Preface to Third Edition

Since the manuscript of the second edition was sent to press in 1971, rapid strides have been made in different facets of chromosome research. At the level of light microscopy, new techniques have aided in the clarification of chromosome details and the resolution of its finer structure. Even chromosomes of differentiated nuclei have been amenable to analysis and the dynamic behaviour of chromosomes during organogenesis has been demonstrated.

Considerable refinements in fluorescence technology, coupled with the various modifications of banding procedure, have opened new avenues for chromosome identification in eukaryotes in general, and in mammalian and human systems in particular. These advancements have stimulated researches on human chromosome analysis in different centres of the world. The study of sequence complexity of deoxyribonucleic acid in higher organisms is now no longer considered a difficult proposition.

Molecular hybridisation at the chromosome level, in conjunction with refined methods of extraction including column separation, have not only identified the repeated sequences in chromosomes but to a certain extent their functions as well. One may look forward to significant developments in the analysis of functional chromosome segments in the near future.

Electron microscopy has undergone further sophistication and knowledge of ultrastructural details of chromosome segments has led to the unravelling of several problems hitherto unsolved. The extent of progress can be assessed by the very fact that bands and even hybridised segments of chromosomes may now be subjected to analysis.

Chromosome research has received significant stimulus from *in vitro* culture of protoplast cells, tissues and organs. New techniques are being devised to study the chromosomes from such systems, including their identification in fused protoplasts.

In the last few years, chromosome scientists have thus been able to exploit fully the advanced sophistications in biophysical and biochemical techniques. In chromosome analysis, molecular and cellular methodologies have undergone a remarkable synthesis; techniques in cell biology have come to the forefront; *in vitro* study has become a routine procedure and new dimensions have been added to ultrastructure research. An attempt has been made in the present edition to bring all these achievements into focus, and to deal with the technological processes, with their principles, limitations and recent

developments. A broad spectrum of the principal methods, ranging from the very elementary to the most complicated ones, has been provided. The aim of the book will be fulfilled if it proves to be useful in all biological, agricultural and medical institutions where chromosome research is pursued at cellular, sub-cellular, ultrastructural and/or molecular levels of analysis.

In addition to the scientists who had kindly permitted their preparations to be included in the second edition, the authors are also grateful to Professor Keith Jones (Kew), Dr. C. G. Vosa (Oxford), Dr. Marina Seabright (Salisbury) and Dr. M. Ray (Winnipeg) for photographs of their preparations included in this edition. Sincere thanks are also due to our publishers, Butterworths, for their patience and promptness in processing the manuscript.

Preface to Second Edition

The last eight years, since the first edition went to press, have witnessed tremendous advances made in all aspects of chromosome methodology. In addition to overall refinements to the methods already in vogue, outstanding progress has been achieved in the fields of human and mammalian chromosome methodology, including the study of malignant cells, mammalian chromosome analysis, and chromosomes in culture, together with somatic cell hybridisation, electron microscopy, high-resolution autoradiography and other modes of quantitation. These advancements in technology, along with a wide appreciation of the first edition—which resulted in its reprinting—aided by the criticisms and suggestions received from reviewers, prompted us to venture on a new edition of the book. Each chapter has been rewritten with suitable additions, and deletions of the relatively less important techniques. Several new chapters have been incorporated but limitations imposed by the cost of production did not allow us to deal with the details of instrumentation on which a number of treatises are available.

In addition to those scientists, who had kindly given us the original microphotographs of their preparations for the first edition, the present edition has been further enriched by the inclusion of valuable photographs presented by the following experts, to whom we wish to express our sincere gratitude: Dr. E. G. Barry (Dept. of Botany, University of North Carolina, Chapel Hill); Prof. W. Beermann (Max-Planck-Institute, Tübingen); Prof. J. G. Gall and Dr. M. L. Pardue (Dept. of Biology, Yale University, New Haven); Prof. H. Harris (William Dunn School of Pathology, University of Oxford); Dr. T. C. Hsu (M. D. Anderson Hospital, University of Texas); Prof. B. John (Dept. of Genetics, University of Southampton); Prof. B. A. Kihlman (Dept. of Genetics, Royal Agricultural College, Uppsala); Dr. T. N. Khoshoo (National Botanic Gardens, Lucknow); Dr. S. Ohno (Dept. of Biology, City of Hope Nat. Med. Center, Duarte, Calif.); Prof. S. P. Raychaudhuri (Dept. of Zoology, Banaras); Dr. M. Ray (Children's Hospital, Winnipeg); Dr. V. Sorsa (Dept. of Genetics, Univ. of Helsinki); Dr. M. S. Swaminathan (Indian Agricultural Research Institute, New Delhi); Prof. J. Wahrman (Dept. of Zoology, Hebrew University, Jerusalem); Dr. F. Weiner (Karolinska Institute, Stockholm); and Prof. M. J. D. White (Dept. of Genetics, University of Melbourne, Victoria).

This endeavour would be considered a success if it proves useful to all workers interested in any aspect of chromosome study. Lastly, we are grateful

to our publishers for their patience and meticulous care in attending to the revised manuscript.

Archana Sharma

Preface to First Edition

The tremendous progress of the discipline of cytology within the last 20 years has been responsible for making the study of chromosomes a science in itself with its own theories and techniques and its own achievements. The continued enthusiasm for refinement in methods owes its impetus to the outstanding discoveries on the finer structure of chromosomes, the chromosomal basis of differentiation and the role and association of chromosomes in human abnormalities and cancer. Technological advances have also led to widening of the outlook on chromosome structure from a purely cytogenetical level towards a cytochemical and cytophysical analysis. This approach has given the cell biologist an insight into the pattern or organisation at the microscopical, submicroscopical, ultrastructural and even molecular levels. Achievements in methodology have further revealed the dynamic nature of chromosomes, in spite of their basic uniformity and their multiplicity in structure and chemistry, together with their development and physiology at different phases of growth.

A serious handicap to a cytologist is the absence of any comprehensive single treatise on the methodology of all aspects of chromosome structure and behaviour in all organisms and at different stages of their differentiation. Chromosome science, responsible for the unification in biology, should be viewed as a whole—as fundamental to all organisms and not as a series of compartmental sciences in separate realms of plants, animals or human beings. Not only does the need for a comprehensive treatise limit the study of chromosome science, but the absence of any book dealing with the chemistry of reactions between reagents and chromosomes is also a serious impediment to advanced research. The idea that the chemistry of the reactions is not known does not represent the true state of affairs. A number of reactions, though studied by experimenters, have not been published; those that are published, have not been compiled and presented for the convenience of the worker. The absence of any information on the chemical principles underlying chromosome techniques has resulted in the general practice of random trials with different fluids in search of a suitable one.

This unscientific approach must necessarily be replaced by scientific and rational treatment. The difficulties that we faced as student, as research worker and as teacher, prompted one of us to start a probe into the technological aspects about 20 years ago. The intervening years have seen considerable advances in this field from different centres, including our own. The need

for the presentation of the data obtained, in a critical and comprehensive form, is strongly felt—hence this publication.

In this book, efforts have been directed at presenting the technological aspects of chromosome study with particular emphasis on the principles underlying the different techniques and on the outlining of schedules. Methods have been described along with an account of their advantages, limitations and applicability, to enable the worker to plan a project directed either towards refining the methods given, discovering newer ones or applying them to various objects. As a natural sequence, the achievements too have been pointed out in brief. In order to meet the above ends a considerable amount of theoretical discussion has been incorporated which, it is hoped, would be of use to anyone interested in chromosome study.

This book is designed to meet the requirements of teachers, research workers and students alike, engaged in chromosome studies on plants, animals and human beings. No claim is made however to regard it as an encyclopedia; for discussions on certain aspects of instrumentation, such as in electron microscopy or ultraviolet photometry, the reader is referred to the works of experts in the field. Efforts have been made to provide the widest possible fundamental knowledge for those whose only instruction in chromosome science would be this book, and maximum specialisation for those who intend to pursue it further. Modern developments in chromosome science have not only undergone evolution towards extreme specialisation but simultaneously towards greater simplification of the existing schedules. That is why chromosome science can now be pursued in any laboratory, however ill-equipped it may be, the category of research naturally depending on the availability of equipment. The object of the book will be achieved if it can meet the demands of workers engaged in this field in any type of laboratory.

The task has been made easier by the existence of certain books, invaluable in their own fields, chief of which are: *Histochemistry* by A. G. E. Pearse; *An Encyclopaedia of Microscopic Stains* by G. T. Gurr; *The Microtomists Vade-mecum* edited by B. Lee, and *Cytological Technique* by J. R. Baker. Our thanks are due to our co-workers in the field of cytology from several countries, whose good wishes gave us the impetus to finish this work. Special thanks are due to Prof. P. C. Koller of the Chester Beatty Research Institute, Drs. S. Makino and M. S. Sasaki of Hokkaido University, Drs. A. Levan and W. W. Nichols of South Jersey Medical Research Foundation, Prof. H. G. Callan of the University of St. Andrews, Drs. Wenner Schmid and T. C. Hsu of the University of Texas M. D. Anderson Hospital and Research Institute, Prof. J. H. Taylor of the University of Florida, Drs. H. H. Smith and W. Prensky of Brookhaven National Laboratory, Drs. P. Harris and D. Mazia of the University of California, Dr. J. Mitra of the University of New York and Prof. R. P. Roy of Patna University, for very kindly sending original photographs of their preparations for the book. We would also like to thank our colleagues here, notably, Drs. N. K. Bhattacharyya, U. C. Bhattacharyya, S. Sen (Miss), M. Chaudhuri, A. K. Chatterjee, C. Talukdar and R. Mallick, for their preparations, original photographs of which have been included. Lastly our thanks are due to our publishers, Butterworths, for their patience and cooperation in finishing this work.

1
Introduction

The analysis of chromosome structure starts with the understanding of a clear delimitation between the chromosomes of lower organisms, including viruses and bacteria on the one hand and those of higher organisms on the other. In the former, the chromosome is a genophore, being studied mainly through electron diffraction patterns and mutation and recombination data. In the latter, the chromosome is an extremely complex body, which has other constituents in addition to the DNA genophore, and it may be analysed under a light microscope. The genic effect on metabolism in the former can be studied immediately, whereas in the latter there is a wide gap and a series of reactions intervenes between the initial reaction at gene level and its manifestation in the phenotype. A concept of the evolutionary advance, step by step, from the genophore of the prokaryotes to the complex chromosome structure of eukaryotes, correlated with functional diversities and specialisation of segments, has been proposed (Sharma, 1978).

Research in the nineteenth and twentieth centuries has clearly established that 'chromosomes', which bear the hereditary materials or 'genes' in a linear sequence, are of permanent fibrous constitution (*see* Darlington, 1965). The term 'chomosome', meaning colour body, is based on its ability to absorb certain dyes. The importance and scope of the different techniques in the study of chromosomes can only be realised as the gradual advancement, aided through technical refinements resulting in the modern concept of chromosome structure, is outlined.

Notwithstanding the fact that the fibrous constitution of chromosomes has been unequivocally accepted, much discussion has been occasioned with regard to the longitudinal constitution of the thread, and the ultimate number of fibrous units composing it in Eukaryota (Hand, 1979; Peacock, 1979; Ris and Korenberg, 1979). Reconciliation between the chromomere and chromonema hypotheses has been effected in later years. The filamentous nature of chomosomes was first visualised in the chromomere hypothesis. This hypothesis assumed that the chromosome is composed of longitudinally aligned chromatic granules, otherwise termed 'chromomeres', joined by an achromatic thread. The chromonema hypothesis, on the other hand, visualised a uniformly thick continuous structure in a chromosome, capable of spiralisation in mitosis.

The multistranded nature of chomosomes has been claimed by various workers, both through ultrastructural and other evidences, and the implica-

tion of these findings has been discussed in several treatises and excellent reviews (Keyl, 1965; Sparvoli, Gay and Kaufmann, 1966; Gay, 1967; Sueoka, Chiang and Kates, 1967). The problem of interpreting the series of 20–25 nm thick fibrils in chromosomes has been outlined by Dupraw (1965), Wolfe (1965), Gall (1966) and Ris (1967). The synchronous functioning of multi-stranded fibrils with respect to gene action has been explained in terms of a master gene, the rest being derogated to the category of slave genes (Callan, 1973; Whitehouse, 1967; *see* Edström, 1967). The theories of chromosome division do not necessarily require any modification in the light of the lamellar concept (Sharma and Sharma, 1958; Sharma, 1974).

Most of the evidences, however, on ultrastructural analysis of chromosomes indicate the presence of fibrils 2–3 nm in diameter (Kaufmann, Gay and McDonald, 1960; Ris, 1961; Lampert and Lampert, 1970). This fibril, which is possibly a DNA protein complex, is folded several times to yield a fibre of 10 nm thickness which may measure 20–30 nm due to treatment (Schwarzacher, 1976, *see* Hozier, Renz and Nehis, 1977). The chomosome represents a continuous deoxynucleoprotein fibre in which condensed and decondensed segments may alternate. The condensed segements may represent chromomeres, corresponding to Giemsa-positive intercalary (*G*) bands (*see* Luciani *et al.*, 1976; Olins *et al.*, 1977; Prescott, 1977; Judd, 1979). Simultaneously due to the presence of histones, certain areas may show localised thickenings (Kornberg, 1974; Baldwin *et al.*, 1975; Kedes, 1976). All the evidences so far obtained suggest a uninemic nature of the chromosome thread (Prescott, 1970; Schwarzacher, 1976) but there may be polynemy under certain conditions of growth and differentiation. In any case, the inference that the chomatid represents a single long chain DNA molecule with several replicating units of replicons laid in several folds is yet to be fully reconciled with the dimensions of chomosomes under light microscope (Hand, 1979; Peacock, 1979).

The refinements in technique have brought about a complete reorientation of outlook in the study of chromosome morphology. Formerly the conventional method of describing a chromosome was to refer to it as a J or V shaped structure, or rather as acro- or metacentric, without any description of its morphology. This was principally due to the inadequacy of the techniques then available, which could not clarify the details of the structure.

Gradually, as the need for an intensive research into chromosomal details was realised, techniques were invented from different centres (Flemming, La Cour, Lewitsky, etc.), which allowed further resolution of the details, including the clarification of primary and even secondary constriction regions responsible for the formation of the nucleolus (*see* Denton *et al.*, 1976). Further advances led to an understanding of the heterochromatic and euchromatic segments of chomosomes, which could be differentiated through temperature and other treatments. These two types of segments are characterised by different staining cycles in the different phases of growth and division (*see* Sharma and Sharma, 1958; Brown and Chandra, 1977). The presence of different types of heterochromatin, with regard to different functions, was also realised (Brown, 1966; Wolf and Wolf, 1969; Ris and Korenberg, 1979).

The molecular pattern has yet to be correlated with the observed transverse differentiation of chromosome segments, though several models have been

outlined (*see* Hamilton, 1968). The centromere, secondary constriction regions, telomeric segments and other heterochromatic regions must fit in the molecular structure of the genophore, since they are regions which have been differentiated functionally. The occurrence of divalent cations, histones and even lipids are often regarded as transverse incorporations.

The discovery of the fluorescent banding patterns in chromosomes by Caspersson and colleagues (Caspersson, Lomakka and Zech, 1971; Caspersson *et al.*, 1974; Zech, 1973) has proved to be an effective tool in the identification of chromosome segments. There has been the concomitant discovery of the other banding techniques following giemsa and orcein staining, the importance of which in the localisation of differentiated segments of chromosomes can hardly be overrated (Seabright, 1972; Comings, 1974; Sharma, 1975 and *see* Hecht, Wyandt and Magenis, 1974). A correlation has been established between stained and fluorescent bands on the one hand and reannealed segments after denaturation of DNA. Chromosome banding technique as it stands today is a synthetic procedure allowing a visualisation of the molecular sequence complexity of DNA at the cellular *vis-a-vis* light microscopic level. A quantitative assessment of the chemical constituents through microphotometric analysis of the bands at different phases of development and differentiation may lead to an insight into the chromosomal control of differentiation.

Advances in instrumentation have led also to automatic chromosome identification through high-speed scanning devices (Castleman and Wall, 1973; Lubs and Ledley, 1973; Mendelsohn *et al.*, 1973; Gallus and Regoliosi, 1974; Lundsteen and Granum, 1976; Overton *et al.*, 1976). The photographic negatives can be scanned reading the picture on-line into the high-speed memory of a programmed digital computer. The optical density measurements of chromosome spread can also be recorded on a tape. Such an automated analysis of chromosome segments at different phases of growth is expected to unravel the complexity of genetic control of differentiation in the eukaryotic system.

A major achievement in the study of chromosome science is the understanding of its dynamicity, replacing the concept of its uniformity and monotonous behaviour in all organs (Sharma, 1976, 1978). The dynamicity in chromosome behaviour in respect to differentiation and development has been seen clearly in Drosophila and other Diptera (Beermann, 1967, 1972; Pavan and Da Cunha, 1969). The synthesis of ribonucleoprotein for certain segments in the lamp brush chromosome at certain stages in vertebrate oocytes (*see* Callan, 1973) as well as puffing at different segments of salivary chromosomes in different growth phases in Drosophila present direct evidence of chromosomal control of metabolism.

Further examples of this behaviour are the differential replications in meristematic and adult differentiated nuclei. While the behaviour of the chromosome thread follows the usual sequence in the former, it undergoes endomitotic replication in adult nuclei. (Nagl, 1977). This interpretation can explain the genic control of differentiation, which is maximum at the adult stage, as well as the apparently non-dividing stage of the chromosomes. The cause of chromosome duplication without separation in adult nuclei has been attributed to regulated deficiency of the sugar component of DNA (Sharma and Mookerjea, 1954). The polytene state, due to endomitotic

replication, has been confirmed by inducing division in these nuclei through IAA treatment by Huskins (1947) and by the precursors of nucleic acids and related chemicals in our laboratory. However, a generalisation from the evidence obtained from lower organisms implies that transcription and translation responsible for gene action and differentiation are not necessarily associated with gene duplication. The endomitotic replication, occurring with diploidy, and the polytenic constitution of some differentiated nuclei, are, however, observational facts, the association of which in differentiation requires clarification. These observations raise the problem of the transcribing limit of a DNA strand and the necessity of fresh strands for transcription. In any case, it is a clear index of the dynamicity of chromosome behaviour in response to the need for differentiation.

In the last several years considerable strides have been made in the study of chromosome structure, due to the invention of a number of pre-treatment chemicals. Special treatments, previous to fixation, have been responsible for a clear understanding of the structure of the different parts of chromosomes, including the centromere—the chromosome segment necessary for attachment and movement along the spindle. Knowledge regarding the structure of the centromere was vague until its quadruple nature in metaphase was observed, which has been further clarified through later works. Refinements in methods have led to a clear understanding of the structure of the spindle and its relationship with the chromosome (Wada, 1966; Sakai, 1968).

Such changes in pattern, associated with phasic development, growth and differentiation of plants, indicate that, in spite of a basic genetic uniformity, the structural pattern of chromosomes is dynamic. Even the study of their chemical nature, discussed later, has shown that the chromosomes which are packaged for transmission are not identical in all respects with those of the somatic cells responsible for differentiation.

Further evidence of dynamicity and its control in the reproduction of species is seen in the chromosome behaviour in asexually reproducing species studied extensively in our laboratory. Chromosome complements of the somatic issue universally exhibit numerical and structural changes and the constancy of the chromosomes is not maintained as such in different cells of the same tissue, but a chromosome mosaic is formed. This regulated abnormal behaviour is of great importance in species identification since the changed chromosome complements may enter into the growing apex of the vegetative shoots and form genotypically new individuals without the act of fertilisation. This outstanding example of dynamicity in chromosome behaviour, observed with the aid of refinements in techniques, shows the response to reproductive necessity under abnormal conditions.

The invention of methods for chromosomes does not follow a normal pattern of behaviour in malignant cells. Mitotic instability, uncontrolled cell proliferation and mosaics of different chromosome numbers often characterise the different tumorous and cancerous cells. The technique for such studies, though simple, was not available for a considerable period and its discovery has led to outstanding achievements in this field. The convenient schedules evolved for culturing leucocytes from blood have opened up new avenues of research and several congenital anomalies have been correlated with definite chromosomal characteristics (*see* Talukder and Sharma, A., 1979). The advances in the study of human chromosome behaviour, shown through recent

developments in methodology, cannot be overrated since they have been instrumental in understanding the overall control of chromosomes in maintaining hereditary stability, as well in species replication and the hitherto unexplained processes of development and differentiation.

Finally, before dealing with the details of techniques, a few words about the modifications of chromosome structure, occasioned by physical and chemical treatments, are necessary.

Since the discovery of polyploidisation through colchicine, and mutation and chromosome breakage through x-rays, vigorous research on these and allied aspects is being carried out throughout the world. The fundamental and utilitarian implications of such findings are outlined in their respective chapters. This aspect of study involves two lines of investigation, one dealing with the techniques for inducing chromosomal abnormalities, and the other concerning the methods adopted for scoring the results.

For the study of the different aspects of the physical structure of chromosomes, varied techniques have been devised from time to time. The details of these techniques—their principles, applicability, drawbacks and recent developments—are discussed in the subsequent chapters.

2
Pre-treatment and hypotonic treatment

Pre-treatment for the study of chromosomes is generally performed for several special reasons. It may be carried out for: (a) clearing the cytoplasm, (b) separation of the middle lamella causing softening of the tissue, or (c) bringing about scattering of chromosomes with clarification of constriction regions. Pre-treatment may also be needed to achieve rapid penetration of the fixative by removing undesirable deposits on the tissue as well as for the study of the spiral structure of chromosomes (La Cour, 1935). The first two applications involve removal of extranuclear limitations, whereas the third and most important one exerts a direct effect on the chromosomes.

PRE-TREATMENT FOR CLEARING THE CYTOPLASM AND SOFTENING THE TISSUE

In order to clear the cytoplasm from its heavy contents, acid treatment has often been found to be very effective. Short treatment in normal hydrochloric acid brings about transparency of the cytoplasmic background. Such treatments, however, require thorough washing for the removal of excess acid and acid soluble materials. However, acid treatment affects the basophilia of the chromosomes also and so mordanting may become necessary after acid treatment and washing. It hampers banding patterns as well.

In addition to acid, several enzyme preparations are applied for clearing the cytoplasm and cell separation through digestion. McKay and Clarke (1946) applied pectinase with success, not only achieving tissue softening, but also securing clearing of the cytoplasm. Similarly, cytase extracted from snail stomach at a particular pH was successfully utilised by Fabergé (1945). Cytoplasmic clearing was obtained by Brachet (1940) with ribonuclease, which brought about digestion of ribonucleic acid—the principal constituent of the cytoplasm. A complex enzyme preparation 'Clarase' was used by Emsweller and Stuart (1944), yielding brilliant preparations following staining. In the authors' laboratory, treatment with cellulase has given very satisfactory preparations in difficult dicotyledonous materials. Once a particular difficulty in obtaining successful results in any material is ascertained, the application of special enzymes for its elimination may be regarded as an accurate and scientific approach towards the solution of the problem. But one of the serious limitations of this aspect of pre-treatment is that an enzyme

preparation, completely free from contaminants, is difficult to obtain and, as such, several nuclear components may be undesirably affected after this procedure. Even in the absence of contaminants, some of the enzymes such as 'ribonuclease' may affect chromosomes in the purest form. This is understandable, as ribonucleic acid has been occasionally claimed as a constituent of chromosomes, at least of animals, by a number of workers, and therefore, in cases requiring critical observation, enzyme treatment, if necessary, should be cautiously performed. The use of enzymes for cell separation has been dealt with in the chapters on tissue culture and mammalian chromosomes.

Occasionally it also becomes necessary to employ alkali solutions as pre-treatment agents. This step is desirable for materials having heavy oil content in the cytoplasm since alkalis remove the oil by saponification. Alkali solutions commonly employed are sodium hydroxide or sodium carbonate. As in acid treatment, thorough washing in water is necessary after the tissue has been kept in alkali solution.

In certain cases, pre-treatment may be necessary to remove deposits of secretory and excretory substances from the surface of the tissue which may hinder the access of the fixing fluid. The best example is the application of hydrofluoric acid to remove siliceous deposits prior to fixation in bamboos; similarly, a very short treatment in Carnoy's fluid, containing chloroform, is needed to remove oily or other secretory deposits on the cell walls before fixation in a number of plant materials.

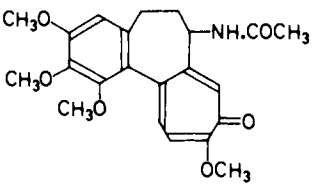
SEPARATION OF CHROMOSOME AND CLARIFICATION OF CONSTRICTIONS

The underlying principle of these important aspects of pre-treatment is the viscosity change in the cytoplasm. As spindle formation is dependent on the viscosity balance between cytoplasmic and spindle constituents, a change in cytoplasmic viscosity brings about a destruction of the spindle mechanism with the chromosomes remaining free or, more precisely, not attached to any binding force within the cell. Pressure applied during smearing results in the scattering of chromosomes throughout the cell surface. Changes in cytoplasmic viscosity simultaneously affect the chromosome too, which undergoes differential hydration in its segments, and due to this differential effect, constriction regions in chromosomes appear well clarified. Several pre-treatment chemicals have so far been applied for the purpose, colchicine being the most important one.

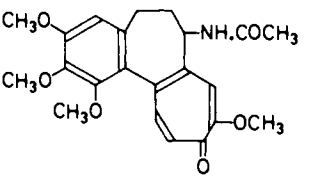
In addition, pre-treatments are often performed on tissues to secure a high frequency of metaphase stages through spindle inhibition. For this purpose colchicine is supposed to be the most active substance, and also compounds having similar properties, such as chloral hydrate, gammexane, acenaphthene, vinblastine sulphate (Velban) (Krishnan, 1968) and vincaleucoblastine (Kolodny and Hirschhorn, 1964), have yielded good results with human materials. 3-amino-1,2,4-triazole has a limited application in leaf and shoot-tip squashes (George and Sobhana, 1976).

Colchicine

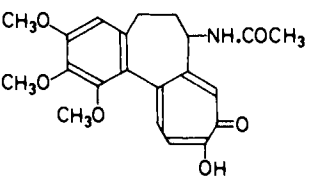
Colchicine was first isolated from the roots of *Colchicum autumnale* by Zeisel in 1883. Its empirical formula is $C_{22}H_{25}O_6N$, as determined by T. Y. Johnstone in Glasgow. The general method of extraction is through the use of ethanol and subsequent dilution with water; finally the aqueous solution is extracted with chloroform and crystals of colchicine are obtained along with the solvent. By gradual evaporation and distillation of chloroform, amorphous colchicine can be obtained. The chemical structure of colchicine, as suggested by Windaus in 1924 and modified by Dewar (1945), shows that it has a three-ringed structure. Barton, Cook and Loudon (1945) consider that the second ring is 7-membered and Dewar suggests that the third ring is also 7-membered. Steinegger and Levan (1947) have regarded Dewar's modification as the most reasonable one.



Colchicine



Isocolchicine



Colchiceine

Summing up, Eigsti and Dustin (1957) hold that colchicine is the methyl ether of an enolone containing three additional methoxy groups, an acetylated primary amino group and three non-benzenoid double bonds. Levan (1949) has noted that the threshold regions of colchicine-mitotic activity are identical for both crystalline and amorphous forms; chloroform exerts no appreciable effect. One of Levan's significant findings in *Allium cepa* is that whenever isocolchicine is used instead of colchicine, no *c*-mitotic action is observed. The latter differs from the former only in minor details of structure.

Colchicine is soluble in water (500.00 in 10^{-6} mol/l). Ferguson (1939) worked out the thermodynamic activity of several narcotics and showed that they can be classified under two categories: (a) those in which there is a direct correlation between activity and physical properties, such as water solubility, and (b) those showing no such correlation.

Steinegger and Levan (1947) and Levan (1949) also demonstrated a relationship between water solubility and activity threshold, the two being directly proportional. Colchicine is remarkable in the sense that, though highly water-soluble, it is very active at an extremely low concentration. It falls under Ferguson's second category of compounds and the reaction is

chemical. Originally the role of colchicine was considered to be that of a catalyst (Bhaduri, 1939). It brings about a change in the colloidal state of the cytoplasm, causing spindle disturbance.

With regard to the exact reactive groups in the colchicine molecule, Eigsti and Dustin (1957) reviewed in detail the observations presented by different workers (Ludford, 1936; Lettré and colleagues, 1947, 1952; Branch and colleagues, 1949; Leiter and colleagues, 1952). These data imply that: (a) at least one methoxy group in ring A is necessary for colchicine action; (b) ring C must be 7-membered and the hydroxyl group should preferably be replaced by an amino group; (c) esterification of amino group in ring B increases the activity; and (d) isocolchicine and its derivatives are less active. A proper distance should be maintained between esterified side chains of rings B and C. This last statement is based on the fact that in isocolchicine, where the position of the methoxy group is reversed in ring C, the decrease in efficacy has been considered to be due to the presence of hydrogen bonds between the side chains of rings B and C. In the case of 'colchiceine', the weak action is the result of the iso-form of this molecule.

Though these data indicate the reactive groups responsible for colchicine action, the exact reaction involved in spindle inactivation is not yet fully clear. Pertinent suggestions have been made on the basis of results obtained with spindle poisons of different chemical structure. Östergren (1950), who regarded colchicine action as narcosis, suggested a relationship between spindle poisoning and lipoid solubility. Eigsti and Dustin (1957) pointed out that the exact relationship between lipoids and the function of the spindle is yet to be clarified; they emphasised the need of specific biochemical evidence to substantiate this statement. A number of lipoid-soluble hydrocarbons have been found to have the property of narcotising mitosis. Lettré, Fernholz and Harwig (1952) suggested that ATP may be responsible for spindle activity and mitosis, and that colchicine may modify this mechanism. A number of sulphydryl poisons, such as iodoacetamide, dimercaptopropanol (BAL), mercaptoethanol, sodium diethyldithiocarbamate, etc. (Dustin, 1949, 1950), act in the same way as colchicine. These results may not strictly be regarded as suggesting that sulphydryl poisoning is involved in colchicine action, but at least they imply that colchicine enters into a chemical combination with some intracellular receptor.

In the study of chromosomes, without inducing polyploidy, colchicine has to be applied in a low concentration, such as 0.5 per cent for 1 h, whereby straightening of the chromosome arms can be achieved, which allows a thorough study of the constriction regions. It is especially effective for long chromosomes, as otherwise the chromosome arms remain foreshortened. The chromosome arms, though split, are held together at the constriction region.

Different types of fixatives, both metallic and non-metallic, can be applied after colchicine treatment. One of the most essential requisites in the use of this alkaloid is that the tissue must be thoroughly washed to free it of colchicine before fixation; otherwise the superficial deposition of this alkaloid hampers visibility of the chromosomes and penetration of the fixative. It is always necessary to use a rapidly penetrating fluid, such as acetic–ethanol after colchicine treatment, as otherwise the nuclei may rapidly enter into the metabolic phase at the time of fixation. Though such fixation yields the

desired results, colchicine should not be regarded as incompatible with other fixatives. McKay and Clarke (1946) have shown that satisfactory results can be obtained if both enzyme treatment and fixation are done after the application of colchicine.

In the authors' laboratory, colchicine has been effectively employed in the study of chromosome structure by analysing the tissue following smearing instead of through block preparation. The scattering effect, obtained in squash, is difficult to secure in block preparations. The two effects—straightening of chromosome arms and loosening of spirals—are best observed in squash preparations.

Compared with other pre-treatment chemicals, colchicine has the added advantage of being active within a very wide range of temperature. In the tropics, even during summer when the temperature rises to 43.3 °C, no significant effect on colchicine action has been noted. In this laboratory colchicine has been tried on tissues kept at 8–9 °C and the frequency of metaphase plates is observed to be distinctly higher in these tissues than in those sets kept for a similar period at room temperature (Sharma and Sarkar, 1963). The clarification of chromosome structure too is obtained within a very short period.

Regarding the applicability of colchicine to arrest metaphase, nearly all plant organs and a number of animal organs as well respond to its treatment. In plants, the somatic tissue responds more readily to colchicine action than the meiotic cells. Germination of seeds in colchicine solution gives a large number of metaphase plates in the root-tips (Wolff and Luippold, 1956). For the study of the haploid mitosis, pollen tube culture, with colchicine added in the medium, is considered to be most satisfactory. In animals, spermatogonial cells as well as the larval tissue respond well to colchicine. In mammalian tissue, including human tissue, colchicine treatment has yielded a high number of divisional figures, particularly in the endometrium, bone marrow, leucocytes, regenerating liver, normal and neoplastic cells, fibroblast cultures, eggs of sea urchin, etc. Though metaphase has been arrested in these cases, the polyploidising effect of colchicine is not marked in animals; investigation into the cause of this differential susceptibility is necessary. Colcemid, a derivative of colchicine, has been used successfully in mammalian tissue to obtain well-scattered metaphase plates. It is free from the limitations of colchicine and if injected, is absorbed more easily by the tissue.

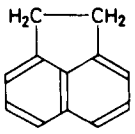
The period necessary for the manifestation of the colchicine effect varies in different plant and animal groups. The range of concentrations is also wide, lying between 0.001 and 1 per cent. In animal cells the method of application is preferably by injection or by addition to culture medium 2 h prior to harvesting, whereas in plant tissue it is applied through soaking, plugging and injection. It can also be used in lanolin paste and in agar. In artificial culture of both plant and animal tissues, colchicine is added in the medium. To avoid toxicity affecting other metabolic processes, this alkaloid is generally applied in a low concentration to animal cells.

In general, it may be stated that the drug is exceptionally suitable for the study of chromosome structure and metaphase arrest, provided that strict control is maintained over the concentration and period of treatment. Any excess of these factors may lead to a heavy contraction of chromosomes and polyploidy, obscuring analysis.

Colcemid (Ciba) is de-acetyl methyl colchicine and is used more extensively in *in vitro* studies of mammalian chromosomes since it does not show certain toxic effects attributed to colchicine. Its use in certain rapidly dividing tissues, like ascitic fluids, has occasionally been considered to be superfluous (Clarke, 1962; Lejeune, 1959). It, or even colchicine itself, has no effect on cells entering division or in prophase stages (Hamerton, 1971; Hughes, 1952).

Acenaphthene

Kostoff in 1939 demonstrated that acenaphthene has the same property as colchicine of arresting metaphase. As its structure is quite different from that of colchicine, several other aromatic compounds were tried and various derivatives of benzene and naphthalene were found to be effective.



Acenaphthene

Several haloid derivatives were also tried by Gavauden and shown to have the same effect (Gavauden, 1938). He observed that though benzene itself is ineffective, the presence of side chains is responsible for its *c*-mitotic property; the case with naphthalene derivatives is similar. Acenaphthene too follows the principle of Ferguson's (1939) thermodynamic activity and its mitotic poisoning effect is related to low water solubility.

As acenaphthene is sparingly soluble in water, it should be applied in saturated solution in water for treatment of the plant tissue. From trials with acenaphthene on different types of plant tissue, it is seen to be most effective in clarifying the chromosomes of the pollen tubes (Swanson, 1940). Comparative effects of this chemical have been studied on different organs of the same plant in the authors' laboratory and it has been observed that, with the exception of the pollen grains, the tissues do not respond to the treatment at all, this differential behaviour being attributed to the varied constitution of the plasma in different organs (Sharma and Sarkar, 1957). Being effective principally on the microspores, the actual use of acenaphthene is limited to the culture medium only. In view of the fact that only a few species of plants produce pollen of favourable constitution, the application of this technique is extremely restricted.

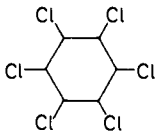
Chloral hydrate

Another agent used for inducing metaphase arrest is chloral hydrate. It has been used as a narcotic since 1904 (Nemec, 1904), and as a pre-treatment chemical in cytology since 1935 (Peto, 1935). It has the formula $CCl_3CH(OH)_2$, the same effect as colchicine, and is less expensive. It was originally intended as an important hypnotic and stimulant. The concentration required for chloral hydrate treatment is the same as that of colchicine, though they have different chemical compositions. It is quite effective in smears, and both

metallic and non-metallic fixatives can be used after the treatment. In the authors' experience, this chemical, though effective in certain species of plants, is ineffective in others. Moreover, its erratic behaviour requires serious consideration. Unless a complete understanding about the reaction of chloral hydrate with several intra- and extracellular factors is achieved, wide use of this chemical cannot be recommended.

Gammexane

Metaphase arrest has also been secured by the use of γ-hexachlorocyclohexane, commonly known as gammexane, by different authors. Principally, the chemical has been tried on somatic cells of *Allium cepa* and other species. In addition to metaphase arrest, polyploidy and fragmentation have also been recorded in some cases. Later, its 8-isomer was found to be similarly effective. Meso-inositol, which has the same isomeric structure as gammexane, acts as an antagonist of the latter, possibly due to the substitution of the Cl atoms by OH groups.



Gammexane

Polyploidy induced by gammexane has, however, not been found to be of permanent nature, at least in the plants tried out in this laboratory (Sharma and Chaudhuri, 1959). If the somatic tissue is cultured in gammexane medium, there is a direct duplication of chromosome number up to a certain threshold point, after which it undergoes reduction due to many spindle formations within the cell. Though such multispindle and multinucleate conditions have been observed in a high frequency, it is not certain whether any regularity exists in the formation of these nuclei. How far the normal number with the normal complement is restored through such reductional separation is not fully known.

A study of the effects of gammexane at different temperatures has shown it to be most active at low temperatures (12–16 °C) (Sharma and Chaudhuri, 1961). Metaphase arrest can be secured following treatment with a saturated solution within a period of 3 h. Compared with colchicine and acenaphthene, it is less active than the former but more active than the latter. In the meiotic cells, with metaphase arrest, a considerable amount of mitotic disturbance has been recorded, though polyploidy is very rare. The mitotic instability indicates that instead of causing absolute spindle inactivation, gammexane leads to abnormalities in spindle formation.

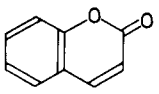
With regard to the exact metabolic paths affected by gammexane, analysis so far carried out has revealed that it has the capacity of affecting all the metabolic paths except those in which Mg, S and Ca are involved. Further, being effective at a very low concentration, chemical changes may be involved in gammexane-induced reactions. The metabolic disorders caused by colchicine and gammexane have been found to differ significantly. Nybom and Knutsson (1947) inferred that the action of gammexane is dependent on its

lipoid-solubility, the evidence being obtained from the highly narcotic reactions in γ-isomers, which have a heavy lipoid solubility. Levan and Östergren (1943) suggested that possibly certain enzymic functions of the cell are affected, whereas Östergren and Levan (1950) pointed out that fibrous components of the spindle are brought to assume a corpuscular shape (*see* Mazia, 1955, 1959). All this evidence, taken in conjunction with its activity at low concentration and temperature dependence, suggests the chemical nature of the reaction.

Coumarin and its derivatives

Coumarin

The importance of coumarin in chromosome analysis was pointed out by Sharma and Bal (1953). It was also used for the study of the gross chromosome number in cancer of the human cervix by Manna and Raychaudhuri (1953).



Coumarin

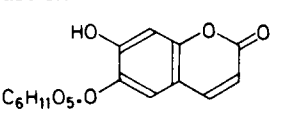
Coumarin is the *o*-coumaric acid lactone found mostly in the glycoside form in plants. Several natural and synthetic coumarins are available and Quercioli (1955) studied in detail the cytological property of synthetic coumarins. Data on natural coumarins are available from work in this laboratory (Sharma and Bal, 1953; Sharma and Sarkar, 1955; Sharma and Chaudhuri, 1962).

This chemical was tried on a variety of plants, especially those belonging to the monocotyledonous group, and clarification of constriction regions and especially of the centromere has been obtained through this treatment. It is effective even at a temperature of 30 °C, though cold treatment causes rapid action. In plants so far studied it is ineffective in species with a high chromosome number, even after 2–3 h of treatment. With chromosomes of the human cervix, even a short treatment of 5 min results in their perfect scattering. Being sparingly soluble in water—its solubility is approximately 0.02 per cent—coumarin is used as a saturated solution.

Coumarin, as an agent for chromosome breakage, was demonstrated by D'Amato and Avanzi (1954). Earlier, Sharma and Bal (1953) had observed that agents inducing chromosome breaks can be effectively employed for karyotype analysis if they are applied at a lower concentration or for small periods of treatment. The same holds good for coumarin.

Aesculine

It is a derivative of coumarin. It is extracted from *Aesculus hippocastanum* Tourn. Its chemical structure is:

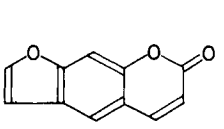


Aesculine

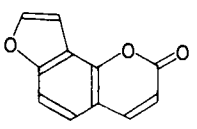
It is the direct derivative of aesculetin, in which the H from the —OH group in the 6-position is replaced by $C_6H_{11}O_5$. This particular compound has been found to be suitable for different groups of plants having chromosome numbers ranging from very high to very low (Sharma and Sarkar, 1955). The length of application needed for chromosome analysis also varies, from 30 min in species of *Allium* up to 24 h in different species of palms. Aesculine has a wide applicability, yet one of its serious limitations (shared by coumarin) is its capacity to induce fragmentation of the chromosomes after prolonged treatment. Its approximate solubility is 0.04 per cent in water, and for chromosome analysis it is applied both in saturated and half-saturated solutions. It is effective only at very low temperatures, ranging between 4 and 16 °C.

Isopsoralene

Another natural derivative of coumarin, it gives excellent results in different groups of plants (Chaudhuri, Chakravarty and Sharma, 1962), which have so far proved difficult to analyse, such as species of *Sanseviera*, *Ophiopogon*, etc. Even in species with very high chromosome numbers, such as species of *Pteris*, clarification of the chromosomes is very satisfactory. Isopsoralene is extracted from *Psoralea corylifolia*. Its chemical structure is:



Psoralene

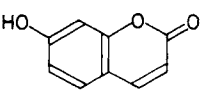


Isopsoralene

Both psoralene and its isomer isopsoralene were tried out, and the former was found to be unsuitable for chromosome study. In view of this differential action Chaudhuri, Chakravarty and Sharma (1962) inferred that the position of the furan ring is an important controlling factor in the manifestation of karyotype clarification.

Umbelliferone

This is another derivative of coumarin shown to have the property of clarifying chromosomes. It is extracted from several species belonging to the family Umbelliferae and has the chemical structure:



Umbelliferone

Its application is very limited. In some of the plant species having a high chromosome number, umbelliferone has been found to yield very good results (Sharma and Chaudhuri, unpublished).

The majority of the coumarin derivatives can be employed for the study of chromosome analysis, but the best results have been obtained with the four mentioned above. Their applicability is restricted mostly to specific

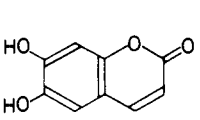
groups of plants, with the exception of aesculine which has a very wide application.

As viscosity change constitutes the principal basis of action of all of these compounds, attempts were made to find out the degree of change in viscosity induced by these derivatives (Sharma and Chaudhuri, 1962). The technical principle involved was to study the effect of the chemical on the streaming rotation movement of the protoplasm of *Vallisneria spiralis* or on the staminal hairs of *Tradescantia paludosa*—the movement of the protoplasm being inversely proportional to the degree of viscosity change induced.

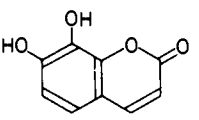
Another method is to centrifuge the treated tissue. The time taken for the total displacement of the nuclei to the corner of the cell in tissues with various chemicals and at a constant revolution per min gives an idea of the differential change in viscosity.

Following these two methods, Sharma and Chaudhuri (1962) observed that, of coumarin and three of its derivatives (namely, aesculine, daphnetin, and aesculetin), daphnetin causes an increase in viscosity of the plasma within a very short period, the other three differing with respect to this property, the effect of coumarin being least. These results indicate the differential efficacy of different chemicals as pre-treatment agents.

The chemical structures of these compounds are:



Aesculetin



Daphnetin

A noteworthy feature is that daphnetin, which is extracted from *Daphne mezereum* Linn., and aesculetin, derived from *Euphorbia lathyrus* Linn., are isomers of each other. The solubility of aesculetin is 0.007 per cent while that of daphnetin is 0.005 per cent. The comparatively rapid action, with increased solubility, deviates slightly from Ferguson's law of thermodynamic activity as specially elaborated by Gavauden and Gavauden (1939). Coumarin and aesculine, however, follow Ferguson's principle, as coumarin is the most water soluble member (0.02 per cent) but also the least active one.

Oxyquinoline (OQ)

One of the most important groups of compounds investigated for their action in studying chromosome structure, is the quinoline complex. Tjio and Levan (1950) first worked out the importance of 8-hydroxyquinoline in chromosome analysis. They showed that it not only causes mitotic arrest, thus demonstrating its *c*-mitotic property, but at the same time it is also endowed with certain characteristics not shared by colchicine. The spindle is inactivated and, as such, does not cause any hindrance to the chromosomes being spread out during squashing; the chromosome arms contract equally. Unlike colchicine, OQ allows the metaphase chromosomes to maintain their relative arrangements at the equatorial plane. Both primary and secondary constrictions

become conspicuous and the satellite gap appears to be greatly exaggerated. The centromeric structure can easily be analysed.

The *c*-mitotic property of oxyquinoline is not unusual as it is highly lipoid-soluble, but the very fact that the arrangement of the chromosomes is maintained intact on the spindle suggests that they are still attached to the spindle (the increased viscosity of the plasma does not allow the movement of the chromosomes). Further evidence of the attachment of the chromosomes to the spindle is provided by the 'centromeric reaction': this region becomes exaggerated due to a heavy contraction of chromosome arms against a rigid plasma which keeps the arms in their original position. According to Tjio and Levan (1950), the contraction operates towards the middle of each chromosome arm from the ends and the centromere, the centromeric gaps becoming pronounced due to the fact that the primary constriction region acts as a fixed point.

With regard to the mode of action of OQ, Stålfelt (1950) studied in detail the possibility of change in plasma viscosity. He observed that OQ, in concentrations of the same strength as used by Tjio and Levan, increased the viscosity in leaf cells of *Elodea* sp. No dislocation of plastids, after centrifuging, was observed, due to the rigidity attained by the plasma in higher concentrations.

Though a similar increase in rigidity of the plasma has been obtained with a number of lethal chemicals, yet their strong pyknotic reaction on chromosomes makes them unsuitable agents for karyotype. With colchicine as well, the increase in viscosity comes gradually and the chromosomes undergo movement during treatment, so that metaphase arrangement is disturbed. The influence of OQ on plasma viscosity is of such a nature that it does not alter the metaphase arrangement.

Oxyquinoline has been tried on different plant materials and has been found to be specially suitable for species having long chromosomes. The study of human chromosomes too, following OQ treatment, as demonstrated by Tjio and Levan (1956), has been made possible. One of the limitations of pre-treatment with OQ in plants is that it requires a long period of treatment. Other chemicals, worked out later, have given equally satisfactory results in much less time. Radiomimetic action of OQ too has been recorded in some cases (Tjio and Levan, 1950), which should be considered during pre-treatment. However, such effects are very rare and if properly controlled OQ can be safely recommended as a pre-treatment agent for chromosome analysis.

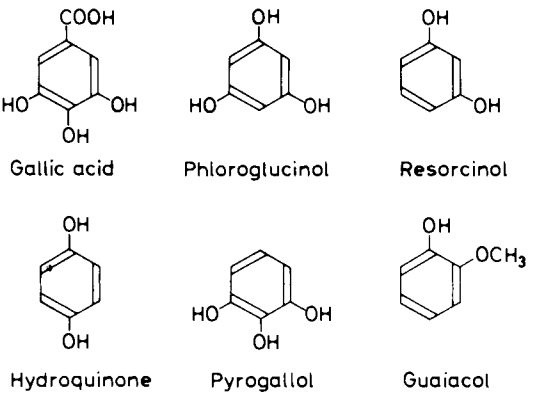
Phenols

The radiomimetic action of phenols was observed by Levan and Tjio (1948). In view of the fact that a number of radiomimetic chemicals can be applied for the analysis of chromosomes, different types of mono-, di- and trihydric phenols were investigated in the authors' laboratory (Sharma and Bhattacharyya, 1956a). Of the dihydric types, resorcinol and hydroquinone were tested, whereas trihydric ones were represented by phloroglucinol and pyrogallol. Of the monohydric forms, several cresols have been tried. Guaiacol, in which there is an $—OCH_3$ group in addition to an —OH, was included to

study the effect of the addition of methoxy group. A derivative of pyrogallol, gallic acid, was also tried out (Sharma and De, 1954).

It has been observed that phenols can be effectively employed for the study of chromosome morphology if applied at concentrations below the one causing chromosomal abnormalities. The most interesting feature is the absence of any effect in guaiacol indicating the role of the —OCH_3 group in suppressing the property of viscosity change.

The importance of the presence and location of hydroxyl (—OH) groups is seen from the data so far obtained. Though all the three types of phenols,



mono-, di- and trihydric, can help in the clarification of chromosome morphology, yet dihydric forms are the most effective ones, being active at a very low concentration. Even amongst the dihydric types, such as resorcinol and hydroquinone, the location of the —OH groups is possibly responsible for their differential activity.

Low temperature appears to be essential for the activity of phenols. The roots have to be treated at a temperature ranging between 10 and 16 °C approximately; moreover the extremely low concentration, such as 10^{-3} M, which is sufficient for the activity, indicates that the reaction involved is chemical in nature. As with other groups of chemicals, not only is there spindle inactivation, but the differential hydration of chromosome segments also leads to the clarification of chromosome morphology.

The time required for treatment in phenols varies in different materials, although in no case has less than 3 h of treatment been found to be effective. They are applicable to almost all groups of plants, with modifications in the period of treatment and concentration, and are compatible with both metallic and non-metallic fluids, which can be used as fixatives after treatment in phenol. Following appropriate schedules for squashes and paraffin blocks, these compounds can be used in various procedures without in any way hindering the staining of chromosomes with any dye.

Gallic acid is useful in a number of species of water plants. The effective concentration range is not very wide (0.0005 M) and the period of treatment is quite long, at least 3 h. There are no true sub-narcotic and narcotic zones in the action of this chemical, and with higher concentrations lethality ensues; therefore it cannot be safely recommended for karyotype analysis.

p-Dichlorobenzene (*p*DB)

Of the benzene derivatives, the most useful one in chromosome work is *p*-dichlorobenzene (*p*DB). It is sparingly soluble in water and has the following chemical structure:

Meyer (1945) first demonstrated the importance of *p*DB as a pre-treatment agent. It is also employed as a reagent for the production of polyploidy in plants, and because of its very low solubility is used as saturated solution in water. Later workers (Dermen and Scott, 1950; Conagin, 1951) employed it effectively for chromosome counts. A detailed use of this compound has been made by Sharma and Mookerjea (1955) in plants. In their technique the entire schedule has been shortened by the omission of fixation after pre-treatment so that the tissue can be directly transferred to the staining mixture. The staining with acid–dye mixture, applied after pre-treatment, serves the purpose of fixation to some extent, but it has been noted that the direct transfer of the tissue to the acid–dye mixture, without pre-treatment, results in inadequate fixation with badly preserved chromosome structure. In different organs of the body the chemical was applied for the clarification of chromosomes and in all cases, even including leaves, successful preparations have been secured. In the case of leaves, the compound is specially helpful since, being a benzene derivative, it aids in clearing the cytoplasm.

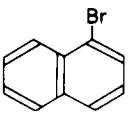
Similar to aesculine and other coumarin derivatives, *p*DB not only causes spindle inhibition but also leads to clarification of chromosome constrictions due to the contraction and differential hydration of chromosome segments. Of all the chemicals tried so far, it has a comparatively much wider application, and complements with both long and short chromosomes appear to respond equally, even though the period of treatment may require modification. It is especially advantageous in the case of complements with many chromosomes as well as for tissues from different parts of the plant body which make it more useful in cytological research, and it has been recommended for difficult materials having chromosome complements with high number and small size.

One of the serious drawbacks of *p*DB treatment is that in the majority of cases the period of treatment necessary is at least 3 h. In the case of aesculine, this period may even be as little as 30 min. The temperature required too is rather specific and cold treatment at 10–16 °C is essential. Another limitation of *p*DB technique, brought out by Sharma and Bhattacharyya (1956b), is that after only $3\frac{1}{2}$ h of treatment, profuse chromosome fragments appear in the preparations. As the period needed for optimum clarification of the chromosome morphology, that is 3 h, and the period necessary for inducing radiomimetic activity are fairly close, a cautious use of this agent is necessary to secure an accurate picture of the chromosomes. In order to minimise this error, dilution of the saturated solution is recommended. If utilised under

properly controlled conditions, it can be applied in almost all groups of plants and animals.

Monobromonaphthalene

This naphthalene derivative has the structural formula given below and is sparingly soluble in water.



The property of spindle inhibition of 5-bromoacenaphthene and α-bromonaphthalene was demonstrated in rye and wheat by Schmuck and Kostoff (1939). Östergren (1944) worked out the mitotic property of α-bromonaphthalene. O'Mara (1948) utilised this chemical as a preparation agent meant for contraction and clarification of constriction regions of chromosomes. Bhaduri and Ghosh (1954) established its efficacy in the study of wheat chromosomes, and claimed that transparency of the chromosomes is not lost even after Feulgen staining. O'Mara (1948) suggested non-metallic fixation after a minimum of 2 h of treatment in α-bromonaphthalene. For the study of prophase chromosomes, methanol-added fixative is chosen. Sharma (1956) suggested that the purpose of such special treatment after the application of monobromonaphthalene is possibly twofold. It is possible that the chromosome, at the time of pre-treatment, undergoes certain changes so that it cannot respond to any of the fixing agents, except the one recommended, or the chemical nature of the cytoplasm undergoes such an alteration that it becomes impermeable to any other fixative. In any case, a chemical change in the chromosome can be visualised, as even the effect on the cytoplasm would consequently affect the chromosomes.

Although in O'Mara's schedule prolonged pre-treatment for 2–4 h was suggested, it has been observed that even 10–15 min treatment at low temperature in saturated aqueous solution of monobromonaphthalene may bring about the desired representation of chromosome morphology in certain groups of plants. For aquatic angiosperms especially, pre-treatment with this chemical is usually effective. The principal cause is the rapid rate of penetration of this chemical into the tissues. In hydrophytes, both submerged and aquatic, the adaptations of their tissues to their habit, such as air spaces, etc., necessitate a rapid penetration of the chemical for exerting any effect. Like *p*-dichlorobenzene, it has a clearing effect on the cytoplasm but it is not as pronounced as that of the former.

Veratrine

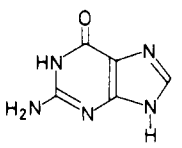
Another important alkaloid, shown to possess the property of clarifying chromosome structure, is veratrine, $C_{32}H_{49}NO_9$ (Sharma and Sarkar, 1956). Cold treatment is found to be essential for its activity. Radiomimetic action of this chemical has also been demonstrated. At lower concentrations, it

effectively clarifies chromosome morphology. Both dicotyledonous and monocotyledonous plants respond well to its application, the former group being more susceptible than the latter. An advantage of its application is its rapid action on somatic chromosomes, which can be observed within 30–40 min of treatment. Its effective concentration range is wide, between 0.05 and 4 per cent. It is sparingly soluble in water.

Hormones, heterocyclic bases, vitamins and vegetable oils

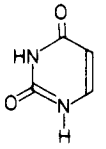
The importance of hormones in chromosome analysis has been worked out (Sharma and Mookerjea, 1954). β-Naphthoxyacetic acid, α-naphthylacetic acid, phenylacetic acid, indolylacetic acid, indolylpropionic acid and indolylbutyric acid have been shown to induce viscosity changes in the plasma at 10–16 °C, so that scattered metaphase plates, with clarified chromosome structure, are obtained. No correlation between water solubility and the effect of the hormones has been observed. It has only been noted that the higher the maximum point or upper threshold of the hormone, the lower is its minimum point or lower threshold of activity. The concentration needed for clearing chromosomal details is always higher than that needed for the promotion of growth. As there are a variety of hormones, they can be used in a variety of organisms.

Some of the heterocyclic bases, such as guanine, uracil and maleic hydrazide, have also been seen to induce change in plasma viscosity leading to spindle arrest and chromosome clarification (Sharma and De, 1956). The chemical structures of these compounds are:



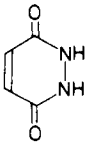
Guanine

(2-amino-6-oxypurine)



Uracil

(2,4-dioxypyrimidine)



Maleic hydrazide

Their solubility is low and low temperature is essential for their effect. In all cases, the concentration to bring out the details of chromosome structure is always below the one causing sub-narcotic effect. Evidently, such pretreatment agents should be applied under controlled conditions, as prolonged treatment or higher concentrations will lead to chromosome breaks.

The capacity of some vitamins in clearing chromosome morphology was also explored. Of those studied, only ascorbic acid (Sharma and Datta, 1956) is effective. In some species of Liliaceae it acts at a concentration of

0.05 M at low temperatures. The application of this group of chemicals is, however, very limited.

Swaminathan and Natarajan (1957) have demonstrated that scattered chromosomes in metaphase plates can be secured through treatment in a number of vegetable oils, especially the oil of *Sesamum*. Evidently, molecules of these compounds react with their solvent in the cytoplasm and thus alter the viscosity of the plasma. As sub-narcotic effects have also been observed with these oils, investigations are needed to explore the property of a number of essential oils in chromosome clarification such as eugenol, lavender, etc., the radiomimetic actions of which have been reported by D'Amato and Avanzi (1949). A homogenised mixture of 1 drop of castor oil and 5 ml of 0.003 M aqueous OQ solution has been used for chromosomes of *Sequoia sempervirens* (Fozdar and Libby, 1968).

O-Isopropyl-*n*-phenylcarbamate (IPC)

Pure IPC is a white crystalline powder, highly soluble in ethanol, but only soluble in water to the extent of 250 ppm at 25 °C. It is decomposed in soil by micro-organisms and also in unrefrigerated aqueous solutions. In mammals, its toxicity is low, the LD_{50} being 3000 mg/kg body weight. Concentrations effective on plants lie between 2.5 and 20 ppm, for periods of treatment ranging between 1–4 h. The solvent ethanol must be removed for pre-treatment schedules. It is preferable to use solutions in water. The main effects of this chemical are: immediate cessation of mitotic activity, followed by contraction of chromosomes in prophase, metaphase and anaphase. In some cases, the chromosomes may be reduced to about one quarter of their original length (Mann, Jordan and Day, 1965; Storey and Mann, 1967). Sawamura (1965) noted that CIPC, a *m*-chloroanalogue of IPC, causes inhibition of phragmoplast and spindle development.

HYPOTONIC TREATMENT FOR CHROMOSOME SPREAD

This is used after colcemid treatment for almost all animal preparations. It is based on the same principle of swelling the cells for dispersion of chromosomes. It was first utilised by Hsu (1952) for human chromosomes. Solutions, to be effective, must be of low osmotic pressure and ionic strength (Hungerford and Di Berardino, 1958). The solutions used by different workers include water, hypotonic sodium citrate and sodium chloride, potassium glycerophosphate, 0.65 M, potassium chloride, 0.075 M, diluted balanced salt solutions and culture medium. Included are also three, four or five parts distilled water to one part isotonic solution or medium; 0.17 per cent saline in distilled water; four parts 0.17 per cent saline to one part isotonic solution or medium and 1 per cent sodium citrate (Priest, 1969). The length of treatment ranges from 3 to 40 min and the temperature from 23 to 37 °C.

Water in pre-treatment

Several of the pre-treatment chemicals tested so far are used in aqueous solutions and are sparingly soluble in water. As many are almost insoluble in distilled water, tap water is often used as a solvent. The use of isotonic solution for swelling and chromosome scattering has been described in the chapter on mammalian chromosomes. The effects of water distilled under different conditions—tank water, tap water (Sharma and Sen, 1954) and isotonic solution of $CaCl_2$ (Sharma and Mookerjea, 1955)—have been studied in the clarification of chromosome morphology. In order to check the degree of their effect, controlled experiments were performed in which fixation and staining were carried out without any pre-treatment. Three types of distilled water were used, namely: (a) distilled in metallic retort, (b) distilled once in glass distillator and (c) distilled several times in glass distillator. The purpose of using glass-distilled and re-distilled water was to eliminate any error arising through the presence of any metal in the water.

Root tips, directly treated in the fixing-cum-staining mixture, revealed clumped chromosomes. Satisfactory contraction of chromosomes and straightening of arms were obtained with tap water, tank water and with water distilled in a metallic retort, though the effect of the latter was less than that of the former. The high frequency of metaphase plates, as compared to control, suggests spindle abnormality. Pronounced scattering of chromosomes could be secured in some of the water plants, such as species of *Vallisneria* and *Hydrilla*, with water distilled twice in a glass distillator. These data suggest that the chemicals need not be present in significant amounts to change plasma viscosity, necessary for chromosome clarification. Not only tap water, which is rather alkaline, and tank water, yielded satisfactory results, but even an isotonic solution of calcium chloride in water yielded well scattered chromosome plates in *Dieffenbachia picta*, a member of the Araceae having as high a chromosome number as $2n = 126$. Of course, as all these pre-treatments were performed under low temperature, it is obvious that cooling accelerated the reaction. That the entire effect on this species is not due to cooling is proved by the complete absence of any reaction in roots of this species which are merely cooled without being kept in the pre-treatment medium. However, Lesins (1954) recorded that keeping plants on snow overnight prior to direct fixation gave good results for certain species. Any nucleic acid starvation effect due to cold was counteracted by a treatment in 3 per cent ferric ammonium sulphate solution for 3 h or overnight before treatment. For animal chromosomes, specially of cancerous tissue, water pre-treatment is very effective. In certain species, if the water treatment is prolonged, chromosome breakage may result, which has also been noted by Macfarlane (1951) and others. Cold treatment alone at 0–2 °C, and 8–10 °C, for 4–24 h in water, has been used for screening wheat aneuploids (Tsunewaki and Jenkins, 1960).

The distinct response of nucleus and cytoplasm to such dilute solutions as isotonic calcium chloride, tap water or even re-distilled water suggests the existence of an extremely subtle metabolic equilibrium necessary for the functioning of the spindle and maintenance of chromosome structure. Any change in the medium, however minimal the chemical concentration may be,

Table 2.1 Some common pre-treatment chemicals

Chemical	*Effective concentration of aqueous solution*	*Period of treatment needed for karyotype clarification*	*Temperature (°C)*	*Remarks*
Acenaphthene	Saturated	1–4 h	Room temperature	Application is limited to specific organs, particularly to pollen tubes
Aesculine	Saturated or half saturated	5 min–24 h	4–16	Widely applicable in both plants and animals
Aesculetin	Saturated	Variable	10–16	Limited to only a few plants
α-Bromonaphthalene	Saturated	10 min–4 h	10–16	Very effective particularly for aquatic plants and wheat chromosomes
Chloral hydrate	0.5–1%	30 min–2 h	10–16	Effective in a number of plants but the results are rather inconsistent
Colchicine	0.5–1%	30 min–1 h for plants but 5–30 min for animals	Preferably between 8 and 16	Very wide range of effects. Equally suitable for plants and animals
Coumarin	Saturated	3–6 h for plants, 5–60 min for animals	Both cold and room temperature	Effective for long chromosomes and for animals
Daphnetin	Saturated	Variable	10–16	Limited application
Colcemid	0.5 μg/ml to 0.05 μg/ml	1–6 h	Room temperature	Effective in bone marrow and peripheral blood
Vinblastine sulphate	0.1 μg/ml to 0.01 μg/ml	1 to 3 h, up to 6 h	37	Peripheral blood culture
Vincaleucoblastine	0.15 ml of stock soln of 0.5 g/ml/10 ml of culture	1 to 3 h	37	Peripheral blood culture
Hypotonic solutions	Variable	3–40 min	23–37	Animal and human

Table 2.1 (*continued*)

Chemical	*Effective concentration of aqueous solution*	*Period of treatment needed for karyotype clarification*	*Temperature* (°C)	*Remarks*
p-Dichlorobenzene	Saturated	3–5 h	12–16	Very effective, particularly on plants with a very high number of chromosomes
Gammexane	Saturated	1–3 h	12–16	Effective mainly on plant tissue
Hormones	0.0002–0.02%	3–3½ h	10–16	Effective on plants with both low and high number of chromosomes
Isopsoralene	Saturated	1–2 h	12–14	Very effective on mitotic chromosomes of a number of plants
Oxyquinoline	0.002 M	3–4 h	12–16	Very effective on plants, particularly with medium sized to long chromosomes
Phenols	Variable, usually low doses	3–6 h	10–16	Applicable to almost all groups of plants with changes in concentration
Umbelliferone	Saturated	1–3 h	12–16	Applicable to some plant groups having high chromosome number
Veratrine	0.05–4%	30–40 min	12–16	Applicable to several groups of plants
Miscellaneous fluids	(i) 0.6% NaCl in double-distilled water: 6 parts			Used for minced mouse fetus.
(a) Hungerford's fluid (1955)	(ii) Colchicine in modified Ringer's solution (0.82% NaCl, 0.02% K, 0.02% $CaCl_2.2H_2O$ in double-distilled water) in proportion $1/10^6$: 1 part			Incubated at 37 °C in covered depression slide for 30–60 min with agitation after treatment for 5–10 min
(b) Dilute isotonic salt solution can also be used				

may upset the balance, resulting in spindle disturbance and contraction of the chromosome and its segments. The differences in water treatment can be explained by taking into consideration the fact that re-distilled water does not constitute the normal medium for growth of roots in nature. As evidently the cytoplasmic constitution of the different groups of organisms is different, the degree of viscosity change required to cause spindle disturbance is not identical in different species. Because of this difference in requirement all the species do not respond in a similar way to a pre-treatment chemical. It has already been mentioned that pre-treatment chemicals differ with respect to their capacity for causing viscosity change in the cytoplasm. This is the reason why different groups of organisms may require different pre-treatment chemicals for spindle arrest and clarification of chromosome morphology. In the absence of inventions whereby cytoplasmic constitution of a species can be detected without detailed analysis, successive trials are necessary to find out the pre-treatment chemical necessary for a species. In general, it may only be stated that related species with similar genotypes have preference for a common pre-treatment agent.

3
Fixation

Fixation may be defined as the process by which tissues or their components are fixed selectively at a particular stage to a desired extent. The purpose of fixation is to kill the tissue without causing any distortion of the components to be studied, as far as is practicable. In chromosome study, the purpose may vary to a significant extent. In certain cases, it may be necessary to study the phospholipid component of the chromosome, and for this purpose a specialised schedule is used. On the other hand, for nucleoprotein precipitation the method is different. In order to study the enzyme activity in the chromosome, freeze–drying methods are often applied. These instances indicate the extent to which the purpose of study varies even when studying the chromosome alone.

Suitable fixation, which is essential for the study of chromosome structure, has always intrigued cytologists. Since the scope of cytological study has been extended to include different disciplines of biological science, the need of critical fixation is being more and more realised. Even now, very little is known about the exact changes undergone at an intracellular level following fixation, and as such the cytologist is handicapped in having to rely partly on chance.

The term fixation was previously used in a wide sense involving, principally, the mere visibility of chromosome structure. With the extension of the scope of cytological study, the necessity for a differential analysis of chromosome segments was felt. Fixation, as is now realised, must be *critical*. It should not only increase visibility of the chromosome structure but should also clarify the details of chromosome morphology, such as the chromatic and heterochromatic regions and the primary and secondary constrictions. In view of the limited number and inadequacy of techniques available in the past, somatic chromosomes could not be studied to the desired extent in the majority of species. The inadequacy of the techniques was chiefly due to the fact that the earlier workers did not realise the importance of critical fixation in the analysis of chromosome structure.

The study of fixation and its principles is in itself a specialised line of investigation. Species differ greatly in their response to a fixing chemical. In the case of plants, monocotyledonous and dicotyledonous groups show different responses. Similarly, a fixative proved to be suitable for a plant species may be inadequate for animals. Mammalian chromosomes require special methods of fixation. All these facts imply that the cytoplasmic

constitution of each individual taxon is one of its principal characteristics and is therefore one of the principal factors controlling its response to a chemical fixative. The main limitation in the analysis of the exact effect of fixation at an intracellular level is the inherent complexity of all biological objects. In every multicellular living object, so many intracellular variable factors are present that it is very difficult to analyse the effect of the fixing chemical on any one of them.

Although a number of fixing reagents have been devised by various workers, all of them possess certain common characteristics which are essential for a fixative. Each fixing chemical is lethal in its action. In fact, Levan (1949) has classified the lethal chemicals into two categories.

Under one category fall those compounds which cause pyknosis of chromosomes or detachment of nucleic acid from the protein thread, and in the other are included compounds which maintain the chromosome structure intact. In a fixing chemical, therefore, lethality must not be associated with pyknosis of chromosomes or the dissolution of the nucleic acid from the protein thread. The structural integrity of the chromosome must be maintained intact. Precipitation of the chromatin matter is essential to render the chromosome visible and to increase its basophilic nature in staining. Under living conditions, the phase difference between different components of the cell is not enough to permit them to be observed as distinct entities. Coagulation of protein and consequent precipitation cause a marked change in the refractive index of the chromosomes, helping them to appear as differentiated bodies within the cell. All fixatives, so far used, have the property of crosslinking proteins. The primary requisite of a fixative for the study of chromosomes is therefore the possession of the *property of precipitating chromatin*. A fixative for chromosomes is, generally, a mixture of several compounds and at least one of its constituents must have this property.

Another important requisite of a fixative is that it should have the property of rapid penetration so that the tissue is killed instantaneously, the divisional figures being arrested at their respective phases. *Immediate killing* is essential as otherwise the nuclear division may proceed further and attain the so-called 'resting' or metabolic phase. Divisional configurations are necessary for visualising the chromosomes correctly. Conversion to the resting stage makes it useless for chromosome study.

With the death of the cells, certain consequent changes occur which are detrimental to the preservation of chromosome structure. The most important change is the autolysis of protein. Under normal conditions for the tissue, enzymes are present which help to build up the proteins. With lethality, as the medium becomes acidic, these enzymes act in the reverse direction and cause a breakdown of the complex protein into simpler amino acids. As polypeptide forms one of the principal constituents of the chromosomes, the effect of denaturation will cause ultimate disorganisation of the chromosome structure. Therefore, a fixative should also be able to *check autolysis of proteins*.

With the onset of lethality, bacterial action causes the tissue to decompose. Another prerequisite for a good fixative is to *prevent this decomposition* by maintaining an aseptic condition in which bacterial decay cannot take place.

As the purpose of chromosome study is to observe the minute details of chromosome morphology, the staining should be perfect. A number of

chemicals, e.g. formaldehyde, though otherwise possessing all the qualifications of good fixatives, may often affect the basophilia of chromosomes. Such chemicals, when used alone, cannot be recommended for chromosome fixation. A proper fixative should, in general, *enhance the basophilia* of the chromosome.

A fixing mixture which fulfils all the conditions detailed above can be considered to be a truly effective fixative for chromosome study, but since all these properties are rarely to be found within a single chemical, a fixative is generally a combination of several compatible fluids which jointly satisfy all the above requirements.

Even with the best fixatives, the chemical changes undergone by the nuclear bodies cannot be ignored as there are certain inherent disadvantages in the entire process. Firstly, at least some of the post-mortem changes are difficult to overcome. Secondly, there is a possibility of the extraction of diffusible components. Lastly, even with all precautions, it is very difficult to keep the enzyme activity unaffected, and in addition the tissue shows a tendency to shrink on coming into contact with the chemicals.

All these disadvantages can be eliminated by fixing through freezing at low temperature, followed by drying the tissue—the principle involving rapid cooling of the tissue to a low temperature, followed by extraction of water in a vacuum. This method allows a life-like preservation of the tissue. The cooling process must be so rapid that the water cannot crystallise during freezing, as this results in the distortion of cellular components, and consequent misinterpretation of chromosome structure. The initial water contents of the tissue, the shape and size of the material, the temperature of the tissue and of the cooling bath are all factors contributing to proper fixation by freezing without forming ice crystals. Water can be frozen into amorphous ice in a cooling bath of $-175\,^{\circ}C$, secured by condensation and liquid nitrogen (Stephenson, 1956; Gersh, 1959; Burstone, 1969).

After fixation by freezing, water must be removed. The process is usually carried out in vacuum at a low temperature. The material can also be dried by passing it through a stream of dry cool gas (Treffenberg, 1953; Jensen and Kavaljian, 1957). It has been argued that the water molecules may form crystals during the process of drying (De Nordwall and Staveley, 1956), but up to the present time no evidence in favour of this contention has been obtained. The material can be cut directly or before sectioning, and may be infiltrated with paraffin or some other medium. Post-fixation too, depending on the purpose for which it is needed, may be employed (Bell, 1956; Clements, 1962; McClintock, 1964; Rutherford, Hardy and Isherwood, 1964; Lotke and Dolan, 1965; Pearse, 1972; Burstone, 1969). Several freeze–drying equipments and cryostats have now been developed.

The freezing method of fixation has a number of advantages, such as: (a) minimum distortion of the tissue after its death, (b) least possibility of diffusion, and (c) no significant effect on the enzyme system. Further, the tissue can be directly embedded in paraffin without dehydration or clearing. Even then, its inherent drawbacks cannot be ignored. For example, all the above advantages can be nullified by the distortion of cellular components during embedding or sectioning. Interference may occur with very small materials by crystallisation of water while preparing the material in bulk, and disintegration of the tissue between developing ice crystals, which cannot be

checked. The extremely high cost involved in setting up the apparatus hinders its use in all laboratories.

Some of these limitations, however, have been eliminated in the process of dehydration by freezing–substitution. In this technique, the specimen is rapidly frozen, followed by dehydration at a very low temperature (-20 to $-78\,^{\circ}C$) through any one of the following reagents: *n*-propanol, *n*-butanol, methanol, ethanol, methyl cellosolve, or the chemical fixatives, as will be discussed later. After complete dehydration, the material is brought back to room temperature slowly (Bullivant, 1965; Rebhun, 1965; Pease, 1966; Malhotra, 1968; Cope, 1968). During this process there is a possibility of the extraction of diffusible substances and lipids but the proteins are kept intact. The extraction of lipids prevents a proper preservation of chromosome structure as phospholipid is one of the likely components of the chromosome.

The freeze–drying method of fixation no doubt has numerous advantages over the chemical one. It is particularly accurate for the study of the effect of chemical and physical agents on the chromosome, where the immediate effect has to be analysed, but it is not very useful for the study of the structure and behaviour of chromosomes during the process of division under normal conditions. Other advantages of chemical fixation, such as increase in the basophilia of chromosomes, differential precipitation of chromatin matter in its different segments and so on, cannot be obtained by means of the freezing–substitution technique. These factors, taken together, have contributed largely to the wide use of chemical fixatives in routine work on chromosome studies, and only under special circumstances, as mentioned above, is freezing–substitution applied.

The fixing chemicals, in general, may be classified into two categories, precipitants and non-precipitants, based on their property of precipitating proteins within the cell. The best examples of precipitant fixatives are chromic acid, mercuric chloride, ethanol, etc. Among the non-precipitant fixatives can be included osmium tetroxide, potassium dichromate, etc. There are certain fixatives which undergo chemical combination with proteins, as Baker (1966) has pointed out, some of which precipitate out proteins, while others do not. A fixative may also alter the nature of proteins without the necessary addition of new atoms to them, thus causing denaturation, and subsequently the solubility of the protein is lost (*see* Wolman, 1955). That denaturation does not involve any addition of atoms is proved by the observation of a similar effect after heat treatment. It is possible that denaturation causes the molecules to straighten out into a fibrous form, the chemical change being the appearance of reactive sulphydryl groups.

Whenever a fixative has a strong precipitating action, it is usually counteracted to a certain extent by the addition of other reagents. To deal with any possible error in the interpretation of their combined action at an intracellular level, Baker (1944) suggested that the best fixation would be possible with a simple non-precipitant (unmixed) fixative, to which non-fixative salts have been added. No doubt the action of such a fixative can easily be interpreted, but for chromosome study, where a variety of reactions is needed for differential clarification of segments, it is nearly impossible to secure a single chemical combining all the desirable qualities.

Fixatives having the property of precipitating proteins cause the nuclei to have a spongy appearance. Telleyesniczky (1905) first suggested that such

sponge work is absent in the living nucleus and it appears only after fixation with a protein precipitant. Even then, precipitation has an added advantage in paraffin embedding, as the latter infiltrates readily into the meshes of the sponge. Non-precipitant fixatives, on the other hand, preserve the structure very badly after embedding. For the proper observation of chromosomes, some amount of precipitation is necessary and therefore in a fixative a slight precipitating action is preferred.

The swelling of the cells and shrinkage of chromosomes are the two principal factors controlling the merit of a fixative. It has always been difficult to check the initial changes in volume occurring during fixation. Undoubtedly, with larger molecules of fixatives, the initial swelling is retarded (Bahr, 1957; Bloom and Friberg, 1957). A heavy shrinkage was observed in xylol and paraffin infiltration when lower alcohols were used. An overall alteration in the volume of the cell or a contraction or swelling of chromosome structure is not harmful, but a differential shrinkage of the constituents of the cell results in distortion of chromosome structure, which must be avoided. Osmotic concentration was previously considered to be one of the principal factors affecting the swelling or distortion of the cellular structures. Therefore isotonic solution was often used for fixation. Telleyesniczsky (1905) claimed that osmotic concentration is not the controlling factor because the tissue, at the time of fixation, loses its capacity to respond to any change in osmotic pressure. Baker (1966) also confirmed the validity of this statement. Dilute acetic acid, having a pressure of 20 atm, causes the tissue to swell, whereas picric acid, with a low pressure of $2\frac{1}{2}$ atm, induces shrinkage to a significant extent. All this evidence suggests that osmotic concentration or pressure is of little significance in controlling the efficacy of a fixative. On the other hand, picric acid is a strong protein precipitant and acetic acid is not. Therefore Baker (1966) suggested that this property is possibly the controlling factor in causing shrinkage. Hence, all the above factors are taken into consideration when a fixative is selected.

The main chemicals which have been used as fixatives, or more precisely, as ingredients of a fixing mixture, are: (a) non-metallic—ethanol, methanol, acetic acid, formaldehyde, propionic acid, picric acid, chloroform; (b) metallic —chromic acid, osmic acid, platinic chloride, mercuric chloride, uranium nitrate, lanthanum acetate, etc. Several of these compounds are also used as vapour fixatives, with the sole object of converting the soluble substances into insoluble ones, before coming into contact with water or other solvents, so that *in situ* preservation is maintained.

Most non-metallic fixatives, except formalin in cytochemical work, have one advantage over the metallic ones—that no washing in water is required after fixation.

Of all the fixatives employed so far, Law's method (1943) is supposed to be the most simple, in which the fixation is performed by boiling water. This brings about coagulation of protein and especially uncoiling of chromosome spirals. This method is only useful for temporary study of merely the divisional figures. Chromosome structure cannot be well preserved following this technique of fixation.

In materials where the cells are loosely scattered in a suspension, as for example, in mammalian peripheral blood cultures, fixation is improved by decreasing the amount of fluid surrounding the cells. The cells, therefore, are

centrifuged into a small pellet and the supernatant liquid removed. The fixative is added and allowed to remain undisturbed for up to 30 min. The cells may be centrifuged into a pellet again, followed by the addition of fresh fixative. Cells on a coverglass or a slide are fixed usually for not less than 5 min or more than 24 h.

The properties of the different fixing chemicals, the merits and demerits of their uses and their applicability are discussed below.

FIXING FLUIDS

Non-metallic fixatives

Ethanol (C_2H_5OH)

It is used extensively as a constituent of chromosome fixatives. The suitable percentage for fixation varies from 70 to 100 per cent. One of the most important advantages of the use of ethanol is its capacity for immediate penetration. Fischer (1899) noted that it precipitates nucleic acid. Its dehydrating property is well known and it causes an irreversible denaturation of proteins. It also has an undesirable hardening effect on the tissue. The denaturating action on proteins due to precipitation may convert the molecule into a form impermeable to reagents or approximating closely to the separated groups in protein chains (Pearse, 1972). It has been claimed to break the hydrogen bonds and salt links in protein chains, thus revealing several side groups (Kauzmann, 1959; Okunuki, 1961). As the stereochemical pattern is often altered, its effect in misrepresenting the structure is to be considered.

Being a reducing agent, it undergoes immediate oxidation to acetaldehyde and then to acetic acid in the presence of an oxidiser, and so cannot be used in combination with many metallic fixatives, such as chromic acid or osmium tetroxide. Baker (1966) further suggested that it is not an effective fixative for chromatin. Therefore it can be used principally in combination with acetic acid, formaldehyde or chloroform. Chilled ethanol fixation is often used for the preservation of certain enzymes, as the reactive groups of enzymes generally remain undisturbed. It also does not affect the isoelectric point appreciably, which is an added advantage for cytochemical purposes (Lojda, 1965). For enzyme studies on chromosomes, chilled 80 per cent ethanol fixation for 1 h or more is recommended and for monolayer cultures, absolute or 96 per cent ethanol fixation for 1–15 min is often applied (Smetana, 1967).

Acetic acid (CH_3COOH)

One of the primary advantages of using acetic acid in a fixing mixture is that it can be combined with any of the other fixatives so far studied. It can be mixed in all proportions with water and ethanol or methanol. It can be used from very low concentration, i.e. 1 per cent, to even glacial (100 per cent) form. The term 'glacial' is derived from the fact that it freezes to a form resembling ice at very cold temperatures. This acid has a remarkable penetrating property, even higher than alcohols; possibly its smaller ions are responsible for this property.

Pischinger (1937) noted that acetic acid can precipitate nucleic acid and dissolve the histones, but it is incapable of fixing cytoplasmic protein. It cannot be recommended for the observation of phospholipids in the chromosomes. Potassium dichromate, which is a good fixative for lipids, loses this property if used in combination with acetic acid. Baker (1966) suggested that it can precipitate nucleoprotein but not albumin. Wolman (1955) pointed out that acetic acid affects fixation of proteins like nucleoproteins and mucoproteins, the isoelectric point of which is near the pH value of the acid solution employed. The bound water layer, which is normally present around the ionised groups of the protein molecules, disappears with the loss of the electric charge, and the protein molecules are then free to form as the reactive points come closer together. The main use of acetic acid in the study of chromosome structure is to check shrinkage and to preserve the chromosome structure without distortion. The materials fixed in acetic acid can resist hardening in alcohols.

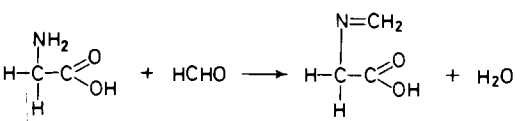
Acetic acid is, in general, an ideal fixative for chromosomes, and in spite of Pischinger's finding that it dissolves histones, it has been observed to maintain the chromosome structure intact, presumably not causing any distortion of the nucleoprotein. One of the limitations of this fixative is the excessive swelling of the chromosome segments induced by it. Therefore where a study of detailed structure of chromosomes is needed, this point must be borne in mind, and acetic acid should be used in combination with alcohols, or similar chemicals, which shrink and harden the tissue. For the study of meiotic chromosomes, where the purpose is to study the behaviour instead of the structural details, acetic acid is quite suitable. In pachytene chromosome analysis, where clear chromosomal details are required, acetic acid serves as an ideal fixative.

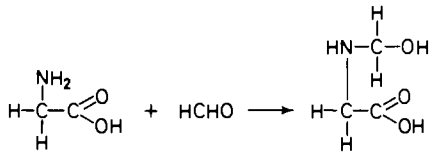
Acetic acid is also a good solvent for aniline dyes, and due to this property it is a necessary component of staining-cum-fixing mixtures, like acetic–carmine, acetic–orcein, acetic–lacmoid, etc.

Formaldehyde (HCHO)

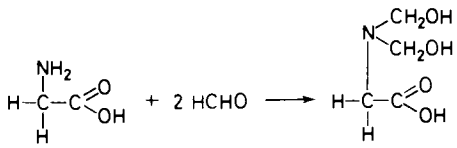
Formaldehyde is a gas and its commercial form, known as 'formalin', contains a 40 per cent solution of formaldehyde in water. It is a bifunctional compound capable of forming crosslinks between protein end groups (Pearse, 1968). For the fixation of chromosomes 10–40 per cent solution of commercial formalin in water is used. It has a very low precipitating action on protein in high concentrations.

The action of formaldehyde is chiefly on proteins. It reacts with the amino groups of proteins, with the production of water, or simply attaches itself to the amino acid without the liberation of water (*see* Woodroffe, 1941; Baker, 1966). The reactions can be interpreted as:





Levy (1933) suggested that two molecules of formaldehyde may react with one of amino acid:



The reaction does not necessarily mean that formaldehyde can react only with one amino group at the end of a polypeptide chain, because in a number of amino acids, like lysine, there are two amino groups, one being engaged in the polypeptide chain and the other remaining free and reacting with formaldehyde. Moreover, not only —NH_2 groups, but also —NH groups can react with formaldehyde. The methyl compounds formed may further react with amines of other groupings containing active H in another protein molecule, forming methylene bridges. Such bridges may be formed between two —NH_2, or —NH_2 and —NH, or —NH_2 and —CONH groups (Pearse, 1968). In strong alkaline solutions, with more than pH 8.0, it reduces S—S to —SH groups and then reacts to form a methylene bridge (S—CH_2—S) (Middlebrook and Phillips, 1942). These crosslinks may be responsible for the hardening effect of formaldehyde. Several other chemical groups of the protein molecules can react with HCHO (*see* French and Edsall, 1945; Walker, 1953; Lojda, 1965). Further, as concentrated formalin exists principally in a polymerised form and depolymerisation is not instantaneous, the possibility of a reaction between polymerised formaldehyde and tissue proteins has been hinted at by Wolman (1955).

Formaldehyde hardens the tissue to a remarkable extent and should not be considered, by itself, as a good fixative for chromosomes. The vapour has, however, the capacity of preserving the cell constituents in an excellent way so that their life-like structure is maintained (Falck and Owman, 1965). This reagent does not afford any protection to the chromosomes against damage caused by ethanol, benzene or paraffin dehydration and block preparation.

Formaldehyde easily oxidises to formic acid and should never be used in conjunction with oxidising agents like chromic acid or osmium tetroxide. However, it is often used even in such combinations in classic fixatives because, the speed of oxidation being very low, fixation can be accomplished by the time the oxidation has been completed. Often neutral formalin is used (Lillie, 1954), prepared by adding basic magnesium or calcium carbonate to the solution. For cytochemical work, fixation at 4 °C for 30 min to 2 h in 10 per cent neutral formalin, after adjusting the pH by calcium carbonate or buffer is recommended (Marinozzi, 1963; Smetana and Busch, 1964; Smetana, 1967). In short, the use of formaldehyde in fixation lies in its property of combining with proteins and forming bridges between adjacent molecules.

Tissues, which are placed in fixatives containing formaldehyde, often show well scattered chromosomes, especially after sectioning from paraffin blocks. The cell volume increases considerably, resulting in spreading of the chromosomes over a larger area. The constriction regions appear slightly exaggerated due to contraction of the euchromatic segments. This effect is possibly due to the action of formaldehyde on the chromosome proteins—doubtless one of the advantages of fixation in formaldehyde. In cytochemical work, washing after formalin fixation is essential so that the reactive groups of proteins remain unmasked to combine with the reagents, e.g. Sakaguchi reaction for arginine cannot be carried out satisfactorily without washing off excess formalin as otherwise guanidyl groups remain blocked (Pearse, 1972).

Another serious disadvantage in using formaldehyde as a fixing agent is possibly the fact that the tissue treated with this reagent is difficult to smear; the exceptional hardening, which is a result of its action on protein, being responsible for this. Further, even in block preparations, if formaldehyde is not used in suitable proportions, extreme granulation of chromosomes can be observed, which implies that the linkage between nucleic acid and protein may be affected by formaldehyde at certain susceptible segments, so that these segments become slightly depleted of nucleic acids. The differential distribution of nucleic acids, induced thereby, has an adverse effect on the basophilia of chromosomes and culminates in the appearance of granulated segments. This appearance closely resembles the nucleic acid starved areas of Darlington, observed after cold treatment. The granular representation makes study of the constriction regions difficult, as they cannot be distinguished from the areas showing low basophilia. Therefore formaldehyde should always be used as a component in a fixing mixture in suitable concentrations for chromosome analysis. It is widely used for both plant and animal materials.

Methanol (CH_3OH)

It is occasionally used in chromosome studies of plants but is extensively employed in fixing animal chromosomes. It is obtained from destructive distillation of wood, as a component of pyroligneous acid, but does not possess the essential requirements of a typical alcoholic fixative. While ethanol causes heavy shrinkage of chromosomes, methanol causes swelling and this property has been used advantageously in the preparation of fixatives where a swelling agent is often needed to compensate for the shrinking effect of other chemicals. Its effective concentrations are the same as ethanol. It is a colourless poisonous liquid and is miscible with water in all proportions. It should not be used with an oxidising agent, as it is then immediately oxidised to formic acid. In properties, it closely resembles ethanol, except for the fact that the oxidation products of the two chemicals are different and methanol does not give the haloform reaction given by ethanol.

Acrolein and glutaraldehyde

These two aldehydes, namely, acrylic aldehyde, $H_2CCHCHO$ and glutaric dialdehyde $(CH_2)_3CHO_2$, have the property of crosslinking protein molecules more actively than formaldehyde (Bowes, 1963; Sabatini, Bensch and

Barrnett, 1963). Though their use in ultrastructural studies has been established (*see* Chapter 9, electron microscopy), they cannot be recommended for wide use in chromosome fixation.

Propionic acid (C_2H_5COOH)

Propionic acid has been used extensively in the fixation of chromosomes. It is a fatty acid like acetic acid, and is a colourless liquid with an acrid odour; it is also miscible with water, ethanol and ether in all proportions, and is a good solvent for aniline dyes. It is present in pyroligneous acid though it can be commercially obtained from the oxidation of *n*-propanol.

In view of the above properties, it is generally used as a good substitute for acetic acid. Its penetration is not as rapid as that of acetic acid but it causes much less swelling of the chromosomes. It can be used, similar to acetic acid, in staining-cum-fixing mixtures, like propionic–carmine, propionic–orcein, etc.

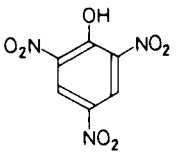
Chloroform ($CHCl_3$)

Chloroform is a trihalogen derivative of methane; it is a colourless liquid with a sickly sweet smell and is sparingly soluble in water. It is miscible in all proportions with alcohols, ether and acetone. It has a narcotising action and is used as an anaesthetic. It is slowly converted into highly poisonous carbonyl chloride in the presence of air and light. It is a good solvent for fatty substances, a property which has been advantageously used in fixation. In the study of plant chromosomes, chloroform is generally used in the fixative to dissolve the fatty and waxy secretions from the upper surface, facilitating the penetration of the fixative. In the study of chromosomes from animal tissues, chloroform is frequently used to dissolve the fats which are present as accessories in the desired tissue.

A judicious use of chloroform in fixing mixtures is recommended, as an excessive dose or long period of treatment may be toxic. Ethanol should be an essential component of a fixative containing chloroform as the former checks the decomposition of the latter into carbonyl chloride. As the tissue becomes extremely brittle after treatment in chloroform, it has a limited use in smear preparations.

Picric acid

Picric acid is 2,4,6-trinitrophenol having the chemical structure:



It is a yellow crystalline solid with a bitter taste; insoluble in cold water but soluble in hot water, ether, ethanol, benzene and xylol. The NO_2 groups in 2 and 4 positions are responsible for the maximum amount of resonance of this acid and, being a nitrophenol, it is strongly acidic. Its yellow colour is due to NO_2 chromophoric groups.

It is used in saturated or nearly saturated solutions for cytological work. Jones (1920) first observed its protein-precipitating action on nuclein. Pischinger (1937) observed that it can precipitate both histone and nucleic acid. It is remarkable that neither *p*-nitrophenol nor 2,4-dinitrophenol is capable of precipitating protein (Holmes, 1944). Evidently, all three $—NO_2$ groups are important factors controlling the activity of picric acid. Baker (1966) suggested that the action of picric acid on proteins is different from other protein precipitants in the sense that, as complex anions precipitate proteins, an actual chemical compound, protein picrate, is formed in this case. Badder and Mikhail (1949), and Anderson and Hammick (1950) observed that 2,4,6-nitro groups behave as inducing dipoles and activity may increase further, due to several resonance states of the picric acid molecules. Protein molecules may be bridged by picric acid due to weak electrostatic forces, linkage being due partly to ionic forces and partly to polarity induced in many polarisable moieties of the protein molecule. The protein precipitating action has also been worked out by Lison (1960) and Lojda (1965).

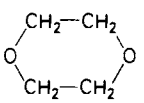
The penetration of picric acid is slow and a significant amount of shrinkage of chromosomes is observed. Being an acid, it should cause swelling of the cellular components but it is possible that shrinkage due to protein precipitation over-balances this effect. Due to its acidity, however, the hardening of the tissue, which is inherent in protein shrinkage, is checked. Picric acid, therefore, may be considered as a good ingredient in a fixative for protein precipitation without causing undesirable hardening.

The usual practice of washing after picric acid treatment is carried out by passing through different grades of ethanol during the usual dehydration procedure followed for block preparation.

For plant tissues, picric acid is not generally recommended in chromosome study because of heavy protein precipitation and shrinkage. These effects often result in a distortion of the nuclear and cytoplasmic components. In animal material, however, where the main object is to study the gross behaviour of the chromosomes, it is used always as an ingredient of a fixing mixture, such as Bouin's fluid, but never alone.

Dioxane

Dioxane is diethylene dioxide with a structural formula:



It is a colourless liquid, mixing in all proportions with water and most organic solvents, is fairly toxic in action and isomeric with ethyl acetate. It dissolves resins, fatty oils, etc., and because of this property, which assists the

rapid penetration of the fluid, and also because of its ready miscibility with most solvents, it forms a good ingredient of fixing mixtures.

Ether

The ether of commercial use is diethyl ether with a formula $(C_2H_5)_2O$. It is a colourless volatile liquid, fairly soluble in water and mixes well with alcohols or liquid hydrocarbons in all proportions, being a solvent for fats and oils. Its use in local anaesthesia can be attributed to intense cooling, resulting from rapid evaporation. Ethanol is generally present as an impurity in ether. It should always be kept in airtight containers in cold dark places.

Formerly, ether was not used in fixing mixtures because chloroform, which is less toxic and easier to handle, could be used for the same function. It has been used in a few fixing mixtures, like Newcomer's fluid (1952), to clear the cytoplasm and the cell of the fatty and oily substances, so that the other components can reach the substrate easily.

Isopropanol

Isopropanol is a colourless liquid with a formula $CH_3CH(OH)CH_3$, being soluble in water, ethanol and ether. Although having the same effect as ethanol on chromatin, it has been preferred by some authors due to its comparatively less drastic action.

Acetone

Acetone is dimethyl ketone with a formula $(CH_3)_2CO$, and is a colourless liquid, miscible with water, ethanol and ether in all proportions. It is a good solvent for cellulose acetate and for many organic compounds, and when acting in a fixing mixture serves the same purpose as chloroform or ether in clearing the cytoplasm by dissolving the organic matter.

Similar to ethanol, it is likely (Wolman, 1955) that lipids, which are bound to protein molecules by their hydrophilic groups, neutralise some of the actively charged molecular groups of proteins. As soon as the lipids are dissolved by ethanol or acetone, the charged groups of protein are unmasked and made more reactive; consequently the protein molecules attract each other and form crosslinks (cf. Kauzmann, 1959; Okunuki, 1961).

Metallic fixatives

Osmium tetroxide (OsO_4)

Osmium tetroxide, an expensive chemical, was first used in cytology by Schultze and Rudneff in 1865. The metal osmium is closely related to platinum and at high temperatures undergoes oxidation in the presence of air to OsO_4.

The metal itself has the property of remaining unaffected by any acid acting alone. It is a strong oxidising agent and should never be mixed with formaldehyde or alcohol. In solution, it oxidises aliphatic and aromatic double bonds, alcoholic (OH) groups, amines, —SH groups and other nitrogenous groups as well, but generally the carboxyl and carbonyl groups are not affected. The details of its chemical action were worked out by Wolman (1955). Berg (1927) first studied the chemistry of its action and divided the effect into two categories, primary and secondary. During the primary effect, the entire molecule combines with the amino groups of proteins. In the secondary phase, the compound formed undergoes oxidation, during which the residual part of osmium tetroxide is reduced to a lower oxide or hydroxide. Due to this, the tissue fixed in osmium tetroxide turns black. Criegee (1936) attributed blackening to the oxidation of double bonds between adjacent carbon atoms (cf. Wigglesworth, 1957). Bahr (1955) obtained positive reaction of osmium tetroxide with several amino acids and noted that the reaction of amines is directly proportional to chain length, whereas aldehydes and ketones are reactive only in long chains. Adams (1960) did not get confirmatory proof of reduction of osmium tetroxide by proteins or polysaccharides, but his observations were refuted by Wigglesworth (1964) and Hake (1965).

Stockkenius and Mohr (1965) concluded that, excepting phosphatidyl serine, carbon double bonds are the primary site of reaction of osmium tetroxide. Details of its reaction with lipoproteins have been worked out by Finean (1954), Khan, Riemersma and Booij (1961), Riemersma and Booij (1962), Riemersma (1963), Salem (1962), Hayes, Lindgren and Gofman (1963) and *see* Pearse (1972). Bahr (1954), however, suggested that nucleic acids do not react with osmium. Porter and Kallman (1953) claimed that intermolecular linkages are formed at points containing double bonds in osmic tetroxide fixation. Wolman (1955) suggested that it is quite likely that ethylene bonds are not the only points where the links are formed.

Osmium tetroxide fixes both fats and lipids and the blackening is due to the fact that in all animal cells, an unsaturated substance, olein, is present which reduces the compound to lower oxide or hydroxide. In general, it fixes homogeneously, maintaining a life-like preservation of the tissue. It penetrates very slowly and a number of post-mortem changes may occur if the tissue is fixed in this fluid alone. In fact, Sjöstrand (1956) suggested that only the outer layer of tissue, up to 40 μm in depth, is fixed properly. In the case of thick materials, the fixation is very uneven, the outermost layers being overfixed, the middle region properly fixed and the innermost layers not fixed at all. Gibbons and Bradfield (1956) considered that there is at least partial preservation of the distribution of chromatin.

An excellent advantage of osmium fixation is that it does not cause much shrinkage of the tissue, but on the other hand, there is a slight swelling. The texture of the osmium-fixed tissue, though not very soft, is suitable for cutting for observation under light microscopes. The low degree of shrinkage is often compensated for during dehydration in ethanol (Fernandez-Moran and Finean, 1957). Osmium tetroxide does not allow ethanol to cause precipitation during dehydration.

The effect of osmium fixation depends to a significant extent on the pH, toxicity and temperature of the fixing mixture (Baker, 1966; Sjöstrand, 1969).

Hairston (1956) suggested isosmotic fixation where vacuoles show osmotic effect. For the fixation of bacteria, too, the ionic environment is a significant factor (Maaløe and Birch-Andersen, 1956). Sjöstrand (1956, 1969) also observed that reduction of temperature aids fixation in osmium tetroxide. It is often called 'osmic acid', though actually it is not. It is neutral to indicators and is a non-electrolyte. Although osmium fixation preserves chromosomes during the divisional cycle, it cannot be recommended for the study of the interkinetic nuclei. Moreover, as it often results in protein loss (Dallam, 1957), it is to be used with caution (Pearse, 1972).

The method of preparation of osmium tetroxide solution requires special mention. It is generally sold in sealed glass containers in measured quantities. The container is cut open and, with its contents, is put in a glass bottle and a required quantity of water is added. The solution is shaken and the glass bottle stoppered tightly to prevent evaporation. It is wrapped in dark paper and kept in a cool place, as light causes its reduction to lower hydroxides. Care should be taken while handling this chemical as it has a damaging effect on eyes and mucous membranes. 1 to 2 per cent solution in distilled water or buffer is used. Fixation in the cold is necessary if colloidine buffer is employed (Marinozzi, 1963; Smetana, 1967).

A serious limitation of osmium fixation is the blackening of the tissue. Bleaching with hydrogen peroxide forms an essential step in fixation by osmium tetroxide, but on the other hand, affects chromosome stainability. Washing overnight in water is essential after fixation. With these limitations, it is often preferred as a fixative due to the excellent preservation of the nuclear and cytoplasmic structures. In animals it is often applied even when the blood circulation is continuing in order to minimise the time interval between fixation and interruption of circulation.

The best result with osmium tetroxide is obtained if the fixative is applied in the form of vapour (Gibson, 1885, referred to in Gatenby and Beams, 1950, and in Darlington and La Cour, 1968). This can, however, be applied only on small materials, such as prothalli of ferns, unicellular objects or materials having no cellulose wall, such as smeared animal tissues. Rapid penetration without any deformation of the tissue is the special advantage of this method. In electron microscopy, osmium fixation is widely utilised.

Materials, after osmium fixation, require bleaching to remove the black precipitate produced by fats. Usually, bleaching is performed with hydrogen peroxide when the slide is brought down to water prior to staining. The slide is transferred from 80 per cent ethanol to a jar containing H_2O_2 and 80 per cent ethanol in equal proportions and kept from 1 to 12 h. It is examined to see if the black precipitate has been bleached and is then processed and stained as usual. For bleached tissues, pre-mordanting in 1 per cent chromic acid solution is necessary.

Platinum chloride (H_2PtCl_6)

Platinum chloride is hydrochloroplatinic acid, the deliquescent brown red crystals being water soluble (Gatenby and Beams, 1950). Platinum chloride solution in water is often applied in place of osmium tetroxide, especially in the somatic tissue of plants. It does not have the same capacity as osmium

tetroxide of preserving the life-like structures of the cell, but its capacity for penetration is decidedly greater. It is sold in glass capsules and its preparation is similar to that of osmium tetroxide. It is compatible with formalin and can be used as a substitute for chromic acid in chromic–formalin mixed fixing fluids, but its application is rather limited. It is very effective for solanaceous groups of plants. Fixation in platinum chloride requires bleaching of the fixed tissue as well.

