved by the column tends to increase due to axial mixing effects. For columns with a diameter greater than 1 ft (0.3 m), doughnut-shaped baffle plates may be added every 5 plates (typically) within the plate stack to minimize axial mixing. A Karr column also is well suited

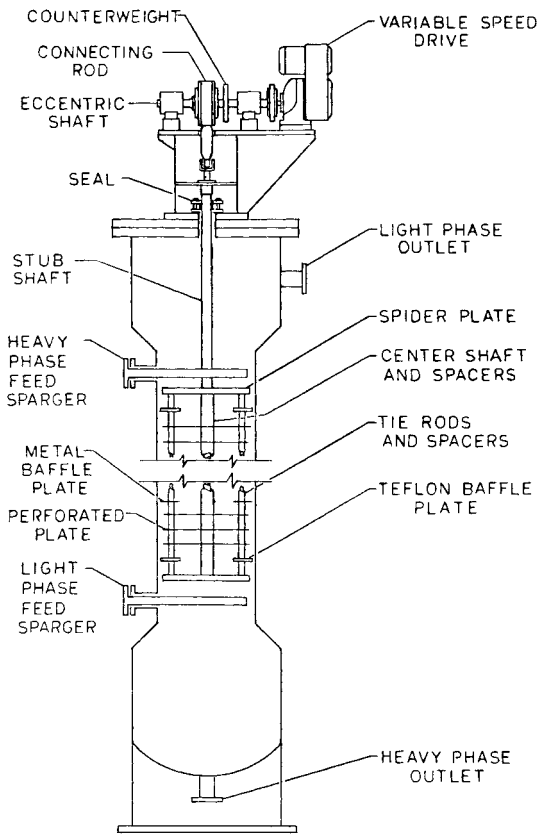

**FIG. 15-50** Karr reciprocating-plate extraction column.

for corrosive systems since the plates can be fabricated from nonmetallic materials. Pratt and Stevens [Chap. 8 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thornton, ed. (Oxford, 1992), p. 556] provide recommended geometric design and operating conditions for a Karr column as follows: reciprocation amplitude = 1 to 2 in (2.5 to 5 cm) with a 1-in amplitude being most common; reciprocation speed = 10 to 400 complete strokes (up and down) per minute; plate spacing = 2 to 6 in (5 to 15 cm); hole pitch = 0.625 to 0.75 in (1.6 to 1.9 cm); hole diameter = 0.50 to 0.625 in (1.3 to 1.6 cm); plate wall clearance = 1.25 to 2.5 in (3.2 to 6.4 cm). The plate spacing may be graduated to produce uniform drop size and population density along the length of the column, particularly for systems with high solute concentrations and depending upon how physical properties change along the column length [Karr, U.S. Patent 4,200,525 (1980)].

Baird et al. [Chap. 11 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994)] discuss and summarize correlations for predicting holdup and flooding, mean drop diameter, axial mixing, mass transfer, and reciprocating-plate column performance. Kumar and Hartland [*Ind. Eng. Chem. Res.*, **38**(3), pp. 1040–1056 (1999)] present a correlation-based computational procedure for design of a Karr reciprocating-plate column, and they give an example for separation of acetone from water by using toluene. A backmixing model is described by Stella et al. [*Ind. Eng. Chem. Res.*, **45**(19), pp. 6555–6562 (2006)].

As with other agitated extractors, the final design of a commercial-scale Karr column is based on pilot test data. The column vendor should be consulted for specific information. The following general procedure is recommended:

1. For specifying commercial columns up to 6.5 ft (2 m) in diameter, testing in a pilot column of 1-in (25-mm) diameter is sufficient. If the anticipated scaled-up diameter is greater than 6.5 ft, then the pilot tests should be conducted in a 2-in- (50-mm-) diameter column. The column should be tall enough to accomplish the complete extraction. This may require several iterations on column height.

2. The column is first optimized with regard to plate spacing. The plate spacing is adjusted along the length of the column to obtain the same tendency to flood everywhere in the column. If one particular section appears to flood early, limiting the throughput, then the plate spacing should be increased in this section. This will decrease the power input into that section. Similarly, in sections that appear to be undermixed because the population of drops is low, the plate spacing should be decreased.

3. Once the plate spacing is optimized, the column is run over a range of total throughputs ($V_d + V_c$) and agitation speeds. There should be a minimum of three throughput levels and at each throughput three agitation speeds. After steady state is attained at each condition (usually 3 to 5 turnovers of column volume), samples are taken and the separation is measured. At each condition the flood point also is determined. In small-scale tests, the data used for scale-up should be collected at a point very close to flooding, say, 95 percent of flooding. Scaling these data typically results in a commercial-scale unit that operates at roughly 80 or 85 percent of flooding.

4. From the data, plots are made of volumetric efficiency and agitation speed at each throughput level. From these plots the condition that gives the maximum volumetric efficiency is selected for scale-up. For additional discussion, see Lo and Prochazka, Chap. 12 in *Handbook of Solvent Extraction,* Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991).

5. For scale-up, the following parameters are kept constant: total throughput per unit area, plate spacing, and stroke length. The height and agitation speed of the scaled-up column are then calculated from the following relationships:

$$\frac{Z_t(2)}{Z_t(1)} = \left(\frac{D_{\text{col}}(2)}{D_{\text{col}}(1)}\right)^{0.38} \tag{15-167}$$

$$\frac{\text{SPM}(2)}{\text{SPM}(1)} = \left(\frac{D_{\text{col}}(1)}{D_{\text{col}}(2)}\right)^{0.14} \tag{15-168}$$

Here $Z_t$ is the plate stack height, $D_{\text{col}}$ is the column diameter, SPM is the reciprocating speed (complete strokes per minute), and 1 and 2 denote the pilot column and the scaled-up column, respectively.

Karr and Ramanujam [St. Louis AIChE Symposium (March 19, 1987)] propose a power per unit volume normalization factor for scale-up of the reciprocation speed if the pilot column plates have a different open area than the industrial scale plates, as follows:

$$\frac{\text{SPM}(2)}{\text{SPM}(1)} = \left(\frac{D_{\text{col}}(1)}{D_{\text{col}}(2)}\right)^{0.14}\left(\frac{\varepsilon(2)^2}{1-\varepsilon(2)^2}\right)\left(\frac{1-\varepsilon(1)^2}{\varepsilon(1)^2}\right) \tag{15-169}$$

where $\varepsilon$ is the fractional open area of the perforated plate.

**Rotating-Disk Contactor** The rotary-disk contactor (RDC) is a vertical column containing an assembly of rotating disks and stationary baffles or stators. A typical design is illustrated in Fig. 15-51. The column is formed into compartments by horizontal doughnut-shaped or annular baffles, and within each compartment agitation is provided by a rotating, centrally located, horizontal disk. The rotating disk is smooth and flat and has a diameter less than that of the opening in the stationary baffles. The RDC extractor has been widely used because of its simplicity of construction, availability in relatively large diameters for high production rates, and low power consumption. For detailed reviews, see Chaps. 9 and 17 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994); and Chaps. 13.1 and 13.2 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991). Also see Al-Rahawi, *Chem. Eng. Technol.*, **30**(2), pp. 184–192 (2007); Drumm and Bart, *Chem. Eng. Technol.*, **29**(11), pp. 1297–1302 (2006).

The RDC has a moderate throughput typically in the range of 20 to 35 $m^3/(h \cdot m^2)$ [500 to 850 gal/(h·ft$^2$)], and it can be turned down to 20 to 35 percent of the design rate. However, the relatively open arrangement leads to some backmixing and results in only moderate mass-transfer performance. As a consequence, some RDC columns are being replaced by more efficient extractor designs. The RDC can be

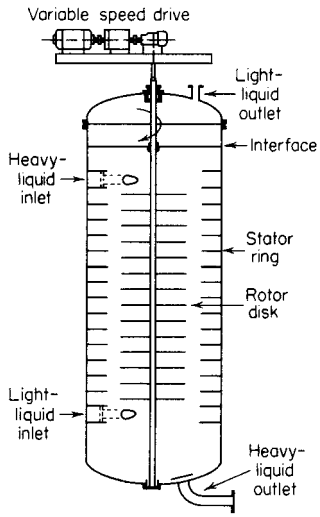

**FIG. 15-51** Typical rotating-disk contactor.

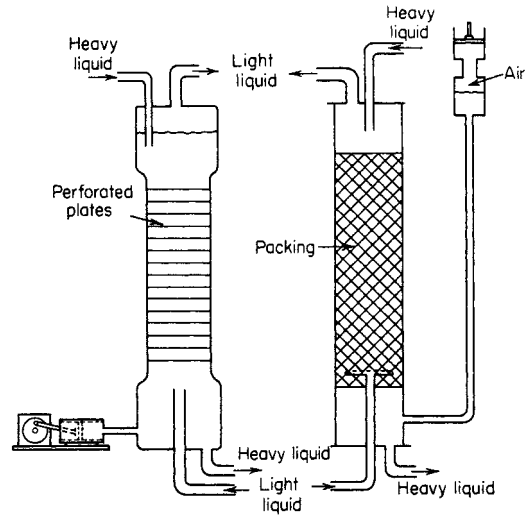

**FIG. 15-52** Pulsed-liquid columns. (*a*) Sieve tray column with pump-type pulse generator. (*b*) Packed column with air pulser.

used for systems with moderate viscosities up to about 100 cP and can be used for systems that tend to foul easily. The RDC also is suitable for systems with slow mass-transfer rates requiring only a few theoretical stages. An RDC can have difficulty handling feeds with emulsion formation tendencies, so it may not be suitable for some systems with low interfacial tension and low density difference.

**Pulsed-Liquid Columns** These are packed or tray column extractors in which a rapid reciprocating motion of relatively short amplitude is applied to the liquid contents to give improved rates of extraction (Fig. 15-52). Liquid pulsing improves the mass-transfer performance at a cost of somewhat reduced throughput. For detailed reviews of this technology, see Logsdail and Slater, Chap. 11.2 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991)]; Pratt and Stevens, Chap. 8 in *Science and Practice of Liquid-Liquid Extraction*, vol. 1, Thorton, ed. (Oxford, 1992); and Haverland and Slater, Chap. 10 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994). Also see Bujalski et al., *Chem. Eng. Sci.*, **61,** pp. 2930–2938 (2006), for discussion of a disk and doughnut type of column extractor operated with pulsed liquid. Externally pulsing the liquid to impart mechanical agitation allows for a sealed agitated extraction column with no moving parts. This feature is important for special applications involving highly corrosive or dangerously radioactive liquids, and it is the main reason why pulsed columns commonly are applied in the extraction and separation of metals from solutions in atomic energy operations. Pulsed-liquid contactors are similar to reciprocating-plate extractors in their basic operation. However, considerably more energy generally is required to move the entire column of liquid than to move the plates. For this reason, a reciprocating-plate or other type of mechanically agitated column design generally is preferred, unless special conditions require a sealed extraction column.

**Raining-Bucket Contactor (a Horizontal Column)** The "raining-bucket" contactor, originally developed by the Graesser Company in the United Kingdom, consists of a horizontal column or shell, as illustrated in Fig. 15-53. The shell slowly rotates about a central axis, and during operation a main liquid-liquid interface is maintained near the centerline. The light phase is continuous in the upper half of the shell, and the heavy phase is continuous in the lower half. Buckets mounted within the shell pick up continuous phase in one half and discharge it as dispersed droplets into the other half. As a result, each phase is dispersed. The raining-bucket design is intended for systems

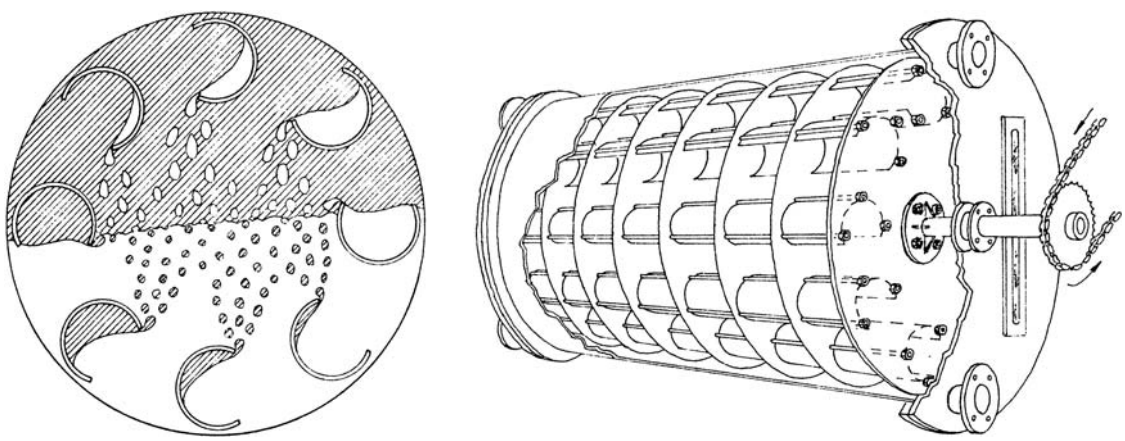

**FIG. 15-53** Schematic views of a Graesser raining-bucket contactor. [*Reprinted from Coleby, Chap. 13.6 in* Handbook of Solvent Extraction, *Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991), with permission.*]

with low density difference and low interfacial tension, i.e., systems that tend to emulsify easily. It was originally developed for handling difficult settling systems in the coal-tar industry. A detailed review is given by Coleby [Chap. 13.6 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Kreiger, 1991)]. Units currently are available through the Biotechna Company.

The rotor assembly of a raining-bucket contactor is made of a series of disks that divide the shell into a series of compartments. Each compartment contains an assembly of buckets. A small gap is maintained between the edge of the disks and the interior wall of the shell to allow for flow between compartments. The gap needs to be small to minimize backmixing. During operation, the phases are fed and removed from opposite ends of the column to produce a countercurrent flow. Throughput generally is low compared to that of other mechanically agitated extractors owing to the limited cross-sectional area available for flow. Rotational speeds are in the range of 0.25 to 40 rpm depending upon the contactor diameter and physical properties of the phases. Coleby [Chap. 13.6 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Kreiger, 1991)] indicates that raining-bucket contactors can achieve up to 0.3 theoretical stage per compartment depending upon the application. Applications should not involve too high a viscosity in either phase, since dispersing drops in a high-viscosity continuous phase can result in slow liquid-liquid phase separation, and this can severely limit mass-transfer performance and the throughput of the extractor. Experience indicates that careful attention to this possibility is needed if viscosity is on the order of 30 cP or greater. A theoretical approach to estimating axial mixing and efficiency in a raining-bucket extractor is presented by Dente and Bozzano [*Ind. Eng. Chem. Res.*, **43**(16), pp. 4761–4767 (2004)]. A biotechnology application is described by Jarndilokkul, Paulsen, and Stuckey [*Biotechnol. Prog.*, **16**(6), pp. 1071–1078 (2000)].

## MIXER-SETTLER EQUIPMENT

Mixer-settlers are used in hydrometallurgical processing for recovery of metals from aqueous acid solutions, and in multistep batchwise production of specialty chemicals including pharmaceuticals and agricultural chemicals, among other applications. In principle, any mixer may be coupled with any settler to obtain a complete stage. The function of a single stage within the cascade is to contact the liquids so that equilibrium is closely approached (achieving a high stage efficiency), and then to separate the liquids so they can be routed to the next stage. The design must strike a balance between contacting and settling requirements; i.e., the liquids should be mixed with sufficient intensity to suspend drops and facilitate good mass transfer, but not so intensely that drop sizes are too small and settling of the resulting dispersion is problematic.

A mixer-settler operation may be carried out batchwise or with a continuous feed. If batchwise operation is chosen, the same vessel used for mixing often is used for settling. Batchwise extraction in a stirred tank is a common operation in multistep, batchwise manufacture of complex organics. Such equipment allows flexibility to accommodate batch-to-batch variability, can ensure a single batch remains isolated from other batches throughout the manufacturing process (sometimes a regulatory requirement for pharmaceuticals), and is suitable for multipurpose plants producing a variety of products in campaigns. A batchwise process may be implemented in cocurrent, cross-current, or countercurrent multistage arrangements. A countercurrent operation is carried out as in Figs. 15-6 and 15-22, by initially treating the feed batch with extract solution as the extract leaves the process. The final treatment is carried out using fresh solvent as it enters the process. A two-stage batchwise countercurrent process scheme is common practice.

Continuously operated devices may place the mixing and settling functions in separate vessels or combine them into a single, specially designed vessel with compartments for mixing and settling. Continuous mixer-settlers are particularly attractive for applications requiring several equilibrium stages and long residence times due to slow extraction kinetics, especially for applications involving the use of reactive extractants or viscous fluids. Mixing commonly is done using rotating impellers. Impeller type, shape, size, tip speed, and position within the mixing vessel may be adjusted to optimize the overall design. A static mixer may be a feasible alternative, but only if the required mass transfer can be accomplished in the short contacting time these devices allow, without generating a difficult-to-separate dispersion. Mixer-settlers may offer other advantages including easy start-up and operation, the ability to handle very high production rates and suspended solids, and the ability to achieve high stage efficiency with proper design. For systems that accumulate rag layers (sludges) between settled liquid layers, the rag material may easily be removed at each settler. As a potential disadvantage, difficult-to-break emulsions may be formed from the shear due to mixing and pumping liquids between tanks. Mixer-settlers also generally require large floor space, and the relatively long residence time in a mixer-settler can be a disadvantage if the desired solute is degraded over time at the required extraction conditions.

**Mass-Transfer Models** Because the mass-transfer coefficient and interfacial area for mass transfer of solute are complex functions of fluid properties and the operational and geometric variables of a stirred-tank extractor or mixer, the approach to design normally involves scale-up of miniplant data. The mass-transfer coefficient and interfacial area are influenced by numerous factors that are difficult to precisely quantify. These include drop coalescence and breakage rates as well as complex flow patterns that exist within the vessel (a function of impeller type, vessel geometry, and power input). Nevertheless, it is instructive to review available mass-transfer coefficient and interfacial area models for the insights they can offer.

The correlation of Skelland and Moeti [*Ind. Eng. Chem. Res.*, **29**(11), pp. 2258–2267 (1990)] for estimating individual continuous-phase mass-transfer coefficients is given by

$$\frac{k_c d_p}{\mathcal{D}_c} = 1.237 \times 10^{-5}\left(\frac{\mu_c}{\rho_c \mathcal{D}_c}\right)^{1/3}\left(\frac{D_i \omega^2}{g}\right)^{5/12}\left(\frac{D_i}{d_p}\right)^2 \times \left(\frac{d_p}{D_t}\right)^{1/2}\left(\frac{\rho_d d_p^2 g}{\sigma}\right)^{5/4}\phi_d^{-1/2} \qquad (15\text{-}170)$$

where $\omega$ is impeller speed (rotations per unit time), $D_i$ is impeller diameter, $D_t$ is tank diameter, and $\mathcal{D}_c$ is the solute diffusion coefficient in the continuous phase. Equation (15-170) is restricted to dispersed-phase holdup values less than $\phi_d = 0.06$. Other studies are described by Schindler and Treybal [*AIChE J.*, **14**(5), pp. 790–798 (1968)] and by Keey and Glen [*AIChE J.*, **15**(6), pp. 942–947 (1969)]. Equation (15-170) normally is used to estimate performance for applications in which the feed phase is the continuous phase and the partition ratio for transfer of solute into the raffinate phase is large. In this case, the overall resistance to mass transfer is dominated by the continuous-phase resistance. Relatively little information is available about individual dispersed-phase mass-transfer coefficients. Skelland and Xien [*Ind. Eng. Chem. Res.*, **29**(3), pp. 415–420 (1990)] offer a correlation of $k_d$ values for batchwise extraction of solute from the dispersed phase into the continuous phase.

To use these correlation equations, it is necessary to identify which phase will be dispersed and to estimate the dispersed drop size and holdup as a function of throughput near flooding conditions. For relevant discussions, see "Factors Affecting Which Phase Is Dispersed" and "Size of Dispersed Drops" under "Liquid-Liquid Dispersion Fundamentals." Holdup is a complex function of flow rates, impeller type, vessel geometry, and power input, as well as physical properties. For most impeller types, correlations for estimating holdup are not available. However, Weinstein and Treybal [*AIChE J.*, **19**(2), pp. 304–312; **19**(4), pp. 851–852 (1973)] offer the following correlations for estimating holdup in a vessel agitated using a six-blade disk-style flat-blade turbine (Rushton): For a baffled vessel with a gas-liquid surface:

$$\frac{\phi_d}{\phi_{d,\text{feed}}} = 0.764\left(\frac{P Q_d \mu_c^2}{V_t \sigma^3}\right)^{0.300}\left(\frac{\mu_c^3}{Q_d \rho_c^2 \sigma}\right)^{0.178}\left(\frac{\rho_c}{\Delta\rho}\right)^{0.0741} \times \left(\frac{\sigma^3 \rho_c}{\mu_c^4 g}\right)^{0.276}\left(\frac{\mu_d}{\mu_c}\right)^{0.136} \qquad (15\text{-}171)$$

For a liquid-full vessel without baffles:

$$\frac{\phi_d}{\phi_{d,\text{feed}}} = 3.39\left(\frac{PQ_d\mu_c^2}{V_t\sigma^3}\right)^{0.247}\left(\frac{\mu_c^3}{Q_d\rho_c^2\sigma}\right)^{0.427}\left(\frac{\rho_c}{\Delta\rho}\right)^{0.430} \times\left(\frac{\sigma^3\rho_c}{\mu_c^4 g}\right)^{0.401}\left(\frac{\mu_d}{\mu_c}\right)^{0.0987} \quad (15\text{-}172)$$

Baffles are not needed if the vessel is operated full of liquid with no head space. In Eqs. (15-171) and (15-172), $\phi_{d,\text{feed}}$ is the volume fraction of the phase that ultimately becomes the dispersed phase, for the combined streams entering the vessel: $\phi_{d,\text{feed}} = Q_d/(Q_d + Q_c)$. If $\phi_d/\phi_{d,\text{feed}}$ is calculated to be greater than 1.0, it should be taken as 1.0. These equations are not applicable to other types of impellers.

When an estimate of $\phi_d$ is available, then $a \approx 6\varepsilon\phi_d/d_p$ [Eq. (15-109)]. If the individual mass-transfer coefficients can be estimated with reasonable accuracy, a value for the overall coefficient $k_{or}$ can be calculated from the individual coefficients as in Eq. (15-68). The stage efficiency for a continuous process can then be estimated from

$$\xi_{mr} = 1 - \exp\left(\frac{-k_{or}a\theta}{\phi_d}\right) \quad (15\text{-}173)$$

where $\xi_{mr}$ is the Murphree raffinate-based stage efficiency and $\theta$ is the residence time for total liquid in the vessel [Treybal, "Liquid Extractor Performance," *Chem. Eng. Prog.*, **62**(9), pp. 67–75 (1966); and Laddha and Degaleesan, *Transport Phenomena in Liquid Extraction* (McGraw-Hill, 1978), p. 418]. Also see the discussion by Skelland and Kanel [*Ind. Eng. Chem. Res.*, **31**(3), pp. 908–920 (1992)]. These authors describe an extraction model framework that includes terms representing drop breakage and coalescence effects.

**Miniplant Tests** As mentioned earlier, for most liquid-liquid extraction applications involving mixer-settlers, the requirements for satisfactory performance with respect to mixing and settling are determined by using small miniplant or pilot-plant tests. For mixer design, the usual procedure is to run continuous experiments for a specific mixer geometry and type of impeller, generating performance data over a range of residence times and agitation intensities. The experimental program typically involves testing a variety of impellers and impeller locations until satisfactory results are obtained, with the ultimate goal of scaling up the miniplant design to achieve the same performance at the commercial scale. The design of settlers is discussed in the section "Liquid-Liquid Separation Equipment." With careful design, most extractions require residence times in the range of 1 to 3 min. However, for reaction-enhanced extractions having relatively slow chemical kinetics compared to mass transfer, longer times in the range of 10 to 15 min are not unusual. As noted earlier, it is important to consider the time required to settle the dispersion after mixing and to determine the optimum mixing intensity that provides good mass transfer with reasonable ease of settling.

In these tests, extraction efficiency may be expressed in terms of a Murphree efficiency as

$$\xi = \frac{C_o - C_t}{C_o - C^*} \quad (15\text{-}174)$$

where $C_o$ is the initial concentration of solute in the feed, $C_t$ is the concentration in the outlet for a given residence time or at time $t$ for a batch process, and $C^*$ is the concentration at equilibrium. Normally, the extraction efficiency is determined from continuous experiments. If batch extraction data are available for the same solvent-to-feed ratio, the efficiency of a continuous process may be estimated by fitting the batch data to a first-order rate expression

$$\xi_{\text{batch}} = 1 - \exp(-kt_b) \quad (15\text{-}175)$$

where $\xi_{\text{batch}}$ for the batch experiment is measured as a function of $t_b$, the batch mixing time [Godfrey, Chap. 12 in *Liquid-Liquid Extraction Equipment,* Godfrey and Slater, eds. (Wiley, 1994)]. The efficiency of the continuous process is calculated from the expression

$$\xi_{\text{continuous}} = \frac{k\theta}{1 + k\theta} \quad (15\text{-}176)$$

where $\theta$ is the total liquid residence time for the continuous process. This approach is valid for most diffusion rate controlled processes, but may not be valid for reaction-enhanced processes in which the chemical reaction rate may be rate-limiting and not necessarily first-order.

When the ratio of phases entering a mixer-settler stage is far from unity, recycling a portion of the minority phase from the settler back to the mixer sometimes improves the settling of the dispersion by boosting the phase ratio in the settler. (See "Gravity Decanters (Settlers)" under "Liquid-Liquid Phase Separation Equipment.") The stage efficiency also may be enhanced. For example, when the extract (solvent) is the minority phase (because $K$ is greater than unity) and mass-transfer rates are poor, recycling the settled extract phase can boost the mass-transfer efficiency [Treybal, *Ind. Eng. Chem. Fundam.*, **3**(3), pp. 185–188 (1964)].

**Liquid-Liquid Mixer Design** Many different types of impellers are used for liquid-liquid extraction, including flat-blade and pitched-blade turbines, marine-type propellers, and special pump-mix impellers. With pump-mix designs, the impeller serves not only to mix the fluids, but also to move the fluids through the extraction stages of a mixer-settler cascade. The agitated vessel should be baffled if the vessel is operated with a gas-liquid surface, to avoid forming a vortex. As noted earlier in reference to Eq. (15-172), baffles are not needed if the vessel is operated with the liquid full [Weinstein and Treybal, *AIChE J.*, **19**(2), pp. 304–312 (1973)].

The design of a liquid-liquid mixer includes specification of impeller type and rotational speed (or tip speed), the number of impellers required, the ratio of impeller diameter to vessel diameter $D_i/D_t$, and the location of impeller(s) and any baffles within the vessel. A single impeller generally can be used for vessels with a height-to-diameter ratio less than 1.2 and liquid density ratios within the range of $0.9 < \rho_d/\rho_c < 1.1$. Multiple impeller designs are used to improve circulation and power distribution in tall vessels. For detailed discussions of liquid-liquid mixer design, see Leng and Calabrese, Chap. 12 in *Handbook of Industrial Mixing, Science and Practice,* Paul, Atiemo-Obeng, and Kresta, eds. (Wiley, 2004); and Edwards and Baker, Chap. 7, and Edwards, Baker, and Godfrey, Chap. 8, in *Mixing in the Process Industries*, 2d ed., Harnby, Edwards, and Nienow, eds. (Butterworth-Heinemann, 1992). Also see Daglas and Stamatoudis, *Chem. Eng. Technol.*, **23**(5), pp. 437–440 (2000), for discussion of the effect of impeller vertical position on drop size; and Willie, Langer, and Werner, *Chem. Eng. Technol.*, **24**(5), pp. 475–479 (2001), for discussion of the influence of power input on drop size distribution for a variety of impeller types.

The mixing power per unit volume $P/\mathcal{V}$ is a function of impeller rotational speed $\omega$, impeller diameter $D_i$, and the Power number ($P_o$) for the type of impeller and vessel geometry:

$$\frac{P}{\mathcal{V}} = P_o\left(\frac{\rho_m\omega^3 D_i^5}{\mathcal{V}_{\text{tank}}}\right) \quad (15\text{-}177)$$

In Eq. (15-177), the mixture mean density is given by

$$\rho_m = \phi_d\rho_d + (1 - \phi_d)\rho_c \quad (15\text{-}178)$$

Power numbers for different impeller types depend upon the impeller Reynolds number. Representative relationships of Power number versus Reynolds number for several types of impellers are given in Fig. 15-54. For additional information on a variety of impellers, see Sec. 6 and Hemrajani and Tatterson, Chap. 6 in *Handbook of Industrial Mixing, Science and Practice,* Paul, Atiemo-Obeng, and Kresta, eds. (Wiley, 2004).

The power $P$ in Eq. (15-177) does not include losses associated with the motor and drive unit. These losses can contribute as much as 30 to 40 percent to the overall power requirement. The drive supplier should be consulted for specific information. For pump-mix impellers, knowledge of the power characteristics for pumping is required in addition to that for mixing. For a discussion of these special cases, see Godfrey,

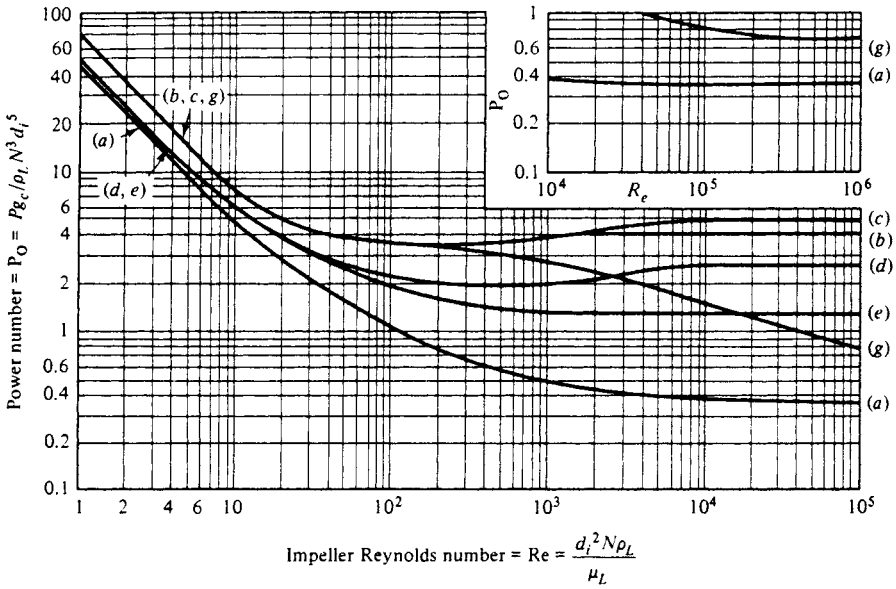

**FIG. 15-54** Power for agitation impellers immersed in single-phase liquids, baffled vessels with a gas-liquid surface (except curves *c* and *g*). Curves correspond to (*a*) marine impellers; (*b*) flat-blade turbines, width = $D_i/5$; (*c*) disk flat-blade turbines (Rushton) with or without a gas-liquid surface; (*d*) curved blade turbines; (*e*) pitched blade turbines; (*g*) flat-blade turbines, no baffles, no gas-liquid interface, no vortex.

Notes on Fig. 15-54:

1. All the curves are for axial impeller shafts, with liquid depth equal to the tank diameter $D_t$.
2. Curves *a* to *e* are for open vessels, with a gas-liquid surface, fitted with four baffles, baffle width = $D_t/10$ to $D_t/12$. The impeller is set at a distance $C = D_i$ or greater from the bottom of the vessel.
3. Curve *a* is for marine propellers, $D_i/D_t \approx \frac{1}{3}$. The effect of changing $D_i/D_t$ is apparently felt only at very high Reynolds numbers.
4. Curves *b* to *e* are for turbines. For disk flat-blade (Rushton) turbines, curve *c*, the effect of changing $D_i/D_t$ is negligible in the range $0.15 < D_i/D_t < 0.50$. For open types (without the disk), curve *b*, the effect of $D_i/D_t$ may be strong.
5. Curve *g* is for disk flat-blade turbines operated in unbaffled vessels filled with liquid and covered, so that no vortex forms. If baffles are present, the power characteristics at high Reynolds numbers are essentially the same as curve *b* for baffled open vessels, with only a slight increase in power.
6. For very deep tanks, two impellers normally are mounted on the same shaft, one above the other. For all flat-blade turbines, at a spacing of $1.5D_i$ or greater, the combined power for both will approximate that for a single turbine.

SOURCE: Treybal, *Mass-Transfer Operations* (McGraw-Hill, 1980), p. 152. For more detailed information, consult *Handbook of Industrial Mixing*, Paul, Atiemo-Obeng, and Kresta, eds. (Wiley, 2004).

Chap. 12 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994); and Singh et al., *Ind. Eng. Chem. Res.*, **46**(7), pp. 2180–2190 (2007).

Skelland and Ramsay [*Ind. Eng. Chem. Res.*, **26**(1), pp. 77–81 (1987)] correlated the minimum impeller speed needed to completely disperse one liquid in another in an agitated vessel with standard baffles as follows:

$$\frac{\omega_{\min}^2 \rho_m D_i}{g \Delta\rho} = C^2 \left(\frac{D_t}{D_i}\right)^{2\alpha} \phi^{0.106} \left(\frac{\mu_m^2 \sigma}{D_i^5 \rho_m g^2 \Delta\rho^2}\right)^{0.084} \qquad (15\text{-}179)$$

The mixture mean density is given by Eq. (15-178), and the mixture mean viscosity is given by

$$\mu_m = \frac{\mu_c}{1-\phi_d}\left(1 + \frac{1.5\mu_d\phi_d}{\mu_d + \mu_c}\right) \qquad (15\text{-}180)$$

The authors determined correlation constants $C$ and $\alpha$ for five common types of impellers (two axial-flow impellers and three radial-flow impellers) and four impeller locations within a standard tank configuration. The specific power requirement can then be estimated by using Eq. (15-177). The power required to disperse one liquid phase into another typically is in the range of 0.2 to 0.8 kW/m$^3$ (1 to 4 hp/1000 gal) [Edwards, Baker, and Godfrey, Chap. 8 in *Mixing in the Process Industries*, 2d ed., Harnby, Edwards, and Nienow, eds. (Butterworth-Heinemann, 1992), p. 144].