Chromic acid (H_2CrO_4)

Chromic acid is formed when chromium trioxide reacts with water. Chromium trioxide is crystalline, light red or brown in colour and is deliquescent and fully soluble in water. Chromic acid is a very weak acid and its salts can be dissociated even by acetic acid. It has a strong oxidising action and is itself reduced to CrO_3; because of this, it should never be used in combination with alcohol or formalin. In a number of fixing fluids, however, chromic acid is used together with formalin—the reducing action being slow, the fixation is completed before the acid is fully reduced. It is a strong precipitant of protein (Baker, 1966) but Berg (1927) found it to be a very weak precipitant of nuclein. The dissociation of chromic acid in water may result in H^+ and $HCrO_4^-$ or $2H^+$ and CrO_4^- ions. According to Berg (1927), protein undergoes denaturation and precipitation by the primary action of chromic acid, and the secondary action results in hardening. He holds that the ion $HCrO_4^-$ is responsible for the secondary action. Chemical reaction probably occurs between protein and chromic acid, but the exact steps are not precisely known. However, the principal affinity of chromium is for the carboxyl and hydroxyl groups (Bowes and Kenten, 1949; Strakov, 1951). Green (1953) suggested that coordinates with —OH and $—NH_2$ are formed after reaction with carboxyl groups. Proteins, acted upon by chromic acid, are resistant to the action of pepsin and trypsin. Chromic acid penetrates the tissues slowly and the hardening induced by this acid makes the tissue resistant to hardening by ethanol in subsequent processing. It does not cause excessive shrinkage of the tissue.

Materials fixed in this acid require thorough washing in water, at least overnight, otherwise the deposition of chromic crystals not only hinders staining but also hampers the observation of chromosomes. Because of its slight hardening action it is difficult to use this fluid as a fixative for squash preparations, unless softened by some strong acid, which may hamper staining. It should never be used alone, as then heavy precipitates are formed causing shrinkage of nucleus and cytoplasm. Materials treated in chromic acid should not be kept in strong sunlight due to the chance of breakdown of proteins. Basic dyes adhere closely to tissue fixed in chromic acid.

In general, chromic acid is considered an essential ingredient of several fixing mixtures. It imparts a better consistency to the tissue and aids staining better than osmium tetroxide.

Potassium dichromate ($K_2Cr_2O_7$)

The crystals of potassium dichromate are orange or orange red in colour, and it was first used in biological studies by Müller in 1859. It is not as soluble

in water as chromic acid, its solubility being 9 per cent. It is a strong oxidising agent, though not so effective as chromic acid and evidently should not be mixed with formalin or alcohols. Baker (1966) claimed that unacidified $K_2Cr_2O_7$ cannot fix proteins effectively, though it renders the latter insoluble in water. The life-like appearance of the cells is maintained and, if acidified, chromatin can also be preserved as such.

Zirkle (1928) demonstrated that over pH 4.6, $K_2Cr_2O_7$ can maintain the structure of chromosomes, whereas, with less acidity, only the cytoplasmic structures are preserved. Any of the ions, anions or cations, obtained from $K_2Cr_2O_7$, can react with proteins, depending on the acidity of the fixing fluid. In addition to chromium combining with proteins, the reduction of the chromate must also be involved, resulting in change of colour to green. Green (1953) suggested that carboxyl groups must combine with proteins. For the stabilisation of the structure he further suggested that this reaction is followed by coordination between amino and hydroxyl groups. Wolman (1955) regarded the primary reaction as that of chromium bridges between protein molecules.

Potassium dichromate, on the whole, is a good fixative for lipids. It has a rapid rate of penetration and shrinkage is not very marked. It does not harden the tissue significantly and, as such, shrinkage in alcohols during subsequent treatment is considerable—this being one of the disadvantages of potassium dichromate fixation. After dichromate fixation cellular constituents respond well to acid dyes, and the response of chromatin to basic dyes can be maintained if the fixation is performed at an acidic level. Because of its rapid rate of penetration, it is often preferred to chromic acid in mixtures in which a nuclear precipitant is added. It is widely used for the fixation of both plant and animal chromosomes, and can be washed away with dilute solution of chloral hydrate in water.

Mercuric chloride ($HgCl_2$)

Mercuric chloride was first introduced in cytological practices by Lang in 1878. It has a moderate solubility (7 per cent) in water, and dissolves very well in ethanol. One of the advantages of mercuric chloride as a fixative is its compatibility with the majority of the fixing fluids. Slightly acidified mercuric chloride precipitates protein very strongly.

Mercury, in aqueous solution, like several cations, has the property of precipitating protein in an insoluble form (Baker, 1966), this reaction taking place at a comparatively moderate temperature. Calvery (1938) suggested that $—NH_2$ groups of amino acids react with mercuric chloride. Hughes (1950) showed that the mercuric ion may be bound by the SH group of proteins and it can form a bridge between two molecules of protein. This suggestion is quite reasonable, as mercury is a bivalent heavy metal. Mercury ions are capable of forming intermolecular links through their reaction with —SH, —COOH and $—NH_2$ groups, a property which is principally responsible for the powerful protein-precipitating action of mercuric chloride.

Because of its strong action, it is preferable not to use mercuric chloride alone as a fixative, especially for delicate materials. Its rapid penetration and

strong protein reaction can be advantageously employed in mixtures with compatible fluids. Its effect on staining, too, is remarkable, and chromosomes respond well to most of the dyes after mercuric fixation. In spite of its beneficial effect, one of the serious limitations of mercuric fixation is that a needle-like precipitate of mercurous chloride is often formed in the tissue following this fixation. No doubt metallic mercury is often removed by alcoholic iodine, but under certain conditions it may remain, necessitating further washing. In view of all these limitations and its strong action on protein, it is not widely used.

Lanthanum acetate

Lanthanum salts can also precipitate nucleic acid. In order to secure a good preservation of chromatin, lanthanum salts are added either in the fixative or after treatment with a recognised fixing fluid. For cytochemical studies, its use is rather limited because it often affects enzyme activity (Opie and Lavin, 1946).

Uranium nitrate

Often in fixing mixtures potassium dichromate is replaced by uranium salts, but it is of extremely limited application. It is preferable to use it as an additional component of the fixing fluid rather than as a substituted metallic compound.

Iridium chloride

If acidified with dilute acetic acid, iridium chloride has been found to be very effective in the fixation of *Triton* sp. However, it is not effective elsewhere, due to its low capacity of nucleo-protein precipitation.

FIXING MIXTURES

Of the different types of mixtures employed for chromosome studies two categories, at least, can be formulated. In one of these, both metallic and non-metallic fluids have been included, whereas the other is constituted purely of non-metallic fixing fluids. The majority of the fixatives, the principal ones of which are listed below, fall under the first category.

Flemming's mixture and other related fluids

The science of chromosome study owes a good deal to Walther Flemming who introduced the term 'chromatin' in 1879. The formula of his fixing fluid was published in 1882, and even now his recipe is considered as one of the few excellent ones so far proposed for chromosome study.

The principal constituents of Flemming's fluid are osmic acid, chromic

acid and acetic acid. Use of the first two fluids for fixation was first made by Flesch in 1879. It remained for Flemming to point out that the use of acetic acid helps in bringing out nuclear details clearly and also accelerates chromosome staining. In 1882, Flemming published a weak formula, using an aqueous solution of chromic acid (0.25 per cent), osmic acid (0.1 per cent) and glacial acetic acid (0.1 per cent). The proportion of the acetic acid was, however, variable. In fact, in this mixture, the two constituents, acetic acid and chromic acid, are good precipitants for chromatin, whereas osmic acid helps to maintain life-like preservation of the cell. Protein precipitation is also aided by chromic acid. The presence of acetic acid inhibits chromic acid from causing heavy shrinkage. The cutting quality of this fixed material is also very satisfactory. The fixation period generally varies between 4 and 24 h. It is always preferable to keep the three constituents separate, and mix them just before use. If necessary, chromic acid and osmic acid can be mixed in required proportions and stored, and acetic acid should be added at the time of fixation.

The most serious drawback of this fluid lies in the unequal fixation of the tissue. It is not uniform in all cell layers. In multicellular, many-layered objects, such as in root tips, the outer peripheral layers are over-fixed due to rapid action of osmic acid and there is an intense blackening of the tissue. The middle layers show excellent fixation in which precipitation is very homogeneous, interkinetic nuclei being excellently preserved due to osmic acid. The other two constituents help in the good preservation of chromosomes in divisional figures. Due to satisfactory precipitation and the presence of heavy metals, the nuclear staining is intense in this region. The innermost segments, on the other hand, show only the effects of chromic acid and acetic acid due to their comparatively rapid entry, whereas osmic acid, because of its slow rate of penetration, does not show its effects at all except causing a blackening of this segment. In spite of this unevenness of fixation, it is widely recommended for chromosome preservation and staining of chromosomes and interkinetic nuclear details which are properly fixed. Weak Flemming is suitable for smaller objects, whereas for larger objects strong Flemming is desirable to secure better penetration. Fixation at a very low temperature often causes better preservation of nuclear details due to lessening of the effect of osmium tetroxide, but this practice has been discouraged by certain authors (Baker, 1966) who consider it improper to use a costly chemical like osmic acid in order to inactivate it at a particular temperature.

A number of fixing fluids was later proposed, based principally on the use of constituents of Flemming's fluid. Benda in 1902 used a modification of Flemming's fluid in which the proportion of acetic acid was much minimised, being reduced to 2–3 drops. In the experience of the authors, Flemming's mixture in plants holds good for meiotic chromosomes whereas for the study of chromosome morphology in mitosis, Benda's modification gives very satisfactory details. Strong acetic acid causes heavy swelling, obscuring chromosome details, an effect which is much minimised in the formulae recommended by Benda.

Young (1935) mentioned that fixation can be spread over a wider area if a little sodium chloride solution, which helps in solubility and penetration, is added in the Flemming's fluid for fixation in cold- and warm-blooded

animals. Meves (1908) observed that the action of chromic acid is accelerated by the addition of sodium chloride. Gatenby and Beams (1950) observed that sodium chloride causes disintegration of the solution and so it should be kept separately and mixed with osmic acid if its use is necessary.

La Cour (1931) evolved a series of formulae, in all of which the principal constituents are chromic acid, potassium dichromate, osmic acid, acetic acid and saponin. In the three mixtures, namely, 2BD, 2BE and 2BX, the relative proportions of the constituents vary: 2BD is recommended for all organisms in general, 2BE for plants only, whereas 2BX is meant for bulk fixation. In the case of tissues providing penetration difficulties, a pre-treatment in Carnoy's fluid has been recommended prior to fixation. The use of saponin is meant to increase surface activity, and Baker (1966) has further claimed that it prevents the fluid from becoming stable. The use of acetic acid shifts the pH of the medium to the acidic side, thus helping in the precipitating effect of potassium dichromate, which then behaves like chromic acid. The purpose of using both chromic acid and potassium dichromate seems to be obscure, and Baker has rightly pointed out that a strong solution of chromic acid would have served the purpose equally well. In the experience of the authors, La Cour's fluids are excellently suited for the study of meiotic chromosomes, but their efficacy is dubious for the study of chromosome morphology from somatic cells.

Champy (1913) also used chromic acid, potassium dichromate and osmic acid in his recommended fluid which is widely used for animal chromosomes, but the reason for using both potassium dichromate and chromic acid is not clear. It is possible that the dichromate's property of rendering the protein insoluble is taken advantage of in this fluid. Minouchi and Koller (referred to in Darlington and La Cour, 1960) have suggested modifications of Champy's fluid. In Minouchi's modification (1928), which is meant for animal chromosomes in general, all the constituents of Champy's fluid have been maintained and only the proportions have been altered. Koller's modification, meant for mammalian chromosomes in particular, does not involve the use of potassium dichromate at all; it therefore appears to be quite rational, especially in view of the properties of the fixing fluids so far known.

Other important modifications of Flemming's fluid were suggested by Johnson (referred to in Gatenby and Beams, 1950) and Hermann (1899). Johnson's modification involved the use of potassium dichromate, osmic acid, platinum chloride and acetic or formic acid. He also considered that acetic acid should be added just before use, the reduction of platinum and osmium being very rapid. The presence of three metallic compounds aids remarkably in the staining of chromatin.

In Hermann's modification (1899), on the other hand, chromic acid has been completely substituted by platinum chloride. Platinum also helps in the staining of chromatin with basic dyes, but is not suitable when staining of both cytoplasm and nucleus is desired, as it prevents cytoplasmic coloration and so acidic dyes do not adhere to the tissue: this modification is thus useful in order to obtain bright staining of chromosomes against comparatively colourless cytoplasm. Because of the presence of platinum, the background generally takes on a light yellowish orange colour and, against this, the chromosome staining with any basic dye appears sharp.

Taylor (1924) and Catcheside (1934) published, for plant chromosomes, different modifications of Flemming's fluid in which maltose was added to prevent clumping and to help spreading of the chromosomes. Carpenter and Nebel (1931) and Catcheside (1935) substituted osmium tetroxide by ruthenium tetroxide and uranium trioxide respectively.

Zenker's fluid

In the remainder of the fluids listed under the first category, formalin forms an invariable constituent except in the mixture recommended by Zenker as early as 1894. The principle of action was clarified later in the works of Zirkle (1928).

Navashin's fluid

Of all the other mixtures having both metallic and non-metallic constituents for chromosome work, Navashin's fixative is the most important.

The original formula of S. Navashin was published in 1912 (*Mem. Soc. Nat. Kiev.* as referred to in Gatenby and Beams, 1950) in which the principal reagents used were chromic acid, acetic acid and formalin. A number of modifications were later suggested by different authors for different types of materials (San Felice, 1918, modified by White, 1940, referred to in Darlington and La Cour, 1968; Navashin, M., 1925; Karpechenko, 1924, 1927; Webber, 1930; Randolph, 1935; Hill and Myers, 1945; Belling, as referred to in Gatenby and Beams, 1950). Of these, Navashin's modification is meant specially for root tips, Karpechenko's for pollen mother cells, Randolph's for plants in general and San Felice and White's for animal tissues. In all these modifications, the constituents remain the same but their proportions vary. The only precaution that is needed in fixation with Navashin's fluid is that chromic acid should never be kept mixed with formalin, for the simple reason that oxidisers are not to be kept with reducers. Even fixation with chromic acid and formalin together in a fluid is theoretically unsound, but as the penetration of these fluids is quite rapid, the fixation is nearly complete before the oxidation. Though recommended, it is therefore useless to keep the tissue in Navashin's fluid for more than 3–4 h. For smears, 1 h only is sufficient, whereas for blocks of tissue, as much as 3–4 h fixation may be needed. In the experience of the authors, Navashin's fluid, especially the modification of Belling, is excellently suited for the study of meiotic chromosomes of plants in general. San Felice's fluid holds good for animal chromosomes; for mitotic analysis, it is just adequate for chromosome counts, but not critical enough for the study of chromosome morphology in detail. Possibly the presence of strong acetic acid results in chromosomes being so much swollen that all the chromosomal details are obscured. Navashin's fluid can be considered as a modification of Flemming's, in which osmium tetroxide has been replaced by formalin. For both plants and animals Navashin's fluid or its modifications can be strongly recommended, especially where the purpose is to study the behaviour and gross morphology of chromosomes.

Bouin–Allen's fluid

The use of picric acid in cytological fixation was made by Bouin in 1897 (as referred to in Gatenby and Beams, 1950). In the original formula as presented by Bouin, picric acid, formalin and acetic acid were the constituents, and the fixative was principally used for animal materials, but later this original fluid did not find much application in chromosome work, because of the strong precipitating and shrinking action of picric acid. A number of modifications of this mixture were proposed, in all of which the effect of picric acid was much minimised through the use of other reagents. Of these, the most important mixtures are those of Allen (1916), Painter (1924, referred to in Darlington and La Cour, 1960, 1968) and other authors. A modification by Carothers (referred to in Gatenby and Beams, 1950) is specially meant for Orthopteran chromosomes. In both Allen and Painter's modifications, chromic acid and urea were added as special components. The former aided nucleoprotein precipitation and the latter was possibly supposed to secure the effect of osmotic pressure of fluid. Penetration in these fluids is very rapid, but the extent to which urea can help in adjusting the osmotic pressure, which is principally controlled by smaller ions, is not yet known.

Carnoy's fixative and other related mixtures

Makino (1932) recorded that for Amphibian chromosomes in general very good results can be secured if acetic acid is omitted from Flemming's fluid. The swelling due to acetic acid may prevent proper representation of chromosomes. He has further observed that the meiosis in eggs can, however, best be studied if a fixing mixture containing only a strong solution of mercuric chloride and very little acetic acid is used. Combinations with mercuric chloride have a wider use in animals as compared to those in plants.

Carnoy and Lebrun (1887), as well as Sansom (referred to in Gatenby and Beams, 1950), have employed mercuric chloride even in combination with chloroform, acetic acid and ethanol. Satisfactory results have been secured with ova of *Ascaris* within 30 s, but the combination of reagents is not rational and compatible, as precipitates of ethyl acetate appear within a short period. It is of very limited application. In the Susa fluid and its modification as made by Ludford (referred to in Gatenby and Beams, 1950), not only is mercuric chloride added to acetic acid and formalin, but trichloracetic acid also forms one of its constituents. Even though it has found application in vertebrate materials, it cannot be recommended for critical study as TCA under certain conditions may remove nucleic acid from chromosomes (Schneider, 1945). In the second category of fixatives come those which are constituted of entirely non-metallic fluids, and in all such instances acetic acid and ethanol are invariable constituents. In fact, acetic–alcohol mixture, the use of which was first introduced by Carnoy in 1886, is considered one of the most rapidly penetrating and quickly acting fixatives for chromosome study. In the same year, Carnoy introduced another formula in which chloroform was added to aid in rapid penetration of the fluid and to remove fatty substances from chromosomes, which helps to secure a clear background for

study. For the study of animal chromosomes, where fats remain associated with several organs, such as testes, etc., Carnoy's fluid is exceptionally useful. It has also been recommended for the study of nucleic acids in cytochemical procedures (Lillie, 1954; McManus and Mowry, 1960; Amano, 1962). In plants, the general practice is to use it as a pre-treatment agent in the fixation of flower buds (Kihara, 1927) though it has also been applied in root-tip fixation. Dipping for just 1 or 2 s in Carnoy's fluid followed by washing prior to fixation removes the secretory or excretory products from the surface, allowing an easy passage of the fixative to the chromosomes.

One limitation of Carnoy fixation, either with or without chloroform, is that the tissues fixed as such do not respond to many of the aqueous solutions of the basic dye unless some special mordanting for staining is employed. This difficulty in staining is principally due to the absence in the fluid of any metal which aids in basophilia of chromosomes. As such it may be necessary to mordant in chromic acid prior to staining the material. In any case, especially because of the rapid penetration, Carnoy's fluids are widely recommended for bulk fixation of animal tissue. However, prolonged fixation in Carnoy's fluid may cause extraction of DNA (Pearse, 1972), and as such, long duration treatment should be avoided.

Smith (1943) and La Cour (1944) not only modified the proportions of acetic acid and alcohols in their fluids but also added formalin as one of the constituents, Smith's fixative being specially meant for insects and La Cour's for blood smears. The addition of formalin helps to increase cell volume and secures chromosome spreading, but the hardening caused by formalin makes the tissue unsuitable for preparing smears. Moreover, the absence of any metallic fluid, in conjunction with the absence of formalin, renders staining difficult, thus limiting its application.

Another very widely used fixative, especially employed for somatic chromosomes of plants, is a mixture of 1 per cent chromic acid and 10 per cent formalin, devised by Lewitsky (1931). A number of modifications (Prokofieva, 1935) of this fluid was later published, depending on the type of tissue investigated. In general, the increase in the proportion of formalin helps to cause wide scattering of chromosomes, which is essential for the study of their morphology, and the constriction regions come out clearly. However, too much formalin may lead to a granulated appearance of chromosomes and a reduction of basophilia.

Chromic acid and formalin, being oxidiser and reducer respectively, are incompatible, but even then satisfactory results have been obtained in chromosome fixation because the period required for oxidation is more than the period needed for fixation. Massive objects or bulk materials cannot be fixed in this fluid as the period of fixation needed will be too long. Mitotic chromosomes of soft and small materials, such as thin root tips, respond well to chromic–formalin fixation.

Kahle (1908) as well as Telleyesniczky (1905) used all three constituents, namely, formalin, acetic acid and ethanol, for cytological studies. The former is widely recommended for animal material, the latter for the ovular tissues of higher plants. Though they may serve the purpose of chromosome counting, the absence of a good shrinking agent makes critical analysis of chromosomes difficult.

Immersion of plant tissue for fixation is facilitated by the addition of a

drop or two of liquid detergent to each 10 ml fixing solution (Miller and Colaiace, 1968). The use of a commercial bleaching agent, like Chlorox, Purex or Hy-Pro, mixed with concentrated HCl and 50 per cent ethanol (2:2:1), after soaking root tips in water, has been found to improve separation of orchid chromosomes (Freytag, 1964).

Table 3.1 Some common fixatives

Chemical	*Molecular weight*	pH *in fresh condition (Lassek and Lunetta, 1950)*	*Used alone or in mixture*	*Concentration commonly used*
Acetic acid	60.05	2.3 (5% aq.)	Both	100% and 45%. When used alone 10% soln. is effective
Acetic acid	60.05	2.3 (5% aq.)	Both	Also 60% alone for human chromosomes
Acetone	58	7.0 (abs.)	Mixture	100%
Chloroform	119.59	7.2 (abs.)	Mixture	100%
Chromic acid	100.01	1.2 (1% aq.)	Mixture	1 and 2%
Dioxane	88.11		Mixture	100%
Ethanol	46	8.4 (abs.)	Both	50–100%
Ether	74		Mixture	Absolute
Formaldehyde	30	3.4 (comm.)	Mixture	40%, 5%
Formic acid	46	2.0 (1% aq.)	Mixture	1%
Hydrochloric acid	36.5		Both	Normal
Isopropanol	60		Mixture	100%
Methanol	32		Mixture	100 and 95%
Mercuric chloride	272	3.0 (6.9%)	Mixture	—
N-butyl alcohol	74.12	6.2 (abs.)	Mixture	100%
Nitric acid	63		Mixture	10%
N-propyl alcohol	60	6.7 (abs.)	Mixture	100%
Osmic acid	255	6.1 (1% aq.)	Both	0.5–2%
Picric acid	229	1.3 (sat.)	Mixture	Sat.
Platinum chloride	518.08	2.5 (1% aq.)	Mixture	0.5–2%
Potassium dichromate	294	3.9 (3% aq.)	Mixture	2–7¼%
Propionic acid	74.08		Mixture	45 and 100%
Trichloracetic acid	163.40	1.2 (1%)	Both	—

Alcoholic

Carnoy's fluid (1886)

Glacial acetic acid	1 part
Absolute ethanol	3 parts

It is effective for all plant, animal and human materials both for squash and block preparations, the period of fixation varying from 15 min to 24 h in cold or at room temperature. The fluid should be washed out with 70 or 90 per cent ethanol. Difficult materials can be mordanted in ethanol: 1–3 per cent ferric ammonium sulphate (7 : 2.5) mixture for 3–12 h after fixation (Lesins,

1954). Certain Rhodophyceae are mordanted in aqueous 0.5–5 per cent ferric ammonium sulphate solution after fixation (Austin, 1959).

Modifications include mixtures in the proportions 1 : 1 (Von Beneden and Neyt, 1887) and 1:2. Zacharias (1888) added a few drops of osmic acid solution to acetic acid–ethanol (1 : 4) mixture. Burns and Yang (1961) fixed *Nicotiana* microspores in acetic acid–95 per cent ethanol mixture (3 : 2) for 15 min after dissolving the pollen grain walls. For electron microscopic studies, anthers can be fixed in a mixture of cadmium chloride and absolute ethanol for 30 min or in only 0.5 M $CdCl_2$ for 10 min followed by refixation in acetic–ethanol (1 : 3). A modification containing acetic acid, 96 per cent ethanol, concentrated HCl and distilled water (1 : 3 : 2 : 2) has been used for mosquito chromosomes after 30 s in Carnoy's fixative (Amirkhanian, 1968).

Carnoy's fluid II (1886)

Glacial acetic acid	1 part
Chloroform	3 parts
Absolute ethanol	6 parts

It is widely used for animal and human tissues and for flower buds. The period of treatment is from 15 min to 24 h in cold or in room temperature. Metzger and Leng (1955) modified it by saturating it with $HgCl_2$ for certain leguminous plants. Another modification, with ingredients in the proportion of 1 : 3 : 4 and 1 : 1 : 3 (Semmen's fluid), has been used in Compositae and other families (Turner, 1956). The fluids, mixed in equal proportions (1 : 1 : 1) have been used on certain Heteroptera.

Carnoy and Lebrun's Fluid (1887)

Glacial acetic acid	1 part
Chloroform	1 part
Absolute ethanol	1 part
Corrosive sublimate to saturation	

A modification by G. S. Sansom contains

Glacial acetic acid	1 part
Chloroform	6 parts
Absolute ethanol	13 parts
Corrosive sublimate to saturation	

The mixture is prepared just before use and is successful for insect ovum with shell and for certain vertebrate materials. It penetrates very rapidly, the period of fixation being from 10–30 min and is washed out with absolute ethanol.

Schaudinn's fluid

Absolute ethanol	1 part
Sublimate soln.	2 parts

If necessary 1–5 per cent glacial acetic acid may be added. It is a common fixative for Protozoa and is also used for higher organisms.

Chromo-nitric acid

(a) Original formula (Perenyi, 1882)

10% aq. nitric acid soln.	4 parts
Absolute ethanol	3 parts
0.5% aq. chromic acid soln.	3 parts

The period of fixation is 4–5 h, followed by washing in 70 per cent and absolute ethanol for 2–3 days.

(b) Modified formula (Perenyi, 1888)

20% aq. nitric acid soln.	3 parts
Absolute ethanol	4 parts
1% aq. chromic acid soln.	3 parts

The period of fixation is 20–30 min, followed by washing for 1 h each in 70 per cent and absolute ethanol. These fixatives are used in embryological studies and for segmenting eggs and their nuclei.

Propionic acid modification

Propionic acid substitutes acetic acid effectively in several mixtures:

(a)	Propionic acid	1 part
	95% ethanol	3 parts

The mixture has been used effectively on perithecia of Ascomycetes. The period of fixation is 24–36 h (Cutter, 1946). It can also be used on other plant tissues and should be washed out with 70 per cent ethanol.

(b)	Propionic acid	100 ml
	95% ethanol	100 ml
	Ferric hydroxide	0.4 g

To each 10 ml, a few drops of carmine are added. This fixative is very effective for plants with small chromosomes (Hyde and Gardella, 1953) and for potato cultivars (Marks, 1960).

(c)	Propionic acid	1 part
	Chloroform	1 part
	Absolute ethanol	2 parts

Newcomer (1952) found 12–24 h fixation in this fluid to be suitable for avian chromosomes. This mixture, in the proportion 1 : 4 : 3, has been used on different plants, e.g. species of *Plantago*.

Bradley fixative (modified): Chloroform, 4; ethanol, 3 and propionic acid, 1).

Iron acetate modification

(a)	Acetic acid	1 part
	Absolute ethanol	3 parts
	Iron acetate	A small quantity

It is suitable for anthers with small chromosomes. Period of fixation is 12 h followed by keeping 5–15 min in:

Saturated soln. of iron acetate in 45% acetic acid	3 parts
45% acetic acid	5 parts
1% aq. formaldehyde soln.	2 parts

The tissue is rinsed in 45 per cent acetic acid (Marks, 1952)

(b) 95% ethanol	3 parts
Acetic–carmine soln. with added iron acetate	1 part
A flake of rusted iron	

The period of fixation is 12–24 h followed by washing and storage in 95 per cent ethanol with iron flake for 5–10 days. The mixture is useful for flower buds of species of *Cucurbita* (McGoldrick, Bohn and Whitaker 1954).

Ethanol–ether mixture

Absolute ethanol	1 part
Pure ether	1 part

Fresh liquefied semen is fixed for 3 min in the mixture and air dried (Casarett, 1953).

Newcomer's fluid (1953)

Isopropyl alcohol	6 parts
Propionic acid	3 parts
Petroleum ether	1 part
Acetone	1 part
Dioxane	1 part

It can be applied to both plants and animals for smears or sections. It is a very stable fixative and can be used in combination with pre-treatment chemicals.

Lactic acid modification (Julien, 1958)

Glacial acetic acid	1 part
Absolute ethanol	6 parts
Lactic acid	1 part

It is effective in fixing perithecia of species of *Venturia*.

Formalin

Original Navashin's fluid (M. Navashin's modification of S. Navashin's fluid, 1925)

Solution A

Chromic anhydride	1.5 g
Glacial acetic acid	10 ml
Dist. water	90 ml

Solution B

40% aq. formaldehyde soln.	40 ml
Dist. water	60 ml

The two solutions, previously prepared, are mixed together in equal proportions immediately before use. The fixative is suitable for both block and squash preparations of flower buds and root tips. The period of fixation is 24 h, followed by washing in running water for 3 h. Diluted Navashin's (50 per cent) fluid has been used in some plants like *Gentiana* species.

The Svalöv modification

Solution A

Chromic anhydride	1 g
Glacial acetic acid	10 ml
Dist. water	85 ml

Solution B

40% aq. formaldehyde soln.	30 ml
95% ethanol	10 ml
Dist. water	55 ml

The application is the same as Navashin's fluid.

Randolph's (CRAF) modification (1935)

Solution A

Chromic anhydride	1 g
Glacial acetic acid	7 ml
Dist. water	92 ml

Solution B

40% aq. formaldehyde soln.	30 ml
Dist. water	70 ml

Its use is similar to Navashin's fluid; 70 per cent ethanol can be used in washing. The period of fixation varies from 10 min in partial vacuum (Bowden, 1949) to overnight.

Karpechenko's fluid (1924)

1% aq. chromic acid soln.	15 parts
Glacial acetic acid	1 part
16% aq. formaldehyde soln.	3 parts
Dist. water	17 parts

A later modification (1927) contains:

2% aq. chromic acid soln.	100 ml
20% acetic acid	67 ml
40% aq. formaldehyde soln.	11 ml
Dist. water	300 ml

The ingredients are mixed just before use. Its use is similar to Navashin's fluid.

Webber's fluid (1930)

Solution A

Chromic anhydride	1 g
Glacial acetic acid	10 ml
Dist. water	65 ml

Solution B

40% aq. formaldehyde soln.	40 ml
Dist. water	35 ml

Belling's modification

Solution A

Chromic anhydride	5 g
Glacial acetic acid	50 ml
Dist. water	320 ml

Solution B_1 (for prophase)

40% aq. formaldehyde soln.	20 ml
Dist. water	175 ml

Solution B_2 (for metaphase)

40% aq. formaldehyde soln.	100 ml
Dist. water	275 ml

Solution A is mixed with an equal quantity of B_1 or B_2 just before use. The fixation period is 3–12 h. The fixative is effective for studying meiosis in flower buds.

Hill and Myer's fluid (1945)

Solution A

Chromic anhydride	1 g
Propionic acid	15 ml
Dist. water	85 ml

Solution B

40% aq. formaldehyde soln.	30 ml
95% ethanol	10 ml
Dist. water	60 ml

Its use is similar to the use of original Navashin's fluid. It is effective in studying chromosomes of grasses.

Langlet's fluid (1948)

Solution A

Chromic anhydride	1 g
Glacial acetic acid	10 ml
Dist. water	8 ml

Solution B

40% aq. formaldehyde soln.	30 ml
95% ethanol	10 ml
Dist. water	130 ml

The solutions are mixed just before use in the proportion of 1A : 9B.

San Felice's fluid (1918)

1% aq. chromic acid soln.	16 ml
40% aq. formaldehyde soln.	8 ml
Glacial acetic acid	1 ml

The ingredients should be freshly mixed before use. The period of fixation varies from 3 h to overnight. Washing in running water is necessary after fixation. The fixative is very effective for block preparation of animal tissues.

Bouin's fixatives

	Original	*Allen's B.15*	*Painter's modification*	*Allen's P.F.A.3*	*B.3*	*Carother's fluid*
Sat. aq. picric acid	75 ml	75 ml	75 ml	75 ml	75 ml	75 ml
40% aq. formaldehyde soln.	25 ml	25 ml	25 ml	15 ml	15 ml	15 ml
Glacial acetic acid	5 ml	5 ml	10 ml	10 ml	10 ml	10 ml
Urea	—	2 g	2 g	1 g	1 g	1.5 g
Chromium trioxide anhydride	—	1.5 g	1.5 g	—	1 g	—

Picric acid is dissolved in distilled water and kept as a mixture with formalin and acetic acid. Just before use, the mixture is heated to 37 °C and chromic anhydride crystals added, stirred, and followed by urea. The tissue is now kept in the fluid at 37–39 °C and allowed to cool gradually. The period of fixation is 4–12 h. The material is then washed in repeated changes of 70 per cent ethanol until no more yellow colour is extracted. The fixative is chiefly applied to animal tissues.

Cleland added 1 g of chromic anhydride to freshly prepared Bouin's solution and substituted 1 g of maltose or lactose for the urea. This modification, followed by iron–haematoxylin staining, gave good results in Onagraceae. Carother's fluid is used specially for Orthopteran chromosomes. Painter's modification is effective on mammalian chromosomes, the period of fixation being $1\frac{1}{2}$–3 h. Washing is carried out successively through different grades of ethanol and aniline oil. Bouin–Allen's modification is useful for amphibian chromosomes.

Levitsky's fixatives

1% aq. chromic acid soln. (A)
10% aq. formaldehyde soln.(B)

They are mixed in different proportions just before use for different materials, such as, 3A : 2B, 4A : 1B, 1A : 1B, 1A : 2B, 1A : 3B and are effective in fixing root-tip chromosomes of plants. The period of fixation is 12–24 h in cold or at room temperature for block preparations and squashes. The root tips require at least 3 h washing in running water after fixation. Brain and ganglion tissues can also be fixed in these fluids (Prokofieva, 1935).

Prokofieva's fluid (1934)

5% aq. chromic acid soln.	1 part
50% formalin soln.	1 part

It has been used for studying Teleost chromosomes.

Kahle's fluid (1908)

Glacial acetic acid	2 ml
40% aq. formaldehyde soln.	12 ml
95% ethanol	30 ml
Dist. water	60 ml

It is effective for animal and human tissues, particularly eggs of insects.

Kahle–Smith's modification contains 95 per cent methanol (15 parts), 40 per cent aqueous formaldehyde (6 parts) and glacial acetic acid (2 parts).

La Cour's fluid (1944)

Glacial acetic acid	2 parts
40% aq. formaldehyde soln.	7 parts
Absolute methanol	100 parts
Dist. water	70 parts

The mixture is suitable for blood smears.

Formaldehyde–acetic ethanol and formaldehyde–propionic ethanol

Glacial acetic acid	1 part
40% aq. formaldehyde soln.	6 parts
Absolute ethanol	14 parts

It is applied especially to insect gonads before squashing in acetic–carmine or Feulgen solution. Propionic acid can be used to replace acetic acid in bulk fixation of ovules (Paolillo, 1960).

A propionic acid modification is:

40% aq. formaldehyde soln.	1 part
95% ethanol	15 parts
Propionic acid	2 parts

The period of fixation is 1–2 h and it can be applied to both plant and animal tissues (Morrison, Leak and Wilson, 1959).

Lillie's modification (1954):

Formalin	10 parts
Glacial acetic acid	5 parts
Absolute ethanol	85 parts

A mixture of 95 per cent ethanol 6 parts, glacial acetic acid, 2 parts and 40 per cent formaldehyde, 1 part, may be used successfully for human cell cultures on coverglass.

Susa mixtures

(a) Original Susa mixture of Heidenhain

Mercuric chloride	4.5 g
Sodium chloride	0.5 g
Trichloracetic acid	2 g
Glacial acetic acid	4 ml
40% aq. formaldehyde soln.	20 ml
Dist. water	80 ml

The period of fixation is 1–24 h followed by washing in 90 per cent ethanol. For preparing the mixture, dissolve mercuric chloride and sodium chloride in water and, just before use, add the remaining ingredients.

(b) Romeis 'Susa' fluid

5% trichloracetic acid	20 ml
40% aq. formaldehyde soln.	5 ml
Dist. water	25 ml
Saturate with mercuric chloride	

Period of fixation is 1–2 h for small tissues and up to 24 h for larger ones. The tissues are washed in 80 or 90 per cent ethanol. The fixative is very effective for amphibian larvae.

Smith's fluid (Referred to in Gatenby and Beams, 1950)

40% aq. formaldehyde soln.	5 ml
Glacial acetic acid	2.5 ml
7½% aq. potassium dichromate soln.	13 ml
Dist. water	80 ml

Chrome alum fixative (Ammerman, 1950)

C.P. chrome alum	3 g
40% aq. formaldehyde soln.	30 ml
Glacial acetic acid	2 ml
Dist. water	238 ml

This fixative is suitable for yolk-rich amphibian eggs, *Euglena* and insect larvae.

Battaglia's 5111 mixture (1957)

95% ethanol	5 parts
Chloroform	1 part
Glacial acetic acid	1 part
40% aq. formaldehyde soln.	1 part

The mixture has been used on both plant and animal tissues. For most plant materials, fixation for 5 min is sufficient.

Baker's mixture (1958, 1966)

Formalin	10 to 15 per cent
Calcium chloride	1 per cent

Osmic acid

Flemming's fixative (1882 and 1884)

(a) Strong Flemming

1% aq. chromic acid soln.	15 ml
Glacial acetic acid	1 ml or less
2% aq. osmic acid soln.	4 ml according to Baker (1950)

or

2% aq. chromic acid soln.	100 ml
2% aq. osmium tetroxide soln.	53 ml
10% aq. acetic acid soln.	133 ml according to Darlington and La Cour (1968)

(b) Medium Flemming

1% aq. chromic acid soln.	30 ml
5% aq. acetic acid soln.	25 ml
2% aq. osmic acid soln.	10 ml

(c) Weak Flemming

2% aq. chromic acid soln.	12.5 ml
Glacial acetic acid	0.1 ml
2% aq. osmic acid soln.	5 ml
Dist. water	83 ml

(d) Benda's modification (1902)

1% aq. chromic acid soln.	15 ml
2% aq. osmic acid soln.	4 ml
Glacial acetic acid	3 drops

Benda's fluid, diluted with an equal part of water, is useful for spermatogonial divisions of Teleosts (Makino, 1934).

(e) Hermann's modification

1% aq. platinic chloride soln.	15 ml
Glacial acetic acid	1 ml
2% aq. osmic acid soln.	2–4 ml

It is used also for embryonic gonads with reduced acetic acid.

Flemming's fixatives should always be mixed just before use. They are suitable for both plant and animal tissues. Strong Flemming is used for bulk fixation. The tissues are fixed from 1 h to overnight, depending on the size, and require washing in running water from 1 h to overnight after fixation. Fixation is more effectively carried out in cold (McClung, 1918).

Fixatives allied to Flemming's fluid

(a) Modified formula with NaCl

Solution A

1% aq. chromic acid soln.

Solution B

2% osmium tetroxide in
4% aq. sodium chloride soln.

The two solutions are mixed before use in the proportion 15A : 4B. For preparing B, osmium tetroxide crystals are first dissolved in water and then sodium chloride is added (Gatenby and Beams, 1950). Meves (1908) and Young (1935) had worked out this modification earlier, but as the solution with NaCl disintegrated, the present formula is more satisfactory.

(b) Hance's fluid (1917)

Flemming's strong fixative	100 ml
0.5% urea soln.	

The tissue is fixed at 4–5 °C for 24 h. It is suitable for mammalian chromosomes and also for embryonic divisions in birds.

(c) Oguma and Kihara's fluid (1923)

This is effective for human material. Thin slices of testes are fixed for 1 min in Carnoy's fluid II and then fixed in strong Flemming's solution for 24 h.

(d) Bonn's fluid

100% aq. chromic acid soln.	0.33 ml
10% aq. acetic acid soln.	3 ml
2% aq. osmic acid soln. in 2% chromic acid	0.62 ml
Dist. water	6.27 ml

(e) Newton and Darlington's fluid

1% aq. chromic acid soln.	60 ml
2% aq. osmic acid soln.	20 ml
10% aq. acetic acid soln.	25 ml

It is suitable for smears of plant anthers.

(f) Taylor's fluid (1924)

10% aq. chromic acid soln	0.2 ml
10% aq. acetic acid soln.	2 ml
2% osmic acid in 2% chromic acid	1.5 ml
Dist. water	8.3 ml
Maltose	0.15 g

(g) Catcheside's fluid

10% aq. chromic acid soln.	3 ml
10% aq. acetic acid soln.	2 ml
2% aq. osmic acid soln.	1.5 ml
Maltose	0.2 g
Dist. water	10 ml

It is used for p.m.c. smears with small chromosomes.

(h) Belar's modification (1929)

2% aq. osmic acid soln.	4 ml
1% aq. chromic acid soln.	15 ml
Glacial acetic acid	1–2 drops

It is satisfactory for smears.

Champy's fluid and allied fixatives

(a) Original Champy's fluid (1913)

2% aq. chromic acid soln.	20 ml
7·5% aq. potassium dichromate soln.	16 ml
2% aq. osmic acid soln.	22 ml
Dist. water	33 ml

(b) Minouchi's modification (1928)

2% aq. chromic acid soln.	5 ml
2% aq. potassium dichromate soln.	15 ml
2% aq. osmic acid soln.	6 ml

(c) Koller's modification (Referred to in Darlington and La Cour, 1968)

2% aq. chromic acid soln.	20 ml
2% aq. osmic acid soln.	10 ml
Dist. water	25 ml

In all these fluids, the ingredients are mixed freshly before use though the mixture has been found to keep for a few weeks. These mixtures have been used successfully on animal tissue, the last one on mammals. The periods of treatment and washing in water are 6–24 h. Original Champy's fluid works well on spermatocyte stages of Teleosts.

(d) Nakamura's mixture (1928)

2% aq. osmic acid soln.	3 parts
1.6% aq. chromic acid soln.	6 parts
6% aq. potassium dichromate soln.	4 parts

It is useful for reptilian chromosomes. The period of fixation is 24 h, followed by washing for the same period.

(e) Makino, Udagawa and Yamashina's fluid (1956)

0.75% aq. chromic acid soln.	8 ml
2% aq. osmic acid soln.	4 ml
3.5% aq. potassium dichromate soln.	8 ml
Urea	1 g

It is effective for Avian testes.

Mann's fluid (1894)

7% aq. mercuric chloride soln.	50 ml
2% aq. osmic acid soln.	25 ml
Dist. water	25 ml
Sodium chloride	0.75 g

The fluid is prepared freshly before use. It is effective in fixing animal tissues, the period of fixation varying from 15 min to 3 h depending on the size of the tissue. Washing in water is necessary after fixation.

La Cour's fixatives (1931)

	2BD (ml)	*2BE* (ml)	*2BX* (ml)
2% aq. chromic acid soln.	100	100	100
2% aq. potassium dichromate soln.	100	100	100
2% aq. osmic acid soln.	60	32	120
10% aq. acetic acid soln.	30	12	60
1% aq. saponin soln.	20	10	10
Dist. water	210	90	50

2 BD is a good general fixative, 2 BE is recommended for plant tissues and 2 BX for bulk fixation. The usual period of fixation is 24 h in cold or in room temperature followed by washing in running water for 3–12 h. The ingredients are mixed just before use. For studying *Hordeum* chromosomes, Morrison, Leak and Wilson (1959) kept roots in a mixture of 1 per cent chromic acid and 2 BD (1 : 1) for 12 h after fixation in 2 BD.

Osmic, dichromate and platinic mixtures

2% aq. potassium dichromate soln.	70 ml
2% aq. osmic acid soln.	10 ml
1% aq. platinum chloride soln.	15 ml
Acetic or formic acid	5 ml

The acetic or formic acid should be added just before use. Period of fixation is 12 h followed by washing in running water.

Smith's fluid (1935)

	S_1	S_2
1% aq. chromic acid soln.	100 ml	75 ml
2% aq. osmic acid soln.	35 ml	25 ml
5% aq. acetic acid soln.	25 ml	12.5 ml
Potassium dichromate	0.5 g	1 g
Saponin	0.05 g	0.05 g
Dist. water	50 ml	46 ml

S_1 is suitable for early prophase and S_2 for diakinesis and metaphase stages in p.m.c.s. Substitutes for osmic acid, such as ruthenium tetroxide or uranium trioxide, have also been used.

Miscellaneous fixing mixtures

Chromo-acetic acid (Flemming, 1882)

Anhydrous chromium trioxide	0.25 g
Glacial acetic acid	0.1 ml
Dist. water	100 ml

The period of fixation is 12 h followed by washing in running water. Though originally recommended for achromatic elements of karyokinesis by Flemming, this mixture is also useful for studying nuclei.

Chromo-formic acid (Rabl, 1884)

0.33% aq. chromic acid soln.	200 ml
Conc. formic acid	4–5 drops

The mixture should be freshly prepared. Period of fixation is 12–24 h, followed by washing in water.

Copper chloride and acetate mixture

Camphor water (not saturated)	75 ml
Dist. water	75 ml
Glacial acetic acid	1 ml
Copper acetate	0.30 g
Copper chloride	0.30 g
Optional: Osmium tetroxide	

The fixative is very moderate and useful for objects studied in as fresh a state as possible. Objects fixed stain easily in methyl green.

Davidson's fixatives (1949)

(a) Tertiary butanol	3 parts
Absolute ethanol	1 part

and

(b) Tertiary butanol	3 parts
Ethyl phosphate	1 part

They are found to be suitable for vaginal smears.

Kollman's fixative (1885)

Potassium dichromate	5 g
Chromium trioxide	2 g
Conc. nitric acid	2 ml
Dist. water	100 ml

The period of fixation is 12 h followed by washing in water for an equal period. The fixative has been used on animal ova.

Makino's fluid (1934)

Glacial acetic acid	1 ml
Dist. water	100 ml
Mercuric chloride	saturation

This mixture is used for meiotic divisions in mature eggs. The gelatinous envelope is removed. The eggs are fixed for 10–15 min and washed in 70 per cent ethanol.

Picric acid–sulphosalicylic acid mixture solution

5% aq. sulphosalicylic acid soln.	1 part
Sat. aq. picric acid soln.	1 part

This fixative is used for fixing mammalian tissues for block preparation. The period of fixation is 48 h at 25 °C followed by washing in distilled water for 30 min. The tissues are then stained in Feulgen's solution before dehydration (Lhotka and Davenport, 1947).

Telleyesniczky's fluid (1889)

Glacial acetic acid	5 ml
Dist. water	100 ml
Potassium dichromate	3 g

Period of fixation is 12–24 h followed by washing in running water.

Zenker's fluid (1894) and Lillie (1954)

Glacial acetic acid	5 ml
Dist. water	100 ml
Mercuric chloride	5 g
Potassium dichromate	2.5 g
Optional: Sodium sulphate	1 g

To the rest of the fluid, glacial acetic acid is added immediately before use. The pH is 2.3. Fixation for several hours to overnight is followed by washing for 24 h in running water and treatment with 0.5 per cent iodine in 70 per cent ethanol to remove the mercury precipitate.

In a modification of Zenker's fluid for vertebrate material acetic acid can be replaced by 5 ml 40 per cent aqueous formaldehyde solution (Helly's fluid).

Picric acid–Parker's medium TC199

This is used for 24 h for human spermatocytes at pachytene (Annéren *et al.*, 1969).

Dry preservation and dried out fixations

(1) Occasionally the fixative evaporates from the phials and leaves the fixed tissue dry with a crust of residues. If the tissue has been fixed in media containing chromic acid or osmic acid, it can be restored by washing for some days in either 10 per cent ethanol or 10 per cent formalin, or by washing the residue away with strong sulphuric acid, washing in water for some hours and then treating as usual.

(2) Dry preservation of plant materials for transport has been suggested by Vaarama (1950). The objects are fixed, washed and stored in 70 per cent ethanol as usual. After 1 h in 70 per cent ethanol (at least three changes), they are dried at room temperature on blotting paper. According to him, they can be kept in this condition for a long period. For use later, the materials are soaked in 10 per cent ethanol for one to several days, treated in 50 per cent ethanol for 3 h and then the usual process is followed for embedding in paraffin and staining by iodine–crystal violet or Feulgen. Dried material fixed in acetic–ethanol mixture (1 : 3) has not turned out to be suitable for squash preparations due to the fragility of chromosomes. Squash preparations can be attempted without applying any pressure, as otherwise the chromosomes undergo fragmentation.

Processing

After suitable fixation, the tissue is processed for further study. Different schedules are followed for block and smear preparations.

BLOCK PREPARATION AND MICROTOMY

In order to study materials which cannot be squashed or smeared, they have to be dehydrated where necessary and embedded in a suitable medium. By embedding, small or delicate objects can be surrounded with some plastic substance which supports it on all sides and allows sections of the material to be cut without distortion. It is also useful for showing the arrangement of cells in a tissue and the sequence of the stages of meiosis in a testis or an anther, or mitotic division in the somatic cells. The embedding material not only fills each cell and interstice, but it also ensures that the position of the minutest detail of structure is retained.

The procedure entails the following operations: washing, dehydration, clearing, infiltration and embedding, microtome-section cutting, and removal of embedding material.

Washing

Except in special cases, the tissue is thoroughly washed to remove all traces of fixing chemical. Different periods of washing in running water, from 1 h to overnight, are employed, depending on the nature and the thickness of the tissue and the fixing fluid used.

Comparatively hard tissue, like flower-buds, root tips or bulk masses of animal tissue, are put into perforated corked porcelain thimbles under running water. If the tissue is very small or delicate, it is kept in the original tube. The fixing fluid is drained off and the tissue is washed in successive changes of warm (44 °C) water at half-hourly intervals.

Alcoholic fixatives should be washed out with alcohols of approximately the same percentage as that of the original solution. Reagents containing picric acid should always be washed out with ethanol and never with water unless there is another constituent present in the fluid which fixes chromatin indissolubly.

In some cases, however, long washing in water is unnecessary. Randolph (1935) and later Upcott and La Cour (1936) omitted washing altogether in studying root tip chromosomes. They transferred the root tips directly from the fixative to the dehydrating agent, 70 per cent ethanol.

Dehydration

Since the embedding material is usually immiscible with water and aqueous solutions, it is necessary to dehydrate the tissues before they can be embedded. Tissues should not be transferred directly from water or aqueous solution to the undiluted dehydrating agent because an unequal shrinkage and distortion of the tissue are caused. The tissue should be passed through a series of solutions, each containing a mixture of the dehydrating agent and water, with the concentration of the former increasing gradually, on to the pure agent.

The most suitable and economical dehydrating agent is ethanol. It also has a hardening effect on the tissue and the schedules are usually so arranged as to utilise both dehydration and hardening effects. The tissue is generally passed through successive grades containing 30, 50, 70, 80, 90, 95 per cent and absolute ethanol, the period of treatment being variable, depending upon the nature and thickness of the specimen. For tissue of the size generally used for chromosome study, 1 h in each is quite long enough, while for plant tissue, overnight treatment in each of 70 per cent and absolute ethanol is found to be most effective. The tissue can be stored in 70 per cent ethanol, if necessary. The different ethanol grades can be prepared from rectified spirit (approx. 96 per cent ethanol) as it is cheaper than absolute ethanol; Table 4.1 gives the relative proportions of rectified spirit and distilled water required to prepare different concentrations.

Variations of the ethanol-dehydration schedule can be made, depending on the nature of the tissue. The entire process can be speeded up for thin and

Table 4.1 Preparation of ethanol of required concentration using rectified spirit (approx. 96 per cent)

Volume of rectified spirit taken	*Volume of water used*	*Ethanol concentration obtained, %*
31.2	68.8	30
52.1	47.9	50
62.5	37.5	60
72.9	27.1	70
83.3	16.7	80
93.5	6.5	90

delicate tissue, and some workers, instead of passing the tissue through different grades, prefer to increase the concentration of the medium containing the tissue gradually by adding drops of strong ethanol at fixed intervals.

The disadvantages of using ethanol as a dehydrating agent are: (a) the schedule is time-consuming, (b) if the fixed schedule is not suited to the tissue, excessive hardening and shrinkage of the tissue result, and (c) as

ethanol does not mix with paraffin or celloidin, an intermediate 'clearing' agent is needed, which unduly lengthens the process.

Several alternative dehydrating agents have been used from time to time, some of which are miscible with the embedding material and so eliminate the use of the clearing agent. The most important of these chemicals are given below.

Tertiary butanol

This was used by Johansen (1940), who claimed that it was the least drastic of all dehydrating agents. He transferred the tissue, which had been dehydrated up to 30, 50 or 70 per cent ethanol, to a mixture of distilled water, ethanol and tertiary butanol, then passed it through a series of grades containing decreasing proportions of distilled water and ethanol and increasing proportions of butanol, till a mixture of butanol and ethanol in proportion 3 : 1 was obtained. Finally the tissue was given three changes in pure tertiary butanol (one overnight). According to Johansen, this treatment removes every trace of unbound water.

Dioxane (diethyl dioxide)

This mixes with water, ethanol and xylol, and dissolves balsam and paraffin wax, and can therefore be used as a substitute at any stage of the usual ethanol–xylol dehydrating and clearing schedule. Direct treatment is also possible. The material can be transferred directly from water to 60 per cent dioxane in distilled water, thence to 70 and 95 per cent and finally given at least two changes of pure dioxane: alternatively, the material can be transferred directly to pure dioxane and then given two changes. As no clearing is required, this can be followed immediately by embedding in paraffin wax. Dioxane was first used in microtomy by Graupner and Weisberger (1933). Later, La Cour (1937), Maheshwari (1939) and Johansen (1940) also used it. Baird (1936) used it effectively in animal tissues.

Though dioxane is very effective in short-term schedules, particularly for animal tissue, it should be used very cautiously as it has a markedly toxic and cumulative action and is an injurious substance which should be handled with extreme care. It is also non-specific in its action, and in addition is heavier than melted paraffin and therefore difficult to remove from tissue during infiltration.

n-Butanol

It can be used in both plant and animal materials (Zirkle, 1930; Margolena, 1932; Stiles, 1934; Randolph, 1935). The material can be transferred, after partial dehydration in a low concentration of ethanol, to a mixture of ethanol and butanol, with successive changes in mixtures containing increasing proportions of *n*-butanol, followed by changes in *n*-butanol alone, and kept overnight. This chemical, however, is not as satisfactory as ethanol. Pure chloroform causes brighter staining but more distortion that butanol (Rawlins and Takahashi, 1947).

Iso- and normal propanols

These can also be used effectively as substitutes for ethanol. The schedule followed is similar (Bradbury, 1931). Hauser (1953) suggested the use of

isopropanol for dehydration, removal of paraffin and clearing before mounting in balsam. A schedule for infiltration includes treatment in 60 per cent, followed by three changes in 99 per cent isopropanol and two changes in molten paraffin (Doxtader, 1948). Reeve (1954) outlined two methods for dehydration:

(1) through primary dehydration by glycerol;
(2) through isopropanol alone—60, 85 and 99 per cent. Tissues are placed over solid paraffin in a phial and heated to 56–58 °C.

Ethylene glycol

As 'Cellosolve' glycol monoethyl ether, ethylene glycol was used as a dehydrating agent by Frost (1935) and Thorp (1936). It is, however, expensive and inflammable, and rapidly absorbs water from the air.

Other chemicals

Other chemicals have also been used as combined dehydrating and clearing agents, like amyl alcohol (Hollande, 1918) and methylal–methylene dimethyl ether (Defrenoy, 1935, Banny and Clark, 1949), followed by paraffin oil.

Dehydration with alcohols is carried out in corked or glass-stoppered phials or in shallow dishes with ground glass tops. Care must be taken not to keep the liquids exposed to moisture in the air. In special cases, dry erythrosine dye can be added in the last tertiary butanol solution in Johansen's (1940) method. The tissue is stained red superficially and can be demarcated during embedding in paraffin wax. For very small materials (Madge, 1936), eosin can be added to the 70 per cent ethanol or fuchsin in the final stages of the ethanol-chloroform clearing process to render the tissue conspicuous.

Glycerol

This is found to cause less distortion than ethanol; 95 per cent ethanol removes some glycerol, sets the protoplasm and improves the staining (Rawlins and Takahashi, 1947).

Clearing

This step is required only when paraffin is the embedding material. For celloidin-embedding, no separate clearing is required, as clearing is done during dehydration itself.

Since paraffin does not mix with many dehydrating agents, an intermediate medium which is miscible with both the dehydrating agent and paraffin is generally necessary, this medium performing the function of ridding the tissue of the dehydrating agent. Most of these reagents render the tissues translucent, as their refractive indices are close to that of the proteins of the tissue and rays of light can pass through without refraction; therefore they are also called 'clearing' agents and the process 'clearing the tissue'. The term is, however, a misnomer, as it suggests that the tissue needs 'clearing', while it is not so. Apàthy (1912) used instead the term 'ante-medium' for those intermediaries, which is probably preferable.

The ideal antemedium should have rapid penetrating power and should mix equally well with both the dehydrating and embedding agents. An immediate transfer from the pure dehydrating agent to the pure antemedium may cause shrinkage or distortion of the tissue and so mixtures of the two fluids should be used in varying proportions before transfer to pure antemedium. The most satisfactory and most widely used antemedium is chloroform ($CHCl_3$). The tissue is usually passed, after dehydration in ethanol, through a series of ethanol–chloroform grades, 3 : 1, 1 : 1 and 1 : 3, being kept for 1 h, or more if necessary, in each, the period of treatment depending on the thickness of the tissue. Finally it is transferred to pure chloroform. Chloroform is an excellent de-alcoholising agent and does not render the tissue brittle within the scheduled period of treatment. The only drawback is that it is too volatile and all phials should be kept tightly corked.

Another effective clearing agent is benzene (C_6H_6). It can be used in a series of grades in combination with the dehydrating agent similar to chloroform.

Xylol is also used extensively, but has a tendency to shrink and harden the tissue (Romeis, 1928; Tarkhan, 1931). Amylacetate has been used for tissue containing yolk (Barron, 1934). Terpineol, toluol and methyl benzoate have also been used at different times (Wetzel, 1931).

Various organic oils, like Bergamot, cedarwood, clove and aniline oils have also been used as antemedia, and of these, cedarwood oil and oil of Bergamot have no hardening effect and can clear bulkier pieces of tissue better than most other reagents. The time of reaction in different grades has to be much longer with these oils than with more volatile liquids. With cedarwood oil, 2–3 h of treatment in each grade is quite enough. The only limitation of these two oils is that they are not good solvents for paraffin and are, therefore, not easily replaced from the tissue by paraffin.

Infiltration and embedding

As mentioned before, embedding methods are employed to surround small and delicate objects with some plastic substance that will support them without injury while sections are being cut (Firminger, 1950; Hale, 1952; Kuhn and Lutz, 1958). Two major methods for embedding are used in the study of chromosomes: the paraffin method and the celloidin or collodion method. A modification is the 'double' embedding method. If, however, the material is to be cut in a quite fresh condition, then the frozen sectioning technique can be employed (*see* page 78).

Paraffin method

This method is the one most extensively used for the study of chromosomes. It has several advantages over the others, such as: (a) it is quite easy and rapid; (b) materials embedded in paraffin can be kept for an indefinite period; (c) very thin serial sections can be obtained by the process; and (d) paraffin mixes easily with most antemedia. As the embedding mass is removed before staining, a wider selection of stains can be used. The chief drawback of paraffin embedding is that, in spite of all precautions, the lengthy procedure

of dehydration, clearing and embedding in molten paraffin causes some amount of shrinkage and distortion, a drawback which also applies to the celloidin method.

The paraffin waxes generally used for embedding have melting points ranging from 46 to 60 °C, depending on the atmospheric temperature: very rarely are waxes with lower or higher melting point used. This material was first used for embedding by Klebs (1869) and later revived by Bowene (1882).

In general, the paraffin method involves three steps.

The *first step* of this process is the saturation with an antemedium, which is also a solvent of paraffin. This step was considered under the heading 'Clearing' (*see* page 74).

The *second step* is the gradual replacement of this solvent by paraffin, this process being called 'infiltration'.

Earlier workers (Apàthy, 1912) transferred the tissue directly from the antemedium to the melted paraffin, but this, however, hardens the tissue, so a gradual increase in the paraffin content, before adding molten paraffin, is necessary.

The most commonly used schedule is to dehydrate the tissue by ethanol and then clear it by passing it through ethanol–chloroform grades, until finally pure chloroform is reached. The tissue is kept in pure chloroform for 10–30 min, and then small chips of paraffin wax, of a melting point lower than the one desired for embedding, are added to the chloroform containing the tissue. The tube with the tissue and the chloroform with paraffin is kept at 35 °C for periods ranging from 2 h to overnight, depending on the nature and thickness of the tissue. Later, the tube is transferred to 45 °C, where it may be kept overnight. It can also be stored in this temperature for an indefinite period, as the temperature is much below the melting point of the paraffin and too low to harm tissues fixed for studying their chemical nature.

The tissue is finally transferred to a hot bath maintained between 55 and 60 °C, at the same or higher temperature as the melting point of the embedding paraffin. As the paraffin–chloroform mixture melts, it is changed immediately with molten embedding paraffin. Two more successive changes are given with molten embedding paraffin at intervals of 15–30 min, the final change in molten paraffin being given only when no trace of the smell of chloroform is left.

This gradual change from a paraffin wax of low melting point to one of high melting point has been criticised by some workers but it has been found to be very effective in the authors' laboratory. An alternative method is gradually to warm, on a hot bath, the chloroform containing the tissue up to the melting point of the paraffin employed and, during warming, to add by degrees small pieces of paraffin to the chloroform. As soon as the bubbles of the tissue cease, the addition of paraffin may be stopped. This process, being a gradual one, minimises the danger of shrinkage, but cannot be recommended for tissues which are to be treated for chemical study.

Numerous alternative infiltration techniques exist to suit the different dehydrating and clearing schedules; and some are mentioned below.

In Johansen's (1940) technique of dehydration with tertiary butanol, described previously, the tissue is transferred from pure butanol to a mixture of paraffin oil and tertiary butanol (1 : 1) and is kept for 1 h. A container is filled three-quarters full with melted Parowax (Standard Oil Company),

the wax being allowed to just solidify, and the material is placed on the top of the Parowax, covered with the butanol–paraffin mixture and placed in an oven at a temperature close to the melting point of Parowax. The material is gradually infiltrated and slowly sinks through the wax until it reaches the bottom. After 1 h the entire mixture is drained off and replaced by pure molten Parowax. The process is repeated twice and a final replacement is given with a rubber Parowax mixture or a paraffin wax of the required melting point. Care should be taken to see that: (a) the original Parowax is solidified but not allowed to get cold, as otherwise the glass vial might crack; (b) the temperature of the oven be such that the wax does not melt too quickly; (c) the oven be well ventilated so that the evaporating alcohol is blown away; and (d) before giving the final change in Parowax there should be no discernible odour of butanol.

The time of infiltration varies with the thickness of the tissue.

Either technique can be followed in dehydration and infiltration with other dehydrating and clearing agents, such as xylol, normal or secondary butanol or an essential oil. Another method of infiltration is to carve a small block of paraffin wax into the form of a long, narrow cone and place it in the container with the pointed end downwards, touching the bottom. It will sink slowly into the antemedium as it dissolves. An alternative method is to cut coarse wire gauze into square pieces, slightly larger in size than the diameter of the container used. The sides of the gauze are bent and the entire gauze is fitted into the bottle so that it forms a shelf, supported by the bent ends. Shavings of paraffin are placed on the shelf and, on dissolving, the paraffin covers the material under it.

The further steps of both these methods, regarding the replacement of the solvent by paraffin, are similar to those of the widely used chloroform–paraffin schedule, discussed previously (*see* page 75).

With dioxane as dehydrating agent, little chips of Parowax are added gradually to the dehydrated material, contained in pure dioxane. The mixture is kept in a warm bath till dioxane, which is not a good paraffin solvent, is saturated with Parowax. The later steps are similar to chloroform–paraffin infiltration.

Acetone can be used as a substitute for ethanol in dehydration, and clearing can be done through acetone–chloroform grades.

The *third step* is *embedding*, after the complete infiltration of the tissue with paraffin. This includes pouring the molten paraffin with the tissue into a suitable receptacle, arranging the tissue in a proper manner and rapidly cooling the paraffin with the material.

For infiltration and embedding in celloidin method, the following procedure is adopted.

The tissue is transferred to a mixture of absolute ethanol and ether (1 : 1) and kept overnight. A hole of a suitable size is made in a piece of junket to hold a part of the tissue and both the tissue and junket are transferred to 2 per cent celloidin solution in a wide-mouthed jar and kept overnight.

In the next step, either of two methods can be employed; with the celloidin used cold or hot.

(1) In the first method, the piece of junket is transferred to the wide-mouthed jar containing 4 per cent celloidin solution with grooved side upward,

the tissue being fitted into the hole or groove. The junket with the tissue is later transferred through 6 and 8 per cent solutions to 10 per cent celloidin solution. The time of immersion in each concentration depends on the nature of the material and may vary from one to many days. The glass container is kept undisturbed away from sunlight till the celloidin solution forms a gel. The entire container is covered first with the glass cover and then with the bell jar.

(2) In the second method, the bottle with the material in 2 per cent celloidin solution is corked very firmly and placed at a temperature between 45 and 55 C. The changes in different concentrations are given at intervals of 24 h. The bottle is always cooled before opening.

After 10 per cent solution is reached, the gel is allowed to set and helped to solidify further by evaporation or by adding small chips of dry celloidin.

In section cutting, rocking microtome for celloidin sections and rotary microtome for paraffin sections are recommended (Melnyk, 1961; Morris, 1965; Wachtel, Grettner and Ornstein, 1966; Collins, 1969). For fixation and mounting sections on slides, Mayer's adhesive is most commonly used (Mayer, 1883; Baker, 1933, 1943) but several other methods are also available (Cove and Schoenfle, 1946; Lewis, 1945; Giovacchini, 1958; Weaver, 1955).

A modification was devised for fixing the section on a slide with Haupt's medium (Lewis, 1945). For obtaining serial sections, the celloidin block is marked with an ink composed of suspension of lamp black in 2 per cent celloidin in ether–ethanol (1 : 1) after each section is cut (Melton, 1956).

Other embedding media

The sections are cut according to the procedure followed for paraffin section. A high relative atmospheric humidity is found to interfere with microtome cutting of tissues embedded in polythene glycol wax. With increase in atmospheric temperature, the tolerance of relative humidity decreases (Hale, 1952). For fixing Carbowax sections to slides, a jelly, of 15 g gelatin, 55 ml distilled water, 50 ml glycerol and 0.5 g phenol, is used (Giovacchini, 1958).

Frozen section technique

The frozen section technique is based on the principle of freezing the tissue directly to harden it, and cutting sections while the tissue is frozen. This possibility was first explored by Raspail (1825) and later by Stilling (1842). The method has several advantages, namely: (a) it takes up much less time than the paraffin and celloidin methods; (b) since the tissue is not dehydrated, the cells retain a life-like appearance with little shrinking; and (c) the tissues can be sectioned, if necessary, without any fixation at all. However, there are also some drawbacks which prevent this technique from being universally applicable, and chief amongst these are that serial sections cannot be cut and that for loose tissues, there is no satisfactory process of holding them together before freezing.

Special models of microtome are available for cutting frozen sections. In older models, ether was used for freezing and the tissue was usually soaked for some hours in gum, dextrine or sugar solutions to prevent ice crystal forming. In later techniques, CO_2 jets are used on the microtome knife for

cooling. The sections are attached to the slide by means of their own fluid. A vibratory microtome for cutting sections of living roots has been used by Persidsky (1953).

The material can be cut fresh or after fixation, and any one of the usual fixatives can be used, the tissue being washed thoroughly. The material may be kept overnight in thick gum-arabic, if necessary, or this step can be omitted. When cells adhere very closely together, as in vertebrate liver, the most successful sections can be cut.

The piece of tissue is trimmed into a size within 3 × 3 cm and is placed on a little water on the microtome table freezer to freeze the tissue to the table, the temperature depending on the nature of the tissue. Tissues with compact cells should be frozen at about −10 to −15 °C while others can be cut at −20 to −30 °C. The knife is oriented with its edge close to the tissue at right angles, and the tap controlling the CO_2 cylinder is opened and closed several times until the tissue is congealed to the table and frozen right through. In order to regulate the freezing, only short jets of CO_2 should be allowed to escape at intervals on the material.

The tissue is left for a few minutes and then the knife is passed over it, till sections begin to cut. If the sections have fine cracks and are brittle or roll up it means that the tissue has been overfrozen and it should be allowed to stand and warm up before being cut again; but if, on the other hand, the sections are too soft and disintegrate or tear or fail to form, the tissue is underfrozen and must be exposed to further jets of CO_2.

As soon as the tissue is ready to be cut, sections should be taken very rapidly and allowed to accumulate in a mass on the knife, and they can then be transferred to a petri dish containing distilled water and their thickness tested. The loose sections can be lifted on clean slides and observed unstained under a cover-glass.

A freeze-drying apparatus devised with liquid nitrogen, permitted section cutting within 5 h after the fresh tissue was obtained (Stowell, 1951). White and Allen (1951) designed a microtome for cutting frozen sections, in which the knife moves across the tissue, in contrast to the sledge type in which the tissue is moved while the knife is stationary. Reiner (1953) described fixation of fresh tissues by undiluted and unbuffered formalin, combined with heating to 56–60 °C, preliminary to freezing and cutting on the 'warm' knife freezing microtome. Woods and Pollister (1955) used cold ethanol as a dehydrating agent after freezing in partially frozen isopentane, cooled with liquid nitrogen for drying frozen plant tissues. In a modification for obtaining thin sections from unfixed tissues for histochemical staining, a microtome with an apparatus for simultaneous cooling of the knife with the freezing stage is used. The sections are processed according to a particular schedule, mounted and dried in warm air (Wachstein and Meisel, 1953). If a cellulose tape is pressed against a paraffin or frozen tissue block just before cutting each section, sections as thin as 1 μm can be obtained. The method has been recommended for very large, hard or brittle specimens (Palmgren, 1954). For cutting frozen sections on a paraffin microtome (Pauly, 1956), the specimen is fixed on the object holder in a drop of water by freezing it in dry ice in a box. Chips of dry ice are wedged between the metal disc and the object clamp of the microtome during cutting.

These sections can also be processed in two ways: they may be attached

to slides by gelatin, or they may be stuck by their own coagulated juice to the slide.

Gelatin-coated slides are prepared by smearing them with a thin film of specially prepared gelatin (2 g of gelatin soaked in 100 ml of distilled water and heated to 50–60 °C) and the slides are dried in a warm dust-proof chamber. The section is lifted out of the water on a gelatin-coated slide. The section is then flattened out by pressing on it with a pad through a piece of wet cigarette paper, and the paper is peeled off. If not already fixed, the slide with the section is placed in a closed container with a plug of cotton wool soaked in formalin for 15–30 s. It is then kept overnight in 10 per cent formol saline before staining.

In a modification of this schedule, the frozen sections are soaked for 5 min or longer in a mixture of 1.5 per cent aqueous gelatin and 80 per cent ethanol (1 : 1), teased on to a slide and blotted with filter paper dampened in rectified spirit. The gelatin congeals, anchoring the section to the slide (Albrecht, 1954).

In the other method, the section is cut out on a dry clean cover-glass held in a pair of forceps just where the section is curling up during cutting. The cover-glass is gently removed with the section which thaws on it and is fixed immediately by exposing it to osmic or formalin vapour. It is then put in a fixing fluid.

Sections of ordinary mammalian tissues, after fixation, can safely be floated in distilled water, but sections of such tissues as mollusc ovotestis and mammalian testis tend to break up if floated and are best cut fresh and fixed dry directly on to slides. They can also be attached directly to gelatin-coated slides.

Removal of the embedding material

After cutting the sections and mounting them on slides, the next step is to remove the embedding material and gradually bring down the tissue to the medium in which the stain is dissolved, usually water. The steps followed are usually the reverse of the process leading to embedding through dehydration and infiltration and the schedules differ depending on the material used for embedding.

Sections embedded in paraffin

For removing paraffin wax from sections, the most effective chemical is xylol because it dissolves paraffin and also because it is cheap and not very volatile. After xylol, a mixture of xylol and absolute ethanol in equal proportions is usually used, followed by pure absolute ethanol and ethanol grades with decreasing percentage of ethanol to water.

All these chemicals are kept in covered wide-mouthed jars, labelled and arranged in a series. The slide is transferred carefully from one jar to the next so that the sections are not dislodged due to rough movement, the period of treatment in the chemicals depending upon the nature and the thickness of the tissue.

A typical grade of chemicals for removing paraffin with the times of treatment is,

2 jars of xylol, I and II; 30 min each
1 jar of xylol and absolute ethanol mixture (1 : 1); 30 min
1 jar of absolute ethanol; 15 min
1 jar of 95 per cent ethanol; 5 min
1 jar of 90 per cent ethanol; 5 min
1 jar of 80 per cent ethanol; 5 min
1 jar of 70 per cent ethanol; 5 min
1 jar of 50 per cent ethanol; 5 min
1 jar of 30 per cent ethanol; 5 min
Distilled water, 5 min

If necessary, the slides can be preserved for an indefinite period in 70 per cent ethanol. If bleaching is necessary for tissues fixed in heavy metallic fixatives containing osmium or platinum, the slides are transferred from 80 per cent ethanol to a jar containing hydrogen peroxide and 80 per cent ethanol mixed in equal proportions and kept overnight on a hot plate at 35 °C. The bleaching period can be prolonged if required. Afterwards the slides are passed through 70, 50 and 30 per cent ethanol and brought down to water.

For thin sections of animal tissue, the period taken in bringing the slides down to water can even be reduced to 10 min in xylol and 5 min in the subsequent grades.

Sections of woody tissues and those containing mucilage, fats, etc., usually get disengaged by the time the slide reaches water and float off, in spite of all precautions. The sections can be stained in a dye without staining celloidin, and the sections and slides can be covered with a thin coating of celloidin. The slides are transferred from the xylol–ethanol stage to a mixture of absolute ethanol and ether (1 : 1), to which enough celloidin solution has been added to make it about 1 per cent. They are kept in the mixture for 5–10 min and then allowed to dry in air till the celloidin is almost dry, forming a whitish film. They are next immersed in 70 per cent ethanol for 5 min to harden the celloidin and are then, as usual, brought down to water.

For softening paraffin-embedded tissues, several procedures are available. Dilute hydrofluoric acid, used alone and with glycerol and ethanol, softens plant materials embedded in paraffin. Tannins and phlobaphene compounds can then be removed by treating the sections for 12–48 h in a mixture of aqueous chromic acid, potassium dichromate and glacial acetic acid (Foster and Gifford, 1947). Exposure to a mixture of glacial acetic acid and 60 per cent ethanol (1 : 9 or 2 : 8) for 2–5 days also gives very good results (Gifford, 1950). Alcorn and Ark (1953) advocate soaking paraffin-embedded plant specimens, after exposing one side of the tissue in a mixture of glycerol, 10 ml; Dreft 1 g and water, 90 ml for 2–3 days at 37 C.

Sections embedded in celloidin

They are usually stained as such, without removal of the celloidin matrix, which does not interfere with staining. The slides with the sections or the individual sections themselves are brought down to water from 70 per cent ethanol and then stained. The matrix, if necessary, can be removed before final mounting in balsam. This method is described in Chapter 5.

SQUASH OR SMEAR PREPARATIONS

Within the last few years, the sectioning method of the tissue has been largely replaced by the smear or squash technique. This method has a great advantage in that the entire process is rapid and also much more suitable for critical observations. In properly prepared smears or squashes, one can carry out observation on separated single cells; moreover, the cell, being released of its compactness, undergoes much enlargement in volume, affording wider space for the chromosomes to become scattered. Owing to these advantages, it has more or less become the universal routine method in chromosome work. The only disadvantage of this method, when specially applied to somatic chromosomes, is that the individual cells, being released from one another, shift from their original site and the original topography is altered.

The terms 'smears' and 'squashes' are often loosely used, resulting in the worker often getting the impression that the two processes are identical, but, strictly speaking, they are not so.

In smears, the cells are directly spread over a slide prior to fixation, and no treatment is necessary to secure cell separation. Pollen mother cells from anthers are the most convenient objects for smears.

In squashes, on the other hand, special treatments are needed for dissolution of the pectic salts of the middle lamella so that separated individual cells can be obtained from a compact mass of cells, this treatment being carried out after fixation or even after staining. After passing through the required steps, the softened bulk material or small tissue can be neatly squashed on a slide by generally applying pressure or tapping with a needle over the cover glass. It is the best way to study mitotic behaviour of chromosomes of root tips.

The term 'smear' is commonly applied to cases where cells have been spread on the slides before fixation, while squashing, on the other hand, is used for the process performed after fixation or staining. Compared to this, the criterion of difference based on the treatment for cell separation as mentioned above seems to be more convenient and rational.

Smears

The general procedure for preparing smears of pollen mother cells is to squeeze out the fluid from the anther on to a dry slide (to ensure success, the slide should be moistened by breathing on it before smearing), spread it with the aid of a scalpel and immediately invert it in a smearing tray containing the fixative. The entire process should be rapidly executed and must not take more than 4–5 s. Quick handling is essential, as otherwise the fluid tends to dry up, resulting in chromosome clumping. The use of a scalpel aids in the addition of iron which acts as a mordant (*see* Chapter 5 for the stain).

In the case of very small anthers, they should be smeared complete. It is necessary, after fixation, to remove the anther debris with the aid of a needle, keeping only the pollen mother cells. For even smaller objects, such as flower buds of Amaranthaceae, Chenopodiaceae, etc., where it is difficult to take out the anthers from the young buds, the smear method should not be tried and

recourse should be made to sectioning. This is one of the limitations of the smearing procedure.

There are certain methods in which pollen mother cells can be smeared or squashed in a fluid which serves the double purpose of fixing and staining. The best example of such a procedure is Belling's (1926) *Iron–Acetic–Carmine Schedule*, when the anther is directly smeared in a drop of a solution containing carmine dissolved in acetic acid. The acetic-carmine method can be applied both in smears and squashes and it has been applied in plant and animal tissues after modifications, principally involving intensification of colour, which are discussed in Chapter 5.

For certain materials it may, however, be necessary to fix the flower buds in Farmer's fluid (acetic–ethanol, 1 : 3) prior to smearing in carmine. This is performed to secure cytoplasmic clearing and for fixation. Before staining, the material is kept in 45 per cent acetic acid for 15–30 min to cause swelling, counteracting the effect of ethanol and to soften the tissue.

Squashes

In squashes, the most important step is the softening of the tissue. The different schedules can be divided into two categories, namely, softening performed prior to staining, and softening, clearing and staining accomplished in the same fluid.

Within the first category are included the various types of chemical agents employed by different authors for this purpose, including enzymes.

Chemical agents

The most important agent needed for softening the tissue is dilute hydrochloric acid. In Feulgen staining (discussed in Chapter 5), this step is essential to secure Schiff's reaction for aldehydes. In addition to liberating aldehydes of sugar, normal hydrochloric acid at 58 °C serves two more important purposes, namely dissolution of pectic salts of the middle lamella, thus helping in cell separation (*see* Sharma and Bhattacharjee, 1952), and clearing of the cytoplasm. These two properties of hydrochloric acid can be advantageously employed as well in other squash schedules after fixation. If dilute hydrochloric acid (such as 10 per cent) is used, for best results, the treatment should be carried out in a slightly warm temperature, such as 58–60 °C for 4–5 min until softening, the acid being washed off either in 45 per cent acetic acid solution or water before staining.

Softening and maceration of the tissue can also be achieved during fixation by the use of a mixture of equal parts of 95 per cent ethanol and concentrated hydrochloric acid as the fixative. No warming is needed and even after 5 min treatment the tissue becomes fixed and softened at the same time. If necessary, hardening the tissue for 10 min in Carnoy's fluid after this treatment can also be carried out (Warmke, 1935). For rather hard materials, ethanol and hydrochloric acid mixed in the proportion of 3 : 1 is more effective. This acidified ethanol treatment is specially effective for materials with thick walls, such as pollen grains, leaves, etc., where slowly penetrating fluids are ineffective.

Sharma (1951) observed that the purposes of cytoplasm clearing and

softening of the tissue can even be achieved by trichloracetic acid. There are, however, two serious disadvantages in this: firstly, it reduces the stainability of the chromosomes, so a further mordanting in metallic acid may be necessary for intensification of colour (*see* Sharma, 1956); and secondly, acid hydrolysis may cause depolymerisation of DNA as well as a break in the nucleoprotein link if the treatment is prolonged, with a probability of causing loss of DNA from the chromosome, amounting to absolute loss of stainability. Acid treatment therefore, should be performed under strictly controlled conditions.

Maceration by chromic acid also can be carried out after fixation, especially with osmium-containing fluids, but this procedure is time consuming and may take at least 24 h to soften the tissue. Since a strong concentration of chromic acid may injure chromosome parts, prolonged treatment with a dilute solution (1 per cent) (Singleton, 1953; Day, Boone and Keith, 1956; Elliott, 1956) is generally preferred. For a critical study of chromosome morphology, this procedure is generally not recommended.

In addition to acids, other reagents may also bring about softening of the tissue. Hydrogen peroxide is used with a trace of sodium or lithium carbonate added, and the middle lamella is initially attacked. Satisfactory dissolution of the middle lamella has been obtained by using a mixture of saturated aqueous solution of ammonium oxalate and hydrogen peroxide mixed in equal proportions for a few minutes. Ford (referred to in Darlington and La Cour, 1960) has recommended it for meristematic tissue fixed in osmic acid. However, for comparatively stiff materials, this reagent is not suitable for softening. Alkali treatment, prior to squashing, was used by Tandler (1959) in plants. The tissue, fixed in acetic–ethanol (1 : 3), is brought to water, hardened in 10 per cent formalin for 4–6 h, treated in a 2 per cent NaOH for 12 h at 25–37 °C, washed, treated in 10 per cent acetic acid and stained by carmine or Feulgen squash method.

Enzyme treatments

The most reliable method of softening and clearing without causing injury to cellular parts is 'enzyme treatment'. Fabergé (1945) used *cytase*, together with other enzymes from the stomach extract of snails, *Helix pomatia*, for the purpose, and this method has been found to be very useful in a wide variety of plants, including fungi (McIntosh, 1954). The use of pectinase for dissolution of pectic salts of the middle lamella has been applied by McKay and Clarke (1946), Setterfield, Schreiber and Woodward (1954) as well as Chayen and Miles (1953), the latter authors using a 5 per cent solution in 1 per cent aqueous peptone for the purpose. This procedure is rather time-consuming and at least 2–5 h of treatment is necessary. Harris and Blackman (1954) treated Feulgen-stained roots in 2 per cent pectinase solution (pH 6.6) for 12 h, followed by a commercial pectin product 'Certo', and then suspended the cells by suction and expulsion through a pipette. The present authors have, however, noted that a 2 per cent aqueous solution of pectinase, if applied for half an hour at 37 C, results in considerable softening of plant materials (Sharma and Chatterjee, 1971). The limitations of the enzyme treatment (as pointed out previously) lie in the difficulty of securing a pure form of enzyme preparation. If it can be obtained, this is the most reliable method of cell separation. Treatment of anthers in 1 per cent clarase solution or an extract prepared by grinding the contents of flask cultures of certain fungi for 10 min

to several hours and squashing in acetic–carmine destroys some of the elasticity of the cytoplasm, so that on pressing, the chromosomes spread out (Emsweller and Stuart, 1944).

Of all the methods so far devised for cell separation and softening, treatment with dilute HCl, in spite of its limitations, is most commonly employed because temperature and period of treatment can be varied as necessary, and principally because of the low cost, easy availability and rapidity of the schedule.

In addition to the above-mentioned methods of softening, there are a number of schedules in which the softening is carried out together with staining. In this procedure the tissue is heated, after fixation, over a flame for a few seconds in a mixture of one of the acetic dyes and hydrochloric acid. The commonly used acetic solutions of dyes are acetic–orcein (La Cour, 1941), acetic–lacmoid (Darlington and La Cour, 1960) and acetic–carmine (*see* Chapter 5). Normal hydrochloric acid is mixed with a 2 or 1 per cent solution of the acetic–dye, usually in the proportion of nine parts of dye to one part of acid. The proportion of acid may be increased if the tissue proves difficult in squashing, the material then being directly squashed under a cover-slip in the mounting medium which is either 45 per cent acetic acid solution or 1 per cent solution of the dye dissolved in 45 per cent acetic acid solution (*see* Chapter 6). This method, though suitable for somatic tissues of plants, may be too drastic for extremely soft animal tissues which may undergo dissolution. It has, however, been observed that as acetic–carmine contains acetic acid as one of its components, mere heating (Markarian, 1957) in acetic–carmine may serve the purpose even for comparatively soft plant tissues.

Summarising the different aspects of smearing and squashing, the situation is as follows. Smearing is a comparatively easier schedule than squashing and should be performed prior to fixing only on cells lying in a fluid medium, such as pollen mother cells. Squashing, on the other hand, involves different steps, such as pre-treatment, fixation and softening. Pre-treatment can be performed with any of the agents mentioned in Chapter 2. Softening can be carried out either by acid, alkali or enzyme treatment after fixation but prior to staining in most cases. In a number of schedules, staining and softening are carried out in the same fluid and following staining, the materials are either first teased with the needle in the mounting medium prior to mounting or mounted directly in the medium under the cover-slip. Final squashing is performed by applying pressure over the cover-slip on a blotting paper before sealing for observation.

The methods of pre-treatment as mentioned above have mostly been devised for plants, though these have been tried in animals as well. Animal materials for chromosome studies provide less difficulty in squashing because of the soft nature of the tissue, and the absence of a cellulose wall in meiotic material.

In order to study meiotic material of animal tissues, such as insects, the testis is generally dissected out in normal saline solution, as dissection in the body fluid itself is difficult to perform. The fats should be removed and the material can be directly squashed in acetic–carmine solution or fixed in Carnoy's fluid before squashing. For permanent smear preparations, spreading on the slide and inverting it in the fixing fluid should be done as for plants;

other staining methods too can be applied as for plants. For avian and reptilian testes, the tissues are generally fixed directly in the fixative without going through normal saline solution. In a method devised for amphibia, 0.5 ml of a mixture of 60 mg of desiccated mammalian pituitary and 3 ml of isotonic amphibian Ringer's solution are injected intraperitoneally into the animal. After 48 h, 0.5 ml of 0.0015 per cent colchicine is injected. The gonads are removed after 2 h and smeared in acetic–orcein (Walsh and Archambault, 1954).

The study of divisional stages from eggs is difficult to carry out because of the very low frequency of divisional cells, and they lie mostly in an arrested condition. For the study of early oogonial divisions, immature eggs are generally taken and the procedure is the same as for testes. For oocyte division, mature eggs before laying are necessary and the shell should be punctured for smearing. To secure a large frequency of metaphase stages, feeding the animal with colchicine and honey 24 h prior to dissection has been effective. With the exception of colchicine, other pre-treatment agents have very rarely been tried on animals and ample scope for investigation still lies in this direction. Owing to the poisonous nature of colchicine, a search for other and more suitable anti-mitotic agents for animals is necessary.

Different methods have been prescribed for the suppression of the yolky material which interferes with staining (Roberts, 1967). Cather (1959) suggested staining in diluted Gomori's chrome alum–haematoxylin following hydrolysis at room temperature in HCl, in marine gastropods. In a method adopted for the American Easter oyster, fixation in Carnoy's fluid (3 : 1) was followed by extraction for 2 h in a microsoxhlet apparatus with chloroform–methanol (1 : 1) and squashing in orcein. A thimble with a glass end, pore size 40 μm, is used as a receptacle for the eggs in the soxhlet apparatus (Longwell and Stiles, 1968). Menzel and Menzel (1965) suggested the use of phase contrast studies in addition to staining for egg cell chromosomes in clams.

The study of both mitosis and meiosis from mammalian tissues, including those of man, deserves independent treatment, due to the vast amount of progress in this field within the last decade. These methods have been discussed in detail in a separate chapter.

The mitotic division of animal material, other than mammalian and human, can be studied from larval tails, ganglia, spermatogonial cells, etc., but before squashing in acetic–carmine solution it is always necessary to fix the tissue, preferably in a fluid having a strong penetrating capacity such as acetic–methanol mixture. The tissue must also be teased out on the slide as a prerequisite for squashing.

Chromosomes of mosquito, ants, Drosophila, larval ganglion cells, etc. have also been studied through modifications of the squash technique (Lewis and Riles, 1960; French, Baker and Kitzmiller, 1962; Imai, 1966).

On the other hand, for mitotic divisions of mammalian tissues, such as bone marrow, endometrium, cervical tissue, cornea, etc., certain specialised methods are generally adopted. Marrows are generally extracted with a hypodermic syringe by puncturing the sternum (Ford and Hamerton, 1956) and aspirated continuously in sodium citrate solution to cause swelling and to prepare a fine suspension before fixing. In the case of solid tissue, homogenisation in sodium citrate solution is needed, followed by incubation at a slightly warm temperature for a few minutes (Smith, 1943; Manna, 1956) to

break and soften the tissue. Nuclei in a mass both from bone marrows and solid tissues are then obtained by centrifuging. For soft endometrial tissue, or even marrows, mere treatment in coumarin for a few minutes, hypotonic salt solution or even water may result in swelling of the cells and scattering of chromosomes.

Details of the schedules adopted for mammalian chromosomes, including human, are discussed in a separate chapter.

AIR-DRYING TECHNIQUES FOR CHROMOSOME STUDY

The evolution of these techniques, which led to the chromosomes being scattered at a single plane, gave rise to a sudden surge in the study of animal, particularly human, chromosomes and they form the basis of numerous methods later improvised.

They are applied principally to tissues of any organism which can be converted easily into cell suspensions, for example, bone marrow, peripheral blood lymphocytes, ascitic fluid and cells from germinal epithelium. Long-term cultures can be handled as monolayers or converted into cell suspensions, by trypsinisation (*see* Sharma, A. and Talukder, 1974). After the cell suspension has been prepared, pre-treated and fixed, air-dried preparations may be made according to the following schedule.

Clean slides are stored in absolute methyl alcohol in cold before use. The fixed material in suspension is centrifuged and most of the supernatant is discarded so that the fluid at the bottom of the tube consists of a small quantity of fixative with a high proportion of suspended cells. A slide is wiped carefully and one surface rinsed with the fixative. A small amount of cell suspension is drawn out by a Pasteur pipette. The slide is tilted at an angle and a drop of suspension allowed to fall at the upper end of the slide on the wet surface. As it runs down the slide, the slide is shaken vigorously to dry the suspension quickly. Alternatively, the slide is kept slanted and the suspension allowed to spread and dry by blowing hot air across it or even passing it through flame. The later steps are discussed under the relevant chapters for animal and human chromosomes.

This method has been modified to suit plant materials but has not been so successful due to the difficulty in bringing the cells to suspension.

WHOLE MOUNT TECHNIQUE FOR CHROMOSOME STUDY

It is difficult to embed and section small organisms for the study of their chromosomes, so a method was originally devised by Schmuck and Metz (1931) and later modified by Whiting (1950), in which small organisms such as small nematodes, insect eggs and embryos, and insect ovaries, can be mounted in entirety and fixed and stained within a short period. The material is fixed in shell vials; if it settles immediately, fluids are poured over it and removed by pipettes while floating materials are kept wrapped in lens paper sacks till ready for mounting. Invertebrate material is fixed in Kahle's fixative (distilled water, 30; rectified spirit, 15; formalin, 6; glacial acetic acid, 1) for

30 min to 24 h. Insect eggs are usually punctured. The material is rinsed in two changes of distilled water for 1 h each and then hydrolysed in N HCl at room temperature for 10 min and then at 60 °C for 10 min, followed by staining for 2 h in leuco-basic fuchsin solution. After a dip in SO_2 water it is washed in two changes of distilled water for 20 min, then run through two changes of triethylphosphate and one of triethylphosphate and xylol mixture (1 : 1), keeping 15 min in each. It is then transferred to xylol and mounted in balsam.

Squash techniques have been applied to whole embryos of animals by certain workers. For fish embryo, Simon (1964) suggested fixation immediately after hatching in acetic–ethanol (1 : 3) in the cold for 24 h. The blastodiscs are removed, treated in acetone for 5 min, rinsed in two changes of acetic–ethanol (1 : 3), stained for 10–15 min in propionic acid: 2 per cent acetic–orcein mixture (1 : 9) and squashed. In Atlantic salmon, embryos were fixed in 45 per cent acetic acid and stained in 4–6 per cent acetic–carmine at 60 C for 15–20 min (Boothroyd, 1959). The squash method was not very efficient for studies on implanted embryos of laboratory mammals (Bomsel-Helmreich and Thibault, 1962; Hungerford, 1958).

The air-drying method as utilised by Tarkowski (1966) for pre-implantation stages of mouse eggs, was not successful for implanted embryos. The technique was used by Butcher and Fugo (1967) on 11.5 day-old rat embryos. A fairly large initial amount of material was required, due to loss during trypsinisation, homogenisation or centrifugation. A further modification, developed by Wroblewska and Dyban (1969), described in the chapter on mammalian chromosomes, utilises dissociation after fixation, followed by air-drying.

For studying the chromosomes of adult trematodes, the entire animal is fixed in 40 per cent acetic acid or acetic–orcein for 24 h, transferred to either Gilson's fluid for sections, or to acetic–ethanol (1 : 3) for squashes, and hydrolysed in 10 per cent perchloric acid at 25 °C for 12 h or N HCl at 60 °C for 10 min prior to staining in Feulgen (Bergan, 1955). Avian microchromosomes can be studied following the squash schedule as well (Krishan, 1962).

There are special methods of making permanent slides from squash preparations; these are discussed in Chapter 6.

Modifications have been developed for both smear and squash techniques to obtain better preparation, better preservation and easier schedules. Preservation of plant tissues by storage at or below −10 °C after fixation in acetic–ethanol (1 : 3) and chloroform–ethanol–acetic acid (4 : 3 : 1) mixture gives very good staining with carmine squash even up to 6 months (Davies, 1952). For mounting histological materials, squashing the stained root tip in a drop of stain between two pieces of plastic, and lamination in an electric press eliminates dehydration (La Croix and Press, 1960). Glass cover slips can be replaced in squashes by cellophane by placing the specimen on an albumin-coated slide, and squashing under a wet square of cellophane. The slide is exposed to formalin vapour for 45 min before stripping off cellophane and staining (Murin, 1960). In another method, the cover-slip is directly glued on a slide by a rubber solution or 10 per cent solution of polyvinyl acetate in acetone–ethanol (1 : 1) mixture. After smearing, fixation and staining on the cover slip, it is detached from the slide by a suitable solvent (Östergren, 1963). Smears can be made on 35 mm photographic film, instead of a glass slide,

and fixed and stained as usual by handling on a photographic film developing reel. The slides are sprayed with a plastic cement and examined, using a special holder to keep the film base flat (Sommer and Pickett, 1961).

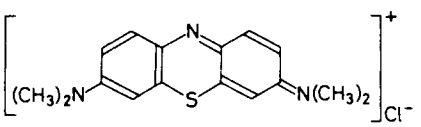
5
Staining

The structure and behaviour of chromosomes can be studied only after they are made visible under the microscope. In order to maintain normal activity at the time of observation it is best to mount the dividing cells in the body fluid of the organism and to observe chromosome movements under a phase contrast microscope. The evaporation of the fluid can be prevented by paraffin oil, which has the added advantage of being oxygen-solvent and non-toxic to the tissue (Ris, 1943). Since body fluid is not always easy to secure, physiological solutions have often been applied for the same purpose with success (Belar, 1929). Duryee (1937) used calcium ions in the medium which improved the visibility of chromosomes. A phase microscope is needed because the refractive indices of the resting nuclei and dividing chromosomes differ so little that it is difficult to distinguish them under an ordinary lens (for details *see* 'Phase contrast and interference microscopy', page 227).

No doubt the movement of chromosomes, as well as the structures related to them, such as the spindle, can best be studied through phase contrast lenses, but phase microscopy has not yet attained that stage of refinement required in cytogenetic and cytochemical analysis which would allow complete visibility of all the chromosome segments in detail. Even today, therefore, stained preparations, in spite of their limitations, have a decided advantage over unstained ones, especially where chromosome studies are concerned.

Staining, as performed on chromosomes, can be classified as 'vital' and 'non-vital'.

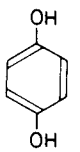
For vital staining, non-toxic dyes are applied to the living tissue so that the latter can be studied without being killed. If isolated cells such as blood, bone marrow, etc. are stained, the staining is called supravital. Of the different vital stains so far applied to the study of chromosomes, methylene blue only, has been found to be effective in demonstrating cell division in tissue culture. It is a basic dye of the thiazine group, $C_{16}H_{18}N_3SCl$, and is soluble in water.



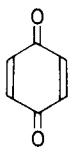
Ludford (1935) observed the advantages of methylene blue as a vital stain in that, in tissues, dividing cells do not stain as intensely as the metabolic cells. Darlington and La Cour (1960), however, stated that even with this staining there is every possibility of the chromosomes undergoing a certain amount of injury. Ludford (1936) observed that spindle formation can be prevented by auramine. Mollendorff (1936) noted that neutral red interfered with mitosis. Brilliant cresyl blue can also cause chromosome breakage (D'Amato, 1951). All this evidence indicates that although vital staining is essential for the study of mitochondria, golgi bodies, etc., it cannot be applied effectively in the study of chromosome structure.

In non-vital staining, the coloration of the chromosomes in the killed tissue is caused by certain chemical agents which are insoluble in the chromosome substance. The principal kinds of dyes that are used to stain chromosomes are synthetic organic dyes, derived from coal tar. The colour of a dye is due to certain chemical configurations, known as *chromophores*; similarly, the tissue must retain the colour which is due to certain chemical configurations in the dye molecule itself, known as the *auxochromes*.

The best example of a chromophoric group is the quinonoid ring. The coloration due to quinonoid arrangement is exemplified by the conversion of colourless hydroquinone to yellow quinone. Auxochromes, responsible for the adherence of the dye to the tissue, are mostly —NH_2 and —OH groups which convert the non-dyeing coloured substance into a form which undergoes electrolytic dissociation in water and is capable of forming salts with acids or bases (Baker, 1950).

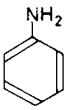


Hydroquinone (colourless)



Quinone (yellow)

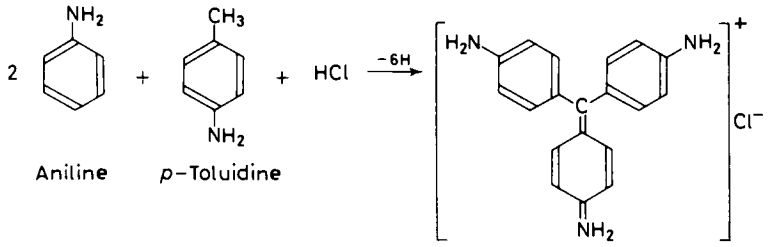
The mere presence of auxochromes cannot confer colour: for example, aniline, having the chemical structure:



is colourless, but if aniline is mixed with *p*-toluidine in the presence of mercuric chloride, basic fuchsin can be obtained. It possesses the quinonoid ring, responsible for its own colour, and also has auxochromes (NH_2) which allow it to be retained in the tissue.

The dyes are generally termed basic or acidic on the basis of their chemical nature and behaviour. In an *acidic* or *anionic* dye, the balance of the charge on the dye ion is negative. In a *basic* or *cationic* dye, however, the dye ion charge is positive. Most of the acid dyes are prepared as metallic salts and are generally neutral or slightly alkaline in reaction, but they react with, and stain substances with, a basic reaction. A basic dye, on the other hand, is manufactured as a salt of mineral or aliphatic organic acids, and it stains substances

which are acidic. Several of the dyes used in the study of the chromosomes are amphoteric, such as orcein; they behave both as acids and bases. The majority of the chromosome dyes are triphenyl methane or aniline derivatives, though other dyes have also been found to stain chromosomes (cf. Kasten, 1967).



Aniline p-Toluidine

Basic fuchsin
(*p*-rosaniline chloride)

In order to stain the chromosomes at specific loci, the general procedure is to over-stain it, followed by the removal of the excess stain—a process called 'differentiation'. Staining can also be performed progressively by gradually increasing the intensity of the colour. The process of differentiation allows the stain to adhere to specific sites of the chromosomes, as often basic dyes stain the cytoplasm as well. Similarly, acidic dyes may stain chromatin by proper differentiation, where quite likely the dye reacts with the protein moiety of the chromosome.

Most of the acid dyes are salts of potassium or sodium, whereas basic dyes are mostly available as chlorides or sulphates. For chromosome staining, basic dyes are applied, chromatin being strongly acidic. Acid dyes colour the cytoplasm which is predominantly basic. The terms basophilic and acidophilic are based on the affinity for basic or acidic dyes, chromosomes being basophilic and cytoplasm acidophilic.

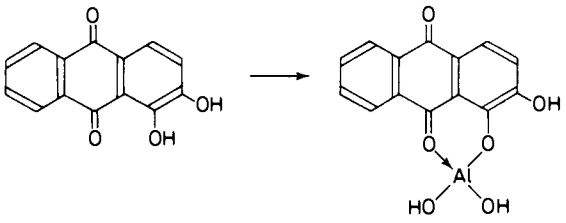
Staining has been claimed to be principally a process of adsorption (*see* Baker, 1958). Adsorption has been defined as 'a process by which a substance accumulates at a boundary surface of two contiguous phases in a concentration higher than that in which it exists in the interior of these two phases' (Michaelis, 1926). It is better to consider, as Baker has pointed out, that staining may simultaneously be a chemical reaction and physical adsorption.

Though chromosome staining is the product of a chemical reaction, yet the intensity of the stain fades with age. The fading may be attributed to the effect of ultraviolet light through continued exposure to daylight, to progressive acidity of the mounting medium or to retention of contamination of elements during the process of staining.

The adherence of a dye to the tissue may also be accelerated through the process of mordanting. Though the term 'mordant' is loosely used, it should only be applied to the salts of di- and tri-valent metals (Lison and Fautrez, 1939). These metallic hydroxides form compounds with the dye which attach the dye to the tissue and are called the 'lake' for the particular dye. The *mordant* is the term applied to the salt used.

In cases where the 'lake' formed is insoluble in water, the general practice is to dip the tissue in the mordant first, followed by staining. In carmine

staining, iron salts are often used as mordants and are added to the stain itself. Baker has dealt with the way in which the mordant forms a double compound, one with the dye and the other with the recipient tissue. Alizarin, a dye having more or less a structure similar to carmine, combines with aluminium hydroxide mordant in the following manner:



$Al(OH)_2$ combines here on the one hand with the dye alizarin and on the other hand with the tissue. The process of combination, as represented between the dye and the mordant, is known as 'chelation', due to the resemblance to the two claws of a crab. —OH groups of $Al(OH)_2$ are free to react with the tissue.

In cytological studies, whenever the dye or the mordant is used separately, the purpose of the mordant is either to modify the isoelectric point of the tissue or to form a chemical link between the stain and the chromosome. In principle, it changes the surface conditions of the fixed chromosomes.