**Scale-up Criteria** It is common practice to scale up a miniplant design on the basis of equal residence time, constant power per unit volume, and geometric similarity such that the ratio $D_i/D_t$ is held constant and the same types of impeller, tank geometry, and baffling are used. Treybal [*Chem. Eng. Prog.*, **62**(9), pp. 67–75 (1966)] indicates that in using this criterion, stage efficiency for liquid-liquid extraction is likely to increase on scale-up, so it is expected to yield a conservative design. With this approach, $P/D_i^3$ is constant and proportional to $P_o\omega^3 D_i^5/D_i^3 = P_o\omega^3 D_i^2$. Assuming that the Power number is independent of scale, this yields the relationship

$$\frac{\omega(2)}{\omega(1)} = \left(\frac{D_i(1)}{D_i(2)}\right)^{2/3} = \left(\frac{D_t(1)}{D_t(2)}\right)^{2/3} \qquad (15\text{-}181)$$

Skelland and Ramsay [*Ind. Eng. Chem. Res.*, **26**(1), pp. 77–81 (1987)] indicate that Eq. (15-181) is somewhat conservative, in general agreement with Treybal. Based on an analysis of mixing data generated at low holdup, they indicate that the exponent $\frac{2}{3}$ may be replaced with 0.71 as

a scale-up rule. Skelland and Ramsay also discuss the criteria for scale-up to a tank design involving a different ratio of $D_i/D_t$ at the large scale.

Leng and Calabrese [Chap. 12 in *Handbook of Industrial Mixing: Science and Practice*, Paul, Atiemo-Obeng, and Kresta, eds. (Wiley, 2004), p. 732] show that constant power per unit volume also yields the following relationship if a change in drop size is desired (again, for applications with low holdup):

$$\frac{d_{\max}(1)}{d_{\max}(2)} \approx \frac{\omega(2)^{6/5} D_i(2)^{4/5}}{\omega(1)^{6/5} D_i(1)^{4/5}} \quad \text{for Re} = \frac{\rho_m \omega D_i^2}{\mu_m} > 10^4 \quad (15\text{-}182)$$

Equation (15-182) reduces to Eq. (15-181) when $d_{\max}(1)$ is set equal to $d_{\max}(2)$.

The constant power per unit volume scale-up criterion is equivalent to scaling the impeller tip speed ($S_{\text{tip}} = \pi D_i \omega$) by the ratio $S_{\text{tip}}(2)/S_{\text{tip}}(1) = [D(2)/D(1)]^{1/3}$. It follows that when the tank diameter is doubled, the impeller tip speed must increase by a factor of 1.26 to maintain constant power per unit volume. If the Skelland and Ramsay exponent of 0.71 is applied in Eq. (15-181) instead of $\frac{2}{3}$, then tip speed scales as $S_{\text{tip}}(2)/S_{\text{tip}}(1) = [D(2)/D(1)]^{0.29}$ and doubling the tank diameter involves increasing the tip speed by a factor of 1.22.

Podgórska and Bałdyga [*Chem. Eng. Sci.*, **56,** pp. 741–746 (2001)] present a model of drop breakage and coalescence and compare four scale-up criteria for agitated liquid-liquid dispersions:

I. Equal power per unit volume and geometric similarity
II. Equal average circulation time and geometric similarity
III. Equal power per unit volume and equal average circulation time ($D_i/D_t \neq$ constant)
IV. Equal tip speed and geometric similarity

For slow-coalescing systems and systems at low holdup, the rate of drop breakage dominates. In this case, according to the analysis of Podgórska and Bałdyga, criteria I and II yield smaller drops on scale-up, and criteria III and IV yield larger drops. For fast-coalescing systems, the rate of drop coalescence begins to dominate breakage. In this case, the authors indicate that I and III yield almost constant drop size with scale-up, II yields much smaller drops, and IV yields larger drops. Podgórska and Bałdyga recommend III for fast-coalescing systems, although they point out a limitation in terms of the maximum size of tank that this criterion will allow. See Leng and Calabrese, Chap. 12 in *Handbook of Industrial Mixing: Science and Practice*, Paul, Atiemo-Obeng, and Kresta, eds. (Wiley, 2004), pp. 682–687, for detailed discussion of factors influencing coalescence and their impact on scale-up difficulty.

Based on the analyses described above, taken together, it appears that scaling according to constant power per unit volume and geometric similarity generally will give satisfactory results, although the resulting design may not be optimal. For a new design, generally it is advisable to specify a variable-speed drive that can operate within a range of tip speeds. This provides flexibility for further adjustment and optimization of the process in the plant, and it also allows flexibility to accommodate variability in feed composition (a likely scenario in an industrial process).

**Specialized Mixer-Settler Equipment** As mentioned earlier, any mixer and settler can be combined to produce a stage, and the stages in turn arranged in a multistage cascade. A great many specialized designs have been developed in an effort to reduce costs, e.g., by minimizing or eliminating interstage pumping or by combining the various stages into a single vessel. With proper design, these devices generally can achieve overall stage efficiencies in excess of 80 percent, with many providing 90 to 95 percent stage efficiency. Only a few of the more commonly used types are mentioned here. For more detailed discussions, see Chaps. 9.1 to 9.5 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991).

Several pump-mix combinations have been developed by industry to simplify overall plant layout and minimize the number of pumps, at the expense of more expensive mixer design or complexity. The IMI axial pump-mix and draft tube (Fig. 15-55*a*) has the pumping

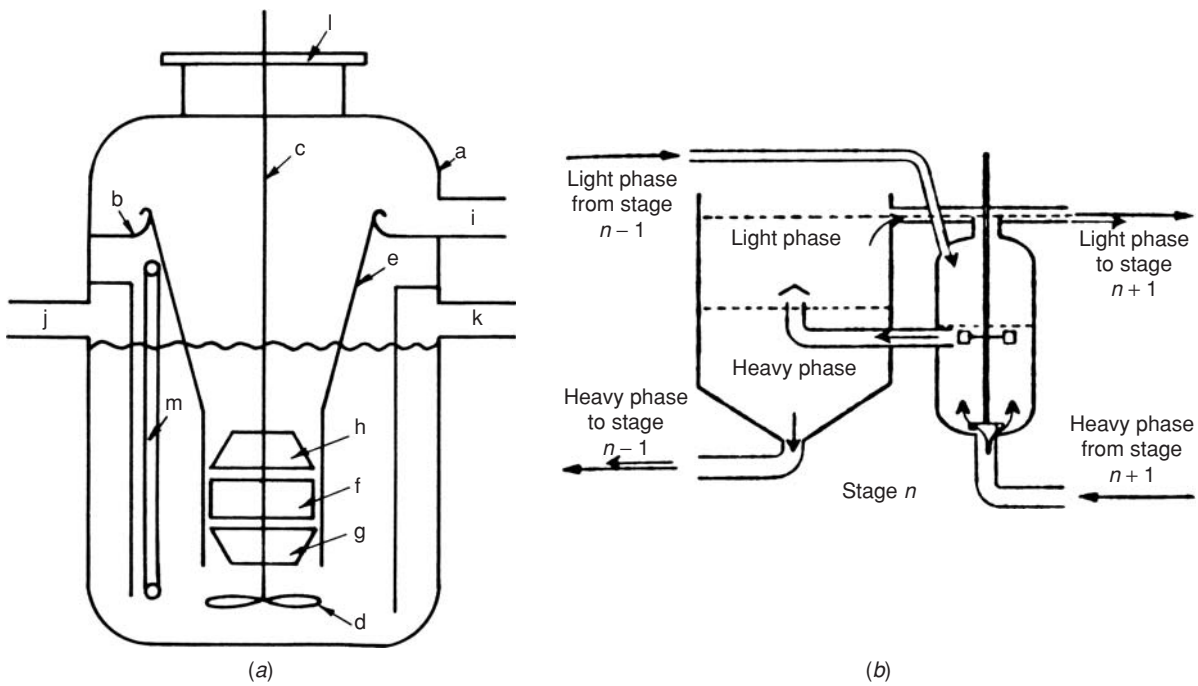

**FIG. 15-55** Types of pump-mix arrangements for mixer-settler extractors. (*a*) IMI pump mix with mixing and pumping impellers (a, vessel; b, internal deck; c, shaft; d, mixing impeller; e, draft tube; f, pumping impeller; g and h, guide vanes; i, dispersion discharge; j, light-phase feed; k, heavy-phase-feed; l, mounting flange; m, sight glass). (*b*) Kemira mixer-settler. [*Figure 15-55a taken from* Handbook of Solvent Extraction, *Lo, Baird, and Hansen, eds. (Wiley, 1983; Krieger, 1991), with permission. Figure 15-55b taken from Mattila*, ISEC '74 Proc., *London, 1974, with permission.*]

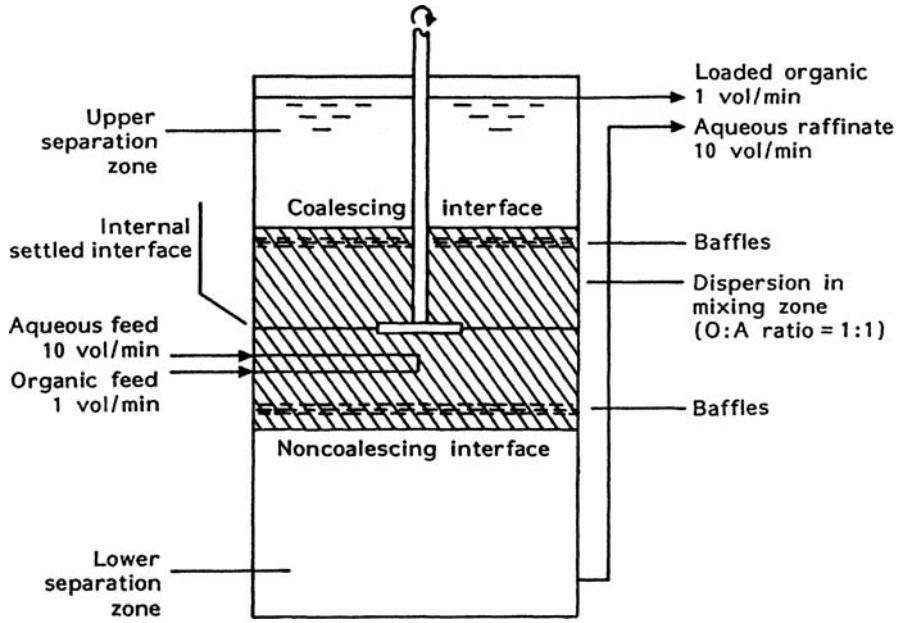

**FIG. 15-56** Davy CMS extractor with pump-mix impeller and phase separation zones. [*Reprinted from* Liquid-Liquid Extraction Equipment, *Godfrey and Slater, eds. (Wiley, 1994), with permission. Copyright 1994 John Wiley & Sons Ltd.*]

and mixing impellers on the same shaft. The upper part of the tank contains the draft tube and the mixing-impeller. The pumping-impeller for transferring the dispersion to the settler is in the lower part of the tank. There is a potential disadvantage of forming smaller and hard to separate drops when pumping a dispersion versus pumping a single phase. The Kemira design (Fig. 15-55*b*) uses a pumping-impeller located near the bottom of the tank along with a mixing-impeller located near the central zone of the tank. The draft tube is eliminated and a dispersion is not pumped in this design. The Davy CMS design (Fig. 15-56) uses a pump-mix impeller in a large tank that provides both mixing and settling capability over a wide range of phase flow ratios. The dispersion occurs in the central section of the tank, and the separation occurs in the upper and lower separation zones.

A compact alternating arrangement of mixers and settlers has been adopted in many of the "box-type" extractors developed originally for processing radioactive solutions. These designs are used for many other processes, with literally dozens of modifications. An example is the pump-mix mixer-settler (Fig. 15-57), in which adjacent stages have common walls [Coplan, Davidson, and Zebroski, *Chem. Eng. Prog.*, **50**(8), pp. 403–408 (1954)]. In this case, the impellers pump as well as mix by drawing the heavy liquid upward through the hollow impeller shaft and discharging it at a higher level through the hollow impeller. Rectangular tanks are not ideal for good mixing; however, the compromise in mixing and settling performance is offset by the compact and economical design.

Vertical arrangement of the stages is desirable, since then a single drive may be used for agitators and the floor space requirement of a cascade is reduced to that of a single stage. The Lurgi extractor configuration has the mixer and settlers in separate vertical shells interconnected with piping [Guccione, *Chem. Eng. Magazine*, **73**(4), pp. 78–80 (1966)]. A great many other designs are known. For example, the Fenske and Long extractor [Fenske and Long, *Chem. Eng. Prog.*, **51**(4), pp. 194–198 (1955); Long and Fenske, *Ind. Eng. Chem.*, **53**(10), pp. 791–798 (1961); Long, *Ind. Eng. Chem. Fundam.*, **1,** p. 152 (1962)] is a vertical stack of mixer-settler stages. This design employs a reciprocating plate at each stage to mix the two phases.

**Suspended-Fiber Contactor** The Merichem Fiber-Film® contactor is used in petroleum refining operations to wash hydrocarbon streams with caustic or other treating solutions [Suarez, U.S. Patent 5,997,731 (1999)]. The hydrocarbon feed and wash fluid are brought together within a vertical pipe or wash column containing fibers suspended from the top, as shown in Fig. 15-58. The two liquids flow cocurrently down the column through the bed of fibers. The fibers are attached at the top of the column but not at the bottom. Liquid-liquid contacting is facilitated through capillary and surface-wetting effects. This arrangement avoids (or minimizes) formation of small dispersed

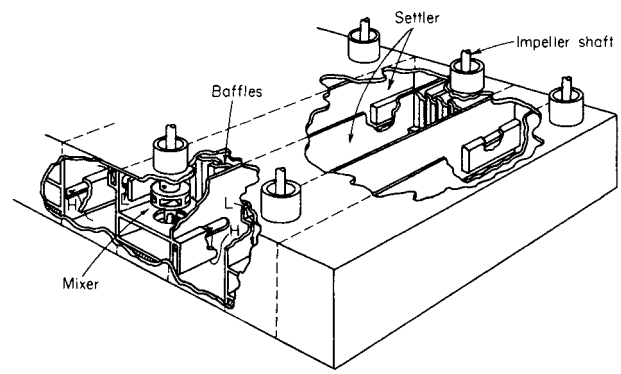

**FIG. 15-57** Pump-mix box-type mixer-settler. [*Taken from Coplan, Davidson, and Zebroski,* Chem. Eng. Prog., ***50,*** *p. 403 (1954), with permission.*]

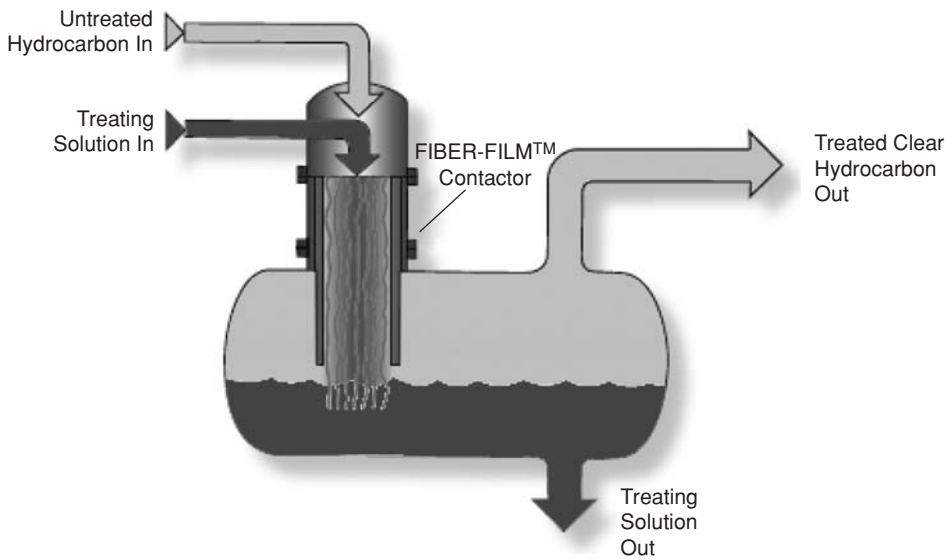

**FIG. 15-58** Merichem Fiber-Film™ contactor. (*Courtesy of Merichem Chemicals and Refinery Services, LLC.*)

drops, and this helps to minimize entrainment of aqueous phase into the hydrocarbon outlet. Little information about the mass-transfer performance and design requirements for this type of contactor has been published.

## CENTRIFUGAL EXTRACTORS

A centrifugal extractor multiplies the force of gravity acting on two liquid phases. Centrifugal extractors can facilitate a liquid-liquid extraction process by reducing diffusion path lengths and increasing the driving force for liquid-liquid phase separation. They can achieve very high specific throughput with very low liquid residence time. A wide variety of machine types are available, ranging from relatively simple devices used primarily for phase separation or for single-stage liquid-liquid contacting with separation to more complex machines designed to provide the equivalent of multistage liquid-liquid contacting within a single unit. Some machines are designed to handle feeds containing solids such as whole fermentation broth. This section provides a brief overview with a description of several machines for illustration. More detailed descriptions of centrifuge design and performance are available from equipment vendors. For additional discussion, see Janoske and Piesche, *Chem. Eng. Technol.*, **22**(3), pp. 213–216 (1999); Leonard, Chamberlain, and Conner, *Sep. Sci. Tech.*, **32**(1–4), pp. 193–210 (1997); Blass, Chap. 14 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994); Schügerl, *Solvent Extraction in Biotechnology* (Springer-Verlag, 1994); Otillinger and Blass, "Mass Transfer in Centrifugal Extractors," *Chem. Eng. Technol.*, **11,** pp. 312–320 (1988); and Hafez, Chap. 15 in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991).

Centrifugal extractors can be beneficial when the liquid density difference is small, when short contact time is needed to avoid product degradation, when feed and solvent easily emulsify, or in cases where high specific throughput is needed due to limitations in available floor space or ceiling height. Centrifugal extractors also can provide flexibility in operation in cases where feed variability is high, by allowing adjustment of feed rate and rotational speed as needed to obtain satisfactory performance. Potential disadvantages generally derive from difficulties associated with maintaining high-speed rotating machinery, relatively high purchase prices compared to those of some other types of extractors, and limitations as to the number of theoretical stages that can be achieved per machine (generally < 1 or up to 5 or 6 theoretical stages depending upon throughput and the type of machine). Another consideration for some machines with close internal clearances is the potential for plugging if any solids are present in the feed; however, as noted above, some machines are specifically designed to handle and discharge solids.

Commercial-scale centrifuges almost always are continuously fed machines, unless the scale of the operation is very low, as in some low-volume bioprocessing operations where very-high-$g$ operation and long processing times are needed. A continuously fed centrifugal extractor can deliver high multiples of $g$, but at much lower residence time (given by holdup volume of the feed phase divided by volumetric feed rate) compared to a batch process. The maximum hydraulic capacity (or nominal capacity) of a continuously operated machine often is not realized in commercial applications, because the feed rate needs to be turned down in order to have sufficient residence time for good extraction and phase separation performance.

In evaluating options, it generally is not possible to accurately predict performance because of the complexity of the hydrodynamics within a centrifuge. While high-$g$ operation can promote good performance, in certain cases the extremely rapid acceleration generated within the machine also can promote backmixing or emulsification. Miniplant tests using small units generally are needed, and vendors often offer testing services.

**Single-Stage Centrifugal Extractors** The types of centrifuges used in extraction operations are quite varied. Differences include vertical versus horizontal configuration, fluid-filled versus operation with an air core, pressurized or unpressurized operation, generation of low to extremely high multiples of gravitational acceleration (500 up to 20,000 × $g$ or higher), as well as differences in the liquid holdup volume, design of internals, internal clearances, and purchase price. The simpler machines, such as the CINC separator from CINC Processing Equipment, Inc. (Fig. 15-59) and the Rousselet-Robatel model BXP, have relatively large internal clearances. An air core is maintained within the machine, and liquid layers decant over internal weirs. Flow restrictions in the overflow piping need to be minimized to avoid any pressure imbalance between light- and heavy-liquid overflow lines, since this can affect the location of the liquid-liquid interface and the liquid overflow/underflow split. These machines often are used for washing operations and other extraction applications with high $K$ values requiring few theoretical stages. They often serve as the separator in a mixer-settler stage, such that solvent and

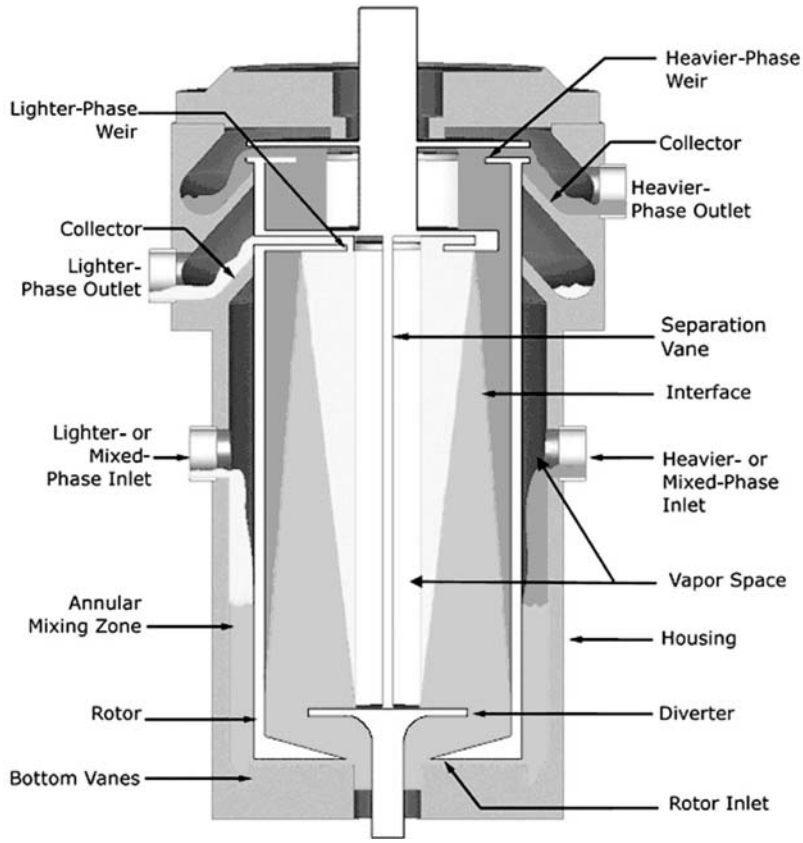

**FIG. 15-59** CINC centrifugal separator. (*Courtesy of CINC Processing Equipment, Inc.*)

feed are first mixed in a static mixer or a separate vessel before being fed to the centrifuge. Some mixing occurs within the centrifuge itself; so if the extraction is sufficiently fast, solvent and feed might be fed directly to the centrifuge to accomplish both mixing and phase separation. Multiple units can be connected in a countercurrent mixer-settler cascade if needed. Processes with 5 to 7 units are typical, while processes with as many as 50 units have been reported. Multiple-unit mixer-settler processes utilizing centrifuges at each stage generally involve production of high-value, low-volume products. Stacked-disk types of machines also are available from numerous vendors and may be used in a similar extraction scheme (generally requiring some type of mixer in the feed line). These machines contain an internal stack of conical disks with a small gap between disks on the order of millimeters [Janoske and Piesche, *Chem. Eng. Technol.*, **22**(3), pp. 213–216 (1999); and Mannweiler and Hoare, *Bioproc. Biosystems Eng.*, **8**(1–2), pp. 19–25 (1992)]. Stacked-disk machines can be thought of as inclined-plate or lamella-type decanters operating in a centrifugal field (see "Liquid-Liquid Phase Separation Equipment"). They magnify the separation power by greatly reducing the distance the dispersed phase must travel before coalescing at a surface, at the expense of somewhat higher complexity and closer internal clearances.

Figure 15-59 shows a cutaway drawing of a CINC separator showing an outer annular space where solvent and feed mix before entering the interior of a rotating drum. Although this type of machine is not designed to separate solids from feeds, a clean-in-place option is offered to facilitate periodic removal of solids that accumulate in the internals. In applications in which one or more of the feed liquids is somewhat viscous, special consideration must be given to the design of the centrifuge internals such that pressure drop through the machine is not excessive. In certain applications, feed with viscosities as high as several hundred centipoise may be handled; however, special modifications to the internals are needed, and throughput must be reduced compared to that in typical operation. Maximum or nominal volumetric flow capacities for CINC machines range from 110 L/h to 136 $m^3$/h (0.5 to 600 gal/min) depending upon the size of the unit. The Rousselet-Robatel design is somewhat similar. These machines range in size from 50 L/h up to 80 $m^3$/h (0.2 to 350 gal/min). They are designed to generate only moderate centrifugal force and are generally limited to applications requiring no more than about 25,000$g$·s (maximum $g$ acceleration times the liquid residence time based on total volumetric flow rate and liquid holdup in the machine).

The CENTREK single-stage extractor from MEAB consists of a funnel-shaped centrifugal-bowl centrifuge mounted above a mixing tank containing a submerged stirrer. An internal "hydrolock" is used to control the position of the liquid-liquid interface in the bowl. According to the manufacturer, this is especially important for multistage, cascade operation. The unit can tolerate some amount of solids in the feed and is available in nominal capacities of 20 L/h to 20 $m^3$/h (0.1 to 90 gal/min).

**Centrifugal Extractors Designed for Multistage Performance** At the other end of the spectrum are the more complex machines designed to provide multistage or differential liquid-liquid contacting and separation within a single unit. Some machines promote formation of very thin films for efficient liquid-liquid contacting and separation. Others provide multiple zones for mixing and separating the phases. All are designed with complex internals and close clearances. These machines typically achieve 2 to 5 theoretical stages

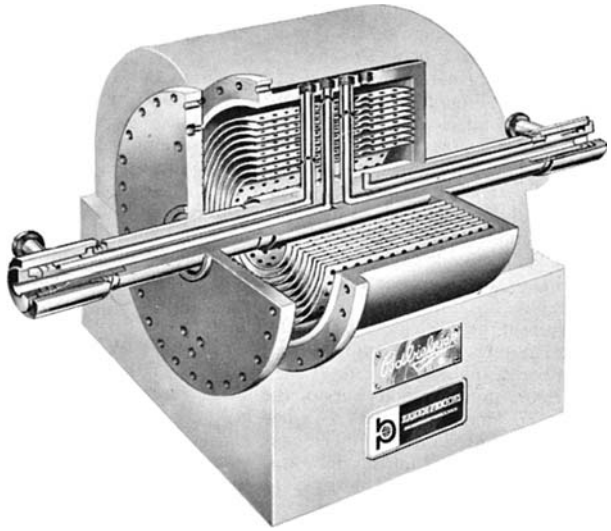

**FIG. 15-60** Podbielniak centrifugal extractor. (*Courtesy of Baker Perkins, Inc.*)

depending upon operating conditions, with some authors claiming as many as 7 or 8 stages.

The classic machine of this type is the Podbielniak extractor available from Baker-Perkins (Fig. 15-60). The body of the extractor is a horizontal cylindrical drum containing concentric perforated cylinders. The liquids are introduced through the horizontal rotating shaft with the help of special mechanical seals; the light liquid is fed internally to the drum periphery and the heavy liquid to the axis of the drum. Rapid rotation (up to several thousand revolutions per minute, depending on size) causes radial counterflow of the liquids, which then flow out through the shaft. Materials of construction include steel, stainless steel, Hastelloy, and other corrosion-resistant alloys. The Podbielniak design provides extremely low holdup of liquid per stage, and this led to its extensive use in the extraction of antibiotics, such as penicillin and the like, for which multistage extraction and phase separation must be done rapidly to avoid chemical destruction of the product under conditions of extraction [Podbielniak, Kaiser, and Ziegenhorn, Chap. VI in *Chemical Engineering Progress Symposium Series No. 100*, vol. **66,** pp. 43–50 (1970)]. Podbielniak extractors have been used in all phases of pharmaceutical manufacturing, in petroleum processing (both solvent refining and acid treating), in extraction of uranium from ore leach liquors, and for clarification and phase separation work. Jacobsen and Beyer [*AIChE J.*, **2**(3), pp. 283–289 (1956)] describe operating characteristics and the number of theoretical stages achieved for a specific application.

The Quadronics (Liquid Dynamics) extractor is a horizontally rotated device, a variant of the Podbielniak extractor, in which either fixed or adjustable orifices may be inserted radially as a package. These permit control of the mixing intensity as the liquids pass radially through the extractor. Flow capacities, depending on machine size, range from 0.34 to 340 $m^3/h$ (1.5 to 1500 gal/min).

The Luwesta (Centriwesta) extractor is a development from Coutor [Eisenlohr, *Ind. Chem.*, **27,** p. 271 (1951)]. This centrifuge revolves about a vertical axis and contains three actual stages. It operates at 3800 rotations per minute and handles approximately 5 $m^3/h$ (1300 gal/h) total liquid flow at 12-kW power requirement. Provision is made in the machine for the accumulation of solids separated from the liquids, for periodic removal. It is used, more extensively in Europe than in the United States, for the extraction of acetic acid, pharmaceuticals, and similar products.

The de Laval extractor contains a number of perforated cylinders revolving about a vertical shaft [Palmqvist and Beskow, U.S. Patent 3,108,953 (1959)]. The liquids follow a spiral path about 25 m (82 ft) long, in countercurrent fashion radially, and mix when passing through the perforations. There are no published performance data.

The Rousselet-Robatel LX multistage centrifugal extractor is designed with up to 7 internal mixing/separation stages. Each stage consists of a mixing chamber where the two phases are mixed by means of a stationary agitation disk mounted on a central drum. The high relative speed between the stationary disk and the rotating walls of the mixing chamber creates a liquid-liquid dispersion with high interfacial area to facilitate rapid mass transfer. The agitation disk and the mixing chamber's inlet and outlet channels form a pump which draws the two phases from the adjacent stages and transfers the dispersion to a settling chamber, where it is separated by centrifugal force. The manufacturer claims that high stage efficiencies can be achieved. Extract and raffinate phases are removed from the machine by gravity discharge, or an internal centripetal pump can be employed to discharge these streams under pressure. Nominal flow rates range from 25 L/h up to 80 $m^3/h$.

# PROCESS CONTROL CONSIDERATIONS

**General References:** Wilkinson and Ingham, Chap. 27.2, and S. Plonsky, Chap. 27.3, in *Handbook of Solvent Extraction*, Lo, Baird, and Hanson, eds. (Wiley, 1983; Krieger, 1991).

## STEADY-STATE PROCESS CONTROL

Control of a continuous liquid-liquid extraction process generally refers to maintaining satisfactory dispersion of one phase in another for good mass-transfer performance while also maintaining the required production rate. This must be done without entering a flooding condition. It is common practice to set up a continuously fed extractor to handle a range of feed rates while maintaining other operating variables at constant preset values. These include the solvent flow rate, temperatures, and mechanical variables (if agitation or centrifugation is employed). For extraction processes that experience large swings in feed flow rate, the solvent flow rate may be manipulated to maintain a constant solvent-to-feed ratio, in order to reduce the volume of extract that needs to be processed. In this case, the extractor must be able to operate within a fairly wide range of volumetric throughput.

A common cause of upsets in operation is contamination of the feed by trace amounts of impurities that affect interfacial tension, so it is important to control upstream operations to avoid contamination. Upsets or deviations from desired performance also can be caused by changes in the purity of solvent entering from solvent recovery equipment, so adequate control of closely coupled auxiliary operations is needed to ensure good extractor performance. Periodic monitoring of the interfacial tension of light and heavy phases at the feed location (where interfacial tension is likely to be lowest due to higher solute concentration) may be useful for understanding the range of values that can be tolerated, and trends in the data may provide warning of an impending flooding or coalescence problem.

Steady-state control of a continuously fed extraction column requires maintenance of the location of the liquid-liquid interface at one end of the column. The main interface will appear at the top of the column when the light phase is dispersed and at the bottom of the column when the heavy phase is dispersed. If needed, extraction columns can be designed with an expanded-diameter settling zone to facilitate liquid-liquid phase separation by reducing liquid velocities. If sufficient clarification of the phases cannot be achieved, then it may be necessary to add an external device such as a gravity decanter or centrifuge. (See "Liquid-Liquid Phase Separation Equipment.") Sometimes a column is built with expanded ends at

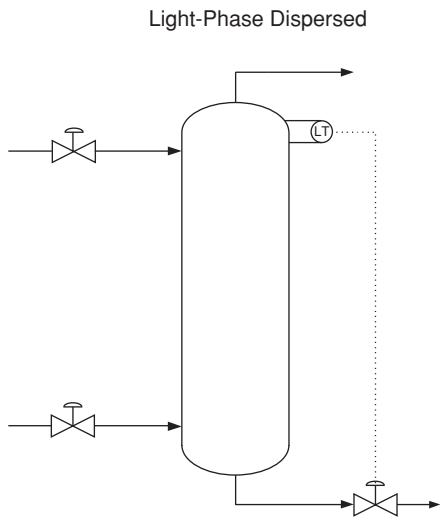

**FIG. 15-61** Typical interface control for a light-phase dispersed process (with the main interface located at the top of the column). The same basic arrangement can be used for the heavy-phase dispersed case, but the level transmitter would be located differently to reflect the location of the main interface at the bottom of the column.

both top and bottom to allow the option of operating with either phase dispersed.

The position of the main operating interface in an extraction column, whether located at the top or the bottom, generally is controlled by adjusting the outlet flow of the heavy phase; the heavy-phase outlet valve opens to lower the interface and closes to raise the interface, and the light phase is allowed to overflow the top of the column. The location of the interface often can be maintained at a set position by measuring the differential pressure (if density difference is sufficiently large) or the capacitance of the liquid across the settling zone (for aqueous/organic systems) and manipulating the control valve in the bottom outlet stream to control a set point. Another technique uses a float that rests at the position of the interface. The general concept is illustrated in Fig. 15-61. Weinstein, Semiat, and Lewin [*Chem. Eng. Sci.*, **53**(2), pp. 325–339 (1998)] studied the light-phase dispersed case (with the main interface maintained at the top of the column) and recommend controlling the main interface level by manipulating the continuous-phase feed flow rate instead of the continuous-phase outlet flow rate. The authors developed a dynamic model of the hydrodynamics and mass transfer in a countercurrent liquid-liquid extraction column, and the simulation results indicate faster dynamic response using their alternative scheme.