Several types of mordants are used in cytology, though according to Baker, as mentioned above, the term should be rather limited. Chromium trioxide, iodine in ethanol, iron alum (ferric ammonium sulphate), ammonium molybdate and picric acid are the more commonly used mordants. In cases where mordants are used prior to staining, they evidently modify the chromosome surface in such a manner that the dye adheres strongly to the chromosomes. Chromium trioxide mordanting before crystal violet staining and iron alum mordanting before haematoxylin staining, are applied for this purpose. Mordanting in iodine–ethanol, picric acid and even iron alum solution is used after staining. Post-mordanting not only helps to retain the stain for a prolonged period, but also clears the cytoplasm. The latter effect is caused by removing the undesirable stain at non-specific sites from the cell. This effect is due to the acidity of the mordant, such as iodine in ethanol, which, being higher than the cytoplasm, removes the stain from its surface. Chromatin, on the other hand, having a stronger acidity, retains the stain. Iron alum, as mentioned before, is applied both before and after staining. During pre-mordanting or mordanting prior to staining, the excess alum, which does not react with the chromosome, remains in the cytoplasm. This extra alum, during staining, forms a dye–alum compound not bound to the tissue. Post-mordanting in iron alum removes this component. Chromium trioxide is also used after staining as a post-mordant and helps to retain the stain for a prolonged period; however, the cytoplasm takes up a yellow colour, which makes post-mordanting in chromium trioxide undesirable. The purpose of post-mordanting is more or less to bleach out the undesirable elements. An oxidising post-mordant oxidises the dye, present at certain sites, to a colourless substance.

Certain authors (Darlington and La Cour, 1960) consider even acid

hydrolysis needed for Feulgen staining as mordanting, but in our opinion the term should be used more critically. Hydrolysis in normal HCl helps to liberate aldehyde groups (*see* 'Feulgen staining', page 97) without the acid itself combining with the dye or the tissue. The application of the term as such is undesirable.

The term 'mordant' should preferably be restricted to those agents which are applied before staining and which form a complex with the dye or the tissue. Agents, when applied after staining, act more as differentiating chemicals than as mordants, therefore this epithet is not suitable for iron alum or iodine in ethanol, applied after staining. Unless the term 'mordant' is used strictly in the sense already denoted, it may merge with other chemicals like clove oil, etc., which are used solely for differentiation.

OUTLINE OF DIFFERENT TYPES OF STAINING PROCEDURES AND PRINCIPLES

Fuchsin

Of all the different staining methods employed for the study of chromosomes, the Feulgen reaction is considered to be the most effective with regard to chromosome staining, the chemistry having been well worked out by different authors (Feulgen and Rossenbeck, 1924; Hillary, 1939; Gulick, 1941; Li and Stacey, 1949; Overend and Stacey, 1949; Overend, 1950; Lessler, 1951, 1953; Kurnick, 1955; Swift, 1955) and considerable knowledge, even of the factors controlling the process, has been gained. Meischer first isolated the nuclear material 'Nuclein' from pus cells in 1869, but the cytological and chemical demonstration of its acidic component, nucleic acid, was not possible for a long time. In 1924, Feulgen and Rossenbeck devised a method based on the Schiff's reaction for aldehydes which stains the nucleic acid of the chromosomes specifically and, as such, has been effectively employed for the visualisation of chromosomes.

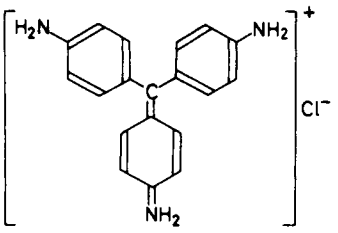
Feulgen solution or, more precisely, fuchsin sulphurous acid is prepared from the dye, basic fuchsin, and its preparation involves several steps. Its composition and properties are now outlined.

Basic fuchsin

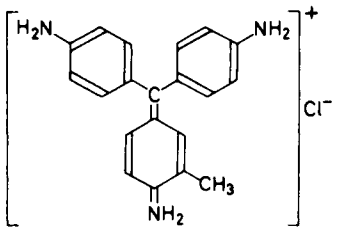
This dye belongs to the triphenyl methane series and is magenta red in colour. It can be derived, as mentioned before, by combining a few millilitres of aniline with *p*-toluidine in the presence of mercuric chloride. The commercially obtained 'basic fuchsin' is a mixture of three compounds, namely *p*-rosaniline chloride (Michrome No. 722), basic magenta (rosaniline chloride, Michrome No. 623), and new magenta (new fuchsin, Michrome No. 624) (Conn, 1953; Gurr, 1960).

The molecular weights of these compounds are 328.815 for *p*-rosaniline chloride ($C_{19}H_{18}N_3Cl$), 227.841 for basic magenta ($C_{20}H_{20}N_3Cl$) and 365.893 for new magenta ($C_{22}H_{24}N_3Cl$). It is evident that all these three compounds are characterised by quinonoid arrangements within the molecule; in fact, the chief constituent of basic fuchsin is *p*-rosaniline or triamino-

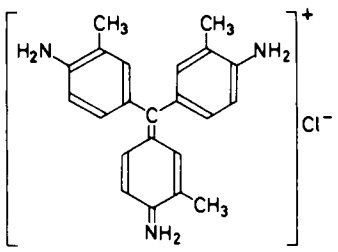
triphenyl methane chloride; the quinonoid structure makes the dye unstable and it undergoes oxidation easily. All these different compounds can be separately obtained as chlorides or acetates, though in chromosome studies the demand for basic fuchsin is much more than any of these compounds. For critical work, however, *p*-rosaniline chloride is occasionally used instead of basic fuchsin. Increasing methylation adds to the bluish shade in the colouring of the dye, and therefore *p*-rosaniline chloride with no methyl group has less colour than basic magenta or new magenta. Complete replacement of the hydrogen of amino groups by methyl groups results in violet coloration of the dye. Fuchsin base is the colourless carbinol base of the dye.



p–Rosaniline chloride



Rosaniline chloride



New Magenta

Basic fuchsin is easily soluble in water and alcohols, and for the preparation of Feulgen reagent, 0.5 per cent solution is prepared in boiling distilled water.

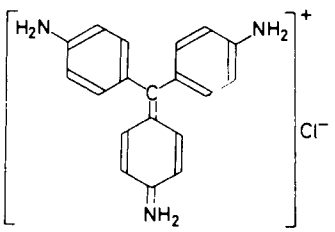
Preparation of Feulgen solution

The principle of preparing the Feulgen or Schiff's reagent is to treat the basic fuchsin solution with sulphurous acid, the product obtained being colourless fuchsin sulphurous acid. This reagent is the Schiff's reagent, utilised by Feulgen and Rossenbeck (1924) for the demonstration of the DNA component of chromosomes. The method of preparation has been modified by different workers (Coleman, 1938; Mallory, 1938; Tobie, 1942; Rafalko, 1946; Ely and Ross, 1949; Lillie, 1951; Atkinson, 1952; Longley, 1952; Casselman, 1959, etc.). The procedure involves, in short, the preparation of a basic fuchsin solution in warm water, followed by cooling at a particular temperature and the subsequent addition of hydrochloric acid and potassium metabisulphite, needed for the liberation of SO_2, prior to storage in a sealed container in a cool, dark place. The last two steps can be replaced by passing SO_2 water (Tobie, 1942; Rafalko, 1946), which gives not only a colourless solution but a very sensitive reagent as well. The addition of activated charcoal, as suggested by Coleman (1938), Longley (1952), etc.,

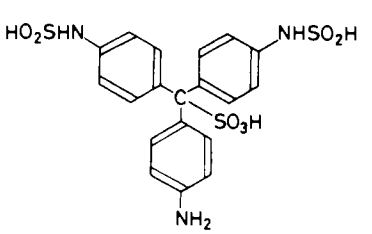
removes the yellowish impurities and, as such, a transparent colourless reagent can be obtained. However, as activated charcoal often removes a small amount of acid as well, it should be added in strictly limited quantity. The colour of Schiff's reagent varies, depending upon the type of dye used, the hydrogen ion concentration and SO_2 content; but without using activated charcoal, the solution should be straw-coloured. The reagent is unstable, as it loses SO_2 on continued exposure to air and becomes coloured again. This coloured product is, however, different from the product obtained on reaction with aldehydes (Shriner and Fuson, 1948). The colour is, therefore, non-specific. Though Atkinson (1952) noted that the particular reducing agent used in preparing Schiff's reagent has a marked effect on the potency of the solution, Casselman's (1959) re-investigation did not reveal any such effect whatsoever. For this reason it should be kept in a sealed container wrapped in black paper away from light. In order to avoid any contamination, used Schiff's reagent should not be mixed with the stock solution.

The preparation of the reagent is one of the most critical steps in the execution of Feulgen reaction. It must be carried out under strictly controlled conditions and in addition to the factors mentioned above, the temperature in the different steps of the reaction, as well as during the period of bleaching, also requires vigilance.

The principle underlying the preparation of Schiff's reagent from *p*-rosaniline is that, the basic fuchsin solution, or more precisely, *p*-rosaniline chloride solution, undergoes conversion to leucosulphinic acid, which is colourless. This conversion is caused by the addition of sulphurous acid across the quinonoid nucleus of the dye. Sulphurous acid is obtained through the action of HCl on potassium metabisulphite. The excess of SO_2 undergoes



p-Rosaniline chloride



N,N Sulphinic acid derivative of *p*-rosaniline

reaction with leucosulphinic acid to produce bi-N-aminosulphinic acid, popularly known as Schiff's reagent.

Procedure for Feulgen reaction

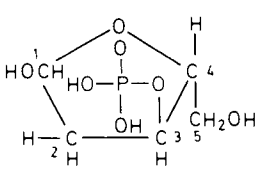
In order to carry out the test, the procedure in outline involves hydrolysis of the fixed tissue in normal HCl at 56–60 C, for a period varying from 4 to 20 min before immersing the material in Schiff's reagent. The colour develops within a short time and the chromosomes take up a magenta colour and can be observed after mounting in 45 per cent acetic acid. If the test is performed strictly according to the recommended procedure, the chromosomes appear to be specifically coloured against a clear cytoplasmic background. Prolonged

keeping in Schiff's reagent is undesirable, as further hydrolysis may take place due to the reagent being an acid (Serra, 1948); moreover, a rinse in sulphite solution or SO_2 water is often helpful to remove excess of colour, if any, in the cytoplasm.

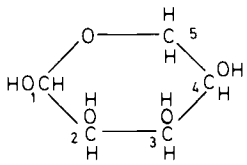
The chemical basis of the reaction, as outlined by Feulgen (1926), Levene and Bass (1931), Gulick (1941), etc., includes two principal steps:

(1) By hydrolysis with normal HCl, the purine-containing fraction of deoxyribonucleic acid (DNA) is separated from the sugar, unmasking the aldehyde groups of the latter.

(2) The reactive aldehyde groups then enter into combination with fuchsin sulphurous acid to yield the typical magenta colour. Feulgen reaction is, therefore, based essentially on the Schiff's reaction for aldehydes. After removal of the base, carbon atom 1 of the furanose sugar is so arranged as to form a potential aldehyde, capable of reacting with fuchsin sulphurous acid. The ribose sugar, with an —OH in place of —H at carbon 2, is not hydrolysed by normal HCl and so does not react with fuchsin sulphurous acid. In the pyrimidine–sugar linkage, on dissociation, the aldehyde groups are not free to react, unlike the open and reactive aldehydes obtained after breakdown of the purine–sugar linkage.



2-deoxyribofuranose -3-phosphate



D-ribose

Kissane and Robins (1958), through fluorescent assay, suggested a fluorescent-quinaldine reaction in Feulgen hydrolysis which, however, has not been confirmed (Stoward, 1963). The reaction of the aldehyde with bis-N-aminosulphinic acid is not yet fully disclosed. Wieland and Scheuing (1921) suggested that two molecules of aldehydes react to yield a reddish purple complex. Following the addition of these two molecules, the addition complex undergoes a molecular rearrangement to form a complex having quinonoid arrangement. The reaction, as outlined by Wieland and Scheuing, is shown on page 99.

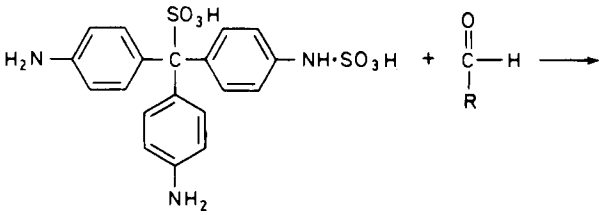
If this interpretation of the reaction of two aldehyde molecules with one of leucofuchsin is accepted, then it implies that two nucleotides enter into combination with one leucofuchsin molecule.

The coloured aldehyde-addition complex, formed as a result of Feulgen reaction, is entirely different from the original basic fuchsin, and therefore the term 'restoration of colour' should never be used. Stowell and Albers (1943) demonstrated that the absorption spectra of the original basic fuchsin and the aldehyde addition complex are different.

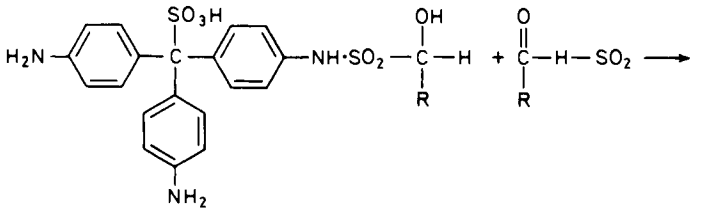
Lessler (1953) suggested, on the basis of the original concept of alternate arrangement of purines and pyrimidines in the nucleic acid molecule, that the aldehydes reacting with the Schiff's reagent must be present in alternate

nucleotides, but the demonstration of the two-strand nature of DNA (Watson and Crick, 1953) reveals that each nucleotide pair contains one purine and one pyrimidine group. Evidently, two purines are available in adjacent pairs, though located on complementary strands and therefore the two aldehyde groups, as visualised by Wieland and Scheuing, are available from two adjacent strands to react with one molecule of leucofuchsin. This interpretation is commonly accepted (Kasten, 1960).

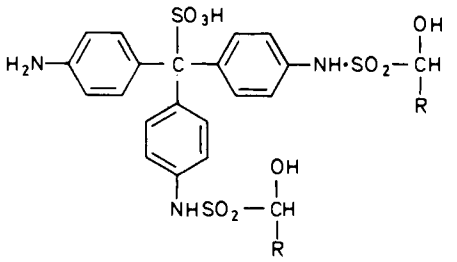
Rumpf (1935) and Hörmann, Grassman and Fries (1958) suggested an entirely different structure for Schiff's reagent, which, according to them, fits



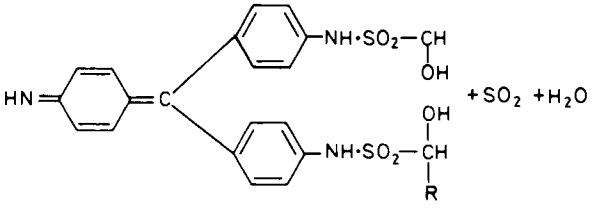
Fuchsin sulphurous acid Aldehyde



N-sulphinic acid - aldehyde (colourless)



Colourless compound

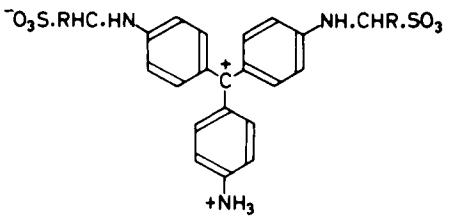


Coloured compound

in well with the reaction for aldehydes. According to them, instead of sulphinic acid, alkyl sulphonic acid is formed.

Barka and Ornstein (1960) and Hiraoka (1960) criticised Wieland and Scheuing's hypothesis. Sloane-Stanley and Bowler (1962) suggested that in Schiff's reagent, for every molecule of fuchsin, there are three aldehydes, not two. Lacoste and Martell (1955) claimed that even two —H atoms of one amino group can be replaced by two methylene sulphonic acids. The view that alkylsulphonic acid ($NHCHRSO_3H$) is the product formed is also supported by Hardonk and van Duijn (1964). They observed that staining intensity was identical both with pararosaniline and Schiff's reagent, after rinsing with sulphite and then water, thus refuting the Wieland–Scheuing hypothesis. Stoward (1966), however, was of the opinion that these observations would even fit azomethine or N-sulphinic acid as the end product. He regarded the electron-deficient central methane carbon atom as the essential chromophore.

With regard to the unmasking of aldehyde groups responsible for the Feulgen reaction, it was claimed by certain authors (Li and Stacey, 1949; Overend and Stacey, 1949) that all the purine-containing fractions need not necessarily



be separated from the sugar to yield the magenta colour. They showed that if sperm deoxyribonucleic acid is depolymerised by dialysis of a solution of its sodium salt against tap water, a white crystalline non-fibrous powder can be obtained which gives intense Feulgen reaction while retaining its original purine contents. Apparently, therefore, the breakdown of all purine–sugar linkage is not an essential step in executing the Feulgen reaction, and only a few of the aldehyde groups are necessary for the colour reaction, and the maximum intensity of colour can be obtained with the optimum period of hydrolysis. The suggestion is therefore that the breakdown of nucleic acid components takes place in two distinct steps. At the initial step, the sugar linkages engaged in polymeric bonding are attacked, and this is followed by a second step involving rupture of the glycosidic linkage between sugar and bases. The deoxyribose components revealed thereby still remain attached through phosphate linkages at C_3 and C_5 positions of the main nucleic acid chain; thus they are held strongly in the furanose form, which immediately undergoes transformation into the aldehyde form. This revealed that the aldehyde group undergoes Feulgen reaction as suggested by Wieland and Scheuing to form nucleic acid–aldehyde groups: *p*-rosaniline–SO_2 dye.

If the two steps above are taken into consideration, Feulgen test under optimum conditions should be interpreted as the reaction of fuchsin sulphurous acid with aldehydes of the deoxyribose sugar liberated after the breakdown of polymeric and glycofuranosidic linkages by acid hydrolysis to yield the magenta coloured addition complex.

In addition to normal hydrochloric acid, several other acids have also been

tried out by different workers to bring about hydrolysis. Citric acid was used by Widström (1928); perchloric acid by Di Stefano (1948, 1952); trichloracetic acid by Sharma (1951); phosphoric acid by Hashim (1952); and chromic, nitric and sulphuric acids and bromine by Barka (1956). Hot acids, which may sometimes cause removal of the tissue from the slide, have been substituted by Itikawa and Ogura (1954) with prolonged keeping in concentrated acid at room temperature, but hydrochloric acid has been seen to give the best possible results compared with others tried so far.

Attempts have been made to substitute Schiff's reagent with other aldehyde reagents (Pearse, 1951; Pearse, 1960, 1972). Casselman (1959) claimed that none of them gives any significant advantage over Schiff's reagent.

In order to demonstrate the Feulgen reaction, it is always necessary to keep controlled unhydrolysed sections, as pointed out by Bauer (1932, 1933). Free aldehydes may be present in the cytoplasm as lipids (Gerard, 1935; Gomori, 1942; Lessler, 1953, and also *see Int. Rev. Cytol.*, 1961). Similarly, higher aliphatic aldehydes, released from acetal phosphatides, may be obtained in the cytoplasm (Cain, 1949; Hayes, 1949). Polysaccharides, after oxidation by chromic acid fixation, may release aldehydes to react with the Feulgen solution (Bauer, 1932, 1933). All these aldehydes are available without hydrolysis and can undergo colour reaction. Chayen and Norris (1953) suggested the possibility of false localisation of DNA by acid hydrolysis and the presence of cytoplasmic particles which may be digested by deoxyribonuclease.

Moreover, Lison (1932) claimed that Schiff's reaction may occur with aliphatic ketones, unsaturated compounds, amino oxides and catalytic oxidisers in addition to aldehydes. Hydrolysis removes all these components together with aldehydes, thus allowing only specific nuclear reaction. In plants, lignin, suberin, etc., also undergo Feulgen reaction but adequate control for their tests should be maintained in parallel sets in cases where such materials are present. Cytoplasmic aldehydes are removed, not only through acid hydrolysis but also through the complicated process of dehydration in alcohols, embedding in paraffin, etc., involved in block preparation (Danielli, 1949).

Semmens (1940) criticised the aldehyde reaction in the Feulgen test and suggested that colour may be due to purine components of the nucleic acid. This was substantiated by the fact that if piperidine and pyridine are added to the Feulgen reagent, development of colour is observed. Barber and Price (1940) claimed that this development of colour, which is attributable to their basic properties, cannot be compared with the typical Feulgen reaction.

Factors controlling reaction and its intensity

The critical preparation of materials through Feulgen staining depends on several factors, especially hydrolysis, method of fixation and type of tissue used. In addition, the concentration of DNA is no doubt one of the principal factors.

Several authors, namely Bauer (1932), Hillary (1939), Di Stefano (1948) noted that the time required for hydrolysis depends on the type of fixation applied. With acetic–ethanol fixation, a very short period of hydrolysis is necessary, whereas with metallic fixatives, like chromic acid, a considerably

longer period of hydrolysis may be required. Osmium- and platinum-fixed materials, if not properly bleached, do not yield a good colour reaction. As pointed out by Darlington and La Cour (1960) and also confirmed from this laboratory, fixation with formalin, which is often recommended, leads to cytoplasmic staining if formalin is not properly washed out. Sibatani and Fukuda (1953) observed the minimum loss of DNA in fixed tissues after formalin or ethanol–formalin fixation. Helly's fixative has been recommended by Murgatroyd (1968) for mouse pancreas. Swift (1950) noted that formaldehyde fixation yields more intense colour than acetic–ethanol fixed materials. Lower concentrations of formalin, on the other hand, result in brighter colour than that obtained with higher concentrations (*see* Sibatani and Fukuda, 1953). Post-mortem changes, prior to fixation, may affect the intensity of the colour (Lhotka and Davenport, 1951). Acetic–ethanol fixation yields the maximum intensity in the Feulgen reaction, as observed by the present authors in plant materials, though the formation of acetaldehyde due to fixation after-effect, which is removed with mild acid hydrolysis, is another limitation of this process. However, it has been observed that alcoholic fixative causes violet coloration whereas the colour that appears after fixation in a mixture containing chromium is red (Darlington and La Cour, 1960). Penetration of the fixative is also another important factor, as, in a block of tissue, Swift (1955) noted stronger reaction in the periphery as compared to that in the centre. No variation in intensity was observed in freeze–dried tissue preparations in different parts.

The development of the actual magenta colour may be related to the type of aldehyde undergoing reaction. Pearse (1960) suggested that, though colour itself indicates a positive reaction, yet departure from the normal colour may have interesting significance. Variation in colour in different types of aromatic and aliphatic aldehydes has been demonstrated by Gomori (1950) and Casselman (1959). Hydrogen ion concentration also plays an important role in this process (Dutt, 1968, 1971). Moreover, it has been shown that SO_2 content is an important factor in colour formation. On aldehydes combining with low SO_2–Schiff, the colour is reddish whereas with high SO_2–Schiff, it is bluish (Elftman, 1959; Barka and Ornstein, 1960).

The temperature is another factor to be taken into consideration, and results are more quickly obtained if the hydrolysis is carried out for a short period at a higher temperature; also the duration affects the specificity of the colour to a significant extent. With hydrolysis for a period shorter than the recommended one, the cytoplasm shows a diffuse colour, indicating that other aldehyde components of the cytoplasm have not been removed, due to inadequate acid treatment. On the other hand, if hydrolysis is carried out for a longer period than recommended, a similar diffuse colour in the cytoplasm is observed, cytoplasmic coloration in this case being attributed to free depolymerised nucleic acid molecules lying in the cytoplasm on being detached from the nucleoprotein component of the chromosome. That longer hydrolysis in hydrochloric acid frees the chromosome of its nucleic acid component has been observed by Taylor, Woods and Hughes (1957) and others, and thus an optimum reaction can only be obtained under strictly controlled hydrolysis. Jordanov (1963) suggested hydrolysis with 5N HCl at room temperature. The importance of temperature in hydrolysis has also been stressed by other authors (Aldridge and Watson, 1963). The time of hydrolysis

has been found to play a role in dye binding of normal and tumour cells, where Böhm and Sandritter (1966) visualised the presence of two types of DNA against one type in mouse liver as claimed by Kasten (1965). It may be mentioned that Lima de Faria (1962) suggested the presence of non-Feulgen-positive DNA in the cytoplasm of several species of amoeba, *Lilium* and *Gryllus*.

Different species as well as different tissues often require different periods of hydrolysis for the optimum reaction and development of the maximum intensity of colour. Nuclei of *Spirogyra* require a much longer period as compared to other plant cells (Hillary, 1939); sea urchin eggs require a shorter period than that necessary for most animal cells, and root tips of *Chrysanthemum* need an unusually long period for a proper development of their colour (Dowrick, 1952). It is easier to stain a testicular tissue than a fatty one, possibly because the former permits easy penetration. Thymus tissue, in general, has been found to be more resistant to hydrolysis than other tissues (De Lamater, Mescon and Barger, 1950). Brachet and Quertier (1963) used hydrochloric acid in ethanol in a modified Feulgen reaction to localise oocyte cytoplasmic DNA (cf. Cowden, 1965).

The differential response to hydrolysis in different species and tissues clearly suggests that nuclear and cytoplasmic constitutions play an important role in the manifestation of the Feulgen reaction, and that organs and species differ in the constituents of the cytoplasm. Inhibiting agents, which may not allow the colour to develop, may be present in the cytoplasm, and in some instances the associated protein may interfere with the Feulgen reaction (Shinke, Ishida and Ueda, 1957). The association of other nuclear components with DNA may also protect the latter against hydrolysis. In view of these considerations, it is always necessary to adjust the specific requirements of the Feulgen reaction in every species and organ.

The intensity of the colour may also depend on the amount of DNA present. Haploid, diploid and higher polyploid cells differ in the intensity of the colour due to the amount of DNA present (Vendrely and Vendrely, 1956). In fact, because of the specific nature of the stain and proportionate increase of the staining intensity with the amount of DNA, quantitative estimation through microspectrophotometry of Feulgen-stained tissues is commonly carried out, and in this connection it is important that the thickness of the sections should be considered.

Validity of the Feulgen test

Although the Feulgen nuclear reaction has been widely accepted as a specific test for localising DNA *in situ*, some authors have persistently raised objections regarding the specificity of the test. These objections have been reviewed in detail by different workers (Stowell, 1946; Gomori, 1952; Sharma, 1952; Lessler, 1953; Kurnick, 1955; Kasten, 1956, 1960; Pearse, 1960, 1972). Only the outlines of the objections, pertinent to the test, will be mentioned here.

It was first pointed out by Carr (1945) that the colour of Schiff's reagent is regenerated by adsorption on the chromosome surface. He further suggested that nuclear coloration depends on the destruction of cytoplasmic constituents by acid hydrolysis. An excess of sulphur dioxide does not block the

reaction, which would happen if the reaction depended on the presence of aldehydes.

This objection has been refuted by different workers. Dodson (1946) showed that chromosomes are not mere adsorbants of the Schiff's reagent, and further claimed that hydrolysis causes only a negligible loss of cytoplasm. That the Feulgen reaction is a typical aldehyde reaction has been established by Lessler (1951), who observed that after acid hydrolysis, if aldehyde-coupling reagents such as sodium bisulphite, trimethyl aminoacetohydrazide, semi-carbazide, phenylhydrazine or hydroxylamine are added, the Feulgen reaction is completely checked due to blocking of aldehydes.

A serious criticism of the Feulgen test is made by Stedman and Stedman (1943, 1948). They do not object to the aldehyde reaction in the Feulgen test, but hold that the latter is incapable of localising DNA *in situ* and according to their interpretation, DNA is the principal component of the nuclear sap. After acid hydrolysis and the application of fuchsin sulphurous acid, the colour develops outside the chromosome. The dye formed is a diffusible and water-soluble basic substance which is adsorbed on the chromosome surface by an acidic protein of the chromosome, which they term 'chromosomin'. On this basis, the Feulgen reaction is not fundamentally different from other staining procedures and differs only in the fact that in other cases a coloured solution is used as the staining medium whereas in the Feulgen test, the dye solution is prepared inside the cell from a decolorised compound. In support of their claim, they cited Choudhuri's (1943) observation that chromosome staining can be secured by the coloured compound obtained by interaction of Feulgen reagent and hydrolysed DNA. Stedman and Stedman (1950) also claimed that hydrolysis in the Feulgen test causes a profound change of the original product in extracted nuclei, and that considerable loss of nucleic acid, phosphorus and histones from the cell following acid hydrolysis also occurs. The diffusion of fragments containing a considerable amount of phosphorus into the hydrolysis fluid, giving a strong Mollisch reaction, was also noted, and they are of the opinion that similar behaviour occurs within the cell following acid hydrolysis, and diffusion products are formed both in the extracted nuclei as well as at an intracellular level. On the basis of these results, the unsuitability of the Feulgen test for *in situ* localisation and for quantitative estimation of DNA has been asserted.

The objections by Stedman and Stedman were refuted by several workers. Danielli (1947) pointed out that staining of squashes by the Feulgen technique is entirely different from the staining obtained by the action of the pre-formed Schiff's base, as in Choudhuri's material. This statement is based on the fact that the cytoplasm becomes stained in the latter but remains uncoloured in the former. Baker and Sanders (1946) suggested that if the products can diffuse through the tissues away from the place where they have first been formed, they can also diffuse into the fluid in the staining jar and thus be lost. Stedman and Stedman, however, consider that the diffusion of substances within the nuclear fluid is much less than in water. Overend and Stacey (1949) pursued the problem in detail by synthesising a number of 2-deoxysugars and studying their properties, and the results obtained by them have led them to conclude that aldehyde forms an actual complex at the chromosome level with decolorised *p*-rosaniline.

Lessler (1953) brought out several fallacies in Stedman's arguments. He

stated that the reaction between free hydrolysed DNA and Feulgen reagent may produce a soluble coloured product, but it is washed off during acid hydrolysis. He also points out that nucleic acid, at intranuclear levels, may behave very differently from the isolated nucleic acid of Stedman as the nuclear nucleic acid exists as nucleoprotein complex. Caspersson (1944) also observed, through spectroscopic studies, that nucleic acid is present in the metaphase chromosome and is not a component of the nuclear sap. Kasten (1956, 1960) demonstrated that the Feulgen reaction is a specific test for DNA and is not a simple staining reaction as suggested by Stedman and Stedman.

Further evidence of the specificity of the test was secured by Brachet (1947). If the nuclei are treated with thymonucleodepolymerase, which removes DNA, the Feulgen reaction becomes negative for the nucleus. Similar observations were reported by Catcheside and Holmes (1947). They observed that the deoxyribonuclease treatment removed Feulgen-positive bands from the salivary gland chromosomes of *Drosophila*.

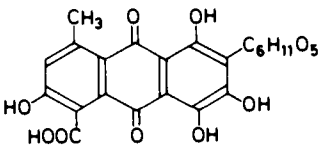
All the above evidence no doubt points out the validity of the reaction as a specific test for precise localisation of DNA *in situ*, but as different factors control the development of the colour it is always necessary to keep a strict control over temperature and duration of hydrolysis and the type of fixation. With a check through the control, the specificity of the test is unquestionable. The possibility, suggested by Pearse (1972), that there are several structural arrangements depending on the availability of SO_2 as well as the dye and aldehyde molecules, cannot be ruled out.

Carmine

One of the most widely used dyes for chromosome staining is carmine. It is prepared from the ground-up dried bodies of *cochineal*, the dried females of *Coccus cacti*, a tropical American Homoptera living on the plant *Opuntia coccinellifera*. Due to the fact that the product yielded by this insect may often vary because of the different species used, the carmine of commerce is generally variable in quality.

This dye is a crimson-coloured product prepared by adding compounds of aluminium or calcium to cochineal extract. It is not truly a definite chemical compound but a mixture of substances, the composition of which often varies on the basis of the method of manufacture. The active principle of carmine, to which its staining property is due, is carminic acid. If this is applied in a pure form, it does not give any better staining than carmine; but it may be applied in a critical study, as its exact chemical composition is known.

Carminic acid (Michrome No. 214) can be obtained by extracting cochineal with boiling water followed by treatment with lead acetate and decomposition of lead carminate with sulphuric acid (Gatenby and Beams, 1950). This dye belongs to the anthraquinone group and has the formula $C_{22}\ H_{20}O_{13}$, the molecular weight being 492.38. Its chemical structure is



The chromophoric property is attributed to its quinonoid linkage and auxochromes are also present. It is soluble in water in all proportions (Gurr, 1960), and is a dibasic acid and claimed to be nearly insoluble at its isoelectric point, pH 4–4.5 (Baker, 1950). If it is dissolved on the acid side of its isoelectric point it acquires a positive charge, behaves like a basic dye and stains chromatin, but if dissolved in alkaline solution it can behave as an acid dye. Carminic acid is not used as such for nuclear studies, except in the form of carmalum as recommended by Mayer (cited in Baker, 1958) for animal tissues. Carmalum mixture is composed of carminic acid, potassium aluminium sulphate and water, with sodium salicylate as the preservative. Evidently the purpose of potash alum here is to form a lake (*see* page 93). This mixture, however, is now obsolete.

In chromosome studies, carmine is used in solution with 45 per cent acetic acid, and the stain thus prepared is known as acetic-carmine (Belling, 1921). This solution serves the double purpose of fixation and staining, as acetic acid is a good fixative for chromatin and is a rapidly penetrating fluid. In the original schedule of Belling, which is widely followed, 1 per cent solution of the dye is prepared in hot 45 per cent acetic acid, whereas certain authors (Schneider as quoted in Gurr, 1960) prefer even 5 per cent solution. Belling suggested the addition of ferric hydroxide in acetic–carmine during its preparation and the purpose was evidently to allow the formation of a lake needed for the intensification of colour. According to Gatenby and Beams (1950), the best way of adding iron is in the form of a solution of ferric hydrate in 50 per cent acetic acid. The addition of a few drops of ferric chloride or ferric acetate solution also serves to intensify the colour, but iron must not be added in too heavy an amount as an excess of iron causes blackening of the entire cytoplasm.

The common procedure of using acetic–carmine as a stain is to squash the tissue in a drop of the dye solution. Warmke (1935) recommended the use of warm carmine on even smears. In the case of bulk compact tissues, such as root tips, leaf tips, etc., materials can be treated in hot acetic–carmine and hydrochloric acid mixture which serves the double purpose of softening and staining. Materials which provide difficulty in staining due possibly to inadequate fixation can be fixed in Carnoy's fluid prior to acetic–carmine staining; also, if needed, the use of a 2 per cent iron alum solution for a few minutes prior to staining may serve the purpose of mordanting and thus help in the intensification of colour. While squashing, the best way of adding iron is to tease the tissue in a drop of carmine with the help of a scalpel, or penetration can be aided by slight warming. Being present in the form of an acetic solution, carmine is not a suitable stain for sectioned materials. In certain cases acetic acid is substituted by propionic acid—the stain thus prepared is called propionic–carmine—and by this means the excessive swelling effect of acetic acid is generally eliminated; but prior to staining, fixation in acetic–alcohols is substituted by propionic–alcohols. This method has been found to be suitable for grass chromosomes (Swaminathan, Magoon and Mehra, 1954). Hydrochloric acid–ethanol mixture can be also used as a solvent for carmine for staining tissues in bulk (Snow, 1963).

Occasionally, both plant and animal tissues which present difficulties in Feulgen staining are mounted in acetic–carmine (Schreiber, 1954) after Schiff's reaction. In such cases, hydrolysis in normal HCl as well as treatment

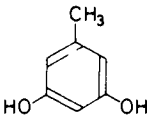
with fuchsin sulphurous acid clears the cytoplasm allowing specific coloration of the chromosomes.

The application of carmine as a chromosome stain is widespread. Starting from the lower groups of plants like algae (Godward, 1948), it can be applied to all other advanced groups, including all animal and human tissues. Even in the study of special chromosomes like the salivary gland chromosomes of *Drosophila*, its effect is remarkable.

In order to obtain permanent preparations from carmine squashes, McClintock's schedule or its modifications are commonly used in addition to the dry ice or vapour method (*see* Chapter 7), but in all these cases one of the serious limitations lies in the gradual fading of colour following prolonged keeping. No doubt, if the acidity of the mounting medium and other conditions are controlled, the fading may be checked to a certain extent, but the presence of acetic acid itself in the dye makes it liable to be acidic in time. In spite of this limitation, the convenience in chromosome staining and rapidity of the schedule make it the most widely used stain in the study of chromosomes.

Orcein

Orcein was first employed as a chromosome stain by La Cour in 1941. The dye has a molecular weight of 500.488, the formula being $C_{28}H_{24}N_2O_7$ (Michrome No. 375), but its exact chemical structure is unknown. It is a deep purple-coloured dye, obtained from the action of hydrogen peroxide and ammonia on the colourless parent substance *orcinol*.



Orcinol is 3,5-dihydroxytoluene, having a molecular weight 160.166 and the formula $C_7H_8O_2$. It is available both in natural and synthetic forms. In nature, it is obtained from the two species of lichens, *Rocella tinctoria* and *Lecanora parella*. As a chromosome stain, Conn (1953) indicated that synthetic orcein is not so effective as natural orcein. Engle and Dempsey (1954), from studying the physical and chemical properties of four fractions of orcein, separated by chromatography, concluded that both orcein and its fractions are valuable chromosomal stains.

Orcein is soluble in water as well as in ethanol. Under certain conditions, it can behave as an amphoteric dye (Gurr, 1960). Fullmer and Lillie (1956), working exhaustively on orcein staining, demonstrated its basic properties. In the study of chromosomes it is used in the form of acetic–orcein, that is, 1 per cent solution in 45 per cent acetic acid. It can be used in the same way as acetic-carmine and has the added advantage that no iron mordanting is necessary. In our experience the intensity of the stain, especially for meiotic materials, is not as good as carmine, though it is effective where carmine staining fails. It has been found to be a very effective stain for salivary gland chromosomes (Darlington and La Cour, 1960) as well as the chromosomes of mosses (Vaarama, 1949). For the study of root tip and leaf tip chromosomes,

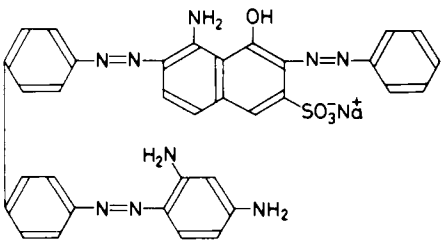
the use of a stronger hot solution of acetic–orcein and normal HCl, mixed in a specific proportion, is necessary for softening the tissue before mounting in a dilute solution of acetic–orcein (Tjio and Levan, 1950; Sharma and Sharma, 1957). In various species of fungi, especially those belonging to Ascomycetes, hydrolysis in normal HCl for a few minutes at 60 °C, after fixation and prior to staining, has been found to be very effective (Singleton, 1953; Elliott, 1956). Just like carmine, acetic–orcein can be substituted by propionic–orcein (Cotton, 1959), which has been found to be useful in studying the chromosomes of *Heteroptera*.

It is found to be specially useful in the study of somatic chromosomes though applied frequently for meiotic chromosomes as well. It has, however, to be applied with extreme caution, since overheating in orcein–HCl mixture has been found to induce chromosome breakage (Sharma and Roy, 1955). Therefore, at least for the study of chemical effects on chromosomes, orcein staining should preferably not be applied as its effect may often mask the effect of chemicals. Sen (1965) has shown that staining involves condensation of the phenolic dye at the point of polypeptide linkage of chromosome protein. Following prolonged heating under acidic conditions, tertiary amine involved in polypeptide linkage results in the production of ammonium chloride and breakage of the link, causing chromosome breakage.

Chlorazol black

A solution of chlorazol black E in ethanol has been applied by Nebel (1940) as an auxiliary stain for chromosomes, along with acetic–carmine. This dye was applied after fixation prior to acetic–carmine staining and proved effective for species of Rosaceae, where ordinary acetic–carmine stain was ineffective. It has even been applied as a stain by itself and has been found to be effective for the study of root tip chromosomes of plants (Nebel, 1940; Conn, 1943).

Chlorazol black E, however, is an acid dye of the trisazo group (Cannon, 1937) and has a molecular weight of 781.738 (Michrome No. 92). Its formula is $C_{34}H_{25}N_9O_7S_2Na_2$. It has the following structure:



Chlorazol black E

It is highly soluble in water and sparingly in ethanol. Being an acidic dye, the basis of its stainability with chromosomes is not clear, but it is probable that it stains the protein component. Chlorazol black is possibly effective in materials where protein components of the chromosome are high, which

accounts for the limited application of the dye. More evidence is necessary to substantiate this suggestion.

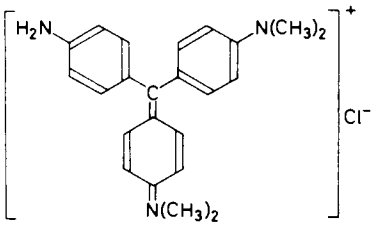
Crystal violet

The discovery of crystal violet as a stain for chromosomes is attributed to Newton (1926). In fact, in his studies Newton used gentian violet (Michrome No. 417) which is a mixture of crystal violet and tetra- and penta-methyl *p*-rosaniline chlorides. Crystal violet itself is hexamethyl *p*-rosaniline chloride. Gentian violet is a basic dye belonging to the triphenyl methane series. The structures of the three compounds constituting gentian violet are shown on page 109.

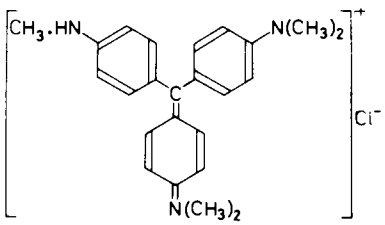
The molecular formulae and weights of the three compounds are $C_{23}H_{26}N_3Cl$: 379.919; $C_{24}H_{28}N_3Cl$: 393.945; and $C_{25}H_{30}N_3Cl$: 407.971 respectively. Gentian violet is soluble in both water and alcohols.

Crystal violet (Michrome No. 103), which is supposed to be one of the most adequate stains for chromosomes, is a bluish violet dye. The term itself is derived from the fact that it forms large crystals with nine molecules of water. The dye is closely allied to basic fuchsin from which it can be derived by the replacement of the six hydrogen atoms of three amino groups by six methyl groups. It is soluble in both water and alcohols. In chromosome studies, aqueous 1 per cent solution is used.

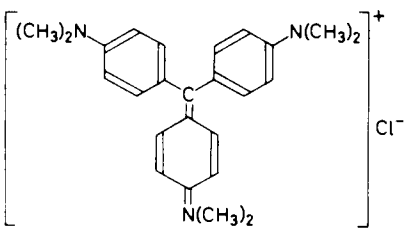
In Newton's crystal–iodine technique, after the application of the stain to the sections or smears, the excess dye is first washed off in water. Then the slides are processed through iodine and potassium iodide in ethanol mordant, followed by dehydration in ethanol; differentiation in clove oil and clearing in xylol before final mounting in balsam.



Tetramethyl *p*–rosaniline chloride



Pentamethyl *p*–rosaniline chloride



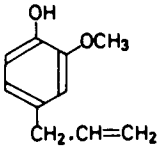
Hexamethyl *p*–rosaniline chloride (crystal violet)

The use of iodine as a mordant, after crystal violet staining, is based on the Gram effect on bacteria. During dehydration, crystal violet can easily be washed off in ethanol, but de-staining can be prevented if iodine is added to bacteria. The same principle holds good for chromosome staining; in fact, after the addition of iodine, the stain becomes bluish-black from violet. Baker (1950, 1958) stated that the liability of crystal violet to be removed by ethanol is actually lessened by iodine treatment, which results in the chromosomes retaining the dye against a clear cytoplasmic background. In order to obtain a proper coloration of the chromosomes in difficult materials, iodine mordanting, which is normally carried out for a few seconds, should be further reduced, but in no case should this step be omitted, as acidic components of the cytoplasm also take up the colour which is removed by iodine in ethanol (for details, *see* page 94). Although Baker has recommended the omission of the iodine step in certain materials, in the experience of the present authors, the shortened schedule is ineffective.

The closely related dyes or rosanilines, which can be obtained by combining one molecule of aniline, one of *o*-toluidine and one of *p*-rosaniline, do not show this Gram effect (Baker, 1950, 1958). Schmidt (1944) suggested that iodine causes the *p*-rosaniline dyes to undergo a molecular aggregation, which is possibly interfered with by the methyl group of *o*-toluidine.

Differentiation in clove oil is an essential step in the crystal violet technique. Due to the rapid passage through ethanol, dehydration remains incomplete and it is finally completed in a slowly differentiating fluid, clove oil.

Clove oil is an essential oil, yielded by the flower buds of *Eugenia caryophyllata*. It consists principally of eugenol, a guaiacol derivative with the formula



In addition, it also contains other organic compounds, such as methanol, furfural, etc. Differentiation in clove oil completes the dehydration, clears the cytoplasmic background and imparts a crisp colour to the chromosomes.

All the ethanol in clove oil should be removed by continually stirring the slide in the fluid. The retention of ethanol may cause cloudiness and lessening of the stain on mounting in balsam.

Final clearing in xylol, $C_6H_4(CH_3)_2$, or dimethyl benzene is an essential step, as clove oil must be completely removed before final mounting. The retention of this oil ultimately leads to the fading of colour.

For materials that are difficult to stain, slides can be mordanted in 1 per cent chromic acid and washed prior to staining. In order to secure complete cytoplasmic clearing in materials having a heavy cytoplasmic content, the slides can be further mordanted in chromic acid in between the different ethanol grades, after mordanting in iodine. The underlying principles are discussed in the chapter on mordanting.

Crystal violet is widely used as a chromosome stain for plants, animals and lower organisms. It is most effective on pollen mother cell smears or for mitotic and meiotic studies from sectioned tissues. Unfortunately it cannot be

applied effectively on tissues to be squashed after staining. This disadvantage may be attributed to two main reasons: (1) Being an aqueous stain, its rate of penetration is very slow and, as such, the different cell layers will have different intensities of colour. Makino and others used crystal violet dissolved in acetic acid for smears of mammalian chromosomes. (2) As it is a non-specific basic dye, acidic components of cytoplasm also take up the colour. Washing of the cytoplasmic colour through iodine mordanting from bulk tissue is rather difficult.

Barring these limitations, crystal violet can be safely recommended for the staining of chromosomes.

Certain other basic dyes of the triphenyl methane series are able to replace basic fuchsin, to some extent, like dahlia violet, magenta roth, methyl violet, brilliant green, malachite green and light green as observed in our laboratory. The methods of preparation and staining are similar to that followed for leucobasic fuchsin. A direct correlation is observed between the colour of the different dyes and the active groups present in them. The amino group, in general, produces mauve and magenta colour, while ethyl and methyl groups principally impart violet to greenish coloration. In basic fuchsin, amino groups impart mauve coloration in the nuclei whereas their replacement by methyl groups in crystal violet results in completely violet coloration. Magenta roth is a suitable substitute for basic fuchsin and results in a magenta colour. With crystal violet and methyl violet, the chromosomes colour violet in Feulgen reaction. Brilliant green shows better effect than the other green dyes and the ethyl group is more easily reacted upon than the methyl, as shown in *Table 5.1*.

Table 5.1

Dye	*MI No.*	*No. of batches*	*Active group*	*Colour of nuclei*
Basic fuchsin	421	3	$-NH_2$	Mauve
Dahlia violet	105	2	$-C_2H_5$	Mauvish violet
Magenta roth	624	1	$-NH_2$	Magenta
Methyl violet 6B	180	2	$-CH_3$	Violet
Crystal violet	103	2	$-CH_3$	Deep violet
Brilliant green	406	1	$-C_2H_5$	Blue-green
Malachite green	315	1	$-CH_3$	Green
Light green		1	$-CH_3$	Yellow-green

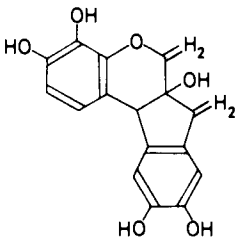
(Golechha, 1968; Golechha and Sharma, unpublished)

Haematoxylin

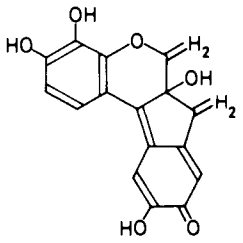
This natural colouring substance is obtained from the heartwood of *Haematoxylin campechianum*, a native of Mexico. The crude product is generally manufactured by boiling small chips of the wood in water followed by filtration and evaporation to dryness. Extraction of this crude product with ether yields *haematoxylin*.

The dyeing property of haematoxylin is attributed to its oxidation product, haematein (Michrome No. 360), as haematoxylin is itself not a dye. Haematoxylin has the molecular formula, $C_{16}H_{14}O_6$, the molecular weight being 302.272. The molecular formula of haematein is $C_{16}H_{12}O_6$, the molecular

weight being 300.256. The structural formulae of the two are:



Haematoxylin



Haematein

The structural formula of haematoxylin was first worked out by Perkin and Everest (1918), and Baker (1950) rearranged the structural formulae of the two as outlined above so that the presence of quinonoid arrangement in haematein and its absence in haematoxylin is clear. The process of oxidation, which is otherwise known as 'ripening', may take several weeks, spontaneously, but this process may be hastened by the use of oxidising agents such as sodium iodate, hydrogen peroxide, chloral hydrate, potassium permanganate, etc. Slow atmospheric oxidation is, however, preferred to the use of oxidising agents, as too much oxidation may make haematein quite unfit for the purpose of staining.

In view of the necessity of oxidation in the preparation of haematein from haematoxylin, the aqueous solution of haematoxylin is prepared and allowed to ripen for several weeks (Heidenhain, 1896). For rapid oxidation, a small quantity of sodium iodate is often added if the solution has to be used immediately, but without sodium iodate, at least a few weeks are necessary for the colour to ripen. Shortt (1923) suggested the addition of carbolic acid to haematoxylin solution, which apparently acts as a preservative.

Without the use of a mordant, haematoxylin solution is entirely ineffective in staining chromosomes. Commonly used mordants are potassium aluminium sulphate, iron alum and ammonium alum. They form lakes which become positively charged and behave as basic dyes. For chromosome studies, potassium aluminium sulphate (Mayer, 1903) and iron alum (Benda, 1896) are widely used, the latter being more effective. The potash alum lake of haematoxylin is used for progressive staining, whereas iron alum is utilised in regressive staining (*see* page 94). Progressive staining implies gradual addition of the stain till the maximum colour is obtained, whereas regressive staining involves overstaining the material and subsequently washing off the excess stain.

When aluminium alum is used as the mordant, the dye and the mordant solution can be kept mixed together forming the lake; but when iron alum is used, it cannot be kept mixed with the dye because of the possibility of heavy iron precipitation.

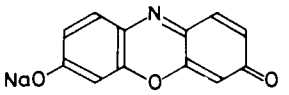
Haematein, after ferric mordanting, has a strong tendency to accumulate around densely stained materials. For this reason, it has most often been used in chromosome studies. On the basis of Heidenhain's schedule, the sections or smears in water are first mordanted in a strong solution of iron alum (4 per cent), followed by washing in water and staining in haematoxylin. Differentiation is carried out in a dilute solution of iron alum or picric acid to wash off the excess stain from the cytoplasm (*see* page 94). In properly

controlled differentiated preparations, chromosomes appear intensely black. After washing once more in water, the tissue is dehydrated through ethanol, cleared in xylol and mounted in balsam.

As haematoxylin acts as a non-specific basic dye, cytoplasmic components and spindle initially become coloured. As the differentiation is gradual in iron alum or picric acid solution, it can be adjusted to retain the spindle stain, if necessary. However, so far as plant chromosomes are concerned, haematoxylin staining is not very effective, due to the heavy cytoplasmic content. Animal materials (such as testes, smears of grasshopper and other insects, very thin sections, etc.) can be stained with haematoxylin, and being devoid of any strong acid or clove oil in the staining schedule, the chromosomal stain, once obtained, does not fade in permanent slides. Chromosomes of *Nephrops norvegicus* (Decapoda nephropidae) stain deeply with haematoxylin but not with orcein (Farmer, 1974). It has been superseded in recent years by crystal violet, acetic–carmine and other chromosomal stains due to the limitations of non-specific coloration, complicated procedure of preparation and the time-consuming process of differentiation observed in the haematoxylin schedule.

Lacmoid

Lacmoid (otherwise known as resorcin blue) is a blue acidic dye of the oxazine series. According to Conn (1953), the exact molecular structure of lacmoid is not fully worked out, but Gurr (1960) has given the following structure:



Oxazine

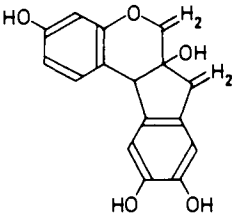
Its empirical formula is $C_{12}H_6NO_3Na$, the molecular weight being 235.173. It can be obtained by heating resorcinol with sodium nitrate until the smell of ammonia is no longer present. Similar to carmine, it can be used as an acid–base indicator and, when dissolved in acetic acid, it behaves as a basic dye. Unlike carmine, it is fairly soluble both in water and alcohols.

Darlington and La Cour (1942, 1960) used it in place of carmine, and acetic–lacmoid solution has been found to be very effective for the chromosomes of root tips, embryo sacs and pollen grains. Koller utilised this method for the study of the chromosomes of tumours. For comparatively compact tissues of plants, like root tips, similar to orcein, heating in acetic–lacmoid–HCl mixture is needed prior to squashing for dissolution of the pectic salts of the middle lamella. Cedarwood oil and euparal are recommended as mounting media.

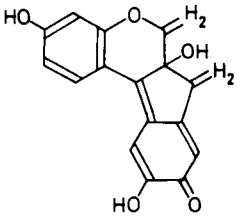
However, acetic–lacmoid as a stain cannot be universally applied like acetic–carmine. It has a comparatively limited application and may be tried on those materials where other stains have failed.

Brazilin

Belling (1924) and Capinpin (1930) used brazilin for staining chromosomes. It is a dye which is extracted from Brazil wood. Similar to haematoxylin, it



Brazilin



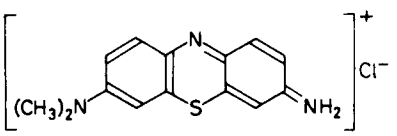
Brazilein

is not a dye in itself and its tinctorial property is due to brazilein—its oxidation product. In its preparation, like haematoxylin, it needs ripening.

The empirical formula of brazilin is $C_{16}H_{14}O_5$ whereas that of brazilein is $C_{16}H_{12}O_5$, the respective molecular weights being 286.272 and 284.256. Brazilin is highly soluble both in water and in alcohols. Under certain conditions, brazilin can act as an amphoteric dye. Belling (1928, as mentioned by Conn, 1953), used brazilin instead of carmine for staining plant chromosomes. Like haematoxylin, it has the defect of staining the cytoplasm as well, and even in the chromosome the stain is much weaker.

Azure A (Michrome No. 718)

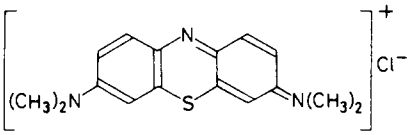
Azure A (a basic dye) is a member of the thiazine series and is violet blue in colour. It can be prepared by oxidation of methylene blue with potassium dichromate. It has the empirical formula $C_{14}H_{14}N_3SCl$, the molecular weight being 291.799. The structure is:



Himes and Moriber (1956) prepared leuco-azure A just like Schiff's reagent by substituting azure A in place of basic fuchsin. The aldehyde reaction in DNA of chromatin was obtained. De Lamater (1951) demonstrated nuclear staining by azure A in the presence of SO_2, after hydrolysing the tissue in normal HCl at 60 °C. Evidently, in such cases also, typical aldehyde reaction is demonstrated. Though it has been employed extensively in stomach, intestine, thyroid tissues and root tips of plants, the aldehyde reaction for the staining of chromosomes is much brighter with basic fuchsin than with azure A.

Azure B (Michrome No. 357)

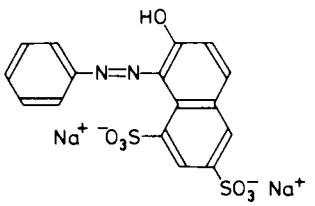
Azure B is also a member of the thiazine series and is prepared by the oxidation of methylene blue with potassium dichromate, though the method employed is slightly different from that of azure A. It is blue violet in colour and has the chemical structure:



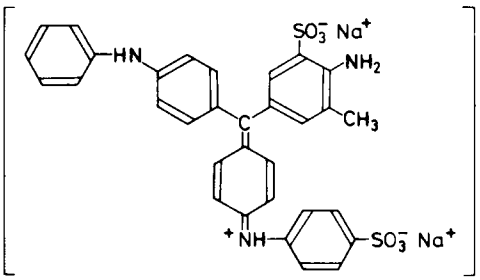
Although in a few cases staining with azure B is recommended more than that with azure A, Gurr (1960) considers that azure A staining, which is more convenient and less expensive, should be followed. However, Saez (1952) employed this stain for securing differential coloration of the sex chromosomes at the prophase stage of meiosis, and according to him, by hot water treatment, heterochromatic sex chromosomes can be made to stain *m*-chromatically instead of *o*-chromatically. Acid pH is, however, necessary. Flax and Himes (1952) obtained metachromatic staining of testes tissue. Their method involves treatment of the Carnoy-fixed tissue in tepid water for a few minutes, followed by staining for 3 h in Azure B solution (0.2–0.1 mg/ml in potassium citrate buffer, pH 4.0) and dehydrating in tertiary butanol before mounting.

Orange G–aniline blue

Orange G is an acid dye belonging to the monoazo series, with the structure:



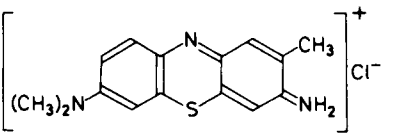
It is golden orange in colour, the molecular formula being $C_{16}H_{10}N_2O_7S_2Na_2$, and the molecular weight is 452.382. It is highly soluble in water and fairly soluble in ethanol. Mallory was the first to use this technique in combination with aniline blue. The latter is a blue acid dye belonging to the triphenyl methane series, its molecular weight being 737.736, and its formula $C_{32}H_{25}N_3O_9S_3Na_2$. It is used dissolved in water and has the structure:



La Cour (1958 in Darlington and La Cour, 1960, 1968) utilised the combination of these two dyes for staining heterochromatin at the resting stage and telophase, and chromosomes in other stages of mitosis. The basic principle of this staining is however not clear, though the dyes, being acidic in nature, may be considered as staining the protein component of the chromosomes. The protein stainability may be attributed to either of these two dyes.

Toluidine blue (Michrome No. 641)

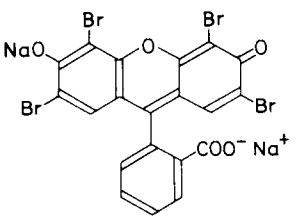
Toluidine blue, a basic dye of the thiazine series, is bluish violet in colour. Its molecular weight is 305.825, the formula being $C_{15}H_{16}N_3SCl$. The structure is:



Robinson and Bacsich (1958) suggested the preparation of a lake of toluidine blue with mercuric chloride or potassium iodide. The dried dye which is already mordanted, evidently yields a very intense colour, staining both types of nucleic acids, and it can be used selectively for DNA if normal hydrochloric acid hydrolysis is performed for a very short period prior to staining. Pelc (1956) utilised toluidine blue for staining through film in autoradiographic procedure, it being applied in an aqueous solution which is soluble both in water and alcohols. In view of its restricted application, it is not recommended as a general stain for chromatin.

Giemsa (Michrome No. 144)

Giemsa is not a single dye but a mixture of several dyes, namely methylene blue and its oxidation products, the azures as well as eosin Y. The quality of the stain varies with regard to the proportion of the dyes used.



Eosin y

Eosin Y itself is an acidic dye, rose pink in colour, and belongs to the xanthene series; for methylene blue and azures, reference should be made to the earlier part of this chapter. The combination stain, Giemsa, is generally prepared by dissolving the powdered mixture in glycerin and methanol, and in staining, chromatin is stained red and cytoplasm blue.

Giemsa has been used extensively for staining different types of bacteria (Robinow, 1941), and later in the study of nuclei and chromosomes of yeast by Lindegren, Williams and McClary (1956), McClary and colleagues (1957), Ganesan and Swaminathan (1958) and mammals. Darlington and La Cour (1960) have cited Belar as recommending Giemsa staining (Gelei, 1921) for animal or bacterial materials. In this modification, mordanting in ammonium molybdate is necessary before staining. The importance of Giemsa in chromosome staining has increased substantially after the advent of the banding pattern techniques in the early 1970s. The details are dealt with in Chapter 13.

Fluorochromes

Dyes for fluorescent staining have achieved increased prominence after the evolution of the methods for fluorescent banding of chromosomes based on the principle of staining with fluorochromes binding to a particular component of the nucleus, followed by observation under ultraviolet light.

Several fluorochromes bind specially to DNA or RNA, depending on the nature of the helix.

Acridine orange (AO, Gurr)
This has been used successfully in staining mammalian chromosomes as a 1:1000 solution in ethanol; the optimum period is 10 min. It is washed off in phosphate buffer at pH 7.6. It fluoresces green in combination with double stranded and red with single stranded nucleic acids. The methods of fixation affect the secondary nature of deoxyribonucleoprotein complex and interfere with AO-binding capacity of chromosomes.

Quinacrine dihydrochloride ($C_{23}H_{30}Cl\ N_3O.\ O.\ 2HCl.2H_2O$) (Winthrop or Sigma)
This dye is employed widely. For mammalian chromosomes, a 0.5 per cent solution in water is suitable. The period of staining ranges from 4 to 6 min, followed by washing for 2 min in distilled water and differentiation in McIlvaine's phosphate buffer solution at pH 5.5. Commercial antimalarial atabrine powder (atabrine dihydrochloride or atabrine hydrochloride) can be used in routine studies instead of chemically pure quinacrine dihydrochloride as 100 mg to 20 ml glass distilled water. The concentrations for specific staining may vary, as for example for mammalian Y chromosome analysis, and have been given under the respective chapters.

Quinacrine mustard (QM)
This chemical, initially synthesised by E. J. Modest at Boston, gives highly specific banding patterns, particularly of human chromosomes. It is regarded to bind DNA both through the alkylating group reacting primarily with the guanine content of DNA (Caspersson *et al.*, 1968) and by intercalation of the quinacrine group in the double helix of DNA. The amount of fluorescence exhibited by different segments of a chromosome stained with QM is controlled by the quantity of DNA located on them and by the qualitative

differences in QM-binding capacity of the DNA in different segments. The pattern is determined by irregularities in DNA distribution, reflecting the chromosome pattern and also by a superimposed pattern due to particularly strong QM-binding in particular locations. The accessibility of DNA to QM is determined by steric relations between DNA and chromosomal proteins. In the human karyotype, the pattern of QM-binding in approximately 98 per cent of the length of total metaphase chromosomes shows very constant and reproducible banding patterns, capable of identifying the segments. Some of the smallest bands used in identification, e.g. in chromosome 19 of human karyotype, contain the order of 10^{-15} g DNA, corresponding to about 10^6 nucleotide pairs or 100 to 1000 genes (Caspersson *et al.*, 1972).

Weisblum and de Haseth (1972), however, suggest that strong fluorescence with QM reflects the presence of DNA with high A–T content against Caspersson's contention that it indicates local differences in G–C content. Other workers (Kelberman and Barlow, 1971; O'Riordan *et al.*, 1971) are also of the opinion that since other fluorochromes, like quinacrine dihydrochloride (Q) and ethidium bromide, which lack the alkylating group, can induce similar bands as QM, it is unlikely that the selective binding of QM to the N_7 atom of guanine is responsible for specific banding patterns.

Proflavine and acriflavine

The fluorescence patterns produced by these chemicals are less clear and in some cases, quite different from the QM ones.

Ethidium bromide (EB, 2,7-diamino-10-ethyl-9-phenyl anthridinium bromide) Ethidium bromide reacts specifically with both DNA and RNA by intercalation, to form relatively stable complexes with markedly increased fluorescence (Waring, 1965; Le Pecq and Paoletti, 1967; Burns, 1971). Caspersson *et al.* (1972) and Vosa (1970) found that some plant chromosomes fixed in acetic–ethanol (1 : 3) and stained with EB gave a reversed pattern to QM while other plants stained uniformly. It yields reasonably consistent results with plant chromosomes but is less satisfactory with animal material. It (0.005 per cent) at pH 6.8, colours bright orange with native DNA and dull orange with denatured DNA.

Fluorescein-tagged reagents

These have been employed in antinucleoside antibody binding methods for the banding of human chromosomes (Dev *et al.*, 1972; Erlanger *et al.*, 1972; Freeman *et al.*, 1971; Schreck *et al.*, 1973).

Base-specific antinucleoside antibodies react with specific nucleoside bases in single stranded DNA *in vitro*. They attach to fixed chromosomes on being treated with denaturing agents like NaOH. A banding pattern may be obtained with antibodies which react specifically with only one of the nucleoside bases in DNA.

The anti-adenosine (anti-A) antibodies are prepared by immunising rabbits to adenosine monophosphate conjugated to bovine serum albumin. Antibodies to rabbit gammaglobulin are induced in sheep and fluorescein-tagged (for details, *see* Beiser and Erlanger, 1966).

Hoechst 33258
This is used as a stock solution of 50 μg/ml in water (Holmquist, 1975).

Quinacrine conjugates
Quinacrine derivatives of polylysine stain the chromosomes in a banded fluorescence pattern similar to QM. A 2×10^{-6} M solution of the QM-conjugate of poly-L-lysine ($\bar{n} = 24$, lysine/dye = 3) is used to stain leucocyte preparations, previously treated with McIlvaine's citrate–phosphate buffer (pH 4.1). Slides are washed and mounted in citrate–phosphate buffer (pH 7.0).

DNA-binding nucleoside specific antibiotics
Two DNA-binding guanine-specific antibiotics, chromomycin A_3 (CMA) and mithramycin (MM) have been used as chromosome fluorescent dyes, as also the A–T specific fluorochrome 4′-6-diamidino-2-phenylindole (DAPI). Non-fluorescent dyes may be used as counterstain—methyl green with CMA and actinomycin D (AMD) with DAPI.

SOME COMMON STAINS AND THEIR PREPARATION

Feulgen reagent (fuchsin sulphurous acid)

Materials required

Basic fuchsin	0.5 g
N HCl	10 ml
Potassium metabisulphite	0.5 g
Activated charcoal	0.5 g
Distilled water	100 ml

Preparation
Dissolve 0.5 g of basic fuchsin gradually in 100 ml boiling distilled water. Cool at 58 °C. Filter, cool the filtrate down to 26 °C. Add it to 10 ml N HCl and 0.5 g potassium metabisulphite. Close the mouth of the container with a stopper, seal with paraffin, wrap the container in black paper and store in a cool dark chamber. After 24 h, take out the container. If the solution is transparent and straw-coloured, it is ready for use. If otherwise coloured, add to it 0.5 g of charcoal powder, shake thoroughly and keep overnight in cold temperature (4 °C). Filter and use.

Alternatively, after dissolving the dye, bubble a stream of SO_2 through the solution. Filter and store (Itikawa and Ogura, 1954).

Precaution
Always keep the container sealed after use and store in cool temperature away from light. According to Lhotka and Davenport (1949), Feulgen reagent in sealed containers, kept at 0–5 °C, retains its efficiency for six months.

Modifications
(1) Newcomer (1959) doubled the amount of potassium metabisulphite in Schiff's reagent for staining tissues prior to embedding.

(2) *Acetic–basic fuchsin* is prepared by dissolving 1 g of basic fuchsin in 50 ml 40 per cent acetic acid at 50 °C, cooling to 25–30 °C and filtering. the staining process involves hydrolysis at 60 °C in N HCl for 15–60 s, followed by staining for 1–3 h and squashing in 30 per cent acetic acid (Tanaka, 1961).

(3) *Carbol fuchsin*

0.3% soln. of basic fuchsin in 5% phenol	45 ml
Glacial acetic acid	6 ml
37% aq. formaldehyde soln.	6 ml

It is found to be effective for human tissue cultures. The period of staining is 2–5 min (Carr and Walker, 1961). Insect chromosomes give good staining with carbol fuchsin following dissection of testis in 1 per cent sodium citrate and fixation in acetic–ethanol for 10 min (Yadav and Pillai, 1974).

(4) Tissues stained following Feulgen reaction can be squashed in 1 per cent acetic–carmine solution instead of 45 per cent acetic acid. It has been employed for studying chromosomes of eggs (Schreiber, 1954) and is effective for plant chromosomes as well.

(5) Fuchsin solution can be prepared in solvents other than water. 1 per cent basic fuchsin in 30 per cent ethanol (2 min) or 0.2–0.4 per cent fuchsin in 5–10 per cent lactic acid (5–20 min) have been employed on animal chromosomes (Makino and Nishimura, 1952).

(6) In a simplified method, Schiff's reagent can be prepared by adding fuchsin (1 g) and sodium metabisulphite (1.9 g) to 100 ml 0.15 N HCl, shaking mechanically for 2 h, decolorising with fresh activated charcoal and filtering (Lillie, 1951).

(7) Normal hydrochloric acid is substituted by trichloracetic acid (Sharma, 1951; Bloch and Godman, 1955); 5 N hydrochloric acid and 5 N nitric acid (Itikawa and Ogura, 1954); perchloric acid (Cassel, 1950; Di Stefano, 1952) as well as by bromine in carbon tetrachloride (Barka, 1956) and phosphoric acid (Hashim, 1952).

An alternative method (Barger and DeLamater, 1948) involves dissolving 1 g basic fuchsin in 400 ml boiling water. After cooling and filtration, 1 ml thionyl chloride is added. The solution is kept in the dark in a sealed chamber overnight. Shaking with activated charcoal (2 g) for 1 min, followed by filtering, yields a clear solution. The method is based on the reaction $SOCl_2 + H.OH = SO_2 + 2HCl$.

Purification of parafuchsin (pararosaniline CI 42500) (Gabler, 1965)
Dissolve 4 g parafuchsin in 800 ml ethanol at room temperature. Add 8 g activated charcoal, boil and filter immediately. Repeat this procedure four times, each time taking 8 g charcoal. Evaporate in vacuum with slight warming. After purification, dissolve in ethanol–chloroform mixture (1 : 1) and pass through an aluminium oxide column. The region to be eluted is indicated by a broad dark-red zone, which on drying in vacuum, after elution, yields a dye that can be decolorised by the usual procedure.

(8) Both plant and animal materials, after fixation, hydrolysis, and staining in leuco-basic fuchsin solution, can be stored in 45 per cent acetic acid for

an indefinite period at 14 °C. On squashing, the results are as good as fresh material. If the stain is faint, the material can be squashed in 1 per cent acetic–carmine or acetic–orcein solutions (Ford and Hamerton, 1956). Storage of somatic material in distilled water between Feulgen staining and squashing is, however, preferable to storage in 70 per cent ethanol between fixation and staining (Flagg, 1961).

(9) Some modifications of the use of basic fuchsin for fungi are (De Lamater, 1948):
   (a) Staining in 0.25 per cent aqueous basic fuchsin for 5–15 min.
   (b) Mordanting the hydrolysed cells in 2 per cent formalin for 2–4 min before staining.
   (c) Combining mordant and stain in a solution of 0.5 per cent basic fuchsin and 2 per cent formalin in 0.04 N HCl.

(10) Leucobasic fuchsin stains chromosomes from vitelline cell and testis squashes of the caryophyllidean tapeworm *Glaridacris larvei* (Grey and Mackiewicz, 1974).

Acetic–carmine, acetic–orcein, acetic–lacmoid

Materials required

(a) For 2 per cent solution:

Carmine, orcein or lacmoid	2 g
Glacial acetic acid	45 ml
Dist. water	55 ml

(b) For 1 per cent solution:

The same, except for 1 g of the dye

Preparation

Add distilled water to glacial acetic acid to form 45 per cent acetic acid solution. Heat the solution in a conical flask to boiling. Add the dye slowly to the boiling solution, stirring with a glass rod. Boil gently till the dye dissolves. Cool down to room temperature. Filter and store in a bottle with a glass stopper.

Precautions

Keep the mouth of the flask covered with cotton wool while the solution is being heated. Store acetic–orcein as 2.2 g dissolved in 100 ml glacial acetic acid. Dilute as needed.

Procedure

Acetic–carmine: use 1 per cent solution directly for staining and squashing; acetic–orcein or acetic–lacmoid: use 1 per cent solution directly for staining. Alternatively, heat the tissue for a few seconds in a mixture of 2 per cent solution and normal hydrochloric acid (9 : 1) and then squash in 1 per cent solution.

Modifications

(1) In the most common modification of acetic–carmine, variations of Belling's (1921) iron–acetic–carmine are used. Iron is added to 1 per cent acetic–carmine solution as ferric acetate, ferric chloride or ferric hydroxide in different proportions.

(2) A mixture of acetic–carmine (10.5 parts), 45 per cent acetic acid (4.5 parts), N HCl (2 parts) and 1 per cent fast green FCF solution in rectified spirit (1 part) forms a good stain for studying nuclear structures in protozoa (Dippell, 1955).

(3) For polyploids in *Bromus*, 1 per cent orcein in 45 per cent acetic acid is used for heating without any HCl (Markarian, 1957).

(4) For perithecia of Ascomycetes, an effective stain is made up by adding 3 g carmine to 50 ml acetic acid and 90 ml absolute ethanol. Boil gently for 6 h, make up to original volume with absolute ethanol. Filter. Expose the stain to air and light for one week and again make up to original volume with ethanol (Cutter, 1946).

(5) For studying Avian chromosomes from stored material, Newcomer (1952) devised a boiled mixture containing:

Vinyl acetate	10 ml
Tertiary butanol	10 ml
Propionic acid	50 ml
Dist. water	75 ml
Carmine	0.25 g
Orcein	0.25 g

Stored materials are stained and squashed in this mixture.

(6) For *Zaprionus* glands, pre-staining acid hydrolysis gives good results (Hartmann-Goldstein, 1961). The stain used is:

1% orcein in conc. lactic acid	50 ml
30% acetic acid	50 ml

The period of treatment is for 1 min in saturated acetic–carmine solution, followed by 5 min in the above stain and squashing in the same mixture. This stain has also been used for mouse embryos (Wroblewska and Dyban, 1969). A solution of 1 g orcein in a mixture of 28 ml 85 per cent lactic acid and 22 ml glacial acetic acid has been recommended for chromosomes of ants, Formicinae and Myrmicinae (Imai, 1966). Lacto–aceto–orcein, suitable for salivary gland chromosomes may be prepared by dissolving separately natural orcein in concentrated lactic acid and glacial acetic acid with boiling to obtain saturated solutions and then mixing the two filtered solutions with distilled water in the proportion 1 : 1 : 1 (Yoon, Richardson and Wheeler, 1973).

(7) An alternative stain for the same material is 2.5 per cent orcein in 60 per cent acetic acid, the period needed being 15–20 min.

(8) Treatment in 4–5 per cent aqueous pectinase solution for 45 min to 1 h before maceration in 1 per cent acetic–carmine solution gives good effects in pollen tube and p.m.c. smears (Pandey and Henry, 1959).

(9) In orchids, 2 per cent acetic–lacmoid solution in glacial acid has been used, diluted with an equal quantity of water. The roots are macerated in 10–20 per cent HCl for 5–15 min before staining (Wimber, 1956). Carmine solution, prepared by gently boiling in a mixture of acetic acid,

85 per cent lactic acid, and water (25 : 20 : 40) with a trace of rusty iron, for 1 h has been used effectively for orchid chromosomes. The root tips, after fixation in acetic–lactic–ethanol (1 : 1 : 4) for 4–16 h, are heated in concentrated HCl with 50 per cent ethanol (1 : 4), followed by treatment in 50 per cent ethanol for 5–10 min, then heating three times (at intervals of 5 min) in the carmine stain mixed with an equal amount of 50 per cent ethanol, and keeping for 1–2 h before squashing (Freytag, 1963).

(10) For *Cucurbita*, a stain was used containing 45 per cent acetic acid, 1 per cent acetic–carmine and brown storage solution (95 per cent ethanol with a flake of rusty iron), 1 : 1 : 1 (McGoldrick, Bohn and Whitaker, 1954).

(11) The preparation and application of propionic–carmine and propionic–orcein are similar to those of acetic–carmine and acetic–orcein except that propionic acid is used instead of acetic acid.

(12) Carmalum (Mayer)

Carminic acid	0.5 g
5% aq. potash alum soln.	100 ml

(13) Lithium carmine

Saturated aq. lithium carbonate soln.	100 ml
Carmine	5 g

Alternatively:

Lithium carmine powder	2 g
Dist. water	50 ml

Heat to boiling, cool and filter.

(14) Lactic–propionic–orcein, prepared by dissolving 2 g natural orcein in 100 ml lactic and propionic acids mixture (1 : 1) and diluted to 45 per cent with water, is very effective for p.m.c.s. For mitotic preparations, maceration in 1 N HCl at 60 C for 5 min between fixation and staining is necessary (Dyer, 1963).

(15) For *Solanum* microsporocytes, Matsubayashi (1963) advocated keeping the anther in 1 per cent acetic–carmine solution in 45 per cent acetic acid for several days till the contents were fully stained.

(16) A 1 per cent acetic–carmine : 2 per cent acetic–orcein : N HCl mixture (9 : 9 : 1) is effective for meiotic chromosomes of *Ipomea* (Raghuvanshi and Joshi, 1963).

(17) In a modification devised by Snow (1963), 4 g carmine is gently boiled in 15 ml distilled water to which 1 ml concentrated HCl has been added. After cooling, 95 ml 85 per cent ethanol is added and the solution is filtered. This stain can be used for tissues in bulk.

Crystal violet (Newton's schedule)

Materials required

Crystal violet	1 g
Dist. water	100 ml

Preparation

Dissolve the dye in water with constant stirring and boiling. Filter. Allow it to mature for a week before use.

Modifications

(1) If difficulty is experienced in staining with crystal violet schedule, dissolve 5 g commercial crystal violet in 10 ml absolute ethanol. Keep the solution in an open watch-glass and allow the ethanol to evaporate. On complete drying, weigh the stain and prepare an aqueous solution as usual.
(2) Infiltrate fixed root tips with chloroform, stain them for 15–30 min in leuco-basic fuchsin, wash in water for 1–4 h and double stain with crystal violet (Bowden, 1949).

Giemsa

Preparation of stock solution: 3.8 g of powdered Giemsa (R66-Gurr) is added to 250 ml glycerine or alternatively 1.0 g to 66 ml glycerine. The mixture is maintained at 55 to 60 °C for 1½ to 2 h. Then an equal quantity of methyl alcohol is added.

Preparation of phosphate buffer, pH 6.4

Solution A

11.336 g/100 ml dist. water or,
56.68 g/100 ml dist. water.

Solution B

8.662 g/100 ml dist. water or,
43.31 g/100 ml dist. water.

5 ml of each of the solutions A and B are mixed and made up to 1.0 l with distilled water. The pH is adjusted to 6.4 with 0.1 N HCl.

Preparation of stain

For mammalian materials, the Giemsa stain is prepared by adding 2 ml of the stock to 2 ml of the phosphate buffer (pH 6.4) and making up to 50 ml with distilled water. The slide is rinsed twice in distilled water followed by air drying. Variants of the stain are described under the respective schedules under the relevant chapters (*see* Sharma, A. and Talukder, 1974).

10 drops of Giemsa stain in 5 ml phosphate buffer stain mycelia of *Helminthosporium sativum* after 2 h treatment (Hrushovetz, 1956).

To obtain a Giemsa stain of uniform composition, oxidise methylene blue, neutralise and precipitate with eosin (Lillie, 1943).

Bismarck Brown

Can be used as a counterstain for Feulgen reaction for mast cells in mitosis. Fix mesentery of rat in 10 per cent formalin for 1 h. Stain first in Feulgen solution and then in 0.5 per cent Bismarck Brown dissolved in 50 per cent ethanol containing 0.2 per cent acetic acid (Meggers and Allen, 1962).

Phenyl diamine and quinone diimine (Meyer, 1948)

(a) *p*-Phenyl diamine	0.2 g
20% aq. acetic acid soln.	20 ml
30% aq. hydrogen peroxide soln.	0.1 ml

Dissolve the dye in hot acetic acid, add H_2O_2 and cool the mixture. Treatment for 1 h stains *Drosophila* salivary glands effectively.

(b) Quinone diimine	10 mg
70% aq. acetic acid soln.	1 ml

This solution also has a similar effect.

Trypan blue

Trypan blue	0.2 g
Cresol	10 ml
Absolute ethanol	60 ml
Dist. water	30 ml

This mixture has been recommended for plant smears (Hoffmeister, 1953).

Tetrachrome stain (MacNeal)

The components are rather similar to those of Giemsa and the stain used for mammalian chromosomes.

Ingredients

Methyl blue chloride	1.0 g
Azure A	0.6 g
Methylene violet	0.2 g
Eosin Y	1.0 g

Mixed when dry; also available in a commercial mixture form.

Preparation and use

0.15 g of dry mixture is dissolved in 100 ml neutral methanol by heating to 50 °C with shaking. The solution is kept at 37 °C for 24 h with occasional shaking. It is filtered and stored in a dark airtight bottle.

For use, 1.0 ml of the solution is added to 2.0 ml phosphate buffer pH 6.4 (prepared by adding 2.53 g disodiumhydrogen phosphate and 6.65 g potassium dihydrogen phosphate to 1.0 l distilled water). The staining mixture is shaken gently and the required amount placed on the slide with a dropper. The slide is stained for 2 min or more, washed in distilled water and air-dried.

Safranin

Safranin has a limited application in staining human chromosomes as a 2.5 per cent tincture in 95 per cent ethanol added to 100 ml distilled water. The slide is obtained for 30–60 s, washed in water and air-dried.

Wright stain

This stain has been employed for staining human chromosomes and nuclei rapidly (Tubiash, 1961).

Leishman stain

This has a limited application in mammalian chromosomes. 0.2 g of powdered dye is added to 200–250 ml distilled water, followed by 100 ml methanol. The mixture is warmed to 50 °C for 15 min with shaking. The solution is filtered and allowed to mature at 37 °C. The slide is stained in a few drops of this solution for 2 min, then flooded with its double amount of buffered water and kept in the diluted stain for 5–7 min. It is washed in distilled water and air-dried.

Thionin

Thionin has been utilised, with acid hydrolysis, for sections and smears of mammalian chromosomes.

The stock solution is prepared by dissolving 1.0 g thionin in 100 ml 50 per cent ethanol. For use, 32 ml of 0.1 N HCl and 28 ml of Michaelis buffer (prepared by adding sodium acetate, 9.7 g and sodium barbiturate 14.7 g to 500 ml boiled distilled water are brought to 100 ml with thionin stock solution at an effective pH of 5.7 $\pm$ 2, Culling, 1966; Klinger and Ludwig, 1957).

Toluidine blue

Toluidine blue has very limited application in mammalian chromosomes.

In a method for combined stain and mounting medium (Breckon and Evans, 1969), the stain is an aqueous solution of toluidine blue mixed with a saturated solution of a water soluble resin, usually dimethyl hydantoin formaldehyde, since its viscosity alters very little with increasing concentration. The powdered resin is mixed with water in the ratio of 70 g to 30 ml with periodic shaking, more resin being added till all has dissolved. The solution is filtered after a week and 2 per cent aqueous toluidine blue solution is added to it till tests with chromosome preparations show that it stains chromosomes satisfactorily an intense blue. Staining of the cytoplasm can be decolorised by immersion in 5 N HCl for 2 min at room temperature. The preparation can be air-dried after rinsing successively in 50 and 90 per cent and absolute ethanol.

Nigrosine

It is soluble in ethanol and is a complex basic dye of the azine series. It can be used as 1 per cent solution in 70 per cent ethanol for studying salivary gland chromosomes of *Drosophila* (Pares, 1953).

Acetic–dahlia (Ehrlich)

Dahlia is a reddish violet basic dye of the triphenyl methane series. A 2 per cent solution in 45 per cent acetic acid is useful in staining animal tissues. It has been used for squashing testes of moth larva and is used frequently in staining ascitic suspension.

Alcian blue (Allied Chemical)

A 1 per cent solution in 3 per cent acetic acid, pH 1.07 gives banding patterns with human chromosomes after 30–60 min.

Aniline blue

(a) Aqueous aniline blue

Aniline blue	1 g
Dist. water	100 ml

(b) Mallory's aniline blue–Orange G

Aniline blue	0.5 g
Orange G	2 g
Phosphomolybdic acid	1 g
Dist. water	100 ml

Gallocyanin (Einarson)

Gallocyanin	0.3 g
Chrome alum	10 g
Dist. water	200 ml

Methylene blue (Loeffler)

(a) Alkaline (Loeffler)

Methylene blue	3 g
Absolute ethanol	30 ml
1% aq. potassium hydroxide soln.	1 ml
Dist. water	99 ml

(b) Acidic (Lillie)

Methylene blue	1 g
0.5% acetic acid in 20% ethanol	100 ml

It can be used as counterstain after carbol fuchsin for bacteria.

Methyl violet (Jensen)

Methyl violet 6 B	0.5 g
Dist. water	100 ml

Neutral red (Jensen)

1% aq. neutral red soln.	10 ml
1% aq. acetic acid soln.	0.2 ml
Dist. water	100 ml

Celestine blue B with iron (Gray *et al.*, 1956)

Conc. sulphuric acid	0.5 ml
Celestine blue B	1 g
2.5% aq. ferric alum soln.	100 ml
Glycerol	14 ml

Add the acid to the stain and dissolve the mass in the mixture of ferric alum solution and glycerol.

Sudan black B

This is used in various combinations with some of the lower fatty acids and related acids (Cohen, 1949). For chromosomes of mouse, mix together equal parts of 1 per cent Sudan black B solutions in propionic acid, in 85 per cent lactic acid, in 20 per cent formic acid and water, and filter. Mix drops of cell suspensions of neoplasma; stain or mince the solid tissue and mix with the stain for 10–60 min. Dehydrate in ethanol vapour and mount in euparal or diaphane (Bunker, 1961).

Chlorazol black E

Chlorazol black E	1 g
Dist. water	100 ml

It has been used effectively on root tips and the chromosomes take up a deep black stain.

Brilliant cresyl blue

Brilliant cresyl blue	2 g
Glacial acetic acid	45 ml
Dist. water	55 ml

Dissolve the stain in the mixture of acid and water. It has been used for root tip chromosomes (Stewart and Schertiger, 1949).

Calcozine magenta XX has been used to stain *Allium cepa* chromosomes (Sweet, 1974).

Cresylecht violet

Cresylecht violet may be used for human chromosomes as a 1 per cent solution in distilled water.

Cresyl violet

1 per cent solution in 50 per cent acetic acid is found to be effective for both mosquito chromosome spreads and root-tip smears (Amirkhanian, 1964, 1968).

Cresyl violet acetate

Cresyl violet acetate as a 1 per cent aqueous solution stains human nuclei after 30 min (Ferguson-Smith, 1964).

Eosin-Stevenel's blue stain

This is used for mammalian materials.

Ingredients

Eosin, 1.0 g dissolved in 500 ml distilled water; Stevenel's blue, prepared by mixing 1.0 g methylene blue in 75 ml distilled water with 1.5 g potassium permanganate in 75 ml distilled water. The mixture is kept in a water bath at 100 °C for 30 min and filtered after 24 h.

Procedure

An air-dried preparation is kept in ethanol for 10 s; air-dried; immersed in eosin for 30 s, in Stevenel's blue for 30 s, in eosin for 10 s and again Stevenel's blue for 10 s, washing in running water in between successive immersions. It is finally air-dried and mounted (Grove, 1967).

Haematoxylin

(a) Heidenhain's stain

Materials required

Haematoxylin	0.5 g
96% ethanol	10 ml
Dist. water	90 ml

Preparation

Dissolve the stain in the mixture of 96 per cent ethanol and distilled water. Filter and ripen for 6–8 weeks.

(b) Delafield's stain

Materials required

Ammonium alum	10 g
Haematoxylin	1 g
Absolute ethanol	6 ml
Dist. water	100 ml
Glycerol	25 ml
Methanol	25 ml

Preparation

Dissolve ammonium alum in distilled water to prepare a saturated solution. Dissolve haematoxylin in absolute ethanol. Add the latter solution slowly to the former. Expose to air and light for one week. Filter. Add 25 ml glycerol and 25 ml methanol. Allow to stand, exposed to air, until the colour darkens. Filter. Store in a tightly closed container. Allow the solution to ripen for a month before use.

(c) Ehrlich's acid haematoxylin

Materials required

Absolute ethanol	100 ml
Glycerol	100 ml
Glacial acetic acid	10 ml
Haematoxylin	2 g
Dist. water	100 ml
Alum	in excess

Preparation

Dissolve haematoxylin in ethanol, add acetic acid, then glycerol and water. Allow the mixture to ripen in light, with occasional admission of air, till it acquires a dark red colour. For quick ripening, use either potassium permanganate or chloramine T and barium peroxide.

(d) Cole's iodine haematoxylin (1943)

Materials required

Haematoxylin	0.5 g
1% iodine soln. in 95% ethanol	50 ml
Warm dist. water	250 ml
Sat. aq. ammonium alum soln.	700 ml

Preparation

Dissolve haematoxylin in warm water. Add iodine and alum solutions. Bring to boil and allow to cool.

Modifications

(1) For quickly ripening haematoxylin stain, bubble pure oxygen through the freshly prepared stain (Hance and Green, 1959).

(2) Groat's modification of haematoxylin (1949)

Ferric ammonium sulphate	1 g
Sulphuric acid	0.80 ml
95% ethanol	50 ml
Haematoxylin	0.5 ml

Add these chemicals successively to 50 ml distilled water. Filter and use. The best period for staining is after 5 h and before 4–8 weeks of standing. Staining time is 3–30 min. De-staining can be done in a mixture of water (50 ml), rectified spirit (50 ml) and sulphuric acid (0.18 ml).

(3) Haematoxylin as nuclear stain was double stained by neutral red, followed by differentiation in aniline–xylol in paraffin sections (Duffett, 1949).

(4) Haemalum (Harris)

Haematoxylin	0.5 g
Mercuric chloride	0.25 g
Potash alum	5 g
Dist. water	100 ml

It has been used on tails of Urodele larvae (Finkhauser, 1945).

(5) Haemalum (Mayer)

Haematein	0.1 g
Absolute ethanol	5 ml
Potash alum	5 g
Dist. water	100 ml

(6) Chrome haematoxylin (Gomori)

5% aq. haematoxylin soln.	100 ml
Chrome alum	1.5 g
Potassium dichromate	0.1 g
Conc. sulphuric acid	0.1 ml

After staining for 15 min at room temperature, differentiation in 1 per cent HCl in ethanol for 1 min and counterstaining with phloxine is suitable for sections. For tissues, staining at 60 C for 40 min and differentiation in 45 per cent acetic acid for 30 min before squashing is recommended (Melander and Wingstrand, 1953).

(7) Harris's modification of haematoxylin

10% haematoxylin in absolute ethanol	5 ml
Mercuric oxide	0.25 g
10% aq. potash alum soln.	100 ml
Glacial acetic acid	4 ml

Mix the haematoxylin and alum solutions and heat to boiling. Add mercuric oxide and when the solution turns deep purple, turn off the heat. Cool and add acetic acid.

(8) Regaud's haematoxylin

10% haematoxylin in absolute ethanol	10 ml
Glycerol	10 ml
Dist. water	80 ml

(9) Weigert's haematoxylin

(a) 10% ripened haematoxylin in absolute ethanol	10 ml
Absolute ethanol	90 ml
(b) 30% aq. ferric chloride soln.	4 ml
Hydrochloric acid	1 ml
Dist. water	95 ml

Wittmann's acetic–iron–haematoxylin (1962)

Chrome alum	0.1 g
Iron alum	0.1 g
Iodic acid	0.1 g

Add to 6 ml of a mixture of HCl and ethanol (1 : 1). Treat plant material fixed in acetic–ethanol (1 : 3) in the mixture for 10 min, then in Carnoy's fluid (6 : 3 : 1) for 10–20 min, squash in a drop of stain containing 4 per cent haematoxylin and 1 per cent iron alum in 45 per cent acetic acid and heat gently. Lowry (1963) utilised this stain for studying basidia of agarics.

A further adaptation for materials not requiring hydrolysis, like leucocytes, ascites cells, etc. contains (Wittmann, 1965):

Stock solution:

Haematoxylin	4 g
Iron alum	1 g
45% acetic acid	100 ml
Ripen for 1–7 days.	

Stain (working solution):
Stock solution, 5 ml : Chloral hydrate 2 g.
(For schedule, *see* chapter on human chromosomes.)

This technique was modified by Serra and Vincente (1960) but does not have a wide application.

(10) Modification by Henderson and Lu (1968)
Stock:

(a) 2% haematoxylin
(b) 0.5% iron alum, both in 50 per cent propionic acid

Mix, keep for 1 day and use as carmine or orcein after fixation, or as a fixative-cum-stain. With unripened A, equal proportions of A and B are needed, but with increased ripening of A, the amount of B needed decreases.

Polychrome methylene blue

Polychrome methylene blue has been employed for mammalian nuclei (Field, 1940).

Ingredients

Stain A

Methylene blue	1.3 g
Disodium hydrogen phosphate	12.6 g
Potassium dihydrogen phosphate	6.25 g
Dist. water	500 ml

The first two ingredients are dissolved in 50 ml water, boiled and evaporated almost to dryness. Potassium dihydrogen phosphate and 50 ml freshly boiled water are then added with stirring. The solution is filtered after 24 h.

Stain B

Eosin	1.2 g
Disodium hydrogen phosphate	12.6 g
Potassium dihydrogen phosphate	6.25 g
Dist. water	500 ml

The phosphates are dissolved in warm freshly boiled water and the dye added. The solution is filtered after 24 h.

Procedure

The air-dried slide is kept in stain A for 1 to 2 s, rinsed in buffered water (pH 6.8 to 7.0) for 5 to 10 s, stained in stain B for 1 s and rinsed in buffered water for 10 s.

Some miscellaneous double stains

Gallocyanin and other stains

Tissues warmed in gallocyanin solution for 2–4 min can be counterstained in Biebrich scarlet, phloxine or eosin Y (Cole, 1947).

Safranin O and aniline blue

Root tips are stained 15 min in 1 per cent aqueous safranin O and rinsed in distilled water. They are then stained in 1.0 per cent aniline blue W.S. in 95 per cent ethanol for 2 min (Darrow, 1944).

Carbol fuchsin and methylene blue

Seminal fluid can be stained in a mixture of carbol fuchsin and rectified spirit (1 : 1), followed by a rinse in water and staining for 2 min in 1.3 aqueous methylene blue solution (Isenberg, 1949).

Orange G and aniline blue

These have been used for both mitotic and meiotic chromosomes. Sections fixed in chromic–formalin (1 : 1) are rinsed in potassium citrate buffer, stained in a mixture containing 2 g orange G and 0.5 g aniline blue dissolved in 100 ml potassium citrate buffer for up to 3 min, washed in the buffer, dehydrated and mounted (La Cour and Chayen, 1958).

Ruthenium red and orange G after fuchsin staining

Stem tips, after 30 min hydrolysis, are stained in fuchsin solution for 24 h, rinsed, stained in aqueous ruthenium red solution for 30 min, dehydrated, stained for $1\frac{1}{2}$ min in orange G in absolute ethanol and clove oil, run through clove oil and xylol and mounted in balsam. Chromosomes take up deep purple stain and resting nuclei less intense stain (Flint and Matzke, 1948).

Feulgen and a Schiff-type reagent

To check differential contraction by different pre-treatments, a common sample treated in two chemicals is stained separately, one in Feulgen and the

other in Schiff type reagent, Toluidine blue, Azure A or Chrysoidin yellow. After smearing under one cover glass, the contrast in colour can be used as an aid in analysis (Savage, 1967).

Mixed aniline blue–eosin B

5% aq. aniline blue soln.	2 parts
5% aq. eosin B soln.	1 part
1% aq. phenol	1 part

Liquefied semen can be stained in the above mixture at 40–60 C for 5–7 min (Casarett, 1953).

Croceine scarlet and celestine blue

Croceine scarlet	0.38 g
Celestine blue B	114 ml

The dispersion of the former dye in the latter gives results similar to haematoxylin–eosin (Gray and colleagues, 1958).

Crystal violet and eosin

(a) Crystal violet 1% aq. soln.
(b) 3% eosin–HCl in 70% ethanol

Prepared by adding 10 per cent HCl to 5 per cent aqueous solution of eosin Y, filtering, washing and drying the precipitate before dissolving in ethanol. It is used for selective staining of mitosis in follicle bulbs of sheep skin. Hydrolyse paraffin sections, after bringing down to water for 10 min in N HCl at 45 C, rinse in water, stain for 1 min in crystal violet solution, rinse, treat with Lugol's iodine (1 g iodine, 2 g potassium iodide, 100 ml water) for 1 min, rinse. Counterstain with eosin–HCl in 70 per cent ethanol for 5 s, rinse, keep in 70 per cent ethanol for 3 min, dehydrate, clear and mount (Clarke and Maddocks, 1963).

Staining tissue with small quantities of stain (Engle and Souders, 1952)

In order to stain tissues for long periods on slides with small quantities of dye, paraffin is painted on the free edge of a small glass beaker of 5 ml capacity. The stain is collected in the beaker. The slide to be stained is heated slightly and placed on the open end of the beaker so that the tissue to be stained is in the beaker. The beaker and slide are pressed together till the paraffin hardens. The slide and beaker are then inverted so that the tissue is immersed in the dye for the required period. Several slides can be stained with the same small quantity of dye.

6
Mounting

After staining, the tissue, whether in the form of section or smear, is mounted in a suitable medium for observation under the microscope. The nature of the medium depends on the type of stain used and the type of preparation required, and the process of mounting also depends on the medium used. If the tissue is observed under the microscope without mounting, it will usually dry up and be rendered opaque. The chief aims of mounting are to render the tissue transparent, to increase its visibility under the microscope, to hold it with the protecting cover-glass firmly in place and to preserve it for a period of time or indefinitely.

MOUNTING MEDIA

All preservative media may be used for mounting, though the only media that afford absolutely sure preservation of soft tissues are the resinous ones.

The prerequisites of a good mounting medium are:

(1) It should have a refractive index which is the same or slightly higher than that of the glass slide and almost the same as the tissue. If the tissue is impregnated with the medium, a light ray passing through the almost homogeneous mass of glass slide, embedding medium with tissue and cover-glass, will not be lost through refraction. This will aid in the optical visibility.
(2) It should harden quickly in contact with air so as to fix the cover-glass firmly to the slide.
(3) It should check de-staining and prevent acidity in the preparation.
(4) It should be stable and not decompose with storage or changes of temperature.

A number of substances are used as mounting media depending on the type of preparation desired. *Table 6.1* lists the commonly used ones with their refractive indices.

In addition to these chemicals, temporary squashes can be mounted either in stain or its solvent. For permanent mounts, some of these chemicals are more widely used than others. The better-known ones are now described.

Table 6.1 Refractive indices of mounting media*

Resin		*Solvents*		*Water-soluble media*	
Balsam (dry)	1.535	Absolute ethyl alcohol	1.367	Abopon	1.4372
Balsam (in xylol)	1.5322	Aniline oil	1.580	Apáthy-Lillie	1.4189
Balsam (60:40 in xylol)	1.5300	Castor oil	1.490	Distilled water	1.336
		Cedarwood oil (thickened)	1.520	Farrant's glycerol	
Clarite X (do)	1.5352	Cinnamon oil	1.567	Gum arabic	1.4417
Dammar resin (do)	1.5317	Clove oil	1.533	Fructose syrup	1.4362
Diaphane (colourless)	1.4777	Creosote	1.538	Glycerol jelly	1.4353
Euparal	1.483	Glycerol	1.4674	Glycerin (50% aq. soln.)	1.397
Harleco resin (in xylol)	1.5202	Liq. paraffin	1.471	Sea water	1.343
Lucite (in xylol)	1.4962	Methyl alcohol	1.323	Solution of white of egg	1.350
Mahady micromount (solid resin)	1.4879	Methyl benzoate	1.517		
		Oil of aniseed	1.557		
		Oil of bergamot	1.464		
Permount (solid resin)	1.5376	Oil of turpentine	1.473		
Polystyrene (in xylol 1:1)	1.5378	Olive oil	1.473		
		Polyvinyl alcohol	1.386		
Polystyrene (solid resin)	1.6279	Terpinol	1.484		
		Toluene	1.4956		
		Xylol	1.4982		

* Refractive index of Crown Glass: 1.518

Balsam

Balsam is probably the soundest mounting medium optically. When dissolved in xylol, its refractive index (1.53) is very close to that of glass (1.518). When quite dry, the refractive index is approximately 1.535. It also has almost the same optical dispersion as glass.

Preparation

It is an oleoresin collected from blisters formed in the bark of *Abies balsamea*. An oleoresin is an essential oil in which resins, themselves oxidation products of essential oils, are dissolved. The balsam used in cytological work, commonly known as Canada balsam, is a very thick, light yellow, transparent liquid, 24 per cent of which is essential oil. The remaining 76 per cent is composed chiefly of a resin soluble in both xylol and ethanol, and partly of a resin which is soluble in xylol but insoluble in ethanol. Hence Canada balsam is fully soluble in xylol but partially soluble in ethanol. On drying, the essential oils are removed.

Advantages
Canada balsam fulfils most of the conditions necessary for a perfect mounting medium. It has almost the same refractive index and optical dispersion as glass and is transparent and almost colourless. It is thick and affixes the cover-glass firmly to the slide and in the presence of air forms a very hard medium. It is stable and does not decompose or granulate in heat or after long storage.

Drawbacks
The chief drawback of Canada balsam is that it darkens and becomes acidic with time by slowly oxidising xylol, in which it is dissolved, to toluol and phthalic acids. The acidity causes certain basic stains to fade. Various neutral resins have been devised, such as neutral balsam in sealed tubes and 'Clarite X', to eliminate this possibility. Canada balsam and the allied modified media are usually used dissolved in xylol, though occasionally toluol, benzol, dioxane or trichlorethylene can also be used. The tissue, after staining, is usually dehydrated in ethanol and passed through xylol grades before mounting in balsam, but xylol can be replaced by any of the solvents mentioned above, both as ante-medium and as solvent for the mounting medium. Hillary (1938, 1939, 1940) recommended dioxane and dioxane balsam for dehydration and mounting.

Precautions
The essential precautions in using Canada balsam are: it should never be heated for melting, and a piece of clean marble can be kept inside the bottle to prevent acidity, replacing it occasionally with a fresh piece.

Dammar balsam or gum dammar

Dammar balsam or gum dammar is sometimes used for microscopical preparations, and is prepared by melting the solid gum over a hot flame in a container and then pouring it into the solvent, which is usually benzol. It is then carefully filtered and used. It is composed of unsaturated resin acids and a little ester (m.p. 100 °C).

Euparal

Euparal is used extensively. It is a mixture of camsal, sandarac, eucalyptol and paraldehyde and has a higher refractive index than Canada balsam. Camsal is a liquid formed by the mutual solution of the two solids, sodium salicylate and camphor, in the proportion of 3:2. Gum sandarac is an unsaturated acid resin, composed typically of sandaracolic acid and callitrolic acid.