When a continuous extraction column begins to flood, often one of the first indications is the appearance of an interface at the wrong end of the column; so adding instrumentation that can detect such an interface (such as one or more conductivity probes when phase inversion involves formation of a continuous aqueous phase) may help identify a flooding condition in time to take corrective action. Sometimes a rag layer will accumulate at the liquid-liquid interface, and it is necessary to provide a means for periodically draining the rag to avoid entrainment into the extract or raffinate. It may be useful to add instrumentation that can detect the rag at high positions to warn an operator before breakthrough occurs; however, often the approach taken is to drain the interface region on a predetermined schedule. Installing sensors to detect a rag layer can be problematic because they are easily fouled.

For a continuous extraction column, it is important to control the holdup of each phase within the column to obtain high interfacial area for good mass transfer. For nonagitated extraction columns, this is set by proper design of the internals and maintaining flow rates during operation within a fairly narrow range of values needed for good performance. Agitated columns allow greater flexibility in this regard, because agitation intensity can be adjusted in the plant to maintain good performance over a wider range of flow rates and as the properties of the feed change. In industrial practice, agitation intensity normally is set at a constant rate or manually adjusted at infrequent intervals in response to a significant change in feed characteristics. Model-based control schemes offer potential for automatic adjustment of agitation intensity and other variables for faster response [Mjalli, *Chem. Eng. Sci.*, **60**(1), pp. 239–253 (2005); and Mjalli, Abdel-Jabbar, and Fletcher, *Chem. Eng. Processing*, **44,** pp. 531–542 and 543–555 (2005)]. Careful programming will be needed to avoid inappropriate control actions when sensors are out of calibration. Real-time measurement of dispersed-phase holdup also may be helpful; Chen et al. [*Ind. Eng. Chem. Res.*, **41**(7), pp. 1868–1872 (2002)] report a method for a pulsed-liquid column. They studied a system consisting of 30% trialkyl($C_{6-8}$) phosphine oxide in kerosene + nitric acid solution, with the acid phase dispersed.

For some extraction operations, particularly fractional extractions, it may be useful to control a temperature profile across the process. In extraction columns, this is normally done by controlling the temperature of entering feed and solvent streams. Heating jackets generally are not effective because of insufficient heat-transfer area. Internal heating or cooling coils are problematic because they are difficult and expensive to install and can interfere with other column internals and liquid-liquid traffic within the column. For fractional extraction, the stripping and washing operations may be carried out in separate equipment with external heating or cooling of the streams entering the equipment.

For startup of column extractors, it generally is best to start from dilute-solute conditions to avoid unstable operation. For example, when starting a column in which the feed is the continuous phase, first fill the column with solute-lean feed liquid before starting the flow of solvent and actual feed. This way, the solvent quickly becomes dispersed and mass transfer approaches steady state from dilute conditions, promoting faster and more stable startup.

## SIEVE TRAY COLUMN INTERFACE CONTROL

Control of the main liquid-liquid interface for a sieve tray column can be counterintuitive because of complexity caused by the presence of multiple interfaces within the column. For example, if the interface level is too high, the usual control response is to allow the heavy phase to flow out the bottom of the column for a time until the desired level is reached (using the scheme outlined in Fig. 15-61). Ideally, this should lower the interface level, as shown in Fig. 15-62*a*. This is a typical response for most differential contactors such as packed or spray columns. However, for the sieve tray column the initial response can actually be a rise in the interface level for a short time, as shown in Fig. 15-62*b*. In some cases, this can result in entrainment of heavy phase out the top of the tower.

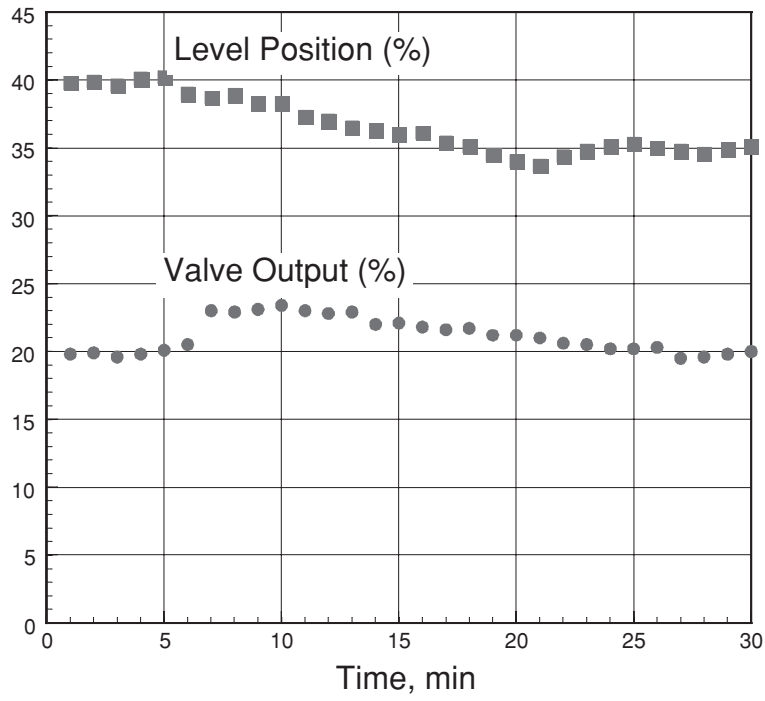
The inverse response is caused by changes in the coalesced layer heights at each tray. Neglecting any correction for dispersed-phase holdup, the height of the coalesced layer is affected by the pressure drop through the sieve holes and downcomer:

$$h \approx \frac{\Delta P_o + \Delta P_{\text{dow}}}{\Delta \rho g} = \frac{C_1 V_o^2 + C_2 V_{\text{dow}}^2}{\Delta \rho g} \qquad (15\text{-}183)$$

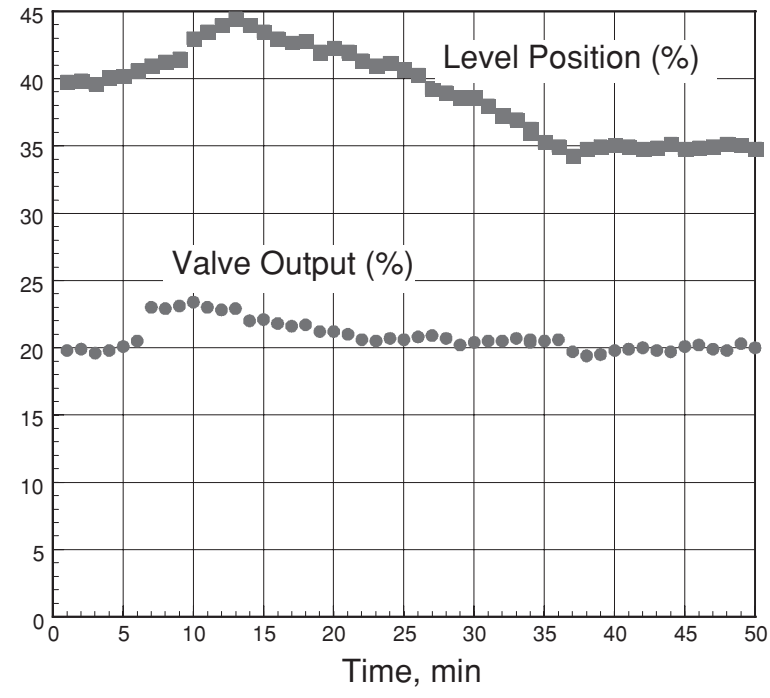
where $h$ is the coalesced layer height, $\Delta P_o$ is the pressure drop through perforations, $\Delta P_{\text{dow}}$ is the pressure drop through the downcomer, $V_o$ is the average velocity through a perforation (orifice), $V_{\text{dow}}$ is the average velocity through the downcomer, and $C_1$ and $C_2$ are constants related to tray geometry and physical properties. Tray designs often vary as to which contribution, orifice or downcomer pressure drop, controls the height of the coalesced layer. The inverse response can cause significant control problems if the downcomer pressure drop is much greater than the orifice pressure drop, and this issue should be addressed during design.

## CONTROLLED-CYCLING MODE OF OPERATION

Extraction columns usually are operated in a steady-state continuous-flow mode of operation with one liquid dispersed in the other. Mass transfer is then promoted by using various fixed or moving elements (various types of packings, trays, or agitators). These elements are



(*a*)



(*b*)

**FIG. 15-62** Dynamic response to a change in heavy-phase flow rate. (*a*) Normal dynamic response to increasing outlet heavy-phase flow (packing). (*b*) Dynamic response to increasing outlet heavy-phase flow rate (sieve trays).

designed to strike a balance between throughput capacity and mass-transfer efficiency. An alternative mode of operation is the controlled-cycling mode in which light and heavy phases are alternately dispersed and coalesced. Flow is stopped periodically so the phases can switch roles (dispersed versus continuous phase) for the next portion of the cycle. While these coalescing periods reduce the net throughput, the overall mass-transfer effectiveness can be enhanced.

The concept of controlled cycling of phase contactors in general was introduced in the early 1950s by Cannon [*Oil Gas J.*, **51**(12), p. 268 (1952); *Oil Gas J.*, **55**(38), p. 68 (1956); and *Ind. Eng. Chem.*, **53**(8), p. 629 (1961)]. When applied to extraction, it normally involves the use of perforated tray columns, where both phases can flow through the same openings. Since only one phase flows at a time, downcomers are not necessary, and dual-flow trays generally are used. A cycle is completed by the following sequence of events: (1) A light-phase flow period, during which the heavy phase does not flow; (2) a coalescing period, during which neither phase flows; (3) a heavy-phase flow period, during which the light phase does not flow; and (4) a repeat of the coalescing period. The net result can be an increase in overall stage efficiency, roughly doubling the number of theoretical stages the column can achieve, provided the total holdup of each phase is displaced during each cycle. Robinson and Engel [*Ind. Eng. Chem.*, **59**(3), pp. 22–29 (1967)] provide a theoretical analysis for describing the advantages of controlled cycling, and Lövland [*Ind. Eng. Chem. Proc. Des. Dev.*, **7**(1), pp. 65–67 (1968)] discussed a graphical method for determining the number of theoretical stages.

Belter and Speaker [*Ind. Eng. Chem. Proc. Des. Dev.*, **6**(1), pp. 36–42 (1967)] reported studies using a 6-in-diameter column and the system cyclohexane + ethyl acetate + ethanol + water, a low-interfacial-tension system (1.2 dyn/cm, equal to $1.2 \times 10^{-3}$ N/m). Excellent stage efficiencies were reported in the range of 50 to 75 percent. Darsi and Feick [*Can. J. Chem. Eng.*, **49**(2), p. 95 (1971)] determined the effects of hole size, direction of solute transfer, and throughput using a 4-in-diameter extractor and a MIBK + acetic acid + water test mixture. They reported that smaller holes and transfer from the organic phase enhanced mass transfer. Stage efficiencies ranged up to 50 percent. Seibert, Humphrey, and Fair [*Solvent Extraction and Ion Exchange*, **4**(5), p. 1049 (1986)] observed that the volume of phase transferred within a cycle should be less than the total holdup volume per stage to minimize backmixing. They also showed that the capacity of a controlled cyclic extractor, while lower than that of a conventional sieve tray extractor, could be higher than that of a pulsed sieve tray extractor.

# LIQUID-LIQUID PHASE SEPARATION EQUIPMENT

(McGraw-Hill, 1997); Hartland and Jeelani, Chap. 13 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994); Monnery and Svrcek, *Chem. Eng. Prog.*, **90**(9), pp. 29–40 (1994); and Jacobs and Penney, Chap. 3 in *Handbook of Separation Process Technology*, Rousseau, ed. (Wiley, 1987).

## OVERALL PROCESS CONSIDERATIONS

The ability to separate a mixture of two liquid phases is critical to the successful operation of many chemical and petrochemical processes. Besides its obvious importance to liquid-liquid extraction and washing operations, liquid-liquid phase separation can be a critical factor in other operations including two-liquid-phase reaction, azeotropic distillation, and industrial wastewater treatment. Sometimes the required phase separation can be accomplished within the main process equipment, such as in using an extraction column or a batch-wise, stirred-tank reactor; but in many cases a stand-alone separator is used. These include many types of gravity decanters, filter-type coalescers, coalescers filled with granular media, centrifuges, and hydrocyclones.

The path that a liquid-liquid mixture takes through a chemical process on its way to the separator often has a dramatic impact on separation difficulty once the mixture arrives. For this reason, the first steps toward designing a decanter or other type of liquid-liquid phase separator should include a study of the overall process flow sheet to determine whether changes in upstream processing conditions can make for an easier and more robust separation. For example, if the main stream entering the separator is produced by mixing a number of smaller streams, look for opportunities to remove fine solids that contaminate the main stream by filtering solids from one or more small streams before they enter the larger stream. Also, standard centrifugal pumps are notorious for producing stable dispersions. If this type of pump is used, determine whether the turbulence caused by the pump is contributing to phase separation difficulty; and if so, consider using gravity flow (if possible) or replacing a high-shear pump and piping system with a lower-shear design. If a dispersion proves to be particularly difficult to separate, it may be due to the presence of some contaminant acting as a surfactant. Contaminants may be oxidation products produced in trace amounts owing to leakage of air into the process, or they may be the products of corrosion of upstream equipment. They also may be materials that are intentionally added upstream to solve a problem there, such as cleaning agents and antifouling agents, but their presence, even in very small concentration, may cause unintended phase separation difficulties downstream.

## FEED CHARACTERISTICS

Traditionally, the guidelines for selection and design of a gravity decanter or other type of separator focus on the size of dispersed drops. However, drop diameter often cannot be accurately predicted during the design of a new process, especially the size of the smaller drops in the distribution of drop sizes, and often this information is not available for an existing process because of sampling difficulties. Furthermore, knowledge of drop size alone is not sufficient because it says nothing about the rate of drop coalescence. In light of this, it is recommended instead to characterize the feed material in terms of the results of simple shake tests, as indicated in Table 15-24. This basic information can be very helpful in identifying an appropriate separator.

In Table 15-24, feed materials are classified into four main types according to the results of a shake test. Typical values of interfacial tension, density difference, and viscosity also are listed. The shake test can be as simple as vigorously shaking a representative feed by hand in a sealed graduated cylinder (about an inch in diameter) for 30 s or 1 min. The graduated cylinder is then placed on the bench, the time is recorded, and the progress of the separation is observed. For systems with drops that coalesce quickly, a sharp interface will quickly form between two settling liquid layers, and the rate at which drops fall or rise to the interface will determine the rate of phase separation or clarification of the layers. For many other systems, however, drops will accumulate at the interface forming a dispersion band, i.e., a layer of slowly coalescing drops, and the rate at which the drops coalesce determines the rate of phase separation. Whether a system is fast-coalescing or slow-coalescing is an important question that is easily answered by performing a simple shake test. Figure 15-63 illustrates the details of a batch settling profile. Once the dispersion band has disappeared, one or both of the phases may remain cloudy. If so, this typically indicates the presence of droplets on the order of 100 μm in diameter or smaller. For additional discussion of dispersion properties, see "Liquid-Liquid Dispersion Fundamentals."

**TABLE 15-24 Shake Test Characterizations**

| Type | Shake test observations | Interfacial tension* | Density difference* | Viscosity of each phase* | Presence of fine solids or surfactants* |
|---|---|---|---|---|---|
| I | Dispersion band collapses within 5 min with crystal-clear liquids on top and bottom | Moderate to high, 10 dyn/cm or higher | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 5$ cP | Negligible |
| II | Dispersion band collapses within 10 to 20 min with clear liquids on top and bottom | Moderate, ~10 dyn/cm | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 20$ cP | Negligible |
| III | Dispersion band collapses within 20 min but one or more phases remain cloudy | Low to moderate, 3–10 dyn/cm | $\Delta\rho > 0.05$ g/cm$^3$ | $\mu < 100$ cP | Might be present in low concentration |
| IVa | Stable dispersion is formed (dispersion band does not collapse within an hour or longer)—high viscosity | Low to high | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu > 100$ cP in one of the phases | Negligible |
| IVb | Stable dispersion is formed—low interfacial tension | < 3 dyn/cm | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 100$ cP | Negligible |
| IVc | Stable dispersion is formed—low density difference | Low to high | $\Delta\rho < 0.05$ g/cm$^3$ | $\mu < 100$ cP | Negligible |
| IVd | Stable dispersion is formed—stabilized by surface-active components or solids | Low | $\Delta\rho > 0.1$ g/cm$^3$ | $\mu < 100$ cP | Enough surfactant/ solids to keep emulsion stable |

*Typical physical properties. Behavior also depends upon the shear history of the fluid. For this test, a sample is characterized by the results of the shake test (second column), not its physical properties. Physical properties are listed only as typical values.