Advantages
The advantages of euparal are: it does not dry too rapidly and, as it is soluble in butanol and ethanol, in addition to xylol, toluol, etc., the tissue can be

mounted directly from ethanol in euparal, thus shortening the dehydration schedule. Its use helps in keeping the material on the slide without involving the risk of being washed off.

Drawbacks

The drawbacks of euparal as a mounting medium are that it has a slight solvent action on celloidin, but this property can be taken advantage of in flattening out curled or too stiff sections; it has a tendency to cloud readily, but the cloudiness can be dispelled by slight warming.

Diaphane is a similar semi-synthetic mixture, allied to euparal.

Lactophenol

Lactophenol is a mixture of equal parts of phenol crystals, lactic acid, glycerin and distilled water, but the proportion of glycerin can be increased as necessary. The application of this medium is rather limited, however. Tissues can be mounted in it after staining or from any of the alcohol grades. The preparations have to be sealed as lactophenol is unable to attach cover-glasses firmly to the slides.

Cedarwood oil

The advantage of this medium is that its refractive index is very close to that of glass. It also preserves stains well. After mounting, however, cedarwood oil hardens only along the edges of the cover-glass, the inside remaining liquid. The tissue has to be dehydrated and then passed through xylol before mounting in this oil, as xylol is its most commonly used solvent.

Glycerin jelly

Glycerin jelly is probably the most widely used aqueous mounting medium. The medium is a mixture of gelatin, used as adhesive, glycerin, used for increasing the refractive index, cresol or phenol, used as a preservative, and distilled water.

Preparation

The mixture can be prepared, according to Baker, as follows: 5 g of gelatin are soaked in 25 ml distilled water for 1 h and then warmed in a hot bath until the gelatin is completely dissolved; 35 ml glycerin, 40 ml distilled water and 0.25 ml cresol are mixed together and kept in the hot bath. The two fluids are mixed thoroughly and filtered through a muslin strainer in an incubator and the medium is poured into its container whilst still warm. When needed for mounting the mixture is warmed so that it melts, and on cooling, or through evaporation, it sets into a gel and attaches the cover-glass firmly to the slide.

Alternative medium by Evens (1961):
Stock:

(a)	Gelatin	4 g
	Glycerin	60 ml
	Water to make	100 ml
(b)	Formalin	10 ml
	Glycerin	60 ml
	Water to make	100 ml

Mix in equal proportions before use. Add precipitated chalk for alkalinisation.

Another medium (Beeks, 1955) for use after 1 per cent acetic carmine contains:

Water	50 ml
Gum arabic	30 g
Chloral hydrate	200 g
Glycerin	16 ml

Uses
This medium is used for most temporary squash techniques, and the tissue can be transferred to it directly from water after staining.

The medium should be divided into several small containers as it deteriorates on continuous remelting.

Various other synthetic media

Various other synthetic media have also been devised from time to time, some of which are naturally occurring resins and others synthetic substitutes.

Styrene ($C_6H_5CHCH_3$)
It can be obtained as a plant product or can be synthesised. It is polymerised on heating.

Distrene 80
This is a derivative of styrene and its exact formula is not disclosed by its manufacturers. It is readily soluble in xylol and is a good mounting medium for tissues which have been dehydrated and brought through ethanol–xylol grades. It has, however, a tendency to shrink on drying, which can be prevented by adding a plasticiser, tricresylphosphate. This mixture is known as Kirkpatrick and Lendrum's DPX and is prepared by mixing 7.5 ml of tricresylphosphate with 40 ml xylol and adding to it 10 g distrene.

DPX mixture can be used in the same way as Canada balsam and its advantages are that the pH does not change on storage and it preserves the colour of basic dyes, and that the medium, being completely colourless, aids visibility.

Alternatively, dibutylphthalate can be used as a substitute for tricresylphosphate in DPX.

Clarite X
This is another synthetic medium and has the following advantages over Canada balsam: it is colourless, neutral, inert, homogeneous and dries

quickly. It cannot, however, be used for acetic–carmine preparations and becomes milky with ethanol. An 80 per cent solution in xylol is used for mounting plant specimens and a 60 per cent solution in toluol for animal tissues. The tissues have to be thoroughly dehydrated and passed through ethanol–xylol grades before mounting in clarite.

Several other resins are also available, like Abopon, but they are not so universally effective.

Oils

Several oils, like clove oil, castor oil, bergamot oil, aniseed oil, turpentine oil, etc., have been used as mounting media. Optically, they are quite effective, but their chief defect is that they thicken very slowly and do not attach the cover-glass firmly.

Polyvinyl alcohol

Polyvinyl alcohol is also frequently used as a mounting medium. It is prepared by adding 15 g of polyvinyl alcohol (Elvanol H-24 from Du Pont) to 100 ml cold distilled water, which is then stirred and heated till the resultant substance thickens, and is then filtered and used as stock solution; 56 ml of the stock solution is mixed with 22 ml lactic acid and 22 ml phenol to give the required mounting medium. Its refractive index is 1.386, which increases with the evaporation of the alcohol. The sections can be mounted in it directly from 70 per cent ethanol. However, it is not very good for eosin-stained material.

PROCESSES OF MOUNTING

Depending on the medium used and on the type of preparation required, the different schedules, used after staining, can be classified into the following groups:

(1) temporary mounts;
(2) permanent mounts further divisible into:
    (a) permanent mounts of sections,
    (b) permanent mounts of squashes and smears directly processed for permanency,
    (c) permanent mounts prepared indirectly from temporary squashes and smears;
(3) miscellaneous.

For observations under phase contrast, Crossman (1949) suggested temporary mounting in aqueous glycerin or butyl carbitol to find out the proper index liquid. Later, a solid mounting medium having a close refractive index is substituted.

Temporary mounts

Temporary mounts are made mostly of squashes and smears. The medium for mounting is either the stain itself or its solvent. In the former case, the processes of staining and mounting are done simultaneously, the tissue then being lifted on to the slide containing a drop of the stain and squashed as described in Chapter 5. In the latter, the tissue is stained and squashed on a slide in a solvent of the stain. In both cases, the cover-glass is ringed with paraffin wax and then observed.

The usual media are the stains themselves, for example:

1 per cent acetic–orcein solution
Tissues heated in 2 per cent acetic–orcein–N HCl mixtures are squashed in 1 per cent acetic–orcein solution and the preparations are sealed for observation, for example, root tips, tumour tissue, endosperm, leaf tip, etc. Alternatively, the tissues are directly placed in a drop of 1 per cent acetic–orcein solution, squashed as usual and sealed—for example, anther cells, testes, etc.

1 per cent acetic–carmine solution
Anthers, testes, etc., can be directly squashed in 1 per cent acetic–carmine solution and sealed. Root tips and similar tissue, after heating in 2 per cent acetic–orcein–N HCl mixture or 2 per cent propionic–carmine–N HCl mixture can be squashed in 1 per cent acetic–carmine solution (Zirkle, 1939).

1 per cent propionic–carmine solution
This can be used instead of 1 per cent acetic–carmine in similar types of tissue, particularly where background cleansing becomes necessary.

1 per cent acetic–orcein solution
This is used in cases similar to 1 per cent acetic–orcein for squashing and mounting tissues which have been heated in 2 per cent propionic–orcein–N HCl mixture.

Solvents are, for example:

Distilled water
For immediate observation, tissues can be mounted in distilled water after staining and the cover-glass ringed with paraffin. However, the tissue cannot be kept intact for any long period.

Sea water
Sea water is also suitable as a temporary mounting medium after staining in any of the aqueous stains.

45 per cent acetic acid
This is used for squashing stained tissues. For example, tissues stained in Feulgen solution or in 2 per cent acetic–orcein–N HCl mixture can be

squashed and mounted in 45 per cent acetic acid. Alternatively, smears of tissues on slides, stained in Feulgen solution can also be mounted in 45 per cent acetic acid.

Subsequent to ringing the cover-glass with paraffin, the slides can be kept for nearly a week, after which the material tends to dry up. Dentists' sticky wax can also be used for ringing coverslips (Conger, 1960). The rubber solution is also widely used for sealing temporary preparations.

Permanent mounts

Permanent mounts indicate mounting the tissue, after suitable processing, so that the preparations can be kept for a long period, often for several years, without appreciable distortion of the structure or intensity of stain.

Permanent mounts of sections from paraffin blocks

The different steps in the process usually depend on the medium in which the stain is dissolved. In general, the entire process is based on first dehydrating the tissue, then impregnating it with the solvent of the mounting medium and finally mounting with the medium chosen.

The most commonly used dehydrating agent for paraffin sections is ethanol, though acetone and various other alcohols are also used. As the tissue has already been embedded in paraffin and therefore has attained a permanent shape, dehydration does not have to be done in gradual stages. If the stain is dissolved in water, the sections can be transferred directly to absolute ethanol after staining and mordanting. If, however, a counter-stain in a lower grade of ethanol is applied, the tissue has to be passed through the required grade before transference to absolute ethanol. Usually two or three jars containing absolute ethanol are kept and the slides are kept for 4–5 s in each.

The slides can be transferred directly from absolute ethanol to the mounting medium, e.g. to euparal or to a mixture of the solvent of the mounting medium and absolute ethanol in equal proportions, then to the pure solvent, as in the case of preparations stained in Feulgen and mounted in Canada balsam. Alternatively, they may be transferred to a differentiating medium for removing excess of the stain before transference to the solvent of the mounting medium, for example, tissues stained in crystal violet and mounted in Canada balsam.

The choice of differentiating or clearing medium usually depends upon the stain used. The most suitable differentiating agent for crystal violet or gentian violet is clove oil. It removes superfluous stain from the cytoplasm, thus rendering the stain in the chromosomes brighter, and also completing the dehydration. Usually the slides are kept for 2–5 min in the clearing medium. As soon as the surplus stain is washed off, they are transferred to the pure solvent for the mounting medium. Often two jars of clove oil are kept as, after some time, clove oil gets slightly coloured. The clearing agent may be a solvent for the stain or a mordant, as iron alum solution for haematoxylin stain.

The next step is to transfer the tissue to a solvent of the mounting medium. This step can be omitted for mounting media which are soluble in absolute ethanol, like euparal and lactophenol. For Canada balsam, which is partially insoluble in ethanol, an intermediate step of transfer to xylol is needed. The sections may be kept from half an hour to an indefinite period in xylol. Usually two or three successive jars of xylol are used, as the xylol in the jar immediately after the clove oil grades tends to become coloured. In such cases, the slides are kept for the longest period in the xylol immediately preceding the mounting medium, to remove all traces of clove oil from sections along with clearing.

The last step is to mount the sections in the mounting medium. Rectangular cover-glasses are generally used for mounting sections. The instruments required are a needle and a pair of forceps. The slide is lifted out and the xylol drained off. The under-surface of the slide is wiped and it is placed face upwards on a sheet of blotting paper. A drop of the mounting medium is placed near the end of the slide at the left side of the sections, and a clean cover-glass is lifted up by means of the forceps and is placed with its left edge touching the slide—the right edge of the cover-glass is kept tilted upwards with the forceps or with a needle. The cover-glass is allowed to settle down slowly on the drop of medium by gently lowering the needle, and as the cover-glass descends it slowly pushes the medium ahead and helps it to spread uniformly throughout the area of the cover-glass. After the entire cover-glass has settled down, the forceps or needle supporting it is removed and the cover-glass is pressed slightly from the top to remove any air bubbles that might have lingered within the medium. The slides are then kept, face upwards, on a hot plate between 35 and 45 °C for a day or two and finally, when partly dry, they are kept in slide cabinets.

The necessary precautions which have to be adopted during mounting are as follows.

The cover-glasses must be absolutely clean and dry. They should be kept in rectified spirit, thoroughly wiped with a clean cloth before use and kept on a clean piece of paper in a tilted condition. If necessary they are passed quickly through an ethanol flame for dehydrating. They are handled with a pair of fine forceps or, if fingers are used, they should always be held across the edges to avoid any smudges. The mounting medium must be placed on the slide as quickly as possible after lifting it out of xylol. Otherwise the sections may dry up. The cover-glass is placed very gently on the medium to prevent air bubbles entering the preparation.

The size of the drop of mounting medium depends on the thickness of the medium and the size of the cover-glass. If after mounting it is found that the medium does not cover the entire area within the cover-glass, a small drop of medium can be inserted under one edge of the cover-glass, holding the slide in a slanting position. If, however, the medium is in excess, the top of the slide and cover-glass are wiped carefully with a soft cloth moistened in xylol to remove the excess medium.

When the cover-glass is first applied, it should be held in the exact position desired. After settling down, it should never be removed sideways in any direction, as otherwise the sections may be damaged.

For sections embedded in celloidin, a slightly different procedure is followed. Since celloidin has a suitable refractive index, it can be retained

in the final mount, because it holds the cells together. For this purpose, dehydration with ethanol is omitted, as celloidin is soluble in ethanol. The slide, after staining, is passed through 90 per cent ethanol to ethanol–chloroform mixture (1 : 1) and kept in it for 2 min. It is next transferred to a mixture of absolute ethanol, chloroform and xylol (1 : 1 : 1) and kept for 2 min. Finally the slide is given two changes in pure xylol and mounted in Canada balsam or in one of the synthetic resins.

Permanent mounts of squashes and smears directly processed for permanency

These more or less follow the same procedure as that used for permanent mounts of paraffin sections. With Canada balsam and synthetic resins the usual steps of dehydration in absolute ethanol are followed, the period being reduced to 2–3 dips in each jar. Differentiation in clove oil, if necessary, is done for 5 min. The period of treatment in xylol is from 1 h to overnight.

With euparal or other mounting media, clove oil and xylol stages are not necessary.

Permanent mounts prepared indirectly from temporary squashes and smears

Several techniques have been devised to render the temporary squashes and smears, as described previously, permanent. They can be divided into two general categories: methods involving the removal of the cover-glass, and methods without removing the cover-glass.

The methods involving the removal of the cover-glass are quite numerous. They generally face two difficulties, namely: the problem of attaching the tissue to the slide after the cover-glass has been removed, and the problem of retaining the stain. Some of the more commonly used techniques are discussed here.

The acetic–alcohol schedule was first devised by McClintock (1929, 1942), and modified forms of this method are used even now. This technique is based on the principle of detaching the cover-glass in a solvent, dehydrating and clearing before mounting in the desired medium.

The solvent used for detaching the cover-glass is either an aqueous solution of the acid in which the medium used in mounting the tissue has been dissolved, or a mixture of the acid and the dehydrating agent.

For tissues stained and mounted in stains dissolved in 45 per cent acetic acid, like acetic–carmine, acetic–orcein or acetic–lacmoid, 10 per cent acetic acid or a mixture of glacial acetic acid and absolute ethanol (1 : 1) is used. On the other hand, for propionic–carmine or propionic–orcein, 10 per cent propionic acid or a mixture of propionic acid and absolute ethanol (1 : 1) is used. Similarly for tissues mounted in 45 per cent acetic acid, like those stained by the Feulgen reaction, 45 per cent acetic acid or acetic ethanol (1 : 1) is a good solvent.

The paraffin seal around the cover-glass of the temporary preparation is removed carefully by wiping the top of the cover-glass with xylol. The slide is now inverted in a covered tray containing the solvent. The cover-glass detaches and falls to the bottom of the tray after some time. A part of the material adheres to the cover-glass and comes off with it. The slide and cover-glass are transferred to a mixture of the acid and absolute ethanol (1 : 1) and treated for 15 min. Later they are passed through acetic–ethanol

mixture (1 : 3) and two grades of absolute ethanol, keeping them 5 min in each. If needed, slides with tissues stained in 1 per cent acetic–carmine solution are mounted in euparal, while those with tissues stained in acetic–orcein or acetic–lacmoid are mounted in cedarwood oil or euparal.

To mount the preparation in Canada balsam, however, the slide with tissue and cover-glass is transferred from absolute ethanol to ethanol–xylol mixtures (1 : 1), and (1 : 3) and finally to pure xylol, keeping it in each for about 5 min. It can be kept in pure xylol for 30 min and then mounted in Canada balsam. The slide and the cover-glass are mounted separately.

Different variations of this basic schedule are available, depending mainly on the periods of treatment and the different stages of dehydration.

The drawbacks of this system are that the process is rather time consuming, particularly if the ethanol–xylol grades are incorporated, and a lot of the material is lost while passing the slide through the grades. In spite of careful handling, the material is liable to be washed away while transferring the slides. An airtight container lined with absorbent paper which is saturated with ethanol for 24 h can be employed for dehydration (Bridges, 1937).

The tertiary butanol schedule

This involves the use of tertiary butanol as a solvent as well as a dehydrating agent.

After the seal has been removed from the cover-glass, the slide with the material is kept in a covered tray containing tertiary butanol overnight. The cover-glass, which has fallen off, and the slide are now mounted separately in euparal.

This technique is applicable to tissues stained with almost all stains. It has the advantage over the acetic–ethanol schedule of being much less complicated and, hence, the loss of material is also much reduced. However, it has been found in the authors' laboratory that the stain of the tissue made permanent through the tertiary butanol technique shows a tendency to diffuse.

Alternatively, the slide may be passed through glacial acetic acid–butanol grades (1 : 1, 1 : 3) till the cover-slip is detached, before treating in butanol and mounting in euparal (Celarier, 1956).

Dry ice technique

This method was devised by Conger and Fairchild in 1953. It is at present the most convenient technique for making temporary preparations permanent and is based on the principle of freezing a temporary preparation on dry ice to remove the cover-glass and subsequently dehydrating it before mounting.

Slides are frozen at the stage at which dehydration would ordinarily begin or at the time at which slide and cover-glass would be separated. Acetic- or propionic-stained slides are frozen while they are still in the stain, while Feulgen-stained tissue is frozen after squashing in 45 per cent acetic acid.

The slide is laid on a flat block of dry ice with the cover-glass facing upwards. It is then pressed against the ice with weights or with a hard scalpel or pencil so that the material is completely frozen. The usual time for freezing is 30 s, but a longer period is not harmful. The cover-glass is prised off by inserting a blade between it and the slide.

The frozen slide and cover-glass are lifted off the block of dry ice and placed immediately, before thawing, in 95 per cent or absolute ethanol. After treatment for 5 min, they are transferred to another jar of absolute ethanol, where they can be kept from 10 min to 5 h. They are then mounted in euparal. Temporary preparations, in which the stain has partly diffused, can be cleared by adding 5–20 per cent acetic acid to the first ethanol.

The advantages of this technique are its speed, the ease with which the cover-glass is separated, prevention of the loss of material and the retention of the original stain in the permanent slides.

The precautions to be observed during this process are: the frozen slides must be transferred to 95 per cent ethanol immediately, before thawing; the slides should be removed from the last alcohol without draining off the excess liquid; a large drop of euparal should be used in mounting, and the excess mounting medium allowed to dry and not pressed out.

The only drawback so far observed is that the cells occasionally collapse on being transferred to the mounting medium from absolute ethanol.

Liquid air can be used as an alternative for dry ice for freezing materials mounted in slides and covered with a cover-glass. Liquid CO_2 can also be used. The slides are clamped to a 22 mm square hole on a freezing microtome specimen holder. The cover-slip is removed, the specimen dehydrated and mounted (Bower, 1956). A surgical microtome freezing head can be modified to allow rapid freezing (Johnson and Janick, 1962). In order to remove cover slips from old preparations, the slide is frozen for 10 min, the cover slip removed and the slide remounted with new balsam (Simms, 1957). Instead of CO_2 or liquid air, a Freon-aerosol mixture can be sprayed on to the slide, with a nozzle spray tube, for a few seconds, to cover the underside (Elston and Sheehan, 1967).

For permanent mounts, after staining mammalian tissue for 5 min in acetic–orcein at 60 °C, the tissue is rinsed in chilled ethanol–acetone mixture (1 : 1), held for 2 h or more at 20°C by dry ice. It is differentiated for 30 s at room temperature in 95 per cent ethanol with 1 per cent HCl, counterstained in 0.01 per cent fast green FCF in ethanol for 10 s, passed through xylol and mounted (Peary, 1955).

In all techniques where removal of the cover-glass is involved, it can be prepared by smearing thinly with Mayer's albumin and drying over the flame for a few seconds. It may otherwise be coated with silicon (Dri-film 9987 from General Electric). These treatments facilitate its removal.

Alternative schedules

After staining with haematoxylin, coal tar dyes or other stains, the coloured pieces are immersed in glycerin and squashed. The glycerin is removed with water by capillarity and later by ethanol. The slide is mounted in an ethanol-soluble resin (Serra, 1947).

A commercial preparation, Clearcol, can be added in the final stage of any acetic–carmine squash schedule to make the stain permanent, thus omitting dehydration and clearing (Zuck, 1947).

The technique for making a preparation permanent without removing the cover-glass is based on dehydrating and mounting the tissue by allowing a

few drops of the fluid to run beneath the cover-glass, without dislodging it.

The paraffin seal is first wiped off with xylol. A drop of the stain in which the tissue has been mounted is placed at the end of the cover-glass and allowed to penetrate under it. The slide is placed on an end in an ethanol vapour jar and left for 4–6 h. A few drops of absolute ethanol are placed at the edge of the cover-glass and allowed to flow under it; then it is pressed out. Euparal is now applied all around the edge of the cover-glass and the slide is placed with the cover-glass in an ethanol vapour container in which the atmosphere is *not* ethanol-saturated. (For this 10–15 drops of absolute ethanol may be used in a closed pair of petri dishes of 10 × 10 × 1.5 cm dimensions.) The slide is removed after 24 h and the mounting medium allowed to harden at room temperature. After acetic–iron haematoxylin squashes, the cover slip can be ringed with Karo corn syrup or the squash mounted in the syrup, after removing the cover slip, by CO_2 freezing (Wittmann, 1963).

Miscellaneous

Some media have been invented for staining, fixing and making permanent mounts in a single step for different objects. Of these, two methods devised by Traub are effective.

Traub's T-101 method

This medium can be used with the Feulgen reaction or when acetic preparations are squashed in 45 per cent acetic acid. It is prepared by mixing 1 g of pure dry arabinic acid with 1.2 g 83 per cent sorbitol syrup ('Artax') and 9.8 ml 45 per cent acetic acid, and allowing to stand in the dark at 25 °C until the arabinic acid dissolves. The period may be for several months. The clear supernatant liquid is decanted and used.

After staining, the tissue is squashed in one drop of the T-101 medium on a slide. The excess medium is blotted off and the acetic acid in the medium within the cover-glass is allowed to evaporate in a low temperature, causing the medium to solidify.

Traub's T-103 method

This can be used for natural orcein and carmine stained preparations but is not recommended for synthetic orcein. The medium contains 1 g of arabinic acid, 1.2 g of 83 per cent sorbitol syrup and 98 ml Belling's 1 per cent ferric acetic–carmine solution. It is prepared in the same manner as T-101.

The tissues, after staining, are placed in a drop of the medium on a slide and squashed. The slide is gently heated and the cover-glass pressed down tightly. The acetic acid soon evaporates at room temperature, causing the medium to solidify. If the stain of the tissue tends to fade, the proportion of the dye in the medium may be increased.

Venetian turpentine mounting medium

Venetian turpentine—a natural resin mixed with a small amount of water and carmine—was used as a combined staining and mounting medium (Zirkle, 1940). The carmine was frequently precipitated however and the resin

was insufficient to prevent drying. A modification by Wilson (1945) omitted the carmine and iron mordant was used. A recent medium contains venetian turpentine 50 ml, 90 per cent liquid phenol 45 ml; 98 per cent propionic acid 35 ml, glacial acetic acid 10 ml, and water 15 ml (Haunold, 1968). Root tips stained in Feulgen are macerated in a minimum amount of propionic–carmine. A drop of the mounting medium is mixed with carmine, the cover slip applied and firmly squashed.

Representative schedules for direct observation of chromosomes from plants and animals

Some sample schedules for the study of chromosomes in different tissues are considered in this chapter.

SCHEDULES FOR THE STUDY OF MITOTIC CHROMOSOMES

In plant materials

In root tips

Schedule A. From paraffin sections dehydrated through alcohol chloroform grades and stained in crystal violet

Material used
Fresh young roots of *Allium cepa*. The following steps are involved:

(1) *Fixation* Cut fresh root tips of *Allium cepa*, about 1 cm long, wash away dirt particles with water and a brush and transfer the root tips to a tube containing a mixture of 1 per cent chromic acid and 10 per cent formalin (CF 1 : 1). Keep for 12–24 h.

(2) *Washing* Wash the roots in a porcelain thimble in running water for 3 h.

(3) *Dehydration* Transfer the roots to a glass phial containing 30 per cent ethanol and keep for 1 h; then to 50 per cent ethanol, keeping for 1 h; to 70 per cent ethanol, treating overnight; through 80, 90 and 95 per cent ethanol, keeping the roots for 1 h in each. Finally keep overnight in absolute ethanol.

(4) *Clearing* Keep in ethanol–chloroform mixtures (3 : 1, 1 : 1 and 1 : 3) successively for 1 h in each.

Transfer to pure chloroform and keep for 10 min; then change the used chloroform with pure chloroform, and add small shavings of paraffin.

(5) *Infiltration* Keep overnight on a hot plate at 35 °C, then remove the stopper, add a little more wax and keep the phial with contents at 45 °C

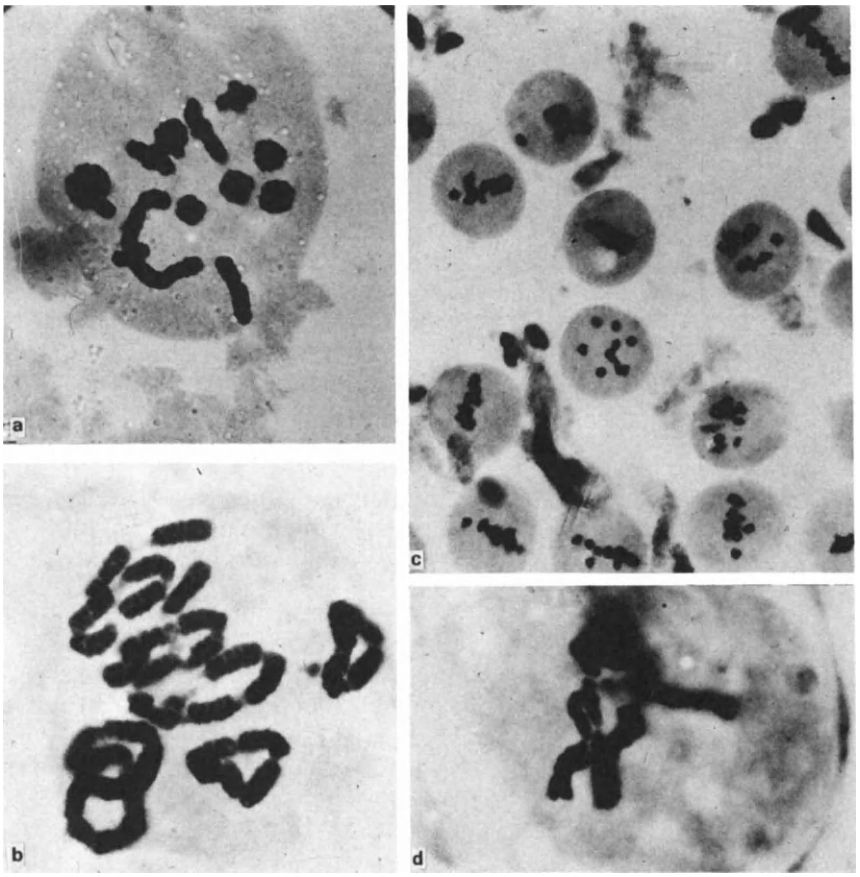

Plate 7.1
(a) to (c) *Acetic-carmine pollen mother cell smears:* (a) *of* Commelina zebrina, *showing one quadrivalent and ten bivalents:* (b) *of* Tradescantia virginiana *showing quadrivalents; and* (c) *of* Cyanotis axillaris *showing secondary association of ten bivalents.* (a), (b), (c) (courtesy of Drs. U. C. Bhattacharyya and S. Sen, Cytogenetics Laboratory, Department of Botany, University of Calcutta). (d) *Somatic crossing-over in* Haplopappus gracilis (2n = 4), *from a free floating cell in tissue culture* (courtesy of Drs. J. Mitra and F. C. Steward and the Editor, *American Journal of Botany*)

for 2 days and transfer to 60 °C. Change the wax containing the material with fresh molten wax at intervals of 30 min for 2 h.

(6) *Embedding* Pour the molten paraffin with roots into a paper tray and add some more molten wax, then orient the roots in groups of three with their tips pointing to the same side at the same level. After the wax has cooled slightly, plunge the block into cold water.

(7) *Section-cutting* Trim the block and cut transverse sections of the root tips 14 μm thick on the microtome. Cut the ribbons into suitable segments and mount serially in water on a slide previously coated with Mayer's adhesive. For coating a slide, put a tiny drop of Mayer's adhesive, about the size of a mustard grain, on the slide and smear it three-quarters over the surface, then place the slide on a hot plate and help the ribbons to stretch with a pair of needles. Drain off the water and keep the slide overnight on the hot plate to dry.

(8) *Bringing to water* Place the slide with sections in pure xylol grades I and II, keeping in each for 30 min. Transfer the slide to a jar of ethanol–xylol (1 : 1) and keep for 15 min, then pass through absolute ethanol, 95, 90, 80, 70, 50 and 30 per cent ethanol, keeping in the first 3 for 10 min each, and 5 min in each of the rest, and then transfer to water.

(9) *Pre-mordanting* Keep the slide in 1 per cent aqueous chromic acid solution overnight. Wash in running water for 3 h.

(10) *Staining* Stain in 0.5 per cent aqueous crystal violet solution for 20 min. Rinse in water.

(11) *Mordanting* Keep in 1 per cent iodine and 1 per cent KI mixture in 80 per cent ethanol for 30–45 s, then dip in absolute ethanol for 2 s.

(12) *Dehydration* Pass through three successive grades of absolute ethanol dipping in each for 2 s.

(13) *Differentiation* Transfer to clove oil I, then differentiate under the microscope after keeping in clove oil II for 2 min.

(14) *Clearing* Transfer to xylol grade I and keep for 30 min; pass through pure xylol II and III, keeping 1 h in the former and 30 min in the latter.

(15) *Mounting* From xylol III, mount in Canada balsam under a cover-glass. Allow the slide to dry overnight on the hot plate.

Alternative fixative

Any one mixture of the list of fixatives given in the chapter on fixatives can be used, depending on the material.

Alternative clearing agent

n-Butyl alcohol can be used instead of chloroform in the clearing process.

Alternative pre-mordanting

For materials which stain easily, pre-mordanting in 1 per cent chromic acid solution can be omitted; for materials difficult to stain, Navashin's fluid A can be used instead of 1 per cent chromic acid solution in pre-mordanting.

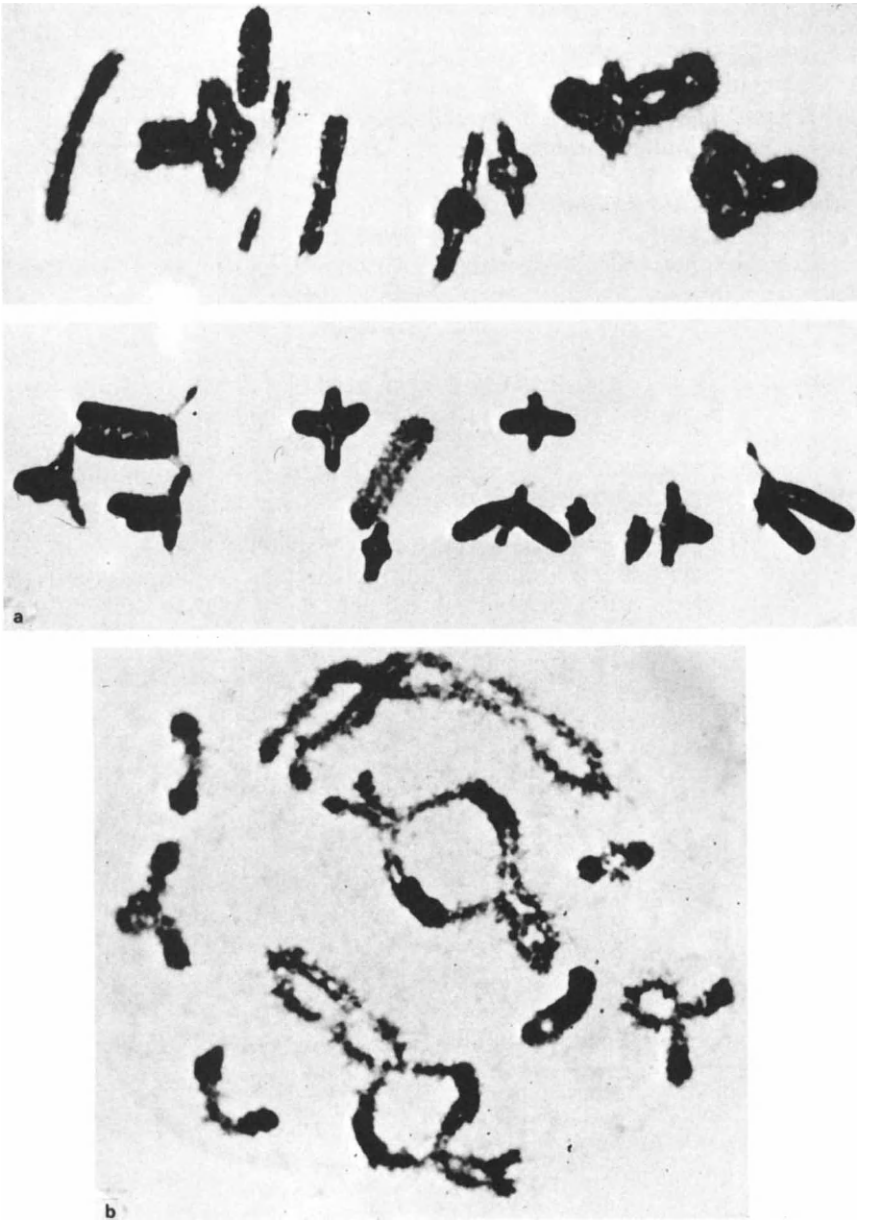

Plate 7.2
Lactic–propionic–orcein squashes (courtesy of Prof. B. John). (a) *First metaphase of male meiosis of* (*upper*) Omocestus viridulus (2n = 17) *and* (*lower*) Perapleurus alliaceous (2n = 23) *with a heteropycnotic X univalent respectively.* (b) *Diplotene of male in* Stauroderus scalaris (2n = 17). *showing blocks of heterochromatin in autosomes and secondary constriction in X*

Alternative mordanting

Gram's aqueous solution of potassium iodide and iodine can be used instead of the solution KI and I_2 in 80 per cent ethanol.

For materials in which the background retains stain even after mordanting in KI and I_2 solution, keep the slide in 1 per cent chromic acid solution after step (11) and before step (12) for 15 s.

Alternative differentiation

For high accuracy in staining, after dehydration by dipping in grades of absolute ethanol, transfer the slides to very thin terpineol, keep for 1–2 min, then rinse in xylol and transfer to clove oil. Differentiate as usual.

Schedule B. From paraffin preparations dehydrated by rapid dioxane methods and stained in crystal violet

This method is suitable only for root tips (La Cour, 1936) and differs from the usual procedure with regard to dehydration and embedding.

(1) and (2) *Fixation and washing* As in the previous schedule.
(3) *Dehydration* Transfer the roots through aqueous solutions of dioxane, 25 and 75 per cent, keeping 2 h in each. Keep in pure dioxane overnight.
(4) *Infiltration* Transfer the phial to 60 °C, adding paraffin of low melting point at intervals of 30 min for 4 h, then add pure molten wax and keep the roots in it for 2 h before embedding.

The remaining steps are the same as the previous schedule.

Schedule C. From paraffin sections stained in haematoxylin

Materials used

Root tips of *Pisum sativum*. The initial stages, from fixation to block preparation and bringing the sections down to water, are the same as followed in Schedule A, steps (1)–(8).

Of the numerous schedules followed for staining, only two are given below: In an older method:

(9) *Mordanting* Mordant the slide in alum (3 per cent ferri-ammonium sulphate) solution for at least 3 h.
(10) Rinse thoroughly in water.
(11) Stain for 24 h in 0.5 per cent aqueous haematoxylin solution.
(12) Rinse in water.
(13) Differentiate and de-stain in alum for 5 min or more.
(14) Rinse for 15 min in running water.
(15) Dehydrate by passing through ethanol series 50, 70, 90, 95 per cent and absolute, keeping for 5 min in each.
(16) Pass through ethanol-xylol (1 : 1) and pure xylol I, keeping in the former for 15 min and in the latter for 1 h.
(17) Mount in Canada balsam.

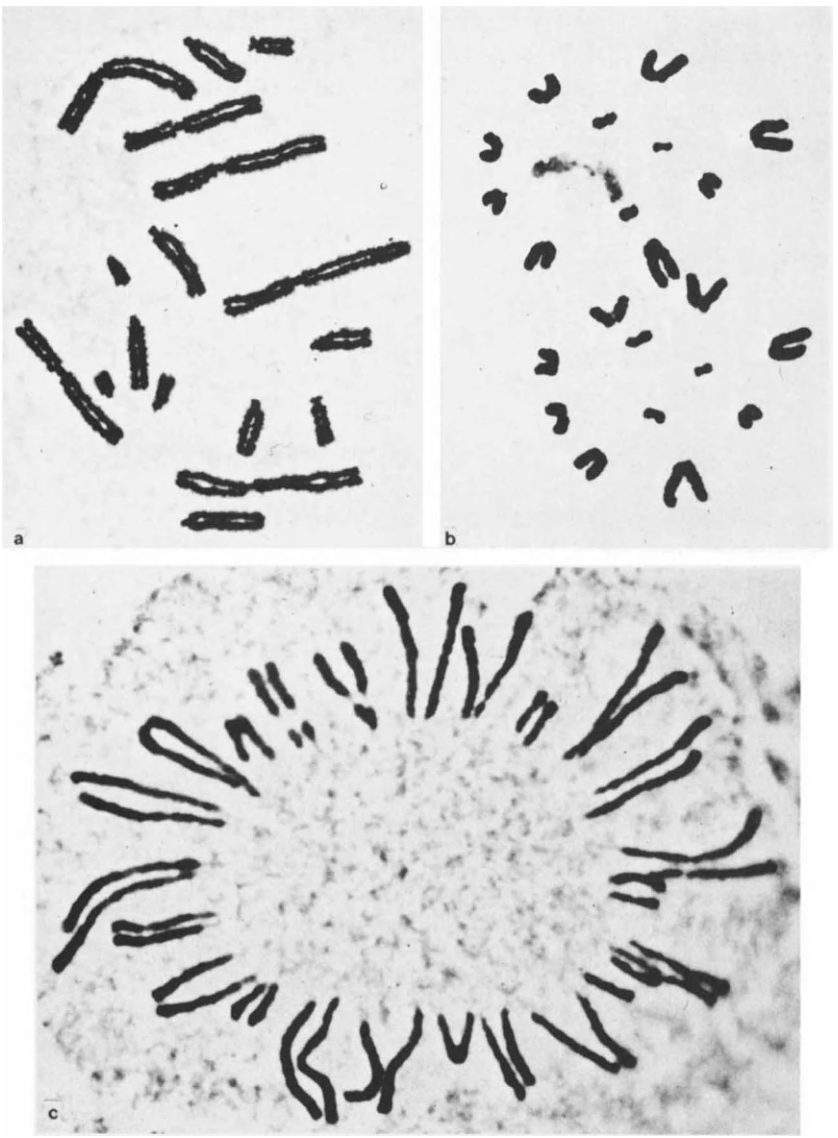

Plate 7.3
Lactic–propionic–orcein squashes (courtesy of Prof. B. John). (a) *Neuroblast mitosis from a male embryo of* Myrmeleotettix maculatus (2n = 16 + X). (b) *First anaphase of meiosis in the male* Pezotettix giornii (2n = 23), *showing heteropycnotic X*. (c) *Early mitotic anaphase in a neuroblast cell of a female embryo of* Schistocera gregaria (2n = 24)

A later and more rapid technique is:

(9) Mordant in 4 per cent alum solution for 10–20 min.
(10) Rinse in running water for 10 min.
(11) Stain in 0.5 per cent haematoxylin (ripened) solution for 5–15 min.
(12) Wash in water and de-stain for 5–20 min in saturated aqueous picric acid.
(13) Keep for 1 min in a jar containing water with 1 or 2 drops of 0.88 per cent ammonia. Rinse in running water for 30 min.
(14) Dehydrate through ethanol grades 20, 60, 80 per cent and absolute. The remaining steps are similar to the previous method.

Basic fuchsin method (Arzac, 1950)

Reagents

Hydrochloric acid	1 N
Sulphuric acid	1 N soln in 96% ethanol

Reagent a

Basic fuchsin in 10 % ethanol	0.05 ml
Absolute ethanol	5 ml
Phenol crystals	3 g
Dist. water	95 ml

Dissolve the phenol in distilled water and add fuchsin solution and ethanol.

Reagent b

10% aq potassium meta-bisulphite soln	2 vols
1 N aq sulphuric acid soln	1–2 vols

Procedure

(1) Bring the sections of materials (originally fixed in alcoholic or formalin-mixed fixatives) down to distilled water.
(2) Hydrolyse in 1 N HCl for 5 min at room temperature.
(3) Keep in 1 N HCl at 60 °C for 15 min.
(4) Immerse in 1 N HCl at room temperature.
(5) Wash in water. Stain for 2–3 min in reagent a.
(6) Transfer immediately, without washing, to reagent b and keep for 5 min.
(7) Immerse in a second lot of reagent b for another 5 min. Rinse in water.
(8) Immerse in 1 N H_2SO_4 in 96 per cent ethanol, for 3–5 min. Wash thoroughly in water.
(9) Dehydrate through ethanol and xylol grades and mount in Canada balsam.
(10) DNA takes up magenta colour.

Aldehyde alkaline silver reaction

Korson (1964) and de Martino *et al.* (1965) demonstrated aldehyde of DNA with alkaline silver reaction involving hydrolysis in molar citric acid or N HCl at 60 °C, followed by treatment with hexamine silver solution.

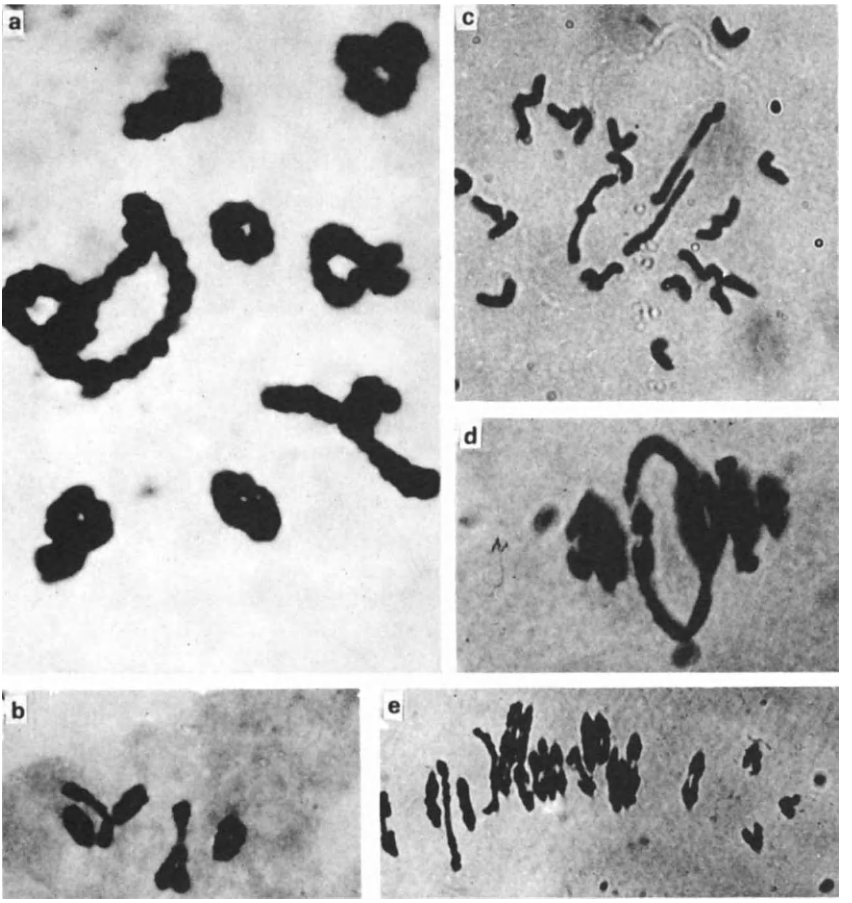

Plate 7.4

Schedule D. From pre-treated squash preparations

(*a*) *Stained in Feulgen*

Materials used Root tips of *Hemerocallis fulva.*

(1) *Pre-treatment* Fresh root tips in 0.02 oxyquinoline solution at 10–12 °C for 3 h.
(2) *Fixation* Transfer to acetic ethanol (1 : 1) mixture and keep for 1 h.
(3) *Washing* Rinse in distilled water.
(4) *Hydrolysis* Hydrolyse the root tips in N HCl at 60 °C for 12 min.
(5) *Washing* Rinse in water.
(6) *Staining* Transfer root tips to leuco-basic fuchsin solution and keep in it for 30 min to 1 h till the tips are magenta coloured.
(7) *Squashing* Transfer each tip to a drop of 45 per cent acetic acid on a slide, cut out the tip region and discard the other tissue. Place a cover-glass over the tip and squash it, applying uniform pressure with the thumb on a piece of blotting paper placed on the whole.
(8) *Observation* The preparation can be ringed with paraffin wax and observed.
(9) *Making permanent* Invert the slide in a closed tray containing glacial acetic acid–ethanol (3 : 1) mixture. After the cover-glass falls off, pass both slide with material and cover-glass through acetic–ethanol (1 : 1, 1 : 3) mixtures, pure ethanol, ethanol–xylol (1 : 1) mixture and xylol I and II, keeping 5 min in each. Mount in Canada Balsam.

For making permanent, the other schedules for mounting (*see* Chapter 6) can also be followed.

Modifications

Pre-treatment chemicals include *p*-dichlorobenzene, acenaphthene, coumarin, aesculine, isopsoralene, etc., for different materials.

Root tips of sugar cane are difficult materials for squash schedules (Li, Ma and Shang, 1954; Stevenson, 1965). Pre-treat in sat. α-bromonapthalene solution in 0.05 per cent saponin for 3 h in the cold, fix in acetic-ethanol (1 : 3) for 48–72 h, hydrolyse in N HCl at 60 °C for 7–8 min, treat with 3 per cent pectinase solution in pH 3.6 acetate buffer for 60–90 min and stain according to the Feulgen technique (Sisodia, 1968).

An earlier method by Bhaduri and Ghosh (1954) for cereals suggests: soak root tips for 1–2 h at 18–20 °C in saturated aqueous α-bromonaphthalene, 1–2 h in water, and 0.5–1 h at 10–14 °C in a mixture of 1 per cent chromic acid 5 ml, 2 per cent osmic acid 1 ml, and aqueous 0.002 M OQ 1 ml. Treat successively in water for 1–2 min, 1 per cent sulphuric acid solution for 10–15 min, water for 1–2 min, 1 per cent chromic acid solution for $\frac{1}{2}$–1 h, and squash in acetic–carmine.

Treatment in aqueous α-bromonaphthalene followed by successive washing in water and 22 per cent acetic acid, fixation in N HCl: 22 per cent acetic acid mixture (1 : 12), prior to usual hydrolysis and Feulgen staining schedule can be effectively used for members of Triticinae (Upadhya, 1963; Dylanok and Karmyinskaya, 1973).

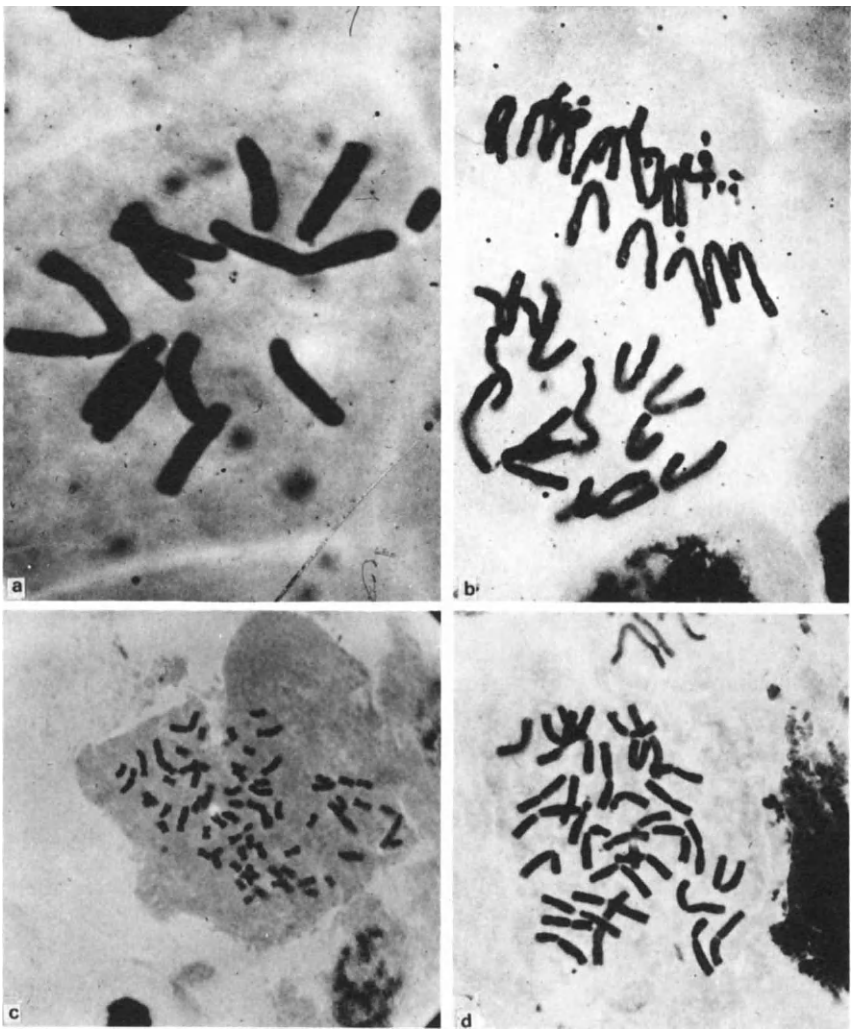

Plate 7.6
(a) *Somatic chromosomes of* Vicia faba *root, showing labile nature of secondary constriction region following treatment with* 1000 R *of x-rays.* (b) *Somatic anaphase stage in* Allium stracheyii *root, showing B-chromosomes, Feulgen stain.* (c) *Somatic metaphase in* Ophiopogon intermedium *root, following pre-treatment with sat. isopsoralene solution, acetic–orcein stain.* (d) *Somatic metaphase in* Allium tuberosum *root* (4n), *showing four satellited chromosomes after pre-treatment with aesculine and acetic–orcein stain* (courtesy of Drs. S. Sen, M. Sarma and Ashoke Chatterjee, Cytogenetics Laboratory, Department of Botany, University of Calcutta)

For *Briza*, pre-treat in sat. *p*-dichlorobenzene solution for 18 to 20 h at 4 °C, fix in acetic–ethanol (1 : 3), treat with aqueous pectinase for 2 h at room temperature; hydrolyse at 60 °C in N HCl for 8 min and stain in Feulgen for 2 h (Murray, 1975). Haque *et al.* (1976) have used concentrated HCl to separate cells and haematoxylin stain followed by squashing in 0.5 per cent aceto–carmine in grasses.

(*b*) *Stained in acetic–orcein solution*

Material used Root tips of *Aloe vera.*

(1) *Pre-treatment* Treat fresh root tips in saturated aqueous solution of *p*-dichlorobenzene (PDB) for $2\frac{1}{2}$–3 h at 12–14 °C.
(2) *Fixation* Transfer to glacial acetic acid–ethanol mixture (1 : 2) and keep for 30 min to 2 h, followed by treatment in 45 per cent acetic acid for 15 min.
(3) *Staining* Transfer the root tips to 2 per cent acetic–orcein solution and N HCl mixture in the proportion of 9 : 1, and heat gently over a flame for 5–10 s, taking care that the liquid does not boil.
(4) *Squashing* Lift a root tip from the mixture and put it in a drop of 1 per cent acetic–orcein solution on a slide and cut off and remove the older part of the tip. Place a cover-glass on the tip and squash by applying uniform pressure on the cover-glass with the thumb through a piece of blotting paper.
(5) *Observation* Ring the cover-glass with paraffin and observe under the microscope.
(6) *Making permanent* Invert the slide with cover-glass after squashing in a covered tray containing tertiary butyl alcohol and keep till cover-glass is detached. Mount slide and cover-glass separately in euparal.

Alternative pre-treatment chemical
OQ, coumarin, aesculine, α-bromonaphthalene, etc.

Alternative stain and fixative
2 per cent propionic–orcein, 1 per cent propionic acid and propionic–ethanol can be used instead of 2 per cent acetic–orcein, 1 per cent acetic–orcein and acetic–ethanol solutions in the respective steps. Treatment in 45 per cent acetic acid in step (2) is optional.

To intensify stain
A drop of aqueous ferric chloride solution can be added to the acetic–orcein–N HCl mixture or the tissue can be kept in the staining mixture for a period extending up to 12 h and then mounted in 45 per cent acetic acid.

(*c*) *Stained in acetic–lacmoid solution*

(1) and (2) *Pre-treatment and fixation* As for the acetic–orcein schedule.
(3) *Staining* Stain the tissue by transferring the root tips to a glass phial containing 10 ml standard acetic–lacmoid solution and 1 ml N HCl, and heat for 5–10 s over a flame, taking care not to boil the fluid, then leave for 10 min.

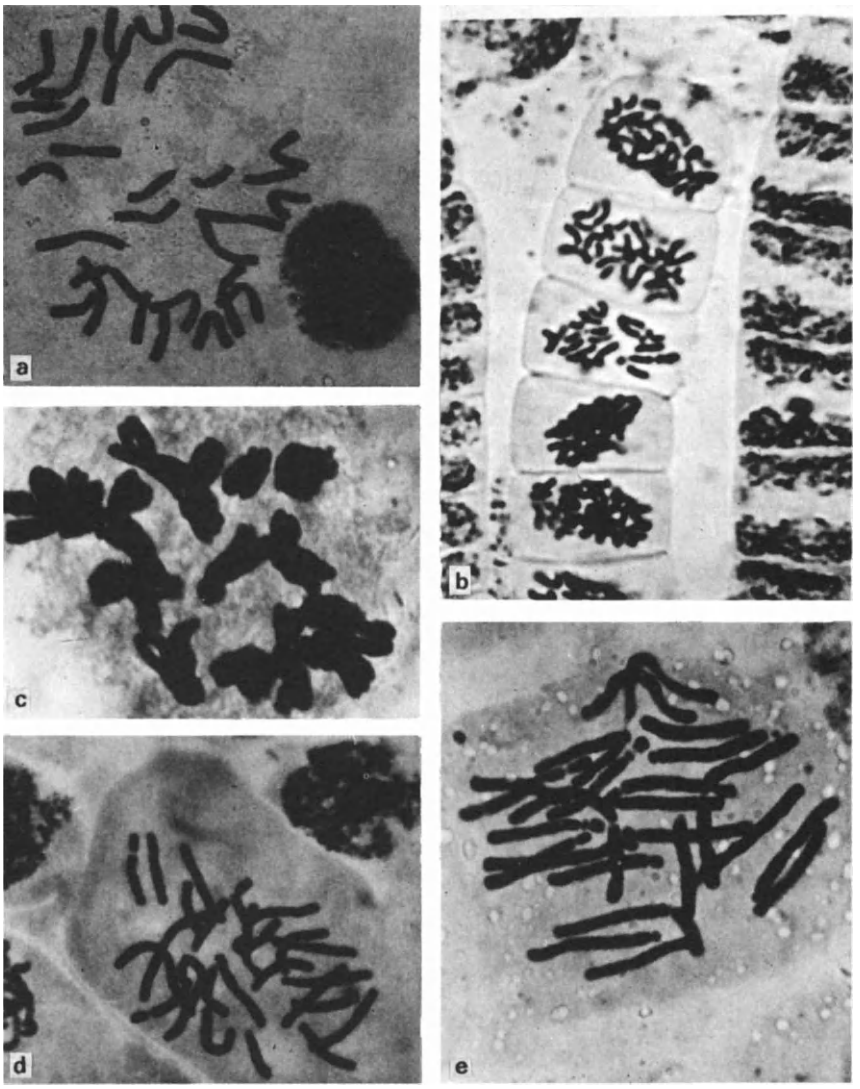

Plate 7.7
(a) *Endosperm of* Nothoscordum fragrans, *pre-treatment in aesculine and acetic–orcein stain.* (b) *Antheridial filament of* Chara socotrensis (*green alga*) *showing polysomaty and synchronous, division, acetic-orcein stain.* (c) *Somatic chromosomes of* Vicia faba *following IBA treatment inducing excess endoreplication, acetic–orcein stain.* (d) and (e) *Somatic chromosomes of* Lilium giganteum (2n = 24) *and* L. longiflorum (2n = 24) *respectively, showing pronounced secondary constrictions after treatment in colchicine and* p*-dichlorobenzene mixture, acetic–orcein stain* (courtesy of Drs. S. Sen and P. Chatterjee, Cytogenetics Laboratory, Department of Botany, University of Calcutta)

(4) *Mounting* Transfer a root tip to a drop of standard acetic–lacmoid solution on a slide and squash as usual as in previous schedules.

Steps (5) and (6) are similar to the acetic–orcein schedule.

In leaf tips

Fixation for paraffin blocks is rather ineffective. Usually squashes made after pre-treatment yield the best results. A sample schedule is given below (Sharma and Mookerjea, 1955):

Material Leaf tip of *Cestrum nocturnum*

(1) *Pre-treatment* Dissect out very young leaf tips of *Cestrum nocturnum*, wash in water and immerse in a corked glass phial containing saturated aqueous solution of aesculine and keep at 12–14 °C for 15 min to 24 h.
(2) *Fixation* Fix the materials in acetic–ethanol (1 : 1) mixture for at least 3 h, the period being extended, if necessary, up to 24 h.
(3) *Staining* Transfer the tips to a mixture of 2 per cent acetic–orcein solution and N HCl (9 : 1), heat over a flame for 3–4 s, then leave the tips in the mixture at 30 °C for 30 min.
(4) *Squashing* Squash the tips on a dry slide in a drop of 1 per cent acetic–orcein solution with a cover-glass, applying uniform pressure with the help of blotting paper.
(5) *Making permanent* Similar to root tip smears.

Alternative pre-treatment chemicals for root tips can be used here.

The period of fixation in acetic–ethanol should be increased, if necessary, to remove the chlorophyll completely. Acetic–ethanol mixture (1 : 2) or (1 : 3), chilled 80 per cent ethanol or acidulated ethanol (conc. HCl—95 per cent ethanol 1 : 3) can be used instead of acetic–ethanol (1 : 1) mixture.

Modifications

(1) Pre-treatment in saturated solution of α-bromonaphthalene in 0.05 per cent saponin for 3 h in the cold gives good results with grass leaf chromosomes. Expose young leaf, sever top of the shoot and cut slits into the remaining tube for penetration (Latour, 1960; Bennett, 1964).
(2) For *Saccharum* leaf, pre-treatment with 0.2 per cent colchicine at room temperature for 2 h is effective (Price, 1956, 1962).
(3) For tea leaf, pre-treatment in aqueous saturated *p*-dichlorobenzene (2–3 h) at 4–10 °C, fixation for 6–12 h in a mixture of propionic acid, chloroform and ethanol (1 : 3 : 6), staining with 2 per cent propionic–orcein at 80 °C and squashing in 1 per cent propionic–orcein is recommended (Bezbaruah, 1968).
(4) For grass leaf, soak longitudinal sections of leaf shoots for 2–4 h in aqueous 0.002 M OQ at 25 °C, blot and fix in ethanol, chloroform and acetic acid mixture (3 : 4 : 1). Macerate at 45 °C for 30 min in a pectinase solution before staining and squashing (Powell, 1968).

(5) Rice chromosomes need longer fixation, elimination of hydrolysis and phase contrast microscopy (Khan, 1975)
(6) Keeping for 2–3 h at 23–27 °C in 2 per cent aceto–orcein–N HCl mixture (9 : 1), followed by heating to 90 °C in the same mixture for 8 s, have given better preparations in *Crinum* (Fujishima, 1975).

In pollen grains

For studying the mitotic division in pollen grains, the following steps are taken:

Material Flowers of *Nothoscordum fragrans.*

(1) *Dissection* Dissect out an anther from a flower bud of suitable size, put in a drop of 1 per cent acetic–carmine solution on a dry slide and smear the anther with a clean scalpel, cover with a cover-glass and observe under the microscope. In flower buds of a suitable size, mitotic division is observed in the pollen grains.
(2) *Smearing* Dissect out the remaining anthers from the flower bud in which pollen grain division was observed. Place the anthers on a clean dry slide, cut off the edges of each anther with a clean scalpel, squeeze out the inner fluid and reject the empty anther lobes, then smear the fluid with a clean scalpel.
(3) *Fixation* Immediately invert the slides in a covered tray containing Navashin's A and B fixatives, mixed in the proportion 1 : 1 and keep overnight.
(4) *Staining* Wash the slides in running water for 3 h, then stain in 0.5 per cent aqueous crystal violet for 30 min and rinse in water.
(5) The subsequent steps, namely *mordanting*, *dehydration*, *differentiation*, *clearing* and *mounting* are similar to the corresponding steps (11), (12), (13), (14) and (15) of the technique followed in staining root tip sections cut from paraffin blocks (*see* Schedule A, page 154).

Modifications

(1) For wheat pollen, treat anthers at 18–20 °C in 0.5 per cent aqueous colchicine and 0.002 M aq. oxyquinoline solutions at 10–14 °C for 1 h, fix in Carnoy's fluid for 6 h, wash, hydrolyse in HCl, stain in leucobasic–fuchsin and smear in 1 per cent acetic–carmine (Bhaduri and Majumdar, 1955). For *Saccharum* and related genera, pre-treat in 0.5 per cent aqueous colchicine for 1 h, wash, treat in 0.002 M aqueous OQ for 1 h, wash, fix in a mixture of methanol 60 ml; chloroform 30 ml; water 20 ml; picric acid 1 g and mercuric chloride 1 g, for 24 h. The remaining schedule is similar to that adopted for wheat (Jagathesan and Sreenivasan, 1966).
(2) For studying chromosomes from herbarium sheets of *Impatiens*, soak anthers overnight in a saturated solution of iron acetate in 45 per cent acetic acid, rinse and smear in dilute acetic–carmine. Heat several times to boiling and seal (Khoshoo, 1956; Chinappa and Gill, 1974).

Precautions

The operation of smearing the dissected anthers should be carried out swiftly so that the fluid does not dry before inversion in the fixative. Smearing should be carried out away from any direct air current which may dry the fluid within the anthers.

Alternative methods

(1) The slides can be made permanent immediately after acetic–carmine smearing by ethanol–vapour or tertiary butyl alcohol techniques.
(2) If the stain taken by the chromosomes is not satisfactory, pre-mordanting in 1 per cent chromic acid solution, as in the case of root tip sections, described before, is followed.

In endosperm

For the study of the mitotic division from endosperm tissue, two different methods can be followed, in addition to others described elsewhere (*see* Chapter 8).

Feulgen squash method (Rutishauser and Hunziker, 1950)

(1) *Fixation* Dissect out very young developing seeds and fix in acetic–ethanol mixture (1 : 2) for 1–2 h and keep overnight in 95 per cent ethanol.
(2) *Washing* Run the seeds through 70, 50 and 30 per cent ethanol, keeping them for 10 min in each, then wash in running water in a porcelain thimble for 10 min.
(3) *Hydrolyse* Hydrolyse in N HCl at 60°C for 8–12 min.
(4) *Staining* Rinse in water and stain in leucobasic fuchsin solution for 2 h, then wash for 10 min in two changes of tap water.
(5) *Mounting* Dissect out the endosperm on a clean dry slide in a drop of 45 per cent acetic acid solution, under a dissecting microscope using tungsten needles pointed in molten $NaNO_2$. Using Mayer's adhesive, film a cover-glass and dry it by passing over a flame, then squash the dissected endosperm under the cover-glass, exerting strong but uniform pressure under a piece of blotting paper.
(6) *Making permanent* The slides can be made permanent following any one of the schedules described under the chapter on mounting.

Modifications
For intensifying the stain, 1 per cent acetic–orcein solution can be used instead of 45 per cent acetic acid as the mounting medium.

Acetic-orcein squash method (Sharma and Varma, 1960)

Material used Endosperm of *Cestrum nocturnum.*

(1) *Pre-treatment* Dissect out the very young developing seeds under a dissecting microscope and place them immediately in a saturated solution of aesculine, keep at 10–12 °C for 3 h.
(2) *Fixation* Fix in acetic–ethanol mixture (1 : 1) at room temperature for 2 h.
(3) *Staining* Heat in a mixture of 2 per cent acetic–orcein solution and N HCl (9 : 1) over a flame for 9 or 10 s, removing the tube at intervals so that the fluid does not boil. Keep for 30 min.
(4) *Squashing* Transfer each seed to a clean slide in a drop of 1 per cent acetic–orcein solution, cut it into two or three pieces with a scalpel and keep the pieces at a little distance from each other. Squash the whole under a long cover-glass, exerting strong and uniform pressure and ring with paraffin.
(5) *Making permanent* The slides can be made permanent following any one of the methods described previously.

Notes

The seeds selected should be as young as possible, preferably taken within a week of fertilisation. If the seeds are very small the entire seed should be squashed, but if, however, the seeds are comparatively large, the endosperm should be dissected out before mounting, under a dissecting microscope, and then squashed. The endosperm can be excised, placed directly in acetic–carmine, macerated and brought to boiling, the nuclei and mitotic figures are separated by centrifugation (Persidsky and Duncan, 1957).

In pollen tube

For the study of mitosis from the division of the generative nucleus in germinating pollen grains, the methods involve: (a) germination of the pollen tube, and (b) treatment for observation of the chromosomes. Of the numerous techniques followed, three representative ones are described here.

Hanging drop culture method

Material Seeds of *Papaver* sp.

(1) *Pollen grain culture* Fit a ring on a slide and smear both rims of the ring with vaseline so that it is attached to the slide at one end. Place a drop of 3 per cent sugar solution on a clean cover-glass, then dust pollen grains from an opened flower into the solution. Invert the cover-glass with the drop of sugar solution on it and attach it to the other vaselined rim of the ring, so that the drop with pollen grains hangs in

the closed chamber enclosed by the ring. Growth of the pollen tubes can be noted by observing the ringed slide under the microscope. After about 3 h, remove a few pollen tubes for observation at intervals of 1 h till the optimum time is reached.

(2) *Treatment for chromosome study* Lift out the pollen tubes with a brush, put in a drop of 1 per cent acetic–orcein solution on a clean slide, warm slightly and squash as usual under a cover-glass applying uniform pressure.

(3) *Permanent preparation* The slides can be made permanent, if the dividing time is found to be correct, by the alcohol vapour technique.

Modifications

For accumulating metaphase, 0.05 per cent colchicine can be added to the sugar solution. For controlling humidity of the hanging drop chamber, add a drop of water on the slide or place a drop of sugar solution beside the hanging drop.

Coated slide technique (Conger, 1953) and modifications

Material used *Tradescantia virginiana*

(1) *Preparation of medium* Weigh out 12 g of lactone, 1.5 g of agar and 0.01 g of colchicine. Heat the lactone and agar with 100 ml distilled water in a double boiler until the agar is dissolved, then add colchicine when the medium has cooled to 80–60 °C. Keep the medium at about 60–70 °C.

(2) *Preparation of slides* Coat slides cleaned in ethanol with a thin layer of egg white. Dip in a beaker containing the medium at 60 °C until it warms up, then withdraw the slide, drain off the medium, and wipe the back with a piece of clean cloth.

(3) *Preparing the pollen* When the medium has set, but is not dry, pick up the pollen with a brush, and dust a thin film on the medium. Immediately place the slide sown with pollen in a moist growing box, the box being a horizontal glass staining dish lined with damp blotting paper on the two sides and top, and keep the temperature between 20 and 25 °C. Observe at intervals till the optimum period for maximum division is found.

(4) *Fixation and staining* Add a drop of 1 per cent acetic–carmine solution to the pollen tube, squash under a cover-glass and observe.

(5) *Making permanent* The ethanol vapour technique can be used.

Modification

(1) The slides can also be stained by the Feulgen schedule after 12 min hydrolysis in N HCl at 60 °C. They must be handled carefully, as otherwise the medium may be washed off.

(2) For species with binucleate pollen, germinate in a medium containing H_3BO_3, 0.01 g; $Ca(NO_3)_2 . 4H_2O$, 0.03 g; $MgSO_4 . 7H_2O$, 0.02 g; KNO_3, 0.01 g; sucrose, 10 g; water, 100 ml, on a slide resting on moist filter

paper in a closed petri dish for 24 h. Place crystals of acenaphthene on filter paper. After 24 h, squash pollen tubes in propionic–orcein solution (Dyer, 1966).

(3) For convenient handling of germinated pollen during Feulgen and autoradiographic procedure, grow pollen on an autoclaved membrane filter (Millipore AA WP 025 00) in contact with a sterilised medium which contains agar 0.5–1 per cent; sucrose 0.1–0.5 per cent, and boric acid 0.01 per cent, for 2 h to overnight at 2–4 C on a filter paper with a mixture of OsO_4, 1 g; CrO_3, 1.66 g and water, 233 ml. For *Persica* pollen, add 10 per cent acetic acid. Wash in water, bleach in a mixture of 3 per cent hydrogen peroxide and saturated aqueous ammonium oxalate solution on filter paper. Hydrolyse with 5 N HCl for 18 min at room temperature, stain in Feulgen, wash in three changes of 2 per cent $K_2S_2O_5$ at pH 2.3 (KH_2 PO_4, 1.4 g; conc. HCl, 0.35 ml; distilled water, 100 ml) by placing membrane on filter paper wet with the respective fluids. Transfer pollen to glacial acetic acid, squash and process (Jona, 1967).

(4) Sow *Tradescantia* pollen on lactose–agar medium at 38–39 C for 16 h. Fix slides in acetic–ethanol (1 : 3) for 1–3 h, hydrolyse in N HCl at 60 C, treat with water at 65 C. Delaminate upper layer of medium in cold water. Flatten and fix remaining single layer of pollen tubes to the slide by pressing under a cover-glass by quick freeze technique, stain in Feulgen and mount as usual (Ma, 1967).

(5) For palm chromosomes, sow pollen in a medium containing H_3BO_3, 100 ppm; colchicine, 0.04 per cent, lactose, 12 per cent, gelatin, 5 per cent and egg albumen, 1 drop in 10 ml (Read, 1964).

Collodion membrane technique (Savage, 1957)

(1) Mix 1 part of collodion (necol collodion solution from BDH, England) with three parts acetone. Prepare 3 per cent aqueous sugar solution in a petri dish and warm and put a drop of collodion–acetone mixture on it.

This drop rapidly spreads out in a thin film over the surface and the film hardens into a thin membrane as acetone evaporates. Cover the open dishes lightly by filter paper and leave in a warm dry place for 3 h till acetone evaporates completely.

(2) Dust the pollen with a brush or directly from the anther on to the smooth areas of the floating membrane towards the centre, replace the lid on the petri dish and transfer it to an incubator.

(3) After the pollen tubes have germinated, with a pair of scissors cut out a piece of the membrane, about 1 cm in diameter, with the pollen tubes, while it is still floating on the sugar solution; lift it with a needle on to a clean dry slide, add a drop of 1 per cent acetic–orcein solution and squash under an albuminised cover-glass, applying uniform pressure. Ring with paraffin for observation.

(4) Invert the slide, after wiping off the paraffin with xylol, in a covered tray containing acetic–ethanol mixture (1 : 3) and after the cover-glass is detached with the membrane run it through two changes of absolute ethanol–xylol (1 : 1) mixture and pure xylol, keeping for 10 min in each.

Mount the cover-glass, pollen side down, in a drop of Canada balsam on a clean slide.

Modification

Feulgen staining is used in an alternative method.

(1) The earlier steps are similar, up to the germination of pollen.
(2) Float the cut membrane with pollen tubes on a slide and blot off excess solution. Add a drop of acetic–ethanol mixture (1 : 3) to the pollen and cover with an albuminised cover-glass. Press gently and invert in a tray containing acetic–ethanol mixture.
(3) After $1\frac{1}{2}$ h, remove the cover-glass with pollen tubes to 95 per cent ethanol and treat overnight.
(4) Bring down to water through 80, 70, 50 and 30 per cent ethanol, keep 2 min in each, rinse and hydrolyse for 12 min at 60 °C in N HCl.
(5) Rinse in water and stain in leuco-basin fuchsin solution for 30 min and squash in 45 per cent acetic acid on a clean slide.
(6) For making permanent, the usual techniques described before can be followed.

Metaphase arrest technique

This method completely excludes nutrient medium in the germination of the pollen tube (De, 1958).

Materials used *Tradescantia virginiana*

(1) Line both bottom and cover of a pair of petri dishes with well-moistened filter paper and place a clean slide in the petri dish and dust on it pollen grains from a newly opened flower. Spread 50–100 mg of fine acenaphthene crystals on the filter paper close to the slide and cover and keep at 20–22 °C for 24 h (Swanson, 1940).
(2) Add a drop of 1 per cent acetic–carmine solution to the pollen tubes on the slide and squash under a cover-glass.

In animal material

Squash preparation

The usual sources of material are: larval tails, ganglia, and spermatogonial cells.

Material Urodele larva

(1) Cut off the tail of a growing larva of suitable size immediately behind the anus.
(2) Fix in acetic–methanol mixture (1 : 1) for 2–24 h in a glass phial.
(3) Remove the tissue from the phial and place it on a clean slide in a drop

of 1 per cent acetic–carmine solution to which a trace of iron has been added. The tissue may be teased by means of two needles before squashing.

(4) Squash by placing a cover-glass on the preparation and pressing gently so as not to crush the cells. Ring with paraffin and observe.
(5) If necessary, the slide can be made permanent by any one of the techniques outlined previously.

Modifications

Acetic–lacmoid solution can be used instead of acetic–carmine.

For Feulgen staining, after fixation in step (2), hydrolyse the material in N HCl at 60 °C for 12 min. Modify the treatment if necessary, rinse, stain in leuco–basic fuchsin solution for 30 min and squash in 45 per cent acetic acid.

Carnoy's fluid or Newcomer's fluid can be used as a fixative instead of acetic–ethanol mixture.

This method is applicable to all the other tissues. Small ciliates, cultured in petri dishes, may be fixed in San Felice's fluid, attached to slides (Ruthmann and Heckmann, 1961) and stained with Feulgen (Ruthmann and Hauser, 1974). Ticks are dissected out in Shen's insect saline solution or 1 per cent sodium extract for 10 min and squashed in 2 per cent aceto–orcein (Oliver, Tanaka and Sawada, 1974). Entire embryos can be squashed when of suitable size, as for example parthenogenetic psocids (Insecta: Psocoptera, Jostes, 1975).

Material Salivary gland chromosomes of *Drosophila*

(1) Dissect out third instar larvae in physiological solution.
(2) Place the salivary glands in 45 per cent acetic acid for 5–7 s.
(3) Fix in 1 N HCl for 30 s.
(4) Stain in lactic–acetic–orcein for 30–40 min on a slide.
(5) Warm (35 °C) the slide for 10 s.
(6) Transfer the excess stained gland to lactic–acetic acid (lactic acid: 60 per cent acetic acid, 1 : 1) on a siliconised slide.
(7) Wash thrice in lactic–acetic acid and mount in the same solution. Squash under a cover-glass exerting pressure.

Paraffin block preparation

This method is principally recommended for the study of different divisional figures.

Material Urodele larva

(1) *Fixation* Cut out the growing tail of a larva near the anus and fix in San Felice's fluid (1 per cent chromic acid: 16 ml, 40 per cent formaldehyde: 8 ml, and glacial acetic acid: 1 ml) for 12 h.
(2) *Washing* Transfer the tissue to a porcelain thimble and wash in running water for 3 h.

(3) *Dehydration* Transfer the tissue to 30 per cent ethanol and keep for 1 h. Pass the tissue to 50 per cent ethanol, keeping it in for 1 h; then to 70 per cent ethanol and keep overnight; to 80, 90 and 95 per cent ethanol, keeping 1 h in each; and finally store overnight in absolute ethanol.

(4) *Clearing* Transfer the tissue through ethanol–chloroform grades (3 : 1, 1 : 1 and 1 : 3), keeping in each for 1 h, then to pure chloroform for 10 min. Give another change in pure chloroform, and add shavings of paraffin wax.

(5) *Infiltration* Keep the phial containing the tissue in the mixture of chloroform and molten wax on a hot plate at 35 °C for 24 h, transfer to 45 °C, remove the cork and keep for 24 h, then transfer to 60 °C. Change the wax with fresh molten paraffin wax, at half-hourly intervals, for 2 h until the smell of chloroform has completely disappeared.

(6) *Embedding* Pour the molten paraffin with the material into a paper tray, add some more molten wax, orient the material, placing each piece at a distance of 1 cm from its neighbours, and after the wax has cooled slightly, plunge the block into cold water.

(7) *Section cutting* Trim the block, attach it to the holder and cut sections 12 μm thick on a Spencer's rotary microtome. Cut the ribbons into segments of equal size. Put a minute drop of Mayer's adhesive on a clean slide and rub it into a thin film along three-quarters of the area of the slide. Put a few drops of distilled water on the slide and float the ribbons serially on the water. Place the slide on a hot plate and stretch the ribbons with needles. Drain off the water, arrange the sections in neat rows and allow the slide to dry overnight on the hot plate.

(8) *Bringing down to water* Run the slide with sections through pure xylol I and II, keeping 30 min in each, pass through xylol–ethanol (1 : 1) mixture and absolute ethanol grades, the period of immersion being 15 min in each, and gradually transfer the slide through 95, 90, 80, 70, 50 and 30 per cent grades, keeping 2–3 min in each, finally rinsing thoroughly in water.

(9) *Mordanting* Keep the slide with material in 4 per cent iron alum solution for 10–20 min.

(10) *Washing* Rinse in running water for 10–15 min.

(11) *Staining* Stain in 0.5 per cent haematoxylin solution (ripened for 1–2 months) for 5–15 min.

(12) *De-staining* Rinse in water and de-stain for 5–20 min in saturated aqueous solution of picric acid.

(13) *Blueing* Blue the stain by placing the slide in 100 ml distilled water containing 1 or 2 drops of 0.88 per cent ammonia for 1 min.

(14) *Dehydration* Pass through 30, 60, 80 per cent and absolute ethanol grades, keeping the slide for 2 min in each.

(15) *Differentiation* Transfer to clove oil and keep for 2–3 min, then lift out the slide, wipe off the extra oil from the back of the slide and observe under a microscope to judge the stain.

(16) *Clearing* If stain is unsatisfactory, transfer the slide to pure xylol and keep in xylol I for 30 min, xylol II for 1 h and xylol III for 30 min to overnight.

(17) *Mounting* Mount in Canada balsam or clarite X.

Modifications

This technique can also be applied to ganglia and other somatic tissue, except bone marrow cells. For difficult materials, the tissue can be pre-fixed in acetic–methanol (1 : 3) mixture for 1 h before fixing in San Felice's fluid as usual. Some alternative fixatives which can be used are Flemming's strong fluid, Champy's fluid and Minouchi's fluid (*see* list of fixatives). For haematoxylin staining, the more prolonged schedule as followed for plants in Schedule C (page 158) is also applicable in the case of animals. The Newton's crystal violet staining schedule already described can also be applied to animal materials.

Smear preparations from bone marrow

This technique was devised for the bone marrow cells of mammals after pretreatment (Ford and Hamerton, 1956). However, it can also be applied to thymus, spleen, cornea and other tissues.

(1) *Injection* Inject 0.5 ml of 0.025 per cent (w/v) colchicine solution intraperitoneally in the animal and leave for 1 h or more. Too much toxicity should be avoided. Prolonged keeping may result in polyploidy.
(1) *Kill* Remove femurs and cut of epiphyses. Wash out the marrow into a small phial with warm 0.12 per cent aqueous solution of sodium citrate, using a hypodermic syringe with a fine needle.
(3) *Gently aspirate* the marrow in and out of the syringe till it breaks up into a fine suspension, and keep the phial, with the suspension, in a water bath at 37 °C for 10 min.
(4) *Filter* by centrifuging the suspension through nylon bolting cloth in a bacterial infiltration tube to obtain a fine clean suspension without any debris.
(5) *Fix* in chilled acetic–methanol (1 : 3) mixture for 30 min to 2 h.
(6) *Transfer* to 30 per cent methanol and keep for 15 min, then add water and rinse for 15 min.
(7) *Hydrolyse* in 1 N HCl at 60 °C for 4 min, then transfer the tissue to chilled water and keep for 1–2 min.
(8) *Stain* in leuco-basic fuchsin solution for 1 h.
(9) Place the material on a clean slide in 45 per cent acetic acid and squash under a cover-glass. Ring with paraffin for observation.
(10) The slide can be made permanent following the dry ice or alcohol vapour schedules and mounted in euparal.

Modifications

Materials which fail to stain in leuco-basic fuchsin solution can be restained by squashing them in 1 per cent acetic–orcein solution.

The animal can be killed by cervical dislocation or by chloroform. The period of hydrolysis is varied according to the material. Colcemid from CIBA Laboratories Ltd. can be used instead of colchicine as it is less toxic. Tissues

other than bone marrow should be chopped into very small pieces in the hypotonic citrate solution and then the rest of the schedule from step (5) should be followed,

In an alternative technique (Sparano, 1961), transfer the suspension to a mixture of 2 per cent acetic–orcein and N HCl (9 : 1), heat for a few seconds and mount in 45 per cent acetic acid. The steps from (5)–(9) of the sample schedule can be omitted.

This method has been applied successfully to almost all vertebrates. In certain amphibians, the air-drying or blaze-drying technique has been adapted before staining (Haertel, Owczarzak and Storm, 1974). In fishes, direct preparations have been made from epithelium from fins, scales, gills and internal organs like kidney, liver and spleen (Ojima, Ueno and Hayashi, 1973; Denton, 1973).

Epithelial cells can be isolated from rat intestine by placing it *in toto* in a hypotonic solution and subsequently centrifuging and fixing them in chilled acetic–methanol (Likhachev, 1974). Other organs have been similarly fixed after pre-treatment in hypotonic solution from *Myxine glutinosa*, sacrificed 3 h after injecting 0.8 ml 0.5 per cent colchicine/100 g body weight (Nygren and Jahnke, 1972). Regenerating tissues of freshwater planarians can be similarly squashed after colchicine treatment and orcein staining (Oki and Tamura, 1975) as also blastulae of fishes (Booke, 1974, 1975).

In all animal materials, acetic acid–methanol (1 : 3) is a more effective fixative than acetic acid–ethanol mixture.

Permanent smear preparation

Smith (1943), for insects, modified by Manna (1957) in mammalian chromosomes (also applied to other materials):

(1) Take any dividing tissue, e.g. cornea, bone marrow, liver, testes, etc.
(2) If the cells are in suspension as in bone marrow, follow the procedure recommended by Ford and Hamerton (1956), as given in a later chapter.
    If the tissue is solid, macerate it by means of a homogeniser in sodium citrate solution (for swelling), incubate the suspension in 37 °C and leave for 15 min.
(3) Centrifuge gently at about 1000 rev/min for 5 min.
(4) Decant off the supernatant fluid, add acetic–methanol mixture (1 : 3) to the sediment and flush it with a pipette, then fix for 15 min or more (it can be kept overnight in cold). If the fixed cells settle down at the bottom, decant; if they remain in the supernatant, gentle centrifuging may also be applied.
(5) Add a drop of 45 per cent acetic acid solution and make it a milk emulsion.
(6) Place a very small drop on a slide and squash by a cover-glass, with gentle pressure by means of a thumb (uniform layer).
(7) Dry the squashed slide over a small flame (preferably spirit lamp) for about 45 min till the edge of the cover-glass appears to be dry. Avoid overheating.
(8) Place the slide in 50 per cent ethanol and allow the cover-glass to detach.

Otherwise it may be removed by the edge of a sharp scalpel. The slide with detached cover-glass can be stored in 70 per cent ethanol and can be stained with any standard cytological stain.

Details of the principles and procedures for vertebrate chromosomes are given in Chapter 13.

SCHEDULES FOR THE STUDY OF MEIOTIC CHROMOSOMES

In plant materials

Meiotic chromosomes are studied usually from pollen mother cells and occasionally from embryosac mother cells.

Study from pollen mother cells

Temporary squash technique

Material Flower buds of *Solanum torvum*

(1) Take flower buds serially from an inflorescence, starting from the smallest and working up to the largest, until the correct bud having divisional stages is found.
(2) Dissect out a single anther from a bud with a needle. Place it on a clean slide.
(3) With a clean scalpel, smear the entire anther on the slide and add a drop of 1 per cent iron–acetic–carmine solution to it immediately. Remove the debris.
(4) Heat slightly over a flame. Cover with a cover-glass and ring with paraffin.

Modifications

Instead of fresh anthers, anthers fixed in acetic–ethanol (1 : 1) mixture or in Carnoy's fluid, and later stored in 70 per cent ethanol can also be observed following this method. If stored in 70 per cent ethanol, keeping 1 h in each of acetic–ethanol and 45 per cent acetic acid solutions is necessary before smearing in 1 per cent acetic–carmine solution. For materials taking bright stain, treatment in acetic–ethanol can be omitted.

Instead of iron–acetic–carmine solution, 1 per cent acetic–carmine solution can be used and a trace of iron added by rubbing a rusty needle in the drop of stain on the slide.

In this schedule, 1 per cent acetic–carmine solution can be replaced by acetic–orcein, acetic–lacmoid, nigrosine, etc., solutions.

The slides can be kept as such in a refrigerator for a few weeks and then made permanent, following either of the schedules described earlier.

Very small buds in tight inflorescences can be fixed in acetic–ethanol mixture or in Carnoy's fluid for 1 h, hydrolysed at 60 C for 5–10 min in N HCl, rinsed in water and stained for 1–3 h in leuco-basic fuchsin solution. They should be rinsed in two or three changes of 45 per cent acetic acid solution. Single anthers are to be dissected out, squashed in 45 per cent acetic acid and made permanent as usual.

Maceration in a mixture of 15 per cent chromic acid, 10 per cent nitric acid, 5 per cent HCl (2 : 1 : 1) for 5–7 min and hardening in ethanol–propionic acid (1 : 1), between fixation and staining has been used in *Gossypium* microspores (Bernardo, 1965). Restoration of deteriorated temporary acetic–carmine preparations involves replacing the acetic–carmine under the cover-glass first with 2 N HCl and then with 1 per cent acetic–carmine (Persidsky, 1954).

Permanent smear technique

Material Flower buds of *Datura fastuosa*

(1) Take flower buds of different sizes. Dissect out a single anther from each bud and observe by squashing in 1 per cent iron–acetic–carmine solution as given in the last temporary technique until, in the bud of a particular size, meiotic divisional figures are observed.
(2) Dissect out the remaining anthers of the bud showing division and place each on a clean slide, cut off one end with a clean scalpel and squeeze out the contents by pressing with the left thumb. Discard the empty anther lobe. Quickly draw the fluid into a thin smear on the slide with a clean scalpel and immerse immediately in a tray containing Navashin's fluids A and B, freshly mixed in equal proportion. Keep in the fixative for 3–12 h.
(3) Wash the slide in running water for 1 h.
(4) Stain in 0.5 per cent aqueous crystal violet solution for 20 min or more and rinse in water.
(5) Mordant in 1 per cent solution of I_2 and KI in 80 per cent ethyl alcohol for 45 s.
(6) Dehydrate by passing the slide through absolute alcohol grades I, II and III, keeping about 2–3 s in each.
(7) Transfer the slide to clove oil I, keep for 2–3 min, take out the slide and observe the staining under a microscope. If found satisfactory, transfer the slide to clove oil II and keep for 2–3 min.
(8) Pass the slide through xylol grades I, II and III, for 30 min, 1 h and 30 min respectively.
(9) Mount in Canada balsam or clarite X.

Modifications

Materials difficult to stain should be pre-mordanted overnight in 1 per cent chromic acid solution after fixing and washing, i.e. after step (3). They are then to be washed in running water for 3 h before staining.

In an alternative method, after smearing on a clean slide, immerse the material in acetic–ethanol mixture and keep for 1 h. Treat the slide with material in 45 per cent acetic acid for 15 min and hydrolyse in N HCl at 60 °C for 15 min and, finally, rinse it in water, stain in leuco-basin fuchsin solution for 1–2 h and mount with 45 per cent acetic acid. Enzymatic digestion of p.m.c. walls with cellulase is used from early pachytene onwards for *in situ* nucleic acid hybridisation (Narayan, 1976).

Permanent paraffin section technique

Material Flower buds of *Allium cepa*

(1) *Determination of size* Test single anthers of individual flower buds until a bud of suitable size with divisional figures is obtained. Collect several buds of approximately the same size.

(2) *Fixation* Dip each bud, holding it with a pair of fine forceps, in Carnoy's fluid and keep for 2–3 s. Drop it in a container of water and rinse thoroughly, then transfer the bud to a phial containing a mixture of Navashin's A and B fluids (1 : 1) and keep for 24 h.

(3)–(7) *Washing, dehydration, clearing, infiltration and embedding* are to be carried out in the same way as described under the corresponding steps in the paraffin section technique for root tips (Schedule A, page 154). While embedding, orient the flower buds in groups, depending on their size, about 1 cm away from each other.

(8) *Section-cutting* The process is similar to that followed for root tips already described. Cut longitudinal sections 12 μm thick. Mount the ribbons as given before.

(9)–(16) *Bringing down to water, pre-mordanting in 1 per cent chromic acid solution, staining in crystal violet, mordanting, dehydration, differentiation, clearing and mounting* are similar to the methods followed in the case of root tips.

Modifications

Haematoxylin staining can be done after step (9), bringing the slides down to water, following the schedule given for root tips. Pre-mordanting in 1 per cent chromic acid can be omitted for materials that are easy to stain. In plants with very small flowers, like members of Araceae, the entire inflorescence is cut into equal segments and fixed as such. Transverse sections of the inflorescence are cut serially for study. In plants with very large flowers, the anthers are dissected out and fixed.

For scattering chromosomes, 0.002 M oxyquinoline solution can be mixed with the fixative (1 : 1) (Sharma and Ghosh, 1951). Instead of Navashin's A and B fluids, other regular fixatives can also be used (*see* Chapter 3).

Study from embryosac mother cells

Squash technique for young embryosac

(1) Dissect out ovules from the ovary and fix in Carnoy's fluid for 1 day.
(2) Keep in 95 per cent ethanol for 1–2 days. Run through 90, 80, 70, 50 and 30 per cent ethanol, keeping in each for 5–10 min. Rinse in water. Two separate staining schedules can be followed.

(a) ***Staining in Feulgen solution***

(3) Hydrolyse for 8–10 min at 60 °C in N HCl.
(4) Rinse in water and stain in leuco-basic fuchsin solution for 2 h.
(5) Intensify the stain by keeping in water for 15 min.
(6) Transfer to a drop of 45 per cent acetic acid on a clean slide and squash under cover-glass, applying uniform pressure.
(7) Dehydrate by inverting in tertiary butyl alcohol and mount in euparal.

(b) ***Staining in acetic–orcein solution***

(3) Transfer the ovules from water to a mixture of 2 per cent acetic–orcein solution and N HCl (9 : 1). Heat gently for 5–10 s without boiling the fluid.
(4) Keep for 20 min in the mixture.
(5) Transfer to a drop of 1 per cent acetic–orcein solution on a clean slide and squash under a cover-glass, exerting uniform pressure.
(6) Make the slide permanent by any of the schedules described in the chapter on mounting.

Modifications

In plants with very small ovules, the entire ovary can be cut into tiny pieces and treated. Acetic–lacmoid solution can be used instead of acetic–orcein solution in staining. Acetic–ethanol mixture (1 : 1) can be used instead of Carnoy's fluid.

Squash technique for mature embryosac

(1) Fix the ovary in Carnoy's fluid for 2 days.
(2) Transfer to a mixture containing 10 drops of saturated solution of iron acetate in 45 per cent acetic acid and 10 ml 4 per cent iron alum solution. Keep the phial containing the material in the mixture in a water bath at 75 °C for 3 min.
(3) Give two changes with distilled water heated to 75 °C, keeping for 2 min in each.
(4) Transfer to cold water and keep for 2–3 min.
(5) Hydrolyse in 50 per cent HCl for 10 min.

(6) Rinse in several changes of distilled water for 20 min.
(7) Transfer the ovary to a drop of 1 per cent iron–acetic–carmine solution on a clean slide. Dissect out the ovules with needles into the stain and remove the rest of the ovary.
(8) Tap the ovules with a flat-bladed scalpel until the cells are separated.
(9) Apply a cover-glass and heat the slide gently.
(10) Squash and seal. The slide can be made permanent according to the usual schedules.

Paraffin block preparation for embryosac mother cells

(1) *Fixation* Fix the dissected ovules overnight in La Cour's 2BX fixative (2 per cent chromic acid, 2 per cent potassium dichromate, 2 per cent osmic acid, 10 per cent acetic acid, 1 per cent saponin, distilled water in ratio 10:10:12:6:1:5).
(2) Wash overnight in running water.

The later steps, namely, dehydration, clearing, infiltration, embedding and section cutting are similar to the corresponding steps in paraffin preparations of root tips. Sections are cut 15–20 μm thick.

(3) Run the slides with sections through xylol I and II grades, keeping in each for 30 min. Pass through ethanol–xylol and absolute ethanol grades (15 min in each). Keep in 95 per cent ethanol for 10 min.
(4) *Bleaching* Keep in a mixture of 80 per cent ethanol and hydrogen peroxide (3:1) for 24 h. Observe, and if the background is not clear, keep for another 24 h.
(5) Transfer to 70 per cent ethanol, then 50 and 30 per cent ethanol, keeping 5 min in each. Rinse thoroughly in water.

The next steps in the schedule, pre-mordanting in 1 per cent chromic acid, staining in crystal violet, mordanting, dehydration, differentiation, clearing and mounting are done as in the case of paraffin preparations of root tips described in earlier schedules.

Restaining schedules for both mitotic and meiotic preparations

Permanent slides kept for a long period usually lose the brightness of their stain, as almost all stains fade in certain environmental conditions. The principal factors responsible for this fading are: (a) the progressive acidity of the mounting medium, chiefly Canada balsam—this defect can be remedied by using neutral mounting media; (b) exposure to ultraviolet light by leaving the slides lying about carelessly or by exposure to arc lamp projectors; and (c) failure to remove all extraneous chemicals. If dehydration and later clearing in xylol are insufficient and traces of any solvent of the stain are carried over into the mounting medium, the stain fades quite rapidly.

Preparations, in which the stain has faded, can be re-stained in some cases. For re-staining, the original stain itself or some other stain which suits the fixative in which the tissue was originally fixed is used. The process consists of the following steps:

(1) *Removal of the mounting medium* The slides are placed in a solvent of the mounting medium, usually xylol, till the cover-glass is detached. They are usually given a change in xylol to remove the mounting medium completely.
(2) *Bringing down to water* The slides are then brought down to water through ethanol–xylol mixture (1 : 1), absolute ethanol, 95, 90, 80, 70, 60, 50 and 30 per cent ethanol grades, keeping 10 min in each.
(3) *Staining* The original schedule is followed. Both pre-mordanting and post-mordanting in 1 per cent chromic acid are done for slides being stained by crystal violet schedule. Also slides originally fixed in Flemming's fluid and stained in crystal violet can be restained following Feulgen schedule.
(4) *Making permanent* For any staining, the usual procedure is followed.

The restaining procedure is also applied to slides which have not taken satisfactory stain in the original schedule and have been rejected during differentiation. For example, during the crystal violet schedule, if on differentiation in clove oil the tissue is seen to have taken insufficient stain, the slide is transferred directly to down grade xylol I and allowed to remain overnight. Afterwards it is brought down to water, pre-mordanted and stained as usual.

The exceptions to the re-staining process are Feulgen stain and fluorochromes. Slides with insufficient stain cannot be re-hydrolysed and restained in leuco-basic Fuchsin solution. However, several other alternatives can be suggested:

(1) For tissues originally fixed in acetic fixatives, acetic stains, like acetic–orcein or acetic–lacmoid solution, can be used.
(2) Tissues fixed in aqueous fixatives can be stained following the crystal violet schedule.
(3) After fixation in alcohol fixatives, haematoxylin staining is employed.
(4) For slides which have taken insufficient Feulgen stain, the chromosome stain can be brightened by immersing the slide in 1 per cent acetic–carmine or acetic–orcein solution for 2–5 min.

In animal material

Studies of meiotic stages from testes

Temporary squash schedules

In grasshopper testes

Dissect out the testes of a male grasshopper in 0.75 per cent normal saline solution by pulling with two fine forceps at the two ends, separate the head region from the rest of the body, trailing out the intact salivary glands and the anterior portion of the alimentary canal. Remove the glands by breaking off the duct attaching them with a pair of forceps.

For smear

Take a few lobules on a clean cover-glass and remove the excess saline by

touching the edge of a filter paper. Cut the tip of the lobules by means of a cataract knife, and the fluid should be spread quickly in uniform layers over the slide. Invert the slide immediately on a tray containing acetic–ethanol solution or any other fixative. Staining can be carried out in the usual way.

Acetic–carmine squash

Put testes lobules in a drop of acetic–carmine solution for 5 min and squash. The bulk testes should be fixed in acetic–methanol mixture (1 : 3) and then put in acetic–carmine solution for 5–15 min.

Squash, according to Smith (1943), is performed on the tissue prior to staining.

Squash after staining: Feulgen staining

Bring bulk tissue fixed in acetic–ethanol mixture down through ethanol grades to water. Wash in water and put in cold HCl (N). Hydrolyse in N HCl for 12 min (or adjust accordingly) at 60 °C. Rinse in cold HCl and put in Feulgen solution (15 min–1 h). Take a few lobules of the stained tissue in a small drop of 45 per cent acetic acid on a slide and squash gently by applying pressure on a cover-glass. Seal and observe. For temporary observation, materials can be sectioned 25 μm thick. This method has been used for Japanese weevils (Coleoptera, Curculionidae; Takenouchi, 1974a, b).

In amphibian testes

(1) *Dissection* Dissect out the testes from the newt, *Triturus* sp. Cut into very small pieces.
(2) *Fixation* Fix in acetic–ethanol mixture (1 : 3) or, in Carnoy's fluid in a glass phial for 2–3 days.
(3) *Staining and squashing* Lift a piece of the tissue on a drop of 1 per cent iron–acetic–carmine solution on a clean slide. Squash under a cover-glass, warm and seal with paraffin wax.
(4) The preparation can be made permanent following one of the usual schedules.

In Culex testes

(1) *Dissection* Place the pupa on a clean slide in a drop of Ringer solution A (0.65 g of NaCl, 0.025 g of KCl, 0.03 g of $CaCl_2$, 0.02 g of Na_2CO_3 in 100 ml distilled water) and observe under a dissecting microscope. Pull the head and tail of the larva with two needles, breaking it in two. Lift out small translucent testes with a needle.
(2) *Fixation* Place the testes in a phial containing acetic–ethanol (1 : 3) mixture or Carnoy's fluid and fix for 2 min.
(3) *Staining* Transfer to a drop of 1 per cent iron–acetic–carmine solution on a clean slide, warm slightly, cover with a cover-glass and squash through blotting paper.
(4) The slides can be made permanent following one of the usual schedules.

Notes
(1) This technique can be followed for most small insects.
(2) Acetic–carmine can be replaced by 1 per cent acetic–orcein solution.
(3) For Feulgen staining, transfer the testes to N HCl after fixation and hydrolyse at 60 °C for 4 min. Rinse in water and transfer to leuco-basic fuchsin solution. After 20 min, squash under a cover-glass on a clean slide in 45 per cent acetic acid. The entire operation can be carried out on a slide.

In mammalian testes

(1) *Dissection* Remove the testes entire. Cut into very thin sections.
(2) *Fixation* Fix directly in acetic–ethanol mixture (1 : 3) or 80 per cent chilled ethanol at 10–12 °C for 1 h.
(3) *Staining* Lift up a section, put it in 1 per cent iron–acetic–carmine solution, tease out the tubules; warm slightly, and squash under a cover-glass and ring with paraffin wax. This method is not very satisfactory.

For details, *see* Chapter 13.

In avian and reptilian testes
The techniques for avian and reptilian testes are similar to those for mammals and have been discussed in detail in Chapter 13.

Note
Invertebrate testes are usually dissected out in Ringer's solution A, but this step is not necessary for vertebrates.

Testes of trematodes
These are squashed for chromosome studies, following collection, 37 days after inoculation into eyes of chicks (Fried, 1975).

In silkworm testes (Murakami and Imai, 1974)

(1) Dissect out larval sex organs in 0.01 per cent colchicine in 0.45 per cent sodium nitrate solution.
(2) Change the solution with fresh hypotonic and keep at room temperature for 30–45 min.
(3) Transfer tissue to dry slide, add a drop of 60 per cent acetic–ethanol (1 : 3), dissect and squash for 1 min.
(4) Freeze on dry ice for 2–3 min, melt, keep in glacial acetic acid for 30 s and air-dry.
(5) Stain in Giemsa diluted 30 times in Sörensen's phosphate buffer (pH 6.8) for 7–10 min at room temperature.

A similar technique has been employed for ants (Imai and Kubota, 1972; Imai, 1974) and a slightly modified one for gonads and other parts of Diptera (De Lello, Toledo and Foresti, 1974).

In pulmonate land snails (Babrakzai and Miller, 1974)

(1) Inject 0.1 ml 10^{-3} M colchicine/g body weight.
(2) Remove ovotestis and cut it up in hypotonic solution.
(3) Fix and stain in lacto–aceto–orcein, lacto–propiono–orcein or Sudan black B.
(4) Mount and squash.

Paraffin section schedules for animal testes in general

(1) *Dissection* Dissect out the testes. If they are large, cut them carefully into small pieces.
(2) *Fixation* Fix the tissues overnight in any of the fixatives given in Chapter 3.

The remaining steps, namely washing, dehydration, infiltration, embedding, section cutting, bringing down to water, staining, mordanting, differentiation and mounting are similar to those followed for the somatic tissue described previously. Sections should be cut between 10 and 16 μm thick.

For haematoxylin staining, Schedule C is used.

Studies of meiotic stages from eggs

Oogonial division

(1) For early oogonial divisions, when the ovary is relatively immature, the techniques used for study are similar to those for testes.
(2) For studying older ovaries, both squash and paraffin section techniques are followed.

Oocyte division

Take mature eggs before laying, and follow the usual schedule.

Squash technique

This can be applied to those eggs which have a thin shell and little yolk.