## GRAVITY DECANTERS (SETTLERS)

Gravity decanters or settlers are simple vessels designed to allow time for two liquid phases to settle into separate layers (Fig. 15-64). Ideally, clear top and bottom layers form above and below a sharp interface or dispersion band. The top and bottom layers serve as clarifying zones. The height of the dispersion band, if present, generally remains constant during steady-state operation, although it may vary with position. The choice of where to locate the phase boundary within the vessel depends on whether more or less height is needed in the upper or lower clarification zones to obtain the desired clarity in the discharge streams. It can also depend on whether the inventory of one particular layer within the vessel should be minimized, as when handling reactive fluids such as monomers. Gravity decanters are well suited for separating type I feeds defined in Table 15-24 and, in most cases, type II feeds as well. It is common for coalescence to be the limiting factor in the separation of type II mixtures, so the design and sizing of the decanter will differ from those of the fast-coalescing systems.

**Design Considerations** Gravity decanters normally are specified as horizontal vessels with a length-to-diameter ratio greater than 2 (and often greater than 4) to maximize the phase boundary (cross-sectional area) between the two settled layers. This provides more effective utilization of the vessel volume compared to vertical decanters, although vertical decanters may be more practical for low-flow applications or when space requirements limit the footprint of the vessel.

The volume fraction of the minority phase is an important parameter in the operation of a decanter. Vessels handling less than 10 to 20 percent dispersed phase typically contain a wider distribution of droplet diameters with a long tail in the small size range [Barnea and Mizrahi, *Trans. Instn. Chem. Engrs.*, **53,** pp. 61–69 (1975)]. These decanters have a smaller capacity than when they contain more-concentrated dispersions. If one of the phases has a concentration lower than 20 percent in the feed mixture, it might be worthwhile to recycle the low-concentration phase to the feed point to boost the phase ratio within the separator vessel. Also, in certain cases increasing the operating temperature increases the drop coalescence rate. The result is a reduction in the dispersion band height for a given throughput, allowing an increase in the capacity of the settler. This behavior often can be attributed to a reduction in the continuous-phase viscosity.

Numerous methods are used to control the location of the interface inside the decanter. A boot or sump sometimes is included in the design to increase the path traveled by the heavy phase before exiting the vessel, to maximize the clarification zone for the light phase, or to minimize the inventory of heavy phase within the vessel. The interface can even be located inside the boot for one of these reasons. When a rag layer forms at the interface between settled layers, adding one or more nozzles in the vicinity of the interface will allow periodic draining of the rag (Fig. 15-65). Instruments such as differential pressure cells, conductance probes, or density meters are commonly used to control the location of the interface in a decanter. These instruments can be prone to fouling, and their operation can be compromised by the presence of a dispersion band or a rag layer. In that case, an alternative is to use an overflow leg or seal loop as illustrated in Figs. 15-64 and 15-65. The following expression can be used to specify the loop dimensions [Bocangel, *Chem. Eng. Magazine*, **93**(2), pp. 133–135 (1986); and Aerstin and Street, *Applied Chemical Process Design* (Plenum, 1982)]:

$$Z_2 = \frac{(h_L + Z_1 - Z_3)\rho_L}{\rho_H} + Z_3 - h_H \qquad (15\text{-}184)$$

where $Z_1$, $Z_2$, and $Z_3$ are the heights shown in Fig. 15-65 and $h_L$ and $h_H$ are the head losses in the light- and heavy-liquid discharge piping. An overflow leg can work reasonably well, provided that the densities of the two phases and the height of the dispersion band do not change significantly in operation (as in an upset). The light phase also may be removed through a takeoff tube entering the vessel from the bottom. This design provides added flexibility by allowing adjustment of the pipe length in the field without altering the vessel itself. Care should be taken to avoid the possibility of inducing a swirling motion as liquid enters the top of the weir. Swirling motions may be avoided or minimized by adding vanes or slots at the entrance.

To allow the phases to settle and remain calm, any form of turbulence or vortexing inside the decanter should be avoided. Introduction of the feed stream into the decanter should be located close to the interface to facilitate phase separation. Turbulence can arise from the inlet liquid entering the vessel at too high a velocity, forming a jet that disturbs the liquid layers. To counter these flow patterns, the feed into the gravity settler should enter the vessel at a velocity of less than

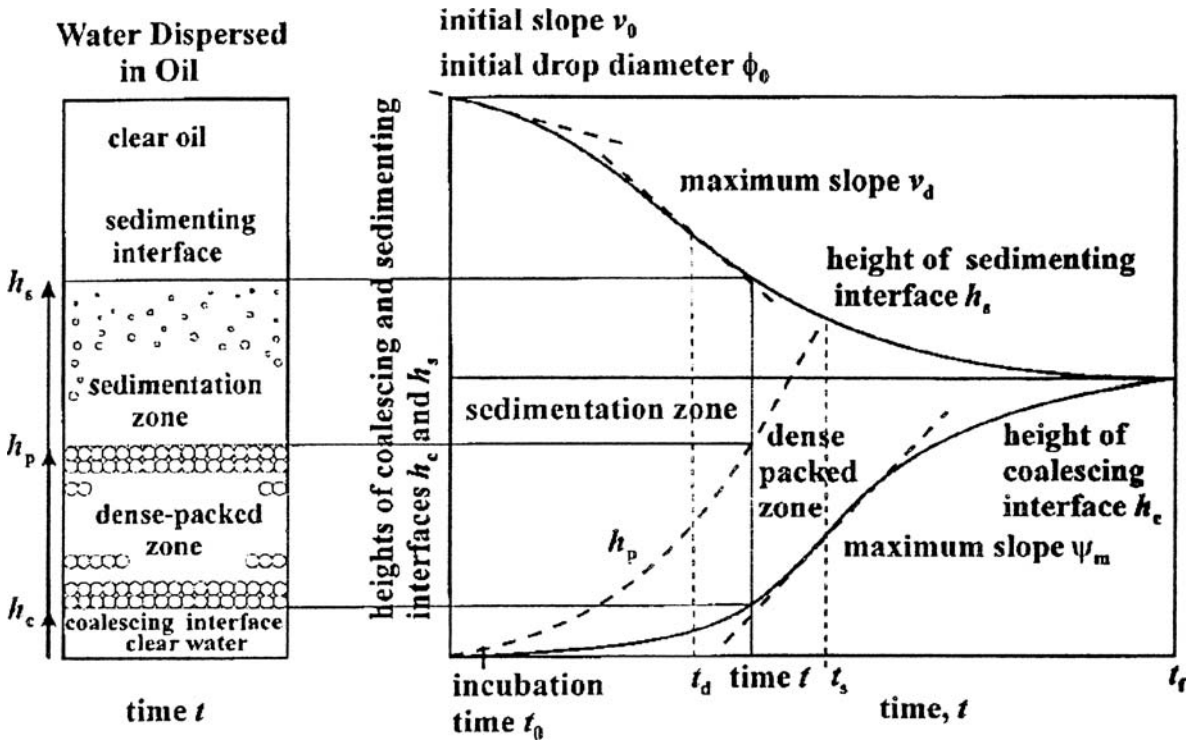


**FIG. 15-63** Batch settling profile showing four regions: a top clarified phase, a sedimentation zone, a dense-packed dispersion zone, and a bottom clarified phase. [*Reprinted from Jeelani, Panoussopoulos, and Hartland,* Ind. Eng. Chem. Res., **38**(2), *pp. 493–501 (1999), with permission. Copyright 1999 American Chemical Society.*] Consult the original article for a detailed description.

about 1 m/s (3 ft/s) as a general rule. This can be achieved by enlarging the feed line in the last 1 to 2 m (3 to 6 ft) leading to the vessel, to slow down the feed velocity at the inlet nozzle. In addition, a quiet feed zone may be created by installing a baffle plate in front of the feed pipe or a cap at the end of the feed line, with slots machined into the side of the pipe. Some designers are now using computational fluid dynamics (CFD) methods to analyze general flow patterns as an aid to specifying decanter designs.

**Vented Decanters** When the liquid-liquid stream to be decanted also contains a gas or vapor, provisions for venting the decanter must be included. This often is the case when decanting overheads condensate from an azeotropic distillation tower operating under vacuum, since some amount of air leakage is virtually unavoidable, or when decanting liquids from an extractor operating at a higher pressure. A common design used for this service when the amount of gas is low is shown in Fig. 15-66. The feed enters the vessel at a point below the liquid level, so any gas must flow up through the liquid before disengaging in the vapor head space. An alternative design is illustrated in Fig. 15-67. With this design, the feed is introduced to the top of the vessel in the vapor headspace so that gases can be freely discharged and disengaged with no back-pressure. One drawback to this approach is that the feed liquids are dropped onto the light liquid surface, and significant quantities of heavy liquid may be carried over to the light liquid draw-off nozzle owing to the resulting turbulence. To mitigate this effect, a quiescent zone may be

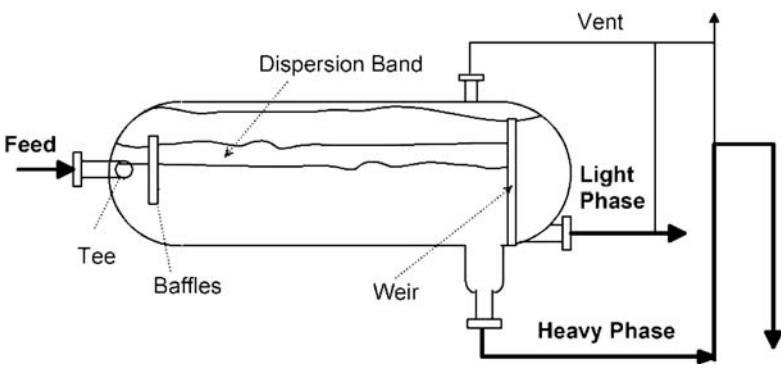

**FIG. 15-64** Typical horizontal gravity decanter design.

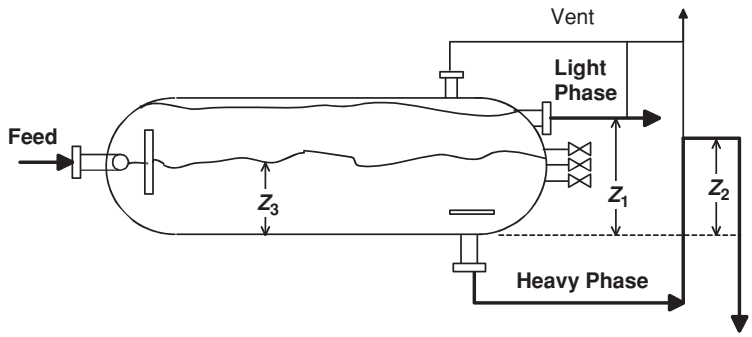

**FIG. 15-65** Overflow loop for the control of the main interface in a decanter.

provided immediately below the top feed nozzle by means of a perforated baffle, as shown in Fig. 15-67. The baffle separates the disturbance caused by the entering feed from a calm separation zone where the two liquid phases can coalesce and disengage prior to draw-off.

**Decanters with Coalescing Internals** Adding coalescing internals may improve decanter performance by promoting the growth of drops and may reduce the size of vessel required to handle dispersions with slow coalescence (as in type II systems in Table 15-24). A wide variety of internals have been used including wire mesh, knitted wire or fibers, and flat or corrugated plates. When plates are used, the coalescer is sometimes referred to as a lamella-type coalescer. Plates typically are arranged in packets installed at a slight angle with respect to horizontal. The plates shorten the distance that drops must rise or fall to a coalescing surface and guide the flow of the resulting coalesced film [Menon, Rommel, and Blass, *Chem. Eng. Sci.*, **48**(1), pp. 159–168 (1993); and Menon and Blass, *Chem. Eng. Technol.*, **14,** pp. 11–19 (1991)]. Arranging the plates in packets of opposite slopes promotes flow reversal, and this may lead to more frequent drop-drop collisions [Berger, *Int. Chem. Eng.*, **29**(3), pp. 377–387 (1989)]. The Merichem Fiber-Film® contactor described earlier in "Suspended-Fiber Contactor" under "Mixer-Settler Equipment" also may be used to promote growth of dispersed drops in a stream feeding a gravity decanter. In any case, the dispersed phase normally must preferentially wet the coalescence media for the media to be effective. If the feed contains solids, the potential for plugging the internals should be carefully evaluated. In certain cases, it may be necessary to allow access to the vessel internals for thorough cleaning. For more information, see Mueller et al., "Liquid-Liquid Extraction," *Ullmann's Encyclopedia of Industrial Chemistry*, 6th ed. (Wiley-VCH, 2002).

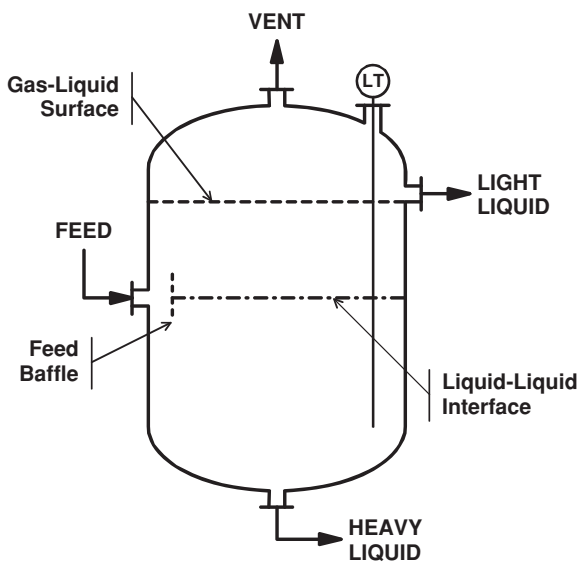

**FIG. 15-66** Vertical decanter with submerged feed.

**Sizing Methods** Sizing a decanter involves quantifying the relationship between the velocity of liquid to the phase boundary between settled layers and the average height of a dispersion band formed at the boundary. For fast-coalescing systems, the height of the dispersion band is negligible. Performance is determined solely by the rate of droplet rise or fall to the interface compared with the rate of flow through the decanter. In this case, design methods based on Stokes' law may be used to size the decanter, and residence time in the vessel becomes a key parameter. In many cases, however, coalescence is slow and the shake tests show a coalescence band that requires a fair amount of time to disappear. Then performance is determined by the volumetric flow rate of liquid to the boundary between the two settled layers, the boundary area available for coalescence, and the steady-state height of the dispersion band. For these systems, residence time is not a useful parameter for characterizing performance requirements.

***Stokes' Law Design Method*** This method is described by Hooper [Sec. 1.11 in *Handbook of Separation Techniques for Chemical Engineers*, 3d ed., Schweitzer, ed. (McGraw-Hill, 1997)]; and by Jacobs and Penney [Chap. 3 in *Handbook of Separation Process Technology*, Rousseau, ed. (Wiley, 1987)]. It assumes that the drop coalescence rate is rapid and relies on knowledge of drop size. The terminal settling velocity of a drop is computed by using Stokes' law

$$u_t = \frac{gd^2\Delta\rho}{18\mu_c} \tag{15-185}$$

where $d$ is a characteristic minimum drop diameter. (See Sec. 6 for detailed discussion of terminal settling velocity.) Note that which phase is continuous and which is dispersed can make a significant difference, since only the continuous-phase viscosity appears in Eq. (15-185). The decanter size is then specified such that

$$\frac{Q_c}{A} < u_t \tag{15-186}$$

where $Q_c$ is the volumetric flow rate of the continuous phase and $A$ is the cross-sectional area between the settled layers. This analysis assumes no effect of swirling or other deviation from quiescent flow, so a safety factor of 20 percent often is applied. Hooper and Jacobs indicate that designing for a Reynolds number $\mathrm{Re} = VD_h\rho_c/\mu_c$ less than 5000 or so should provide sufficiently quiescent conditions, where $V$ is the continuous-phase cross-flow velocity and $D_h$ is the

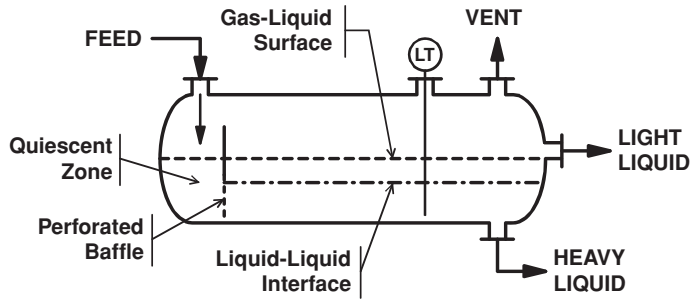

**FIG. 15-67** Horizontal decanter with feed entering from the top and a baffled quiescent zone.

hydraulic diameter of the continuous-phase layer (given by 4 times the flow area divided by the perimeter of the flow channel including the interface). Decanter design methods based on Stokes' law generally assume a minimum droplet size of 150 μm, and this appears to be a reasonably conservative value for many chemical process applications. For separating secondary dispersions, it is common to assume a drop size in the range 70 to 100 μm. For more detailed discussion, see Hartland and Jeelani, Chap. 13, pp. 509–516, in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994).