(1) Puncture the shell of the egg. Smear and fix the contents in acetic–ethanol mixture (1 : 1) for a few hours, hydrolyse in N HCl and stain following the Feulgen schedule.
(2) Puncture the wall to bring out the contents and allow them to dry on a slide. Stain the dried eggs with aqueous Bismarck brown.
(3) Certain insects can be fed with a mixture of honey and 1 per cent colchicine solution for 24 h. Dissect out the ovary, keep them in 0.5 per cent colchicine solution for 5–10 min and squash in 1 per cent acetic–carmine solution. Orcein is used in staining squashes of eggs and gonadal tissues in *Pteriomorpha* sp. (Bivalvia; Ieyama and Inaba, 1974; Ieyama, 1975).

The meiotic studies from eggs are difficult to perform; the divisional stages are rarely found and lie in an arrested condition.

Permanent paraffin block preparations

(1) *Dissection and fixation* Dissect out the ovary and fix in Smith's modification of Kahle's fluid (100 ml absolute ethanol, 7 ml glacial acetic acid and 40 ml chloroform) for 2 h.
(2) *Dehydration* Pass the tissue through progressive ethanol, *n*-butyl alcohol and phenol grades (1 h in water–ethanol–*n*-butyl alcohol–phenol mixture 3:5:2:0, 24 h in 1:50:35:4, 1 h in 0:5:40:55 and 1 h in 0:1:3:0). Transfer to 4 per cent phenol in *n*-butyl alcohol. Change once after 10 min.
(3) *Infiltration* To the material in 4 per cent phenol in *n*-butyl alcohol, add an equal quantity of paraffin wax and keep in an oven. Change to pure molten wax after 16 h.
(4) *Embedding* Give two more changes in molten wax and embed as described in earlier schedule.
(5) *Section cutting* Trim the block. Cut off one end to expose the material and soak it in water for 24 h, then cut sections described before and bring the slide down to water.
(6) Hydrolyse in N HCl for 6 min and stain in leuco-basic fuchsin solution for 1 h. Mount in 45 per cent ethanol.
(7) The slides can be made permanent following any of the techniques previously described.

Note
If necessary, the eggs should be punctured with a needle to permit the fluid to enter.

Alternative schedule for marine invertebrate eggs (Cather, 1958)

(1) Place the eggs in a drop of water on an albuminised slide.
(2) Add a few drops of fixative (absolute ethanol 1.5, tertiary butyl alcohol 1, acetic acid 1) to the eggs, allow it to flow over the eggs and drain off.
(3) Similarly add 70 and 50 per cent ethanol and distilled water, treating in each for 10 min and then drain off.
(4) Hydrolyse at room temperature with three changes of HCl—1 N HCl for 5 min, 5 N HCl for 15 min and again 1 N HCl for 3–5 min.
(5) Stain in a jar containing Gomori's chromalum haematoxylin solution at 60 °C for 30 min.
(6) Mordant in 1 N HCl for 3–5 min.
(7) Keep in water for 10 min.
(8) Rinse in SO_2 water for 5 min. Treat with chilled 45 per cent acetic acid for 5 min.
(9) Wash in water for 5 min.
(10) Treat in 1 per cent aqueous papain solution for 10 min. This causes the tubules to shrink.
(11) Wash in water and transfer to 60 per cent acetic acid. The cells swell to greater than the original size.

(12) Place the cover-glass on the material and squash under blotting paper, applying uniform pressure.
(13) The slides can be made permanent, following one of the usual schedules.
(14) Change through 30, 50, 70, 95 per cent and absolute ethanol, keeping 10 min in each. Treat in pure xylol for 30 min and mount in Canada balsam.

Air-drying schedule
Pachytene chromosome study in insects (Traut, 1976)

Material Bombyx mori

(1) Dissect out ovaries of fourth and sixth instar larvae, fix for 30 min in Carnoy's fluid and transfer to dry slide.
(2) Add 60 per cent acetic acid, tear ovary into small bits with tungsten needles.
(3) Keep for 30 s at 45 °C, move drop a few mm along slide; repeat three to five times.
(4) Draw up extra liquid with pipette and reject.
(5) Air-dry, stain and mount in lacto–aceto–orcein. Seal.

Detailed descriptions of animal chromosome methods have been given in Chapter 13.

8
Methods for special materials

The special techniques for the study of the differential nature of chromosome segments can be put into groups according to the nature of the chromosomes —1, spiral structure; 2, centromere; 3, secondary constriction; 4, heterochromatin; 5, salivary gland chromosomes; 6, lamp brush chromosomes; 7, pachytene chromosomes; 8, prochromosomes; 9, pollen grains; 10, embryosac mother cells; 11, endosperm; 12, study of nucleolus. The methods adopted for studying chromosomes of thallophytes have also been included in this chapter.

SPIRAL STRUCTURE

The spiral nature of chromosomes was first observed by Baranetzky in 1880 in metaphase plates of *Tradescantia*. Sakamura in 1927 demonstrated internal spirals in the same plant during meiosis by fixation in boiling water. Gradually various schedules were developed for the study of the spirals, and, in general, they fall into three groups: those based on uncoiling the chromosome threads through some shock; those based on dissolving the outer envelope of nucleic acid, exposing the inner thread; and those based on causing the chromosomes to swell, by differential hydration of the segments.

These methods have been applied in both plants and animals for the study of mitosis and meiosis.

First group

Several agents are used for uncoiling the chromosome thread, including (a) acid fumes, (b) ammonia vapour, (c) cold temperature and (d) boiling water. They can be applied to both mitotic and meiotic chromosomes.

Acid fumes

For mitotic cells, expose the tissue directly in the living state to the fumes of concentrated nitric acid, hydrochloric acid or acetic acid for 1–2 min (for example, bulbs of *Allium cepa* with roots intact are held with the roots

near the mouth of a jar containing the acid). Fix the tissue (cut root tips in case of *Allium cepa* in acetic–ethanol (1 : 1) for ½ h and wash successively in 70 per cent ethanol and water. Hydrolyse in N HCl for 10 min at 58–60 °C. Wash in water, stain in leuco-basic fuchsin solution for 30 min (Feulgen schedule), squash in 45 per cent acetic acid and seal with paraffin.

For meiotic cells, smear the tissue, expose to the acid fumes for 1 min, fix overnight in La Cour's 2BE or Navashin's A and B fluids, wash in running water, stain following the crystal violet schedule (*see* Chapter 7), and mount in Canada balsam.

Ammonia vapour

Expose the tissue, in its medium, to fumes of ammonia for 5–15 s. (For example, pollen mother cells are kept in 3 per cent sucrose solution during exposure to ammonia vapour.) Fix the tissue in the requisite fixative, stain and mount. Kuwada and Nakamura (1934) smeared flower buds after exposure in 1 per cent acetic–carmine solution; pollen mother cells can also be exposed after smearing and fixed and stained according to the schedule followed for exposure to acid fumes. Both roots and anthers can also be fixed in acetic–ethanol after exposure, and hydrolysed and stained according to Feulgen technique as given with the acid fumes (La Cour, 1935).

Cold temperature

Root tips, on being frozen for 3–5 days, show nucleic acid starvation. If they are then fixed and stained following the Feulgen schedule, the major spirals can be seen (Callan, 1942).

Micro-incineration

Barigozzi (1937) and Über (1940) used micro-incineration for demonstrating the spiral nature of chromosomes.

Second group

The comparatively more effective schedules based on dissolving the outer nucleic acid envelope are as follows.

Ammonia–ethanol schedule

Treat the tissue with ammonia in 30 per cent ethanol (6 drops in 50 ml) for 5–20 s. Wash in water and fix overnight in Flemming's fluid. Wash in running water for 3 h, stain in crystal violet (*see* Chapter 5), and mount in Canada balsam. This method is effective for studying *meiosis* in both plants and animals (Sax and Humphrey, 1934; Creighton, 1938), but for mitosis an alternative method is to fix the tissue after exposure in acetic–alcohols and to stain following the Feulgen schedule, as given before.

(d) *The left end of lampbrush bivalent VIII of* Triturus cristatus carnifex *showing in particular the telomeres and a sphere fusion* (courtesy of Prof. H. Callan and the Royal Society)

Weak alkali

Weak alkaline solvents of nucleic acid are used, like NaOH, $NaHCO_3$ or NaOH in 1/100 g mol solutions. Place the tissue in the alkali for 15 s to 5 min, depending on the material, and fix in Flemming's fluid and stain in crystal violet or fix in acetic–alcohols and stain by the Feulgen schedule as given before (Oura, 1936: Kuwada, Shinke and Oura, 1938; Hillary, 1940). The pollen mother cells can be smeared before treatment on a dry slide and the smears subjected to treatment.

Precipitation of DNA

This method is based on the principle of precipitating the nucleic acid as a metallic salt and subsequently partially digesting the protein.

Treat the tissue (slides with smears in case of meiotic cells) in 1/100 g mol solution of NaCN for 30 s. Fix overnight in Flemming's fluid and then in water for 3 h, and keep the tissue in 0.1 per cent lanthanum acetate for 12 h to precipitate the nucleic acid as lanthanum salt. Digest in 1 per cent trypsin solution containing a trace of lanthanum acetate for 24 h at 37 °C, and hydrolyse and stain, following the usual Feulgen schedule (Hillary, 1940).

An alternative method for root tips is to treat them in ammonia followed by thorium nitrate solution (Nebel, 1934). The tissue can also be treated in 0.00005 mol solution of NaCN, followed by acetic–ethanol fixation and Feulgen schedule, as given previously (Coleman, 1940).

Third group

Treatment of the tissue, particularly of root tips, in any of the pre-treatment chemicals for a specified period at a requisite cold temperature results in changes in the cytoplasm. These changes cause a differential hydration and subsequent swelling of the chromosome arms, and often the major spirals can clearly be observed in the swollen chromosomes.

For this purpose, treat the root tips in a pre-treatment chemical like aesculine, *p*-dichlorobenzene, or 8-oxyquinoline for a certain period (1 h for aesculine, 4 h for *p*DB, 3 h for OQ) at cold temperature (10–15 °C). Fix in acetic–ethanol, heat in 2 per cent acetic–orcein–N HCl (9 : 1) mixture and squash in 1 per cent acetic–orcein solution.

CENTROMERE

The centromere has been the object of close scrutiny for many years (Carothers, 1936; Darlington, 1939; Schrader, 1939; Natsuura, 1941; Sharp, 1943; Östergren, 1947; Lima de Faria, 1969).

Under the light microscope, the centromeric apparatus is now seen to consist of several chromomeres attached to each other and to the chromatid arms by interchromomeric threads.

These centromeric bodies show the same divisional cycle as the chromatids,

and in order to study the structure of the centromere, the gap should be increased. For this purpose, the material is first treated at cold temperature in a pre-treatment chemical, fixed and stained. The most satisfactory pre-treatment chemical has been found to be 8-oxyquinoline (OQ) solution.

The principle underlying the process is that the pre-treatment chemical when cold, changes the viscosity of the cytoplasm, causing the spindle to break. The chromosome segments undergo differential hydration and contract while the more or less rigid plasma keeps the chromosome arms in their original position, causing a contraction towards the middle of each chromosome arm. As a result, the centromeric gap is exaggerated and the structure of the centromeric apparatus is brought out clearly.

A general schedule for centromere study is given below (Tjio and Levan, 1950).

(1) Cut fresh root tips and treat in aqueous solution of 8-oxyquinoline (0.002 M) at 12–18 °C for 3 h.
(2) Heat the root tips in a mixture of 2 per cent acetic–orcein solution and N HCl (9 : 1) for 3–4 s.
(3) Squash the tips in 1 per cent acetic–orcein solution, seal and observe.

Lima de Faria (1969) found that the fixation in acetic–ethanol mixture (1 : 1) tends to reduce the stainability of the centromere.

For the study of *centromere in flower buds*, Lima-de-Faria (1948) dissected out the anthers, placed them in a drop of 1 per cent acetic–carmine solution, added a trace of iron by macerating them with a needle, heated slightly, squashed and sealed. In some cases, he fixed the buds in acetic–ethanol (1 : 4) for 4 h, transferred to 95 per cent ethanol (overnight), stored for some days in 70 per cent ethanol and followed the schedule outlined above.

Lima de Faria (1969) found that the fixation in acetic–ethanol mixture meiotic centromere in Feulgen solution. The technique, used on flower buds of *Agapanthus umbellatus*, is as follows.

(1) Fix the buds in acetic–ethanol mixture (1 : 4) for 7–9 h. Transfer to 95 per cent ethanol (overnight) and store in 70 per cent ethanol for 2–3 days.
(2) Cut the anthers and squeeze out the pollen mother cells into a drop of 45 per cent acetic acid on a slide.
(3) Squash by placing a cover-glass over the pollen mother cells.
(4) Gently heat the slide once over a flame.
(5) Invert the slide in 1 per cent aqueous acetic acid.
(6) After the cover-glass falls off, keep both slide and cover-glass in a tray containing Belling's modification of Navashin's fixative for 3 days.
(7) Wash in distilled water for 1 h.
(8) Immerse in N HCl at 60 °C for 6 min.
(9) Wash in distilled water (1–2 min) and immerse in fuchsin sulphurous acid for $3\frac{1}{2}$ h.
(10) Pass through fresh SO_2 water, three changes of 10 min each.
(11) Rinse in distilled water, pass through 20, 50, 70, 95 per cent and absolute ethanol, keeping in each for 3 min. Mount separately in euparal and seal.

The chromosomes take up the characteristic violet red colour. The centro-

meric chromomeres, being intercalated among longer fibrillae than the chromomeres of the arms, can be clearly distinguished.

All these techniques have been carried out on plant chromosomes. They can, if necessary, be applied to animal materials with modifications. Thus there is ample scope for improvement.

SECONDARY CONSTRICTION

Secondary constrictions lack a centromere, are heterochromatic in nature and do not generally exhibit allocycly. They are the loci where nucleoli are organised, as suggested by Heitz (1931), McClintock (1934) and others. Their universal nucleolar nature has, however, been disputed by Darlington (1926) and Darlington and La Cour (1942), *see* Lettré and Siebs (1961). Special staining schedules for this region are given under N-banding in Chapter 13.

The secondary constriction is generally represented as a distinct gap during the divisional cycle. When the constriction is present at the end and the distal chromatic part appears as a knob, it is known as a *satellite*. Often a thin chromatic thread, called a satellite thread, is seen to bridge the gap. Sometimes more than one secondary constriction is observed on the same chromosome, being called *supernumerary constrictions*.

For the study of secondary constrictions, the gap has to be exaggerated. This can chiefly be brought about by two means: cold treatment, and pre-treatment by chemicals.

Cold treatment

The phenomenon underlying this technique is the nucleic acid starvation observed at cold temperatures. Keep the plant overnight in a cold chamber at 3–7 °C. Cut out the root tips, wash in water and fix in acetic–ethanol (1 : 1) for 2 h, heat in a mixture of 2 per cent acetic–orcein and N HCl for a few seconds, squash in 1 per cent acetic–orcein under a cover-glass, and seal. The secondary constrictions are observed as unstained gaps in the chromosome.

Pre-treatment

Pre-treatment in the various cold pre-fixing fluids tends to cause viscosity change in the cytoplasm and differential hydration and dehydration of the chromosome segments. The secondary constriction regions are de-spiralised and expand, and the contraction of the swollen arms on either side tends to exaggerate this region, which becomes very pronounced.

Treat cut root tips with a saturated solution of 8-oxyquinoline for 4 h at 10–15 °C. Fix in acetic-ethanol mixture (1 : 1) for 1 h and follow the acetic–orcein squash technique as given in the previous treatment. The secondary constrictions appear as pronounced unstained gaps.

The Feulgen schedule can be employed in lieu of acetic–orcein after fixation in acetic–ethanol.

HETEROCHROMATIN

Heterochromatin was originally defined by its expression in the phenotype of the chromosome (Pontecorvo, 1944; Brown, 1966; Wolf and Wolf, 1969).

Heterochromatic segments may be defined as those segments which differ in any respect from euchromatic ones. They may show allocycly (e.g., prochromosomes), may be positively heteropyknotic throughout the division cycle (sex chromosomes) or may be negatively heteropyknotic in all the stages. They are of a heterogeneous nature and include the centromeric heterochromatin (called 'chromocenters'), intercalary heterochromatin, telomeric heterochromatin and also the heterochromatin in the secondary constriction regions. Entire chromosomes may be heterochromatic, like sex chromosomes in *Drosophila*, supernumerary chromosomes and B chromosomes in maize. Heterochromatic regions exhibit, in general: extreme susceptibility to external conditions, like cold; heteropyknosity and allocycly, in most cases; property of heterochromatising adjacent euchromatic segments; temporary genetic inactivity; absence of template activity *in vitro*; late or early DNA replication in S phase; and a high content of repetitive DNA.

The techniques for *Q*, *G*, *R*, *O* and *C* banding, discussed in Chapter 13 are based on the presence of heterochromatic segments. They appear as positively staining bands in metaphase with *Q*, *G* and *O* techniques and as negatively staining bands with *R*-banding. The *C* band regions correspond with the centromeric type of heterochromatin, which may be located, as in certain plants, in regions other than centromere as well. *G*, *O* and *Q* bands are correlated with the intercalary heterochromatin (*see* Sharma, A., 1976).

In this chapter only the methods for demonstrating the heterochromatic segments of a chromosome, other than the chromocenters and secondary constriction regions, are described. Two techniques, digestion with trichloracetic acid, and digestion with mercuric nitrate, have given best results. For other methods, please *see* Chapter 13.

Treatment with trichloracetic acid

This method is based on the initial digestion of the tissue in a particular concentration of TCA for a definite period, resulting in differential removal of DNA from the chromosomes, followed by staining (Sharma, 1951).

Fix the cut tissue in acetic–ethanol mixture (1 : 1) or 80 per cent ethanol in cold (10 °C) for 2 h to overnight. Treat in 0.25 M TCA at 60 °C for 40 min. Wash in distilled water. Keep in leucofuchsin solution for 30 min, and squash under a cover-glass in 45 per cent acetic acid. The heterochromatin, particularly that of the centromeric and telomeric regions, stains sharply in leucofuchsin, the rest of the chromosome remaining unstained. The secondary constrictions do not show any basophilia.

Treatment with mercuric nitrate (Levan, 1946)

The tissue is initially treated in an inorganic salt for a period in cold temperature followed by fixation and staining, when the chromosome arms show

differential staining in the heterochromatic regions (Levan, 1948, 1949, 1952). The most effective salt solution is mercuric nitrate.

Wash the tissue and pre-fix in 0.005 mol aqueous mercuric nitrate solution for 4 h at 10–12 °C. Transfer to a mixture of equal parts of Navashin A and B solutions, mixed just before use, and keep overnight. Wash, embed in paraffin, cut longitudinal sections and stain and mount following the usual crystal violet staining schedule.

During the divisional cycle, the chromosome is de-stained and becomes hyaline except for the heterochromatic regions on the two sides of the centromere and the telomeres. The maximum stain is retained in the chromocenters.

SALIVARY GLAND CHROMOSOMES

Balbiani in 1881 first observed giant chromosomes in the salivary gland cells of some Dipteran species. These chromosomes, also found in some other gland tissue, remain in a state of permanent prophase. Later, Kostoff (1930), Heitz and Bauer (1933) and Painter (1933, 1934) studied their structure and nature in detail.

These giant chromosomes are the largest available for chromosome study, being approximately 100 times the length of somatic metaphase chromosomes. The homologous chromosomes show a type of close synapsis, and also reveal a distinctive pattern of bands, consisting of alternating chromatic and achromatic areas. These bands differ in the details of structure so distinctly that on this basis each chromosome can be accurately mapped throughout its euchromatic length (Schrader, 1939).

Structurally each giant chromosome shows a 'polytene' or 'multiple' nature (Metz, 1941; Painter, 1941). The chromosome remains in a permanent prophase condition, in which the chromomeres and chromonemata continue to duplicate without separation, the result being a multi-stranded structure, visible under a hand lens when stained. The aggregation of the homologous chromosomes produces the transverse chromatic bands, and the numerous chromonemata, which may be as many as 1024, according to Painter (1941) and Swift and Rasch (1955), are associated in parallel lines. Others, like Kodani (1942) and Ris and Crouse (1945) disagreed with the polytene concept, regarding the chromonemata to be swollen by lateral enlargement of the interband regions, and the bands to be coiled structures.

The salivary gland nuclei are held to be polytenic due to the giant size of the chromosomes, their multiple nature and their total DNA content, which is many times higher than that of ordinary nuclei (Beermann, 1972; Lefevre, 1974).

The salivary gland chromosomes present a constant pattern of linear differentiation which aids in their study with relation to genetics and systematics. Caspersson (1940) utilised them in microchemical studies of cell structure, while Pavan and Ficq (1957) used in chromosomes of *Rhynchosciara angelae* for autoradiographic experiments with H^3-labelled thymidine for studying genic metabolism.

For the study of these chromosomes, the salivary glands of different Dipteran larvae are the most suitable material, although they also occur in

the cells of malphigian tubules, fat bodies, ovarian nurse cells and gut epithelia. For general experiments, the insects most commonly used are *Chironomus* (Poulson and Metz, 1938), *Bibio* (Heitz and Bauer, 1933), *Drosophila* (Demerec, 1950), *Sciara* (Metz, 1935); and *Rhyncosciara* (Pavan and Da Cunha, 1969).

Old fat larvae, bred on rich yeast food at 16–20 °C, show the largest chromosomes. The diet varies with the type of larva used. The number of the cells in a salivary gland ranges from 28–32 in *Sciara*, 28–44 in *Chironomus* to 100–120 in *Drosophila*, all in different stages of development.

For the study of the chromosomes, the following schedule may be followed.

(1) Place the full-grown larva on a slide in a drop of Ringer's solution or 0.73 per cent isotonic salt solution. Cut off the head with a scalpel and press the body with a needle at the same time. Remove the pressure. The salivary glands float out. Transfer them to a clean slide with the dissecting fluid using a pipette. The material is now ready for staining. For storage, add a few drops of paraffin oil to the material and place a cover-glass over the whole. It will remain fresh for 24 h (Bauer, 1935).

(2) Staining may be done in either acetic–carmine or acetic–orcein solution. For *Drosophila*, the most effective stain is 2 per cent acetic–orcein in 70 per cent acetic acid; while 1 per cent acetic–orcein in 45 per cent acetic acid, plus 1 ml chloroform may be used for *Sciara*; and 2 per cent orcein in 50 per cent acetic acid for *Chironomus*.

Transfer the tissue to a drop of the stain on a clean slide with a pipette. Leave for 5–10 min, depending on the material.

(3) Prepare the cover-glass by smearing thinly with Mayer's albumin and dry over a flame for 1–3 s.

(4) Add the cover-glass on the tissue, drain off the excess stain with filter paper, blot the preparation with filter paper, applying uniform pressure over the cover-glass to flatten out the chromosomes and remove more stain. If the glands do not rupture, press with a blunt needle over the cover-glass. Seal and observe.

(5) For permanent preparations, keep the slide with squashed material and cover-glass in a closed trough, lined with filter paper soaked in 95 per cent ethanol. After 24 h remove the cover-glass and mount in euparal. Alternatively, the slides may be inverted in *n*-butanol until the cover glass is detached, and mounted separately.

Modifications of the schedule given above were suggested by many workers. Zirkle (1937) suggested a mixture of acetic acid (50 ml), water (50 ml), glycerin (1 ml), powdered gelatin (10 g), dextrose (4 g), $FeCl_3$ (0.05 g) and carmine to saturation, boiled and filtered, to be used instead of the usual acetic–orcein stain. Heilborn (1937), in an alternative method, transferred the glands from Ringer's solution to 50 per cent acetic acid, fixed for 4–8 min and then transferred to a *dry slide*, covered with a cover-glass, moistened with glycerin and squashed, suspended in 95 per cent ethanol until the cover-glass detached, washed in water, stained overnight in 1 per cent acetic–carmine, washed again and then dehydrated following ethanol–xylol grades and mounted as usual (*see also* Chapter 7).

LAMP BRUSH CHROMOSOMES

In a large number of vertebrates, within the developing oocytes during diplotene, the chromosomes undergo a phase called 'lamp brush', characterised by a great increase in length and the formation of numerous side loops radiating from the chromosomes. These loops grow in number and size up to diplotene but increase and disappear before metaphase. They have also been found in the spermatocytes of some invertebrates (Ris, 1945). The most satisfactory materials, are, however, the shark *Pristiurus*, some birds and amphibians (Duryee, 1941; Gall, 1952, 1954, 1956; Alfert, 1954; Callan, 1963, 1966; Izawa, Allfrey and Mirsky, 1963; MacGregor, 1965; Miller, 1965; Rogers, 1965; Hess, 1971). The longest lamp brush chromosomes are found in the newt, *Triturus viridescens*, ranging from 350 to 800 μm in length.

Lamp brush chromosomes are very elastic and may be pulled to many times their length without injury; however the lateral coils, though elastic, are more fragile. The main axes and loops are DNA-positive and resistant to several chemical treatments. Obviously, the long lateral loops are formed at definite loci due to metabolic activity of genes at these regions (Callan and Lloyd, 1956, 1960).

The lamp brush chromosomes are of special interest, due to their great length and extreme fragility. The principal purpose of using them is that the synthesis of ribonucleoprotein in the metabolically active DNA loop can be studied. For observation under a living constitution, the use of a phase contrast microscope is recommended.

A general schedule for study is given below (Gall, 1966).

(1) Dissect out the ovary or several oocytes, making a small incision at the ventral side of the animal (for example, the newt) anaesthetised with light ether or 0.1 per cent MS 222 solution for 15 min, and place it in a dry watch-glass containing the coelome with adequate moisture, seal and keep at 4 °C for up to two days. Transfer a piece of oocyte or ovary to a mixture of 5 parts 0.1 M KCl and 1 part of 0.1 M NaCl buffered to pH 0.8–7.2 with 0.01 M phosphate. This ratio may vary in different species (Callan and Lloyd, 1960; Naora *et al.*, 1962).
(2) With a pair of fine micro-forceps, break the oocyte and take out the translucent nucleus. Puncturing the cell, followed by squeezing with the needle also results in ejection of the nucleus. In both cases, the nucleus starts swelling on isolation. Transfer the nucleus immediately to the observation chamber filled with the same 5 : 1 solution.
(3) For preparation of the observation chamber, bore a 6.4 mm hole through the centre of a 76.2 × 25.4 mm slide and place a cover-glass across the hole and seal with paraffin wax. Fill it with S11 solution before transferring the nucleus.
(4) In the observation chamber, remove the nuclear membrane carefully, under a dissecting microscope with the help of a pair of very fine forceps and a tungsten needle pointed by dipping in molten sodium nitrate. The chromosomes are then liberated and confined in the hole in the slide on the cover-glass forming its bottom. It can be kept in the cold for observation for a day in the unfixed condition. For fixation, it

is preferable to keep the slide 3–5 min in a formaldehyde chamber or to add a drop of concentrated formalin. After fixation, the preparations can be kept for several weeks. Cover the slide on the other side with another cover-glass and seal.

(5) Invert the optical train of the phase contrast microscope and observe the preparation under it. The chromosomes will be observed as coiled loops in a state of continuous movement.

Care must be taken to handle the preparation very gently. Microphotographs are taken in flashlight.

For making permanent preparations

Use a slide instead of a cover slip at the bottom of the observation chamber so that the chromosome can be isolated on the slide or alternatively, the cover slip may be used.

(1) After isolation and clearing of the nucleus in 5 : 1 medium (calcium free), pass the nucleus quickly through a watch glass containing 0.1 M 511 and 0.5×10^{-4} M $CaCl_2$ and transfer to the observation chamber again.

(2) Remove the nuclear membrane, isolate the chromosome as above and transfer to a moist chamber for an hour, which later on becomes transformed to a formaldehyde chamber till the chromosome gets attached to the slide (in about 15 min). The pH may be lowered to facilitate attachment.

(3) Transfer the set-up to a jar containing 2–4 per cent of 5–10 per cent formalin, buffered to pH 4–5, and keep for 1 h.

(4) With a scalpel, separate the slide from the observation chamber. Dehydrate in ethanol, removing paraffin or vaseline with which the slide was attached and follow the usual procedure for staining in Feulgen solution for DNA and Azure B at pH 4 for RNA.

Notes

(1) The medium should be diluted, if necessary, especially for the study of the chromomeres and the operation should be performed very quickly, to prevent the sap from becoming completely liquefied.

(2) To check sap dispersal, osmium fixation is recommended, for which the chromosomes should be isolated in saline solution, dispersed in water and a moist chamber, fixed in osmium vapour and finally attached with 1 per cent aqueous acetic acid or vapour. Ethanol vapour may also be tried.

For autoradiography

In securing autoradiographs, lamp brush chromosomes are convenient materials, since the incorporation of precursors is very rapid. Specific

radioactive precursors, such as, tritium-labelled uridine (100–300 mCi–specific activity 0.5–5.0 Ci/mmol) may be injected into the body cavity. If the explanting is carried out at 48–72 h, profuse labelling indicating synthesis of RNA or DNA loops can be obtained. But for short term and rapid incorporation, explanted ovaries can be treated in concentrated radioactive precursors taken in a watch glass. Both stripping film and emulsion coating can be performed as outlined in the chapter on autoradiography.

For electron microscope studies

Lamp brush chromosomes are not convenient materials due to the thickness of the chromosomes and the difficulty in interpreting the isolated material (Gall, 1966). However, chromosomes attached to cover slips can be dehydrated and then polymerised, after inverting over a gelatin capsule filled with plastic monomer and the cover slip separated out, using the freezing technique. In whole mounts, mounting directly on steel or platinum grids coated with carbon can be performed (Lafontaine and Ris, 1958), as given in the chapter on electron microscopy. Gall (1966) devised a method for agar spreading of lamp brush chromosomes.

PACHYTENE CHROMOSOMES

Due to their configuration during the pachytene stage in pollen mother cells, the chromosomes of a large number of plants present very good material for the study of their individual structure and the nature of pairing. Different techniques have been devised for the study of the various structures and a few of the schedules followed are now considered.

For chromosome study

Lima de Faria, in 1948, employed a modification of the iron–acetic–carmine technique to study the B-chromosomes of rye at pachytene. Later, in 1952, he used this method for chromomere analysis of rye. In brief, the method includes the following steps.

(1) Fix a complete spike of rye with awns cut close in acetic–ethanol mixture (1 : 4) for 3–4 h. Keep overnight in 95 per cent ethanol and pass on to 70 per cent ethanol. Dissect out the three anthers of each flower.
(2) Transfer one anther to a drop of iron–acetic–carmine solution (two drops of iron acetate in 10 ml acetic–carmine solution). Under a wide-field binocular microscope, cut the anther into two pieces, press each half gently to squeeze out the pollen mother cells, and remove all pieces of anther wall and tapetum with a needle, leaving only the pollen mother cells.
(3) Observe under the microscope if the nuclei are in the pachytene stage. If so, add another drop of stain, place a cover-glass on the material and heat gently over a flame three or four times.

(4) Apply uniform pressure vertically with a U-shaped needle-point, blotting off excess stain from the side; check under a microscope. If stronger pressure is wanted, add more stain, heat again and press. Careless application of pressure may break up the chromosomes.
(5) Heat again and invert the slide whilst still warm in 10 per cent aqueous acetic acid and after the cover-glass falls off, pass both slide and cover-glass through acetic–ethanol and ethanol–xylol grades and mount in Canada balsam.

For mammalian materials, both squash and air-drying methods may be used to study pachytene chromosomes. The squash method involves the following steps (Gardner and Punnett, 1964).

(1) Place a piece of testicular tissue in 0.3 per cent aqueous sodium nitrate solution for 1 to 6 h, depending on the size.
(2) Dissect out and observe a few tubules in stain to ascertain the presence of the required stage.
(3) Keep tissue in 3 M glucono-deltalactone solution for 2 h for softening; stain in 1 per cent acetic or propionic–carmine for 10–12 h; wash in four changes of 70 per cent ethanol; and transfer to acetic–ethanol (1 : 1) mixture.
(4) Mince into a thick suspension; filter through several layers of cheese-cloth; centrifuge at 250 rev/min for 15 min and pipette off the fluid between the supernatant and coarse precipitate.
(5) To a drop of fluid containing the cell suspension; add a drop of water soluble mounting medium (Hoyer's medium, Alexopoulos and Beneke, 1962); cover with cover-glass; blot: warm and squash, exerting uniform pressure.

For air-dry preparations (Hungerford, 1971).

(1) Take fresh tissue after biopsy in tissue culture medium containing Eagle's basal amino acids and vitamins at double concentration in Eagle's BSS adjusted to pH 7.0 with 7.5 per cent $NaHCO_3$ with glutamine 2 mM, penicillin 100 units/ml, streptomycin 100 μg/ml, phenol red 7 μg/ml, newborn agammaglobin bovine serum 15 per cent and USP heparin sodium 20 000 units.
(2) Mince tissue in BSS at 37 °C; centrifuge suspension at 100 g for a few min.
(3) Centrifuge supernatant at 150 g for 4 min; discard supernatant and resuspend pellet in excess 0.125 M KCl with heparin added (20 000 units/l) and incubate at 37 °C for 1 h.
(4) Centrifuge, discard supernatant and resuspend pellet in acetic–methanol (1 : 3) for 10–15 min.
(5) Take a drop on a cooled slide and allow the fixative to evaporate in *warm* air as the drop flows down. Stain the dried slide for 2 h in 1 per cent solution of orcein in 60 per cent acetic acid and mount with Diaphane.

For the study of general structure

For a general analysis of the chromosomes of barley, Sarvella, Holmgren

and Nilan (1958) tried out a modification of Lima-de-Faria's technique. Fix the anthers in three parts 95 per cent ethanol: one part acetic acid. Tease out the pollen mother cells and place in iron–acetic–carmine solution. Place the slides over a hot water bath, and before final squashing, tap gently on the cover-glass to separate the pollen mother cells. The slides are made permanent by Conger's dry ice technique and mounted in balsam.

For the study of heterochromatin

Brown (1949) devised a modified technique involving the use of iron alum mordanting before staining in 1 per cent acetic–carmine solution as usual. He applied this method in *Lycopersicum esculentum.*

Several modified techniques have been employed by different workers at various periods for the study of pachytene chromosomes from different organisms, including, (a) Darlington's (1933) technique for studying the centromere structure in *Agapanthus*, (b) Brown's (1954) technique for the study of diffuse centromere in *Luzula*, (c) McClintock's (1934) technique for studying the nucleolar organiser region in *Zea mays*, (d) Pairing in diploid plants of *Zea mays* observed by McClintock (1931, 1933), (e) Techniques devised by Darlington (1929), Upcott (1939) and Gottschalk (1955) for the study of pairing in tetraploids of different plants, (f) Ford (1969) studied in detail the chromomere patterns of human chromosomes.

PROCHROMOSOMES

The term 'prochromosome' is applied to the heterochromatic blocks of the interphase stage and the appearance of these blocks is due to the positive stainability of the heterochromatin lying at both sides of the centromere. The region appearing as a stained block during interphase remains de-stained during metaphase, representing true allocycly. The number of prochromosomes may be equal to, or if fused, less than, the number of chromosomes in the complement. The polyploid nature of chromosome threads in the differentiated nuclei was first observed by Huskins through the prochromosome counts.

For the study of prochromosomes, the pre-treatment and Feulgen schedule adopted for centromere study, as described earlier, is equally effective. An ideal material is the root tip of *Scilla sibirica.* The prochromosomes appear as magenta-coloured bodies in the nuclei at resting stage.

POLLEN GRAINS

The pollen grains of Angiosperms are utilised for studying (a) mitotic division in pollen grains; (b) fertility of the grains, and (c) mitotic division in the generative cell inside the growing pollen tube.

Study of mitotic division in pollen grains

For the study of the first mitotic divisions in the pollen grain the methods followed are similar to those adopted for the study of meiosis in pollen mother cells (*see* chapter on representative schedules).

Study of fertility of pollen grains

In order to study the apparent fertility of pollen grains two sets of methods are available: (a) based on staining the contents of the grains, and (b) based on the germination of the pollen tube.

Staining the contents of the grains

This method involves staining the grains with different dyes and counting the percentage of empty and coloured grains. A number of staining media are available.

A very convenient method is to stain the pollen grains in Müntzing's mixture of glycerol and 1 per cent acetic–carmine solution for some hours. The filled grains take up the stain while the empty ones do not. The acetic acid evaporates, but glycerol remains. By ringing with paraffin, the preparation can be stored for a long time.

Another method is staining with Owzarzak's methyl green phloxine. The medium preserves the slides for several months. The walls of all the grains take colour but only the filled grains take up both colours.

These methods show the frequency of filled pollen grains, but they only give an indication of their fertility percentage, since only the empty grains are certainly sterile, while the filled grains are not necessarily able to germinate.

Germination of the pollen tube

The methods, based on the actual germination of the pollen tubes, give a sure indication of the actual fertility of the pollen grains. They are described, in connection with pollen tube mitosis, later.

Study of mitotic division in generative cells inside pollen tubes

For the study of pollen tube mitosis the practice is to study the mitotic division of the generative nucleus into the two sperm nuclei, which usually takes place between 2 and 48 h after germination of the pollen tube.

The methods generally include two main stages, (a) germination of the pollen tube, and (b) study of the chromosome structure.

The chief factors necessary for the artificial germination of pollen tubes are temperature, humidity and culture media. According to Bishop (1949), however, pollen tubes can be germinated without media. The chief principle underlying the preparation of artificial media is to provide a condition as closely approaching the normal secretion of the stigma as possible.

The different kinds of culture media available are:

(1) Cane sugar: 3–30 per cent solution in water.
(2) Agar or gelatin: 2 per cent solution in water.
(3) Extract of style and placenta or stigma alone in water.
(4) Stigmatic secretion in normal conditions.

The optimum temperature for germination is 20 °C and the optimum humidity is that approaching saturation. However, the optimum concentration of the medium for a particular plant depends on the species or the individual studied and partly on the temperature. The concentration of the medium is inversely proportional to the temperature of germination.

The methods vary chiefly with regard to the details adopted for bringing the pollen grains in contact with the medium. Some of the general methods are now given.

The hanging drop method

This method is based on growing the pollen tube in a hanging drop of medium within a moist chamber. It is most suitable for growing the tubes in an atmosphere of controlled humidity. The floor and slides of the chamber are formed by placing a ring coated with vaseline on a slide. A drop of the medium is placed on a clean cover-glass and pollen dusted on it. The cover-glass is inverted on the ring so that the drop with pollen hangs inside the chamber formed by the ring. The humidity is controlled by placing a drop of water on the slide or a drop of agar inside the chamber. In an alternative method, the ring is not coated with vaseline and the entire preparation is kept inside a desiccator containing an aqueous solution of glycerol to control humidity. After the pollen tubes have grown to a suitable length, they can be stained in staining-cum-fixing fluids or fixed in a metallic mixture and stained in crystal violet.

The floating cellophane method

This was devised by La Cour and Fabergé (1943) and is based on growing pollen grains on a square of cellophane paper (about 2 cm × 2 cm) which is floated in sugar solution in a petri dish. The pollen is dusted on to the upper surface of cellophane paper. The petri dish is covered and kept at 20 °C.

The germinated tubes can be stained in a staining-cum-fixing mixture and observed; otherwise they can be fixed in acetic–ethanol mixture for 2–24 h, hydrolysed in N HCl for 6 min and stained in fuchsin sulphurous acid solution.

Precautions to be observed are: the cellophane must not be thicker than 0.04 mm and should be of the non-waterproof type, and for accumulating metaphase, 0.05 per cent colchicine solution can be added to the sugar solution or acenaphthene crystals scattered on the petri dish.

This method, while generally satisfactory, has two limitations: cellophane stains readily with acetic stain fixatives and so details in temporary mounts are obscured within a short time; and a considerable proportion of pollen is washed off during staining and mounting.

The coated slide method

This technique was first worked out by Conger and Fairchild (1952, 1953).

The slide is coated with the medium containing sugar, agar and colchicine dissolved in distilled water. The pollen is dusted on the medium and grown in human conditions. The slides, with the pollen tubes, are stained directly.

The advantages of this technique are: the material is handled easily, being attached to the slide itself, and the loss of materials during the process of transfer and staining is minimised.

The chief drawback, however, lies in the fact that the presence of the medium in the final preparations slightly distorts the visibility. Variations of this technique have been evolved by Dyer (1966), Jona (1967) and Ma (1967), details being given in the chapter on representative schedules.

The collodion membrane technique

This technique (Savage, 1957) is a modification of the cellophane technique, in which the processing has been omitted and the disadvantages rectified. It is based on the formation of a membrane when a drop of collodion in acetone is allowed to spread over warmed sugar solution.

A drop of collodion–acetone solution, when put on warmed sugar solution in a petri dish, spreads out into a thin membrane on the surface, which hardens on evaporation of the acetone. The most satisfactory solution contains approximately one part collodion in three parts acetone. After complete evaporation of acetone, pollen is dusted on the smooth areas of the membrane and allowed to germinate at 20 °C. When necessary for observation, a piece of the membrane with pollen tubes is cut out and floated on a slide and observed by adding a drop of staining-cum-fixing mixture and covering with a cover-glass. Since collodion does not stain in acetic–stain, the temporary preparation can be kept for a long time or made permanent by the acetic–ethanol schedule.

An alternative method for Feulgen staining of these pollen tubes has been devised by the same author (*see* schedules).

The pollen tube germination without culture medium, Swanson (1940) and De (1958)

This is based on the idea that a germinating medium is not necessary for the growth of the pollen tube, provided suitable temperature and humidity are given. The pollen tubes are grown in a closed moist chamber in the presence of crystals of acenaphthene, fumes from which disturb the spindle mechanism and provide contracted chromosomes in metaphase for cytological analysis (*see* Chapter 7).

An advantage is that no culture medium for the growth of the pollen tube is required; therefore it yields very satisfactory preparations for the study of the male gametophyte with the electron microscope.

Another method for germination in the absence of medium, given by Thomas (referred to in Darlington and La Cour, 1960), consists of dusting the dry pollen over a cover-glass and inverting over the hanging drop chamber containing a small piece of wet filter paper.

In all these techniques for accumulating metaphase plates, sometimes 0.05 per cent colchicine solution is added to the medium or acenaphthene crystals can be scattered on the petri dish (Eigsti, 1942; Read, 1964). These methods are used in studying the haploid chromosome set from the pollen tube

mitosis. Several modifications of the squash schedule are available for different materials (Morrison, 1953; Östergren and Heenan, 1962), including the use of pectinase for chromosome separation in wheat (Bhowal, 1963). They can also be employed to study the effect of x-rays or other rays on pollen and also the effect of oxygen in chromosome division (Bishop, 1949; Conger and Fairchild, 1952).

STUDY OF DIVISION IN EMBRYOSAC MOTHER CELLS

Meiotic division can also be studied from the embryosac mother cells; it usually takes place after the meiotic division in anthers, sometimes as long as three weeks afterwards.

The preliminary step in the process is to expose the ovules to the treatment fluids, having first dissected them out, this being easy for large ovules. For the very large ovules it is necessary, to expose them, to remove the ovary wall. In a number of monocotyledonous plants, the ovules can be dissected out on entire strings and are easily handled, but small ovules are more difficult to handle, as they tend to get lost if dissected out. Ovule squash technique, the small ovules being detached from the placenta just before squashing, involves maceration in N HCl and staining with Feulgen reaction (Hillary, 1940) or by the acetic–orcein, acetic–carmine or acetic–lacmoid schedule (Darlington and La Cour, 1942; Bradley, 1948, Haque, 1954). The former technique is more useful for larger ovules while the latter can be used for both small and large ones, the unwanted tissue being dissected out before final squashing.

For squash preparations, the most effective fixative is a modification of Carnoy's fluid having four parts chloroform, three parts absolute ethanol and one part glacial acetic acid. The high proportion of chloroform is necessary to keep the pliability of cell structures (Bradley, 1948). The period of fixation may vary from two days to three weeks. Whole mounts can be prepared by fixing in bulk for 24 h followed by hydrolysis and staining in Feulgen solution. The ovules are then dissected out (Paolillo, 1960).

For the study of small ovules and difficult materials paraffin blocks are prepared; the fixative used should be strong and should penetrate rapidly the covering tissues—La Cour's 2BX is effective (Darlington and La Cour, 1960, 1968).

The sections may be stained following the haematoxylin or crystal violet schedules.

STUDY OF ENDOSPERM CHROMOSOMES

For the study of endosperm chromosomes, different methods of pre-treatment and staining are available which are more or less similar to those followed for other mitotic chromosomes (*see* Chapter 7). Methods are available for the study of endosperm chromosomes in the living state, clarification of their birefringent property, the effect of chemicals on them, as well as their cinemicrographic analysis (Bajer, 1955; Bajer and Molé Bajer, 1956; Östergren and Bajer, 1958; Inoué and Bajer, 1961). Two such representative methods are now outlined.

Permanent preparation of endosperm cells flattened in the living stage (Östergren and Bajer, 1958)

Endosperm cells of *Haemanthus katherinae* serve as good material.

(1) Select a suitable ovule and take out the contents of the embryo sac. Press the contents on to a cover-glass smeared with a thin layer of a mixture of 0.5 per cent agar, 0.5 per cent gelatin and 3.5 per cent glucose and remove any excess of endosperm fluid. Surface tension aids in flattening the cells. Arrange the preparation in a moist chamber so as to avoid drying before fixation.
(2) Fix cover-glass with the material in chrome–acetic–formalin fixative diluted in equal parts with distilled water for at least 12 h.
(3) Rinse in water and treat in a mixture of decinormal potassium cyanide and 2 per cent magnesium sulphate mixed in equal parts for 1 h. Wash off the cyanide by several changes in water.
(4) Hydrolyse the cover-glass with material for 4 h at room temperature in a mixture of rectified spirit and concentrated hydrochloric acid (3 : 1).
(5) Dip in water and stain in Feulgen solution for 12 h.
(6) Wash in sulphur dioxide water, dehydrate as usual, pass through xylol and mount in balsam.

Study of birefringence in endosperm mitosis (Inoué and Bajer, 1961)

(1) With the stem material, follow step (1) as above without using gelatin, and use cover-glass originally ringed with vaseline–paraffin.
(2) Place the cover-glass with the material on another glucose–agar coated cover-glass and seal with ringed vaseline-paraffin.
(3) When the desired flattening of the cells is secured, tilt the preparation to allow excess liquid to drain on to the lower cover-glass. The excess liquid can also be drained off by inserting a filter paper in between the two cover-glasses.
(4) By proper adjustment, flatten the endosperm cells to obtain the chromosomes in one plane. Break the liquid contact between the top and bottom cover-glasses and stabilise the preparation.
(5) Study birefringence in a special polarising microscope with non-rectified coated stain-free 25 × 0.65 n.a. Leitz oil immersion objective in conjunction with 10 × 0.25 n.a. American optical coated objective as condenser. Pure green light (546 nm) from a high-pressure mercury arc lamp can be isolated with a multilayer high transmission interference filter.
(6) Birefringence in kinetochore region of the chromosome fibril can be observed.
(7) Wada (1966) has studied in detail the spindle fibres and their arrangement.

STUDY OF NUCLEOLUS

In order to study chromosome–nucleolus relationship, some of the different schedules developed are outlined below.

(1) Staining of nucleolonema (Estable and Sotelo, 1952): (a) Silver impregnation procedures and iron–pyrogallic stain for fixed material, and (b) phase contrast microscopy, dark-field illumination and oblique transillumination for fresh material have been used for studying the filamentous structures within the nucleolus.
(2) Acetic–carmine staining: For staining nucleoli, treat tissues with rectified spirit, 2; formalin, 1; 5 per cent glacial acetic acid, 1; hydrolyse with HCl at 60 °C for fixed periods and squash in 1 per cent acetic–carmine solution (Rattenbury, 1952).
(3) Feulgen-light green schedule (Semmens and Bhaduri, 1941): Bring down sections fixed in a fixative without acetic acid to water. Treat for 2–3 h in 75 per cent ethanol. Wash in distilled water. Hydrolyse for 10 min in N HCl at 60 °C. Stain for 2 h in leuco-basic fuchsin solution. Wash in two changes of SO_2 water, keep for 10 min in each. Rinse successively in distilled water, 50 and 70 per cent alcohols. Mordant for 1 h in 80 per cent ethanol saturated with Na_2CO_3. Dip in 80 and 95 per cent ethanol. Stain for 20–25 min in filtered saturated alcoholic solution of light green with 2–3 drops of aniline oil. Drain. Rinse in a saturated solution of Na_2CO_3 in 80 per cent ethanol, 10 ml and 90 ml 80 per cent ethanol. Differentiate in 95 per cent ethanol. Dehydrate through absolute ethanol, ethanol–xylol and xylol grades and mount in balsam. For smears and squashes, the initial treatment in 75 per cent alcohol is omitted. In squashes, squash cells after Feulgen staining in 45 per cent acetic acid. Separate cover-glass in 40 per cent ethanol and proceed as usual.
(4) Toluidine blue–molydate method (Löve, 1962; Löve and Walsh, 1963; Löve, Clark and Studzinski, 1964), based on the principle of gradual blocking of $—NH_2$ group of nucleoprotein and unmasking of phosphate groups of nucleic acids binding cationic dyes.

Toluidine blue—molybdate method for ribonucleoprotein

According to Löve (1962) and Löve and Walsh (1963) and using tissue cultures or smears after wet fixation, with treatment in TCA and formal sublimate.

(1) The dyes giving satisfactory results are: Coleman Bell CU-3, National Aniline NU-2 and NU-17, Harleco NU-14, Matheson-Coleman Bell CU-9 and Biological Stain Commission NU-19. The dyes are dissolved in McIlvaine's buffer at pH 3.0 at 20 °C.
(2) Wash tissue culture in 0.85 per cent saline for 10 s before fixation.
(3) Treat two slides in 5 per cent aqueous trichloracetic acid for 10 min. Wash in distilled water.
(4) Fix one slide for 5 min and another for 10 min in formal sublimate,

containing 40 per cent formaldehyde, 1 part, and 6 per cent aqueous mercuric chloride, 9 parts.
(5) Rinse in tap water and treat, with Lugol's iodine for 5 min.
(6) Immerse the slides in 5 per cent sodium thiosulphate for 5 min and rinse in water.
(7) Stain for 30 min in toluidine blue.
(8) Treat with 4 per cent aqueous ammonium molybdate solution for 15 min.
(9) Wash in tap water.
(10) Dehydrate in tertiary butyl alcohol, clear in xylol and mount in a synthetic resin.
(11) The *pars amorpha* of the nucleolus takes up bluish-green stain while the nucleolini are bright purple.

Chromic acid treatment has been used in mammalian materials (*see* Studzinski *et al.*, 1967). A combined schedule was developed by Morrison, Leak and Wilson (1959).

The later techniques with special *N*-banding have been included in Chapter 13.

STUDY OF CHROMOSOMES FROM THALLOPHYTES

Algae

Chromosome study in algae has made tremendous progress within the last 20 years. Research has been initiated in nearly all groups of algae, some of it yielding crucial data on the evolution of chromosome structure. A critical analysis of the chromosome methodology of the group has been presented by Godward (1966).

A feature in common with the members of Tracheophyta is the wide occurrence of polyploidy and aneuploidy amongst the algae; certain groups, like the Chlorophyceae, showing more aneuploids than polyploids. The successful survival of these cytological variants may possibly be attributed to their aquatic environment, which provides a plentiful supply of nutrition, thus eliminating the severity of competition and struggle for survival between the normal and abnormal forms. The organisation of the body structure of an alga, is, in addition, very well suited for the maximum utilisation of the nutrition supplied by the environment.

Chromosome structure in algae is of particular interest since the group presents a variable pattern. In most of the forms, including a majority of Chlorophyceae, chromosome morphology is comparable to that of higher plants, whereas in others, like Conjugales, Euglenophyceae, and especially Dinophyceae, the structure demonstrates a number of unusual characteristics. In Conjugales (King, 1960; Godward, 1961; Brandham, 1964; Godward and Newnham, 1965), the chromosomes are devoid of localised centromeres, comparable to some extent with the structure reported in *Luzula* of angiosperms. Euglenophyceae show certain features of special interest like the absence of a typical equatorial plate and centromere (Leedale 1958, 1962; cf. Saito, 1961) and the persistence of RNA-containing endosome throughout

mitosis, as well as a quite different type of chromosome aggregation and movement from higher plants. In Dinoflagellates (Grasse *et al.*, 1965; Grell and Schwalbach, 1965; Dodge, 1966), the cytochemical and ultrastructural data have shown the chromosomes to be sausage-shaped structures (Ris, 1962) composed of continuous fine fibrils of DNA only, without any basic protein—a structure finding a parallel with the genophore of procaryotes, that is, bacteria and blue green algae, but differing fundamentally from the latter in having a nucleus. Several authors have already suggested that this group represents a step linking the procaryotes with eucaryotes and the term Mesocaryota has been attributed to it (Godward, 1966).

Intensive research on the study of the flagellate chromosomes may ultimately lead to a complete understanding of the steps starting from the gene-bearing structure, or genophore, of procaryotes to the well-organised chromosomes of eucaryotes. Cytological studies on Phaeophyceae (Inoh and Hiroe, 1956; Subrahmanyan, 1957; Naylor, 1958; Kumagae, Inoh and Nishibayashi, 1960; Yabu, 1965) and Rhodophyceae (Iyengar and Balakrishnan, 1950; Drew, 1956; Svedelius, 1956; Austin, 1960; Yabu and Tokida, 1963; Magne, 1964) also show immense possibilities. The existence of several alternating generations in them is of special significance in relation to differentiation. Detailed cytochemical, structural and ultrastructural analyses of the chromosomes from different alternating phases may yield facts of fundamental significance regarding the genic control of differentiation.

Advance in the knowledge of the fine structure of chromosomes and their chemical make up in different biological groups has been phenomenal in recent years. This progress has led to the realisation that increasing complexity in the nature and seat of the gene-bearing structure has been an associated feature of evolution. This complexity of both chemical make up and behaviour has been a natural prerequisite for providing guidelines in the life cycle of organisms with extremely complex physical organisation and sequential and phasic growth and development. Amongst the algal groups, leaving aside the blue-green forms, one extreme is represented by the flagellates and the other by a miniature complex form observed in the Rhodophyceae. The scope and possibilities of their chromosome analysis cannot be over-estimated.

The methods of chromosome study in algae principally include two separate stages: culture of the algae to obtain suitable divisional figures, and processing to observe the chromosomes.

Culture is usually necessary, in the case of most forms of algae, for acquiring a sufficient number of metaphase plates in polar view for chromosome analysis. Algae growing in the wild condition have been found to show both somatic and germinal divisional figures, as seen in marine *Cladophora*, and *Ulva* and most forms of red algae. In the simplest form, the alga is grown in its natural medium, but progressively complex media with different proportions have been devised for obtaining better growth and synchronisation of mitosis to collect the highest number of mitotic stages. The other major factor is light period and in most cases, artificial light and dark photoperiods are provided.

For successful culture of any alga, and green algae in particular, the bulk material after collection is to be teased out under dissecting/compound microscopes to separate pure filaments from mixed ones. Media ranging from

water of the habitat to different types of synthetic media have been devised. However, only limited success has been gained though new media are still being obtained (*see* Hutner *et al.*, 1950; Pringsheim, 1951; Provasoli, 1958; Droop, 1959; Nizam, 1960; Patel, 1961; Myers, 1962; Abbas, 1963; Provasoli and Hutner, 1964). Soil, peat or leaf extract added to a solution of mineral salts is sometimes effective. Trace elements and vitamins, and occasionally chelating agents are used, as for species of *Chlorella*. Amino acids and DNA precursors, added to the medium, serve to increase the growth rate. By adjusting the photoperiod, synchronisation of mitosis is possible, e.g. through an artificial light photoperiod of 18 h and a dark period of 6 h in a culture chamber, mitosis takes place during the dark period. As many as 14 per cent cells in mitosis can be obtained by changes in the length of photoperiod restricting the mitosis to the dark period (Leedale, 1958, 1966; James and Cook, 1960; Newnham, 1962; Tamiya, 1963; Brandham, 1964). In Chlorophyceae and certain other algae, such synchrony in division can be obtained even in culture without any special treatment. Godward (1962, 1966) suggested the possibility of synchronisation of division through temperature control in continuous light with bubbled air enriched with 4 per cent carbon dioxide and by continuous culture in medium which is continuously renewed. She has also stressed the possibility of the evolution of variant races in cultures maintained for a long time by mitotic changes or mutations. It has been noted, however, that where extensive works have been carried out, algae, and Chlorophyceae in particular, are highly resistant to the action of colchicine and x-rays as compared to higher plants (Sarma, 1958, 1969; Godward, 1962); with colchicine, a concentration below 0.5 per cent is rarely effective. Similarly in *Spirogyra*, even 20 k R dosage of x-rays allows the plants to remain alive.

Smaller members of marine Dinophyceae can be cultured in sea water, to which nitrate, phosphate and soil extracts have been added (50 ml soil extract; 0.2 g sodium nitrate and 0.03 sodium phosphate, both in 10 ml of water added per litre of sea water). Both soil extract and sea water have been replaced by artificial components by some workers (Provasoli, McLaughlin and Droop, 1957). The cultures are kept under fluorescent lighting between 1076–2152 lx at a temperature of 15–25 °C for 12–18 h. Cultures on fresh water forms are not so successful (*see* Dodge, 1966).

Culture of gametophytes and sporophytes of the Laminariales is influenced by nutrient, temperature and light. Sea water enriched by various nutrients has been used effectively (Schreiber, 1930; Harris, 1932). Naylor (1956) modified the nutrient recommended by Schreiber by including soil extract which is named Erdschreiber solution.

The most suitable temperature is between 10–16 °C. Harris (1932) advocated an indirect light intensity of 538–3228 lx as the most suitable, but never direct sunlight. Two commonly used nutrients are:

Nutrient A 0.01 M KH_2PO_4, 0.5 ml
0.01 M KNO_3, 0.5 ml, added to 25 ml of sea water every 14 days.

Nutrient B 10^{-5} M KH_2PO_4 ($\frac{1}{20}$th of nutrient A stock);
5×10^{-5} M KNO_3 ($\frac{1}{4}$th of nutrient A stock)
0.5 ml of each added to 25 ml sea water every 14 days.

ASP_2 solution is a more complex nutrient. These media, under different conditions of light and temperature, have been successfully used in culturing different members of Laminariales, for vegetative and gametophytic growth (for details, *see* Evans, 1966).

For a number of varieties belonging to the Phaeophyceae, Roberts (1966) used the same culture technique. Large pieces of the fruiting region are collected, washed in jets of boiled sea water and immersed in boiled sea water. After the zoospores are released, the suspension is poured in a flat dish containing sterilised slides or cover slips. After 30 min, the cover slips are removed with forceps and placed in a culture chamber. Roberts suggests the use of slides instead of cover slips, which may be placed back to back in cellophane covered glass pots. Slides are easier to handle during transport and subsequent processes of fixation, staining and cooling. Rapid growth is ensured by long hours of daylight or by permanent illumination with three 80 W fluorescent tubes at about 15 °C. As growth medium, the Erdschreiber medium is a very suitable one (for details, *see* Roberts, 1966). In the Rhodophyta, culture methods have only a limited application; the habitat medium, with frequent changes, is sufficient in most cases. Complex media developed by Provasoli, McLaughlin and Droop (1957 and *see* Fries, 1963) are often not necessary for cultures required for cytological study alone. Small quantities of soil extract or other nutrients, however, show a beneficial effect. A major factor in the culture of the members of Rhodophyta is contamination by epiphytes, like diatoms. Several methods are adopted for their elimination (*see* Dixon, 1966).

Chromosome studies

As in the higher plants, schedules for studying the chromosomes of algae involve mainly fixation, staining and mounting. Pre-treatment is given in specific cases, as are also different maceration techniques. There is considerable variation in response to fixatives and stains, not only between the different groups, but also between different genera and species, and in some cases between different parts of the same plant. Decolorisation of the pigment is an important factor in the choice of a fixative.

Fixation

Among the different fixatives used are:

(1) *Formalin–ethanol* Used in different proportions. In Rhodophyceae, it is suitable for haematoxylin or brazilin stains but useless for feulgen or acetic–carmine. For green algae, however, Godward (1966) finds fixatives containing formalin or mercuric chloride to be unsatisfactory.

(2) *Formalin–acetic–ethanol* Also used in different formulae, the one by Westbrook (1935) being glacial acetic acid, 2.5 ml; 40 per cent formaldehyde, 6.5 ml, and 50 per cent ethanol, 100 ml. It is recommended for immediate use in Rhodophyceae since storage may cause shrinkage of the nucleus and later disintegration of the material (Magne, 1964).

(3) *Amongst the metallic fixatives* Chromic acid–acetic acid mixtures have been used in a large range of variations, a very common one being the

modification of Karpechenko's fluid given by Papenfuss (1946). It includes: Solution A containing chromic acid, 1 g; glacial acetic acid, 5 ml, sea water, 65 ml and Solution B with 40 per cent formaldehyde, 40 ml in 35 ml sea water. The two solutions are mixed immediately before use. Sea water is replaced by distilled water for fresh-water forms and the use of formaldehyde is optional. Naylor (1957) used chrom–acetic–formalin as fixative for large parenchymatous Phaeophyceae, followed by softening in sodium carbonate and occasional bleaching with H_2O_2. Osmic acid vapour, nitric acid vapour, 2 per cent osmic acid solution, Belling's Navashin solution enriched with osmic acid, iodine water, bromine water and chromic acid solution have all been successfully used in different members of Chlorophyceae (Leedale, 1958; Sarma, 1958; King, 1960; Patel, 1961; Sinha, 1963; Brandham, 1964; Thakur, 1964; Dodge, 1966; Godward, 1966). Fixation in osmic acid must be a brief one and the osmium must be washed out before it forms a black deposit.

(4) *Acetic acid: ethanol and acetic acid: methanol mixtures* With different concentrations and proportions of the constituents are widely used. Mixtures of glacial acetic acid and 95 per cent ethanol (1 : 1, 1 : 2, 1 : 3) are effective for Rhodophyceae, the two former giving better results. However, they can cause shrinkage in large-celled delicate forms and disintegration of calcified materials. Smaller thalli need only a few minutes treatment, but 1–6 h immersion is recommended for cartilaginous forms. The materials should be processed immediately after fixation and storage should be avoided wherever possible (for details, *see* Austin 1959; Dixon, 1966).

Within Phaeophyceae, filamentous forms can be fixed in acetic acid–ethanol mixture (1 : 3) for up to 24 h, preferably changing the fixative after 1 h. Evans (1963a, b) used lithium chloride for large parenchymatous plants after fixation as a softening agent. Decolorisation is usually satisfactory after 24 h.

Acetic–ethanol (1 : 3) is equally satisfactory for members of the Dinophyceae which are large and easy to handle. Acetic acid–methanol, in different proportions, gives very good results. Fixation is carried out in centrifuge tubes and the cells collected by centrifugation. Addition of a few drops of saturated ferric acetate (in acetic acid) to the fixative 1 h before staining is beneficial for certain species.

Various modifications have been used in different types of green algae. Mixtures of glacial acetic acid and 95 per cent ethanol (1 : 1, 1 : 2, 1 : 3) and also ethanol or methanol alone, gave good results in different forms (*see* Godward, 1966).

Processing

(1) Whole mounts are possible for uniseriate filamentous thalli in the Rhodophyceae as also for various members of the Dinophyceae and Chlorophyceae.

(2) Serial sections of paraffin-embedded material are utilised only in cases of certain Rhodophyceae following the usual block preparation schedule (*see* page 75).

(3) Squash preparations are most commonly used in studying algal chromo-

somes. The fixed material can be squashed directly or it may require a softening process, depending upon the hardness of the material. The softening agent and the period and conditions of treatment depend mainly upon the material but also on the fixative and stain used. Dilute solutions of acid or alkali in water or ethanol are used for softening, the more common ones being HCl or NaOH in concentrations ranging from 1 to 50 per cent (Papenfuss, 1937; Drew, 1945; Norris, 1957; Cole, 1963). Magne (1964) advocated the use of dilute solutions of sodium carbonate.

Since in the Rhodophyceae, the carpogonium or young carposporophyte is encased by a large amount of unwanted tissue, sections of the fertile axis (50–100 μm) are cut on a freezing microtome with dilute gelatin as the supporting medium and these sections are then squashed.

Since the brown algae are rather tough and resilient, they require special softening pre-treatments. The pre-treatment chemical used may be sodium carbonate (Naylor, 1959), lithium chloride (Evans, 1963a) or a mixture of ammonium oxalate and hydrogen peroxide (Lewis, 1956).

Staining

The stains commonly applied to higher plants have also been used for algae, like acetic–carmine, feulgen, haematoxylin, brazilin and methyl green pyronin.

The *acetic–carmine* stain is the one most widely applied following the iron alum–acetic–carmine method developed by Godward (1948). In Chlorophyceae, the fixation is followed by mordanting in aqueous iron alum solution, used in different dilutions, depending on the material, for a period not exceeding 30 s. The material is washed repeatedly. Super-saturated carmine solution in 45 per cent acetic acid is added and the preparation boiled to dissolve the starch. Filamentous forms are held with forceps and passed through the solutions, spores are handled as settled on slides or cover slips, and unicellular cultures in centrifuge tubes. The carmine-stained preparations are passed as usual through acetic acid–ethanol (1 : 3), 95 per cent and absolute ethanol grades before mounting in euparal. Acetic–orcein has been used instead of carmine but gives a paler stain. In a method followed by Thomas (1940), a few drops of super-saturated solution of ferric acetate in 45 per cent acetic acid is added to the fixative (acetic–ethanol 1 : 3). This addition of iron salt has also been found to be very effective in Charophyceae. The material is transferred directly from the fixative to carmine and back to the fixative, followed by 95 per cent euparal essence and euparal.

Members of the Dinophyceae are stained after fixation in a drop of acetic–carmine on a slide. Acetic–orcein is equally effective. For Laminariales, acetic–carmine, containing 1 drop of saturated ferric acetate solution per 25 ml, is added to the material *after* squashing; followed by alternate heating and cooling. Large parenchymatous brown algae require fixation in acetic–ethanol (1 : 3), enriched by a few drops of ferric acetate. The material is washed in 70 per cent ethanol, hand sections are cut and mounted in 6 per cent Na_2CO_3. After squashing, distilled water and later the stain, are added

and the slide gently boiled. The iron–acetic–carmine schedule has also been used successfully for the Rhodophyceae after slight modifications (Cole, 1963).

Feulgen staining schedule has been applied in almost all forms of algae. The method of handling of the material is similar to that for acetic–carmine staining, both for members of the Chlorophyceae and Dinophyceae. Gametophyte materials of Laminariales take up bright stain in this method. For large parenchymatous brown algae, fixation in Karpechenko's fluid is followed by washing in running water and bleaching for 3–4 h in 20 per cent aqueous H_2O_2 solution and again washing in running water. The material is heated to 60 °C in distilled water, hydrolysed in N HCl at 60 °C for 7–10 min. Without bleaching, hydrolysis has to be done for 15–30 min. The material is transferred to cold distilled water, washed in-running water for 10 min, hand sections are cut and squashed in SO_2 water (N HCl, 5 ml; 10 per cent $K_2S_2O_5$, 5 ml, water, 100 ml). Feulgen staining, however, does not yield consistent results with the red algae.

Heidenhain's haematoxylin schedule and its modifications have been used in the red algae. Haematoxylin in acetic acid stains the nuclei in green algae but it is not permanent.

Brazilin was extensively used by Drew (1934) in red algae. Both the stain and its mordant require a long period of ripening in the dark to give satisfactory preparations. Sections of squash preparations are treated in a 2 per cent ferric ammonium sulphate solution in 70 per cent ethanol for 1 h, washed in 70 per cent ethanol and stained for 12–16 h in 0.5 per cent brazilin in 70 per cent ethanol. Finally they are washed twice in 70 per cent ethanol and dehydrated through ethanol grades. This stain avoids the swelling of chromosomes due to aqueous solutions and the procedure is much shorter than haematoxylin.

Methyl green pyronin staining schedule has been applied in the green algae, using a BDH dye mixture. A very small amount is dissolved in water and the material, after acetic fixation, is mounted in it (Godward, 1966). However, it has not given good results with the red algae (Magne, 1964).

Preparation of permanent slides from temporary ones can be made by any of the schedules followed for higher plants (chapter on mounting).

In addition to the general methods, as outlined above, a few sample schedules used specially for members of the Phaeophyta are given in brief as in this group a special method for softening is necessary.

(1) Acetic–carmine preparations as used in Laminariales (Evans, 1966).

Fix in acetic–ethanol (1 : 3) for 12–18 h, wash in running water; immerse in 1 M lithium chloride solution for 15 min; keep in water for 15 min; dissect out material and squash under a cover slip; insert a few drops of acetic–carmine solution with a trace of ferric acetate at the side of the cover slip, heat at intervals for 30 s without boiling, squash again and blot excess stain. If over-stained, de-stain by heating in a mixture of acetic–carmine solution and glacial acetic acid (1 : 5) for 15 s. Treatment in lithium chloride can be omitted for filamentous material, like gametophytes.

In filamentous Phaeophyta, fixation is carried out for 24 h and a few drops of saturated ferric acetate in 45 per cent acetic acid is added to the

fixative. After washing in acetic–ethanol (1 : 3), add stain, cover, boil squash.

(2) Feulgen schedule for Phaeophyta (Naylor, 1959).

Fix cover slips with growing gametophytes in acetic–ethanol (1 : 3), wash, hydrolyse in N HCl at 60 °C for 8–10 min, transfer to cold water, and then keep in decolorised Schiff's reagent for 8 h at room temperature, bleach in three changes of SO_2 water; squash in SO_2 water and later dehydrate through ethanol grades and mount in euparal. Variations in hydrolysis and staining periods are adopted for different materials.

(3) For softening and isolating female conceptacles, split the receptacles longitudinally and fix for 12 h, followed by treatment for 20 min in a mixture of saturated ammonium oxalate solution and 20 vol. H_2O_2 (1 : 1), wash for 15 min before staining. Alternatively, for male material, macerate 30 g for 4 min in 150 ml of fixative in a Waring Blendor; transfer to a graduated cylinder; pipette off middle layer with sex organs and stain as usual (Lewis, 1956).

Fungi

A group of simple organisms living as parasites or saprophytes and categorised as fungi, hold a unique position in the plant kingdom. Even though belonging to Eukaryota in its nuclear constitution, this group is quite distinctive in its extremely simple thalloid constitution and absence of such pigments that are universal for higher plants. The meagre cytological data so far available have also indicated the occurrence of unusual features in certain groups such as the existence of nuclear membrane during division and the controversial double reduction division during meiosis. Needless to say, from the standpoint of the evolution of the structure and behaviour of chromosomes, there is immense potentiality in the cytological analysis of this assemblage. Unfortunately, it has not attracted the attention of chromosome cytologists to the extent that it should (McIntosh, 1954; Mundkur, 1954; McClary *et al.*, 1957; Roberts, 1957; Bakerspiegel, 1959; Dowding and Weijer, 1960; Somers, Wagner and Hsu, 1960; Turian and Cautino, 1960; Emerson, 1967).

Chromosome analysis in fungi is not only important from a fundamental standpoint, including biochemical mutagenesis in *Neurospora crassa*, but also because of their implications in utilitarian research. The genetic basis of the fermenting capacity of the *Saccharomyces* complex, the medicinal values of scores of fungi including species of *Aspergillus* and *Penicillium* and the infecting capacity of fungi, need solutions in which chromosome research may play a significant role. An understanding of the cytogenetic basis of these properties would pave the way for their improvement, or prevention, with the aid of physical and chemical agents having established mutachromosomic property.

Some methods are outlined here.

Fixatives

Helly's modified fluid (mercuric chloride, 5 g; potassium dichromate 3 g; distilled water, 100 ml; add 5 ml formalin just before use) is found to

be very successful as a fixative in a wide range of fungi (Heim, 1952, 1954, 1956, 1958; Robinow, 1961). Other fixatives used are osmium tetroxide vapour and acetic–ethanol but their effects are less desirable.

Stains

Different chromosomal stains have been tried out, some of the commoner ones being described here.

Giemsa staining gives effective results for quite a large number of filamentous fungi and yeasts. The preparations can be stained directly or after hydrolysis in N HCl. A stain used for yeast chromosomes contains 16 drops of Gurr's Giemsa R66 dissolved in 10–12 ml of Gurr's Giemsa buffer at pH 6.9.

If hydrolysis is required, fixed cells are usually extracted for $1\frac{1}{2}$ h with 1 per cent NaCl at 60 °C, the time, concentration and temperatures depending on the material (Ganesan, 1959); then treated for 10 min with N HCl at 60 °C, rinsed with tap water and kept in the stain for several hours.

Haematoxylin staining has been advocated by Henderson and Lu (1968) for squash preparations, following fixation in Lu's BAC fixative (1962).

Feulgen staining is utilised according to the usual schedule of acid hydrolysis followed by staining.

Schiff reagent prepared with Diamant Fuchsin is used for yeast chromosomes (Robinow, 1961). The smears can be mounted in water or acetic–carmine.

Representative schedules

For yeast (following Robinow, 1961)

Place a loopful of slimy growth from a 2–5 day-old plate culture on a No. 1 cover slip. Place another cover slip on top with corners turned away at an angle of 5 degrees to the former. Allow the drop to spread, pull apart the cover slips so that a smear is formed on each and immerse in Helly's modified fixative for 10 min. Rinse thoroughly in 70 per cent ethanol, transfer to Newcomer's fixative for preservation in the cold (for composition, *see* chapter on fixatives). The film must not be permitted to dry prior to fixation. The yeast culture may be exposed briefly to formalin vapour before the smear is drawn for better preparation. In Giemsa staining, extract fixed cells for $1\frac{1}{2}$ h with 1 per cent NaCl at 60 °C, treat for 10 min in N HCl at 60 °C, rinse in tap water and stain for several hours in Giemsa solution. Differentiate by moving the smears repeatedly for 10–12 s at a time in 40 ml distilled water to which a few drops of acetic acid have been added (pH 4.2). Observe under a water immersion lens to control extraction of excess stain. When the nuclei are brightly differentiated, mount the cover slip on a slide in a drop of buffer containing 2–3 drops of Giemsa per 10 ml. Blot excess medium, squash with uniform pressure, seal and observe. Squashing without pressure may also be done.

In feulgen schedule, hydrolyse the smear for 10 min, rinse with tap water,

stain in Schiff's reagent for $3\frac{1}{2}$ h, rinse quickly in 10 changes of SO_2 water (tap water 90 ml; N HCl 5 ml; 10 per cent sodium metabisulphite 5 ml), keep in running water for 20 min and mount in water or acetic–carmine.

For mitosis in basidiomycetes (Ward and Ciurysek, 1961)
Centrifuge the culture and suspend in distilled water. Homogenise, spread in a thin film on slide, air dry, fix in acetic–lactic–ethanol (6 : 1 : 1) for 10 min, pass through 95 per cent and 70 per cent ethanol and rinse in water. Hydrolyse in N HCl at room temperature for 5 min, then at 60 °C for 6 min, wash thoroughly in distilled water and suspend for 5 min in a phosphate buffer (pH 7.2). Stain for 25 min in Giemsa's stain, rinse successively in water and buffer, drain, flood with Abopon and cover with a cover slip.

For general mitotic preparations (Lu, 1962)
Pour a mixture of BAC fixative (*n*-butanol, acetic acid and 10 per cent aqueous chromic acid solution, 9 : 6 : 2) over the culture in a petri dish and store under partial vacuum at 0–6 °C for 1–5 days. Dissect out fruit bodies in a mixture of conc. HCl and 95 per cent ethanol (1 : 1), heat gently, wash with Carnoy's fixative for 1–2 min, heat in propionic–carmine solution with a trace of iron, apply cover slip, allow to stand, heat to boiling and press the cover slip. Add a drop of 45 per cent acetic acid to all corners, apply a drop of glycerin–acetic acid mixture to one corner, blot and seal.

For members of the Pezizales
Fixation in Carnoy's fluid for 24–72 h followed by either direct squashing in acetic–carmine or hydrolysis in N HCl, staining in Feulgen and squashing in acetic–carmine have been found to yield suitable preparations (Thind and Waraitch, 1968; Sahay and Prasad, 1968).

For basidia of agarics (Lowry, 1963)
Fix bits of hymenial tissue in Newcomer's fixative for 1–12 h, hydrolyse and mordant in aqueous N HCl containing 2 per cent aluminium alum, 2 per cent chrome alum and 2 per cent iodic acid for 5 min at room temperature, then at 60 °C for 10–15 min. Wash in three changes of distilled water and keep in Wittmann's acetic–iron–haematoxylin for 2 h. Mount in a drop of stain, cover with a cover slip, press, heat to just below boiling and seal.

For chromosomes of Neurospora (E. G. Barry)
Dip strips of agar containing perithecia, after four days of crossing, in ethanol : acetic acid : 85 per cent lactic acid mixture (6 : 1 : 1) in closed vials and store in deep freeze. Prepare stain by mixing a stock solution of 47 ml acetic acid and 20 ml lactic acid solution (1 ml 85 per cent lactic acid in 24 ml distilled water) with 5 ml N HCl and 28 ml distilled water at room temperature. Mix 5 ml of this fluid with 100 mg Natural Green (Gurr) and reflux for 4 min after boiling over a low flame, in a small beaker covered by a petri plate bottom containing two ice cubes. Tease out the asci in a drop of stain, mount after separation in another drop under a cover-glass, heat slightly and seal with dental wax.

Microscopy

ORDINARY LIGHT MICROSCOPY

In light microscopy, the underlying principle is to obtain a real, inverted, and enlarged image of the material by means of the objective lens, followed by the formation of a virtual image by means of the eyepiece lens. In the study of chromosomes, where only light microscopes are required, the compound microscope should have at least the following attachments:

(1) Apochromatic objective and oil immersion lenses (× 100)—(1.3–1.4 n.a.);
(2) Sub-stage aplanatic and achromatic condenser—1.4 n.a.;
(3) Compensating eyepieces (× 10, × 15, × 20);
(4) Fitted mechanical stage.

The tube length for each microscope is fixed for the operation of particular objectives. In British instruments, it is generally 160 mm (Haskell and Wills, 1968). Details of the instrumentation in microscopes are available in several textbooks; the designs are based on two original types of instrument, named after their inventors, the Huygens and Ramsdens. For convenient reference, Corrington (1941) and Oliver (1947) may be mentioned. The principles of the use of special types of lenses are here outlined.

Special lenses are used principally to eliminate two types of aberration: spherical and chromatic. Spherical aberration is inherent in lenses with spherical surfaces. Here the rays passing through the periphery of the lens focus at a different point to those passing through the centre or close to the axis. In *aplanatic* lenses, which are compound and constituted of different kinds of glass, all the rays are brought to a common focus by suitable corrections.

Chromatic aberrations imply that ordinary sources of illumination, being composed of light of different wavelengths, or in other words of different colours, focus at different points because of a variation in the path followed by the rays. Colour fringes sometimes appear. In suitably constructed lenses, these aberrations are eliminated as far as is practicable, so that preferred rays are made to focus at a common point. In *achromatic* objectives the chromatic aberration is corrected for two colours, or more precisely, two wavelengths, and the spherical aberration for one colour. In *semi-apochromats* or *fluorite* lenses, a higher degree of correction than the former is achieved. In *apochromatic* lenses, the chromatic aberration is corrected

for three colours and spherical aberration for two colours. Such lenses do not allow for formation of any secondary spectrum.

Different colours undergo different degrees of magnification, which may result in a number of images of different colours; because of superimposition, difficulties arise in the proper clarification of the object. This inequality of colour magnification is corrected by means of *compensating* eyepieces, while apochromatic lenses are used as the objectives. In the case of achromatic lenses, this defect is generally corrected in its own combination.

The separation of finer details in an image is dependent not on the magnification of the lenses but on their resolving power—this power, or resolution, being dependent on the wavelength of the illuminating source as well as on the *numerical aperture* of the lens. The numerical aperture is calculated on two factors; the angular aperture of the lens, and the refractive index of the medium through which the light enters. Resolution is always proportional to the numerical aperture, which is $n \sin \mu$, n being the refractive index of the cover slip, and μ the maximum angle to the optical axis formed by any ray passing through the specimen, before the formation of total internal reflection. With an objective of n.a. 1.4, it has been calculated that good resolution can be achieved if the intervening minimum distance from the specimen is 0.24×0.001 mm (Haskell and Wills, 1968). Brightness increases with increase in numerical aperture, but decreases with increase in magnification. Visual magnification is obtained by multiplying the magnification of the objective with that of the eyepiece.

Oil immersion objectives are used for critical work where the scattering of light, due to its passage through media of different refractive indices, is to be avoided. If a fluid of refractive index similar to that of glass and Canada balsam is used to bridge the gap between the cover slip and objective lens (and if necessary, between slide and condenser), then a homogeneous medium can be achieved for the path of light, avoiding light scattering as far as possible. Cedarwood oil is generally used for the purpose, its refractive index (1.510) being close to that of glass (1.518), and balsam in xylol (1.524), but several synthetic media are now available. Darlington and La Cour (1968) used media with liquid paraffin and α-bromonaphthalene, or olive oil and α-bromonaphthalene, as constituents. For the source of illumination, Pointolite, Ribbon filament, mercury arc, or, if these are not available, even a 100 W ordinary lamp may be used. Proper screens should always be chosen for observation, depending on the colour of the light and stain used. Wratten yellow-green filters for violet-stained preparations and blue filters for red-stained preparations are useful.

Setting up the microscope

(1) Set the microscope on the desk at a level convenient for the worker. In absence of a built-in illuminator the microscope should be set up in front of a lamp with ground glass and a uniform emitting surface and is to be adjusted for proper angle of inclination so that the light falls on the centre of the mirror. The plane mirror is to be used in a microscope with a sub-stage condenser.

(2) Place the slide and object in position and focus with the low power

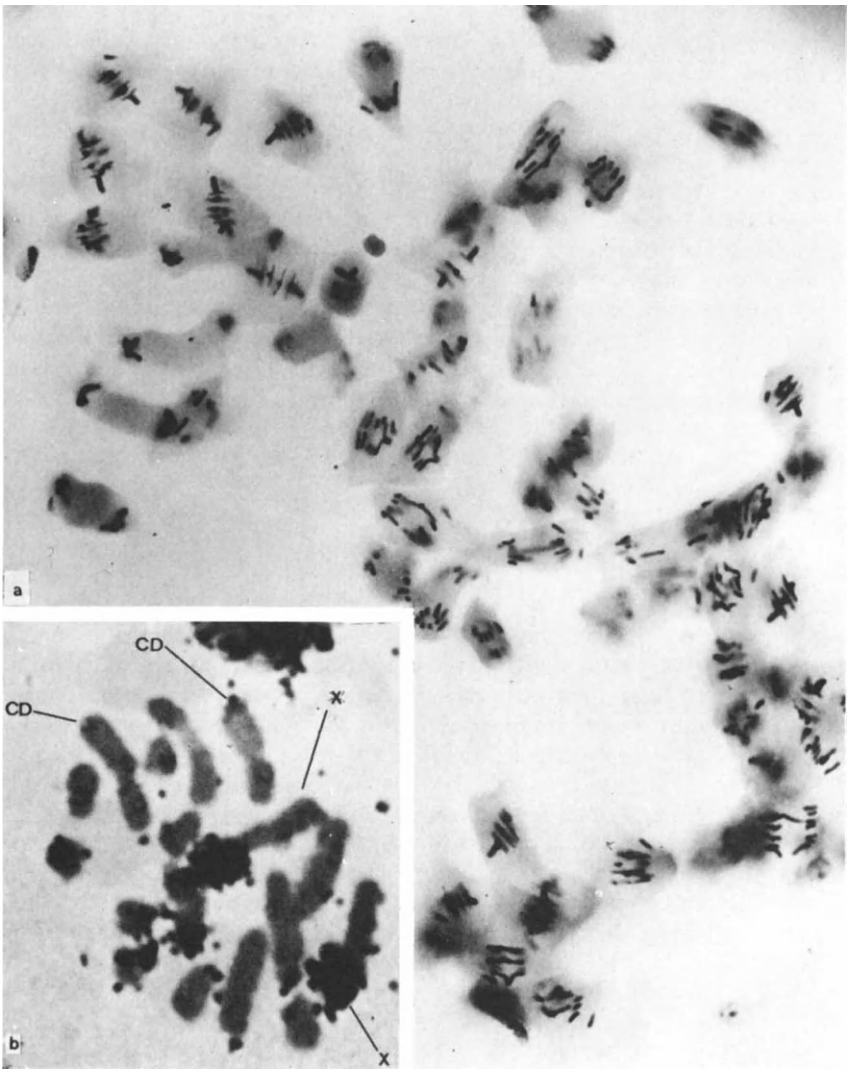

Plate 9.1

objective. Without built-in light, adjust the mirror to obtain maximum illumination.

(3) Adjust the condenser so that the grain of the ground glass or the tungsten coil or ribbon filament of the lamp is visible in the plane of the object. Adjust the light so that the grain or the filament does not interfere with the image.

(4) Adjust the iris diaphragm of the condenser so that the back lens of the objective is evenly illuminated.

For centring the light source of the lamp without built-in illuminator, open the iris diaphragm of the lamp, move the condenser lens away and insert a piece of paper on the aperture of the iris diaphragm. With the aid of centring screws, centre the illuminated area.

(5) For observation with oil immersion objective, raise the tube, bring the low power objective in position, lower the condenser and place a drop of oil on the top lens of the condenser and refocus the condenser. Raise the tube slightly again, and place a drop of immersion oil on the slide over the point of visible light. Bring the oil immersion objective in position, gradually lower the tube till the lens touches the oil and with the fine adjustment screw gradually bring the object in focus.

In *critical illumination*, principally, the light source is focused at the level of the object, whereas with *Köhler illumination*, the light is focused at the level of the iris diaphragm of the substage condenser.

Camera lucida, drawing head or drawing prisms (Zeiss, Leitz, etc.) may be used for drawing on a board placed next to the microscope, and for direct measurements ocular micrometers may be used if necessary. The scale in the ocular micrometer is standardised with the stage micrometer in which the value of each division is known. The latter is fitted onto the stage in place of the slide and, by focusing, the ocular and the stage micrometer scales are brought into the same focus. The number of ocular divisions per stage division is worked out in several readings and from the mean, the value of each ocular division can be calculated. The magnification of the drawing can be estimated by drawing a stage division on the paper, with the same combination of lenses and drawing head as used for observation of the material. The length of the drawing is measured on a millimetre scale. The value (in millimetres) of the drawing, divided by the actual value of stage division (which is known) gives the magnification of the drawing.

For photography, a Zeiss (Ikon) 35 mm camera or plate camera may be used. The camera is fitted over the eyepiece and a number of cameras with microphotographic attachments, like Zeiss, Leitz, Olympus, etc. are now available. They are designed as a 35 mm or plate camera without the lenses, as the real image is formed over the eyepiece. These cameras are always fitted with adaptors for fitting in the microscope tube. Elaborate, and even built-in camera attachments can also be obtained with several microscopes, with provision for timing and exposure (*see* Stevens, 1957; Needham, 1958 etc.).

Both slow- and high-speed films are satisfactory, depending on the requirements, the former requiring a longer exposure period. Rapid process panchromatic plates, Kodak, Gavaert or Ilford, are most suitable. The plate size is generally $3\frac{1}{4} \times 4\frac{1}{4}$ in but 9×12 cm plates may also be obtained.

The selection of an adequate period of exposure is a matter of experience

and is fixed after some trials. For developing and printing, the procedure for ordinary photography is followed, using the proper developers recommended for particular films. Preparation of lantern slides from negatives with the aid of enlargers and slides from contact prints, can be made following the usual procedure.

PHASE AND INTERFERENCE MICROSCOPY

In principle, these two types of microscopy are identical in the sense that the purpose is to bring about visible change in intensity from an undetectable phase change. The basic resemblance between the phase contrast and the interference has been elaborated diagrammatically and mathematically (*see* Barer, 1966). In spite of their fundamental similarity, considerably greater attention has been given to developing interference methods than to standard phase contrast. Interference systems, being more plastic, allow variable phase changes. The variable phase contrast system can also be planned, although for quantitative measurement it is of little use. One can say that the phase contrast system is just an imperfect form of interference.

The phase change is represented as $\phi = (n_p - n_m)t$, where n_p and n_m are the refractive indices of the object and the immersion medium respectively and t is the thickness of the object. The formula indicates that with increase in the value of t, there will be a decrease in the detectable difference between the refractive indices.

The advantages of phase microscopy are:

(1) Simple and easily adjustable arrangement.
(2) Low cost of the apparatus.
(3) Insensitivity to slight variations in slide and cover slip.
(4) Internal details are often better resolved through 'zone of action' effect.

The *principal limitation* of the phase system is that it is not possible to carry out quantitative measurements conveniently and the presence of a 'halo' prevents proper resolution to some extent. This limitation is inherent in the very principle of phase contrast microscopy. The direct light is allowed to fall on a conjugate area (annulus) here, while the diffracted light is separated and falls on the entire phase plate. Consequently, the conjugate area also receives some diffracted light, which is responsible for the formation of a 'halo' around the object.

In addition to the attachments of an ordinary microscope, the phase contrast microscope is fitted with: (a) a sub-stage annular diaphragm to produce a narrow cone of light for illuminating the object, and (b) a 'diffraction' plate fitted on the rear focal plane of the objective, where the deviated and undeviated light rays are separated after emerging from the object. A layer of phase retarding material is present on that portion of the diffraction plate which is covered by either of the two rays, and it helps in changing the relative phase of the two rays. Two types of phase contrast microscopes are generally available, namely, (a) the instruments based on the principle of negative phase contrast, and (b) those depending on positive phase contrast. In the positive phase contrast system, the slightly retarding object details appear brighter against a lighter background, thus resembling visually stained preparations; while in the negative system, the object is decidedly lighter than the background. For routine use in cytology, the former is usually preferred due to the excellent contrast of living cells in aqueous media.

The importance of phase contrast microscopy has been widely appreciated in recent years and in cytological laboratories it has become a routine method for the study of various aspects of the structure and movement of chromosomes in the living cell. All good research microscopes can now be fitted with phase contrast equipment, including proper objectives and a sub-stage condenser. In view of its capacity to resolve the phase difference, it is effectively employed for the study of the three-dimensional nature of the objects and the phases of chromosome movement in a living cell. In the study of bacterial nuclei, phase contrast microscopy has helped considerably in resolving the details (*see* Barer 1956, 1966).

For measuring the refractive index and solid concentration of cell structures, the method of 'immersion refractometry' has been applied in phase contrast microscopy. This method is based on the principle that, if an object is immersed in a medium having a refractive index equal to its own, it affords the least contrast to the viewer. In addition, in order to have a choice of media for watching, a large number of fluids (isotonic solutions with different refractive indices) should be used. In the case of living materials, however, the choice of the immersion medium must be restricted to compounds which show no toxicity and which lack the ability to penetrate the cell or deform the cellular structure. The cell is initially observed in physio-

logical saline or body fluid by positive phase contrast. Later, the observation is carried out in isotonic protein solution. If the refractive index of the medium is more than that of the cytoplasm, the latter presents a bright appearance, and vice versa. After several trials with different strengths of the medium, an optimum stage can be obtained, where the two will be nearly identical. The concentration of the solid can be worked out in g/100 ml of protoplasm, on the basis of the formula (Barer, 1966):

$$C = (n_p - n_s)/(\alpha \cdot n_s)$$

where n_s is the refractive index of the solvent, which is either water or dilute salt solution. For protoplasm, the value of α is 0.0018. In terms of wet weight, the gramme concentration of solid per 100 g of protoplasm, is $\frac{C}{1 + C/400}$. Following immersion refractometry, the change in refractive index during cell division has been observed and it has been contended that there is a decrease in cytoplasmic concentration, which reaches minimum density during diplotene (Ross, 1954) or early metaphase (Joseph, 1963). This method allows a study of the changes in the refractive index of the cellular constituents during cell division.

The convenience of securing quantitative results is the principal reason for the development of interference microscopy. The basis is empirical in determining the mass of single and different tissue elements. The actual optical path difference, or phase change, imparts a quantitative aspect to the measurement by interference microscopy (*see* Barer 1956, 1964 and Davies, 1958). In interference microscopy, the light is split into two beams by a beam-splitting mirror, one beam being transmitted through the object and the other passing some distance to the side of it. The interference is produced by the two beams combining at the semi-reflecting mirror.

The advantages of interference microscopy are (Barer, 1966):

(1) Phase changes of the material can be measured.
(2) Bright colour effect can be secured.
(3) The contrast can be varied, allowing a proper type of contrast to be selected with respect to the object, to secure the intracellular details. The system is elastic; variable phase contrast can be obtained.
(4) 'Halo' and 'Zone' effects are absent.
(5) Mass per unit area of the cell can be conveniently measured.

The flatness of the image obtained and glare are serious disadvantages of the interference system.

Microscope interferometry, in conjunction with immersion refractometry, permits the determination of the refractive index, the solid concentration, the thickness of structures and the dry mass. With the aid of microscope interferometry, the changes in the amount of protein and DNA in the nuclei of mouse fibroblasts, as well as in ascites cells, have been measured, and other cancerous tissues studied (Longwell, 1961). Mellors and others (*see* Mellors, 1959) claimed to have measured the total protein in the chromosomes, interphase nuclei, and sperm heads in mice, and have concluded that in the prophase of germ cells (haploid) the chromosome set is equal in mass to the sperm head; similarly, the double set of chromosomes equals in mass

the resting somatic nucleus of mouse liver. The implication is, therefore, that all the protein of the nucleus, at least in prophase, is located in the chromosomes. These conclusions have, however, been questioned by other workers (Richards and Davies, 1958). Davies has suggested that the protein associated with the haploid set of chromosomes is definitely more than the amount associated with DNA in the sperm head.

An additional use of interference microscopy has been in the investigations on isolated nuclei. The total protein content determination is claimed to be more reliable from interferometry than that by the ultraviolet-absorption technique. The results of Hale and Kay (1956), on the measurement of dry mass of nucleoprotein of calf thymus, isolated in three media (namely, citric acid, sucrose calcium chloride and non-aqueous solution) are nearly identical with those obtained by ordinary weighing procedures. Cell division has been filmed by using the interference system with excellent colour effects (Ambrose and Bajer, 1960; Ambrose, 1963).

Interference microscopes, though sometimes applied for standard observation, are chiefly measuring instruments, whereas for routine work phase contrast is definitely adequate and until now irreplaceable. The details of the two-beam interference microscope including scanning interferometry have been dealt with exhaustively by several workers (Davies, 1958; Hale, 1958; Barer, 1959, 1966; Francon, 1961; Krug *et al.*, 1964; Goldstein and Hartmann-Goldstein, 1974; Goldstein, 1977).

POLARISATION MICROSCOPY

Polarisation microscopy is based on the principle of birefringence against polarised light exhibited by certain objects of complex molecular arrangement (Hallimand, 1970). This gives an indication of the physical heterogeneity of the structure at the molecular level. With the development of electron microscopy, the importance of this method has been minimised, but birefringence and dichroism can reveal the molecular orientation of structures beyond the resolution of electron microscopy. When a beam of polarised light is received by such a structure, the ray is split into two rays polarised in mutually perpendicular lines. Of these, the ray which obeys the ordinary laws of refraction is known as the 'ordinary' ray, and the other, whose velocity through the object is different, is known as the 'extraordinary' ray. The difference in the refractive indices $(\mu_e - \mu_o)$ associated with the process gives the value of birefringence. The two polarised rays, after emerging from the object, recombine but, because of different velocities through the object, one shows retardation as compared with the other. The value of 'retardation' T, which is based on the birefringent property, is counted by multiplying birefringence $(\mu_e - \mu_o)$ with the thickness of this object t, i.e., $T = (\mu_e - \mu_o)$ t and is expressed in terms of wavelength in nanometres.

Birefringent or anisotropic objects possess one, or several, optical axes. In general, the optical axis of the fibre of a biological object coincides with its lengthwise or perpendicular direction. 'Positive birefringence' signifies that the refractive index for light vibrating parallel to the long axis is greater than the one perpendicular to it. Similarly, 'negative birefringence' denotes the reverse property. Nucleic acid and nucleoprotein fibres are negatively

birefringent, whereas mere protein fibres are positively birefringent. 'Isotropic' objects are those in which, owing to their complexity and heterogeneity of structure, both properties are present and one neutralises the other. 'Intrinsic birefringence' is due to regularity in the pattern of molecules whereas 'form birefringence' in elements is caused by preferred orientation of asymmetrical particles.

Polarisation microscopes are more or less identical in principle to ordinary microscopes, but fitted with polarising elements. Instead of the ordinary light, a low intensity carbon arc or a high pressure mercury arc is used as the source of illumination. Two principal polarising elements fitted to the microscope are the 'polariser' and 'analyser'. A sheet of 'polaroid' film (iodine polyvinyl alcohol polarising film) fitted below the substage condenser serves as the polariser; it is better than the prism polarisers used previously, and the analyser is fitted in the body tube of the microscope, above the objective lens, and can be rotated to obtain alternate bright and dark appearances at every 180 degrees turn. When the axis of transmission of the analyser is parallel to that of the polariser, the maximum amount of light transmission can be obtained, while in the case of no transmission, otherwise known as extinction, the positions of polariser and analyser are crosswise. In addition to these two, the 'compensator' is another necessary component, being formed of birefringent plates or crystals, and as its 'retardation' value is known, it helps in determining the slow and fast axes of transmission of an object. A weak birefringent object when viewed between the crossed polariser and analyser assumes a faintly bright appearance against a dark background. Maximum brightness can be observed when the object axis lies at 45 degrees with respect to the analyser. At this stage, if the compensator is inserted below the analyser, the object will brighten when the compensator is rotated in one direction, and lighten when it is rotated in the opposite direction. When the object shows maximum brightness, it is implied that the directions of the slow ray of the compensator and the object are identical. The brightness is thus due to the joint refraction of the two.

In polarisation microscopy the lens selected should not contain components (fluorite) which often show anomalous birefringence. Moreover, in order to reduce scattering of light through air–glass surfaces, it becomes necessary to 'gloom' the lens surface which involves the deposition of a thin transparent film of desired refractive index and thickness. For details on polarisation microscopy, the reader is referred to Bennett (1950), Frey-Wyssling (1953), Mellors (1959) and Hallimand (1970).

In cytology, polarisation microscopy has been particularly helpful in studying the structure of the mitotic spindle and the changes it undergoes during cell division (Barer, 1955; Inoué, 1959; *see* Mazia, 1961; Harris and Mazia, 1962). Because of the birefringent nature of the specimen, phase contrast microscopy is not suitable. On the basis of his observations on the birefringence of fibrils in centrifuged and compressed eggs of sea urchins, Inoué (1951) suggested the presence of chromosome fibres at least between pole and chromosome and spindle fibres from pole to pole (*see* Swann, 1951). Birefringence apparently decreases at anaphase. Swann interpreted it as being due to the release of some active substances from the chromosomes. Inoué interprets the inactivation of the spindle by colchicine as due to the disorganisation of micelles by depolymerisation.

Birefringence in the sperm head is claimed to be due to the DNA molecules, oriented parallel to the longitudinal axis of the chromosomes (Schmidt, 1937). This arrangement of the DNA molecules has also been suggested for the salivary gland chromosomes of diptera. Frey-Wyssling (1943), on the other hand, presented evidence against the assumption of this parallel arrangement in living chromosomes. Birefringence has also been attributed to the effects of ethanol fixation. Inoué and Sato (1962) suggested the orientation of DNA molecules in the form of a 200 nm thick coil—a constituent of a supercoil of 800 nm thickness in the living sperms of *Ceutrophilous nigricans.* In living endosperm cells, Inoué and Bajer (1961) noted birefringence in the centromere.

Though birefringence still presents a number of difficulties in the interpretation of structures, it provides a rational approach to understanding the orientation of birefringent objects, and should be supplemented with other methods to interpret the property of the oriented molecules.

As compared with birefringence, dichroism in ultraviolet light, which is specific at least in relation to certain compounds, has been found to be more useful in the study of molecular orientation. Ambrose and Gopal-Ayengar (1952), on the basis of observations on chromosomes vitally stained with neutral red, suggested the folded nature of the DNA molecule, the chains in these folds lying parallel to one another, in dipteran salivary gland chromosomes. Caspersson's (1940) method of analysing dichroism in ultraviolet rays, and the differential absorption of nucleic acids (260 nm) and proteins (280–290 nm) has been employed to work out the molecular relationship between the two in chromosomes (Wilkins, 1951; Seeds, 1953). High absorption has been regarded as an index of molecular direction. Parallel arrangement of DNA molecules has been indicated to some extent. Ruch (1966), with the aid of an apparatus meant for measuring weak anisotropic objects, studied the orientation of DNA and protein in dipteran salivary gland chromosomes fixed in 50 per cent acetic acid with 1 per cent lanthanum acetate. Slight longitudinal orientation of DNA molecules has been shown and comparative analysis under fixed and living conditions has been recommended. Undoubtedly the study of dichroism in ultraviolet rays is emerging as an additional tool in studying molecular inter-relationships of cellular constituents, but at the present level of refinement, its use in the study of chromosome structure is rather limited.

X-RAY MICROSCOPY

The direct study of biological materials at the molecular level is principally by electron microscopy, although it generally does not allow the clear resolution of structures below 0.5 nm. In polypeptide chains, where the distance between the atoms is of much lower magnitude (0.15 nm), resolution by this method is not possible. On the other hand, x-rays are scattered due to diffraction by all forms of matter and from the diffraction pattern, which is dependent on the position of atoms, one can get an idea of the molecular orientation. This method even allows the study of molecular patterns from gels and concentrated solutions.

In studying the chemical and physical nature of chromosomes, different

properties of x-rays, such as diffraction, emission and absorption are advantageously employed. For analysis of the x-ray diffraction pattern, a narrow beam of x-rays is passed through the object, and a scattering of rays occurs because of diffraction by the atoms. On emerging from the object, the rays diverge, following the pattern of diffraction which is recorded on a photographic plate placed in the vicinity of the object (0.06–0.1 cm). The plate is developed later, using an amber glass safe lamp. The symmetry and pattern of the structure can be determined on the basis of the angle and intensity of the diffraction patterns. In the study of biomolecular structures when repeating units are present, the distance between each unit can also be worked out by the diffraction pattern of x-rays of known wavelength from the fact that the angle of diffraction and the distance between the units are inversely proportional (Astbury, 1947; Furberg, 1950; Oster, 1950, 1951; Bragg, Kendrew and Perutz, 1950). In the study of chromosomes, an outstanding achievement made with the aid of this technique is the establishment of the double helix configuration of the DNA molecule (Watson and Crick, 1953; Wilkins and colleagues, 1953) and the pattern of arrangement of the different components (*see* Pardon and Richards, 1979).