The method described above neglects any reduction in settling velocity due to the presence of neighboring drops at high population density (hindered settling). For best results, experimental data showing the relationship between settling velocity and initial dispersed-phase holdup should be generated. A simplified expression that neglects any drop coalescence during settling may be suitable for approximate design purposes

$$u_t \approx u_{t\infty}(1 - \phi_o)\,\frac{\mu_c}{\mu_d} \tag{15-187}$$

where $u_t$ is an average settling velocity used to specify the decanter design, $u_{t\infty}$ is the velocity of an isolated drop calculated from Eq. (15-185), and $\phi_o$ is the initial holdup. For more detailed discussion, see Ishii and Zuber, *AIChE J.*, **25,** pp. 843–855 (1979); and Das, *Chem. Eng. Technol.*, **20,** pp. 475–477 (1997).

***Design Methods for Systems with Slow Coalescence*** For slow-coalescing systems, simple Stokes' law calculations will not provide a reliable design. Instead, it is necessary to understand the height of the dispersion band as a function of throughput. Jeelani and Hartland [*AIChE J.*, **31,** pp. 711–720 (1985)] recommend correlating decanter performance by using an expression of the form

$$\frac{1}{Q/A} = \frac{1}{k_1 \Delta H} + \frac{1}{k_2} \tag{15-188}$$

where $\Delta H$ is an average steady-state dispersion band height, $Q$ is total volumetric throughput, and $k_1$ and $k_2$ are empirical constants. The general relationship between $\Delta H$ and $Q/A$ also may be expressed in terms of a power law equation of the form

$$\Delta H \propto \left(\frac{Q}{A}\right)^a \propto \left(\frac{Q_c}{A}\right)^a \propto \left(\frac{Q_d}{A}\right)^a \tag{15-189}$$

Equations (15-188) and (15-189) represent decanter performance for a given feed with constant properties, i.e., a constant composition and phase ratio. Note that the analysis can be done in terms of total flow $Q$ or the flow of continuous phase $Q_c$ or dispersed phase $Q_d$. Typically, the value of the exponent $a$ is greater than 2.5 [Barnea and Mizrahi, *Trans. Inst. Chem. Eng.*, **53,** pp. 61–91 (1975); and Golob and Modic, *Trans. Inst. Chem. Eng.*, **55,** pp. 207–211 (1977)]. The required size of a commercial-scale decanter may be determined by operating a small miniplant decanter to obtain values for the constants in Eqs. (15-188) and (15-189), since scale-up to the larger size generally follows the same relationship as long as the phase ratio and other operating variables are maintained constant. A commercial-scale decanter normally is designed for a throughput $Q/A$ that yields a value of $\Delta H$ no larger than 15 percent of the total decanter height. Designs specifying taller dispersion bands are avoided because a sudden change in feed rate can trigger a dramatic increase in the height of the dispersion band that quickly floods the vessel. The dynamic response of $\Delta H$ has been studied by Jeelani and Hartland [*AIChE J.*, **34**(2), pp. 335–340 (1988)].

In certain cases, batch experiments may be used to size a continuous decanter [Jeelani and Hartland, *AIChE J.*, **31,** pp. 711–720 (1985)]. In a batch experiment similar to the simple shake test described earlier, the change in the height of the dispersion band with time may follow a relationship given by

$$\frac{1}{-dh/dt} = \frac{1}{k_1 h} + \frac{1}{k_2} \tag{15-190}$$

where $h$ is the height of the batch dispersion band varying with time $t$. The constants $k_1$ and $k_2$ in Eq. (15-190) are the same as those used in the steady-state equation [Eq. (15-188)], assuming the batch test conditions (phase ratio and turbulence) are the same. Jeelani and Hartland have derived a number of models for systems with different coalescence behaviors [Jeelani and Hartland, *Chem. Eng. Sci.*, **42**(8), pp. 1927–1938 (1987)]. The most appropriate coalescence model is determined in batch tests and then is used to estimate $\Delta H$ versus throughput $Q/A$ for a continuous decanter. For additional information, see Hartland and Jeelani, Chap. 13 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994); Nadiv and Semiat, *Ind. Eng. Chem. Res.*, **34**(7), pp. 2427–2435 (1995); Jeelani and Hartland, *Ind. Eng. Chem. Res.*, **37**(2), pp. 547–554 (1998); Jeelani, Panoussopoulos, and Hartland, *Ind. Eng. Chem. Res.*, **38**(2), pp. 493–501 (1999); and Yu and Mao, *Chem. Eng. Technol.*, **27**(4), pp. 407–413 (2004). Development of design methods for specifying continuous decanters with coalescing internals using batch test data is a current area of research [Hülswitt and Pfennig, *ISEC '05*, Biejing, China (September 2005)].

Several authors have derived correlations relating the height of the dispersion band to the density of each phase, the density difference, the viscosities, and the interfacial tension of aqueous/organic or aqueous/aqueous two-phase systems [Golob and Modic, *Trans. Inst. Chem. Eng.*, **55,** pp. 207–211 (1977); and Asenjo et al., *Biotech. and Bioeng.*, **79**(2), pp. 217–223 (2002)]. These correlations can provide useful estimates, but the results are generally valid only for the systems used to develop the correlations and should be used with caution. For new applications, some experimental work will be needed for reliable design.

## OTHER TYPES OF SEPARATORS

**Coalescers** As noted earlier, adding coalescing internals to a decanter can improve decanter performance by promoting growth of small drops. The same concept can be applied in a separate coalescer vessel to treat the stream feeding the decanter. Systems of type III or type IV (Table 15-24) in particular may benefit, i.e., applications involving a need to break a secondary dispersion. Coalescers typically are packed with a granular material, a mesh made of metal wire or polymer filaments (or both), or fine fibers in woven or nonwoven composite sheets. The typical flow configuration is upflow if the light phase is dispersed and downflow if the heavy phase is dispersed. Coalescers containing fairly large media such as beds of granules or wire mesh may be able to tolerate a feed containing some fine solids. Coalescers containing fine granules or fine fibers require that the feed be free of solids to avoid plugging, so prefiltration may be necessary. For more detailed information, see Li and Gu, *Sep. and Purif. Tech.*, **42,** pp. 1–13 (2005); Shin and Chase, *AIChE J.*, **50**(2), pp. 343–350 (2004); Wines and Brown, *Chem. Eng. Magazine*, **104**(12), pp. 104–109 (1997); Hennessey et al., *Hydrocarbon Proc.*, **74,** pp. 107–124 (1995); Madia et al., *Env. Sci. Technol.*, **10**(10), pp. 1044–1046 (1976); Davies, Jeffreys, and Azfal, *Brit. Chem. Eng. Proc. Tech.*, **17**(9), pp. 709–712 (1972); and Hazlett, *Ind. Eng. Chem. Fund.*, **8**(4), pp. 625–632 (1969).

In most applications, the packing material should be wetted by the dispersed phase to some degree for best performance; however, this will depend on the size of dispersed droplets. For very fine droplets on the order of 10 μm or smaller, surface wetting is not the primary coalescence mechanism [Davies and Jeffreys, *Filtration and Separation*, pp. 349–354 (July/August 1969)]. In these cases, the packing promotes coalescence by providing a tortuous path that holds dispersed drops in close contact, facilitating drop-drop collisions. In other cases involving larger drops, a drop interception and wettability mechanism becomes important; i.e., the media provide a target for drop–solid surface collisions, and the surface becomes wetted with drops that merge together and leave the media as larger drops. In this case, an intermediate (optimum) wettability may be needed to most effectively promote the growth and dislodging of drops from the media [Shin and Chase, *AIChE J.*, **50**(2), pp. 343–350 (2004)]. In general, the degree to which flow path/collision mechanisms and/or surface wettability are important for good performance depends on the drop size distribution and dispersed-phase holdup in the feed, as well as system physical properties and whether surfactants or fine particulates are present. (See "Stability of Liquid-Liquid Dispersions" under "Liquid-Liquid Dispersion Fundamentals.") All this affects the choice of media, media size and porosity, and coalescer dimensions as a function of throughput. For a given application, some experimental work generally will be needed to sort this out and identify an effective and reliable design.

In cases where wettability is important, various types of sand, zeolites, glass fibers, and other inorganic materials may be used to facilitate coalescence of aqueous drops dispersed in organic feeds. Carbon granules, polymer beads, or polymer fibers may be useful in coalescing organic drops dispersed in water. The packing material should resist disarming by impurities, meaning that impurities should not become adsorbed and degrade the surface wettability characteristics over time. This can happen with charged or surfactantlike impurities; Paria and Yuet [*Ind. Eng. Chem. Res.*, **45**(2), pp. 712–718 (2006)] describe the adsorption of cationic surfactants at sand-water interfaces, a phenomenon that can alter surface wettability. In a few cases, the packing needs to age in service to develop its most effective surface properties.

Madia et al. [*Env. Sci. Technol.*, **10**(10), pp. 1044–1046 (1976)] describe a chromatography method for screening potential media with regard to surface wettability. The method involves measuring the retention times of water and heptane (or other components of interest) by using columns filled with the packing materials of interest (reduced in size if needed); the longer the relative retention time, the greater is the wettability of the packing for that component. The authors used gas chromatography of water and heptane to characterize coalescence for an oil-in-water dispersion; but it should be possible to characterize other systems by using this approach, and liquid chromatography methods might be used for components with low volatility.

For granular bed coalescers, typical granule sizes include 12 × 16 Tyler screen mesh (between 1.4 and 1 mm) and 24 × 48 Tyler mesh (0.7 to 0.3 mm). Smaller sizes sometimes are used as well. Typical bed heights range from 8 in to 4 ft (0.2 to 1.2 m), with the taller beds used with the larger granules. Layered beds may be used. For example, the front of the coalescer may contain a thin layer of fine media with low porosity and high tortuosity characteristics to facilitate drop-drop collisions of very small droplets, followed by a layer of coarser media having the wetting characteristics needed to further grow and shed larger drops.

For fine-fiber coalescers, the coalescing media normally are arranged in the form of a filter cartridge. Wines and Brown [*Chem. Eng. Magazine*, **104**(12), pp. 104–109 (1997)] describe a coalescing mechanism in which a drop (on the order of 0.2 to 50 μm) becomes adsorbed onto a fiber and then moves along the fiber with the bulk liquid flow until colliding with another adsorbed drop at the intersection where two fibers cross. Fiber diameter and wettability are important properties as they affect porosity (tortuous path) and wettable surface area. Like a packed-bed coalescer, a filter-type coalescer may be constructed in layers: an initial prefilter zone to remove particulates and minimize fouling, a primary coalescence zone where small droplets grow to larger ones, and a secondary coalescence zone with greater porosity and having surface-wetting characteristics optimized to grow the larger drops.

Pressure drop, an important consideration in the design of any coalescer, depends upon media size and shape, bed height or filter thickness, and throughput. Methods for calculating pressure drop through packed beds and porous media are described in Sec. 6. For approximately spherical media, the pressure drop due to frictional losses, assuming incompressible media, may be estimated from

$$\frac{\Delta P}{L} = \frac{150(1-\varphi)^2\mu V}{d_m^2\varphi^3} + \frac{1.75\rho_c V^2}{d_m\varphi^3} \qquad \mathrm{Re}_{\mathrm{particle}} = \frac{V\rho_c d_m}{\mu} \le 10 \tag{15-191}$$

where $L$ is the length of the packed section, $V$ is the superficial velocity of the total liquid flow, $d_m$ is an equivalent spherical diameter of the media particles (given by 6 times the mean ratio of particle volume to particle surface area), and $\varphi$ is the volume fraction of voids (flow channels) within the bed [Ergun, *Chem. Eng. Prog.*, **48**(2), pp. 89–94 (1952)]. Also see Leva, *Chem. Eng. Magazine*, **56**(5), pp. 115–117 (1949), or Leva, *Fluidization* (McGraw-Hill, 1959). The minimum value of $\varphi$ for a tightly ordered bed of uniform spherical particles is 0.26, but of course for real media this will vary depending upon the particle size distribution and particle shape. The second term in Eq. (15-191) often is neglected at $\mathrm{Re}_{\mathrm{particle}} \le 1$. For fiber media, $d_m$ can be thought of as a characteristic fiber dimension. For discussion of pressure drop through fiber beds, see Shin and Chase, *AIChE J.*, **50**(2), pp. 343–350 (2004); and Li and Gu, *Sep. and Purif. Tech.*, **42,** pp. 1–13 (2005). In practice, pressure drop data may be correlated by using an equation of the same form as Eq. (15-191), $\Delta P/L = aV + bV^2$, where $a$ and $b$ are empirically determined constants. Media and equipment suppliers generally will have some experimental data showing $\Delta P/L$ versus flow rate.

**Centrifuges** A stacked-disk centrifuge or other type of centrifuge may be a cost-effective option for liquid-liquid phase separation whenever use of a gravity decanter/coalescer proves to be impractical because rates of drop settling or coalescence are too low. This may be the case for type III and type IV systems (Table 15-24) in particular. Factors involved in specifying a centrifuge are discussed in "Centrifugal Extractors" under "Liquid-Liquid Extraction Equipment."

**Hydrocyclones** Liquid-liquid hydrocyclones, like centrifuges, utilize centrifugal force to facilitate the separation of two liquid phases [*Hydrocyclones: Analysis and Applications,* Svarovsky and Thew, eds. (Kluwer, 1992); and Bradley, *The Hydrocyclone* (Pergamon, 1965)]. Instead of using rotating internals, as in a centrifuge, a hydrocyclone

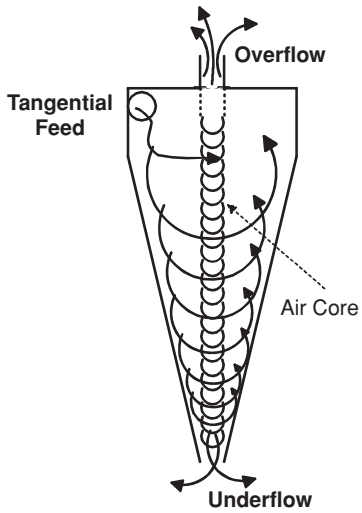

**FIG. 15-68** Flow patterns in a hydrocyclone.

generates centrifugal force through fluid pressure to create rotational fluid motion (Fig. 15-68). Feed enters the hydrocyclone through a tangential-entry nozzle. A primary vortex rich in the heavy phase forms along the inner wall, and a secondary vortex rich in the light phase forms near the centerline. The underflow stream (heavy phase) exits the cyclone through the apex of the cone (underflow nozzle). The overflow stream (light phase) exits through the vortex finder, a tube extending from the cylinder roof into the interior. The feed split can be adjusted by changing the relative diameters of the vortex finder and underfow nozzle. A hydrocyclone is not completely filled with liquid; an air core exists at the centerline. A commercial-scale hydrocyclone multiplies the force of gravity by a factor of 100 to 1000 or so, depending on the diameter and operating pressure. Hydrocyclones traditionally have been used for liquid-solid separations, but by adjusting their design (cone angle and length, vortex finder length, and so on) they can be applied to liquid-liquid separations [Mozley, *Filtration and Sep.*, pp. 474–477 (Nov./Dec. 1983)].

Since the fluid flow is turbulent at the top of the unit and the rotation of liquid within the device produces a high shear field, mixtures with low interfacial tension tend to emulsify or create foam within a hydrocyclone. However, hydrocyclones may be well suited for type I or possibly type II mixtures containing some solids, especially if only a rough cut is needed. The flow pattern established within a hydrocyclone normally requires that a considerable part of the feed leave in the overflow outlet. For this reason, hydrocyclones are generally more efficient for feeds containing only a small fraction of heavy phase, although some authors indicate they can be effective for feeds with a small fraction of light phase through careful specification of hydrocyclone geometry.

The main operating variables for a hydrocyclone are the feed pressure, the feed flow rate, and the split ratio, i.e., the relative amounts of fluid exiting top and bottom. The split ratio may be adjusted by specifying the size of the underflow and overflow nozzles. Choosing a material of construction wetted by the heavy phase for the cone may improve the effectiveness of the device. Experimental work is needed to determine the efficiency of the separation as a function of the split ratio for a series of flow rates and hydrocyclone geometries [Sheng, *Sep. and Purif. Methods*, **6**(1), pp. 89–127 (1977); and Colman and Thew, *Chem. Eng. Res. Des.*, **61**(7), pp. 233–240 (1983)]. If testing indicates satisfactory performance, hydrocyclones can be relatively inexpensive and simple-to-operate units (no moving parts). Because sufficient centrifugal force cannot be generated in large-diameter units, scale-up consists of connecting multiple small units in parallel. Units are sometimes placed in series to provide multiple stages of separation. Hydrocyclones are used on ships and drilling platforms for removing oil from water [Bednarski and Listewnik, *Filtration and Sep.*, pp. 92–97 (March/April 1988)]. Numerical simulations of hydrocyclone performance and flow profiles are described by Bai and Wang [*Chem. Eng. Technol.*, **29**(10), pp. 1161–1166 (2006)] and by Murphy et al. [*Chem. Eng. Sci.*, **62,** pp. 1619–1635 (2007)].

**Ultrafiltration Membranes** These are microporous membranes with pore sizes in the range of 0.1 and 0.001 μm [Porter, "Ultrafiltration," in *Handbook of Industrial Membrane Technology* (Noyes, 1990)]. In this size range, the pores may be used to "filter out" and concentrate micelles from a liquid feed without disrupting (breaking) the micellar structure. Such a membrane may also be used to remove micrometer size droplets from a dilute dispersion. However, if the dispersed-phase content is too high, the membrane may become fouled owing to deposition of a coalesced layer that obstructs the pores. This can be a particular problem when removing oil droplets for an oil-in-water dispersion using a polymeric membrane.