For details on x-ray microscopy, the reader is referred to Oster (1955), Engström (1962) and Wilson and Morrison (1961).

For the application of analytical principles based on the use of x-rays, it is necessary to have an x-ray imaging system. On the basis of x-ray absorption characteristics, several qualitative and quantitative assessments at the cellular level can be carried out. For dehydrated biological specimens and thin sections of soft biological tissues, up to 1–10 μm thick with up to 35 per cent dry mass, it is preferable to generate the spectrum at 500–2000 V. Engström (1966) devised a number of models for microradiography with ultra-soft x-rays, incorporating vacuum system, x-ray tube and high voltage source (Combée and Engström, 1954; Lindström, 1955; Henke, White and Landberg, 1957, etc.). Point projection x-ray microscopes have also been evolved (Cosslett and Nixon, 1960). Projection microscopes have been utilised for obtaining representation of chromosomes, clearly delineating the mass and water distribution (Engström, 1966). In the preparation of microradiographs in connection with dry weight determination of objects, such as ascites tumour cells, salivary gland chromosomes, etc., it is preferable to adopt the smearing technique and freeze-drying of the smears for examination in high vacuum x-ray tubes.

For mass determination, in cells from solid tissues, the best procedure is to use thin frozen sections and freeze-dry in the sample holders. Fixation with chemicals may cause distortion of the structure and is not recommended (Engström, 1966).

Because the molecular interaction between chromosomes and x-radiation follows certain fixed principles, x-ray microscopy is proving to be an extra method for the qualitative and quantitative assessment of the structure and behaviour of chromosomes.

FLUORESCENCE MICROSCOPY

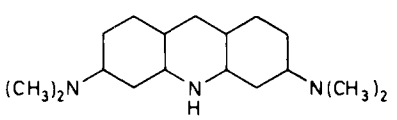
The utilisation of the fluorescence shown by some of the cell constituents, as well as of some special dyes, against ultraviolet light, forms the basic

principle of fluorescence microscopy. In this system, intracellular constituents are detected either through their own property of autofluorescence, or by secondary fluorescence due to the adherence of labelled or fluorescent dye.

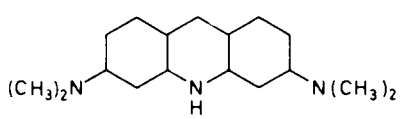
To detect an intracellular constituent on the basis of its own fluorescence, short wavelength ultraviolet light transmitted from a quartz condenser fitted with a microscope is required. Several compounds can be identified on the basis of their own fluorescence, provided an understanding is obtained as to the exact wavelength which excites this, as well as the wavelength of the excited substance.

The general practice in the majority of laboratories is to utilise the property of secondary fluorescence obtained by fluorochrome preparations, but such dyes become effective only in long blue or near ultraviolet light (Cowden, 1960). Like other dyes, these agents are also either acidic, basic or amphoteric in nature and can be used in accordance with their application in cytological practice, but a special technique is necessary for the detection of secondary fluorescence of specific compounds within the cell (Kraft, 1975; Cornelisse and Ploem, 1976). The method involves the observation of frozen sections or squashes against ultraviolet light and through a standard microscope fitted with adequate condensing lenses and filters. A special advantage of this technique is that unfixed materials can be studied, thus eliminating the artefacts which often arise due to fixation.

Conjugated planar dye molecules, in solution, form complexes having properties different from those in monodispersed form. The metachromatin dye polymer complexes allow observation of fluorescence and absorption spectra. One of the planar dye molecules is acridine orange, dissociating near pH 7 (Strugger, 1949; Albert, 1951; Zanker, 1952). Two equivalent resonating structures are,



and



This dye, as a monomer at a pH 6.0, has fluorescence and absorption peaks at 535 and 490 nm, and as a polymer the peaks are at 660 and 455 nm respectively. It is difficult to distinguish spectroscopically between acridine orange–DNA and acridine orange–RNA complexes (Loeser, West and Schoenberg, 1960; Wolf and Aronson, 1961; Steiner and Beers, 1961; Ranadive and Korgaonkar, 1960; West, 1969). However, in fixed preparations (Armstrong and Niven, 1957; Mayer, 1963), it may be possible to distinguish DNA and RNA on the basis of metachromasia of acridine orange, a red colour specifying RNA, and the yellowish-green colour indicating DNA. But under conditions *in vivo*, no such differentiation could be recorded.

On the basis of the assumption that amino groups in the 3, 6 positions

of acridine react with phosphoric groups of nucleic acids, Lerman (1963, 1964) suggested internucleotide binding of planar dye molecules. Dye-polymer complexes and their optical properties have also been studied (Bradley, 1961; Stone, 1964, 1967; Stone and Moss, 1967).

Puchtler, Sweat and Gropp (1967) worked out the relationship between structure and fluorescence of azo dyes. Several azo dyes become fluorescent after combining with tissues. Aromatic compounds in the dye control its fluorescent property. In other classes of dyes, ring closure, coplanarity of chromophores, accumulation of ring system and low dye concentrations exert an inhibiting influence. There are also other factors, which control the fluorescence of triphenyl methane, anthraquinone and quinone-imine dyes.

Quantitative measurements can be carried out by fluorescence micro-spectroscopy. Long exposure time for photographs should be avoided as the intensity may fade with continuous exciting irradiation of the fluoro-chrome-stained cell, in certain cases (*see* West, 1969).

In preparing tissue sections meant for observation under the fluorescent microscope, chemical fixatives are avoided as far as practicable, freeze-dried or chilled preparations of unfixed materials being preferable for study by this method. In cases where natural fluorescence is absent, the choice of proper and specific dyes, with fluorescent properties, is the most critical step in the procedure, as the dye imparts fluorescence to its specific substrate which can be detected *in situ*.

Frozen sections of unfixed tissue can be cut in a microtome and maintained in a refrigerated cabinet at $-20\,^{\circ}C$. Freeze-drying, during which the temperature of the tissue should be maintained at about $-40\,^{\circ}C$ by means of a slush of diethyl oxalate, can also be employed. In principle, this involves molecular distillation, and in order to secure full molecular distillation, the cold spot, that is, the liquid nitrogen water trap ($-196\,^{\circ}C$), is placed within a short distance of the tissue block, the pressure being kept at $2–5 \times 10^{-4}$ mm/mg. This adjustment within a short distance is necessary so that the mean free path of the water vapour molecules, at the pressure employed, will be more than this distance. Within this procedure, freeze-drying can be completed in 7 h. Solid carbon dioxide can also be used as the drying agent, when drying may take 2–3 days (Danielli, 1953). Freeze-dried sections should always be floated on non-aqueous medium or adequate fixative. Glycerine, isobutyl methacrylate, methyl salicylate, etc. are good mounting media.

The most adequate light source, emitting ultraviolet rays, is the carbon arc, preferably with a direct current and fitted with an electromagnetic field. Among other sources, high pressure mercury vapour arcs may be mentioned. Coons (1958) recommended the use of A-H6 (General Electric Co.), HBO 200,109 (Osram), ME/126 (Mazda) mercury vapour arcs.

Suitable condensing lenses of single bispheric type are generally fitted in front of the light source so that the black lens of the dark-field condenser gets the image of the horizontal carbon crater. The filter is prepared in the following manner (Coons, 1958; *see also* Richards, 1955).

A Pyrex water cell, containing copper sulphate solution, is fitted in front of the light source. The cell is fitted with a cooling device by means of a glass coil immersed in the $CuSO_4$ solution inside which running water circulates, as without this cooling device, the $CuSO_4$ solution may boil within a short period of turning on the carbon arc. A filter to remove the

middle range of the spectrum is attached to the side of the cell away from the arc.

The light, passing through the $CuSO_4$ solution and the filter, ultimately falls on an ordinary glass mirror. The microscope receiving the light is a standard one fitted with a chromatic objective and dark-field condenser. A protective Wratten filter must be used in the eyepiece to remove undesirable wavelengths, such filters generally being colourless, as colouring may cause difficulty in detecting fluorescence of the same colour. Monocular lenses are always preferred over binocular ones in order to reduce scattering of light. Image intensity in the microscope is generally directly proportional to the square of the objective (n.a.). Incident light or epi-illumination, through adjustment of lenses on the stage, yields optimum results (Boehm, 1972; Rost, 1972). However, in all fluorescence microscopes, barrier filters for cutting off undesirable wavelengths and excitor filters for excitation of fluorescence are used. The latter may be of wide and narrow band types. Barrier filters are chosen in appropriate combination with excitor filters (Ploem, 1975; Meek and Elder, 1977).

For photography, 35 mm films, with exposure time necessary for fast films, are usually employed; the negatives are generally thin and strong contrast printing is desirable.

The advantages of fluorescence microscopy were first realised in attempts to detect specific antigens. Richards (1955) and Coons (1958) adequately reviewed this aspect of the use of fluorescence microscopy. In principle, the method involves the forced production of antibodies by the injection of antigens labelled with fluorescin isocyanate into the tissue. The conjugation of the gamma globulin of the antibody with fluorescein isocyanate in the antigen, makes visible the site of the antibodies within the tissue.

On the basis of this principle, originally applied to antigens, modifications of the technique were evolved for the detection of proteins, as well as DPN and TPN, in cytological practice (*see* Glick, 1959). A measurement of the amount of fluorescence also allows a quantitative estimation of the substance transmitting secondary fluorescence. As with visible light and ultraviolet photometric methods, fluorescence emission and absorption analyses are also being carried out quantitatively according to the same principle. This analytical method has a wide application. The details of modifications in instrumentation for quantitative fluorometric study have been given by West (1969). Both absorption and emission spectra are used for quantitation. Methods have been developed for photographic microspectroscopy and for photoelectric microspectrophotometry. The fluorometric technique developed by Holter and Marshall (1954) is interesting. With the photomultiplier tube attached to a fluorescent microscope, on the stage, the sample is fitted in a capillary tube.

The method of Lowry, Roberts and Kapphalm (1957) is convenient for the study of DPN and DPNH. DPN does not show any fluorescence as such, but in a strong alkaline medium it develops this property, while DPNH, although it is itself fluorescent, shows an increase of fluorescence if it is oxidised to DPN and treated with a strong alkali. These properties have been made use of in detecting their presence, or absence, as well as their amount in the tissue. Krooth *et al.* (1961) demonstrated that mammalian chromosomes react with several human sera, including those of diseased

patients. The method involves an initial exposure of the chromosome preparation to the serum, followed by exposure to horse anti-human globulin, conjugated with fluorescent dye (Holborow, Weir and Johnson, 1957). Fluorescence has been observed in all the chromosomes, though several diseased sera did not show any reaction. The fluorescence is based on the principle that gamma globulin of the sera reacts with the nuclei.

Further, anti-nuclear globulins from patients with collagen diseases have been shown to bind with various nuclear constituents in the interphase and metaphase (Razavi, 1968). In different sera, the specificity and titre of anti-nuclear factors have been found to differ, though in the majority of cases at least two or more cell constituents are reacted upon. The nuclear constituents which react with serum differ in distribution and concentration in various types of cell, and according to the phase of cell metabolism. As fixation is also an important factor, difficulties are often encountered in the interpretation of fluorescence data. With the aid of fluorescein-labelled anti-DNA serum, the distribution of single stranded DNA in lymphocyte chromosomes has been demonstrated (Razavi, 1968). As gene activity has been found to be continuous throughout the chromosome cycle, it has been suggested that the DNA molecules may just serve as the coding device, whereas gene expression is controlled by changeable cytoplasmic and nuclear factors.

For the study of the effect of chemicals on the nucleus and cytoplasm, fluorescence microscopy is often recommended. In the study of cellular nucleoproteins and nucleic acids, diaminoacridine dyes, such as acriflavine, acridine orange and acridine yellow have been employed because of their affinities (Strugger, 1949). When applied to living cells, as mentioned before, they react principally with nuclear DNA and RNA—as such, they are showing increased application in chromosome study (De Bruyn, Robertson and Farr, 1950; De Bruyn *et al.*, 1953). With acridine orange, RNA and DNA can be differentially stained, as the former appears red and the latter looks green under a fluorescence microscope. This coloration and its intensity show alterations in diseased conditions, or in injury. Therefore, for the detection of the effects of ionising radiations as well, this method has been applied (Meisel *et al.*, 1961; Seydel and Lawson, 1966). The effect of aromatic diaminidines in nuclei and cytoplasm has also been measured through fluorescence microscopy by Snapper *et al.* (1951).

Bushong, Watson and Atchison (1968) demonstrated that the intensity of fluorescence in acridine orange-stained preparations varies at different wavelengths. Maximum effect was observed at 525 nm and a progressive shifting towards shorter wavelengths was noted. At 580 nm, with increase in illumination time, there was a decrease in intensity. At levels lower than 580 nm, initial brightness was followed by a gradual decrease in intensity. In the detection of diseases, such as malignancies (Bertalanffy, L. 1958; Bertalanffy, F. D., 1960; Sherif, 1963), by fluorescence microscopy, the wavelength and intensity, as previously mentioned, are of special importance.

Porro *et al.* (1963) have published a list of biological dyes with detailed information on their fluorescent property and absorption spectra, to which the interested reader is referred. For further details of instrumentation, Richards (1950, 1955), Mellors (1959) and West (1969) should be consulted.

For identification and quantitative estimation of cell constituents, the importance of methods based on absorption and emission of fluorescent

compounds is gradually being realised (*see* Passwater, 1970). Television fluorescence microspectrophotometry (West, 1965) is now allowing the detection of even extremely minute quantities of substances in the living cell. Fluorescent antibody technique has been a powerful aid in detecting chemical differences (Goldman, 1968). In the field of chromosome study, there is ample potentiality in the combined analytical technique based on chromosome isolation and their fluorescence emission analysis as well as specific fluorescence of chromosome segments. With the gradual invention of specific antisera, their application on isolated chromosomes may ultimately lead to chemical identification of specific segments of chromosomes, based on their differential fluorescence.

SCHEDULE FOR THE STUDY OF CHROMOSOME FLUORESCENCE FOLLOWING TREATMENT WITH ANTI-DNA SERUM (Razavi, 1968)

Cell preparations

Use as substrate, intact white cells from mixed short-term unsynchronised primary cultures, washed in globulin-free serum for preliminary experiments. Smear the cells on a slide, applying spirally with a glass rod. Fix the slide in cold acetone for 5 s. Wash in phosphate-buffered saline (pH 7.2, 0.15 M —'PBS') for 5 min at room temperature, and stain.

Prepare osmotically isolated interphase and metaphase nuclei of lymphocytes from partially synchronised phytohaemagglutinin-stimulated cultures at 45–50 h (*see* chapter on human and mammalian chromosomes). Add required amount of distilled water to dilute cultures to 100 mM, determined for each batch of medium with the help of an advanced instrument freezing point osmometer. After 20 min, centrifuge at 500 rev/min for 5 min and decant supernatant. Add 2 ml of pre-cooled acetic acid–methanol (1 : 3) mixture to the tube drop by drop, while gently agitating the cells in an iced water-bath. Keep overnight at 4 °C. Change fixative to acetic acid–methanol mixture (1 : 2). Suspend by pipetting. Centrifuge and remove fixative, keeping only 0.2 ml. Add 0.2 ml of 50 per cent acetic acid, resuspend the cells. Prepare air-dry smears by spreading a drop on a slide at 55 °C and drying for 30 s. Wash and stain.

Nuclease treatment

To one set of unstained slides add deoxyribonuclease solution (0.1 mg/ml) at 37 °C, in PBS containing 0.05 mg $MgCl_2$/ml. Treat controls in enzyme-free solutions, wash all slides in PBS and stain.

Antisera

Conjugate 'reticular' anti-DNA serum procured from microbiological laboratories at a fluor : protein ratio of 1 : 100. Remove the free dye by DEAE-

sephadex chromatography, using saline (buffered at pH 7.0 by 0.0175 M phosphate) as eluant, according to Tokumaru's technique (1962). Concentrate to the original volume by dialysis against 25 per cent pyrrolidone and store at 4 °C with 1 : 10 000 merthiolate as preservative.

Fluorescent antibody staining

Treat slides, in petri dishes lined with damp filter paper, with serum for 1 h at 37 °C. Wash in 500 ml PBS for 15 min with gentle stirring. In preliminary experiments, *see* section (a), a two-layer technique with unlabelled LE serum and conjugated horse anti-human globulin serum (Sylvana, Millburn, N.J.). may be followed.

Ultraviolet microscopy and photomicrography

Mount cover slips with 10 per cent PBS in glycerol. Illuminate by a Sylvania L50 mercury vapour lamp attached to a microscope with a dark-field condenser. Observe through apochromatic objectives, using UG2 (4 mm) exciter and No. 47 barrier filters. Photograph through BG12 exciter and No. 47 barrier filters on Agfachrome 35 mm film with 3 and 6 min exposures.

Observations

From anti-DNA sera tests on osmotically isolated, and acetic–methanol fixed nuclei, obtained in cultures partially synchronised by overnight treatment at room temperature after 8 h initial incubation at 37 °C, discrete attachment of the antibody is seen in interphase and metaphase nuclei. In the brightly stained metaphase chromosomes, the more frequent attachments are telomeric, or near secondary constrictions. Pre-heating to 80 °C for 5 min intensifies these patterns; treatment with deoxyribonuclease reduces them and brief pre-heating in an open flame destroys them.

Localisation of differential segments of chromosomes

For the localisation of chemically differentiated segments of chromosomes, especially the heterochromatic ones, Caspersson *et al.* (1968, 1969, 1971) utilised the different methods of binding of fluorescent DNA reagents, such as, propyl quinacrine and quinacrine mustard dihydrochloride. The principle involved in the treatment is that the biological effect of alkylating agents is the alkylation of nucleophilic sites, i.e. reaction with the N-7 atom of guanine. The guanine-rich segments are expected to show the accumulation of the dye. With the use of bifunctional quinacrine mustard, differentiation of the chromosome segments could be observed. For observation and recording, they have devised methods involving ultramicrospectrophotography (UMSP), computerised sorting and ultramicrofluorometry (UMFL), and for scanning and integration the ultramicrointerferometer has been used. Several

fluorescence microscopes with photometric attachments are available (Reichert, Zeiss, Leitz, Vickers, etc.).

Zech (1969) noted that in human spermatozoa, the distal proportion of the Y chromosome shows brighter fluorescence. For other differences in size and surface properties of cells and other applications, the reader is referred to the review by Beatty (1970) and Chapters 11 and 13.

Vosa (1970), Pearson, Barrow and Vosa (1970) and Barlow and Vosa (1970) have developed methods for identifying Y chromosomes in buccal smears of human interphase nuclei as well as for differentiating specific sites in human lymphocyte chromosome preparations, using quinacrine (0.005 per cent quinacrine mustard in deionised water for sperm, or 0.5 per cent aqueous or 1 per cent solution in absolute ethanol). George (1970) also used quinacrine mustard (250–300 μg/ml in glass distilled water) for human chromosomes. In all these methods, except for sperm, the material after treatment with colchicine or colcemid, is fixed in acetic–methanol or ethanol, washed, rinsed in buffer (pH 4.1–5.5), stained for a few minutes and mounted in distilled water, buffer or buffered glycerol. For photography, Kodak-Tri X-Pan film with exposure time of 10–30 s has been recommended. For viewing, the Zeiss photomicroscope with fluorescent illumination (Filter–tr. range, 300–500 nm) is recommended. Conen, Lewin and Vaco (1970) and Thuline (1971) used the same principle to identify Y chromosomes in blood smears. For details *see* Chapter 13.

LIGHT MICROSCOPE AUTORADIOGRAPHY

GENERAL PRINCIPLES

Becquerel's pioneer attempt in 1896 to detect radioactivity with the aid of a photographic plate has been advantageously used in later years to develop autoradiographic techniques. The purpose of this method is to locate radio-

active material in a specimen with the help of photography. Whereas with the Geiger counter, an electronic wave is measured by an electrical device, in autoradiography, the radioactive material is detected by a photographic process of development. The method is based on the principle that if a photographic emulsion is brought into contact with radioactive material, the ionising radiation will so convert the emulsion as to show spots at certain points after being developed.

Specimen and film are brought into contact with each other for a certain period of exposure and there is decay of radioactive atoms. The radiation thus emitted affects the emulsion, activating silver halide crystals. The final result is the formation of a latent image which can be developed to denote the location, intensity and distribution of radioactive material. If the radioactive substance is tagged with a metabolic precursor, the distribution of the grains in the autoradiograph will indicate the distribution of the precursors and thus the metabolic path can be determined with accuracy.

STATUS OF THE PRINCIPAL METHODS

Of all the methods so far presented, Lacassagne's (1924) technique of using x-ray film and making contact between the sensitive pellicle and the tissue is the simplest, but it is not widely applied because errors occur, due to uneven contact between the object and the film (Hamilton, Soley and Eichorn, 1940). Observation at culture level was made possible for the first time in Belanger and Leblond's technique (1946), due to the direct appearance of the autograph on the section. The sensitive gelatin, separated from a photographic plate, is first moistened and kept in position on the tissue. Two disadvantages of this method are the risk of the appearance of bubbles after the emulsion dries up, and the increasing number of background grains which occur on melting the emulsion, thus giving an incorrect picture (Ficq, 1959). Evans (1947), Endicott and Yagoda (1947) and Bourne (1949) presented a method involving mounting sections on a photographic plate or film, but as the sections remained coated with celloidin, difficulties were often encountered with the tissue when photographic baths were in use. There was always the risk of the loss of material while removing the celloidin.

The stripping film method, as adopted by Pelc (1951, 1956), Andresen (1952), Taylor and McMaster (1954) and Kopriwa and Leblond (1962), was considered, for a long time, to be advantageous for the study of chromosome structure, bringing out a sharp contrast between radioactive spots and background tissue. In this technique, the outline of the schedule is to cover the preparation with a sensitive emulsion with a bottom layer of inert gelatin against a glass plate.

Lately, however, application of emulsion in the liquid form has been found to be most suitable for autoradiography. It is now widely used for plant, animal and human tissues and also for their cultures (Prescott, 1964; Prescott and Bender, 1964). This method allows the formation of a monolayer of emulsion on the tissue. In the study of high resolution autoradiographs (*see* section on high resolution autoradiography), the liquid emulsion technique has been found to be the most convenient one.

In both the above techniques, the film or the emulsion must always be

stored in a cool, dark chamber (18–20 °C). Gude (1957) suggested that film plates be stored at 3–10 °C in a desiccator containing saturated aqueous calcium nitrate solution at a humidity of nearly 51 per cent. Moreover, after the application of the emulsion, air drying of slides and storage should also be carried out under similar conditions.

FACTORS INVOLVED IN THE INCORPORATION OF RADIOACTIVE TRACERS

As the particles are ejected in all directions, the photographic emulsion may become spotted over a much wider area than that covered by the actual location of tracers. This difficulty can, however, be eliminated by the use of particles of a suitable range, as the spreading must be limited within this range. In this respect ^{3}H, ^{14}C, ^{35}C are convenient tracers since they emit soft β-particles, affording good resolution.

The grain yield and radioactive decay should always be taken into account in making a quantitative assessment of the incorporation of tracers in the tissue (Evans, 1975). For example, in the emitters of soft β-rays, such as tritium, self-absorption is one of the important factors: half the particles are emitted in the reverse direction of the emulsion and, as such, a correct estimate of the number of particles emitted will be twice the number obtained in emulsion. Quantitative assessment depends on the correspondence between amount of radioactive material and density of the grains or 'track' in this region.

In order to use a radioactive molecule as a tracer, it is necessary to utilise the specific precursors of the molecule, the distribution of which is to be studied within the cell. For this purpose, in the study of chromosome metabolism, labelled uridine is used for the detection of RNA, thymidine for the detection of DNA, and specific amino acids for the detection of proteins. With ^{32}P alone, the localisation of DNA is difficult, as phosphorus is incorporated in different metabolic products of the cell unless such products are extracted or digested. The measurement of radioactivity for quantitative study, however, depends on several factors, such as the amount of radioisotope, its half-life, and the energy of β-rays emitted.

The concentration of the radioactive tracer in the labelled medium, as well as the time interval between application and fixation, are important factors in the study of autoradiography. As the rate of incorporation varies for different labelled compounds, the period of treatment must be fixed with this information in mind.

To obtain an accurate autoradiograph, the tissue should be treated with at least a certain minimum concentration of the labelled substance. Approximately 10 grains/100 μm^2 of emulsion is just enough, requiring an exposure of $10/\delta/\beta$-particles (where δ denotes the yield of developed grains per particle hitting the film), which were obtained from the decay of double the number of radioactive atoms at the time of exposure. The half-life should also be considered, because for short-lived isotopes, the exposure of two half-lives results in the decay of three-quarters of the atom. In consideration of the various factors, the minimum concentration c for short-lived and long lived isotopes has been suggested (Pelc, 1958) as:

(1) For short-lived isotopes: (half-life H in days, in 5 μm sections and emulsions, and f denoting the proportion of labelled to unlabelled tissue)

$$C = \frac{11.5f}{H^{\delta}} \text{ in } \mu\text{Ci/ml}$$

(2) For long-lived isotopes:

$$C = \frac{12.5f}{d^{\delta}} \text{ in } \mu\text{Ci/ml}$$

The isotope being long-lived in this case, the decay during the time of exposure (d) is negligible.

For fine-grained stripping-film, the value of δ can be taken as 1.

In addition to the factor of minimum concentration, the actual amount of radioactive substance required for feeding the tissue depends on the metabolic role of the metabolite in which it is supposed to be incorporated. For example ^{32}P, when injected into the tissue, mixes with the free phosphate in the organism. To obtain an autoradiograph, therefore, a sufficient quantity of the tracer is needed, but if the tracer is applied labelled with a particular metabolite which is not present in a large amount in the tissue, the quantity of tracer needed will be very low. A specific example is seen in mice, where labelling of DNA requires at least 1 mCi of ^{32}P per mouse while ^{14}C–labelled adenine is required in an amount of 25 μCi. Similarly, in leucocyte culture from peripheral blood, application of tritiated thymidine at 1 μCi/ml for 5–6 h before harvesting is needed for incorporation in chromosomal DNA.

For a detailed consideration of these aspects, the reader is referred to the reviews by Boyd (1955), Pelc (1958), Ficq (1959), Perry (1964) and Evans (1975).

AUTORADIOGRAPHY IN THE STUDY OF CHROMOSOME CHEMISTRY

In order to apply the principle of autoradiography in cytochemistry, precise localisation of the radioactive material within the tissue must be secured. Radioactive substances are introduced into the tissue either in a given chemical form or tagged with certain precursors of metabolism, and as at present specific and precise forms of labels, such as, thymidine, uridine, etc. can be obtained, the method can be usefully employed in the study of chromosome replication as well as in the chemical make-up of chromosomes. The radioactive molecule, at the precise site of its occurrence, following treatment, can be identified by several methods, namely, digestion through enzymes, selective staining techniques, extraction of different components and precipitation. For instance, for extracting DNA and RNA, the trichloracetic acid (Schneider, 1945) and the perchloric acid methods (Ogur and Rosen, 1950) can be followed, and study of the autoradiograph in the non-extracted and extracted slides will give an exact idea of the location of the radioactive tracer in the specific type of nucleic acid. Without autoradiography, scintillation counting gives a measure of the radioactive substance present at a site. The same object can be achieved by using specific nucleic

acid enzymes, like deoxyribonuclease and ribonuclease. For the localisation of basic and non-basic proteins, pepsin and trypsin can be applied to bring about digestion. For details of the enzyme treatment method, please *see* chapter on enzymatic methods.

There are, however, certain inherent limitations in the procedure for extraction. For example, perchloric acid may cause desensitisation of the emulsion. Hydrolysis in N HCl at 56 °C for 5 min (Vendrely and Lipardy, 1946) removes not only purine bases of DNA but RNA as well. This method is utilised for the extraction of RNA (Pearse, 1972). Here it is necessary to find out how far the proteins are affected by hydrolysis. For details of extraction procedures, please *see* chapter on Extraction.

TECHNICAL STEPS IN THE PREPARATION OF AUTORADIOGRAPHS

The different steps followed in autoradiography are: (a) administration of the tracer into the tissue; (b) fixation; (c) paraffin embedding or smearing; (d) staining; (e) application of the photographic emulsion; (f) drying; (g) exposure, and (h) photographic process.

Staining can be done before or after the application of the emulsion. For details of the types of emulsion fluid, developers, exposure time, etc., please *see* chapter on high resolution autoradiography.

Administration of the tracer into the tissue

The radioactive tracer can be obtained in specific salt solutions or tagged with metabolic precursors.

For instance, ^{32}P can be obtained in orthophosphoric acid in dilute HCl solution or as orthophosphate in isotonic saline solution containing phosphate buffer. Similarly, ^{35}S is available as H_2SO_4 in dilute HCl solution or as sulphate in isotonic saline solution. Tagged isotopes are available in the form of tritium (^{3}H) labelled thymidine, ^{14}C-labelled adenine, thymine, uracil, etc., representing nucleic acid bases. Similarly, for proteins ^{35}S-labelled methionine, phenylalanine, etc. are used.

They can be administered in the medium in which the organism grows, or can be injected into the tissue. With animal materials, direct injection of the substance can be made into the tissue concerned, or the tissue can be cultured in an artificial medium containing the radioactive substance at a known concentration. The same procedure is adopted for normal and malignant tissue in human materials. In plants, for somatic cells, intact roots are allowed to grow in the medium. For flower buds, a method has been devised in which the inflorescence is floated in the medium containing the isotope. For culture of excised tissue in artificial media, the principle is the same for all biological objects. For the study of nucleic acid in somatic cells of plants, seedlings can be cultured in water, containing ^{32}P as orthophosphate (Pelc, 1958) or ^{14}C as adenine (Howard and Pelc, 1951; Clowes, 1956) or tritium (^{3}H) labelled thymidine (Taylor, 1956). Marimuthu (1970) studied ^{3}H-thymidine-labelled nuclei in developing pollen of *Tradescantia*. Savage and

Wigglesworth (1971) devised a method of direct injection of ^{3}H thymidine through calyx and corolla (0.001–0.002 mCi for two days, that is, the concentration needed for flooding the precursor pool as recommended by Cleaver, 1971) in buds for the study of post-meiotic stages followed by the routine method for cytological preparation of autoradiographs (Savage, 1967). For meiotic studies, inflorescence can be cultured for 8–24 h in a medium containing ^{32}P in aqueous solution (0.02 mg KH_2PO_4 and 20 μCi of ^{32}P ml) (Taylor, 1953; Taylor and Taylor, 1953) or in White's medium (Plaut, 1953). Similarly, for the study of proteins of chromosomes, materials can be cultured in a medium containing ^{35}S and Na_2SO_4 (Pelc and Howard, 1956). Cut inflorescences can be kept in media containing 0.036 mg of $MgSO_4.7H_2O$ and 10 μCi of ^{35}S/ml (Taylor and Taylor, 1953). For the study of nucleic acid in mammals, intraperitoneal injections of ^{32}P, ^{14}C, adenine and ^{35}S *dl*-methionine can be administered to mice. In the same way, for human bone marrow cells, mouse prostates, etc., culture medium containing the radioactive substance can be used. For peripheral blood cultures too, labelled radioactive compounds can be added to McCoy's or Eagle's medium, together with calf serum. For Chinese hamster fibroblast lines, labelled precursors are added to cell cultures. Application in monolayer cultures is necessary for short pulse exposures (Schmid, 1965). In the study of *Drosophila* salivary gland chromosomes, the tracers can be administered in food in the medium.

Fixation

The fixation can be performed either through freeze substitution (Lison, 1953; Freed, 1955; Woods, 1955; Burstone, 1969) or through a number of non-metallic fixatives, however, the fixative should not leach the radioactivity during preparation. Wolman and Behar (1952) suggested a method for slow fixation at $-8\,^{\circ}C$ for 4 h, followed by washing in ethanol. As far as practicable, metallic fixatives should be avoided; ethanol, a mixture of ethanol and acetic acid, neutral formalin, and formol–saline can all be employed for fixation, especially where isotopes are applied for incorporation into nucleic acid or protein of chromosomes, but the most reliable method so far found is freezing. Taylor (1951, 1952) observed that fixation of cells of anthers of *Tradescantia paludosa* in acetic–ethanol mixture, followed by hydrolysis in HCl for 10 min at $10\,^{\circ}C$ for Feulgen staining, resulted in the complete loss of radioactive phosphorus from the tissue, except that in the nuclei, and as such, the remaining phosphorus, being only in DNA, could be specifically localised. The fixative removes the acid-soluble phosphorus. If necessary, phospholipids can be removed by treatment with hot ether–ethanol (1 : 3) for 5 min (Taylor and Taylor, 1953) after fixation. For bone marrow or fibroblast cell cultures, 50 per cent acetic acid is recommended, though for detachment of fibroblasts, trypsin treatment is necessary (Schmid, 1965). In Chinese hamster fibroblast lines and in other mammals, acetic acid followed by acetic–ethanol (1 : 3) is recommended. Treatment in hypotonic solution and Hank's medium is necessary prior to fixation (Prescott and Bender, 1964). Frøland (1965), for blood cultures too, followed hypotonic treatment in 25 per cent Hank's solution.

Paraffin embedding or smearing

In order to secure a high resolution in paraffin sections, the sections should not exceed 5 μm in thickness, should preferably be cut in a freezing microtome, and should be mounted on slides coated with a film of alum–gelatin (0.5 per cent aqueous solution of gelatin and 0.1 per cent chrome alum) or with egg albumen. Absolute drying for at least 48 h is necessary before mounting the sections. Similar slides should be used in the case of smears, though preparations made with ordinary slides have occasionally yielded good results. In order to soften the tissue for smearing after fixation, the use of pectinase or cellulase is preferable instead of prolonged hydrolysis in N HCl, which often results in the removal of nucleic acids; the sections or smears should not be uneven and, especially in the latter, uniform pressure must be applied after smearing in dilute acetic acid to obtain a one-layered smear. Heating should be avoided as far as practicable.

Staining

Staining of the preparations can be done prior to, or after, the application of the photographic emulsion, but in the former, the protection of the material by a very thin layer of impermeable substance, like celloidin, may be necessary (Pelc, 1958; cf. Belanger, 1961). Experience in this laboratory has shown that uncoated tissue, especially in the study of chromosomes, allowed good resolution.

The dyes chosen should have certain prerequisites, namely, a good penetrating capacity, no injurious effect on the tissue containing the radioactive substance, and moderate staining effect. These qualities must be strictly observed in those instances where the photographic emulsion is applied before staining. Strong dyes and high temperatures are to be avoided, as they often attack the silver grains and artefacts may be produced. Leucobasic fuchsin, methyl green–pyronin, toluidine blue and Leishmann–Giemsa are satisfactory stains for autoradiography (Gude, Upton and Oddl, 1955; Prescott, 1964).

Bergeron (1958) suggested staining of nuclei with basic fuchsin at pH 3.5–4.0 before film development. Frøland (1965) recommended acetic–orcein staining prior to the application of emulsion for human blood cultures. Benge (1960) carried out staining of autoradiographs at low temperatures.

Fussell (1966) described a method for methyl green–pyronin staining of autoradiographs, involving the gradual bringing down to water through ethanol grades of fully processed autoradiographs. Two changes are given in dilute McIlvaine's buffer (1:10) at pH 4.2 for 5 min each, followed by staining for 15 min in a solution containing 80 ml of diluted buffer and 2 ml of 2 per cent aqueous solution of purified methyl green, to which 0.5 g of pyronin is added. The slides are quickly rinsed in two changes of water, blotted and air-dried.

Application of the photographic emulsion

The photographic emulsion can be applied over the section either in the form of a liquid (Belanger and Leblond, 1946; Belanger, 1950) or smear,

or as a film pressed on the material (Pelc, 1956; Taylor, 1956), being composed principally of a fine layer of gelatin, containing numerous silver halide crystals. The formation of radioactive spots is based on the principle of the production of ion pairs due to an electronic event, ultimately manifested in the single grain of black silver. Nuclear emulsion of small grains should not be used because of the possibility of their being washed off during washing. The emulsion should be stored at 4 °C to prevent melting and should be applied at 25–30 °C. Sawicki, Ostrowski and Rowinski (1968) have, however, shown that both storage and exposure of AR-10 films at 18 °C increases overall efficiency. Even though fogging may occur, it does not exceed the safe values of background. Undesirable background effect and artefacts can be avoided if the operation is performed away from the direct illumination of safelight in the dark room. Different types of emulsion with different grain sizes are available in the market. For Kodak, NTB, NTB2, NTB3 denote decreasing grain sizes, with increasing resolution and sensitivity.

Drying

The tissue, after being coated by emulsion, either in liquid form or else as stripped film, must be dried quickly, preferably in a strong current of air in a cold chamber. Quick drying is necessary to prevent the formation of air bubbles within the tissue and also the production of artefacts in the presence of excess moisture.

Exposure

The period of exposure in a cool dark chamber depends on the type of isotope used and its concentration, and is the period required for a specified number of ionised particles to heat a unit area. The time needed for any emulsion can be increased to secure a satisfactory image with a smaller dose —from a few days to even one or two months' continuous exposure may be necessary in certain cases. The relationship between the exposure time and half-life of the isotope has already been discussed. For special techniques, exposure at even −18 °C has been recommended (Sawicki, Ostrowski and Rowinski, 1968).

Photographic process

The photographic process to secure autoradiographs consists of the following steps: development of the latent image, fixation, washing and drying.

Development

The principle of the first step is to develop the latent image in an aqueous solution of a reducing agent in a dark chamber. The widely used developers are hydroquinone and methyl-*p*-aminophenol, which have the property of

reducing the silver halides. The developing solution contains some sulphide salt as well, which helps in the removal of undesirable products, and also potassium bromide, a constituent of the developer, which checks the formation of foggy grains. A number of developers of Kodak and Ilford have been found to be very suitable.

Fixation

The fixation of the intact image involves removal of the silver halide from the emulsion and hardening of the image. It is not possible to wash the silver halide away in water as it is only sparingly soluble; however, it forms a soluble ion complex with the thiosulphate salt, usually of sodium, which is added to remove the silver halide from the solution. In autoradiography the use of an acid-hardener fixing bath becomes necessary for the protection of film or plate; therefore potassium aluminium sulphate (potash alum) or potassium chromium sulphate (chrome alum), which is effective in acid solution, is used in the acid fixing solution, having the added advantage of neutralising any alkaline developer remaining in the solution. The effect of the hardener also prevents swelling and spreading of the gelatin. The authors, however, have noted in the study of chromosomes that a dilute solution of sodium thiosulphate yields quite accurate autoradiographs. The temperature of the chamber should be between 22 and 24 °C, and the humidity should be low. An increase in temperature and humidity causes fading of the image by reaction of metallic silver and sodium thiosulphate.

Washing and drying

Continuous washing in running water is necessary to remove traces of any excess sodium thiosulphate, and a temperature of 15.5–21.0 °C speeds the washing and prevents softening of the emulsion. The slides can then be dried in air or by passing through grades of ethanol, the latter technique being more satisfactory for microscopic work as it does not allow dust particles to accumulate.

Where the experimenter prefers to stain after photographic processing rather than before, the slides can now be stained by the recommended schedules described earlier. Finally the slides may be mounted, the most satisfactory medium being euparal. For observation of unstained slides, mounting can be done either in distilled water or in a special fluid containing 3 g gelatin, 0.2 g chrome alum, 80 ml distilled water and 20 ml glycerol, stored at 4 °C and melted at 50 °C. Messier and Leblond (1957) suggested that, following exposure, the developed emulsion can be protected with a coat of vyrylite and mounted under a cover slip.

SOME IMPORTANT SCHEDULES FOR THE PREPARATION OF AUTORADIOGRAPHS

Method of administration of isotope

For plants

For the study of somatic chromosomes, grow young seedlings of *Vicia faba* in medium containing 2 μCi of ^{32}P (as orthophosphate)/ml in tap water.

Fix young healthy roots at different intervals ranging from two days to one month in acetic–ethanol or chilled 80 per cent ethanol.

For the study of meiosis in plants, 20–75 μCi of ^{32}P in 1 ml of water can be administered (Moses and Taylor, 1955, 1964) on flower buds of *Tradescantia paludosa* or *Rhoeo discolor*, or 4 μCi/ml labelled ^{32}P in White's medium, on inflorescence of *Lilium henryii* (Plaut, 1953).

For the study of proteins in plants, roots can be grown in tap water in which 1 μCi of ^{35}S as Na_2SO_4 is present per ml. The exposure required is at least 70 days. The details of prophase chromosome can be studied (Pelc and Howard, 1956).

For animals

For the study of nucleic acids in mammalian chromosomes, 40 μCi of ^{32}P/g can be injected intraperitoneally in rodents. Similarly, ^{14}C adenine can be injected in the dose of 0.3 μCi/g and the animal can be killed 24 h after injection. Fixation can be made in acetic–ethanol mixture. For salivary gland chromosomes of *Drosophila*, autoradiographs can be prepared after feeding *D. melanogaster* with 20 μCi/ml of ^{14}C adenine for at least 24 h. In other tissues, for the study of proteins for example, intraperitoneal injection of 2 μCi/g of ^{35}S *dl*-methionine can be given. Exposure time may vary from 20 to 70 days. Animal tissues can also be cultured in a medium containing 2 μCi/ml of ^{35}S *dl*-methionine with air exposure time of 14–28 days.

For human material

Human bone marrow cells can be cultured in a medium containing 0.5 μCi/ml of ^{14}C adenine or 1 μCi/ml of ^{32}P (Lajtha, 1952); fixation is performed in methanol. For human peripheral blood culture autoradiograph (Frøland, 1965), preparations can be made following the method of Moorhead and colleagues (1960). Tritiated thymidine (1 μCi/ml) may be added 5–6 h before termination of the culture. Colcemid may also be added 2 h before excising the cells. Air-dried preparations can be made after treatment in hypotonic salt solution and staining the chromosomes with 2 per cent acetic–orcein solution. Slides are then covered with liquid emulsion (Ilford K5) for two days' exposure. Developing is done in Amidol solution for 4 min, followed by fixing in 30 per cent sodium thiosulphate solution for 7 min. Slides are dried in air and mounted in DPX (Frøland, 1965).

For cutting sections or preparing smears, grease-free slides should be used, originally coated with a mixture of photographic gelatin (5 g), chrome alum (0.5 g) and water (1 litre) and dried.

For paraffin blocks, dehydrate by passing through 70 per cent to absolute ethanol grades, followed by ethanol–chloroform grades and the usual process of embedding in paraffin. Cut thin paraffin sections (5 μm thick) and bring the slides down to water after de-paraffinising through xylol by the usual process adopted in microtomy.

For preparing smears, hydrolyse the material in N HCl for 5 min at 60 °C and wash in water.

Slides from both paraffin block and smear schedules are now ready for autoradiography. If staining is desired before applying emulsion, for the former, slides should be hydrolysed for 10–12 min at 60 °C washed in water and stained in leuco-fuchsin solution according to Feulgen procedure; for the latter, the period of hydrolysis is extended by 10 min and the same procedure for Feulgen staining is followed. After staining, the slides are brought to water, passing through 45 per cent acetic acid. Further steps are carried out in a cool dark chamber.

Savage (1962) suggested, for plant materials, squashing in a long subbed cover slip under another rectangular cover in 45 per cent acetic acid, followed by removal of cover slips by dry ice technique. Only the cover slip is to be further processed. Jona (1963) recommended squashing under a scotch-tape which can be removed before applying autoradiographic emulsion.

For coating the slides with emulsion, either of the two following methods can be used.

Coating with liquid emulsion

For emulsion film on glass plate, cut the film with a blade parallel to the four edges at 1.27 cm from the edge. Slowly peel away the emulsion from the glass plate, blowing moist air at the point of bonding; films on 35 mm film-base can also be similarly peeled off. Place the free emulsion strip in distilled water at 18–20 °C, for 10 min, transfer it to a 50 ml beaker on a water bath at 37°C, cover, and allow the emulsion to melt completely without stirring (15 min).

For the bulk emulsions (gels), transfer about 2 ml of the emulsion to a 50 ml beaker with a clean glass spatula.

In both cases, warm the slides and with the warm slide held horizontally between the thumb and the forefinger of one hand, apply two drops of emulsion per square inch of slide from a medicine dropper. Spread the drops quickly with a brush (previously warmed) over an area already outlined by a diamond pencil scratch, rotate the slide from side to side so that the emulsion flows evenly over the area, and keep the slide in the warm condition for 30–60 s for uniform spreading of the emulsion, then transfer to cold temperature for 30 min to harden the emulsion.

The other method, which is more convenient, though requiring more emulsion, is to keep the melted emulsion (melted at 42–45 °C) in a long trough, and dip the subbed slide in it for 4–5 s followed by draining off the emulsion.

Coating with stripping film

For plates, outline with a blade a square area about 3.80 cm^2 on the film. Keep the plate in total darkness for 10 min, then slip the blade under one edge of the outlined square and pull upward slowly. If the humidity is high, stripping becomes difficult, so the plate should first be kept in a desiccator for 10 min. Invert the stripped film and float it, with emulsion downwards, on distilled water at 22–24 °C for 2–3 min. Slip a slide with specimen upwards into the water beneath the floating film and lift the film out on top of the section. Dry in front of a fan at room temperature.

For 35 mm films, cut a piece 3.80 cm long, rub the cut edge and slowly

strip away the film from the film base with thumb and forefinger. The later stages are the same as followed with glass plates.

The slides, when dry, are kept in black boxes containing a desiccant, and are sealed with black tape and kept so that the slides are horizontal. Keep in a refrigerator for a period of one month.

For processing, use dilute Kodak D-19 developer with distilled water (1 : 2) and filter it. Develop the autoradiograph for 2–10 min at 14–20 °C, rinse in distilled water at the same temperature for 30 s, and fix in filtered acid–hardener–fixer at the same temperature until clear. Leave the slides in the fixer for a period equalling half the time taken for clearing, and then wash in running water at 17 °C for 30 min, and dry at room temperature in a dust-free box.

If not done previously, the slides can now be stained, preferably in Feulgen or pyronin–methyl green, in accordance with the usual schedules.

Note: If necessary, in place of ^{32}P, ^{14}C adenine (200 μCi/l) or ^{3}H-labelled thymidine can be used for the study of DNA in chromosome. In the former case, it is necessary to remove the RNA fraction present, by digestion through ribonuclease at 37 °C for 1–2 h (1 mg in 1 ml N/10 NaOH). Distribution of RNA can be studied if ^{14}C-uridine is used as the radioactive substance.

For restaining, after removal of the cover slip with xylene and rehydration, Frøland (1965) suggested treatment in a mixture of iodine (2 g) and potassium iodine (4 g) in 100 ml of water for 1 h to remove silver grains, followed by rinsing in running water and treatment in 30 per cent sodium thiosulphate solution for 30 min. The slides are finally washed in running water before restaining.

For removal of silver grains after taking photographs (carbol fuchsin stained, tritiated human leucocytes), Bianchi, Lima de Faria and Jaworska (1964) recommended that slides should be kept in 7.5 per cent potassium ferricyanide solution for 3 min, followed by keeping in 20 per cent $Na_2S_2O_3.5H_2O$ solution for 3–5 min. The slides should then be washed thoroughly, kept at 37°C for 10 min in 0.2 M Tris buffer (pH 7), water and trypsin mixture (50 ml + 50 ml + 0.19), washed, air dried and observed under Shillaber's immersion oil.

A rapid method for *Drosophila* salivary gland chromosomes has been devised by Mukherjee, A. S. *et al.* (1975), which involves treatment of chromosomes with Scintillation Cocktail Omnifluor toluene mixture, followed by developing the autoradiograph. Best results are obtained within 72 h, involving 24 h dry exposure and 48 h in the fluid.

Liquid emulsion autoradiography for plant, animal and human materials (Prescott, 1964)

In order to study materials fed with labelled amino acids or nucleosides, acetic–ethanol (70–95 per cent) 1 : 3 fixative is recommended. Stock solution of the emulsion should be kept at 22–24 °C. Kodak NTB series is used with different grain sizes. With decrease in grain size, higher resolution and sensitivity are expected. The operations (1) to (5) must be performed in a dark room with a covered safe light (15 W bulb—Wratten Series 1).

Melt the emulsion at 42–45 °C using a constant temperature water bath.

To avoid background effect, it is better to develop a clean dry plate, without any material, as control.

Subbed slide is not necessary if Kodak emulsion is used. Fit two slides with materials back to back and dip in emulsion, kept in a long trough, for 4–5 s. Drain off the emulsion. After separating the slides, dry in racks against a stream of air and keep in slide boxes, sealed with tape, in a cool dark chamber, for the required period of exposure (2–3 weeks).

After exposure, develop the slides in Kodak Dektol, D-11 or D-19 developer for 2 min.

Fix in Kodak Acid-Fixer for 2–5 min.

Rinse in running water for 20 min. Give a final rinse in distilled water and dry.

For staining, three alternative stains are recommended:

(1) 0.25 per cent aqueous solution of toluidine blue (pH 6);
(2) methyl green–pyronin;
(3) Giemsa stain as adopted by Gude, Upton and Oddl (1955).

Wash in 95 per cent ethanol, make air–dry preparations and mount in euparal.

Method for mammalian chromosomes from cultures (Prescott and Bender, 1964) (developed for Chinese hamster fibroblast line CHEF/125 but also applicable to other mammals)

Culture cells in petri dishes and add colchicine (10^{-6M}) a few hours before harvesting.

Decant off the medium and replace it by Hank's phosphate buffered solution.

Replace again by hypotonic saline (10–15 per cent) of Hank's solution, in which the culture may remain even up to 1 h.

After 3–4 min, cells in metaphase are automatically separated from the glass.

Rotate the medium gently so that the cells aggregate in the centre.

Observe under a dissecting microscope and draw out 0.5 μl of medium in a braking pipette.

Withdraw an equal volume of glacial acetic acid in the pipette. As substitute, to minimise loss of material, 0.5 μl of 10 per cent formalin can be taken followed by an equal volume of acetic–ethanol (1 : 3).

After a few seconds, eject the entire contents of the pipette on a slide on which a drop of acetic–ethanol (1 : 3) had been spread a few seconds earlier. Add another drop of acetic–ethanol after a few seconds prior to drying.

Wipe off the excess fluid from the margin and air-dry the preparation.

The remaining procedure is the same as the above method. This technique has several advantages, like the absence of serum protein in the culture; availability of a large number of plates; absence of any cytoplasmic layer between the chromosomes and the emulsion and also of background radioactivity due to clearing the cytoplasm. Moreover, if neutral formalin is used, the loss of chromosomal protein can be checked.

Autoradiography of peripheral blood culture for human chromosomes (Schmid, 1965) (Also applicable to bone marrow and fibroblast cells)

For culture: Allow 10 ml of heparinised blood to stand for 2–3 h at 22–24 °C. Take 2–4 ml of supernatant in a 2 oz flask and make up to 10 ml by adding the medium (McCoy's or Eagle's medium + 20 per cent fetal calf serum). Add 0.1 ml of phytohaemagglutinin M or P.

For continuous labelling of DNA, add ^{3}H-labelled thymidine (1 μCi/ml of medium) 6 h before termination of culture and add colcemid at a final concentration of 0.03 μg/ml. For short pulse labelling, monolayer cultures are necessary, cells need to be centrifuged and colcemid at a concentration of 0.06 μg/ml is needed.

(1) For squash preparations from leucocyte suspension or fibroblasts, detach cells with 0.2 per cent trypsin and centrifuge in 12 ml conical tubes for 4 min at 500 rev/min and pour off the supernatant. Add 10 ml of 1 per cent sodium citrate and leave for 10 min. Re-centrifuge and add 10 ml of 50 per cent acetic acid without disturbing the cell pellet. Decant off the fixative after 20 min and make air-dried smears. If staining is desired, add 2 per cent acetic–orcein and squash. Follow Conger and Fairchild's (1953) dry ice schedule for permanent preparations, treat in absolute ethanol and store the dried slides.
(2) For blood culture, trypsinisation is not necessary and the usual schedule of air-dried preparations can be followed without staining.

In the preparation of autoradiographs, the stripping film coating technique of Kopriwa and Leblond (1962) was followed. All operations should be performed in the dark room in the safelight at 20–22 °C.

(1) Cut 40 × 40 mm squares of AR10 film mounted on glass slides and keep the plate for 3 min in 75 per cent ethanol. Transfer to another tray containing absolute ethanol.
(2) With forceps, lift a single square of film and float, with emulsion side down, in a tray of distilled water, so that the film automatically spreads out.
(3) Bring the glass slides containing the material below the film under water and lift the slides so that the film adheres neatly on the surface of the slide with the material on it. Dry in a stream of air and store in a slide box, sealed with tape, containing silica gel desiccant for the required period in the cold.
(4) Prior to developing, paint the reverse side of the slide, with a paint and dry. Develop with Kodak developer D-196 for 5 min. Treat with the acid fixer as usual, wash and dry. Detach paint and film with a blade and follow the usual procedure for mounting.
(5) For staining, where this has not been performed before, stain with Giemsa (distilled water, 100 ml; 0.1 M citric acid, 3 ml; 0.2 M Na_2HPO_4, 3 ml; methanol and Giemsa stock solution, 5 ml) for 4–7 min. Rinse in distilled water and dry. Detach paint and film and follow the usual procedure for mounting.

PRINCIPAL CONCLUSIONS ON CHROMOSOME STRUCTURE AND METABOLISM ARRIVED AT THROUGH AUTORADIOGRAPHY

This method has been advantageously employed in interpreting the controversial issues regarding the structure and metabolism of chromosomes. This technique, as applied to isolated nuclei, has enabled direct analysis of functional segments (Boyd and Presley, 1973). In this respect, the use of tritium-labelled thymidine, with low energy β-particles has made possible an analysis of the single chromosome and its different loci, and has aided in unravelling the sequence of DNA replication and basic protein metabolism in the macronucleus of *Euplotes* and also the relationship between RNA and DNA metabolism in the 'puff' of salivary gland chromosomes of *Drosophila* and other organisms. The precision of this method has been shown further in the analysis by Levinthal and Thomas (1957) of DNA duplication in single viral particles.

Taylor, Woods and Hughes (1957) have demonstrated clearly, on the basis of their experiments on the uptake of tritiated thymidine by roots, that DNA replication follows the pattern outlined by Watson and Crick (1953). According to the latter authors, the DNA molecule is composed of a double helix, joined by base pairs, and during duplication, each strand serves as a template for the synthesis of a sister strand so that the new molecule, after duplication, is composed of an old and a new strand. Taylor, Woods and Hughes (1957) showed that both chromatids in the first generation of treated cells in metaphase exhibited equal labelling, in the second generation only one of the chromatids was found to be labelled, and in subsequent generations there was an equational decrease in the number of labelled chromatids. Evidently the findings confirm the replication of the double helix as suggested by Watson and Crick (1953). Though this observation has been questioned on technical grounds by La Cour and Pelc (1958), and on unequal labelling of chromosomes by Mazia and Plaut (1956), yet other experimental approaches support the conclusions of Taylor, Woods and Hughes (1957), Taylor (1952, 1968) and the semiconservative replication of DNA has been established.

Evidence of the differential nature of euchromatin and heterochromatin has been secured with the application of autoradiography. Lima de Faria (1959) investigated the uptake of tritium-labelled thymidine in the heterochromatic and euchromatic chromosome segments in *Melanopus* and *Secale* and the data show that heterochromatin synthesises DNA later than euchromatin. The functional differences of even the two types of heterochromatin namely α and β have also been claimed (*see* Wolf, 1969). The results may be taken to imply the specialised nature of heterochromatic segments as suggested by other cytological data as well (*see* Sharma and Sharma, 1958; Brown, 1966).

That DNA synthesis takes place in the interphase has been clearly elucidated through autoradiographic studies involving tritiated thymidine incorporation (for review, *see* Taylor, 1968). The categorisation of the interphase into two growth phases, G_1 and G_2, intercalated by the DNA synthetic 'S' phase has been made possible largely through such incorporation studies.

The study of chromosome structure has also been greatly facilitated through the use of labelled halogenated unusual nucleosides like FUDR and BUDR. Autoradiographs of chromosomes, following their incorporation, have not only demonstrated decisively that DNA forms the fundamental skeleton of chromosomes but at the same time it has adduced evidence that change or breakage of the DNA molecule may ultimately result in gene mutation or chromosome breakage.

The elucidation of the functional aspects of chromosomes has been the most outstanding contribution of autoradiography in recent years. The very dynamicity of the chromosomes during different stages of development and differentiation has been well illustrated in the autoradiographs of the puffing patterns in dipteran salivary gland chromosomes (Beermann, 1972; Keyl and Hagele, 1966; Pelling, 1964; Swift, 1964). The amounts of RNA and proteins associated with chromosomes have been shown to be variable in different stages of development (Busch, 1965; Busch *et al.*, 1964; Edström, 1964; cf. Coleman and Moses, 1964; Plaut and Nash, 1964; Swift, 1964). But later works showing DNA puffs in Sciarideae and variable replication of nucleolar organiser in amphibia (Miller, 1966; Peacock, 1979) have indicated that even the DNA and histone of chromosomes may vary within an organism. The identification of the nature of metabolic DNA, which is synthesised in excess or independently of chromosome duplication, as termed by Pavan (1965) and Pavan and Da Cunha (1968, 1969), was principally due to this method.

An understanding of the DNA replication pattern of the sex chromosomes of mammals (Evans *et al.*, 1965; Lyon, 1963; Monesi, 1965; Mukherjee, B. B. *et al.*, 1957, 1969; Schmid, 1963) and diptera (Berendes, 1965; Mukherjee, A. S. *et al.*, 1968, 1969; Müller and Kaplan, 1966) has been gained through advances in this incorporation technique. The studies by Mukherjee, B. B. and his colleagues (1957, 1969) confirmed the existing concept of the differential rate of late replication of sex chromosome DNA at the synthetic phase. But at the post-implantation stage, their findings further imply that though the pattern of sex chromosome replication varies in different spermatogonia, yet in the spermatocyte, the replication is either earlier or synchronous with the autosomes.

Mukherjee, A. S. and his colleagues (1968, 1969), on the other hand, working on the problem of dosage compensation, have shown that in *Drosophila*, the single X-chromosome in the salivary gland of the male fly, compensates, by its transcriptive activity and enlargement in size, the functions performed by the X-chromosome in the female. But, they have also recorded that the pattern of transcription of the X-chromosomes, in both sexes of two species of *Drosophila*, having different X-chromosome constitutions, is nearly identical.

In the field of differentiation of plant organs, application of autoradiography is gaining importance. The application of photometric principle in the quantitation of autoradiographs is also yielding data on chromosome metabolism (Boren, Wright and Harvus, 1974). In our own laboratory, in the nuclei of mature organs, which have been induced to divide through hormone treatment, the presence of both diploid and polytenic nuclei has been recorded. As gene action, dependent on transciption, has now been shown to be independent of replication, the existence of polyteny raises interesting speculations. A comparative study of the RNA synthesising

activity of the diploid and polytenic strands in the nuclei of mature organs through autoradiography may indicate the *modus operandi* of one aspect of the genetic control of differentiation in higher plants.

In the analysis of chromosome nucleolus relationship, autoradiographic techniques have been of special use. On these studies, it has been claimed that RNA is synthesised independently of the general chromatin in the nucleolus during interphase, even though some of its components might have been ultimately derived from the multiple chromosomal centres at the end of telophase (Brinkley, 1965; Das, 1963; Hsu, Arrighi and Klevecz, 1965; Hay, 1969; La Fontaine, 1969; La Fontaine and Lord, 1966; *see* Perry, 1965, and Prescott and Bender, 1962). Bernhard (1966) and Bernhard and Granboulan (1969) have elucidated, to some extent, the metabolic pathway involving nucleus, nucleolus and cytoplasm. Significantly, the presence of a considerable amount of intranucleolar DNA, in contact with the nucleolus-associated chromatin, has been indicated (Franke *et al.*, 1979). Active incorporation of tritiated thymidine in the nucleolar DNA of vertebrates has been secured.

In the field of molecular hybridisation, at the chromosomal level, as done extensively by Gall, Pardue and others, the incorporation method has thrown considerable light on the loci of differential gene action.

In summing up, the most significant contribution of autoradiography in recent years may be claimed to be the elucidation of the dynamicity of the structure and behaviour of chromosomes (Gay, 1966; Kaufmann, Gay and McDonald, 1960; Sharma, 1978), necessary for controlling differentiation in different phases of development and growth in higher organisms.

ELECTRON MICROSCOPY

The introduction of electron microscopy in the study of ultrastructure has helped to clarify chromosome structure at the submicroscopic level. The high magnification attained, coupled with good fixation and proper preservation of components *in vivo*, has resolved the inner details of chromosome and other cellular components. As the wave properties of the electron and the focusing properties of the magnetic field were recognised, it became possible to design an electron microscope, in pattern with the light microscope. Light

microscopes are generally designed with suitably shaped surfaces of solid media, abruptly reflecting or refracting the light rays. In electron microscopes, electrical or magnetic fields are adequately shaped to refract electrons, producing the desired image. The transformation of the electron image to a visible light image is effected on the fluorescent screen. The limit of resolution of a good electron microscope is at present nearly 0.3 nm and until now very good resolution of biological macromolecules of 0.5–1.0 nm has been achieved. The basic constituents of the electron microscope are assembled in a vertical column. They are: an illuminating system, a specimen chamber, an objective lens, intermediate and projecting lenses, and a viewing chamber with facilities for photographing electron images. In the entire column, vacuum is maintained by oil and mercury diffusion pumps, at specific pressure. The source of the electron providing the illuminating system is generally constructed from a hot tungsten filament, serving as a cathode, and an anode with a surrounding Wehnelt cylinder, provided with a hole for the passage of the electron beam. The resultant image is detected either on a fluorescent screen or on a photographic plate. The majority of electron microscopes have a specimen holder with a cap for fitting the specimen screen. Magnification is dependent on the proximity of the objective lens to the specimen, thus the orientation should be carefully controlled. In short, to the microscope, which lies in a vacuum, a cathode filament supplies the source of electrons forming the illuminating system, the electrons being focused on the material by an electromagnetic condenser lens. Similarly, electromagnetic objective lenses collect the electrons from the materials and form a magnified image. Through further electromagnetic projection by the eyepiece, the specimen is magnified and projected on to a fluorescent screen, the magnification being controlled by manipulating the current in the projector lens, and focusing by varying the magnetic field of the objective lens. For details of instrumentation and the working of the microscopes, such as, RCA-EMU, Philips EM, HITACHI, Siemens ELMISCOP, Zeiss EM, JEOL JEM, AEI Corinth, BENDIX-AKASHI, etc., the reader is referred to Agar, Alderson and Chescoe (1974), Meek (1976). The electron microscopes are operated at conventional accelerating voltages up to 100 kV. Modifications in the operating method have also been devised so that there has been a reduction in the specimen contamination rate, an increase in the life of the filament as well as a decrease in the load on the condenser lens stabiliser (Meek, 1976). Better reproduction of photographic exposures and strong contrast micrographs have been achieved. In principle, contrast signifies the difference in electron scattering power between the object studied and its surrounding medium.

To allow the passage of electrons ejected from a source or their penetration, and for good resolution of the object, ultra-thin sectioning (not thinner than 100 nm) in ultramicrotome is essential. The method devised for cutting such fine sections has helped the use of electron microscopy for the clarification of cytological details, the fine structure being preserved with as little change as possible. For the preparation of materials to be observed under the electron microscope, the following steps should be adopted under strictly controlled conditions: (a) fixation, (b) dehydration, (c) embedding, (d) sectioning and (e) mounting. The advantages and limitations of the different steps are now considered.

FIXATION

Low temperature fixation

With low temperature fixation, the life-like preservation of cells is maintained because of the absence of any chemical compounds used in fixation. Frozen materials, after proper dehydration, either by sublimation of ice as in freeze-drying, or by substitution with organic solvents as in freeze-substitution, have decided advantages in electron microscopy. Cryogenic gases have a boiling point greatly below $-100\,^{\circ}C$ ($-148\,^{\circ}F$) and include nitrogen, oxygen, argon, neon, krypton, xenon, helium, hydrogen, methane, fluorine as well as ethylene. Certain workers prefer rapid freezing with the use of certain cryogenic gases, like helium, while others are of the opinion that slow freezing, with the use of compounds like glycerol, ethylene glycol, propylene glycol, etc., protecting against ice crystal formation, is preferable (*see* Burstone, 1969). Following freezing, the freeze-drying procedure, which includes dehydration from the frozen state in the beginning, involving sublimation of ice *in vacuo*, is generally carried out at -30 to $-40\,^{\circ}C$. After several days of drying in the cold, the temperature of the material is gradually raised and maintained under vacuum for several hours and finally the ice is allowed to sublimate on its surface. Embedding can be done in vacuum or outside, but with precautions against the absorption of moisture from the air.

In order to eliminate chemical reactions resulting from the use of fixatives, Sjöstrand and Baker (1958) employed the freeze-drying method of fixation ($-72\,^{\circ}C$ dry ice temperature seems sufficient). The specimen is dipped in ethyl ether (pre-cooled with dry ice and ethanol mixture), and later the frozen tissue is transferred to a pre-cooled container which should afterwards be evacuated. Freeze-dried tissue presents difficulties in infiltration with a plastic monomer, and in order to avoid damage to the tissue during polymerisation, it is generally done in a vacuum. Some segments of the freeze-dried tissue often show signs of denaturation if the materials are not properly dehydrated. Refrigeration systems for cryostat and freeze-drying equipments have also been developed (*see* Burstone, 1969; Koehler, 1978).

Freeze substitution technique, in which the effects of freezing are separated from those of vacuum drying, involves the substitution of a fluid in the tissue in place of complete vacuum dehydration. This method allows better preservation than freeze-drying. Freeze-drying technique, without the use of chemical fixatives, can no doubt keep the tissue structure intact up to a certain limit (Pease, 1966), but freeze substitution by fixation may often be necessary for better representation of the cellular structure. Fluids used in freeze substitution are methyl cellosolve, ethanol, diethyl ether, chloroform, butanol, iso-amyl alcohol, isopentane, isobutane, propane, propylene (Rebhun, 1965; Burstone, 1969); acetone and ethanol–acetone, the last two showing the most rapid dehydrating action, the temperature being maintained between -38 to $-78\,^{\circ}C$ during dehydration.

Fernandez-Moran (1962) used freeze-substitution to replace fixation. In this method, the tissue can be directly dehydrated and infiltrated with an embedding medium at a low temperature, through cold baths and boxes, and does not require a pumping system, as is needed for freeze-drying. The

operation may be carried out at −130 to −180 °C, and for freezing, isopentane, Freone 22 chilled with liquid nitrogen or helium can be used. Methyl cellosolve can be employed as a substitute for tissue water and glycerol and finally, methacrylate can be used for infiltration. Infiltration is carried out with methacrylate below −75 °C, followed by ultraviolet polymerisation at −20 °C. This procedure is supplemented by a cooling specimen support (−10 to −120 °C), with a modified liquid nitrogen stage for observation under an electron microbeam of low intensity. Persijn, De Vries and Daems (1964), used liquid air instead of mechanical cooling up to about −130 °C. Bullivant (1965) adopted a schedule in which mouse pancreas was infiltrated with glycerol (3–60 per cent) in isotonic veronal acetate buffer (pH 7.2), followed by freezing in liquid propane cooled by liquid nitrogen. The material was then transferred at −75 °C in dried ethanol to a refrigerator. Further substitution was carried out after three changes of ethanol at this temperature, during a period of three weeks, followed by embedding through butyl methyl methacrylate and 1 per cent Lucidol. Durcupan (Stäubli, 1960) and Epon mixture (Luft, 1961) were also tried. Polymerisation was effected with ultraviolet at −20 °C.

Afzelius (1962) recommended acrolein as the substitution fluid at low temperature. Since formalin forms a solid polymer in the cold its use in substitution fluid is limited. Anhydrous OsO_4 vapour has been suggested for freeze-drying techniques. Feder and Sidman (1958) and Fernandez-Moran (1961) proposed 1 per cent OsO_4 solution in acetone as the substitution fluid at −40 to −70 °C. Pease (1964) recommended polymerisation in ultraviolet at −72 °C for freeze-substituted materials. Cope (1968) devised a technique for fixation and embedding at −20 °C, after treatment with an antifreeze designed to prevent ice crystal formation at 0 °C. A mixture of 50 per cent v/v of dimethylsulphoxide (DMSO) mixed with glycerol or ethylene glycol serves as the anti-freeze. In this method, tissue fixation is performed with 5 per cent glutaraldehyde in 50 per cent anti-freeze solution for 6–8 h at −20 °C, followed by dehydration in 2-hydroxy-ethyl-methacrylate. Final embedding is done in a mixture of 70 per cent dihydroxy-ethyl-methacrylate and 30 per cent *n*-butyl methacrylate or styrene. Polymerisation is carried out with the aid of ultraviolet rays at −10 °C.

Freeze-drying and freeze-substitution techniques are generally recommended for the study of enzyme localisation and activity and are not applied directly to the analysis of chromosome structure. But the potentiality of their use in chromosome study cannot be ignored, especially in research involving the distribution of enzymes, such as alkaline phosphatase in chromosomes.

With chemical fixatives

A proper fixative should provide the natural milieu of a living system, especially with regard to pH, osmolarity and ionic concentration. This is necessary to prevent swelling, shrinkage or extraction of the material. Proper choice of a buffer in vehicle is also an important factor, since, excepting phosphates, nearly all other buffers so far used may exert some toxic effects on the tissue. The osmolarity is normally adjusted by changing the buffer

concentration or by addition of sodium chloride, polyvinyl pyrilidone glucose, sucrose and such other non-ionic compounds. The method of fixation for chromosome analysis is immersion in the fluid, though perfusion or injection is also applied for various tissues. Another procedure involves vapour fixation for monolayers of cells. Centrifuged pellets of cells can also be fixed and handled by encapsulating in a 2 per cent agar block.

The chemical fixative consists of a fixing agent and a vehicle which is normally a buffer solution, with salts. The osmolar concentration of the solvent is of special importance (Maunsbach, 1966). Of all the metallic fixatives so far tried, osmium tetroxide (OsO_4) is the most widely used, and the buffered OsO_4 solution, with added calcium in certain cases (*see* Fawcett, 1964) is considered the most adequate one. The addition of Ca^{++} ions checks the extraction of several constituents and maintains structures like spindle fibres intact. That osmium fixatives preserve the cell structure intact, to some extent, is observed by the direct correlation between the spacing of certain structures obtained by birefringence and x-ray on the one hand, and the electron micrograph on the other. As osmium tetroxide is a stain for phospholipides, a sharp contrast is often obtained in osmium-fixed material, but as this contrast imparts brighter staining to non-DNA containing materials, it should be used cautiously in the study of chromosomes. For best results in chromosome preparations with osmium tetroxide as the fixative, both potassium dichromate solution (3 per cent) and lanthanum nitrate solution (2 per cent) are applied in conjunction with 2 per cent osmium tetroxide solution—the lanthanum salt helps in the preservation of nuclear structures. Several workers have tried osmium tetroxide fixation, buffered from pH 4 to 7, and have obtained very satisfactory results. Afzelius (1962) reported that liquid osmium at 4 °C as well as a solution of osmium in 40 per cent carbon tetrachloride, gives good fixation.

The serious drawbacks of osmium fixation are its slow rate of penetration, reduction of enzyme activity (Holt and Hicks, 1962), and its non-reaction with carbohydrates and nucleic acids (Bahr, 1954). Its slow penetration may allow changes to occur during fixation. In cytochemical procedures, the main limitation of OsO_4 fixation lies in its capacity to render the protein impervious to proteinase digestion (Leduc and Bernhard, 1962). Swift (1962) pointed out that osmium fixation causes the protein to become basophilic by combining with amino groups—a drawback which should be avoided. It has been observed that the best contrast with osmium fluid can be obtained if it is used as a post-fixation fluid, after glutaraldehyde. Treatment with osmium fluid may vary from 10 min to 4 h (Sjöstrand, 1969) and a brief washing in isotonic salt solution is always desirable. The following osmium fixatives with buffers have been recommended by Sjöstrand for mammalian tissues.

(1) According to Zetterqvist (1956):

Stock solution A

Sodium acetate	9.714 g
Veronal acetate	14.714 g
Distilled water to make	500 ml

Stock solution B

Sodium chloride	40.25 g
Potassium chloride	2.1 g
Calcium chloride	0.9 g
Distilled water to make	500 ml

Hydrochloric acid 0.1 N

The solutions are mixed in the following proportions:

(a) For mammalian tissue: Solution A, 10 ml; solution B, 3.4 ml; 0.1 N HCl, 11 ml.
(b) For frog tissue: Solution A, 7.4 ml; solution B, 2.6 ml; 0.1 N HCl, 8.1 ml.

Distilled water is added to make 50 ml and the pH adjusted to between 7.2–7.4 by adding 0.1 N HCl. Then 0.5 g osmium tetroxide is added to the mixture and stored in the cold in a brown, glass-stoppered bottle.

(2) According to Millonig (1962):

Solution A

2.26 per cent dibasic sodium phosphate soln.

Solution B

2.52 per cent sodium hydroxide soln.

Solution C

5.4 per cent glucose

Solution D

41.5 ml of solution A + 8.5 ml of solution B.

A mixture is prepared with 45 ml solution D, 5 ml solution C, and 0.5 g osmium tetroxide and the pH corrected to 7.3–7.6.

Several other phosphate and veronal acetate buffers are also in use (*see* Glauert, 1975).

Alternatively, formaldehyde may be used as a fixative (Pease, 1962). Solution C is replaced by a new solution C_{form}, containing 40 per cent formaldehyde and 5.4 per cent glucose. Of this solution, 5 ml is mixed with 45 ml solution D and the pH corrected to 7.3–7.6.

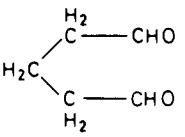
Of the non-metallic fixatives, formaldehyde is used to a certain extent (Baker and McCrae, 1966). The effects of concentration, duration of treatment, as well as temperature, on its action, have all been worked out in detail. Formalin does not have any damaging effect on polymerisation (Swift, 1962). The rapidity of fixation and maintenance of enzyme activity, even after a long period of fixation, are special advantages of formalin fixation. Holt and Hicks (1962) further noted that formalin-fixed materials not only offer resistance to the effect of cold solvents but even allow strong binding with the dye. Formaldehyde vapour is used as a fixative also in freeze-drying (Falck and Owman, 1965). Ris (1962) observed that neutral fixatives containing osmium tetroxide or formalin preserve the distribution of cellular structures.

Leduc and Bernhard (1962) recommended formalin fixation for specific extraction of nucleic acids and proteins and suggested fixation in 10 per cent formaldehyde buffered at pH 7.3 with Michaelis veronal acetate, or with Sörensen's phosphate at −3 °C. Sjöstrand (1969) confirmed Millonig's (1962) observation that phosphate buffer is a good medium for formaldehyde. Pearse (1972), however, stated that formalin should not be used as a fixative

for nucleic acids or nucleoproteins as it blocks a large number of reactive groups, hampering stainability with both acidic and basic dyes. Afzelius (1962) also recorded that formaldehyde-fixed structure is often damaged by electron beams, especially in methacrylate-embedded material, which can be overcome by using other embedding materials like Epon.

In the majority of cases, aldehyde fixation yields very good results if the materials are post-fixed with osmium tetroxide, and stained in a saturated solution of uranyl acetate which may serve even as a fixative (Lewis, Knight and Williams, 1974; Glauert, 1975). The presence of the heavy metal allows better contrast and sharper staining and, as such, this procedure is often recommended for ultrastructural studies (Fawcett, 1964; Sjöstrand, 1969).

An aldehyde with wide use in electron microscopy is glutaraldehyde, or more precisely, glutaric di-aldehyde, $(CH_2)_3\ CHO_2$, with the formula



It was first introduced as a cytochemical fixative by Sabatini, Bensch and Barrnett (1963). Its bifunctional nature, having the property of forming cross linkage, was worked out by Bowes (1963). The commercially available forms of glutaraldehyde are obtained as 25 per cent or 50 per cent solution in water. The monomeric glutaraldehyde is the principal reactive compound (Gillett and Gull, 1972; Korn, Feairheller and Filachiare, 1972) but the commercial forms contain polymers as impurities. It is often necessary to purify by charcoal or distillation. Charcoal purification is performed by shaking a 25 per cent solution of glutaraldehyde with 10 per cent (w/v) activated charcoal at 4 °C for 1 h before filtration. It is desirable to repeat the procedure several times till a typical absorption at 280 nm is obtained. The solution can be stored at 4 °C or −20 °C for a long period. Vacuum distilled glutaraldehyde is commercially available. However, even with re-distilled glutaraldehyde, it is claimed that a network is formed in the nuclear sap and birefringence is lost (Skaer and Whytock, 1976).

In glutaraldehyde fixatives, pH should be kept below 7.5 to check polymerisation. As with aldehyde fixatives in general, phosphate buffer is always preferable. A method of preparation of a glutaraldehyde fixative (final concentration of glutaraldehyde—2 per cent) is outlined below (Glauert, 1975a).

2.26 per cent NaH_2PO_4. H_2O in water	64 ml
25 per cent glutaraldehyde in water	8 ml
2.52 per cent NaOH in water for adjusting pH	required amount
Distilled water to make 100 ml	

For immersion fixation, the most suitable method is to take the tissue in a drop of fixative on a sheet of dental wax, cut into small pieces of required size with a blade, and transfer with the aid of pipette or tweezers to small glass vials containing the fixative (Glauert, 1975a). As with formaldehyde, this compound, if post-fixed with buffered osmium fluids, yields very good results without any deleterious effect on staining. The advantage of glutaraldehyde as a primary fixative is that it reacts rapidly with proteins and stabilises their structure

through crosslinking, thus preventing extraction by buffer (Hayat, 1970). It is assumed to have an osmotic effect (Bone and Ryan, 1972). The advantage of double fixation is that large blocks can be fixed in primary fixative and then suitable pieces may be selected and fixed in the secondary fixative with osmium. In the case of perfusion fixation of brain, kidney, etc., fixation for approximately 5 min is recommended prior to transfer to osmium fluid. Several formulae for fixatives containing glutaraldehyde (Maunsbach, 1966) have been presented by Sjöstrand (1969). They are now widely used in chromosome analysis.

Acrolein, otherwise known as 2-propenal or acrylic aldehyde, is another bifunctional aldehyde having the capacity of forming crosslinks between end-groups of proteins (Bowes, 1963; Cater, 1963). Under laboratory conditions, it is generally prepared by heating a mixture of anhydrous glycerol, acid potassium sulphate, and potassium sulphate, in the presence of a small amount of hydroquinone, followed by distillation in the dark. Acrolein, having the formula CH_2CHCHO (mol. wt. 56.06) is unstable at alkaline pH and polymerises, especially under light, forming a plastic solid (disacryl). The commercial form is liquid and by distillation the polymerised material can be removed (Carstensen *et al.*, 1971). The fixative is usually prepared by 10 per cent acrolein in 0.025 or 0.05 M phosphate buffer (Glauert, 1975a). Watson and Aldridge (1961) used it as a fixative for ultrastructural studies, in which potentially reactive groups other than nucleic acids, are blocked by acetylation. As acrolein is a non-metallic fixative, similar to formalin, the chance of damage due to polymerisation is not significant. Bowes (1963) noted that crosslinks produced by acrolein and glutaraldehyde are more resistant to boiling water and acid hydrolysis than formaldehyde. Afzelius (1962) studied fixation of liver tissue in 10 per cent acrolein followed by post-fixation in osmium fluid. Swift (1962) suggested fixation in 10 per cent acrolein in phosphate or tris buffer, with a post-fixation treatment in 1 per cent osmium tetroxide, buffered at pH 7.6, for 2 h. In general, the use of acrolein is gaining importance in studies on ultrastructure.

Ethanol and acetone, in spite of their fixing properties, are not generally used for electron microscopic studies because of their disturbing effect on the morphology of tissue structures, particularly chromatin shrinkage (Ris, 1962). Moreover, Leduc and Bernhard (1962), in relation to their work on the nucleolus, noted that interchromatinic substances are not properly preserved after ethanol fixation.

Another chemical used in electron microscopic techniques is potassium permanganate, and Luft (1956) suggested that the fixing property is due to permanganate and not to potassium. A serious limitation of this fixative is the presence of black granules in the background which have been attributed to the formation of manganese dioxide granules formed by the decomposition of the permanganate ions. Feder and Sidman (1958) recommended permanganate in acetone as a fixative. Afzelius (1962) observed that different cations differ with regard to the preservation of different structures and calcium permanganate shows a greater lipid stabilising activity than potassium permanganate. In chromosome fixation, potassium permanganate has not proved to be of much use.

DEHYDRATION

Removal of water is usually performed through a sequence of solutions of ethanol or acetone. For embedding in polyester resins, the dehydration is to be carried out in acetone. As an intermediate solvent styrene has also been used (Kurtz, 1961). For embedding in epoxy resins, dehydration is possible both through ethanol or acetone. As these resins react well with propylene oxide (1,2-epoxy propane) too, the latter is often used at the last stage of dehydration. The procedure involves the dehydration of the materials for 10 min each in ethanol or acetone in water (50, 70, 95 per cent) followed by two changes in absolute ethanol or acetone for 15 min each. The specimens are then to be passed twice through propylene oxide for 15 min each before embedding in epoxy resin. It is better to dehydrate at 0 °C throughout, at least during the last phase of dehydration.

Propylene oxide can also be used as the dehydrating agent itself specially for Epon embedding (Kushida, 1961). In that case, the materials are to be dehydrated through aqueous solutions of propylene oxide (20, 40 per cent, 10–15 min each), increasing concentrations of propylene oxide and epon (70, 90, 100 per cent, 1:1, 1:1, 1:1 with epon, 10–15 min each) and finally two changes of pure epon (30 min each). All the steps are to be carried at 24–26 °C except the two changes of epon at 40 °C. To prepare an aqueous mixture of propylene oxide, 2.5 per cent ethanol may be added (Spurr, 1969). Rapid dehydration with small materials can be carried out by passing through ethanol series to absolute ethanol, 2 min each with constant agitation, three changes in absolute ethanol 1 min each, and three changes in propylene oxide at 3 min intervals (Coulter, 1967).

Ethylene glycol is also one of the dehydrating agents for later embedding in epoxy or polyester resins (Pease, 1973). But the tissue shrinkage is one of the serious limitations. Polyethylene glycol 200 with increasing concentration in water has also been utilised for embedding in both epoxy (Kushida, 1963) and epoxy resins (Kushida and Fujita, 1970). In the latter case, methyl methacrylate serves as an intermediate agent. The entire process of dehydration is to be carried out in small vials containing the fixed materials.

EMBEDDING

The principal criteria in the choice of embedding media are its stability in the electron beam, uniform polymerising capacity, convenience in sectioning, low viscosity in the monomer form and solubility in the dehydrating agent, of the three types of embedding media normally employed, i.e. epoxy resins, polyester resins and methacrylates, the former is the most widely used because it generally satisfies all the above conditions. With epoxy monomers, there is extraction of lipid to some extent (Stein and Stein, 1971). Polyester resins suffer from the limitation that some of the components are not stable during storage. With methacrylates, the disadvantage is its non-uniform polymerisation and instability and sublimation against electron bombardment under certain conditions. However, water soluble methacrylates are comparatively more suitable (Glauert, 1975a). A mixture of a butyl and methyl metha-

crylates are often suitable (Newman, Borysko and Swerdlow, 1949).

The embedding medium also contains an accelerator or activator for infiltration which is always freshly prepared. Though final embedding is carried out in polyethylene or gelatin capsules, the intermediate steps for the complete removal of the dehydrating agent are carried out through a sequence of solutions in the glass vials containing the fixed material. These intermediate solutions are normally different for different embedding media. These solutions are removed and replaced with the aid of a pipette and finally with pure embedding medium, the vials are kept overnight with lid open to accelerate evaporation of the dehydrating fluid. For rapid infiltration, vials are often kept in rotary mixers (Kushida, 1969), or continuous stream of nitrogen bubbles for methacrylates, styrene or polyester resins and dehydrated air for epoxy resins are circulated round the specimens (Kushida and Fujita, 1971). For methacrylates and epoxy resins, oxygen is not used as it hampers polymerisation.

For final embedding, gelatin or polyethylene (BEEM or TAAB) capsules are available of different sizes to suit the blocks of proper size. The ends of these blocks are shaped like a pyramid so that very little trimming is needed (Reid, 1974). The completely dried capsules are kept for a minimum period of overnight at 60 °C oven before use and these are kept in rows against a support with proper sized holes to fit the capsules. The capsules are half filled with final embedding medium and the specimens are gently transferred to the bottom of the capsules. It is necessary to insert the label with number, etc. inside the capsule in such a way so that the number can be read from outside. Polymerisation of the embedding medium is carried out at varied temperatures or through the use of ultraviolet lamps. The temperatures may be 4, 30 or 42 °C in a specially designed apparatus (Cole, 1968) kept in a freezer (−16 °C) or 27 or 36 °C as well. Ordinary sun lamps may be used as ultraviolet sources.

Epoxy resins

All epoxy resins chemically are polyaryl ethers of glycerol with terminal epoxy groups. Their viscosity may be different from one another and they are polymerised by bifunctional agents which criss-cross the epoxy groups forming ultimately a three-dimensional structure. The common epoxy resins are Araldites (CY212, 502, 6005, CIBA 506) and Epons (812, 815 Shell) which may be used separately or mixed together. In addition, other epoxy resins are Epon 533 (Low viscosity, Oekn Shoji), Maraglas 655 (Marblett), DER 332 (pure epoxide, Dow) and ERL 4206 (vinyl cyclohexane dioxide, Union Carbide). The epoxy resin embedding media arranged in order of high to low viscosity (cps at 25 °C) are: Araldite 502 (3000), Araldite CY212 (1300–1650), DER 334 (500–700), Maraglas 655 (500), Epon 812 (150–210) and ERL 4206 (7.8) (Glauert, 1975a,b).

All epoxy resin embedding media have in addition to the resin, a hardener and an accelerator. The hardeners of the block are often softened by the addition of additives, plasticisers or flexibilisers. The infiltration time needed is directly proportional to the viscosity of the medium.

The common hardeners differing in viscosity from one another available

in the market are: (a) dodecyl succinic anhydride (DDSA—290 cps at 25 °C), (b) hexahydrophthalic anhydride (HHPA, m.p. 35 °C), (c) methyl nadic anhydride or nadic methyl anhydride (MWA or NMA—175–275 cps at 25 °C), and (d) nonenyl succinic anhydride (NSA—117 cps at 25 °C). The common accelerators are: (a) 2,4,6-tridimethyl amino methyl phenol (DMP 30), (b) benzyldimethyl amine (BDMA) and (c) dimethylamino ethanol (DMAE). The additives generally used are: (a) dibutyl phthalate—plasticiser (DBP), (b) carbowax 200 (polyethylene glycol 200), (c) triallylcyanurate (TAC), (d) polyglycol diepoxide—flexibiliser (DER 732, Dow), (e) diglycidyl ether of propylene glycol (DER 736, Dow), (f) long chain mono-epoxide, flexibiliser (Cardolite NC 513) and (g) polythiodithiol—liquid polymer of low viscosity, flexibiliser (Thiokot LP 8).

Some of the common epoxy embedding mixtures are listed below.

Epon (glycerol based aliphatic epoxy resin)

(1) Epon (812)—10 ml, DDSA—8 ml, BDMA 1 per cent (Finex, 1960).
(2) Epon (812)—10 ml, HHPA—1 ml, MNA—8.5 ml, DMP 30—0.15/0.3 ml. Thiokol. LP8 hardening takes about 4–7 days—1.5/3.0 ml (embedding at 26 °C on room temperature) (Kushida, 1966).
(3) Epon (812)—10 ml, NSA—13 ml, DMP 30—1.5/2 per cent (Kushida and Fujita, 1971).
(4) Epon (812) and (815) (ratio determining hardness)–10 ml, DDSA—14–16 ml, DMP 30 or BDMA—2 ml (Kushida, 1960; Shinagawa, Yahara and Uchida, 1962).

In the method evolved by Luft (1961) for epon embedding, the materials used were: Epon 812 from the Shell Chemical Corporation, San Francisco; dodecenyl succinic anhydride (DDSA) and methyl nadic anhydride (MNA) from the National Aniline Division of the Allied Chemical and Dye Corporation, New York, and trimethyl amino methyl phenol (DMP-30 accelerator) from Rohm and Haas, Philadelphia. Two mixtures were prepared, namely, (a) Mixture A containing epon 812, 62 ml and DDSA 100 ml, (b) Mixture B containing epon 812, 100 ml and MNA 89 ml. The former gives soft blocks and the latter hard ones, and they are mixed in different proportions depending upon the degree of hardness required, a proportion of A : B = 2 : 1 being recommended for general use. The two mixtures are stored separately in the cold; 1.5 per cent v/v of accelerator (DMP-30) is added and A, B and DMP-30 are mixed very thoroughly just before use.

According to Luft (1961), preparation of the mixture is the most crucial factor. Measuring out the mixture in a 10–15 ml conical graduated tube and continuous stirring for 5 min are recommended. After mixing A and B, DMP-30 should be taken in a tuberculin syringe with a long, large-bore needle and then added to the above mixture in the required quantities. Propylene oxide can be handled in a similar syringe. In a modified schedule of Porter (1964), instead of a three-stage incubation programme, vacuum incubation at 60 °C is carried out for 24–36 h, during which time the excess propylene oxide is also evaporated off.

Araldite (aromatic epoxy resin)

(1) Araldite CY 212—10 ml, DDSA—10 ml, BDMA—0.4 ml (Parker, 1972) referred in Glauert, 1975.
(2) Araldite (502)—10 ml, DDSA—7.8 ml, DMP 30—1.5 per cent (Coulter, 1967).

Araldite and Epon

Araldite (506)—81 ml + Epon (812)—62 ml, DDSA—100 ml, DMP (30)—1.5 per cent or BDMA 3 per cent, DBP—4–7 ml (Mollenhauer, 1964).

Epon

Epon (533)—10 ml, MNA—8.6 ml, DMP 30—1.5/2.0 per cent, Carbowax 200 0–2 per cent (Kushida, 1962, 1963).

Maraglas

(1) Maraglas (655)—36 ml, BDMA—1 ml, DER (732)—8 ml + DBP—5 ml (Erlandson, 1964).
(2) Maraglas (655)—48 ml, DMP (30)—2 ml, Cardulite—NC (513)—40 ml + TAC—10 ml (Winborn, 1965).

ERL

ERL (4206)—10 g, NSA—26 g, DMAE—0.4 g, DER (736)—69 m (Spurr, 1969).

In the preparation of the epoxy embedding media, it is always desirable to heat and mix the resin, the hardener and the container at 60 °C. After weighing in a beaker, the mixture should be poured in a vessel containing the accelerator. Stirring may also be needed for mixing. Goryeki (1978) suggested mixing of epoxy resin in weak-walled polythene bags. Storage for a short period can be done at 4 °C but for longer period, keeping at −20 °C is necessary.

Schedule for embedding with epoxy resin media

(1) Drain off the solvent with a pipette. For flushing off, it is preferable to pour it down with a large volume of water in a fume chamber. If propylene oxide is used, keep the material slightly moist.
(2) Add a mixture of solvent and embedding medium (1 : 1) in the vial, shake for thorough mixing.
(3) Keep the vial for 30 min to 1 h at 24–28 °C.
(4) Use pipette to remove the fluid and add the final embedding medium.
(5) Remove the cap from the vial and keep for 16–24 h at room temperature.
(6) Take several dry polyethylene (BEEM) capsules (dried overnight at 60 °C), fit them in a cardboard box with punched holes of proper size,

half fill it with embedding medium and transfer the material with the aid of tweezers into the capsules.

(7) Fill the capsules with the embedding medium and allow polymerisation overnight or more at 60 °C oven.

(8) Before sectioning, keep the capsules for a few days, if possible in the oven.

N.B.

(1) If necessary, before transferring to 60 °C, keep the capsules overnight at 35 °C and then overnight at 45 °C.

(2) To accelerate polymerisation and for materials where raising of temperature may not be harmful, 8 h or less treatment at 70 °C may be adopted.

(3) To avoid heat polymerisation for delicate materials ultraviolet radiation with a sun lamp can also be followed at a lower temperature.

(4) For large blocks where there may be difficulty for complete and uniform infiltration, it is desirable to secure absolute dehydration by keeping for a longer period in the intermediate solvent, to use low viscosity embedding medium, to adapt a series of intermediate solvent and embedding mixtures before putting the material in final embedding medium and to keep the materials in a vacuum desiccator for 30 min before polymerisation (Erlandson, 1964) or reduce the pressure of the oven to 0.5 atm during incubation (Winborn, 1965, *see* Glauert, 1975).

For rapid embedding, particularly for small specimens, rapid dehydration can be adopted as mentioned earlier (Coulter, 1967) by using ethanol and propylene oxide: Epon 812 or Araldite (502) (1 : 2) for 5 min with agitation and 5 min keeping in pure embedding medium and then polymerisation at 95 °C for between 40 min to 12 h (Glauert, 1975). Hayat and Giaquinta (1970) used 100 °C filter for rapid embedding. But schedules using such high temperatures are not desirable for chromosome studies.

Polyester resins

The most common polyester resin is Vestopal W (Ryter and Kellenberger, 1958; Kushida, 1964). In later years, Rigola, 2004, 70F (Kushida, 1960, 1961) Rhodester 1108 (Argagnon and Enjarlbert, 1964) as well as for rapid embedding, Beetle 4416 and Beetle 4134 (Rampley and Morris, 1972) have also been added to the list.

For polyester media, normally a catalyst or initiator and an accelerator are needed for polymerisation.

With Vestopal W, benzoyl peroxide (BP) or tertiary butyl parabenzoate as initiator and cobalt naphthanate (CN) as accelerator are used. But as the two, if mixed together may cause explosion, the initiator is to be mixed thoroughly with the aid of a stirrer with the resin for 20–30 min before the addition of accelerator. Polymerisation can also be achieved omitting CN, and using benzoin alone as a catalyst for ultraviolet irradiation at 24–28 °C or using benzolyl peroxide (BPP—50 per cent benzoyl peroxide in tricresyl phosphate) and heat (Kushida, 1964). All the compounds are stored in cold. Polymerisa-

tion *in vacuo* is preferable. Vestopal W is prepared by esterifying maleic anhydride with glycerol or any other polyhydric alcohol.

Some of the polyester embedding media are listed below.

Vestopal

(1) Vestopal W, BP 1 per cent, CN—0.5 per cent (Ryter and Kellenberger, 1958).
(2) Vestopal W, BPP 1 per cent—heat polymerisation (Kushida, 1964).
(3) Vestopal W, benzoin—0.3 per cent—ultraviolet polymerisation (Kushida, 1964).

Rigolac

Rigolac 70F/Styrene (3 : 7), BP—1 per cent (Shinagawa and Uchida, 1961).

Beetle

Beetle 4116—22.5 ml } Butanox } 0.3 ml, NL 49/ST (styrene based solution)
+Beetle 4134—7.5 ml } M 50 }

containing 1 per cent cobalt) 0.3 ml or Q2 (vanadium based solution)—for rapid embedding (Rampley and Morris, 1972). Catalyst and accelerator should not be mixed together as it may explode.

Schedule for embedding with polyesters

(1) Dehydrate materials in dried acetone or in ethanol followed by ethanol and acetone or styrene or methyl methacrylate mixture as intermediate solvent. This is necessary as polyester resins are insoluble in ethanol.
(2) After passing through intermediate solvents, give two changes in solvent, 30 min each.
(3) Pass through the following grades of acetone/Vestopal mixture, 3 : 1, 1 : 1, 1 : 3 keeping in each for 30 min to 1 h.
(4) Keep in Vestopal W and BP and CN mixture (prepared as mentioned above) for 12–24 h at 60 °C for polymerisation. This step can be substituted by ultraviolet polymerisation with Vestopal W and benzoin, for 10 h at 24–28 °C.

For rapid embedding (Estes and Apicella, 1969), after ethanol dehydration and styrene rinsing, the materials can be kept for 10 min each in styrene/Vestopal W (1 : 1), two changes in Vestopal and BP and CN, polymerise for 1 h in a vacuum oven 45–50 °C, finally followed by 15 min keeping at 70–80 °C and 90–100 °C. The materials are to be cooled at 24–28 °C.

The materials can be polymerised also by 1 h at 60 °C if Beetle embedding medium as mentioned above is used.

Methacrylates

Water insoluble methacrylates normally consist of a mixture of *n*-butyl and methyl methacrylates. They are normally supplied along with an inhibitor

such as hydroquinone to prevent polymerisation. This should be removed through sodium hydroxide shaking in a separating funnel followed by distillation *in vacuo*. Hardening is carried out in fume chamber (Glauert, 1965). As methacrylate monomers mix well with ethanol, the latter is generally employed for dehydration.

Methacrylates have the disadvantage of causing excessive shrinkage of the tissue during polymerisation. Benzoyl peroxide is widely used as the catalyst. For stability against electron beam, divinyl benzene may be added for cross-linking or *n*-butyl methacrylate/styrene mixture may be used (Kushida, 1961; DeLamater *et al.*, 1971). In the latter, the hardness of the block can be adjusted by varying the proportion of the two. The inhibitor supplied with styrene is often retained (Mohr and Cocking, 1968) to secure good results.

Different embedding media

(1) *n*-Butyl and methyl methacrylates (8 : 2), 1–2 per cent benzoyl peroxide—stored at 4 °C for weeks.
(2) *n*-Butyl and methyl methacrylates in suitable proportion—100 ml, divinyl benzene—5 ml, benzoyl peroxide—1 g.
(3) Mixture of distilled *n*-butyl methacrylate and styrene (7 : 3), 1 per cent benzoyl peroxide—dried and filtered.
(4) Distilled *n*-butyl methacrylate—100 ml, divinyl benzene solution—3 ml; terpineol, 3 ml; benzoyl peroxide, 1 g.

To check shrinkage, often partially polymerised methacrylates are used prepared by heating the methacrylate with catalyst at 90 °C with continuous agitation. As soon as the mixture becomes viscous to the required extent, it is to be transferred to cold water.

Schedule for embedding with water insoluble methacrylate

(1) Dehydrate the fixed material in ethanol.
(2) Keep for 1 h in a mixture of ethanol and methacrylate with 1–2 per cent benzoyl peroxide as catalyst.
(3) Give two changes of 1 h each in a mixture of methacrylate and catalyst.
(4) Polymerise for 12–24 h at 60 °C or for a longer period at 47 °C, or 24–48 h at ultraviolet irradiation at 2.54 cm away from the source in corked capsules, to prevent evaporation of methacrylates. Longer embedding time is necessary with partially polymerised methacrylates.

As bubbles are formed in the block due to the presence of water, Moore and Grimley (1957) suggested the use of de-gassed methacrylate under dry N_2 atmosphere to replace O_2 by N_2. Due to the transparent nature of methacrylate, allowing the transmission of light, the material can be observed directly under the microscope when the block, on being detached from the glass plate, is fixed on the stage. The desired portion of the material can be delimited with a marker and trimmed for sectioning. Ordinary light

microscope photographs can be taken for comparing finally with the electron micrograph.

With media (2) polymerise for 24 h at 50 °C and for (3) and (4) follow ultraviolet irradiation for 30 h and 12 h respectively at 24–28 °C (Kushida, 1961, 1962; Watson and Aldridge, 1961).

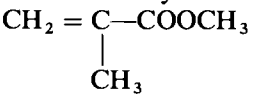
Water soluble embedding media

The use of ethanol, acetone propylene oxide, etc. as dehydrating agents may cause extraction of some of the cell components which is selectively avoided by the use of water soluble epoxy resins or methacrylates. But for chromosome studies, aqueous epoxy resins may have the advantage of acting as fixatives because of interaction with nucleoproteins but methacrylates having no such property may be preferred where selective extraction of chromosome components is desirable.

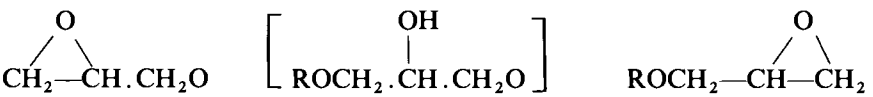
Quite a number of water soluble embedding media have been devised, with the advantage that aqueous fixatives meant for cytochemical work can be used for the selective extraction of chromosome components (Stäubli, 1960; Glauert, 1965; Kushida, 1966). Otherwise the use of strong solvents may damage the cytochemical and enzymatic patterns. The embedding medium itself may further serve as the dehydrating agent. Such water soluble media include Aquon (Gibbons, 1959, 1960)—the water soluble constituent of epon; glycol methacrylate—the ethylene glycol ester of methacrylic acid (Rosenberg, Bartle and Lesko, 1960) and Durcupan—an aliphatic polyepoxide (Stäubli, 1960). The chemical structures of these compounds, as studied on a comparative basis by Leduc and Bernhard (1962), are:

Glycol methacrylate

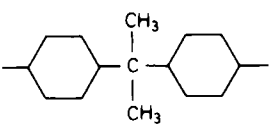
Methyl methacrylate



Epoxy resins: General formula



Where R is usually



Diphenyl propane

Durcupan allows only acid hydrolysis and digestion by proteases (Granboulan and Bernhard, 1961; Bernhard, 1966; Bernhard and Granboulan,

1968). Aquon and glycol methacrylate have a comparatively wider use. In addition, 2-hydroxypropyl methacrylate has been used for the same purpose by Leduc and Holt (1965).

Aquon. is a colourless resin (water soluble part of Epon 812) prepared (Gibbons, 1959) by extraction of Epon 812 with two volumes of water, separation through salting with sodium sulphate and finally drying off the residual water in a vacuum desiccator. It has a low viscosity and at a low temperature (15 °C), is soluble in water. Polyepoxides like aquon form intermolecular linkages with proteins and nucleic acids and may to some extent serve the purpose of fixation. Stacey *et al.* (1958) demonstrated that carbonyl, amino and imidazolyl groups of proteins and sulphydryl groups of denatured proteins are reacted upon by epoxides. They further esterify phosphate groups and nitrogenous bases. The common hardeners used with Durcupan are, dodecynyl succinic anhydride (DDSA), or methyl nadic anhydride (MNA). The accelerator normally used is 2,4,6 tridimethyl amino methyl phenol (DMP 30). Some of the common water soluble epoxy media are:

(1) Durcupan, 5 ml; DDSA, 11.7 ml; DMP 30, 1 ml; (dibutylphthalate DP, 0.2 ml may be added) (Leduc and Bernhard, 1962).
(2) Durcupan, 100 ml, MNA, 120 ml; DMP 30, 1.5 per cent (Thiokol LP8, 20–35 ml may be added in requisite proportion to secure adequate hardness) (Kushida, 1966).
(3) Aquon, 10 ml; DDSA, 25 ml; BDMA (benzyldimethyl amine), 0.35 ml (Gibbons, 1959).
(4) Epon 812, 20 ml; hexahydrophthalic anhyobride (HHPA), 16 ml; BDMA, 1.5 per cent (Craig, Frajola and Greider, 1962).

For aquon the material is fixed in 10 per cent formaldehyde–veronal acetate buffer (pH 7.3) at 3–4 °C and washed. It is dehydrated through increasing concentrations of aquon in water to pure aquon at 4 °C and finally kept immersed in the embedding mixture for 4 h. Curing is performed by transferring the material to a gelatin capsule with fresh embedding mixture and keeping it at 54–60 °C for 4 days. Ultra-thin sections can be cut conveniently with glass knives in a Porter–Blum microtome. Silver interference colour in distilled water can be checked and staining does not require the removal of the embedding medium.

Glycol methacrylate (GMA)

This is a hygroscopic, colourless liquid, readily miscible with water, ether and ethanol. Ethylene glycol monomethacrylate is prepared either by re-esterification of methylmethacrylate or directly by esterifying methacrylic acid (Rosenberg, Bartl and Lesko, 1960). In the former procedure, 0.5 per cent triglycoldimethacrylate is added to glycol methacrylate before polymerisation to secure a three-dimensional polymer. In the latter method, side products ultimately result in the formation of such a polymer. It has a boiling point of 89–92 °C at 7 mmHg, density 1.065 (at 20 °C), viscosity 0.701 poise (20 °C), and refractive index 1.4540.

With Durcupan, no ethanol or acetone is necessary. The entire dehydration and embedding schedule is outlined below.

(1) Pass the materials through 50, 70, 90 per cent aqueous Durcupan

solution keeping in each for 15–30 min and give two changes in pure Durcupan for 30–60 min each, with constant agitation in a shaker at 24–28 °C.

(2) Transfer the materials to a mixture of pure Durcupan and Durcupan embedding media (3 : 1) and keep for 1 h.
(3) Prepare two mixtures as in (2) in the proportion of 1 : 1, 1 : 3 and keep the materials for 1 h in each.
(4) Give two changes in the pure embedding media 1–2 h each.
(5) Polymerise for 50 h at 50 °C.

The glycol methacrylate media (glycol, *n*-butyl and hydroxypropyl) may be prepared in the following way.

(1) 97 per cent GMA in water, 7 ml; *n*-butyl methacrylate (with inhibitor), 3 ml with 2 per cent benzoyl peroxide (Luperco) as catalyst.
(2) GMA, 7 ml; *n*-butyl methacrylate, 3 ml with 1–2 per cent benzoyl peroxide.
(3) GMA, 7 ml; styrene, 3 ml with 1–2 per cent benzoyl peroxide (Cope, 1968).
(4) 80 to 90 per cent hydroxypropylmethacrylate (HPMA) in water with 0.1 per cent azonitrile (catalyst). The HPMA should be kept in dark as it undergoes polymerisation in light and the inhibitor should be removed just before use. Both osmium and glutaraldehyde fixations yield good results.

The schedules for dehydration and embedding are outlined below (Cope and Williams, 1968). The entire process of dehydration and infiltration prior to polymerisation is to be carried out in the cold room at 0–4 °C.

For GMA medium

(1) Dehydrate the fixed or frozen sections through 20, 40, 60, 80 per cent aqueous GMA and four changes in 100 per cent GMA keeping in each for 15 min.
(2) Infiltrate with embedding medium containing catalyst for two changes of 1 h each.
(3) Embed and polymerise in partially polymerised medium (syrupy at 1–3 °C) at 20 °C under ultraviolet light for 48 h.

For HPMA medium (Leduc and Holt, 1965)
Dehydration and embedding are to be carried out with shaking.

(1) Dehydrate with two changes of 85 per cent aqueous HPMA and two changes in 97 per cent aqueous HPMA, keeping in each for 1 h.
(2) Embed in partially polymerised embedding medium for 1 h.
(3) Polymerise at 10 °C under ultraviolet light for 12–24 h or at 56 °C for 2–3 days.

Ethylene glycol has also been used for dehydration before embedding in HPMA (Pease, 1966). For epon embedding, HPMA has been used as intermediate solvent (Brinkley, Murphy and Richardson, 1967) for monolayers of cells.

SECTIONING

Ultramicrotome

For ultra thin sectioning (0.1–0.01 μm), several models of ultramicrotomes are at present available. A detailed historical account has been given by Wachtel, Gettner and Ornstein (1966). The first suitable model was manufactured by Ivan Sorvall Inc. in 1953, commonly known as the Porter–Blum microtome (Sorvall—MT-2). In general, the principle of its operation was based on a system of screw thread, lever arm and proper bearings. When necessary, it could be driven by a motor and due to its simplicity of working, did not require a complicated maintenance process. In the slightly improved model, the specimen holder, which is of a collet type screwed at the free end of the aluminium rod, is moved vertically across a glass or diamond knife. On the return stroke, the specimen end of the aluminium rod is allowed to follow the trajectory of a parallelogram. Coarse and fine adjustment screws are provided for thick sectioning, while for ultra thin sections, there is a mechanical device to advance the block towards the knife. To induce thermal expansion of the aluminium rod, an electric lamp is used. In a later model (Sorvall—MT-2), the whole operation is much more compact; the knife stage allows controlled motion of the knife, permitting proper trimming for ultra thin sections. Two controls are provided to adjust the thickness of sections between 10 nm to 4 μm.

In the Huxley model (Cambridge Instrument Co.), steel leaves are employed for hinging the arm. It is based on a mechanical advance with a double leaf spring suspension system. Here, though the gravitational pull is responsible for section cutting, one oil-filled dashpot controls the rate of downward movement of the cutting arm (*see* Wachtel, Gettner, and Ornstein, 1966).

In the ultramicrotome of LKB-Producter AB-Stockholm, fluctuation in section thickness is eliminated to a significant extent, the principle being based on a thermal advance system. A cantilever arm is the principal moving part, one end of the arm holds the specimen block, the other end is attached to a leaf spring joined to the base of the microtome. This spring causes the up and down motion of the bar. Thermal control of the cutting arm guides the advance of the block against the knife. The gravitational force controls the cutting stroke and a motor regulates the motion and the upward movement. An electromagnetic force which acts during the return stroke, causes the flexing of the base below the knife holder necessary to ensure the bypass of the cutting surface and knife edge during the return stroke.

Several other thermal advance microtomes have been designed, effective ones being the Reichert Om U_2 and later models. The working principles of all the different ultramicrotomes have been discussed in detail in reviews by Wachtel, Gettner and Ornstein (1966), Reid (1974) and Meek (1976).

Knife

Of the different types of knives used, including hard steel (Ekholm, Hallén and Zellander, 1955), diamond (Fernandez–Moran, 1956) and glass (Latta

and Hartmann, 1950), the latter is the most convenient for ultra thin sectioning and is, therefore, widely used. Due to the short life of the glass knife, a diamond one is sometimes recommended: this is often useful for epon embedded materials. But the problem of resharpening and the disadvantage of securing a satisfactory meniscus to receive sections, because of its hydrophobic property, have resulted in only a limited application of the diamond knife. A common method for preparing the glass knife, as developed by Porter (1964) is outlined as follows.

Make a 1.27 cm score mark with a sharp cutter on a clean 20 × 20 cm sheet of plate glass, at right angles to the base of the glass plate. Position the scored edge of the plate to overlap the edge of the working surface by about 0.63 cm. Keep the edge of the glass parallel to the edge of the table. Take a pair of glass breaking pliers with wide parallel jaws. (A narrow strip of adhesive tape is placed on the inner surface, from the cutting edge to halfway to the middle of the bottom jaw. Two lateral strips are placed at the edges of the inner surface of the top jaw. Inner surfaces of both jaws are then covered with wide pieces of adhesive tape, smoothly.) Keep the jaws open and with the central piece of tape of the bottom jaw centred beneath the score mark on the glass, push the face of the bottom jaw flush against the table. Gently squeeze the pliers to produce a slow, even and straight break, with two smooth new surfaces, which will be free of artefacts except for the short line where the initial score was made. Turn the two pieces of glass through a right angle so that the smooth edges are away from the table edge. Score one piece of glass in the centre of the old long edge and repeat the procedure to have two 10 × 10 cm plates. Repeat the process till 2.54 × 2.54 cm squares are obtained, each with at least two smooth edges meeting at a 90 degree angle. Choose the best adjacent edges for the final break. Start a diagonal score 1 mm or so from the apex of the angle where the faces meet and extend to bisect the opposite corner. Carefully centre the pliers halfway along this line and gently increase pressure till the glass breaks to give a triangular knife. The good knife should have an even and straight cutting edge, an absolutely flat front surface and a back face with either a right or left-handed configuration when viewed from above. The part of the knife edge closest to the top of the arc formed by the back surface is best for thin sectioning. A good 45 degree angle knife is usually suitable for cutting tissue embedded in media of average hardness. An angle of 55 degrees has been recommended (Ward, 1977).

Trough

In order to receive sections after cutting in an ultramicrotome, troughs are prepared in various ways. It is necessary because after the sections are cut, ultra thin sections have a tendency to adhere to the dry knife and collection becomes difficult. The trough is an integral part of the section-cutting equipment for diamond knives. With a glass knife, the usual procedure is to prepare a trough with adhesive-backed cloth or paper tape, which is disposable. The exposed adhesive surface of the trough is coated with paraffin to prevent

contamination with the trough liquid. It is sealed to the glass with melted paraffin.

Certain prerequisites are necessary in the liquid in the trough. It should be able to detach the sections from the knife, eliminate all electrostatic charges, spread the sections through solvent action, and should have an adequate surface tension to penetrate the layer between section and knife facet. Gettner and Hillier (1950) first introduced a method of trough and flotation fluid, the section being floated in a fluid which wets the glass without wetting the methacrylate. Different concentrations of acetone, preferably 40 per cent, may be used as the fluid. In order to stretch the sections properly, methacrylate blocks could be softened with a proper solvent, such as xylene, applied with a camel-hair brush to the sections as they float in the trough.

In general, several surface tension reducing mixtures serve as good trough fluids. Acetone in 10–40 per cent concentration may be used. It allows rapid relaxation of compression after sectioning, especially in the case of polymethacrylates. High concentration is avoided as it makes the methacrylate soft. Water may be used but relaxation takes a little longer. Ethanol and dioxane, in 20–60 per cent concentrations, are sometimes used. Ethylene glycol, silicone fluids and glycerine solutions are the other chemicals utilised for this purpose. The higher surface tension fluids are useful for epoxy and polyester embedded materials as well, after the knife has been moistened with water. Pease (1965) recommended the use of glycol for this purpose for hydroxypropyl methacrylate embedded materials. In epon-embedded materials, trichloroethylene has been found to be suitable (Porter, 1964). The fluid must have a slightly convex meniscus and the level in the trough should be just below that of the cutting edge, so that the specimen block is not wetted.

Trimming and sectioning

In the actual procedure, the cutting edge of the knife, the embedding material, the cutting face of the block and operating speed are the principal controlling factors.

In case of hard epoxy-embedded blocks, fine files and jeweller's saws are required for trimming, followed by a final finish with an acetone or chloroform-washed razor blade to ensure that it is free from oil. To prepare the block for sectioning, the side walls of the portion delimited from the tissue should be trimmed—a surface area about 0.3 mm × 0.08 mm is usually desirable. The block should be oriented in the microtome with the long side parallel to the knife edge. After trimming, the final shape of the block should be that of a truncated pyramid or, in the case of larger materials, like a roof-top. Normally the cutting face should be square but some people prefer a trapezoidal block, having asymmetry, with the longer axis oriented towards the cutting face, the upper and lower edges being parallel (Porter, 1964). In general, one side of the pyramid, or the long face of the roof-top-shaped top is adjusted parallel to the knife edge.

Pease (1973) suggested the provision of an added support with a superficial layer of hard wax to protect the tissue from direct contact with the knife during practice. The blocks are dipped in a filtered mixture of Carnauba wax and paraffin (1 : 2) and kept at 80 °C. The tissue specimen can be

oriented by mounting the block on a holder made of a wooden dowel rod 5–16 mm in diameter, which fits well in a Porter–Blum microtome. At times, the orientation of the block in relation to the sectioning plane must be precise. In such cases, after appropriate trimming, the block can be stuck with liquid epoxy against a second block and the microtome chuck can be adjusted slightly.

After the block is fitted in the chuck, the front edges of the jaws should clamp it strongly and the projecting portion alone should not be more than 3–4 mm. The knife should be tilted so as to have a 1–3 degree clearance angle and a rake (knife) angle of about 30 degrees (Sjöstrand, 1969). The factor of the rake angle is important for the prevention of chatter, which in addition to a small knife angle, is also accelerated by a very thin block tip, and by rapid movement of the cutting face. The 'chatter' is caused by the vibration in the block, microtome arm or knife edge. In any case, the experienced worker, when using the microtome, can easily devise his own methods for preventing chatter caused by any of the above factors.

The entire process of sectioning should be performed very gently at uniform operational speed. To ensure proper sectioning, it is preferable to check the entire sectioning operation with a block of pure plastic, without the material.

When the sections have been cut, the ribbon can be detached from the knife edge and transferred to a trough in which the level of the liquid is controlled with a hypodermic syringe fitted at the base with a plastic tube (Gay and Anderson, 1954). The level of the fluid is generally maintained over the knife edge, forming a well-rounded meniscus, and the ribbon can be detached with a fine-hair brush. In order to estimate the thickness of the section correctly, it is always preferable to use reflection of interference colours while the sections are floating in the trough (Porter and Blum, 1953). The light should be adjusted to allow total reflection on the liquid surface. Peachey (1958) published a detailed account of the thickness of the sections and the corresponding interference colours, the former ranging from 60 to 320 nm and the latter from grey to yellow. A satisfactory method of observing sections by reflected light is by a fluorescent lamp.

Sjöstrand (1969) observed that ultra thin sections suitable for high resolution work generally appear dark grey in reflected light while for lower resolution work, a section thickness cf 70 nm with a silvery shine in reflected light is desirable.

MOUNTING

The removal of the ribbon from the fluid needs special care. For examination under the electron microscope, the ribbon must be mounted on a specimen grid with a backing film (Parlodion and Formvar are the common films used for this purpose because they provide good supporting media, being composed of light atoms). The essential requirements are satisfied as they dissolve quickly and become tough when the solvent evaporates. Parlodion is the trade name of nitrocellulose plastic (prepared by Mallinck Rodt Chemical Works, St. Louis). Polyvinyl formal plastic of Shawinigan Products Co., New York is called Formvar. Gay and Anderson's method (1954) appears to be suitable for serial sectioning. The principal implement is a

Table 9.1 Interference colours and corresponding section thickness (according to Wacthel. Gettner and Ornstein, 1966)

Section thickness in μm	*Interference colours*

0.380	Bluish violet		

thin film of Formvar supported by a small wire, and these Formvar-coated loops can be inserted in the liquid of the trough in a tilted position. By suitable adjustment, the ribbon can be centred across the diameter, and when the loop is raised, the sections adhere to the Formvar, after which they can be directly transferred to the supporting grids for examination. The grids are placed on a combination of transparent plastic discs, fitted on the top of an adjustable condenser in a standard microscope, and by lowering the condensers, the grid can be kept below the stage and the ribbon can be suitably arranged. Contact is achieved by lifting the condenser. Pease (1964) states, however, that the one disadvantage of this method is that it requires a heavy supporting grid.

Sections can also be mounted directly on large arc hole grids as shown by Sjöstrand (1969), in a modified version of Gay and Anderson's (1954) method. Another method was developed by Galey and Nilsson (1966) (*see also* the chapter on high resolution autoradiography). Epon embedded materials can be mounted on 300 mesh copper grids (Afzelius, 1962). For araldite-embedded materials, the sections do not require any support for mounting; even a carbon film may serve the purpose.

STAINING

Significant improvement in securing adequate contrast in ultra thin sections has been achieved by the use of suitable staining procedures (Trump, Smuckler and Benditt, 1961; Lewis, Knight and Williams, 1974). The tissue is exposed to heavy metal salts to form metal ion complexes with nuclear components. The formation of such complexes increases the image density in electron micrographs. Formation of cross links by oxygen bridges and also $-CH_2$ bridges with fixed materials has been suggested as the basis of staining (Afzelius, 1962). Positive staining technique involves treatment with components which increase the weight density, whereas in negative staining, the material is surrounded with a structureless material of high weight density. Valentine and Horne (1962), from an assessment of the negative staining techniques, demonstrated that good negative staining can be obtained with sodium tungstate, uranium nitrate or disodium hydrogen phosphate.

The number of staining methods available is increasing gradually and several lead salts, which give a stable staining, such as hydroxide (Watson, 1958), cacodylate (Karnovsky, 1961), tartarate (Millonig, 1961), citrate (Reynolds, 1963) as well as uranyl acetate followed by lead citrate (Reynolds, 1963; Venable and Coggshell, 1965), etc. are applied for securing adequate contrast. Uranyl acetate has been claimed to alter the properties of the molecules so that they bind better with lead citrate. The period of lead staining is generally short, to prevent the formation of lead deposits.

Staining with uranyl nitrate may be performed, using a filtered aqueous saturated solution at pH 4.0. For combined staining, the section on the grid may first be moistened with a drop of distilled water, followed by staining (in an inverted position) in 7.5 per cent uranyl acetate solution for 20 min at 45 °C. The sections are dried on filter paper, again moistened and finally stained with 0.2 per cent aqueous lead citrate solution for 10–60 s (Reynolds, 1963; Venable and Coggshell, 1965). In Salpeter's method (1966), aqueous uranyl acetate or uranyl nitrate staining is followed by a few drops of lead citrate, before floating off the excess stain with water. The stains are usually selected for specific intracellular components, depending on their stability and non-formation of deposits.

IN SITU FIXATION AND EMBEDDING

Several methods have also been developed for fixation and embedding *in situ*, thus avoiding any distortion (Sabbath and Anderson, 1977) or displacement of the structure. This is specially advantageous for cell monolayers. Initially this method was adopted only on glass surfaces such as for *Drosophila* chromosome smears (Gay, 1955) and even using inverted gelatin capsules containing the embedding medium placed on the material in the slide (Howatson and Almeida, 1958). Later the slide had to be separated by rapid freezing with CO_2. Even though several deviations from the original schedule were published from time to time (Gorycki, 1966), the difficulty of separating the cultured cells from the substrate could not be fully overcome.

In order to eliminate this disadvantage, cooled glass surfaces, specially with carbon, for growing cell monolayers was adopted by Bloom (1960).

Later, in addition to carbon (Robbins and Jentzsch, 1967), several other materials, namely silica (Kushida and Suzuki, 1968), 1 per cent nitrocellulose (Flaxman, Lutzner and Van Scott, 1968) or polytetrafluorethane (Buckley, 1971) have also been used but the extent to which they may affect the specimen itself is yet to be investigated.

Chang (1971) developed a comparatively simple technique with least toxicity to the cell. This technique is applicable to monolayers, suspensions, ascites cells, cell smears, frozen materials, etc. and is well suited for chromosome study too. It involves culturing of cell on cover slips sprayed with teflon. The fixation and dehydration of monolayers attached to cover slips are carried out in staining dishes before final embedding in epon or other media using a silicone rubber mould. Cover-glasses are then separated from the block by quick dipping in liquid nitrogen. Light microscope observation can be done on the blocks before ultrastructural analysis of selected areas. The technique allows mass harvesting of cells as the several cover slips with monolayers can be obtained from the single culture flask. In addition to glass, methods have been devised to use synthetic substrate for culture, which can be easily separated from embedding medium. Such substrates include falcon plastic petri dishes (Brinkley and Chang, 1973), silicone rubber membranes (Shahar, Mouzain and Straussman, 1973), vinyl plastic cups (Anderson and Doane, 1967), etc. For ultrastructural analysis of chromosomes at different stages of division, falcon dishes were used by Brinkley, Murphy and Richardson (1967). The procedure involves glutaraldehyde fixation, dehydration in hydroxypropyl methacrylate and *in situ* embedding in epon. Polymerised blocks can be observed and photographed under light microscope and selected areas embedded in BEEM capsules for sectioning. This technique allows rapid analysis of a large number of materials and is specially suited for chromosome analysis.

In order to eliminate this limitation, several methods have been devised in which cells are grown as sectionable substrates. To achieve this objective, polystyrene petri dishes (Nelson and Flaxman, 1972) or cover slips (Richters and Valentine, 1973), millipore filters (McCombs, Benyisch–Melnick and Brunschung, 1968; Lemcke, 1971), thin layer agar jelly (Van Noord, Blansjax and Nakoff, 1973) as well as BEEM capsules have been used for growth of cell layers and sectioning. These have been found to be very suitable for fibroblast cultures as well as human and mouse haematopoietic cells. Egeberg (1965) developed a technique involving sandwich embedding of cell monolayers on thin polymerised resin plates. The only limitation of these methods is the difficulty often encountered in the proliferation of cells on resin substrates (Zaguri, Pappas and Marcus, 1968). Sabbath, Sanderson and Joachim (1973), Sabbath and Anderson (1977) utilised 'spurr' medium (Spurr, 1969) having low viscosity and high penetration in the sandwich technique. It principally involves fixation and embedding of monolayers on spurr discs, which are non-toxic, without any effect on cellular morphology. It has the further advantage of not requiring any anti-adhesives.

STAINING

For ultra thin chromosome staining, Schiff reaction is advantageous excepting the fact that apurinic acid produced during Feulgen reaction is not electron

dense. In order to overcome this limitation, thallium ethylate, an electron stain specific for hydroxyl groups, has been applied by Moyne (1974). In this technique, acetylation before Schiff reaction is done to avoid staining of other hydroxyl groups in cells. The success of the staining is dependent on the removal of all hydroxyl groups excepting those present in the reaction. The schedule is outlined below.

(1) Fix tissues for 1 h in 1.6 per cent glutaraldehyde in phosphate buffer (pH 7.3) at 4 °C.
(2) Give a thorough wash, dehydrate in acetone and treat in a mixture of pyridine acetic anhydride (60 : 40) for overnight at 45 °C for acetylation.
(3) Embed in epon following the usual schedule and cut ultra thin sections.
(4) Float goldgrid mounted sections in 5 N HCl for 20–30 min at 20–22 °C.
(5) Rinse and float again in Schiff's reagent for 30 min and rinse for drying.
(6) Keep for staining in thallium ethylate in ethanol (1 mg/ml) and add a drop of water to increase the intensity of the colour.

Under the electron microscope, chromatin appears electron dense.

Instead of Schiff reagent, a heavy metal polyamine–osmium aminine has also been used for detection of DNA in chromosomes (Gautier *et al.*, 1974). In this method, fixation in osmium tetroxide or potassium permanganate, embedding in epon, and after hydrolysis of sections, staining in osmium aminine previously bubbled with SO_2 for 10 min is recommended. Specificity of DNA reaction has been improved through control experiments.

Schedule for EM chromosome analysis of slime mold—*Echinostomum minutum de* Bary (2 n = 124)

(Haskins, 1976)

(1) Fix plasmodia in a mixture of 3 per cent glutaraldehyde + 1 μM $CaCl_2$ buffer (pH 6.8) with 0.05 M Sorensen's phosphate buffer for 1 h.
(2) Post fix in 1 per cent OsO_4 in 0·05 M phosphate buffer (pH 6.8) for 1 h.
(3) Dehydrate in ethanol series (30, 50, 70, 95 per cent and absolute).
(4) Transfer to propylene oxide and follow the usual procedure of embedding in Epon 812.
(5) Select metaphase cells under phase contrast microscope, cut the selected portion and remount in epon stubs.
(6) Cut 0.5 μm thick sections in ultramicrotome, and mount on Formvar-coated grids.
(7) Stain in 2 per cent uranyl acetate in methanol and later in lead citrate for 45 and 20 min respectively.

N.B. It is desirable to apply a thin layer of carbon to the grids by a screened carbon source.

Schedule for EM chromosome analysis of nematode (*Ascaris lumbricoides var. suum* (Goldstein and Moens, 1976)

(1) Fix the nematode in 2 per cent glutaraldehyde solution in phosphate buffer (pH 7.2).

(2) Dissect ovary and testis and fix them again in the fresh fixative for overnight at 4 °C.
(3) Post fix in Dalton's osmium chromic acid (Zickler and Olson, 1975) at 24–28 °C for 2 h as used for yeast as well.
(4) Dehydrate as usual through ethanol and propylene oxide and embed in epon for sectioning.
(5) Stain with uranyl acetate and lead citrate (Fiske, 1966).

Schedule for EM chromosome analysis of algae (Spring *et al.*, 1976) (*Acetabularia* sp.)

(1) Fix the algae in 5 per cent glutaraldehyde solution in 0.1 M sodium cacodylate buffer (pH 7.2 at 5 °C for 2 h.
(2) Rinse in cold buffer.
(3) Dehydrate through ethanol grades and follow the usual procedure for epon embedding.
(4) Cut 1.3 μm thick sections in ultramicrotome.

N.B. De-eponise one set and observe following haematoxylin staining.

Several methods are available for whole mount chromosomes. For HeLa cells (Moses and Counce, 1974), L cells (Rattner, Branch and Hamkalo, 1975), etc.

Schedule for EM analysis of whole mount metaphase chromosomes (Rattner, Branch and Hamkalo, 1975)

For L cells, grow monolayer cultures in suitable medium (Joklik's medium with 10 per cent calf serum), add colcemid (0.06 μg/ml) to rapidly growing cultures for 4–12 h, and harvest mitotic cells by selective detachment.

(1) Centrifuge the cells and resuspend the pellet in 1 ml colcemid solution.
(2) Dilute 1 vol of cells with 1–3 vol of 0.7 per cent Triton × 100 at pH 9.5 for lysis and observe periodically under phase contrast microscope to achieve lysis (3–7 min). For next step, follow (3a) and (3b).
(3) (a) *For preserving compact metaphase chromosomes*, centrifuge the suspension in absence of formalin, deposit on carbon cooled EM grid, dry the chromosomes on the grid, and follow post-fixation by immersion in 10 per cent formalin (pH 8.5) for 30 s.
(b) *To secure unwinding and dispersal of chromosome arms*, centrifuge in sucrose and formalin (Miller and Bakken, 1972), and mount the lysed material on carbon cooled EM grid.

N.B. To accelerate dispersal treat the lysed cells with 10 per cent formalin or water (pH 9) for up to 10 min.

(4) Stain in either 1 per cent uranyl acetate in ethanol or 1 per cent ethanolic phosphotungstic acid (Miller and Beatty, 1969). For negative staining, use 0.005 M uranyl acetate in methanol. Observe under electron microscope.

To observe kinetochore–microtubule association in chromosome, the entire procedure as mentioned above may be modified as follows:

(1) Wash twice the mitotic cells in fresh medium to remove colcemid and allow spindle reformation for 5 min at 37 °C.
(2) Dilute 1 vol of cells with 3 vol of 0.35 per cent Triton × 100 (pH 6.5), 1 M hexylene glycol and 1 M glycerol and incubate for 5–7 min.
(3) Add equal vol of formalin for chromatin dispersal.
(4) Centrifuge the preparation in sucrose formalin into EM grid.
(5) Follow the rest of the procedure as above.

Schedule for EM analysis of whole mount chromosomes of dinoflagellates (Haapala and Soyer, 1974)

(1) Collect cultured cells of *Gyrodinium* sp. by centrifuging and sonicate in a suitable medium (Honda, Hongladarum and Laties, 1966) at 4 °C. (The medium contains sucrose, tris acetate buffer, ficoll, Dextran 40, bovine serum albumin, glutathione, cysteine, ascorbic acid or mercaptothanol, magnesium acetate and manganese acetate.)
(2) Pipette a drop of suspension on the corner of a cover slip placed in contact with water.
(3) Pick up the spread material on Formvar-coated grids.
(4) Stain with 2 per cent uranyl acetate in 50 per cent ethanol for 10 min during dehydration.
(5) Dry the grids from amyl acetate and observe under the electron microscope.

Schedule for EM analysis of whole mount alkali urea treated polytene chromosomes (Sorsa and Virrankoski–Castrodeza, (1976)

(1) Pre-treat polytene chromosomes from salivary gland of *Drosophila melanogaster* in a mixture of 0.5 M NaOH and 10 M urea (1 : 1) for 5 min in the corner of a siliconised cover slip.
(2) For centrifuging, take centrifuge discs (a modified type of Miller's disc), provided with freshly carbon coated grids, and fill with 10 per cent formalin in a borate buffer (pH 9.2—spreading solution). Centrifuge for 10 min at 3000 rev/min and handle the grids as usual.
(3) Dehydrate in 30, 50, 70, 94 per cent and absolute ethanol for 30 s each, by submerging the grids in solution.
(4) Stain for 30 s in cold 2 per cent uranyl acetate in methanol and rinse for 30 s each ethanol I and II.
(5) Dry the grids in air and observe under the electron microscope.

The presence of axial fibrils in spread polytene chromosomes can be demonstrated by this method.

The whole mount method permits the retention and identification of basic structural features for kinetochores, interchromosomal fibres, centromeric heterochromatin as well as basic chromatin fibre (Jeffrey and Geneix, 1974;

Rattner, Branch and Hamkalo, 1975). Under strictly controlled isolation technique, attachment of kinetochores with the microtubules in the mitotic spindle has been clearly demonstrated. The normally condensed state of basic chromosome fibre has been resolved. The fibre (Rattner, Branch and Hamkalo, 1975) is shown to be composed of regular repeats of nucleoprotein granules 7–9 nm in diameter. Intergranular fibre whose continuity is maintained by DNA is 2–4 nm in diameter. Technological refinements of the whole mount technique as well as the combination of EM method with banding, including BudR incorporation, now allow the identification of specific chromosomes at the ultrastructural level on the basis of their morphology and type of heterochromatin (Binder and Kim, 1975; Filip, Gilly and Mouriquand, 1975; Murzamadiev, 1975; Rattner, Branch and Hamkalo, 1975). The advancement in techniques has opened up the possibility of ultrastructural analysis of different proteins with DNA at eukaryote level at different phases of differentiation.

APPLICATIONS OF ELECTRON MICROSCOPY

It is hard to over-estimate the contributions of electron microscopy, as in the study of the chromosome, its ultrastructure including nucleosomes could only be clarified through this method, aided by autoradiography.

Kaufmann (1960), on the basis of observations on ultrastructural details, claimed that the chromosomes of higher plants and animals are multistranded in nature. Fine fibrillar elements can be observed even in the half-chromatids. The diameters of the fibrils vary from 50 nm to 3 or 4 nm. Shinke (1959) observed elementary chromosome fibrils, 10–20 nm thick, in the chromonemata of metabolic nuclei of several higher plants. The combination of electron microscopy with banding technique however indicates that one fibril is present in one chromatid forming many loops and returning to a main core in between (Schwarzacher, Ruzicka and Sperling, 1975; Schwarzacher, 1976).

Ris (1962) considered 10 nm nucleohistone fibrils as the main constituent of chromosomes. These molecules are claimed to be made up of two 4 nm thick nucleohistone macromolecules, held together by histone linkers. In sperms, where the histone is replaced by other basic proteins, the 4 nm fibrils can be observed individually. Indirect evidence has been brought forward to show that nucleohistone fibrils are linked end to end through a non-histone protein. In *Escherichia coli*, the semi-conservative replication of DNA has been demonstrated and the entire bacterial chromosome replication has been worked out (Cairns, 1963; Person and Osborn, 1964; *see* Bleecken, Strohback and Sarfert, 1966).

Interesting evidence has been obtained in the Dinoflagellates regarding the evolution of chromosome structure (*see* Ris, 1962; Haapala and Soyer, 1974). The members of this group are claimed to have an intermediate structure between viruses and bacteria. Sausage-shaped chromosomes in the interphase nucleus contain fibrils 3–8 nm thick instead of 10 nm fibrils. The observations indicate that chromosomes are formed of 2.5 nm thick fibrils surrounded by a dense coarsely granular substance. The essential structure of the chromosomes contains DNA and is devoid of any basic protein.

Similarly, in the blue-green alga, *Anabaena* sp., fibrils about 2.5–3 nm in diameter, corresponding to DNA macromolecules, have been found in nucleoplasmic areas (Leak, 1965). Significant data are being gathered through ultrastructural studies, throwing light on the evolution of the complexity in gene-bearing structures (Tanaka and Iino, 1973; Hermann, 1974; Golomb and Bahr, 1974). The structure of the mitotic apparatus has also been clarified through electron microscopy, and is now considered to represent a system of filaments embedded in the compact vesicular mass, possibly including the ribosomes but excluding mitochondria and others (*see* Wada, 1966).

By transmission and scanning micrographs of chromosome details, considerable insight has been gathered regarding the mechanism of gene action as controlled by chromosomes through nucleocytoplasmic transfer (Kaufmann and Gay, 1958; Daskal and Busch, 1978). The dynamic role of the nuclear membrane in affecting the nucleocytoplasmic transfer has been clearly revealed.

In the study of cell fractionation and the identification of isolated units, the contributions of electron microscopy are immense. It is now possible to identify subcellular particles in thin sections of centrifuged pellets, which could not have been monitored by previous methods.

In spite of the phenomenal progress in the study of ultrastructural details, there is still ample scope for further improvements. Even now, the progress in solving the problem of lens aberrations has not been very satisfactory, though the resolving power may gradually be raised to 0.1 nm after necessary corrections for mechanical and electrical stability. Refinements in specimen preparation need to be developed to utilise fully the 0.1 nm resolution through which the nucleic acid bases may ultimately be identified. If the rate of progress is an index, success in this line in the near future is assured.

HIGH RESOLUTION AUTORADIOGRAPHY

Since the pioneering work of Liquier–Milward (1956) on the combined use of electron microscopy and autoradiography on tumour cells, high resolution autoradiography has proved to be an effective tool in the study of ultrastructure as correlated with function (*see* Haggis, 1967; Hulser and Rajewsky, 1968; Toner and Curr, 1968; Schultze, 1969; Kerkis, Zhimulev and Belayava, 1975). An insight into the macromolecular pattern of different biological units, varying between 1–2 nm, combined with a knowledge of their strictly delimited functions, has resulted in a better understanding of the processes of life. Such studies, taken in conjunction with cytochemical findings, form a multipronged approach towards an analysis of cell metabolism. High resolution technique has been used on *in situ* RNA/DNA hybrids and its combination with immunofluorescence has allowed the delimitation of functionally specialised segments of chomosomes (Rudkin and Stoller, 1977).

As with autoradiography in general, this aspect of the subject has been much refined through the use of tritiated compounds of high specificity, now available in forms with specific activity even more than 15 Ci/mM—Schwartz Bio Research Inc. They have a very short range of radiation (0.018 MeV—1 μm), and thus eliminate the difficulty of using high energy β particles emitted by ^{14}C (0.155 MeV/40 μm in water), etc. where the range of radiation exceeds the thickness of emulsion. Moreover, the use of fine-grained nuclear emulsions, with grains as small as 0.1 μm (Ilford Nuclear Research Emulsion K5–L4) has facilitated the preparation of emulsion of uniform thickness and rendered the technique more convenient (Pelc, Coombes and Budd, 1961; Revel and Hay, 1961; Silk *et al.*, 1961; Granboulan, Granboulan and Bernhard, 1962; Caro and Palade, 1963). However, the need for an autoradiographic resolution of less than 1 μm, prompted research on the modification of autoradiographic techniques used in the case of ultra thin sections observed under the electron microscope. This requirement was due to the fact that the size of the grains reaches beyond the limit of resolution of light optics and the thinness of the section does not allow sufficient contrast under light microscopy. Not only has it led to a clearer understanding of autoradiographs but it has also become an effective cytochemical tool for correlating structure with function. A simpler method, replacing the earlier time-consuming one, has now been devised (Stevens, 1966) so that electron microscope autoradiographs of high resolution can be obtained conveniently.

It has, however, been found necessary to observe thicker sections (0.3–0.5 μm) under light microscopy, prior to the study of high resolution ultra thin autoradiographs, principally to get an idea about the approximate exposure time needed for ultra thin autoradiographs and for their comparative assessment. Experience has shown (Caro, 1964) that exposure time needed for ultra thin sections is about 10 times more than that required for comparatively thicker sections. A maximum of two weeks exposure in thicker sections is desirable, as more than five months exposure in ultra thin sections results in background interference from heat, light, chemical and other effects. The requirement of two weeks exposure for thicker sections would imply that thinner sections would require an exposure of nearly four to five months.

If, in the thicker sections, even after three to four weeks exposure, the response is not adequate, it is preferable to change the set-up to secure better incorporation. The period required for exposure is dependent on several variables, such as: the specific activity of the isotope and its amount of incorporation, the rate of synthesis of the labelled compound, the extent of its absorption in the tissue, and the nature of the cell itself. The last three factors are extremely specific and, as such, a knowledge of these properties is essential to formulate the appropriate procedure for securing good high resolution autoradiographs. Radiosensitivity of the object to be studied is also an important factor, particularly in eliminating the possibility of radiation damage (Thrasher, 1966). Heavy metal staining as well as energy of radiation of various isotopes has a profound effect on sensitivity and resolution (Salpeter, 1974). The necessity of continuous calibration for the preparation of standard curves in test geometry and self-absorption of the specimen before reaching emulsion introduce sources of variation as well.

In addition to the need to predict the exposure time for ultra thin sections, light microscopy is required to obtain a demarcated picture of the area to be studied in ultra thin sections. For both these purposes, the desirable thickness of the sections is between 150 and 500 nm.

Fixation and embedding

For the study of thin and thick sections, the same buffered osmium tetroxide fixation is generally preferred (Pease, 1972). In the analysis of chromosome structure, osmium tetroxide solution buffered to pH 7.2–7.4 is often recommended (*see* Wood and Luft, 1968). The addition of divalent cations like calcium (10^{-2M}), in the fixative, checks swelling and helps in maintaining uniformly the packed macromolecular configuration as observed in erythrocyte nuclei. Several workers have shown that unbuffered solution of pH (6.0–6.4) is quite suitable for fixation (Ryter *et al.*, 1958; Claude, 1961; Schreil, 1964). Lafontaine (1965, 1968) obtained very satisfactory results with chromosomes of *Vicia faba*, by fixing in 1 per cent unbuffered (pH 6.0–6.4) solution of OsO_4 in double distilled water, to which varying amounts of calcium chloride were added. Freeze-drying methods can also be adopted for dehydration after quick freeze fixation.

For embedding, any of the usual media, such as methacrylate, epoxy resins, araldite (Glauert and Glauert, 1958), Epon (Luft, 1961) or polyester, Vestopal W (Ryter and Kellenberger, 1958), can be employed. Stevens (1966), however, preferred Epon 812 embedding due to lack of polymerisation damage and stability of the resin (Luft, 1961). The advantage of methacrylate is that on removal of the embedding medium the sections can be observed under a phase contrast microscope.

Section-cutting

The slides have to be kept ready before cutting the sections. For this purpose, clean slides with frosted ends should be dipped in the subbing solution (1 g Kodak purified calfskin gelatin is dissolved in 1 l hot distilled water, cooled,

1 g chromium potassium sulphate is added and the solution stored in the cold). The subbed slides are dried in a dustfree chamber and stored in boxes.

To secure thick sections meant for predicting the exposure time needed for ultra thin sections, as well as for comparative assessment, the block is trimmed so as to obtain a much larger face than that needed for ultra thin sections. As a result, more material, greater ease of operation, and serial ribbons can be secured. A glass knife with a smooth cutting edge is used and is adjusted with a metal or a tape boat. A metal boat is preferred since it presents a larger area. After mounting on the microtome, sections of desired thickness (150–500 nm) can be cut by setting the section indicator and observing the interference colour by adjustments of the water level and illumination (*see* Reid, 1974).

When a ribbon with 2–4 sections is cut, the sections are picked up with a damp, fine-haired, clean nylon brush and transferred to a drop of water placed near the edge of a subbed slide. The sections adhere to the end of the brush where the bristles are narrow rather than in the middle, where it would be difficult to separate the sections from the brush. The slides are then dried at 45 °C according to the schedule followed by Caro (1964), and at 60–80 °C according to Stevens (1966).

In order to locate specific regions in ultra thin sections, Stevens (1966) suggested a modified procedure. The block is trimmed in such a way that ultra thin sections can be obtained. A slightly better quality of glass knife is selected, without a scratch mark. First a thick section (120 nm) is cut and transferred to the slide by the method given previously, followed by several ultra thin sections (60–100 nm) which are shifted on the boat, prior to cutting another thick section of the original thickness. The latter is also mounted on the slide and both are observed. If the desired region is present in both the thick sections, the intervening thin sections are mounted on the grid, since the presence of the desired zone or material in the ultra thin sections has been ensured.

Stevens (1966) has adopted a method for handling the thinner and thicker sections alternately, employing a bent nichrome wire loop (4 mm in diameter and arm length 40 mm) with arm wrapped round a piece of glass tubing for handling. After a thick section is cut, it is brought to the centre with the aid of an eyelash, where it is picked up, together with a drop of water, by the loop which had previously been dipped in desiccate and dried. The section is then dropped on a slide by touching the water drop in the loop with a wooden applicator and fixed, and the same procedure repeated for the second thick section, after the ultra thin sections are cut.

When embedding has been done in methacrylate, it can be removed by the application of amyl acetate for a few seconds. The section may be marked with a diamond pencil on the underside of the slide. It is preferable to observe the very thin sections under the dissecting microscope and to mark the locations. Sections 200–500 nm thick may be even examined under phase contrast microscope without staining and comparatively thinner sections (150–200 nm) may be examined following staining with aniline dyes, like Azure A, which gives very good results with epoxy-embedded preparations. Since aniline dyes activate silver halide crystals, sections which can be spared should be stained prior to autoradiography or otherwise, other stains should be applied. To find out the exposure time needed for ultra thin sections,

2–4 days exposure on 0.4 μm sections gives an approximate indication.

Swift (1962) noted that suitable preparations of rat liver can be obtained if the tissue is fixed in 10 per cent formalin in 0.2 M phosphate buffer (pH 7.4), or 10 per cent acrolein in phosphate or tris buffer which prevents damage due to polymerisation. It also avoids the limitation of osmium fixation which is that it causes basophilia in proteins, through combination with the amino groups. He advocates freezing after fixation and cutting sections 50 μm or so thick in a freezing microtome, followed by treatment with buffered osmium tetroxide (pH 7.6) for 2 h before embedding in vestopal or epon. Ultra thin sections, cut in the ultramicrotome in the usual manner, can be mounted in carbon-coated titanium grids and stained in 3 per cent uranyl acetate for up to 4 h, and washed in water to secure contrast between chromosomes and nucleoli.

Stevens (1966) has listed the different stains compatible with the different embedding media generally used (*see also* Agar, Alderson and Chescoe, 1974; Meek, 1976).

Coating with emulsion and observation

The emulsion, either K5 or L4, is first prepared by taking equal volumes of K5 and distilled water and melting at 45 °C for 10–15 min, stirring and cooling for 30 min. The slide is dipped into it, the excess emulsion should be drained off and the slide clamped vertically against a stream of air. A safelight may be used during the process. Occasionally, on prolonged storage, background grains may develop in the emulsion; these can be eliminated by treatment with H_2O_2 vapour (3 per cent) in a moist chamber for 4–6 h and storage in a dark slide box at 4 °C for the required period. At the time of developing, the slides are transferred to a staining jar, brought down to 20 °C, developed in Kodak D-19 developer (2 min for K5, 4 min for L4), rinsed in 1 per cent acetic acid for a few seconds, fixed in Kodak Rapid Fixer for 5 min and then washed. To check fogging, 0.01 per cent benzotriazole in D-19 may be used. Observations may be made under a phase contrast microscope in glycerine. Stained preparations can be examined in an ordinary microscope. Removal of the gelatin, if required for observations under phase contrast, may be carried out by treatment with very dilute NaOH solution.

Swift (1962) preferred an application of 1 per cent potassium permanganate solution before washing in dilute citric acid and water, for Vestopal-embedded materials. He used, for emulsion-coating, a week's exposure to Ilford G5 liquid emulsion at 40 °C (1 : 15 diluted) before developing in Kodak D-19 developer.

Coating of ultra thin sections

Sections embedded in methacrylate, epon, araldite or Vestopal may be used. The success of the operation principally depends on obtaining a fine compact monolayer of silver halide crystals. With increase in the thickness of the layer, the sensitivity increases, at the cost of resolution. Selection of a proper emulsion is one of the most important factors in high resolution autoradio-

graphy. Its sensitivity depends on the extent to which it can register and develop the latent images formed by electrons in their path on silver halide and it is measured by the number of grains developed per unit distance in the track of particles with minimum ionisation. The particle energy and the distance the electron has to traverse through the silver halide, controls the formation of the latent image. Normally, of the isotopes used; ^{32}P, ^{131}I, ^{14}C and ^{35}S have long range ionising particles. With tritium (^{3}H), nearly all electrons emitted into the upper hemisphere can be developed. During exposure, oxidation of the latent image severely affects sensitivity. Protection against oxidation becomes essential with smaller crystals and fine-grained development. For β particles, Pelc, Coombes and Budd (1961) have suggested a 10–50 nm crystal size as suitable. With tritiated compounds, the problems of sensitivity and resolution are not so severe as the emitted β-particles are heavily scattered within one silver halide crystal of Ilford L4 emulsion. With finer grained emulsions, such as Gevaert 307 or Kodak NTE, (crystal size 50 nm), multilayered crystals add to the sensitivity. Caro (1962) has recommended Ilford L4 (crystal size 120 nm) for electron microscopic and Ilford K5 (crystal size 180 nm) for light microscopic autoradiography. A close-packed monolayer of silver halide adds to resolution by preventing the spread of electrons from the source.

For mounting the sections, both the collodion film and the sections must be perfectly smooth. Electroplated Athene-type copper grids are used for coating with collodion with a thin carbon layer (Caro, 1962). For extra strength, the grids are generally covered with 0.25 or 0.5 per cent parlodion-carbon and dried (Stevens, 1966). A thin film is spread so that resolution is not hampered and at the same time, breakage is avoided during the procedure. Sections are mounted on the grid which is added at one edge by a piece of scotch tape (double coated) to a slide. Several grids can be placed on one slide.

Various methods have been proposed for applying a uniform layer of emulsion. It may be applied, either by dipping the slide in the emulsion or dropping it on the slide (5 ml of distilled water per 1 g of emulsion, Hay and Revel, 1963; Granboulan, 1963; Koehler, Mühlethalar and Frey-Wyssling, 1963; Salpeter and Bachman, 1964; Young and Kopriwa, 1964). A thin layer may be allowed to form on a specially constructed loop before applying on specimen grids (Caro and Van Tubergen, 1962; Moses, 1964). The emulsion may be centrifuged directly on the specimen grids (Dohlman *et al.*, 1964) or may be finely layered on agar before application on sections (Caro, 1964.) Salpeter and Bachmann (1964) and Salpeter (1966) suggested the preparation of a substrate of uniform property before applying the emulsion and recommended the formation of the emulsion layer on a fine layer of carbon or silicon monoxide, dried on sections mounted on collodionated glass slides. Caro (1964) suggested two ways of applying the emulsion. In the first one, a 50 per cent solution (5 g/10 ml) of Ilford L4 is prepared by stirring in distilled water at 45 °C. The solution is cooled for a few minutes in an ice bath, followed by cooling at 20–24 °C for 30 min. In emulsions like Kodak IVTE, containing too much gelatin, it is better to dissolve 1 g in 10 ml of warm distilled water, followed by centrifuging till a clear supernatant is obtained (about 14000 g for 10 min). The rotor of the centrifuge should first be heated to help separation of gelatin. The super-

natant is decanted and the precipitate chilled. This concentrated emulsion should be dissolved in 1–2 ml of water (Salpeter, 1966). A thin platinum, silver or copper wire may then be dipped in the viscous solution and a thin layer should then be allowed to form round it, which, when touched on the slide, forms a fine layer. If the viscosity is lower or higher than that required, a period of cooling or warming may be necessary. The amount of emulsion in the loop should be adequate, otherwise the distribution of silver halide crystals would be uneven, resulting in different thicknesses in the emulsion layer.

In another method (Caro and Van Tubergen, 1962; Caro, 1964) the use of forming a thin layer on agar has been shown again. A thin layer of agar in a petri dish may be prepared from a 2 per cent solution of agar in distilled water and stored in a cool place to harden. Small rectangular pieces (2 × 3 cm) are cut and placed on slides, previously dried by slight warming. A solution of 0.2 per cent parlodion in amyl acetate is then applied. The slides can be dried in a vertical position and kept in a dark room where the subsequent operations are performed. A 25 per cent solution 91 for L4 emulsion is prepared in water and cooled at 20–24 °C. A thin film of emulsion, taken on a loop as described previously, may be applied to the agar surface. According to Caro, this method eliminates the limitations of artefacts due to drying because of the percolation of moisture from emulsion to agar and results in a fine, uniform layer. The whole composite structure would then float in water, the emulsion lying on the upper surface. Sections on grids, but not having the supporting membrane, are then fitted, in a fine-meshed metal screen, in water and brought below the composite membrane. They are carefully lifted out of the water, dried and fixed on slides as usual.

Stevens (1966) has outlined a method for applying emulsion, in which thoroughly clean and dry glass rods with rounded tops are placed in filler blocks. A small piece of adhesive tape is scraped and placed on the top of each rod to hold the grid containing the section, which is then laid on the top. One grid may be placed on each rod. The rest of the operation is performed in the dark room. Ilford L4 emulsion (2 g in 10 ml) is melted at 42 °C in a water bath and then diluted with water added in nearly equal proportions, cooled in an ice bath and kept at 32–34 °C. A wire loop is then coated with emulsion, the excess being wiped off in a kimwipe. After the formation of proper interference colour in the upper half (as mentioned below), the gelled emulsion in the loop is brought on the grid and can then be coated with a monolayer and stored in a sealed dark chamber.

Thickness of emulsion layer

The thickness and uniformity of the emulsion layer should be checked by the interference colour, based on the principle that interference colours of emulsion layers in reflected white light depend on their thickness. This can be viewed even in the dark on density differences using a yellow safe light (Filter AO). Interference colour is not only an index of thickness of emulsion but the uniformity of colour also indicates uniformity of the emulsion layer, as against patchy colour indicating unevenness. This observation has been confirmed even at the level of the electron microscope. The refractive indices

of collodion and plastic being close to that of glass, the underlying film does not affect the interference colour. Following an inferometric determination of thickness, Salpeter and Bachmann (1964, 1965) and Salpeter (1966) have formulated a table on the basis of which emulsion thickness can be worked out by interference colours (*see* Bachmann and Salpeter, 1965).

The most appropriate method for ascertaining the thickness needed for quantitative work is to use a developer (Devtol) which does not affect silver halide crystals. After developing, and prior to fixation, the slides can be air-dried and viewed in white light for interference colours. It is always desirable to use Dricrite in the storage chamber to keep the slides dry. The time of exposure has to be deduced from the time required for thicker (0.5 μm or so) sections as mentioned above.

Check against background effect and loss of sensitivity

Before photographic processing, it is always necessary to eliminate background effect, if any. With crystals too small to be resolved under light microscopy, such as those of Ilford L4, the background must be checked under the electron microscope. Background grains generally result from latent images being formed by some outside effects, such as, light, heat, radiation, or some chemical agents, and are manifested in the form of fine grains indistinguishable from the effects of β-particles on silver grains. In order to remove the background effect (Yagoda, 1949), immediately when the emulsion is dried, the slides are kept inside a pair of staining dishes lined with filter paper moistened with 3 per cent hydrogen peroxide solution. Care should be taken to see that the slides do not touch the solution and the chamber is kept air-tight. The background effect can be completely removed after about 6 h treatment. Since hydrogen peroxide oxidises all latent images including those given by β-particles, it is necessary that the vapour treatment be performed just at the beginning of exposure. Caro (1964) demonstrated that, following such a procedure, grains developed in preparations incorporated with leucine —^{3}H, uridine —^{3}H or thymidine —^{3}H were not affected. Stevens (1966) suggested a control preparation to check against the background effect. This method principally involves a control preparation using Parlodion–carbon-coated grids without sections and developing the coated grids just after application of the emulsion. Only a few reduced grains can be seen in a monolayer of emulsion and they do not increase if kept in an air-tight box even up to five months. If the emulsion is not shaken, or exposed to chemicals, heat, and stray radioactivity and the apparatus is kept scrupulously clean, there is no necessity to check background effect, at least with Ilford L4.

In addition to affecting the background, improper storage may influence sensitivity of the crystals and cause obliteration of the latent image. The disappearance of the latent image is mainly caused by oxidation of the particular silver grains. It has been seen that storage in CO_2, nitrogen (Herz, 1959; Ray and Stevens, 1953) and low temperature (LaPalme and Demers, 1947) minimises these adverse effects. However, storage in CO_2 has been shown not to affect the sensitivity to a significant extent with K5 and L4 (Caro, 1964; Herz, 1959). Storage in air of Kodak emulsion for a pro-

longed period (two months) resulted in 60 per cent loss in radiosensitivity, whereas in helium this loss was not noted (Salpeter, 1966). According to him, Ilford L4 does not show any change in sensitivity either in air or in helium.

Developing

After adequate exposure, developing of the photographs should be carried out in clean and dustfree conditions. The use of developer is meant to reduce the exposed silver bromide crystals, carrying the latent image, to metallic silver. It is always necessary, by trial, to find out the optimum period of development which would permit the maximum number of grains to be developed with least background effect. The grids must always be kept in absolute ethanol for 3–4 min before developing. This hardening schedule is an essential step as it checks the sudden swelling caused by aqueous developer and the resultant loss of grains. In all the steps followed for taking electron microscopic autoradiographs, the problem of contamination is a serious one. To check against this limitation, it is always necessary to use a small quantity of fresh, filtered solution for each plate.

Several developers are in vogue and their adequacy depends on the type of emulsion used for coating. Different types of physical and chemical developers are available and the processing is carried out at 20–24 °C. From a look at the developed grains of the latent image, it is rather difficult to locate the exact path of the particles, as in a single crystal of silver halide, at least three images from a single tritium decay have been found. *Chemical developers, which reduce silver halide crystals* result in a coil of silver filament of 0.3–0.4 μm diameter in certain developers like D19, or a long filament as in Microdol X. Since the latter is comparatively easier to interpret in that the initial image may be considered in the middle of the line, it is often preferred (Caro, 1964). Stevens (1966) has suggested a procedure in which Athene-type grids are placed on filter paper for drying after being lifted from ethanol with forceps. The dried grids should be floated in an inverted position on the convex surface of the developer and kept for 6 min at 22–24 °C. After immediate transference to a watch glass containing distilled water, for a few seconds, the grids should be placed in the fixer with the sections facing upwards. The fixer effectively removes all unexposed silver halide crystals and helps in the later removal of the gelatin. Budd (1964) noted that fixers with hardeners cause the emulsion to become brittle and fibrous. After 10 min, the grids should be rinsed in water for 5 min, washed by flushing with distilled water, dried and kept in a dust-free chamber.

With *physical developers*, the highest possible resolution can be obtained. The principle is to *dissolve completely the silver bromide crystals*, only the latent image with silver ions is kept, with the use of 1.0 M sodium sulphite and 0.1 M 4-phenylene diamine, on silver nitrate in varying proportions. (Lumière, Lumière and Seyewez, 1911; James, 1954; Caro, 1964). Development for even 1–2 min at 20 °C is sufficient. This developer is, however, comparatively unstable. With this method, the latent image can be localised with the least possible error and caution is needed because grain size is very small.

Lastly, the gelatin can be dissolved through proteolytic enzymes, such as pepsin (Hampton and Quastler, 1961; Comer and Skipper, 1954; Przybylski, 1961), alkali (Revel and Hay, 1961) or warm water after fixation at 37 °C for 16 h (Silk *et al.*, 1961).

Staining

The gelatin may or may not necessarily be dissolved for staining after the photographic processing is completed. Staining can be performed even before applying the emulsion. In the former case, the gelatin is dissolved by proteolytic enzymes, like an acidic solution of pepsin (Comer and Skipper, 1951; Hampton and Quastler, 1961; Przybylski, 1961) but this method has an inherent limitation in that undigested grains and autoradiographs often look alike and there is a possibility of the loss of grains. Fixation in warm water at 37 °C for 16 h has been recommended by Silk *et al.* (1961) but according to Stevens (1966), this method is yet to be tested with Ilford L4 emulsion. Another procedure (Hay and Revel, 1963; Revel and Hay, 1961) combines gelatin removal and lead staining (Karnovsky, 1961) and yields very satisfactory results but it should also be applied with caution, to check against grain displacement. In Revel and Hay's method (1961), ^{3}H—thymidine incorporation in interphase chromatin fibres of *Amblystoma* larvae was studied.

In order to avoid the limitations caused by removal of the gelatin, Caro (1964) stained the specimens for 10–15 min in a solution containing 1 per cent uranyl acetate and absolute ethanol, to have a final concentration of 30 per cent ethanol (Gibbons and Grimstone, 1960). However, it was applied in methacrylate embedded bacterial material. A serious drawback of keeping the gelatin intact is the possibility of disruption of the grains through shattering of the gelatin layer by the electron beam. The removal of gelatin may be carried out by sublimation by gradually increasing the intensity of electron beams (Moses, 1964). The accuracy of this method is often minimised by the possibility of artefacts—and the risk involved in sublimating the silver grains (Stevens, 1966). In the case of certain stains, such as methylene blue, difficulties arise in securing staining intensity, which requires a temperature of 60 °C before applying the emulsion. The result is excessive background effect due to the reduction of the emulsion by the stain. Hendrickson, Kunz and Kelly (1968) suggested NaOH treatment in addition to HIO_4 (Richardson, Jarett and Finke, 1960) prior to applying emulsion. Both treatments enhance stainability. Stevens (1966) followed a modification of Granboulan's technique in which, prior to staining, gelatin was first dissolved by acid hydrolysis.

In this schedule the grids are first floated for 30 min on the convex surface of distilled water, kept at 37 °C and then transferred to 0.5 N acetic acid at 37 °C and kept for 15 min, followed by rinsing in a stream of distilled water and then floated in a second change of distilled water at 22–25 °C for 10 min. The staining is performed by first wetting the sections with a drop of distilled water, staining in an inverted position in 7.5 per cent aqueous uranyl acetate for 20 min at 45 °C, subsequent drying on filter paper, wetting again with distilled water and then further staining with 0.2 per cent lead citrate for

10–60 s to a few minutes (Reynolds, 1963; Venable and Goggeshall, 1965). It was suggested that uranyl acetate changes the properties of the macromolecules in such a way that they bind better with lead citrate. In order to avoid the possibility of removing or damaging the silver grains. Salpeter (1966) suggested a method of staining prior to the application of the emulsion. In the schedule followed, a few drops of lead stain, or lead citrate (Fiske, 1966) staining for 5–30 min preceded by aqueous uranyl acetate or uranyl nitrate (Reynolds, 1963) may be added to the sections on the slide and the excess stain immediately flushed off with a stream of distilled water. Evaporation of a carbon layer (5–10 nm Union Carbide SPK spectroscopic carbon) over the sections is necessary for screening the stained sections, and the emulsion, and also for providing a base for the emulsion layer.

Caution is desirable, as a thick layer of carbon may prevent proper resolution. The period of lead staining requires shortening too as dense deposits may otherwise be formed (*see* Fakan, 1978).

An excellent combination of high resolution technique with chromosome banding procedure has been adopted by various workers. Crossen, Sen-Pathak and Arrighi (1975) cultured Chinese hamster cells for 1^+, 2^+ cell cycles in presence of BrdU and treated for sister chromatid exchange staining. It may be concluded that *G*-bands may represent clusters of replicons capable of initiating simultaneous DNA synthesis.

In conclusion, it may be stated that the method of high resolution autoradiography as outlined above, with its limitations and advantages, leaves scope for improvements in every step of its methodology. Even so, its superiority over conventional autoradiography is principally reflected in its extremely high resolving power, capacity for strict identification of macromolecular structures in terms of function, and lastly, exceptional contrast in photographs of silver grains and cell structures. As the advantages far outweigh the limitations, which are on their way to refinement, the potentialities of this aspect of biological research are difficult to overestimate.

MICROSPECTROPHOTOMETRY

UNDER ULTRAVIOLET LIGHT

Principle and instrumentation

Ultraviolet radiation was applied, in Köhler's (1904) experiments, to utilise fully the accelerated resolution of numerical aperture due to decreased wavelength. Ultraviolet light, in place of visible light, has the unique advantage of clarifying unstained living cells, due to the strong ultraviolet absorption by nucleoprotein (Caspersson, 1936; 1950; Caspersson and Zech, 1973). Moreover, it aids the quantitative estimation of the cell nucleoprotein owing to the characteristic absorption of purine and pyrimidine components of nucleic acid at 265 nm (Rudkin, 1966). A linear relationship between absorption and section thickness and the concentration of DNA has been clearly demonstrated in nuclei (Greenwood and Berlyn, 1968). Ultraviolet absorption spectra of cytological objects generally show absorption between 20–40 nm; nucleic acids at 260 nm, and proteins free from nucleic acids at about 280 nm.

The absorption of cellular components is principally attributed to covalent unsaturated groups such as C=O, C=N and N=O in organic compounds, i.e. purines and pyrimidines, indole groups of tryptophane, benzene and imidazole rings of tyrosine and histidine, respectively.

The principal difference between an ordinary light microscope and an ultraviolet microscope lies in the fact that in the latter, transparent fused quartz lenses are used in place of optical glasses, which are opaque to shorter ultraviolet wavelengths. The source of ultraviolet rays is generally the mercury vapour lamp. The slides and cover glasses are made of quartz and in order to secure a monochromatic beam, a quartz monochromator is fixed between the source and the microscope. The photographic image is obtained by using a photographic plate and a photoelectric cell. Focusing is generally performed in visible light or on a fluorescent screen (Loeser and West, 1962; Freed and Benner, 1964). Computation of the images can also be obtained (Ledley, 1964; Mendelsohn, Kolman and Bostrom, 1964; Meek and Elder, 1977).

Within the last ten years, the availability of excellent photographic devices, such as quartz fluorite refracting achromatic lenses, ultrafluors, powerful lamps, good monochromators, strong photomultiplier tubes, etc. has been responsible for outstanding developments in ultraviolet-microspectrophotometric studies. Photometric observation of microscopic objects, even after extraction through a micromanipulator, has been possible (Edström, 1964). A television pick-up system which is a very sensitive recording device, is also available.

As illuminator, the commonly accepted method is to have the source through the exit slit of the monochromator. The aperture of the condenser is generally kept at about 0.3 or less for good photometric work. Modern discharge lamps, such as hydrogen and deuterium lamps and low pressure mercury lamps, with good achromatic objectives, have replaced the original rotating electrode resonant metallic arc. Such lamps give a wide band at 254 nm and can be used with suitable monochromators or interference filters.

Most modern equipments, however, take advantage of Xenon compact arcs, which combine intensity with output through the ultraviolet range at 260 nm. In the monochromators meant for selecting the particular wavelengths, a band of energy is emitted whose wavelength distribution is controlled by the dispersion of the elements showing diffraction and refraction and the size of the slits. Several microspectrophotometers are equipped with grating monochromators where the change in wavelength is done by grating rotation. A number of interference filters have been developed, which serve not only as protective filters but also as wavelength selectors. Photography may be adopted for the integration of absorption of objects and the negatives may further be scanned through densitometry. Photoelectric recording is utilised for a study of the series of absorption spectra needed for each wavelength. The most convenient method is to allow the light to pass through a selected area for final recording in a photomultiplier tube. The intensities may be recorded at different wavelengths and the background intensity measured by removing the object and allowing the light to pass through the empty space. Good photomultiplier tubes of high efficiency (quantum efficiency 0.3) are manufactured.

In principle, to measure changes in the quantity of nucleic acid and protein, the microscope is generally used as spectrophotometer. The monochromatic beam of ultraviolet light may be split into two beams, in the split beam device, one falling directly on the photoelectric cell (the blank) and the other passing through the ultraviolet microscope to another photoelectric cell. The sample to be measured is placed in the path of the beam passing through the microscope. The light passing through the material is reduced in intensity; this is calculated by counting the difference in the photoelectric current yielded by the two beams, as indicated by a galvanometer. The data can also be electronically computed and televised.

The measurement of absorption is based principally on Lambert–Beer's law which may be stated as follows:

$$I_x = I_o \times 10^{-kcd}$$

where I_x is the changed intensity of the beam of I_o; I_o the incident intensity, after the ray passes d; d the thickness (in cm) of C; C the concentration (in g/100 ml) of the absorbing molecules; and K the extinction coefficient. As in cytomicrospectrophotometry, relative amounts are obtained, the constant K is ignored, since absolute values are not necessary. The value of K, when necessary, can be worked out from biochemical data.

In the method mentioned above, the values of I_x and I_o can be obtained without changing the position of the material. With the aid of these values, the percentage of transmission (T) can be worked out (I_x/I_o) and the presence of the components per arbitrary units, showing ultraviolet absorption, can be computed. A limitation of ultraviolet microscopy is that the ray may have some deleterious effect on the absorbing material, but in the above method the period of exposure to ultraviolet is very much reduced.

Zeiss–Caspersson ultramicrospectrophotometer UMSP–1 is commercially produced, based on Caspersson's model (Caspersson, 1965). The other types are, the Edinburgh microspectrophotometer with dual microscope, double beam (Walker *et al.*, 1963), Wagenar–Grand Instrument with single microscope double beam (Wagenar and Grand, 1963) and the Leitz microspectro-

graph (Thaer, 1965), in which the absorption spectrum is recorded through image formation with heterochromatic ultraviolet radiation, and light is then dispersed in a spectrograph, following the microscope, from a small region of the plane of the image. For details of ultraviolet microspectrophotometry and its modifications, the reader is referred to Pollister and Ornstein (1959), Mendelsohn (1966), Wied (1966), Freed (1969) and Meek and Elder (1977).

Methods

The fixing fluids for objects meant for spectrophotometric analysis require certain prerequisites in addition to the prevention of any loss or repatterning of structure. Such fluids should not affect the light scattering properties of the specimen and must not contain compounds which undergo deposition under ultraviolet rays. For the study of DNA, ethanol–acetone mixture (Zetterberg, 1966) or acid or *neutral* formalin fixation (Sandritter and Hartlieb, 1955) are suitable. In the case of RNA, however, most of the aqueous fixatives cause extraction of soluble RNA (Swift, 1966) and freeze-substitution method with ethanol–potassium acetate has been shown to retain soluble RNA (Woods and Zubey, 1966). Zetterberg and others (Killander and Zetterberg, 1965; Zetterberg, 1966) demonstrated that nucleoproteins can best be studied in cultured cells either by ethanol-freezing substitution or by chemical fixation with ethanol–acetone (1 : 1) at 4 °C for 24 h.

For a correct assessment of the absorbance data, it is desirable to follow the extraction of specific cellular components simultaneously. Such procedures, in addition to aiding identification of the absorption of particular chemical constituents, may also serve as controls. Further, the most significant use of extraction is to secure a *blank*, so that non-specific light loss and light scatter can be corrected. These purposes are served through digestion with proteases or nucleases, since extraction with acids may alter the absorptive properties (*see* Swift, 1966). In mounting the specimens in ultraviolet microspectrophotometric work, media like pure glycerine, glycerine–water mixture, 45 per cent zinc chloride and paraffin oil possess the essential prerequisite for checking the non-specific light loss (Caspersson, 1950; and *see* Freed, 1969).

Lastly, during the application of the ultraviolet rays, caution is recommended, since continuous exposure for even 10 min at 257 nm in a Köhler microscope may result in the loss of absorption capacity by the chromosomes treated with acidic fixatives.

Techniques for the ultraviolet microscopy of cells in culture have been developed to study conditions and changes *in vivo*, for which perfusion chambers with quartz cover slip windows are generally used (Freed and Benner, 1964; Petriconi, 1964). Modifications of Eagle's medium have been used for cell culture, which have to be replaced later by a salt solution transparent to ultraviolet rays. In the scanning procedure, improvements have been devised (Kamentsky, Melamed and Derman, 1965; Kamentsky and Melamed, 1967), in which large suspended cell populations are quickly analysed with the rapid cell spectrophotometer but the procedure does not allow intrachromosomal analysis.

Photometric observations through ultraviolet rays have also been extended

to chromosomes, or chromosome segments, extracted out of the cell with the micromanipulator (Edström and Beermann, 1962; Slagel and Edström, 1967). Micrurgical extraction of polytene chromosome has been dealt with in the chapter on micrurgical techniques. Extraction of nucleic acid through nucleases and the analysis of a drop of the extract has been made through microspectrophotometry. Methods have even been developed for the determination of base constituents in nucleic acid, extracted from incised segments of chromosomes. The extract is applied to a treated cellular fibre, through which the discharge of electric current results in separation of different ultraviolet-absorbing bands. The photomicrographs of these bands, following densitometric analysis, yield the quantitative values of the substances.

For the identification and quantitation of constituents in the chemical make-up of chromosomes, reliance on microspectrophotometry is continuously increasing and it is hoped that refinements in this last named method will ultimately lead to an understanding of the qualitative and quantitative differentiation of chromosome segments, even at the molecular level.

UNDER VISIBLE LIGHT

Microdensitometry or cytophotometry in visible light is based on the principle that between 400–700 nm light is partially absorbed by the matter due to interaction with outer constellation of electrons. This interaction mainly depends on the physical and chemical nature of the matter and the wavelength of the light. The process follows Bougner–Beer law which holds that the absorbance is dependent on the concentration of the matter and the path-length. It is expressed as logarithms of the reciprocal of transmitted light after absorption. It is in fact the optical density (OD) or extinction (E) i.e. $\log\frac{I_o}{I_s} = \text{OD} = \text{E} = \text{A}$. As the absorbance is dependent on the concentration of the absorbing matter, the technique has been adopted for quantitative estimation of cell *vis-a-vis* chromosome constituents. Absorption measurements are carried out on materials stained with Feulgen solution, methyl green pyronin, azure B, Millon dye and such other compounds capable of staining specific cell constituents (Pollister, 1952; Vendrely, 1955; Leuchtenberger, 1958; Pollister and Ornstein, 1959; Mendelsohn, 1966; Swift, 1966; Wied, 1966; Dutt, 1967; Welch and Debault, 1968; Pollister *et al.*, 1969; Berlyn, 1969; Wied and Bahr, 1970; Garcia, 1970; Jacqmard and Miksche, 1971; Cecich, Lersten and Miksche, 1972; Deaven and Peterson, 1974; Galjaard *et al.*, 1974; Gill and Jotz, 1974; Murray, 1975; Berlyn and Miksche, 1976).

For the fixation of materials, Carnoy's fluid or 10 per cent neutral formalin is widely used to measure chromosomal DNA. Greenwood and Berlyn (1968) studied the effects of formol–acetic–ethanol, Carnoy's fluid, Craf III, formaldehyde and glutaraldehyde fixation on cytophotometric studies and observed that Craf and glutaraldehyde had a depressing effect on the absorption peak and interfered with DNA extraction. Glutaraldehyde caused binding of the dye with the cytoplasm. Neutral 10 per cent formalin has been found to be very suitable, though digestion and extraction procedures were affected, unlike Carnoy's fluid.

Staining may be carried out in Feulgen solution or in pyronin–methyl green mixture or in any other specific dye for binding with nucleic acids or proteins. The method of staining is given in the chapter on staining. Mitchell (1967) has shown that dinitrofluorobenzene treatment may be combined with Feulgen procedure for measuring protein and DNA of the same cell. However, the fixation used, as well as the composition of the DNFB solution, and temperature, affect the coloration.

Microscope and accessories

The appliances needed for visible light photometric or densitometric work are quite simple (Pollister, Swift and Rasch, 1969). For example, in Leitz MPV, they include, in principle, a strong tungsten light source; monochromatic unit, fitted with condensing lens; a microscope (Aristophot) having condenser with low numerical aperture; phototube; measuring variable field diaphragm; a photomultiplier, a power supply unit and galvanometer. Alternate arrangements are available for observing specimens in ordinary light (without monochromator) as well as for photography. Similarly, through suitable accessories, the data can be recorded by a recorder or oscilloscope, instead of a galvanometer. In Reichert Zetopan photometer, interference filters are used in between tube and photocell over the microscope, instead of in monochromator. The guidelines for use are available with each model.

Method of analysis

As in ultraviolet microspectrophotometry, in taking measurements, the data required are the intensity of the background light (I_o) which is taken from a blank area on the slide, and the reduced intensity of light after absorption by the objective (I_s), the *transmission* being calculated as I_s/I_o. The transmission indicates the fraction of light that remains after loss by absorption. In a completely transparent object, this value is 1 and there is a logarithmic decrease in transmission with increase in absorbing molecule, due to concentration or thickness. Therefore extinction or absorbance is:

$$E = \log_{10}\frac{1}{T} = \log_{10}\frac{I_o}{I_s}$$

The above law is fundamental for all cytophotometric calculation. This law, developed for dilute solutions, holds equally well for all cytophotometric, i.e., densitometric observations if reactions are carried out under strictly controlled conditions (Wied and Bahr, 1970; Berlyn and Miksche, 1976).

From the optical density or absorbance data the mass of material can be measured on the basis of the fact that what is obtained in cytophotometry is transmittance (T). In conversation to mass (M), the following equation is adopted: $M = \dfrac{A \log 1/T}{K}$ where A is the area (πr^2, of which π may be omitted) and K, the extinction coefficient. The K is a function of the wave-

length and in relative mass determination, K being constant, this value is also not needed in calculation. This method holds good for homogeneous samples such as interphase. But in densitometry the spatial heterogeneity of the specimen presents 'distribution error' which is quite common to non-uniform microscopic materials such as the distribution of chromosomes. More precisely, it is due to unequal distribution or heterogeneity of DNA in the nucleus. In such cases, the total absorbance of a projected area is dependent on the total amount of such materials present in the projected area. As such it should be the sum total of the absorbance of individual units within the area. To some extent, the distribution error is corrected by measuring the transmission at two different wavelengths (Patau, 1952; Patau and Swift, 1953; Mendelsohn, 1966; Mayall and Mendelsohn, 1970) as outlined below.

The prerequisite of the two-wavelength technique of absorption analysis is the uniform illumination of the area with a monochromatic source and absence of light scatter through the use of proper mounting medium. In Feulgen-stained sections, it is desirable to carry out the analysis on the same slide, since acid hydrolysis—an essential feature of Feulgen staining—affects the reaction to a significant extent. The method of analysis is as follows (Pollister, Swift and Rasch, 1969):

If the two wavelengths selected are λ_1 and λ_2, the extinction (E_1) at the former should be half the extinction (E_2) at the latter, so that $E_2 = 2E_1$. As mentioned above, $E_1 = \log\frac{I_o}{I_s}$ at λ_1, and $E_2 = \log\frac{I_o}{I_s}$ at λ_2. Choice of the proper wavelengths is important. The total amount of absorbing material (M) in a measured area (A) is, $M = KAL_1D$, where K is constant; ($K = \frac{1}{e_1}$, e being the extinction coefficient in λ_1, K may be disregarded for relative determination in cell microspectrophotometry); L_1 is respective light loss and D is the correction factor for distributional error. Area (A) is measured as πr^2 where π may be omitted (Pollister, Swift and Rasch, 1969). From transmissions T_1 and T_2, at λ_1 and λ_2, the degree of light loss may be worked out as follows:

$$L_1 = 1 - T_1 \text{ and } L_2 = 1 - T_2$$

With the ratio L_2/L_1 at hand, the value of D can be worked out from *Table 9.2* given by Garcia (1962), given with detailed principles. The following table taken from Pollister, Swift and Rasch (1969) gives the value of D corresponding to each L_2/L_1 ratio:

In Mendelsohn's method, the value of La C can be worked out from any two transmissions and the value of L_1 D can be obtained by dividing it with 0.868, since $D = 0.868C$, where the values for C have been tabulated by Patau (1952). The two-wavelength method should always be followed for studying the distribution of DNA in non-homogeneous materials.

The best method to avoid distributional error is to take 'integrated aborbance'. As the mean of the logarithms is not equivalent to the logarithms of the mean it is always desirable to scan absorbance from each individual

Table 9.2 Values of D for different values of L_2/L_1

point and to integrate the data (Welford, 1972; Goldstein, 1977). This purpose is achieved in integrating the microdensitometer, in which the transmittance signal, after allowing the light to pass through the photo cell, is connected through the electronic analogue computer into the corresponding absorbance value. The systematic scanning of the specimen can be done by keeping the illuminated area constant and moving the specimen or *vice versa*, the data being indicated in an oscilloscope or pen recorder. The absorbances can be instantaneously recorded electronically and finally the integrated absorbance free from distribution error is obtained. To secure accurate data on integrated absorbance, it is always desirable to have smears or squashes for a monolayer, and avoid the error arising out of stray light or glare by restricting the area of illumination. Normally tungsten lamp is used as the light source and grating or prism monochromator or interference filters are fitted to secure light of proper wavelength. The method of detection and correction, if possible, of microdensitometric errors arising out of lamp and monochromator system, has been outlined by Goldstein (1975).

Different types of microdensitometers are now available (Altmann, 1975) designed with the same objective but they differ with regard to their mechanism of operation. The difference mainly lies in the system of scanning. They can be classified under two categories: (a) in which the object is stationary and the scanning is done along the whole length of the object and in the other, (b) the object is moved with a motor-driven stage and the measuring area is fixed. The moving object densitometers are manufactured by Zeiss, Leitz, etc. while in the instruments of Vickers, Barr and Stroud, the specimen to be scanned remains stationary. In the Barr and Stroud type, the image of the object is enlarged and scanned by a mechanical device, whereas in the Vickers model the fixed object is scanned by moving the reduced image of an illuminated aperture with the aid of a pair of oscillating mirrors. In more sophisticated televised models, a television camera receives the image which is electronically scanned.

The advantage of moving object densitometer is that it permits a wide range of scanning through incident illumination, fluorescence and ultraviolet light because of the interchangeable components and scanning mechanism operating on the microscope stage. The densitometric data can be fed into computer as well. The process however is rather slow because of the motor

driven nature of the stage. The stationary object densitometers are comparatively inexpensive and are fast in operation. The Vickers models are quite flexible in several respects and have the advantage of utilisation for dry mass scanning through micro-interferometry (Goldstein, 1977) with suitable adjustments. Gradual refinements in models have also resulted in high resolution scanning densitometry from photographic negatives of individual chromosomes (Ploeg, Van Duijn and Ploem, 1974).

Use in fluorometry

The principle of microscope photometry can be advantageously employed for fluorescence quantitation as well (Nitsch, Murken and Brück, 1970; Latt, 1974; Prenna, Mazzini and Cova, 1974a, b; Ploem, 1977). The energy of fluorescent light being much less than that of ordinary transmitted light, it is always desirable to use incident illumination (through suitable accessories) —the illuminating lens being the objective itself. A xenon arc lamp may serve as the source of light. In order to secure large optical flux (Piller, 1977), it is desirable to use a fluorite or apochromat objective with a high numerical aperture. Automatic switchover device from low power transmitted light to fluorescence light for measurement (Ruch and Trapp, 1974) is also available. The illuminated field should be large but should not exceed the area to be measured as illumination of other objects may cause change in fluorescence of the specimen to be measured. The immersion medium should also be free from any fluorescence effect.

For fluorescence analysis of chromosomes, it is necessary to get an integrated value of the intensity of the whole fluorescence spectrum. The transmission is obtained also from the barrier filter and the photocathode is so chosen as to be responsive to the entire spectrum. If necessary, spectral distribution of fluorescence can be measured by attaching a continuous spectrum monochromatising device, and a suitable photocathode with a wide range of response (Gijzel and Schwirtlich, 1977).

It is always desirable to take the fluorescence measurement immediately and to keep the specimen protected from light before illumination. This is necessary as there is alteration of fluorescence under illumination and the intensity decreases with time. The chromosome bands for example, lose their identity with continuous illumination. For recording of measurements, a fitted oscilloscope is very suitable. This method has proved to be very advantageous in locating functionally differentiated segments of chromosomes in different mammalian systems (*see* Caspersson and Zech, 1973; Thaer and Sernetz, 1973).

Methods are also available for high speed quantitative karyotyping by flow microfluorometry (Gray *et al.*, 1975). The technique involves isolation of metaphase chromosomes from cells, staining with a DNA specific fluorochrome and measuring for stain content at the rate of 10^5/min in a flow microfluorometer. The results tally well with scanning cytophotometry.

Use in measuring micro autoradiographs

As discussed in chapter on autoradiography, radiation from tagged radio active precursors, such as tritiated thymidine, for DNA of chromosomes, results in accumulations of silver grains following exposure and developing in autoradiography. As the number of grains is proportional to the amount of radioactive material present, its quantity can be measured with transmitted or preferably with reflected light (Przybylski, 1970; Dormer, 1973).

In measurement of micro autoradiographs, the homogeneous dispersion, low density and uniform size of grains are essential otherwise masking effect results in erroneous data. In order to work out a *linear relationship between the number of grains and measuring value*, it is necessary to prepare a reference graph. The relationship between the two is counted in relation to a standard reference substance, the calibration is expressed in an equation, represented graphically or computerised (Pillar, 1977). For light source, it is preferable to have white light and monochromator is not necessary. The linear relationship is measured on the basis of the following equation:

$$N_{sp} = \frac{G_{sp}}{G_{ref}} . N_{ref}$$

where N = no. of grains, G = measuring value, *ref* = reference material and *sp* = specimen. This technique allows the measurement of the path of a tagged precursor of a chromosome metabolite in different steps of organ differentiation.

Conclusion

The significant advantage of microscope photometry or densitometry over other methods of quantitation is its capacity of *in situ* localisation of cell *vis-a-vis* chromosome constituents. It is absolutely free from inherent limitations of isolation techniques which may not exactly represent the conditions *in vivo*. The microdensitometric or photometric method has proved to be a very inexpensive tool for working out the quantitative correlation of DNA with the number of genomes present (Berlyn and Cecich, 1976) and also the cycle distribution of the genic material at different phases of development and growth (Evans *et al.*, 1972; Stöhr, 1975; Sharma, 1976; Banerjee and Sharma, 1979). Through suitable methods, it has been possible to detect nuclear protein as well (Gaub, Auer and Zetterberg, 1975). The universal applicability of densitometric method in future would depend on the invention of a number of stoichiometrically viable specific staining reactions of chromosome constituents, other than deoxyribonucleic acid.

Study of plant chromosomes from tissue culture

Evolution from lower to higher organisms has been associated with specialisation in anatomical details and complexities of internal environment. This internal environment has a specific constancy—though it is endowed with a certain degree of flexibility—which does not undergo considerable changes, even when exposed to a variety of external conditions. Constancy of a complex internal environment is the result of specialisation in evolution.

In this complex environment of cells, the application of any physical and chemical agents or the accumulation of certain metabolites *in vivo* initiates a series of reactions and interactions at the level of cells, tissues and organs, and such reactions are difficult to analyse as they must be studied *in vivo*. Tissue culture technique allows the cultivation of cells, tissues and organs *in vitro* in natural medium or in artificial medium, but reproducing as far as is practicable the conditions *in vivo*.

The technique of tissue culture has immense application in the study of biology in general, and cytology and cytochemistry in particular. In the first place, it allows an analysis of the effects of different physical and chemical agents on the cell of the blood or vascular supply, the importance of which cannot be over-estimated as it gives an understanding as to how far the effect is exerted directly on the cell or is influenced during transport. The effect of a physical or chemical agent on an organism is studied under ordinary conditions after the manifestation of a visible expression, but one of the limitations of this method of approach is that it only allows an analysis of the end-product, and no direct understanding can be obtained of the *modus operandi* as the visible expression is, in principle, many steps ahead of the initial reaction. Tissue culture, on the other hand, allows a complete analysis of the sequence of reactions from the initial stage, and also of the chromosomal mechanism involved in the operation.

Secondly, the mechanism of differentiation can be directly understood only through tissue culture. The cultivation of one morphological type of tissue having the capacity of unrestricted growth offers immense scope in the study of differentiation. Differentiation involves the development of different organs from a tissue potentially capable of giving origin to various tissues during its growth and development; consequently, the culture of this type of tissue *in vitro*, and an analysis of the chemical, morphological and chromosomal behaviour associated with the transformation into different

organs, is considered to be a reasonable approach towards understanding the exact mechanism involved in differentiation.

In the study of cytogenetics in relation to plant breeding, tissue, and embryo, culture has acquired the status of a routine technique in the laboratory. The importance of tissue culture lies principally in its capacity to secure rapid propagation of disease-free clones and of embryo culture in the production of interspecific hybrids and overcoming the incompatibility barrier. The potentiality of protoplast culture in foreign gene incorporation and of pollen culture in the production of haploids is immense. The significance of the totipotency of plant cells in regeneration of whole plants can hardly be overestimated (*see* Vasil *et al.*, 1979).

The most congenial medium for the growth of an organ or tissue is obviously the natural medium of the object concerned. Regarding the preparation of a synthetic medium, the requirements for plants are quite simple and precisely known, and with a gradual understanding of the growth factors in terms of vitamins, nitrogenous substances, hormones, etc., the preparation of a good synthetic medium for the culture of plant tissues has become quite an easy task. Owing to the plastic and versatile nature of their metabolism, plants can utilise very simple molecules for the synthesis of complex substances. Thus it is easier to prepare a synthetic medium containing, principally, sucrose, a mixture of vitamins, glycine, etc., in addition to an inorganic salt mixture, for the cultivation of plant cells *in vitro*.

The presence of a rigid cellulose wall in most of the lower and all higher plants provides another difficulty in the culture of plant cells. In the *in vivo* condition, the presence of plasmodesma and other living factors, which cannot necessarily be reproduced exactly *in vitro*, help in the process of transport and uptake of food between cell and cell; therefore under cultural conditions the access of food at intracellular sites is a problem which needs constant attention.

White (1934) first invented the 'organ culture' technique and successfully cultivated excised roots of tomato *in vitro*. Nobecourt (1937, 1939) and Gautheret (1934, 1939) were pioneers in developing methods for unlimited cultures of undifferentiated materials, raising cambial tissues of tobacco and carrot *in vitro*. White (1939) also cultured tissues from tumours or from fleshy organs composed of undifferentiated parenchyma. Gradual development of the tissue culture method has led to the evolution of techniques for culturing hybrid embryos and also for cultivating sterile crown gall tissue of plant cancer. The methods have been developed and refined to such an extent in later years that even free cells, small cell clusters, special portions of a colony, for example of carrot (Steward, 1958) and *Haplopappus gracilis* (Blakely and Steward, 1961) can all be cultured *in vitro*.

PRINCIPAL STEPS INVOLVED IN TISSUE CULTURE

Due to the restricted nature of growth in certain specialised and local regions, not all the tissues and organs form convenient material for cultural studies. The highly active growing points, such as apices of stem and root, buds, lateral cambium, intercalary meristems, leaf meristems, phloem tissues, etc., provide excellent materials for tissue culture. Pollen, embryos and endosperm

of higher plants, as well as spores and prothalli of lower groups, do not present much difficulty in culturing in a suitable medium (Mehra, 1961). Even flowers, fruits, excised leaves and seed primordia have been cultivated (White, 1954). Phloem tissue of carrot and tomato root, *Haplopappus* stem and pith callus of tobacco, provide ideal materials for study. Dicotyledons appear to be more responsive to callus initiation (Nitsch and Nitsch, 1956; Butenko, 1964; Witham, 1968; Nitsch, 1974; Staba, 1977) from various organs than monocotyledons (Morel and Wetmore, 1957; Trione, Jones and Metzger, 1968; cf. Krishnamurthi, 1976), gymnosperms (Reinert and White, 1956), ferns (Kato, 1964) and bryophytes (Ward, 1960).

One of the important factors in tissue culture is the apparatus used for cultivating the tissue *in vitro*. The different techniques adopted for the explants are based on the same principle, the chief differences being the type of container employed for the purpose. They can be classified under three categories, (a) hanging drop, (b) flask and (c) watch-glass and petri dish techniques. All three different methods are practised for different animal and plant materials and each has separate advantages and disadvantages. Modifications of the different methods have been made on the basis of the requirements of long- or short-term growth or the convenience of observation, and in this connection it should be noted that sub-culture from the primary explant is an essential step in tissue culture. The apparent peripheral expansion of a tissue in culture does not necessarily signify growth of the tissue, as the interior cells of the original tissue may often shift towards the periphery, and no new growth occurs; thus sub-culturing at this stage is fruitless. In order to be certain of tissue regeneration, the best method is to weigh the culture at specific intervals, but other alternative methods are also applied. An increase in weight denotes growth.

The necessity of maintaining strictly aseptic conditions in all phases of tissue culture, including sterilisation of the object, tools, medium, etc., is obvious: contamination at any stage may not only spoil the culture but also give erroneous data (Monant, 1957; Streissle, 1971). Strictly aseptic conditions and regulated temperature and growth are essential for successful tissue culture, and in cases of difficulty in maintaining a well-equipped large laboratory for tissue culture, all the steps necessary can be carried out in small chambers in which temperature, humidity and sterility are strictly controlled. For details of the set-up needed for a tissue culture laboratory, the reader is referred to the treatises by White (1954), Randolph and Randolph (1955), Paul (1959) and Willmer (1965) and for principles, to the review by White (1959), and Reinert and Bajaj (1977).

An outline of the different types of culture methods for the cultivation of tissues is now given.

Several chemical agents are used for tissue sterilisation, the most common ones being calcium hypochlorite (9–10 per cent), sodium hypochlorite (2 per cent), mercuric chloride (0.1–1 per cent), hydrogen peroxide (10–12 per cent), bromine water (1–2 per cent), silver nitrate (1 per cent) and antibiotics (4–50 mg/l). To accelerate sterilisation, occasionally light detergent solution (0.05 per cent Teepol or Lissapol F) may be employed (Street, 1977). Sterilisation is to be performed for explants, seeds, fruits, or any organ or tissue to be cultured. The time required for sterilisation may vary from 1–30 min. In general, explants from a morphologically uniform tissue give rise to

uniform callus initially, whereas heterogenous callus may originate from a complex tissue explant. The viable size of the tissue block to be transferred to the medium varies from species to species. For example a carrot pith explant (taken by a Cork borer) of 3.8 mg containing approx 25 000 cells and an artichoke explant of 8 mg containing approx 20 000 cells constitute viable entities (Street, 1977).

All nutrient media for tissue culture contain essential macro- and micro-elements, sucrose as carbon source, supplemented by vitamins, auxins, amino acids, cytokinins, etc. along with in some cases, antibiotics. The nature of the medium is also an important factor, as a mixture which is effective for callus formation in a liquid medium may not be so in a solid medium. The commonly used media are listed at the end. In general, there is a high concentration of mineral nutrients in Murashige and Skoog and Nitsch and in lower concentration in Gautheret's medium.

Street (1977) has classified the tissues on the basis of their requirements for growth promoters, such as those (a) requiring auxin, (b) auxin and cytokinin both, (c) only cytokinin, or (d) requiring complex natural extracts. Normally the growth promoters used are indolylacetic acid, indolylbutyric acid or 2,4-dichlorophenoxyacetic acid, etc. The natural extracts include coconut milk, yeast extract or tomato juice. Nitsch (1974) suggested that the most effective mixture with natural extract is sucrose (10 per cent) and coconut milk (v/v).

Callus culture can be done either in solid or liquid media. For solid media, the most convenient and simple ingredient used for solidification, is agar though gelatin and silica gel have also been used. The concentration of agar used is 0.6 to 1 per cent. There are however certain inherent limitations of the solid media, such as the formation of gradients from surface to the interior, as well as difficulties in gaseous exchange of embedded tissues. However even then, in view of its simplicity in preparation, it is widely applied in the maintenance of cultures.

The liquid media may be either stationary or agitated, the latter being of wide use as adequate aeration is ensured. The culturing in stationary media involves use of an ashless filter paper positioned at the interface of the medium and the air in the tube, and acting as support for the tissue. The tube may be kept vertical or horizontal (Heller and Gautheret, 1949; Butenko, 1964).

There are several advantages of agitation of culture in media such as easy gaseous exchange, homogenity of the medium and neutralising the polarity and gravitational effect. The shaking or agitation of the medium is achieved by placing the flasks or tubes in shakers which may be horizontal on platform, rotary or spinning. In certain shakers the tissue may remain immersed throughout, though often shifting in position, due to movement. For such continuous immersion, the volume of the liquid medium is generally 20 per cent of the total volume so that there is adequate aeration when the tubes are agitated at 50–100 rev/min. The magnetic stirrers (Street, 1977) too are quite effective to ensure agitation, where the medium containing the tissue and a magnet (covered by an inert material) are rotated at 250 rev/min by a large external magnet with the aid of a motor. The method is quite convenient for short term culture. There are other types of shakers with 'tumble tube' (Steward *et al.*, 1964) which allow periodic immersion of the tissue

as there is rotation of culture tubes end over end. This method made possible the demonstration of totipotency of a single cell of carrot. Preservation of cultures requires periodic transfer to fresh media for sub-culturing. This is necessary because of the exhaustion of nutrients from the initial medium. During sub-culturing, it is always desirable to take small pieces of callus which ultimately after differentiation may lead to rapid propagation of individuals.

For ultrastructure analysis of chromosomes of callus, the most adequate method of fixation is overnight fixation at 6 per cent glutaraldehyde in 0.1 M phosphate buffer (pH 6.9) at 5 °C (initial 2 h being at 25–28 °C) followed by washing in phosphate buffer for 3 h and then post-fixation for 1 h in 1–2 per cent buffered *Osmium* sol (Tulett, Bagshaw and Yeoman, 1969). Dehydration in ethanol, embedding through propylene–araldite to araldite and staining in uranyl acetate are recommended.

Suspension cultures

In suspension cultures, cells or colonies are grown in a liquid medium through dispersion and movement. There is an optimal size of the colony formed following incubation, after which it is desirable to sub-culture the cells in fresh nutrient solution. Materials for suspension culture may be obtained from pieces of friable callus or grounding the tissue or embryo in a homogeniser. In the latter case, after first suspension passage, it is desirable to pipette out the fine suspensions for sub-culturing bearing the macromolecular particles. Moreover, the suspensions may be allowed to settle as well after which the supernatant should be sucked in and cultured. There are different types of shakers—'auxophyton' and culture vessels for suspension culture to ensure horizontal (in platform shakers), rotary, spinning, or periodic immersion movement. The details of instruments are outlined by Street (1977).

The cell suspension after a period of growth may be plated on agar when colonies from single cell can be obtained. The suspension culture filtrate may be subjected to cellular count after pectinase treatment for separation by low speed centrifugation and removal of the supernatant. The 2 ml suspension of the required density is to be mixed with a sterile medium in 0.6 per cent agar, pre-cooled to 35 °C and then finally to be plated in 9 cm sterile petri dishes. The plating efficiences or PE is calculated as

$$\text{PE} = \frac{\text{No. of colonies per plate}}{\text{No. of cell units per plate}} \times 100$$

In cell culture, the minimum effective density or rather the minimum size of the clone which would allow the growth of the culture, is of prime importance and is controlled by the nature of the culture, the nature of the medium and the period and conditions of incubation. It has been noted that the growth of cell colonies is more rapid from aggregate of cells in suspension plates rather than from single cells (Earle and Torrey, 1965; Street, 1968, 1977). This is because the tissue or large aggregates of cells release into the medium certain products of their own (Street, 1977) which again are utilised

by the cells in culture in a feedback system. Single or small cell colonies with nurse cells not having this advantage require nutrient supplementation in the medium.

Chromosome analysis

For chromosome analysis from liquid medium if necessary, the medium should be centrifuged and pellet of cells taken. For callus, it is desirable to take (50 mg or so) samples from different parts, placed in fresh medium for growth for a week or more. The period of maximum frequency of division should be chosen for fixation. Usual schedules may be followed for fixing, hydrolysing and staining of the cells (Sharma and Sharma, 1972), the most common fixative used being acetic ethanol (1:3). A mixture of methanol: chloroform : propionic acid (6 : 2 : 1) (Sunderland, 1966) as well as 50 per cent aqueous formic acid for starch containing cells (Smith and Street, 1974; Bayliss and Gould, 1974) have also been recommended for fixation. If pre-treatment agents *viz.* colchicine paradichlorobenzene, aesculin, etc. are used prior to fixation, it is desirable to keep a control preparation without pre-treatment to detect the chromosomal changes if any, caused by pre-treating agent. For feulgen staining, hydrolysis is preferably carried out in 5 N HCl for 1 h at 24–28 °C (Fox, 1969) rather than for 10 min at 1 N HCl at 60 °C. Kunakh and Levenko (1975) suggested long staining of squash preparation for 10–12 days in 0.8 per cent orcein in 40 per cent acetic acid and subsequent differentiation on the slide by heating to 70–80 °C in two to three changes of 45 per cent acetic acid (Buiatti *et al.*, 1974). Dry ice technique may be adopted for making permanent preparations of squashes followed by mounting in euparal. Carbol fuchsin staining may also be employed.

For softening of the tissue, Kao, Keller and Miller (1970) recommended treatment with mixture of pectinase and cellulase (0.5 per cent of each in 0.1 M sodium acetate buffer, pH 4.5) for 1–2 h. For securing a high frequency of division and large number of metaphases, placing the culture for 12–14 h in darkness at 15 °C followed by 11 h at 27–29 °C and application of colchicine 5 h before harvesting have also been recommended.

Alterations in structure and behaviour of chromosomes *in vitro* have been reported by different authors. Endomitotic replication resulting in increase in chromosome number (Partanen, 1965), polyploidy (Sacristan, 1971; Novak and Vyskot, 1975), nuclear fusion (Collins, Dunwell and Sunderland, 1974; Kasha, 1974; Mahlberg *et al.*, 1975) as well as somatic reduction (Mitra and Steward, 1961; Sidorenko and Kunakh, 1970; Sunderland, 1973) have been reported in addition to other aberrations. Chromosome breakage, polyploidy and aneuploidy are rather common in suspension cultures specially induced by the growth promoters (Heinz, Mee and Nickell, 1969; Torrey, 1967). In view of the chromosomal instability often noted in cultures, several authors (Latta, 1971; Nag and Street, 1975) have suggested deep freezing of cultures for maintaining stability. Bayliss (1975) recommended frequent sub-culturing to achieve stability.

Determination of the cell cycle

The term 'cell cycle' implies the sequential occurrence of different phases of the cell, initiated from a division till the completion of the next cell division. In the actual method of analysis, it involves the time span between one point in a cycle to the same point in the next cycle. The cinematographic analysis of cell division in culture to some extent gives a correct estimate of cell cycle, notwithstanding the fact that even between sister cells, as noticed specially in mammalian cultures, the time requirement may vary to a certain extent (Hsu, 1960, 1965; Sisken and Kinosita, 1961). Leaving aside this complicated and time-consuming method of securing a mean data after statistical analysis, the generally accepted principle of counting the *generation time* is to consider the period during which a particular population doubles its number.

At the time of counting in culture, cells are in the logarithmic phase of growth, in which every cell is active. In this type of culture, the cell count at each stage is nearly proportional to the time taken by the cells to complete this phase. More precisely, if the generation time is 15 h and the frequency of dividing cells is 5 per cent, the time required for mitosis is $15 \times 0.05 = 0.75$ h. This method of calculating the generation time also depends on the nature of the medium and the type of the cell (Lajtha, 1957; Siminovitch *et al.*, 1957; Whitmore *et al.*, 1961). However, irregular mitosis may have a different value for cell cycle and the values may also differ from population to population (Hsu, 1955).

Mitotic indices can also be utilised in working out the duration of the cell cycle (Firket, 1965). The technique is based on the fact that the generation time (T) is inversely proportional to the division frequency of cells per unit time. If M is the mitotic index and d the period of duration of mitosis, then the number of cells entering into mitosis per hour is M/d. The practice of considering the generation time as $T = \frac{d}{M}$ ignores the fact that there is a continuous increase in the total number of cells during the cell cycle and so there is an error of nearly 30 per cent. The following formula for working out the generation time fits well with the observational data (Stanners and Till, 1960; Smith and Dendy, 1962):

$$T = \log_e 2\frac{d}{M} = 0.693\frac{d}{M} .$$

Mitotic index at any given time is,

$$M(t) = \frac{n(t+d) - n(t)}{n(t)}$$

when n is the number of cells at the time t, and d is the mean duration of mitosis. In the logarithmic phase of cell multiplication, as in cultures, the number of cells at any time t is also $n(t) = n_0 . 2\frac{t}{T}$, where n_0 represents the number of cells counted at the beginning of this phase.

The most important change occurring during the cell cycle is the chemical

turnover of nucleoprotein. DNA synthetic phase, during which DNA replication takes place, is only a fraction of the interphase (Taylor, 1958; Firket, 1958). The entire mitotic cycle is divided into four phases (Lajtha, 1957), namely, G_1—growth phase, post telophase; S = DNA synthetic phase; G_2—post-synthetic growth phase, and M—rest of the mitotic phase. Species differ with respect to the durations of these different phases, G_1 phase in general being variable (Mendelsohn, 1960) and taking the maximum and G_2 minimum (except in HeLa cells) periods of interphase. The method of calculating the duration of the different phases in culture is based on autoradiographic procedure. After pulse labelling or short treatment with tritiated thymidine and by varying the time between labelling and fixation, the duration of the three different phases can be worked out. If the cells are fixed after a long interval, only those which were at the S phase at the time of treatment show labelling. The evidence of endoreduplication too, i.e., DNA replication without any visible sign of mitotic activity, has been obtained in cultures of several mammalian tissues (Levan and Hauschka, 1953; Levan and Hsu, 1961).

A FEW SAMPLE TECHNIQUES FOR PLANT TISSUE CULTURE

Plant cultures (*see* White, 1954)

Preparation of media

The reagents necessary are: a standard salt solution, an organic accessory solution, stock solutions of calcium pantothenate, biotin and naphthalene acetic acid, agar, sucrose, ferric sulphate and distilled water.

The apparatus needed are: 125 ml Erlenmeyer flasks, lipless 25 mm × 150 mm test-tubes, 100 mm petri dishes, watch-glasses and battery jars, all sterilised.

The stages in the preparation are as follows.

(1) *For liquid nutrient medium* (a) Add 100 ml of 0.005 per cent aqueous ferric sulphate solution to 500 ml of 8 per cent aqueous sucrose solution, 200 ml of standard salt solution, 2 ml of organic accessory solution and add distilled water to prepare 1000 ml of *stock* solution. (b) Further add 100 ml of distilled water to the stock solution. Distribute in 50 ml portions in flasks and in 10 ml portions in test-tubes. Plug with sterile cotton wool and autoclave at 18 lb pressure for 20 min.

(2) *For agar nutrient medium* (a) Prepare stock liquid nutrient medium as described in (a) above. Add an equal quantity of 1 per cent hot agar solution in water to the liquid nutrient, mix, keep half of the mixture thus prepared in portions of 15 ml in test-tubes. (b) To the remaining half, for every 100 ml of agar nutrient, add 1 ml each of calcium pantothenate, biotin and naphthalene acetic acid solutions, mix, divide into test-tubes, plug and autoclave.