The feed solution is fed to the membrane module under pressure (normally less than 6 bar). The majority of the continuous phase flows through the pores of the membranes by pressure difference and collects on the permeate side as a clarified solution. The micelles or microdroplets are rejected and flow with the remaining continuous phase, tangentially along the membrane surface, to the retentate outlet of the membrane module [Voges, Wu, and Dalan, *Chem. Processing*, pp. 40–43 (April 2001)]. The shear at the surface of the membrane should be high enough to stop the micelles from aggregating on the polymeric surface of the membrane, but low enough to avoid breaking the colloidal particles.

Ultrafiltration membranes can be very efficient at removing colloidal particles of an emulsion but normally will not stop dissolved oil from permeating. Since most membranes are polymeric, they are more stable in the presence of water, so they are best suited for aqueous systems. Since they produce only one well-clarified phase (the permeate), they should be applied to processes with stable micelles where clear continuous phase is required and where losses of continuous phase with the micellar phase can be tolerated. The use of ultrafiltration membranes in an extractive ultrafiltration process for recovery of carboxylic acids is discussed by Rodríguez et al. [*J. Membrane Sci.*, **274**(1–2), pp. 209–218 (2006)].

Selecting the membrane best suited for a given application is best accomplished experimentally. The membrane material must be compatible with the feed, and the module should exhibit high permeation flow while maintaining good micelle rejection. The pore size and the molecular weight cutoff reported by the manufacturer are good indications of membrane performance; but since other factors such as membrane/solute interaction and fouling impact the separation, this information is only a starting point. Key operating parameters include temperature, feed flow rate, and permeate-to-feed ratio. Scale-up consists of adding membrane modules to handle the required production rate [Eykamp and Steen, Chap. 18 in *Handbook of Separation Process Technology,* Rousseau, ed. (Wiley, 1987)].

**Electrotreaters** In an electrostatic coalescer, an electric field is applied to a dispersion to induce dipoles or net charges on the suspended drops. The drops are then attracted to one another, facilitating their coalescence [Waterman, *Chem. Eng. Prog.*, **61**(10), pp. 51–57 (1965); and Yamaguchi, Chap. 16 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994)]. This technology is applicable only to a nonconductive continuous phase and an aqueous dispersed phase. Once the water drops are sufficiently large, they settle to the bottom of the vessel while the clarified oil phase migrates to the top. The top and bottom zones are kept quiet and out of the electric field. In cases where inlet salt content is high, a multistage, countercurrent desalting system can be used. Units with ac or dc voltage are available.

Electrostatic separators are high-voltage electrostatic devices that can arc under certain conditions. For this reason, a careful review of safety considerations is needed, especially for applications involving flammable liquids. Evaluating feasibility and generating design data normally involve close consultation with the equipment vendors. This technology is applied on a very large scale in the petroleum industry for crude oil desalting.

# EMERGING DEVELOPMENTS

## MEMBRANE-BASED PROCESSES

**Polymer Membranes** Extraction processes employing polymer membranes are sometimes referred to as nondispersive or pertraction operations. The use of membranes in extraction offers a number of potential advantages including (1) constant well-defined mass-transfer area; (2) the ability to operate at very low solvent-to-feed ratios independent of other operating variables; (3) very low holdup of solvent and product within the extractor, thus providing low residence time similar to a centrifugal extractor; (4) dispersion-free liquid-liquid contacting that eliminates the need for liquid-liquid interface control and phase separation; (5) no requirement for a difference in density between liquid phases; and (6) linear scale-up by addition of extra modules, so performance at large scale can be determined directly from small-scale tests using a single module. This last point suggests, however, that the economy of scale may not be as large as it is for extractors that are scaled up as a single larger unit.

The most important advantages that membranes can offer to the process designer are those that overcome an inherent limitation of another type of extractor, as in the ability to handle liquids with close or even equal densities and the ability to operate at extremely low solvent-to-feed ratios. Thus, the types of applications where membranes are likely to be most attractive include applications with close densities and/or a $K$ value greater than 50 or so. In principle, $K > 50$ would allow operation using a solvent-to-feed ratio of 1 : 25 or less (for an extraction factor of 2), something that can be difficult to accomplish by using conventional extractors. To take full advantage, the feed would have to be sufficiently dilute that the loading capacity of the solvent is not exceeded. The primary disadvantages of membrane-based extractors are the added mass-transfer resistance across the membrane, limited fiber-side or tube-side throughput, and concerns about fouling and limited membrane life in industrial service. Applications are limited to feeds that are free of solid particles (or can be cost effectively prefiltered); otherwise, the membranes are easily fouled. The useful life of a membrane module also is a critical factor since the frequency with which membrane modules must be replaced has a dramatic impact on overall cost.

The use of nonporous polymer membranes for liquid-liquid extraction suffers from very slow permeation of solute through the membrane, although this approach has been developed for a special case involving reaction-enhanced extraction of an aromatic acid from wastewater through a nonporous silicone membrane into a caustic solution [Ferreira et al., *Desalination*, **148**(1–3), pp. 267–273 (2002)]. For most liquid-liquid extraction applications, however, a porous membrane is used and extraction involves transfer through a liquid-liquid meniscus maintained within the pores. One of the most promising contactors for this type of extraction is the microporous hollow-fiber (MHF) contactor (Fig. 15-69). The MHF contactor resembles a shell-and-tube heat exchanger in which the tube walls are porous and are capable of immobilizing a liquid-liquid interface within the pores. For a hydrophobic polymeric membrane, the aqueous phase normally is fed to the interior of the fiber (the fiber-bore side), while the organic phase is fed to the shell side. In this configuration, the aqueous fluid is maintained at a higher pressure relative to the organic phase, to immobilize the liquid-liquid interface within each pore. Care must be taken to avoid too high an aqueous pressure, or else breakthrough of the aqueous phase can occur. This breakthrough pressure is a function of the interfacial tension and pore size. Earlier versions of MHF contactors provided a parallel-flow design, but this design suffered from shell-side bypassing [Seibert et al., *Sep. Sci. Technol.*, **28**(1–3), p. 343 (1993)]. An improved design that incorporates a central baffle and uniform fiber spacing is currently available (Fig. 15-69). The dimensions are listed in Table 15-25.

In the baffled design, the shell-side fluid is fed through a central perforated distributor. It flows radially through the fiber bundle, around a baffle located in the middle of the module, and leaves the module through the central distributor. As in conventional extraction, the mass transfer of solute occurs across a liquid-liquid interface. However, unlike in conventional extraction, the interface is maintained at micrometer-size pores, and three mass-transfer resistances are present: tube-side ($k_t$), shell-side ($k_s$), and pore or membrane-side ($k_m$). The overall mass-transfer coefficient based on the tube-side liquid $k_{ot}$ is given by

$$\frac{1}{k_{ot}} = \frac{1}{k_t} + \frac{m^{\text{vol}}}{k_s} + \frac{1}{k_m} \tag{15-192}$$

where $m^{\text{vol}}$ is the local slope of the equilibrium line for the solute of interest, with the equilibrium concentration of solute in the tube-side

liquid plotted on the $y$ axis and the equilibrium concentration of solute in the shell-side liquid plotted on the $x$ axis. Equation (15-192) assumes the tube-side fluid wets the pores.

The mass-transfer efficiencies of various MHF contactors have been studied by many researchers. Dahuron and Cussler [*AIChE J.*, **34**(1), pp. 130–136 (1988)] developed a membrane mass-transfer coefficient model ($k_m$); Yang and Cussler [*AIChE J.*, **32**(11), pp. 1910–1916 (1986)] developed a shell-side mass-transfer coefficient model ($k_s$) for flow directed radially into the fibers; and Prasad and Sirkar [*AIChE J.*, **34**(2), pp. 177–188 (1988)] developed a tube-side mass-transfer coefficient model ($k_t$). Additional studies have been published by Prasad and Sirkar ["Membrane-Based Solvent Extraction," in *Membrane Handbook*, Ho and Sirkar, eds. (Chapman & Hall, 1992)]; by Reed, Semmens, and Cussler ["Membrane Contactors," *Membrane Separations Technology: Principles and Applications*, Noble and Stern, eds. (Elsevier, 1995)]; by Qin and Cabral [*AIChE J.*, **43**(8), pp. 1975–1988 (1997)]; by Baudot, Floury, and Smorenburg [*AIChE J.*, **47**(8), pp. 1780–1793 (2001)]; by González-Muñoz et al. [*J. Membane Sci.*, **213**(1–2), pp. 181–193 (2003) and *J. Membrane Sci.*, **255**(1–2), pp. 133–140 (2005)]; by Saikia, Dutta, and Dass [*J. Membrane Sci.*, **225**(1–2), pp. 1–13 (2003)]; by Bocquet et al. [*AIChE J.*, **51**(4), pp. 1067–1079 (2005)]; and by Schlosser, Kertesz, and Martak [*Sep. Purif. Technol.*, **41,** p. 237 (2005)]. A review of mass-transfer correlations for hollow-fiber membrane modules is given by Liang and Long [*Ind. Eng. Chem. Res.*, **44**(20), pp. 7835–7843 (2005)]. Eksangsri, Habaki, and Kawasaki [*Sep. Purif. Technol.*, **46,** pp. 63–71 (2005)] discuss the effect of hydrophobic versus hydrophilic membranes for a specific application involving transfer of solute from an aqueous feed to an organic solvent. Karabelas and Asimakopoulou [*J. Membrane Sci.*, **272**(1–2), pp. 78–92 (2006)] discuss process and equipment design considerations.

In general, researchers have treated MHF contactors as differential contacting devices. However, Seibert and Fair [*Sep. Sci. Technol.,* **32**(1–4), pp. 573–583 (1997)] and Seibert et al. [*ISEC '96 Proc.*, **2,** p. 1137 (1996)] suggest that the baffled MHF contactor can be treated as a staged countercurrent contactor. Their recommendations are based on studies using a commercial-scale skid-mounted extraction system. Their semi-work-scale study demonstrated the performance advantages of the MHF contactor relative to a column filled with structured packing for a system with a high partition ratio. Seibert et al. [*ISEC '96 Proc.*, **2,** p. 1137 (1996)] also provide limited economic data for the extraction of $n$-hexanol from water by using $n$-octanol. Also see the discussion by Yeh [*J. Membrane Sci.*, **269**(1–2), pp. 133–141 (2006)] regarding the use of internal reflux in a cross-flow membrane configuration to boost liquid velocities for enhanced performance.

**Liquid Membranes** Emulsion liquid-membrane (ELM) extraction involves intentional formation of an emulsion between two immiscible liquid phases followed by suspension of the emulsion in a third liquid that forms an outer continuous phase. The encapsulated liquid and the continuous phase are miscible. The liquid-membrane phase is immiscible with the other phases and normally must be stabilized by using surfactants. If the continuous phase is aqueous, the suspended phase is a water-in-oil emulsion. If the continuous phase is organic, the emulsion is the oil-in-water type. This technology differs from traditional liquid-liquid extraction processes in that it allows transfer of solute between miscible liquids by introducing an immiscible liquid membrane between them. A typical process involves first forming a stable emulsion and contacting it with the continuous phase to transfer solute between the encapsulated phase and the continuous phase, followed by steps for separating the emulsion and continuous phases and breaking the emulsion. The emulsion must be sufficiently stable to remain intact during processing, but not so stable that it cannot be broken after processing, and this may present a challenge for commercial implementation. The technology is described by Frankenfeld and Li [Chap. 19 in *Handbook of Separation Process Technology*, Rousseau, ed. (Wiley, 1987)].

Potential applications of ELM extraction include separation of aromatic and aliphatic hydrocarbons [Chakraborty and Bart, *Chem. Eng. Technol.*, **28**(12), pp. 1518–1524 (2005)], separation and concentration of amino acids [Thien, Hatton, and Wang, *Biotech. and Bioeng.*, **32**(5), pp. 604–615 (1988)], and recovery of penicillin G from fermentation broth [Lee, Lee, and Lee, *J. Chem. Technol. Biotechnol.*, **59**(4), pp. 365–370, 371–376 (1994); Lee et al. *J. Membrane Sci.*, **124,** pp. 43–51 (1997); and Lee and Yeo, *J. Ind. Eng. Chem.*, **8**(2), p. 114 (2002)]. The latter application involves transfer of the penicillin G solute ($pK_a = 2.7$) from the continuous phase (consisting of a filtered broth adjusted to a pH of about 3) into the membrane phase (typically $n$-lauryltrialkymethyl amine extractant dissolved in kerosene) and then into the interior aqueous phase (clean water at a pH of about 8). Lee et al. [*J. Membrane Sci.*, **124,** pp. 43–51 (1997)] show that the operation can be carried out in a continuous countercurrent extraction column. The product is later obtained by separating the emulsion droplets from the continuous phase by using filtration, and this is followed by breaking the emulsion and isolating the interior aqueous phase from the amine extractant phase. A polyamine surfactant is used to stabilize the emulsion during extraction.

Supported liquid-membrane (SLM) processes involve introduction of a microporous solid membrane to serve as a support for the liquid-membrane phase. The microporous membrane provides well-defined interfacial area and eliminates the need for a surfactant. As in the penicillin ELM application described above, SLM applications often employ an extractant solution as the liquid-membrane phase to enable a facilitated transport mechanism. The extractant species interacts with the desired solute at the feed side and then carries the solute across the membrane to the other side, where solute transfers into a stripping solution. Such a process, whether using a surfactant-stabilized emulsion or a supported liquid membrane, allows forward and back extraction (or stripping) in a single operation. Ho and Wang [*Ind. Eng. Chem. Res.*, **41**(3), pp. 381–388 (2002)] discuss the application of SLM technology to remove radioactive strontium, Sr-90, from contaminated waters. Other examples involve extraction of metal ions from water [Canet and Seta, *Pure Appl. Chem.* (*IUPAC*), **73**(12), pp. 2039–2046 (2001)] and recovery of aromatic acids or bases from wastewater [Dastgir et al., *Ind. Eng. Chem. Res.*, **44**(20), pp. 7659–7667 (2005)]. One of the challenges encountered in using supported liquid membranes is the difficulty in controlling trans-membrane pressure drop and maintaining the liquid membrane on the support; it may become dislodged and entrained into the flowing phases. Various approaches to stabilizing the supported liquid have been proposed. These are discussed by Dastgir et al. [*Ind. Eng. Chem. Res.*, **44**(20), pp. 7659–7667 (2005)].

## ELECTRICALLY ENHANCED EXTRACTION

An electric field may be used to enhance the performance of an aqueous-organic liquid-liquid contactor, by promoting either drop breakup or drop coalescence, depending upon the operating conditions and how the field is applied. The technology normally involves dispersing an electrically conductive phase (the aqueous phase) within a continuous nonconductive phase, applying a high-voltage electric field (either ac or dc) across the continuous phase, and taking advantage of the effect of the electric field

on the shape, size, and motion of the dispersed drops. The potential advantages of this technology include more precise control of drop size and motion for improved control of mass transfer and phase separation within an extractor. Potential disadvantages include the requirement for more complex equipment, difficulties in scaling up the technology to handle large production rates, and safety hazards involved in processing flammable liquids in high-voltage equipment.

A number of different equipment configurations and operating concepts have been proposed. Yamaguchi [Chap. 16 in *Liquid-Liquid Extraction Equipment*, Godfrey and Slater, eds. (Wiley, 1994)] classifies the proposed equipment into three general types: perforated-plate and spray columns, mixed contactors, and liquid-film contactors. For example, Yamaguchi and Kanno [*AIChE J.*, **42**(9), pp. 2683–2686 (1996)] describe an apparatus in which a dc voltage is applied between two electrodes in the presence of a nitrogen gas interface. Aqueous drops form in the presence of the electric field, and they are first attracted to the gas-liquid interface. Once the drops contact the interface, the charge on the drops is reversed, and the drops fall back to coalesce at the bottom of the vessel. Bailes and Stitt [U.S. Patent 4,747,921 (1988)] describe a rotating-impeller extraction column containing alternating zones of high voltage (to promote dispersed drop coalescence) and high-intensity mixing (to promote redispersion of drops). In this design, the electric field serves to promote drop coalescence so that dispersed drops experience alternating drop breakup and growth as they move through the agitated column. Scott and Wham [*Ind. Eng. Chem. Res.*, **28**(1), pp. 94–97 (1989)] and Scott, DePaoli, and Sisson [*Ind. Eng. Chem. Res.*, **33**(5), pp. 1237–1244 (1994)] describe a nonagitated apparatus called an emulsion-phase contactor. This device employs an electric field to induce formation of a stable emulsion or dispersion band, with clear organic and aqueous layers above and below. The aqueous phase is fed to the middle or top of the dispersion band; it flows down through the band and is removed from a clarified aqueous zone maintained at the bottom. The lighter organic phase is fed to the bottom; it moves up through the dispersion band and is removed from the top. The net result is countercurrent contacting with very high interfacial area and significantly improved mass transfer in terms of the number of transfer units achieved for a given contactor height.