Culture of tomato roots

Method I

(1) Wash and dry a ripe healthy tomato, then cut it into four quarters with a shallow incision with a sterile scalpel and open it to expose the seeds, without touching them.
(2) Transfer selected well formed seeds by forceps to a petri dish on a sterile filter paper moistened with sterile water and germinate in the dark.
(3) After germination, remove healthy roots, 2–3 cm long, with a sterile scalpel and transfer each to a flask of nutrient medium.
(4) After a week, cut out 1 cm long healthy root tips from the developing root system with a pair of scissors and transfer individually to fresh nutrient. The roots can be grown indefinitely.

Method II

(1) Prepare cuttings from a healthy tomato plant, remove the leaves, wash in a mild antiseptic solution, followed by sterile water.
(2) Bore holes in a stiff paraffinised cardboard and cut it to a size slightly larger than the mouth of a battery jar. Push each cutting through the holes in two sheets of this cardboard with stem side up. Place the cardboard covers at the mouth of a battery jar previously lined with sterile blotting paper and containing a thin layer of sterile water at the bottom. The bottom end of the stem protrudes about 25 cm through the cardboard into the moist chamber formed by the battery jar. Roots develop on this end. Keep in dark.
(3) When roots develop, cut out healthy root tips, 1 cm long, with sterile scissors and transfer to a flask containing nutrient medium. Some roots will develop into healthy clones.

Culture of carrot callus

(1) Insert long narrow strips of sterilised filter paper twice along the breadth for thickness into test-tubes containing liquid nutrient medium.
(2) Wash and dry a healthy carrot, about 15 cm long and break in the middle. Remove a series of cores with a sterile cork borer from the middle with the cambium traversing them lengthwise, and put them on a sterile petri dish. Cut the cores into discs 1 mm thick.
(3) Transfer two discs to each test-tube, placing them side by side on the strip of paper. Keep the tube tilted at an angle of 30 degrees, so that the paper is kept moist by dipping in the nutrient medium but the discs are not immersed in it.
(4) The discs develop into callus tissue within a fortnight. They can be transferred to agar nutrient medium with naphthalene acetic acid and will develop into clones, which can grow indefinitely.

Culture of sunflower secondary tumours

(1) Raise healthy plants of *Helianthus annuus* from seeds in good soil, keeping one plant in each pot.

(2) Prepare a 48 h broth culture of *Agrobacterium tumafaciens*. When the stem of the young plant is about 9 cm long above the cotyledons, inject the broth with a hypodermic syringe into the stem just above the cotyledons by a single puncture. Tumours will form at this point. After about six weeks, some of the plants will develop bacteria-free secondary tumours at the bases of petioles of a few leaves just above the point of inoculation.
(3) Cut off the branch 15 cm above and below the secondary tumour. Split the stem at the base through the middle. Continue the split across the tumour to its other end, and separate the pieces, exposing the interior of the tumour.
(4) With a sterile scalpel, cut out small bits of tissue, about 1 mm or so thick from the exposed interior of the tumour and place them in test-tubes containing unsupplemented agar medium. Some of these tissues grow rapidly into large cultures of disorganised tissue, malignant in nature. They can be transplanted under the bark of healthy sunflower stems and develop into tumours there as well.

Tissue culture for observation under phase contrast

(Jones and colleagues, 1960)

The cells are grown in micro-cultures for extended periods in a manner to permit detailed cytological observations.

(1) Prepare hybrid tobacco (*Nicotiana tabacum X.N. glutinosa*) single cell clones, isolated from stem callus and grown in liquid 'tobacco' supplemented by coconut milk (150 ml/l), calcium pantothenate (2.5 mg/l), naphthalene acetic acid (0.1 mg/l) and 2,4-dichlorophenoxyacetic acid (6.0 mg/l), in tubes within a shaker.
(2) Place a drop of paraffin oil near each end of a standard microscope slide. Lower a No. 1, 22 mm square cover slip on to each droplet to form risers for a shallow central chamber on the slide. Put a drop of mineral oil in a rectangle on the slide, connecting the two cover slip risers and covering the inner end of each. Place a droplet of liquid medium at the centre of a third square cover slip.
(3) Isolate a single cell or a small cluster of cells from a culture-tube with a pair of flattened teasing needles under a dissecting microscope and transplant it in the droplet of liquid medium on the third cover slip.
(4) Invert the cover slip over the rectangle of mineral oil on the slide in such a manner that the mineral oil surrounds the liquid medium with its enclosed cells and the ends of the top cover slip lie upon the inner ends of the cover slip risers. The culture thus lies in a liquid medium in a tiny micro-culture chamber filled with liquid paraffin.
(5) Observe the micro-cultures directly under the microscope. Keep them in sterile petri dishes in the dark at 26 °C at controlled humidity.
(6) By this method, the different cytological changes during the growth of the culture in living cells can be observed under both ordinary and phase contrast microscopes.

Isolation and culture of protoplasts

Lately, isolation of protoplasts from the cell and culturing them *in vitro* has become a convenient tool, in the study of the property of the membranes, in securing cell fusion, in the study of photosynthesis, as well as in the incorporation of foreign genes or DNA in the protoplast system (Nickell and Torrey, 1969; Wilson, King and Street, 1971; Ruesink, 1973; Davey and Power, 1975; Edwards, Huber and Gutierrez, 1976; Liebke and Hess, 1977). The objective underlying this technique is to isolate protoplast without causing any irreversible damage to its structure. The maintenance of a correct osmotic level without causing excessive plasmolysis is an important factor in protoplast isolation. The actual concentration of osmotic stabiliser varies from tissue to tissue. At present for isolation, enzyme preparations, such as pectinase (Macerozyme) derived from the fungus *Rhizopus*, cellulase (Onazukacellulase) derived from *Trichoderma viride* (Takebe, Otsuki and Aoki, 1968), driselase—a cellulose enzyme complex derived from a basidiomycete (Street, 1977) as well as hemicellulase (Fowke *et al.*, 1973) are widely used. Helicase from snail was also used by Bhojwani and Cocking, 1972). In view of the fact that enzyme preparations often contain some low molecular weight chemicals, which may cause toxicity by affecting osmotic concentration, it is often desirable to desalt the enzymes through centrifuging in a salt solution such as 15 g of cellulase in 30 ml of 0.5 M NaCl (Kao *et al.*, 1971). Moreover, to free the enzymes from contaminants antibiotics are also added (Power *et al.*, 1976).

Isolation

There are essentially two methods for protoplast isolation based on the principle whether the enzymes are to be put simultaneously or sequentially. The schedules are outlined below. For protoplast fusion *see* chapter on Cell Fusion (modification of R. Contts from Takebe, Otsuki and Aoki, 1968; *see* Street, 1977).

For protoplast isolation, it is always desirable to grow plants under controlled growth conditions such as 1000–10 000 lx light intensity—16 h at 22–25 °C. For best yield of protoplasts, Cassells and Burlass (1978) suggested growth under low light intensity (2.52–10.8 MJ/m^2/day for 15 h a day) with balanced fertiliser containing calcium nitrate for continued supply of mesophyll cells. The entire isolation technique shoud be carried out before a laminar air flow cabinet by treating with 5–7 per cent sodium hypochlorite (Domestos).

Technique I

(1) Sterilise the leaf surface, immersing in 70 per cent alcohol for 30 s followed by 2.5 per cent sodium hypochlorite for 30 min and through washing with sterile water.
(2) Peel off the lower epidermis of the leaf in strips (4–6 g) and place in 20 ml of maceration medium (0.5 per cent macerozyme, 13 per cent mannitol and 1 per cent potassium dextran sulphate).

(3) Adjust the pH to 5.8 with 2 N HCl, before filter sterilisation.
(4) Shake the materials in the maceration medium at 25 °C in a reciprocal shaker (100–120 cycles/min, 4.5 cm stroke).
(5) Isolate cell fractions after 30 min, 1 h, 1–15 min, 2 h and 3 h, replacing the macerating medium each time.
(6) Centrifuge the last two fractions which are almost pure (100–200 × g, 3 min) and resuspend twice in fresh 13 per cent mannitol and centrifuge again.
(7) Put the isolated cells in 40 ml, 4 per cent 'Onazuka' cellulase in 13 per cent mannitol—pH 5.2 (adjusted with 2 N HCl before filter sterilisation).
(8) Incubate the suspension at 36 °C for 3–3½ h with gentle swirling.
(9) Harvest the protoplasts from the medium by slow centrifugation (100 × g) for 1 min.
(10) Resuspend twice for washing in 13 per cent mannitol with 0.1 mM calcium chloride and centrifuge again.
(11) Suspend the protoplasts in 5 ml, 13 per cent mannitol, count a sample in counting chamber and sediment again by centrifugation.
(12) Resuspend in fresh 13 per cent mannitol to get a concentration of 1–4 × 10^6 protoplasts/ml.

Technique II (Power, Frearson and Hayward, 1974)

(1) Surface sterilise the leaves of *Nicotiana* sp. as the technique I, and wash in sterile water.
(2) Take slightly flaccid leaves, remove the lower epidermis.
(3) Cut pieces of peeled areas and float exposed surface downwards in a mixture of 13 per cent mannitol and CPW salts (KH_2PO_4, 27.2 mg/l; KNO_3, 101.0 mg/l; $CaCl_2 2H_2O$, 1480 mg/l; $MgSO_4 7H_2O$, 246.0 mg/l; KI, 0.16 mg/l; $CuSO_4$ $5H_2O$, 0.025 mg/l) (pH 5.8) in a petri dish (14 cm in diameter) for 1–2 h.
(4) Remove the mixture and replace with 20 ml (approx) filter sterilised enzyme mixture (4 per cent w/v meicelase, 0.4 w/v macerozyme, 13 per cent mannitol, CPW salts, pH 5.8, adjusted with 5 N HCl) and incubate for 18 h in the dark.
(5) With forceps, agitate slowly to release protoplasts, tilt the dish and allow the protoplasts to settle for 30 min.
(6) Pipette out the enzyme mixture.
(7) Transfer the protoplasts to screw capped tubes, suspend the mannitol/CPW salts and centrifuge at 35 × g for 10 min.
(8) Remove the supernatant, suspend the protoplasts again in 20 per cent sucrose solution containing CPW salts and centrifuge at 50 × g for 10 min.
(9) Remove the protoplast from the supernatant with a pipette and resuspend in 10 ml mannitol/salts.
(10) Count the sample.
(11) Sediment the protoplasts for 5 min at 35 × g and resuspend in nutrient medium to get a final concentration of 1 × 10^5/ml.

The technique may be modified specially in relation to enzyme levels and plasmolyticum to suit different species (Power *et al.*, 1976; Banks and Evans,

1976). Protoplasts can also be isolated from cultured cells. The friable nature of the cells allows rapid penetration of enzymes. The regeneration of protoplasts from cultured cells is most convenient in view of the fact that the parent material is the product of *in vitro* growth.

The schedule for isolation of protoplasts involving the use of driselase, and pectic acid transeliminase (PATE) (Mayer and Abel, 1975) from cultured cell suspension is outlined below (technique of Mrs. D. George—referred in Street, 1977).

(1) Harvest suspension culture, four days after subculturing.
(2) Allow the cells to settle at the bottom and decant off the medium.
(3) Transfer the suspension to 100 ml flask and remove the residual medium with pipette.
(4) Add 20 ml to each flask, a sterilised mixture of 3 per cent driselase, 6.05 per cent pectic acid transeliminase (PATE), 13 per cent mannitol and CPW salts, pH 8.6.
(5) Incubate while agitating in a slow speed rotary shaker (72 cycles/min) at 27 °C for 2–2½ h.
(6) Add to the suspension, 25 ml of 13 per cent mannitol and CPW salts.
(7) Transfer the entire mixture with protoplasts and cells to screw-capped tubes and centrifuge at 100 × g for 5 min.
(8) Remove the supernatant and add 13 per cent mannitol and CPW salt solution.
(9) Filter the fluid initially through a coarse nylon sieve for removing undigested aggregates and then fine 64 nm nylon sieve.
(10) Centrifuge at 100 × g for 5 min.
(11) Remove supernatant and resuspend sediment in 21 per cent sucrose solution containing CPW salts.
(12) Centrifuge again at 100 × g for 5 min.
(13) Collect the protoplasts with a pipette from the surface and resuspend in known solution of nutrient medium. The maximum yield is 2.5×10^{-1} protoplasts/250 ml flask.
N.B. High plating efficiency is achieved if protoplasts 2.5–5 × 10^6/ml are cultured in medium with NAA (2.0 mg/ml), 6 BAP (0.6 mg/l) and 9 per cent mannitol.

A simple method of protoplast isolation (Okuno and Furusawa, 1977) is to incubate peeled leaves at 20–25 °C for 2–3 h in 0.6 M mannitol containing 1 per cent cellulase at pH 5.6.

Culture of protoplasts

The protoplasts can conveniently be cultured to yield cell colonies and ultimately lead to plant regeneration (Grambow *et al.*, 1972; Hayward and Power, 1975). In liquid culture, it is preferable to keep protoplasts in a stationary phase or with slight shaking to prevent breakage. Shallow 9 cm plastic petri dishes may be used with 6 ml of protoplast suspension. To prevent bursting, 0.04–0.02 per cent Tween 80 (Mayer and Abel, 1975) may be added. Hanging drop culture is also possible. The other method of culture is to have a thin layer of protoplast over a layer of nutrient medium

solidified with agar to secure a high plating efficiency. Colony formation from individual protoplasts can be recorded.

Chromosome analysis

For chromosome analysis, it is desirable to centrifuge the protoplasts and take the sediment with nuclei. Pre-treatment before fixation can be performed with saturated solution of aesculine in water for 30 min at 12 °C before fixing in ethanol acetic acid (3 : 1) for 2–3 h. The next step is to warm in a mixture of acetic–orcein/N HCl (9 : 1) for a few seconds and after 1 h, squashing in 1 per cent acetic–orcein or 45 per cent acetic acid. Carbol fuchsin stain can also be employed.

Anther and pollen culture

The anther and pollen culture technique is adopted to induce embryoids as well as haploids, the callus from pollen culture initially being obtained by Tulecke (1953) in gymnosperms (*see* Bonga and McInnis, 1975). Guha and Maheshwari (1967) first succeeded in securing haploid plants from *Datura innoxia* by culturing pollen within the anthers. Since then, several species have been successfully cultured (Nitsch and Norreel, 1973; Wernicke and Kohlenbach, 1975; Sunderland, 1977 and *see* Nitsch, 1977). In genetic experiments, haploid plants have the unique advantage of yielding homozygous diploids through polyploidisation. For the introduction of foreign genome specially of bacteria (Ledoux, 1975), haploid protoplasts offer immense possibilities. To secure permanent haploids for genetic research, it is desirable to induce haploid in perennials or secure mutants for perennation, in regenerated haploids.

For anther and pollen culture, it is always desirable to choose anthers, where the pollen is undergoing first mitotic division, which may be checked before selecting the anther. Plants should be young, healthy and in optimum blooming season. Suitable photoperiod and temperature treatment of the plants may be necessary under controlled conditions to achieve best results. In addition potentiality of the pollen to develop embryos has been found to be greatly enhanced by chilling the buds but not anthers (Dunwell, 1976) in the refrigerator at 2–4 °C for 48–72 h prior to culturing (Pan *et al.*, 1975; Corduan and Spix, 1975; Street, 1977).

The schedule for anther culture involves surface sterilisation of unopened flower buds at proper stage, removal of sepals and petals, and plating the anthers immediately in basal agar medium of Murashige and Skoog (1962) or floating on liquid medium. Several species may require hormones and cytokinins in conjunction with sucrose for their growth as in *Hordeum*, *Oryza*, *Triticum*, *Brassica* (Matsubayashi and Kuranaki, 1975; Nitsch, 1974). For inducing differentiation and regeneration of plants from callus, alteration of hormone and sucrose components is necessary as in tissue culture. For pollen culture, freshly pricked or chilled anthers may be taken (Debergh and Nitsch, 1973; Nitsch and Norreel, 1973) but in a few cases, culturing

inside the anther for 4–6 days before extraction may be necessary as in *Nicotiana tabacum* (Street, 1977).

The schedule for pollen culture involves initially the gentle grinding of anthers of suitable size in a glass homogeniser containing liquid culture medium as in anther culture. The suspension is filtered through nylon sieve to hold the large particles allowing the pollen suspension to come out as filtrate. The filtrate is centrifuged at 100 × g for 4 min and the pellet is washed repeatedly in culture medium. After the addition of adequate medium, the suspension is transferred to culture vessel and may be gently agitated for aeration, if necessary. The suspension can also be cultured in agar medium.

Sharp, Raskin and Sommer (1972) recommended culturing of pollens on filter paper discs covering anthers, placed on the surface of agar medium. This technique is based on the principle of providing nurse anthers which may be advantageous where the material is limited.

Nutrient for plant tissue culture

White's nutrient solution (1943) for plants

Inorganic salt solution

$Ca(NO_3)_2$	20 g	$MnSO_4$	0.45 g
Na_2SO_4	20 g	$ZnSO_4$	0.15 g
KCl	8 g	H_3BO_3	0.15 g
NaH_2PO_4	16.5 g	KI	0.075 g

Dissolve one at a time in 8000 ml of double distilled water. Dissolve 36 g of $MgSO_4$ separately in 2000 ml of water. Mix the two solutions in a 10 litre bottle to form stock solution, ten times the concentration needed in the nutrient. Store in dark.

Vitamin supplement

Glycine	300 mg
Nicotinic acid	50 mg
Thiamine	10 mg
Pyridoxine	10 mg

Dissolve in 100 ml of water. It is 100 times the concentration needed. Store in cold.

Carbohydrate solution

Dissolve 40 g of sucrose in 100 ml of water. Dissolve 5 mg of $Fe_2(SO_4)_3$ in 50 ml of water and add to sugar solution.

For liquid nutrient

Add to the mixed sugar solution 200 ml of stock salt and 20 ml of stock vitamin solutions and make up to 2000 ml with water.

For semi-solid nutrient

Make up the nutrient solution to half the above volume. Dissolve 10 g of agar in 1000 ml of distilled water and mix in equal proportions with the liquid nutrient.

This formula has been found to be useful for roots, plant tumours, callus and embryos. It was observed in this laboratory that addition of yeast extract and IAA resulted in profuse growth of cells in carrot tissue culture (Roy, 1969).

Gautheret's nutrient medium for plants (1950) and its alternatives

Inorganic stock salt solution (according to Knop)

$Ca(NO_3)_2$	1 g	KH_2PO_4	0.25 g
KNO_3	0.25 g	Distilled	
$MgSO_4$	0.25 g	water	1000 ml

Inorganic stock solution with trace elements (according to Berthelot, 1936).

$Fe_2(SO_4)_3$	50 g	$Ti_2(SO_4)_3$	0.2 g
$MnSO_4$	2 g	$NiSO_4$	0.05 g
KI	0.5 g	$CoCl_3$	0.05 g
$ZnSO_4$	0.1 g	$CuSO_4$	0.05 g
H_3BO_3	0.1 g	H_3BO_3	0.05 g
Conc. H_2SO_4	1 ml	Dist. water	1000 ml

Table 10.6 Pollen and anther culture media (quantities given in mg/l)

Glycine	2.0	1.0	2.0
Glutamine	—	—	—
m-inositol	100	50	—
Sucrose	20 000	30 000	50 000
pH (before autoclaving)	5.5	5,5	5.8

Vitamin stock solution

Cysteine–HCl	100 mg
Thiamine	10 mg
water	100 ml
Autoclave	
Ca-pantothenate	10 mg
water	100 ml
Autoclave	
Biotin	10 mg
water	10 ml
Filter	
Inositol	1 g
water	100 ml
Autoclave	
Naphthalene acetic acid	10 mg
30 per cent ethanol	100 ml

In the different modifications of the final mixture, the proportions shown in *Table 10.7* are used.

Table 10.7

Ingredients	*Solutions*				
	M_1	M_2	M_3	M_4	M_5
Knop's solution	100 ml	100 ml	100 ml	100 ml	100 ml
Berthelot's solution	1 ml	1 ml	1 ml	1 ml	1 ml
Dextrose	30 g	50 g	50 g	50 g	50 g
Agar	6 g	6 g	6 g	6 g	6 g
Cysteine–thiamine	10 ml	10 ml	10 ml	10 ml	—
Ca–pantothenate	1 ml	—	—	—	1 ml
Biotin	1 ml	—	—	—	1 ml
Inositol	10 ml	—	—	—	—
Naphthalene acetic acid	3 ml	1 ml	—	0.5 ml	1 ml
Water	875 ml	886 ml	887 ml	886 ml	840 ml

The final mixture is adjusted with 0.1 N NaOH. Additional ingredients are: 1 ml of each of $CuSO_4$ and MoO_3 solution (at 1.0 mg/l) is added to 1 litre of nutrient (according to Boll and Street, 1951); 30 ml of coconut milk per 1000 ml of nutrient is a beneficial supplement (according to Caplin and Steward, 1948). Boiled extract of 100 mg of yeast in 500 ml of water can be added to the nutrient as a supplement.

Some nutrient solutions for embryo culture

The Randolph–Cox Solution (Randolph and Randolph 1955)

Solution A		*Solution B*	
Calcium nitrate	8.5 g	Ferrous sulphate	0.2 g
Potassium nitrate	23.6 g	Calgon $(NaPO_3)_n$	1 g
Potassium chloride	6.5 g	Magnesium sulphate	3.6 g
Distilled water	500 ml	Distilled water	500 ml

The two solutions are stored separately. For preparing nutrient medium, heat 7 g of agar in 1000 ml of distilled water. Add to it 20 g of sucrose and 5 ml of each of solutions A and B. Distribute in sterilised bottles.

Knudson's solution (Referred to in Randolph and Randolph, 1955)

Calcium nitrate	1 g	Ferrous sulphate	0.025 g
Ammonium sulphate	0.5 g	Manganese sulphate	0.0075 g
Magnesium sulphate	0.25 g	Sucrose	20 g
Potassium phosphate	0.25 g	Agar	15 g
		Dist. water	1000 ml

Concentrated stock solutions of the different chemicals are prepared, except $FeSO_4$. Add proper amounts of each to distilled water in which agar has been dispersed by heating.

Chromosome analysis following short- and long-term cultures in animals, including man

The remarkable progress in the study of cytogenetics in lower species encouraged a comparable study of mammalian, and later, of human cytogenetics. What was almost a completely unexplored terrain has now attracted a large number of investigators from all over the world. There are now many techniques for studying mammalian chromosomes, particularly human ones, each laboratory having evolved its own variant of different published methods. Most of them have been devised in quick succession, as a result of improvements like: development of the tissue culture schedule to obtain cells *in vitro*, either suspended or forming a monolayer; pre-treatment by colchicine or its derivatives to accumulate a large number of mitotic figures; hypotonic solution treatment causing swelling of the cells to aid chromosome scattering and air-drying to force the chromosomes to lie in one plane. The techniques, in general, aid in the study of the karyotype, of the meiosis, and of the sex chromatin. A suitable method for karyotype study must fulfil three demands: (a) adequate scattering of chromosomes, (b) minimum distortion and (c) flattening of the cells. The three principal schedules, with variants, utilised in karyotype analysis, are the short-term peripheral blood culture, the direct bone marrow technique, and the long-term fibroblast culture. For meiotic studies, methods have been developed for use on gonadal tissues. Sex chromatin studies are done from buccal smears, tissue sections and peripheral blood neutrophiles.

As the methods were first developed either for other mammalian materials and then applied to human chromosomes, or vice versa, and because the method employed is decided by the nature of the tissue used, the different schedules will be discussed in relation to the tissue utilised, irrespective of their mammalian or human origin.

The principle of the use of colchicine or other mitostatic chemicals for causing metaphase arrest in both meiotic and mitotic preparations has been discussed in the chapter dealing with pre-treatment. However, since colchicine has been found to produce chromosomal anomalies (Amarose, 1959) and disturbance in DNA synthesis (Lima de Faria and Bose, 1962), Turpin and Lejeune (1969) suggest that it should be avoided unless absolutely necessary. The dispersal of chromosomes by hypotonic shock, as discovered by Hsu (1952), led to the evolution of most of the methods on mammalian chromosomes, but its possible drawback is the loss of certain information, like the probable association of chromosomes with satellites between them,

the somatic pairing of homologues and their spatial arrangement in the equator (Barton and David, 1962, 1963; Barton, David and Merrington, 1963). Similarly, the squash schedule results in possible deformation and displacement of the chromosomes. The simple air-drying technique, as devised by Rothfels and Siminovitch (1958a), gives very satisfactory flattening of the chromosomes and is a common feature of most techniques.

STUDY OF MEIOSIS

Meiotic configurations from mammalian gonads were obtained by Makino and Nishimura (1952) and later by Darlington and Haque (1955), leading to the evolution of various schedules. The kind of pre-treatment depends on the developmental stage of the germ cells to be studied but the procedure for fixing, squashing and staining is similar for all stages.

Gonadal tissues are usually obtained through biopsy and cut into small cubes. For mitotic prophase and telophase figures of germ cells, repeated suspension in a cold isotonic solution like Medium 858, or Hank's basal salt solution, at 3 °C is adequate. It is also suitable for first meiotic prophase figures of male germ cells, obtained by testicular biopsy. In female cells, the divisional figures are numerous in fetal ovaries between the fourth and eighth months. The ovary is immersed in isotonic solution, dissected, incubated at 37 °C in 10 per cent trypsin solution for 30 min, followed by three 10 min rinsings in isotonic solution. Swelling needed for mitotic metaphase and anaphase stages can be acquired by immersion for 10 min in neutral (pH 7) double distilled water, at room temperature, two or three times.

In the male, meiotic metaphase figures are greatly improved by hypotonic pre-treatment. Individual seminiferous tubules are dissected out from the tissue immersed in isotonic solution, transferred to double distilled water at room temperature and kept for 30 min prior to fixation. In the human female, first and second meiotic metaphase figures are difficult to obtain, since they occur only in the mature follicle in the ovary of a woman in her reproductive span, on the day of ovulation. The mature follicle is punctured in other mammals and the ovum dissected out and incubated at 37 °C. It is then transferred by means of a pipette to the fixative (50 per cent acetic acid), kept for 15 min and covered gently to separate the bivalents (*see* Ohno, 1965 and also Edwards, R. G. 1962).

The period of fixation ranges from 15–45 min, a cube of material (2 × 2 × 2 mm) being placed on a slide in 1 ml of fixative and tapped to release the free cells. It is covered with a cover slip and squashed with straight, uniform pressure. Later, the slide is immersed for 1 min in a mixture of dry ice and methanol, dried in air, treated in methanol for 15 min to remove fatty substances, dried, washed in water, hydrolysed in N HCl at 60 °C for 15 min, and then stained, dried and mounted in synthetic balsam. Staining for 3 h with Feulgen reagent or 5 min with Giemsa or 1 min with 0.25 per cent basic fuchsin solution gives good results (Ohno, 1965). Welshons, Gibson and Skandlyn (1962) proposed 2 per cent acetic–lactic–orcein (orcein 2 g, acetic acid 50 ml, 85 per cent lactic acid 42.5 ml, water 7.5 ml) for tubules after fixation in 50 per cent acetic acid added to hypotonic sodium citrate solution.

Schedule for human chromosomes

Study of chromosomes from male germ cells

Germinal cells are usually collected by testicular biopsy, preferably undertaken under general anaesthesia to avoid any interference by injecting an anaesthetic agent locally. Tissue of the size of a safety match head provides enough material in most cases. According to Kjessler (1970), the material can be used even after 24–36 h or mailed, if kept in TC199 and not allowed to become dry.

Two types of schedules are available—for squash and for air or flame-dried preparations (Hamerton, 1971; Sharma, A. and Talukder, 1974).

Squash preparations

The type of pre-treatment required depends on the developmental stage of the germ cells to be studied. The later stages of fixing, squashing and staining are similar.

Method to study first meiotic prophase figures (Ohno, 1965)

(1) Gonadal tissues, obtained by testicular biopsy, are cut into cubes of 2 mm^3 and suspended in an isotonic solution, like Medium 858 or Hank's BSS (Difco) at 3 °C for 10 min.
(2) Two changes are given in the isotonic solution in cold at intervals of 10 min each.
(3) The tissue is then transferred to fresh fixative (glacial acetic acid and distilled water in equal proportions), 50 vol of fixative to 1 vol of the tissue. It is kept for 15 to 45 min.
(4) A cube of the tissue is transferred to a clean grease-free glass slide with about 0.1 ml of fixative. It is tapped gently with a blunt metal instrument to release the free cells. The stringy connective tissue in the free cell suspension is removed with small forceps.
(5) The material is covered carefully with a long cover-glass.
(6) The slide is placed between four layers of filter paper on a flat table and the material squashed by applying firm uniform pressure vertically on the cover-glass.
(7) The slide is kept for 1 min in a mixture of dry ice and methanol in a beaker to freeze the fixative. The cover-glass is then removed by inserting a razor blade.
(8) The slide is dried in air and then kept in methanol for 15 min to dissolve the fatty contents of the gonadal tissue.
(9) It is again dried in air, rinsed in tap water and hydrolysed in normal hydrochloric acid at 60 °C for 15 min to remove most of the RNA from chromosomes and cytoplasm.
(10) The slide is stained using either Giemsa solution (5 min) or Feulgen reagent (3 h) or 0.25 per cent basic fuchsin solution (1 min). It is dried in air, a drop of synthetic balsam is placed on the material and covered with a cover-glass.

Hypotonic treatment in distilled water* (pH 7.0) *for* 30 min; *fixation in* 50 per cent *acetic–methanol for* 40 min, *smear under cover-glass; cover slip removed by freezing in methanol and dry ice; immersion in* 1 N HCl *for* 15 min *at* 60 °C; *Giemsa stain* (courtesy of Dr. S. Ohno)

(11) Pachytene configurations with a heavily condensed XY-bivalent and 22 autosomal bivalents showing chromomeres can be observed.
(12) This schedule can be utilised to study mitotic prophase and telophase figures of germ cells as well.

Method to study first and second meiotic metaphases (Ohno, 1965)
Hypotonic treatment is used for improved quality of the plates in interphase, diakinesis and metaphases but extra precautions are taken to prevent the free cells floating away if the seminiferous tubules are cut into very small pieces.

(1) A piece of fresh tissue, obtained by testicular biopsy, is immersed in isotonic solution. With the help of small forceps under a dissecting microscope, seminiferous tubules, each at least 2 cm long, are isolated.
(2) A long piece of tubule is transferred to 2 ml double distilled water on a clean slide and allowed to stay in it for 30 min at room temperature. The slide may be covered with a glass cylinder to prevent excessive evaporation. This hypotonic treatment causes the tubule to swell to nearly three times its original size.
(3) The excess moisture is blotted off with filter paper. 0.5 ml of 50 per cent acetic acid is added to the tubule. It is fixed for 15 min.
(4) The tubule is then teased into small pieces, using fine forceps. It is covered with a cover-glass and squashed and stained according to steps (6) to (10) of the earlier schedule described for meiotic prophase.
(5) The first meiotic metaphase shows 22 autosomal bivalents with chiasmata and the XY-bivalent, associated end to end. In the second metaphase, 22 autosomes with the chromatids held together at the centromere and a heavily condensed sex chromosome, either X or Y, are seen.
(6) This method can be applied in observing mitotic metaphase and anaphase stages in germ cells as well.

Alternative squash method for study of pachytene stages (Gardner and Punnett, 1964)

(1) A piece of testicular tissue is placed in 0.3 per cent aqueous sodium citrate solution. The period of treatment ranges from 1 to 6 h, depending on the size of the tissue.
(2) A few tubules are dissected out, stained and squashed to confirm that the divisional stages required are present.
(3) The remaining tissue is kept in a 3 M solution of glucono-deltalactone for 2 h for softening.
(4) It is then stained in acetic or propionic–carmine (1 per cent) solution for a period of 10–12 h.
(5) The tissue is washed in four successive changes of 70 per cent ethanol to remove excess stain.
(6) It is transferred to a large watch-glass or petri dish containing acetic acid-ethanol (1 : 1) mixture and minced into a thick suspension.
(7) The cell suspension is filtered through several layers of cheese cloth.
(8) The filtrate is centrifuged at 250 rev/min for 15 min. The upper half of the supernatant is discarded. The fluid remaining just above the

Plate 11.3
Secondary constriction of the X chromosome attached to the nucleolus in the cell line Pt – K_1 *of female rat kangaroo,* Protorous tridactylus (2n = 12), *acetic–orcein squash without pre-treatment* (courtesy of Dr. T. C. Hsu)

coarse precipitate is pipetted off. It contains most of the spermatocytes and if needed, can be stored in cold.

(9) One drop of the cell suspension is dropped from the pipette onto a siliconised slide.

(10) A drop of water-soluble mounting medium—Hoyer's medium (Alexopoulos and Beneke, 1962) is added to the suspension and mixed with it.

(11) A cover-glass is placed on the material and the excess fluid removed by blotting with filter paper.

(12) The slide is warmed on a hot plate to flatten the cells and attach them to it.

(13) The slide is now inverted on several sheets of absorbent paper and squashed, using uniform pressure, with the thumb. If not satisfactory, the slide can be warmed and squashed again to obtain suitable preparations. The slides are known to keep for up to eight months.

Squash method for the study of stages other than first meiotic prophase (Ford, 1961; Turpin and Lejeune, 1969)

(1) The fresh testicular tissue is placed in hypotonic solution (pH 7.0; 50 per cent potassium glycerophosphate, 93.02 ml; 20 per cent glycerophosphoric acid, 24.92 ml and distilled water made up to 200 ml). The tubules are teased out with fine forceps and kept at room temperature for 3 min.

(2) The material is fixed in acetic acid–ethanol (1 : 3) for 1 h and then treated in 30 per cent ethanol and distilled water successively for 3.5 min for hydration.

(3) It is hydrolysed in normal hydrochloric acid at 60 °C for 8 min, stained in Feulgen reagent for 1 h, rinsed successively in SO_2 water and cold 45 per cent acetic acid, keeping 3–5 min in each.

(4) The tubules are transferred to 45 per cent acetic acid and squashed under a cover-glass as described in the earlier schedules. They can also be stored in 45 per cent acid at -12 to -15 °C before squashing.

(5) To improve spreading of the chromosomes, possibly through digestion of the tubule membrane, papain treatment is occasionally adopted. The tubules are treated in 1 per cent aqueous papain solution for 10 min before squashing, rinsed, kept in 60 per cent acetic acid for 5 min, covered and squashed. The cells shrink first in papain and then swell to greater than original size.

Modified squash method (Kjessler, 1970)

(1) Hypotonic solution used is tri-sodium citrate in concentrations varying from 0.55 to 1.12 per cent for 15 min or more.

(2) The specimen is then transferred to a fresh 2 per cent acetic orcein solution and cut into smaller bits with scissors. It is kept in this solution from 15 min to 2 h.

(3) The tissue is then transferred on to a clean grease-free slide, the tubules are teased out on the slide, the debris is rejected and a cover-glass put on the material. The excess fluid is removed by blotting under filter paper. A gentle pressure is applied to squash the chromosomes and the preparation sealed by Krönig's cement.

Plate 11.4
Human leucocyte chromosomes (♂), *following colchicine–hypotonic–acetic–orcein squash* (courtesy of Drs. A. Levan and W. W. Nichols)

(4) For the study of pachytene chromosomes, after hypotonic treatment and before staining in acetic–orcein, the tissue is fixed in a fixative containing saturated picric acid, 1 part and Parker's medium TC 199, 7 parts for up to 24 h (Annéren *et al.*, 1969, in Kjessler, 1970).

Air dry method for the study of pachytene chromosomes (Hungerford, 1971)
The tissues were mainly obtained from bilateral orchiectomy performed in cases of prostatic carcinoma. It is also applicable to specimens acquired through testicular biopsy or through autopsy within 1 h of death.

(1) The tissue is transported immediately after removal in cold to the laboratory in tissue culture medium. The medium contains Eagle's basal amino acids and vitamins at double strength in Earle's balanced salt solution (BSS) adjusted to pH 7.0 with 7.5 per cent $NaHCO_3$, with additives glutamine 2 mM, penicillin 100 units/ml; streptomycin 100 μg/ml; phenol red 7 μg/ml; newborn agammaglobulin bovine serum 15 per cent and USP heparin sodium 20 000 units/l.
(2) The tissue is transferred to BSS at 37 °C and minced into small pieces. The resulting suspension is drawn with a pipette into 15 ml centrifuge tubes.
(3) On centrifugation for a few minutes at 1.0 g, the large particles settle to the bottom. The supernatant, with single cells and small clumps, is transferred to another centrifuge tube.
(4) It is centrifuged at 150 g for 4 min and the supernatant BSS rejected.
(5) The pellet is resuspended in excess 0.125 M KCl, with heparin added (20 000 units/l) and incubated for 1 h at 3 °C.
(6) The material is again centrifuged, the excess supernatant KCl rejected and the cells fixed in acetic–methanol (1 : 3) for 10–15 min.
(7) Air-dried squashes are prepared as described in the earlier schedule.
(8) On drying, the slides are stained for 2 h in 1 per cent solution of orcein in 60 per cent acetic acid and mounted with Diaphane (Will Corp).
(9) Accurately countable pachytene complements were seen. In late pachytene, patterns of discrete chromomeres were present.

Dried preparations

Flame dry method (Sasaki and Makino, 1965)

(1) Fresh testicular tissue, obtained by biopsy or orchiectomy, is placed immediately in a watch-glass or petri dish and minced finely with scissors.
(2) About 0.5 ml or less of the tissue volume is taken and covered with 2 ml of 0.6 per cent hypotonic sodium citrate solution. The tissue is mixed with the solution by inhaling and exhaling through a pipette and allowed to remain for 30 min.
(3) The cells are resuspended in the hypotonic solution. 6 ml acetic–ethanol (1 : 3) is added and the cells fixed in it for 30 min.
(4) The mixture is centrifuged at 100 rev/min for 5 min. The supernatant is discarded and 6 ml of fresh fixative is added to the cells at the bottom of the tube. The process is repeated two to three times at intervals of 20 min.

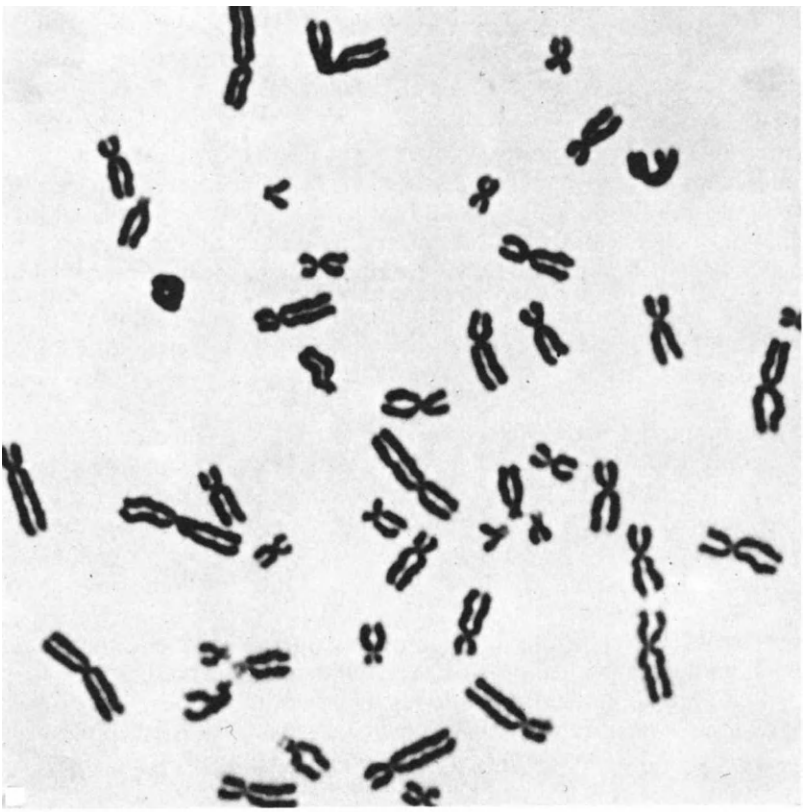

Plate 11.5
Human chromosomes from peripheral leucocyte culture (♀), *with a ring chromosome* 18 (courtesy of Dr. M. Ray)

(5) The cells are then resuspended in 2 ml of fresh fixative, mixed well by pipetting and allowed to stand.
(6) The upper layer of dispersed cell suspension is drawn out. One to two drops are pipetted on to a clean, grease-free slide.
(7) The slide is held close to a bunsen burner flame for a few moments till the fixative burns off completely, leaving the slide dry.
(8) The slide is then stained by immersion in Giemsa (5–10 min) or any other stain as desired. It is mounted with a large cover-glass using a synthetic resin.
(9) Several slides are prepared so that the required configurations are available. Hypotonic treatment in step (2) can be omitted if first meiotic prophases are being observed.

Air drying method

This shows a lower proportion of cell breakage than squash techniques and is suitable for the analysis of late diplotene to second metaphase figures (Evans, Breckson and Ford, 1964; Ford and Evans, 1969). Minor modifications in the amount of chemicals used are employed depending on the quantity of tissue available, which in the case of a normal human specimen, is rather small.

(1) Seminiferous tubules, obtained from fresh biopsy, are placed in a small amount of 2.2 per cent (weight/volume) sodium citrate solution in a small 5 cm petri dish and agitated gently in the solution to remove the excess fat for 15 s.
(2) The material is transferred to 3 ml of fresh 2.2 per cent sodium citrate solution in another petri dish. The tissue is held with small straight forceps and the tubules teased out with curved ones. After 10 min, the total mass is poured into a 4 ml centrifuge tube.
(3) The material is centrifuged for 5 s. The supernatant is pipetted off to a clean 4 ml centrifuge tube. The sediment, containing larger tubule segments, is discarded.
(4) The fluid is centrifuged at 500 rev/min for 5 min. The supernatant is discarded as much as possible. The sediment at the bottom is resuspended in a minimal amount of residual supernatant.
(5) To the suspension, 3 ml of 1.0 per cent sodium citrate solution is added slowly. The suspension is divided equally between two narrow conical tipped Dreyer tubes and kept for 10 min.
(6) The tubes are centrifuged for 5 min at 500 rev/min. Supernatant is discarded. The tubes are allowed to stand for one min and the excess fluid that has drained down the sides is pipetted off.
(7) For fixation, absolute ethanol, glacial acetic acid and chloroform are mixed together in the proportion 45 : 15 : 1 immediately before use. Two alternative schedules may be adopted for fixation:
    (a) In the first alternative, the tube is flicked so that the pellet of cells forms a thick suspension. Two drops of fixative are added, and the tube flicked vigorously. The fixative is added drop by drop while flicking the tube continuously till the latter is about three-quarters full. It is centrifuged for 3 min at 500 rev/min. The supernatant is discarded and fresh fixative added. Fixative is changed after centrifugation twice more. The period of fixation is 15 min.

(b) In the second alternative, the pellet is not disturbed. Fixative is added carefully down the side of the tube till it is filled. The fixative is immediately pipetted off. The pellet is resuspended, fresh fixative is added and allowed to stand for 15 min. The procedure is repeated.

(8) The final suspension of cells in the fixative is dilute. It is allowed to stand for 1 to 3 h. A small quantity of the suspension is withdrawn and 2 to 3 drops transferred to a clean slide. The slide is tilted to permit the fluid to spread out to the maximum extent. Air is blown gently on the slide to dry the fluid. The process is repeated with further drops of the suspension. Several successive drops of a dilute suspension may give better preparations than a single drop of more concentrated suspension.

(9) The slides can be stored dry for examination later or stained immediately in lactic–acetic–orcein or toluidine blue (*see* chapter on stains) or fluorochromes (Caspersson *et al.*, 1971).

***Autoradiographic studies of male germ cells* in vitro** (Matté and Sasaki, 1968, 1971)

Testicular tissue, obtained by biopsy, is minced with scissors, suspended in total volume of 80 ml culture medium (80 per cent NCTC-109 and 20 per cent calf serum). Labelled thymidine is added at a final concentration of 50 μ Ci/ml and incubated for 15 h at 30 °C. The cell suspension is centrifuged at 1000 rev/min for 10 min. The supernatant is discarded. Fresh culture medium with excess cold thymidine is added and the fluid centrifuged. The precipitate is divided into 11 tubes each with 7–8 ml of fresh culture medium. After incubation the tissue is allowed to settle for 1 min. The supernatant is drawn out, fixed and processed for air dry smear and observed as given in the chapter on autoradiography.

Study of chromosomes from female germ cells

The schedules at present available involve squash techniques with modifications for different stages of division (*see also* Yunis, 1974).

Method for the study of first meiotic prophase from fetal tissue (Ohno, 1965; Priest, 1969)

Such configurations occur only in the fetal ovary, although occasionally some pachytene and diplotene stages can be observed in the ovary of a newborn female. Ovaries of embryos between the fourth and eighth months give the highest frequency of meiotic prophase figures. The oocytes at the pachytene and diplotene stages are enclosed in a layer of follicular cells, which have to be removed before processing.

(1) The ovary, obtained from an aborted fetus, is placed in isotonic solution. Its cortical area is dissected out under a dissecting microscope. The tissue is cut into 2 mm pieces.

(2) The pieces are immersed in 10 per cent trypsin solution and incubated at 37 °C for 30 min.

(3) They are then rinsed in isotonic solution, keeping in it for 10 min each time.
(4) The material is then fixed, squashed and stained according to the method followed for testicular tissue, steps (3) to (10) on page 342.
(5) The nucleus at pachytene shows in a normal female 23 bivalents with chromomeric patterns. The sex chromosome bivalent XX does not condense. The autosomal bivalents occasionally form non-homologous associations at the regions of the centromere.

Method for the study of first meiotic metaphase from a mature follicle (Ohno, 1965)

This method, being successful for smaller mammals, has been recommended for human oocytes. As mentioned earlier, the first meiotic metaphase can be obtained only from a mature follicle in the ovary of a woman in her reproductive span on the day of ovulation. Second metaphase can be seen in an ovulated but unfertilised ovum that has moved into the fallopian tube. The method is to be used if such material becomes available.

(1) The freshly obtained mature follicle is punctured using fine-pointed forceps. The fluid inside is poured out into a petri dish.
(2) The petri dish is placed under a dissecting microscope and an ovum located surrounded by the cells of corona radiata.
(3) The petri dish is incubated at 37 °C for 50 min or so until most of the corona radiata cells detach from the ovum.
(4) The petri dish is transferred under the dissecting microscope, the ovum with a small amount of fluid is drawn off with a small pipette and transferred to a drop of 50 per cent acetic acid on a glass slide.
(5) The material is fixed for 15 min and then the glass slide is covered with a cover-glass and a gentle pressure applied to separate the bivalents.

Culture methods for the study of meiosis in oocytes

They have been developed following similar schedules used in other mammals (Edwards, 1965; Yuncken, 1968). They are, however, still in an experimental stage. A technique, involving the use of hormones, is outlined below (Jagiello, Karnicki and Ryan, 1968).

Patients were admitted to the hospital on the third day of the menstrual cycle. Injections of human pituitary follicle stimulating hormone (FSH) were begun on the fourth day and repeated daily till the ninth day. On the ninth day, human chorionic gonadotrophin (HCG) was given and wedges from each ovary removed next day by biopsy. Ova were harvested in sterile conditions. Some were examined immediately after the schedule described earlier. The others were incubated. After 25 to 29 h incubation, eggs were harvested. Air-dried preparations were made by Tarkowski's method (1967) and stained for 25 min in lacto–aceto–orcein. Ovaries can be fixed in acetic–methanol and sent by post. They can be processed after 24 h (Luciani *et al.*, 1974, 1976).

Schedule for mammalian chromosomes

Followed by Evans, Breckson and Ford (1964) and its modifications: Remove testis into 2.2 per cent isotonic sodium citrate solution, swirl. Cut out a portion of the tubule, transfer to 1.125 per cent KCl, mince and tease out the contents. Decant cloudy supernatant and centrifuge at 160 g for 5 min. Discard supernatant, add acetic–methanol (1 : 3), disperse cells and keep overnight at 4 °C. Centrifuge and discard supernatant. Disperse cells in fresh fixative. Place a drop on a pre-cooled clean slide, tilt and allow fixative to evaporate and air dry. Stain with acetic–orcein or lactic–acetic–orcein, dehydrate through ethanol–xylol grades and mount.

With minor modifications, this method is widely used for mammals (Meredith, 1969), reptiles and birds (Dressler and Schmid, 1976). Clendenin (1969) introduced two variations, injection of 4 mg/kg of 1 per cent colchicine solution in Hank's medium intraperitoneally in living animals 1–2 h before killing, and use of 0.563 per cent KCl for swelling the cells. Earlier, Benirschke and Brownhill (1963) had used a variant of this technique in marmoset monkeys by injecting colchicine in the living animals. Peterson, Legator and Jacobson (1967) had emphasised the use of colcemid pre-treatment for meiotic studies and found that hypotonic KCl gave better details of meiotic chromosomes than other chemicals. In a modified schedule (Eicher, 1966), tubules are treated in a 0.7 per cent sodium citrate for 20–30 min, 5 ml glacial acetic acid is added, mixed and kept for 30 min and the supernatant is removed after centrifugation, 3 ml 3 M gluconic acid is added to the tissue, it is treated for 3 h, the acid is then removed and the cells are suspended in acetic–ethanol (1 : 1). Washing in fixative is done by centrifugation and air-dried smears are prepared.

Tarkowski's air-drying method (1966), described in the chapter on processing, was used by him for pre-implantation stages of mouse egg and was adapted for rat eggs as well (Dyban and Udalova, 1967). In an earlier publication, a simpler method of dissecting out the eggs in saline solution, fixing in Carnoy's fluid and floating them in a drop of acetic–carmine between two paraffin ridges on a slide has been described (Spalding and Wellnitz, 1956).

Schedules for lower animals

Hydra

Treat dissected testes successively in 0.001 per cent colchicine solution (2 h), hypotonic sodium citrate (0.37 per cent, 15 to 20 min), acetic–methanol (113, 20 to 30 min), squash in 45 per cent acetic acid, air dry and stain in Giemsa (pH 7.2–7.4 for 30 min) (Datta, 1978).

Lepidoptera

Pre-treat testes in hypotonic solution, fix in Carnoy's fluid and prepare both air-dry squash and suspension slides, stain in Giemsa (Goodpasture, 1976).

Spinous loaches (*Cobitus biwae*)

Culture cells from gonadal tissue for 7 days in TC 199 supplemented with 20 per cent calf serum, 100μm/ml penicillin and 100μg/ml streptomycin, prepare flame-dried slides and stain in Giemsa (Kobayashi, 1976).

KARYOTYPE ANALYSIS

This can be carried out from tissues showing mitotic figures. After Tjio and Levan (1956) definitely established the normal somatic chromosome number in human cells to be 46, their use of colchicine and hypotonic solution on cells *in vitro* was immediately followed by other workers. The biological and clinical significance of this study was established by the demonstration of a specific chromosomal anomaly, trisomy of chromosome G, in mongolism by Lejeune, Gautier and Turpin (1959). Since then, a vast array of data on chromosomal patterns associated with a variety of clinical disorders has been pouring in from centres all over the world. Screening studies suggest, in fact, that approximately 0.6–0.8 per cent of all live-born individuals carry a chromosomal abnormality (report of WHO, 1969). Karyotype analysis has been the principal means for detecting these anomalies and has thus gained increasing importance. Chromosome studies on human materials are also being used in evaluating homotransplantation barriers; in the study of dosage compensation, of drug effect and radiation on mitosis, of chromosome mapping and of mammalian cell genetics in tissue culture (*see also* Yunis, 1974; Emery, 1975; Sharma and Talukder, 1974).

Depending upon the type of tissue available, different methods have been developed and, with variations, have been applied to other mammals as well.

Preparations from bone marrow cells

Several schedules are available, which can be divided into two groups: *direct preparations* and *culture techniques*. Direct processing enables identification of the cell line from which the analysed cells are derived. Two methods, one involving squashing and the other the air-drying schedule of Rothfels and Siminovitch (1958a) have been evolved by Tjio and Whang (1962, 1965). Other techniques include short-term and medium-term cultures and immediate aspiration of bone marrow cells from individuals treated with colchicine.

Short-term culture technique (Ford and Hamerton, 1956a, b, c; Ford, Jacobs and Lajtha, 1958; *see* Sharma and Talukder, 1974; Yunis, 1974)

Withdraw 1 ml bone marrow from the individual, disperse in Ringer's solution containing 1 : 20 000 heparin. Centrifuge at 500–1000 rev/min and discard supernatant. Resuspend in isotonic glucose–saline mixed in equal

parts with human AB serum (or serum of the subject). Transfer aliquots of 2–4 ml to McCartney bottles, keep at room temperature overnight. Incubate at 37 °C for 5 h. Add 0.2–0.4 ml 0.04 per cent isotonic saline solution of colchicine and keep at 37 °C for 2 h. Dilute four times by adding 0.37 per cent sodium citrate solution and keep for 10 min. Centrifuge, discard supernatant, fix and stain by acetic–orcein or Giemsa.

Modifications of this schedule involve elimination of the culture process. Three of them are described below.

Direct squash preparations (Tjio and Whang, 1965)
Aspirate 0.5 ml bone marrow and treat in two changes of 2–3 ml colchicine solution (0.85 per cent NaCl solution with 6.6×10^{-3} M phosphate, pH 7, to which is added 0.3 g/ml colchicine or colcemid). Keep for 1–2 h at 20–30 C. Transfer to a watch-glass with a few drops of 2 per cent acetic–orcein: NHCl (9:1) mixture, heat gently. Squash in a drop of 2 per cent acetic–orcein or Giemsa. Seal and store. It can be made permanent by dry-ice freezing schedule and mounted in permount. It can be used for leukaemia cells (*see* Priest, 1969).

Direct air-dried preparations
The preliminary steps are similar for colchicine treatment as the previous schedule. Centrifuge at 400 rev/min for 4–5 min. Remove supernatant, add 2–3 ml hypotonic aqueous 1 per cent sodium citrate solution, shake and keep for 30 min. Centrifuge, remove supernatant, add acetic–ethanol (1 : 3), re-suspend by shaking, keep 2–5 min and repeat this procedure twice. With a pipette, transfer a droplet of the suspension to a slide. Blow on each droplet as soon as the cells are attached to the glass surface, to assist spreading. Allow to dry. Immerse 10–20 min in 2 per cent acetic–orcein solution, dehydrate through ethanol–xylol grades and mount in permount. Feulgen reagent, Giemsa stain and crystal violet can be used as alternative stains.

Immediate examination (as developed by Bottura and Farrari, 1960)
This proposes intravenous injection of colchicine into the subject 2 h before sternal puncture, followed by direct treatment in hypotonic solution, fixation and staining. Though used extensively in animals, this method is, for obvious reasons, not recommended for human material.

Medium term culture schedules

Liquid medium technique (Fraccaro, Kaijser and Lindsten, 1960a, b; Hirschhorn and Cooper, 1961)
Aspirate out 1 ml bone marrow, suspend in 3 ml culture medium: AB serum, 35 per cent; TC 199 medium, 60 per cent; embryonic extract, 5 per cent. Distribute in petri dishes containing cover slips, incubate at 37 °C for 24–72 h in an atmosphere containing 5 per cent CO_2. Remove the cover slips and

treat them in 0.7 per cent aqueous sodium citrate solution, fix and stain following the acetic–orcein schedule.

Solid medium technique (Turpin and Lejeune, 1969)
Aspirate 1–2 drops of bone marrow in a heparinised syringe, place on a disc in a Leighton tube covered with a film of chick plasma, as described in study of biopsy tissues. Coagulate with one drop of embryonic extract. Add 5 drops of nutrient medium (TC 199, 5; AB serum or patient's serum, 5, and embryonic extract, 2). Seal and incubate at 37 °C for 3–5 days. Replenish culture after observing under the microscope and disperse; fix and stain as described later under fibroblast culture schedules.

The bone marrow schedule, when applied to vertebrates other than man, generally includes injection of an antimitotic agent into the animal 1–4 h before killing it (Young *et al.*, 1960). Several modifications are available. De Vries and van Went (1964) advocated injection of 4 ml of human O-plasma from citrated blood intraperitoneally into a rat 16 h before injecting colchicine. The marrow cells can be washed out from the medullary cavity (Patton, 1967) or expelled from the bone shaft with a needle or a probe (Nadler and Block, 1962). An alternative schedule devised by Lee (1969) is given in outline:

Administer a mitotic inhibitor (0.004 per cent vincaleucoblastine) intraperitoneally into the animal at 0.02 ml/g body weight for animals up to 50 g, and 0.01 ml/g for those above 50 g. Kill the animal, and extract the bone marrow into 1 per cent sodium citrate solution. Keep at 37 °C for 5–15 min. Suspend the cells by inverting the tube. Decant suspension. Centrifuge twice at 500–700 rev/min for 2–3 min, discard the supernatant. Fix in 6–8 ml acetic–methanol (1:3) at 4–6 °C for 2–8 h. Re-suspend and remove debris at the bottom. Wash two to three times in fixative by centrifugation. Re-suspend in 0.5–3.0 ml fixative. Place 4–6 drops on damp, pre-cooled slides and spread by blaze-drying as described in section on peripheral blood technique. Any of the usual chromosomal stains can be used, like acetic–orcein; Feulgen (Battaglia, 1959); Giemsa, haematoxylin, etc., following their respective schedules.

The entire process can also be carried out on a slide (Bohorfoush, 1964). Aspirate 1 ml bone marrow into a syringe with three drops of 15 per cent K_2–EDTA, eject on to a slide with 1–2 extra drops of EDTA. Tilt the slide to remove solution. Bring marrow to the edge and smear over another slide. Air-dry the smear, heat at 120–125 °C for 2 min, treat for 30–45 s with undiluted Wright's stain, dilute with $Na_2S_2O_3$ solution (0.1–0.2 g/l of water) and keep 10–13 min.

Peripheral blood culture techniques

These are now almost universally practised and their use has been extended to practically all vertebrates. These methods are based on the finding that under the influence of phytohaemagglutinin (PHA) and certain other more specific antigens, the lymphocyte in the peripheral blood is morphologically changed into a blast-like cell that divides in culture. The first analysis of

human karyotype with this method was performed by Hungerford *et al.* (1959). A modification developed by Moorhead *et al.* (1960), combining the air-drying method of Rothfels and Siminovitch (1958a), with that of the peripheral blood culture, gave an excellent technique for obtaining well-scattered somatic metaphase plates. This technique has two major advantages: first, the ease with which it can be carried out on large numbers of individuals with a high success rate, and secondly, almost all the cells studied in metaphase are in their first division in culture, if suitably controlled.

In PHA-stimulated cultures, small lymphocytes increase in size and start to synthesise DNA after 24 h and then divide. Court-Brown (1967) observed abundant cells in metaphase after 40 h in culture: virtually all in the first division, as seen from studies with H^3-labelled thymidine. The study of the lymphocyte has gained importance since experiments indicate that it is an immunologically competent cell, that it has the capacity of re-circulation and that lymphocyte populations may survive for long periods *in vivo*.

In the absence of PHA, lymphocytes may also divide in culture in response to stimulation by an antigen, provided they are suitably sensitised. The blood culture technique, though excellent for most studies on karyotype analysis, carries certain limitations regarding the types of abnormality as yet recognisable. It can also be used effectively in the study of chromosome damaging agents, particularly ionising radiations.

The first step is to prevent coagulation of the blood obtained for the culture. Heparin is found to be ideally suitable and heparinised blood can be stored, without loss of mitotic activity, for 12–24 h in the cold before culturing. An alternative anticoagulant is acid–citrate–dextrose in which successful storage has been carried out for two weeks (Petrakis and Politis, 1962). Separated leucocytes (WBC) can be stored for 96 h at 5 °C, retaining their mitotic potential (Mellman, Klevit and Moorhead, 1962). If culture medium is added, they can even survive at room temperatue (Arakaki and Sparkes, 1963).

Leucocytes are separated out from red blood cells (RBC) by centrifugation or gravity sedimentation. Centrifugation at a slow speed (25 g) for 10–15 min is required for fresh blood, and 5–10 min for blood pre-incubated with PHA (Moorhead *et al.*, 1960). High-speed centrifugation has also been found to be effective (Bender and Prescott, 1962). Gravity sedimentation is a useful tool for separating RBC, the optimum temperature being 25–37 °C. More efficient methods are through the application of fibrogen and dextran sedimentation (Skoog and Beck, 1956). These chemicals interfere with the quality of staining, but this may be avoided by washing at the time of harvesting. These two latter methods are most efficacious for leucocyte cultures from small animals (Nichols and Levan, 1962). The presence of a moderate amount of RBC in the leucocyte suspensions does not appear to interfere with mitosis (Mellman, 1965). Tips *et al.* (1963) devised a blood culture method including the whole blood, thus utilising the entire WBC in a given volume. Polymorphonuclear leucocytes (PMN) can be removed by storing the WBC suspensions at 5 °C for 48 h, when the former degenerate. Alternatively, the culture flask is incubated on its side with the cells exposed to a large glass surface for 30–60 min and then stored upright. PMN are eliminated due to their property of adhering to glass, while the other cells settle to the bottom for the remaining period of incubation (Moorhead, 1964).

Hastings *et al.* (1961) used differential centrifugation and iron, to promote the magnetic removal of PMN following their phagocytosis of the iron.

The size of the cell inoculum depends on the different variable factors in the culture conditions. Different workers have laid stress on different aspects, ranging from the number of nutrients, and pH, to the maximum log phase required in the culture (*see* Mellman, 1965). Nowell and Hungerford (1963) recommended determining the inoculum size on the basis of the total white cell concentration in the supernatant plasma.

Mitosis is initiated in blood cultures of normal non-leukaemic individuals by mitogenic agents after a time-lag of 2–3 days. Leukaemic cells, however, divide in culture immediately, without the aid of such chemicals. The principal mitogenic agent used in blood cultures is phytohaemagglutinin (PHA). It is a mucoprotein isolated from seeds of *Phaseolus vulgaris* or *P. communis* by salt extraction (Li and Osgood, 1949; Rigas and Osgood, 1955; Peste, Alexander and Reeve, 1976). At a low pH, two fractions can be separated, a protein haemagglutinin and an inactive polysaccharide. Its capacity of selectively agglutinating and sedimenting mature erythrocytes and of inducing division in leucocytes, has made it an invaluable tool in chromosome analysis from blood culture (Hungerford *et al.*, 1959; Moorhead *et al.*, 1960; Nowell, 1960). Nowell (1960) suggested that the principal action of PHA is on the WBC cell membrane, which on being altered, allows certain substances of the culture medium to penetrate the cell and stimulate mitotic activity. Elves and Wilkinson (1962) considered the mitogenic effect of PHA to be due to the rejuvenation of the lymphocytes, while Cooper, Barhan and Hale (1961) suggested that it might be caused by the induction and progress of DNA synthesis. Hirschhorn *et al.* (1963) held that PHA aggregates the WBC which are converted into dividing cells through close association. This hypothesis is objected to by the fact that WBC divide even while being agitated in spinner cultures (Nowell, 1960). The correlation between mitogenic activity and leucoagglutination has been demonstrated by Hastings *et al.* (1961) and Kolodny and Hirschhorn (1964) Weber (1973) and Skoog *et al.* (1974). Byrd *et al.* (1967) showed that the mitogenic capacity of PHA can be checked by an antiserum.

Experiments were also conducted to find out whether agglutination is caused by actual combination with the compound, or by the alteration of the membrane through enzymic action. The latter was considered unlikely and all types of erythrocytes, including O and Rh negative, were seen to be equally affected. Beckman (1962) showed that it can also precipitate α^2 globulin, plant protein, and α and γ globulins. Jaffe (1959) separated phaseolotoxin A and fraction B from *Phaseolus vulgaris* and noted that phaseolotoxin A contains 13.5–14.5 per cent nitrogen, while B has three principal constituents. Bacto-phytohaemagglutinin is available in two forms, M and P (DIFCO code 0528 and 3110). The former one (M), a stable desiccated muco-phytohaemagglutinin with no toxicity, is the form usually recommended for securing viable leucocyte preparations and nucleated erythrocytes from blood and bone marrow suspensions. The latter (P) is a sterile, highly purified form, from which the polysaccharide has been removed. It is much more potent than M in its mitogenic and agglutinating properties. About 0.1 ml M-form to 5 ml heparinised blood, is adequate for its optimum action, while the P-form is needed only in 1/10th to 1/50th concentration of the former for differential separation. After the addition of PHA, the

container is kept undisturbed for 30 min, followed by centrifugation (500 rev/min) for 1–2 min, and separation of the supernatant containing leucocytes.

Attempts to separate the two distinct cell principles of PHA, one of which has the property of agglutinating RBC and the other of initiating mitosis, are not yet completely successful (Punnett and Punnett, 1963). Unfractionated PHA has been observed to agglutinate RBC preferentially in whole blood but may agglutinate WBC as well when added in larger quantities to WBC suspensions. Therefore, according to Barkhan and Ballas (1963), the non-mitogenic factor in PHA possibly agglutinates RBC and is different from the mitogenic factor agglutinating WBC. Tuberculin has been found to be an effective substitute for PHA, in human lymphocyte cultures from individuals sensitive to tuberculin (Pearmain, Lycette and Fitzgerald, 1963), showing a possible solution to the problem of the nature of PHA activity. Downing, Kemp and Denborough (1968) found that other plant agglutinins commonly agglutinate both RBC and WBC but they seldom also induce mitosis of lymphocytes in tissue culture. This suggests that mitogenic activity in some of them is independent of their agglutinating property.

The basal culture media for leucocyte culture contains mixtures of amino acids, vitamins and buffered salts, the commoner ones being TC 199, NCTC 109, Parker's, Waymouth's, BME Spinner and Eagle's ME media. All of them require serum proteins for successful blood cultures, in a proportion of 10–40 per cent. Calf serum and both autologous and homologous human sera can be used. Mellman (1965) has advocated adding half the volume of the serum to be used as WBC-containing plasma and an equal volume of homologous AB serum. Commercially available fetal calf serum gives better growth. Air-tight bottles are recommended to prevent escape of the CO_2 produced, thus increasing the alkalinity, which has an adverse effect on growth. Alternatively, open vessels can be incubated in an atmosphere of 5 per cent CO_2, or the pH of the medium can be maintained at 7.2 to 7.4 by adding HCl or $NaHCO_3$ daily. Temperature should be kept between 36–37 °C to have peak mitotic activity between 60–72 h, or strictly at 38 °C for optimum activity at 48 h. Bacterial contamination is prevented by the addition of penicillin and streptomycin in human blood cultures. Since certain levels of antibiotics like streptomycin and chloramphenical have been found to be deleterious to mammalian cell cultures (Metzgar and Moskowitz, 1963; Ambrose and Coons, 1963), their use can be omitted if sterile precautions are adopted. The major steps in the preparation of metaphase plates for karyotype study from leucocyte culture involve metaphase arrest, hypotonic treatment, fixation, preparation and staining. Chaudhuri *et al.* (1977) attribute the quality of the preparations to intrinsic factors as well.

For the arrest of mitosis at the metaphase, colchicine or its analogue deacetylmethyl colchicine (Colcemid, CIBA) is most frequently used. The hypotonic treatment for swelling the cell and dispersing the chromosomes, first devised by Hsu (1952) and Hsu and Pomerat (1953) can be carried out by diluting the balanced salt solution used to wash the harvested cells with distilled water and then incubating the cells in it. A solution containing one part human serum to five parts distilled water gives good results in human fibroblast (Lejeune, Gautier and Turpin, 1959a, b; Lejeune, 1960) and leucocyte cultures (Hungerford and Nowell, 1963). To remove the water

present in the culture as much as is practicable, the cells are centrifuged into a small button and the supernatant discarded. The button can be treated in the fixative, with or without shaking, for 30 min. Best fixation results are given by a mixture of glacial acetic acid and methanol (1 : 3). Two or more changes of the fixative may be necessary to remove completely the coating substances of the chromosomes. Both air-drying and squash schedules can be used for the preparation of the slides, the former being more satisfactory. The stains include most of the common stains for chromosomes, like Feulgen, acetic–orcein, Giemsa, Unna's blue and methylene blue, and the method of staining is similar to that followed for bone marrow techniques.

Representative schedules for peripheral blood leucocyte culture

Macromethod

Draw in and eject 1 ml solution of 5000 iu heparin/ml in a syringe, thus coating its walls completely with heparin. Draw 20 ml venous blood into the heparinised syringe.

Decant in a test-tube inclined at 45 degrees and permit the RBC to sediment. The blood can also be kept for sedimentation in the syringe itself, with the needle held upward, at room temperature. After 30–50 min, remove supernatant containing exclusively WBC—5 to 10^6/ml. This decantation procedure of Edwards and Young (1961) avoids an alternative method of slow speed centrifugation (200 rev/min) for separating the leucocytes. Study an aliquot of the supernatant in a Malassez counting cell to obtain finally a concentration of $1–1.5 \times 10^6$ cells/ml, in a medium containing 30–35 per cent of the individual's serum, and 65–70 per cent of the basal medium, by adding required amounts of this medium. Add 0.2 ml bacto-phytohaemagglutinin per 10 ml mixture. Distribute in test tubes, filling them to one-third of their volume. If required, inject a mixture of 5 per cent CO_2 and air before sealing the tube. Incubate at 37 °C for 72 h. Add, 2 h before harvesting, two drops of isotonic colchicine solution at a concentration of 0.04 per cent per ml of the medium.

Decant into a centrifuge tube, spin at 800 rev/min for 5 min, discard supernatant and add hypotonic solution (0.93 per cent aqueous sodium citrate) and treat for 10 min at 37 °C. Centrifuge to a button at 800 rev/min. Remove supernatant and add fixative (1 : 3) acetic–methanol or acetic–ethanol) slowly, suspending the cells. Leave for 30 min and repeat the process using only 2–3 drops of the fixative. Re-suspend cells by pipetting to prevent bubble formation.

Cool several absolutely clean, grease-free slides (or cover slips), by placing on a paper put on an ice block, or on CO_2 snow, so that they are covered with a fine mist. Place a drop of cell suspension over a cover slip which immediately spreads. Hold over a flame, ignite (Scherz, 1962) or place in a 60 °C cabinet to cause evaporation of the fixative, flattening the preparation. Alternatively, tilt slide on its long edge, touching absorbent paper, and blow directly on slide. Dry in air. Store, or stain immediately if necessary.

Modifications generally include the number of centrifugations required

and the stains used. Antibiotics can be added if necessary, a proposed incubation medium being; autologous plasma, AB human serum or fetal calf serum, 1 ml, basal medium TC 199, 6 ml; bacto-phytohaemagglutinin, 0.03–0.05 ml, penicillin (100 000 units/ml) and streptomycin (100 mg/ml) solution, 0.02 ml. It can be prepared and stored at 20 °C. If, in the dried slide, cells are scarce, concentrate the cell suspension, after adding fixative, by centrifugation and removal of part of the fixative. For chromosomes insufficiently spread or shredded, the number of times of suspension in fixative is increased and the flaming schedule is followed for spreading. If chromosomes are overspread, use a small drop of suspension and do not evaporate quickly. Stain in lactic–acetic–orcein (3 to 24 h) and rinse in 45 per cent acetic acid; or stain in Giemsa (pH 7.2) and air dry; or heat in 0.06 M phosphate buffer (pH 6.8 to 7.2) for 10 min, stain in haematoxylin and mordant in 3 per cent aqueous ferrous ammonium sulphate solution (Barnett, Mackinnon and Romero-Sierra, 1973).

Semi micromethods

According to Mellman (1965)
Add 0.1 ml aqueous heparin (1000 units/ml) and 1 ml serum to a 2 ml plastic disposable syringe. Fill to the 2 ml mark with venous blood. Mix the contents. Empty the needle by aspiration. Stand the syringe and allow the RBC to sediment at room temperature, as in the macromethod, till the clear supernatant is about 1 ml (30–60 min).

Bend the needle and inject contents directly in culture vessel without doing WBC count. The vessel contains the complete culture medium described above at room temperature. The later steps are similar to the macromethod.

Adopted by Nowell, Hungerford and Brooks (1958), ***Hungerford and Nowell*** (1963), ***Moore, Gerner and Franklin*** (1967)
Draw 10–20 ml blood in a syringe containing 0.2 ml heparin. Add PHA (M form) to blood (0.2 ml per 10 ml), mix and keep in the cold for 30–45 min. Centrifuge at 25 × g for 10 min at 5 °C, remove supernatant and count leucocytes. Plant leucocytes (10^7) in a medium containing: plasma, 3 ml; medium 3 ml, and antibiotics. Maintain a pH of 7.2–7.4 with HCl or $NaHCO_3$. Incubate at 37 °C for 72 h. The remaining procedure is as above, the hypotonic used being 1 : 5 dilution of serum. The method should strictly be called a macromethod owing to the quantity of blood needed.

Micromethods

These were developed by several workers using only a few drops of blood (Edwards, 1962; Frøland, 1962; Arakaki and Sparkes, 1963; Grouchy, Roubin and Passage, 1964; Reitalu, 1964, Turpin and Lejeune 1969).

Fill centrifuge tubes (capacity 41 ml) with 5 ml human serum, 15 ml TC 199, 4 drops of PHA (mixture of equal parts of phytohaemagglutinin Difco

M and P, or phytohaemagglutinin Wellcome and 4 drops of Liquemin (Roche, or equivalent of 5 mg crystalline heparin).

Disinfect skin of index finger or thumb carefully. Incise with a vaccino-style and remove 4–6 drops of blood with a pipette. Transfer directly to the tube containing the medium. Rinse out pipette with medium to suspend the blood. Alternatively, use a few drops of blood drawn from a vein. Seal and incubate at 37 °C for 48–72 h. Add 2 ml 0.04 per cent isotonic colchicine solution. Re-suspend and incubate for 2 h. Re-suspend, transfer to a conical centrifuge tube. Centrifuge for 5 min of 800 rev/min, discard supernatant.

Fill up to two-thirds of tube with a mixture of animal serum (1); distilled water (5) and hyaluronidase 2.5 iu/ml mixture. Re-suspend and incubate for 7 min.

Centrifuge for 5 min at 800 rev/min, keep 2 min, discard supernatant hypotonic and add Carnoy's fixative (acetic–chloroform–ethanol 1 : 3 : 6). Re-suspend and keep for 45 min.

Centrifuge at 800 rev/min for 5 min, discard supernatant and add acetic–ethanol (1 : 3). It can be sealed and stored in the cold.

Centrifuge at 800 rev/min, discard supernatant and add 5–6 drops of fixative. Re-suspend by pipetting. Follow next steps in macromethod.

After air-drying, hydrolyse for 7.5 min in N HCl at 60 °C, rinse in iced water and stain for 10 min in a solution of 1 part Unna's blue and four parts neutral water. Rinse in water and dry.

Pass through xylol or toluene grades and mount in canada balsam or directly in permount.

A schedule developed by Hungerford (1965) uses a culture medium composed of: Eagle's basal amino acids and vitamins, at double strength, in Earle's balanced salt solution (BSS), adjusted to pH 7.0 with 7.5 per cent $NaHCO_3$, supplemented with glutamine 2mM, penicillin 100 units/ml, streptomycin 100 μg/ml, phenol red 7 μg/ml. Fetal agammaglobulin bovine serum and phytohaemagglutinin M (Difco) are added to make 15 and 2 per cent, respectively, of the final volume and also 20 000 USP units of heparin sodium per litre of complete medium. After the usual schedule of inoculation, incubation and treatment with colchicine, the cells are separated by centrifugation and the medium replaced with 0.075 M KCl, 16 USP units/ml heparin sodium, and incubated for 10 min. Subsequently, KCl is removed and the material fixed in two changes of acetic–methanol (1 : 3), air-dried and stained in 1 per cent orcein in 60 per cent acetic acid. It has the advantage of using a very small quantity of blood and the medium is a modification of an earlier one developed by Hayflick and Moorhead (1961). Wittmann's (1965) acetic–iron–haematoxylin and cresyl violet acetate (Humason and Sanders, 1963) can be used as alternative stains. Vincaleucoblastine (0.15 ml of a stock solution of 0.5 g/ml per 10 ml culture) was used instead of colchicine by Kolodny and Hirschhorn (1964). Other alternatives have been given in Chapters 3 and 4.

Application in other human tissues

Lymph tissue, after maceration, has been cultured, following the micro-method for peripheral blood, giving good chromosome preparations (Baker

and Atkin, 1963). Chromosome analysis from capillary blood has been carried out by leucocyte culture also (Robinson *et al.*, 1964). Autopsy spleen, post-mortem leucocytes (Yoon and Yoon, 1971), thoracic duct lymphocytes (Lindahl-Kiessling, Warner and Book, 1965) and fetal ascitic fluid (Chang and Bowman, 1965) can be similarly analysed. A micromethod was developed for mice by Truman, Davisson and Roderick (1975). Permanent lymphocytoid cell lines have been established from patients with XYY and XXY chromosome constitutions by cultures following leukaphoresis (Moore *et al.*, 1966; 1969). An important aspect of this technique is the study of fetal blood for pre-natal chromosome analysis in order to check possible chromosomal anomalies in the fetus. A small amount (0.5 ml) of blood can be obtained from an umbilical cord, or some such fetal vessel, even by a tiny puncture of the fetal skin. Pre-natal chromosome analysis is usually carried out on cells from the amniotic fluid (drawn out by a syringe) which are concentrated by centrifugation and cultured on tissue culture medium, followed by colcemid treatment, and harvesting as in the schedules described before. This form of analysis could be of value in cases listed for sex chromatin where more data are required; where parents are unaffected carriers of a chromosomal abnormality or have been exposed to mutagens, radiation or virus attacks, and in the rare families having known very high rates of chromosomally abnormal offspring. The method available through amniocentesis usually has several drawbacks including contamination with maternal cells, unreliability of results, and in difficult cases even fetal death by incompatability, through a small quantity of fetal blood passing into the maternal circulation (Wang, McCutcheon and Desforges, 1967). Therefore, extreme caution has to be exercised in such studies (*see* Klinger and Miller, 1968 and Sharma and Talukder, 1974). Kits for human peripheral blood culture are available commercially. Venous blood can also be mailed for study after heparinisation.

Application in other vertebrates

Modifications of the peripheral blood culture technique have been applied successfully in a large number of mammals, like gorilla (Hamerton *et al.*, 1961); rabbit (Stranzinger, Miller and Fechheimer, 1974); domestic pig (McConnell, Fechheimer and Gilmore, 1963; Stone, 1963; Srivastava and Lasley, 1968); macaca (Sanders and Humason, 1964); sheep (McFee, Banner and Murphree, 1965); dog (Ford, L., 1965); spider monkey (Eide, 1963); ox (Biggers and McFeely, 1963); cattle (Halnan, 1977), and the primates (Egozcue and Egozcue, 1966). Ohnuki, Awa and Pomerat (1962), however, suggest that a comparison of the leucocytes of monkey and man, in culture, gives poorer results in monkey cells with an identical method. The schedule has also been successfully adapted for use in snakes, fishes and birds (Newcomer and Donnelly, 1963; Manna, unpublished; Denton, 1973; Blaxhall, 1975; Grammeltvedt, 1975; Legendre, 1975; Kligerman and Bloom, 1976).

The major variations involve the type of medium used, its constituents, the relative amounts of PHA and colchicine needed and the periods of treatment and incubation.

Preparations from fibroblast and other cultures

Cultures

Though relatively time-consuming, fibroblast culture methods can be effectively used for checking unusual karyotypes observed in the blood cells, determining mosaicism by studying chromosomes of different tissues, and for other experimental work where cytogenetic studies are correlated with biochemical, virological or other studies.

In general, any tissue aseptically removed, can give usable cultures. The different techniques have evolved essentially as a result of the manner in which the cells are transferred: *en bloc* in the state in which they are (explant technique, Turpin and Lejeune, 1969), or after trypsinisation (Harnden, 1960; Harnden and Brunton, 1965).

The basic precautions to be adopted during tissue culture are: (a) use of scrupulously clean glassware (b) adoption of sterilisation measures throughout the process. Though antibiotics have lessened the need for this precaution, yet an excess of antibiotics may result in chromosomal aberrations; (c) controlled pH at 7.2, maintained usually by a bicarbonate buffer.

The first step in the technique is a biopsy, which can be obtained from any part of the body by surgical means, the most common one being skin culture. The biopsy should be 2–4 mm in diameter and should include the connective tissue. The surface should be cleaned thoroughly and the use of local anaesthesia is optional. Tissue should preferably be set up in culture immediately, but storage at room temperature overnight is also possible.

The next step is the setting up of the primary cultures and there are several techniques. One way is to digest the tissue with trypsin and plate out the cells thus suspended (Puck, Cieciura and Robinson, 1958). This method, however, is not always recommended, owing to the delicate care required in handling and the uncertain success. The more common method is to cut up the tissue into small bits before placing in culture. Usually the bits are fixed in position by using a plasma clot (Harnden, 1960; Lejeune, Gautier and Turpin, 1959 a, b); or holding them down with perforated cellophane (Hsu and Kellogg, 1960), or rat tail collagen (Swanson and McKee, 1964), or by placing them on a metal grid (Koprowski *et al.*, 1962), or by pinning under a cover slip (De Mars, 1963 in Harnden and Brunton, 1965), but cultures can also be carried out without holding down the tissue (Davidson, Brusilow and Nilowsky, 1963).

The tissue is grown in a liquid medium composed principally of a synthetic culture medium to which serum and a growth stimulant like chick or beef embryo extract have been added. Commercially available TC 199 and Eagle's media give good results. Composition of some of the commoner media is given at the end of this chapter. Human AB serum, pooled human serum, calf serum and fetal calf serum can be used, depending on the material.

Subcultures should be set up only after adequate growth, after 10–14 days from setting up the culture. The medium should be replenished after 2–3 days to maintain a constant pH. Either the original tissue is cut free from the outgrowth and replanted in a fresh plasma clot, or trypsin is used to digest

the cells free from the clot or the vessel. The cells are washed and placed in a new culture vessel, where they adhere to the glass as a monolayer. The medium is replaced at intervals and new subcultures are made whenever the monolayer becomes too heavy. If a 1 in 10 dilution is used in inoculation, subcultures should be made once a week. Puck, Cieciura and Robinson, (1958) recorded the growth of cultures for a year without any deleterious effects, but Hayflick and Moorhead (1961) and Moorhead and Saksela (1963) observed gradual loss of cell multiplication and aneuploidy after a particular period in cultures.

For chromosome preparations, attempts are made to obtain partially synchronous divisions by changing the medium or subculture. The culture is allowed to become acidic and the pH restored to 7.4 by adding $NaHCO_3$ and embryo extract, resulting in a large number of mitosis after 16 h. In most techniques, however, colchicine is added to the culture to obtain metaphase configurations. The next stage is the use of a hypotonic solution, ranging from distilled water to dilute sodium citrate, or diluted salt solution or serum.

For obtaining suitable plates, as discussed later, two methods are available. Either the cells are grown on cover slips and processed while attached to them (Harnden, 1960), or the cells are suspended through trypsin digestion and then processed in any of the methods available for peripheral blood culture. The second method gives more satisfactory results. In fixation, acetic–ethanol or acetic–methanol (1 : 3) is commonly employed. Fixation can be carried out without breaking up the pellet, or by suspending the cells prior to fixation. The cells can be spread by the air-drying schedule used for blood cells. For better spreading, they can be transferred to 75 per cent acetic acid immediately before drying. Squash preparations are not very successful. Giemsa, Feulgen and Unna's blue are the frequently used stains. The length of time from culturing to chromosome preparations may range between 1 and 3 weeks, depending on the method and the material used.

Constituents used in the techniques

Cockerel plasma (CP)
Can be stored at 4 °C for several weeks in wax- or silicone-coated glassware. It is prepared by drawing 20 ml blood from the wing vein of a young bird, centrifuging at 1500 rev/min for 30 min at 4 °C and storing in the cold.

Trypsin (0.25 per cent)
Is prepared by dissolving 2.5 g Bactotrypsin 1–300 in a few ml Hank's solution without Ca and Mg and adjusting the pH to 8.0 with NaOH. The solution is made up to 100 ml with Hank's solution and later diluted with it 10 times before use.

Sodium bicarbonate
(1.4 per cent) contains $NaHCO_3$. 3.5 g; phenol red (0.2 per cent) 2.5 ml, and neutral water 247.5 ml. 5 ml is added to 200 ml Hank's solution before use.

Colchicine
Stock solution contains 0.5 per cent colchicine in neutral water. Working solution of 0.005 per cent colchicine is prepared in BSS. 0.5 ml this solution is added to each 10 ml culture to have a final concentration of 0.0025 per cent.

Antibiotics
Kanamycin, mycostatin, neomycin, penicillin and streptomycin are all dissolved in neutral water to obtain stock solutions and later diluted with culture medium for the required concentrations (for details, *see* Harnden and Brunton, 1965).

Stain
8 ml Giemsa stock solution in 192 ml distilled water.

Chick embryo extract (CEE)
Can be obtained commercially. For large quantities, embryos from hen's eggs incubated for 10 days are collected and homogenised by forcing through a syringe. Hank's BSS medium is added (1.25 vol), the mixture centrifuged at 2500 rev/min for 30 min at 4 °C. The supernatant is decanted, mixed with 2 mg hyaluronidase/100 ml extract, incubated at 37 °C for 1 h, ultra-centrifuged at 25 000 rev/min for 1 h and filtered through No. 03 porosity Selas candle filter under pressure of 8–10 lb/in^2.

Serum
AB serum can be obtained by allowing a pint of human AB venous blood to coagulate at 4 °C, drawing out the serum with a syringe, centrifuging at 1500 rev/min for 30 min and filtering through a No. 03 porosity Selas candle filter.

The constitution of the different media is given at the end of this chapter.

Growth medium
Used in almost all cultures, contains Eagle's medium with antibiotics, 70 parts; human AB serum 20 parts and CEE 10 parts.

Hanging drop method

This technique is otherwise known as the 'slide culture' technique, originally devised by Harrison (1907). In this method, a drop of a suitable medium, such as serum, lymph or salt solution, is generally placed on a cover slip, the tissue is transferred to the medium and the cover slip, with tissue, is inverted over a grooved sterilised slide. The edges of the cover-glass are then sealed with vaseline or paraffin wax and the slide kept in the incubator. After the growth of the tissue, cells can be sub-cultured by following a similar procedure in different sets with bits of tissue taken from the original one. After implantation, the cells soon start growing, and on emerging from the

tissue, spread on the glass surface, provided the latter has the required properties (Rappaport, 1960). For quick and rapid emergence, older tissues may need pre-treatment with 1 per cent trypsin in physiological salt solution. Saline extract of minced embryo tissues or of brain, cartilage and heart may also serve as growth promoters (Moscona *et al.*, 1965). Certain tissues have distinct but changeable points of contact on the glass surface (Ambrose, 1961). Chick connective tissue shows the rapid emergence of mechanocytes with increase in concentration of the medium. The rate may even be 20 μm/h (Moscona, Trowell and Willmer, 1965). Serine (Lockart and Eagle, 1959), inositol (Eagle *et al.*, 1957), cepalin (Fujii, 1941), fetuin— the glycoprotein from fetal calf serum (Puck, 1961), as well as several polypeptides (Lieberman and Ove, 1958), help in the growth and spreading of the tissue.

The problem of surface contact in glass cover slips is often minimised by providing a standardised surface by dipping the cover slips in a dilute solution of celloidin, followed by drying in a vertical position. The cells, on being flattened over the glass or celloidin surface, can conveniently be observed under the microscope.

In addition to a fluid medium, solid media like blood plasma can be utilised for culture. Fowl plasma is one of the most commonly used media, as under strictly controlled conditions it does not undergo clotting. By heparinisation, early clotting can be prevented and the plasma shows clotting only after the tissue is implanted. The plasma not only provides nutrition for the cells, but also facilitates the invasion and spreading of tissues because of the digestibility of its fibrin threads by enzymes. However, the use of embryo extract or plasma is gradually being replaced by more synthetic media, in which the ratio of constituents can be controlled. This method, however, has certain limitations. If the medium is not heavy, evaporation may change its concentration, resulting in degeneration of cells, especially at the centre, due to the increased concentration of metabolites and inadequacy of food and oxygen supply. This difficulty can be minimised to some extent by rapid sub-culturing in fresh medium. For prolonged culture, this method is not very effective, but even then the suspension of free cells on the surface of the cover-glass and convenience of observation under the microscope make it a very suitable technique for the study of tumour cells in particular. Makino (1953) and Makino and Nakahara (1953) pointed out certain limitations of the original hanging drop method, especially as the drying of the fluid with increase in temperature and the condensation of water at the bottom of the slide hamper visibility. These difficulties can be overcome by putting liquid paraffin in the groove of the slide. Following this method, they made phase contrast observations of single tumour cells obtained from ascites fluid.

Slide culture method

In order to overcome the limitations of the hanging drop method, Pomerat (1951) improvised a perfusion chamber, based on the slide culture technique, but having a continuous circulation of the fluid through inlet and outlet tubes surrounding the culture. Tissues cultured in a perfusion chamber are very suitable for cytological studies.

Slide chamber method

Several such chambers have been devised by various authors (Mackaness, 1952; Buchsbaum and Kuntz, 1954; Rose, 1954; Pulvertaft, Haynes and Groves, 1956; Sykes and Moore, 1960). All these chambers are constructed on the basic principle of continually renewing the medium or even securing a slow continuous perfusion. In one of the devices (Rose, 1954), silicone–rubber rings are used to separate the two cover slips and two steel plates are applied for firmly clamping the cover slips. The rubber allows the introduction of a hypodermic needle through which the gas or medium can be injected. By inserting a bubble and rotating the slide, the stirring needed for oxygenation can be obtained. The tissue may be grown directly on the glass in the fluid medium or in plasma. To eliminate the observational difficulties arising out of the growth of different layers on both the interfaces (Rose, 1954), cells are enclosed and sandwiched between two pieces of sterilised cellophane, or cellophane on one side and glass on the other.

In the Mackaness type (Mackaness, 1952), a slide of Lucite (Perspex) or stainless steel is used, having an aperture bored on both sides for fitting two circular cover slips, sealed with wax. Two plugged lateral holes are used for introducing the medium. In the Pulvertaft type (Pulvertaft, Haynes and Groves, 1956), a glass slide is provided with a central pillar of agar, on which the cover slip is placed and its rim sealed. In another device a Lucite slide is used with a central pillar and a moat, and the cover slip on the top is sealed.

Following all these methods, the cells can be grown in a single layer, either between two cellophane sheets, or between glass and cellophane, or between serum agar and glass. Such monolayer growth has decided advantages for observation. Time lapse cinematographic attachment fitted with perfusion systems (Buchsbaum and Kuntz, 1954) has helped in detecting the continuous phase of growth.

Flask and tube method

The Carrel flask technique of 1923, which was later modified by Barski and colleagues (1951) and Harris (1952), allows the growth of tissue in the required medium, within a flask, which is flat at the top and bottom and has an oblique neck at one side. This flask has the advantage of holding a large quantity of medium, which can be repeatedly washed so that frequent sub-clotting of the original tissue is not necessary. The provisions for adding a known gas mixture and its renewal are a decided advantage. One serious drawback of the flask method is that the position of the tissue is not convenient for observation, but this difficulty is, to some extent, overcome by sealing cover slips over the perforations made in the body of the flask or, alternatively, the tissues can be cultured on cover slips inside the flask and removed for observation later.

Gey and Gey (1936) devised the 'roller tube technique' which, though a modification of the 'flask method', is yet much simpler, less expensive and equally effective for many purposes. In this case, flasks are substituted by test-tubes, in which the culture can be made either in flat or obliquely placed

media, but as difficulty is often encountered in measuring growth due to the oblique nature of the bottom of the tube, cultures are often grown on cover slips placed within the test-tubes (Ehrmann and Gey, 1953). Collagen was used to line the tube, thus facilitating adhesion and spreading (Ehrmann and Gey, 1956).

Makino and Hsu (1954) successfully employed the roller tube culture for cytological studies of embryonic lung, spleen, heart and liver of rats. For proper aeration and constant circulation of the nutrients, it may be necessary to rotate the culture in the tube (*see* Hsu and Kellogg, 1960).

As cells on static surfaces suffer from lack of oxygenation, 'shaker flasks' (Earle, Bryant and Schilling, 1954), for large volumes, are now used. The medium is placed in Erlenmeyer flasks or balloon flasks, with living cells and then placed in a shaker oscillating at approximately 400 rev/min, allowing proper aeration, but not permitting the cells to settle on the glass, and free multiplication of cells in this fluid.

Watch-glass technique

One of the most widely used methods is the 'watch-glass technique', originally introduced by Fell and Robinson (1929). It is a very convenient method for the cultivation of organised tissue, such as bone, teeth, eye, etc., and is also employed for the study of tumours and cancers (Fell, 1961).

In the original method, the tissues were grown on the surface of a plasma clot in a watch-glass, enclosed within a petri dish. The bottom of the petri dish was covered with damp cotton wool, serving the purpose of a moist chamber preventing evaporation. Later modifications (Chen, 1954; Shaffer, 1956) involved growing the cultures attached to lens paper or rayon strips, which were fixed on the plasma clot or suspended in the fluid nutrient. An advantage of this technique is that the culture is not detached during transfer. Gaillard (1948) and Wolff and Haffen (1952) suggested the use of embryological watch-glasses. The former author preferred a medium of saline, serum, plasma and tissue extract, whereas the latter suggested a mixture of agar with saline serum and embryo extract as the medium of growth.

Moscona (1956) and Wolff (1957) evolved an excellent technique which involves treatment of the organ with trypsin for organ cultures, as well as for the preparation of cell suspensions, allowing the separation of constituent cells without loss of viability. If the trypsinised disaggregated mass is cultured in nutrient media, reaggregation takes place and the formation of new organs is easily achieved.

Cell isolation and suspension culture

The concept of the pattern of pure strain of cells dates back to 1933 when Baker succeeded in culturing chicken monocytes in serum. The method that was gradually developed was to obtain one class of cells from a suspension by differential centrifugation, in suitable solutions of sucrose or albumen, or gradient sedimentation which was found to be specially effective in blood (Weiss and Fawcett, 1953). Doubtless, to some extent growth of one class

of cells can be obtained even from a tissue explant, provided it is homogeneous, such as: certain epithelial cells, fibroblasts, etc., but this homogeneity appears in certain cases to be questionable. A method of mechanical isolation for pure strain culture was worked out by Sanford, Earle and Likely (1948), in which fibroblast culture in plasma clot was carried out in small capillary tubes, and later the tubes were broken into pieces in such a way that each broken piece contained a single cell. It was then cultured in fresh medium, but even so, abnormalities in growth developed. It has been assumed that single cells, without undergoing mutation or adaptation, cannot continue further growth except in a few cases, an example being HeLa cells (*see* chapter on cancer cells). Later several techniques were developed for preparing cell suspensions, some of which have been outlined here:

Mechanical separation

The simplest method of preparing cell suspension is to make a fine paste of the tissue by grinding and to secure the cells from the sedimented suspension. This method, however, causes serious damage and is not suitable for critical analysis, due to heterogeneity. Rinaldini (1958) outlined different schedules for the preparation of cell suspensions.

The general procedure for securing single cell suspension is through the disintegration of tissues or from standard cell cultures. Such disintegration can be brought about by grinding, in a homogeniser and Waring blender, in which the cells are generally not exposed to chemical treatment. But the damage caused, as well as the denaturing and lytic actions of the disrupted cell products, are serious limitations. Ultrasonic dissociation has also been attempted (Lutz and Lutz-Ostertag, 1959; Bell, 1960) but its consequent effect is yet to be analysed. Trypsinising the tissues, followed by treatment in a vibrating tube (Auerbach and Grobstein, 1958) has been shown to be useful for embryonic tissues. Treatment with chemicals which have no appreciable effect on cell properties, combined with slight mechanical treatment, or enzyme digestion, forms the basis of most of the recent techniques.

Disintegration through chemicals or enzymes

Methods for chemical disintegration involve the elimination of divalent cations like Ca or Mg, chiefly the former which is responsible for maintaining the cell contact and for the attachment of the cell to the substratum. Moscona (1952) observed that such treatment should be associated with trypsin digestion, the principles for which will be discussed later. The chelating agent, versene or ethylene diamine tetra-acetate (EDTA), which affects the calcium binding and the alkaline pH, has been effective in dissociating mammalian embryos (Brochart, 1954), but even then, in most cases, slight mechanical agitation is needed to secure at least appreciably small fragments. The extent to which versene is effective in mature tissue is debated, Anderson (1953) noted that sieving or grinding lead to the dissociation of liver tissue previously treated with versene or citrate.

Dissociation of the tissue through enzyme digestion is widely practised because it causes the least damage to the living tissue. The digestive property

of trypsin was first employed for tissue dissociation in chick embryo culture by Willmer (1945) and later by a number of authors (Dulbecco and Vogt, 1954; Melnick *et al.*, 1955; Rinaldini, 1958, etc.). As the action of trypsin is mainly on arginine and lysine, the constituents of basic proteins, it is presumed that these amino acids are involved in linkages responsible for cell binding. The proteolytic activity of trypsin has been shown to be associated with its cell disrupting effect (Easty and Mutolo, 1960; Moscona, 1963). The enzyme may possibly be taken up ultimately by the cells—a possibility requiring serious consideration in cell culture experiments using serum-free media (Moscona, Trowell and Willmer, 1965). It is due to the fact that in serum-free media, trypsin treatment often results in the appearance of a highly viscous substance around the cells. The nature of this substance has been suggested as DNA (Medawar, 1957; Moscona, 1962) or mucoprotein (Rinaldini, 1958). Serum or pancreatin, having trypsin inhibiting activity, reduces this effect which is possibly caused by the retention of residual trypsin in the cell.

In addition to trypsin, other enzymes have also been tried in cell separation, such as, pancreatin, elastase, elastomucase, papain, aspergillin-o (a proteolytic enzyme isolated from *Aspergillus oryzeae*), etc. (Easty and Mutolo, 1960; Fell, 1961; Sabina, Tosoni and Parker, 1963) and the choice is left to the worker dealing with specific types of tissue. As collagen fibres are not attacked by trypsin, collagenase is effective in adult tissues rich in collagen (Lasfargues, 1957; Laws and Stickland, 1961; Grover, 1962). The schedule of trypsin treatment for cell separation is outlined below (Moscona, 1962).

(1) Incubate fragments of embryonic tissue in Ca and Mg-free solution (CMF) at 38 °C for 10–15 min under 5 per cent CO_2–air mixture.
(2) Incubate further at 38 °C for 15–20 min or more in a solution containing 0.25–1.0 per cent crystalline trypsin in CMF under CO_2–air mixture.
(3) Rinse thrice in excess CMF solution (pH 7.2). Precaution must be taken so that the cells are not disrupted.
(4) Keep the tissue in culture medium and flush through a pipette for dispersal.
(5) Sample the stock solution for plating on a plasma clot.

Cell suspensions, obtained through tissue disintegration, can be induced to undergo a monolayer growth if cultured in nutrient medium at the bottom of culture containers like Carrel flasks, T-tubes, Roller tubes, Erlenmeyer flasks, petri dishes, etc. In order to check the growth rate, it is always preferable to count cells at the time of primary culturing and after a specific period before subculturing. Further counts may be taken after trypsinisation. The number of cells taken in the medium should be adequate for the amount of nutrient medium used, neither less not more. For α-strain of mouse fibroblasts, the adequate number is 100 000 cells in 2 ml of medium containing chick embryo extract, horse serum and balanced salt solution (Earle, Bryant and Schilling, 1954). In addition to the growth of settled cultures (originally derived from suspensions) in Carrel flasks, Roux bottles, Roller tubes, petri dishes, etc., cells can even be grown in suspension by fitting the flask in a horizontal shaker or by rotating the roller tubes vertically through a special device (Owens, Gey and Gey, 1953). Addition of serum, as well as other compounds like hyaluronic acid or methyl cellulose, aid in increasing fluid viscosity and maintaining cell suspension (Earle, Bryant and Schilling, 1954;

Kuchler, Marlowe and Merchant, 1960). 'Darvan' (0.03 per cent)—a sulphonic acid salt polymer, on being added to the medium, checks clumping of cells (Merchant, Kahn and Murphy, 1960) in some cases, by coating the cells and conferring a negative charge.

Attempts to secure clonal growth from single cells are primarily made with the sole object of obtaining a uniform population of cells. It is rather difficult to grow a uniform population, though in a number of cases, it has been made possible. Carcinomatous HeLa cells can be cultured in this way (for details, see chapter on cancer chromosomes).

With epithelial and fibroblast cells, Puck *et al.* (1956, 1957) successfully obtained such colony cultures by securing first a monolayer of growth from a thick suspension, the mitotic activity of which was checked later through heavy irradiation with x-rays. Normal cell suspensions were then plated on these feeder cells and good growth was secured. Later it was observed that feeder cells were not needed, if the medium was supplemented with embryo extract and serum. From normal human fibroblasts as well, Puck, Cieciura and Robinson (1958) succeeded in obtaining such clones. Apparently, however, growth in isolation is not the natural property of a cell; in successful cases, it should be regarded as an abnormal event (Moscona, Trowell and Willmer, 1965). In fact, cells in culture reveal a high frequency of chromosomal abnormalities, which may be attributed to this reason (Hsu and Pomerat, 1953; Chu and Giles, 1959; Frédéric and Corin, 1962).

Schedules

Trypsin-digestion culture method (Harnden and Brunton, 1965)

1. Biopsy

Clean skin with spirit, inject local anaesthetic, make an incision with scalpel and cut off V-shaped skin (2 mm). Place in about 4 ml Eagle's medium in a small screw-capped bottle. Cover the wound.

2. Primary culture

Transfer tissue to glass dish and cut into small pieces. Place equal amount of CEE and CP in two petri dishes. Transfer one bit of tissue to a third petri dish with the help of a pipette and suck out the excess medium. Mix one drop each of CEE and CP and draw them and the piece of tissue into the pipette. Transfer to a culture flask spreading out the CEE/CP mixture in a thin layer. Treat other bits of tissue similarly so that a culture flask with 4 cm diameter has five pieces of tissue. Allow the plasma to clot for a few min. Add 5 ml growth medium. Add 5 per cent CO_2 in air to flask and close with siliconed stopper and incubate at 37 °C.

3. Sub-culture

For first sub-culture, remove growth medium, add 10 ml 0.25 per cent pre-warmed trypsin solution, incubate at 37 °C for 15 min, transfer to centrifuge tube and centrifuge at 500 rev/min for 5–10 min. Discard supernatant and re-suspend cells in 1 ml growth medium. Transfer to fresh culture flask con-

taining 9 ml fresh growth medium, seal and incubate at 37 °C. For subsequent sub-cultures, use trypsin for 5 min only and after suspending cells in 1 ml growth medium, use only 0.1 ml for each sub-culture, to give a 1 in 10 dilution of cells. For maintenance, check cultures every two days for growth, sterility and pH, and replace growth medium. Adjust the pH with 5 per cent CO_2 or $NaHCO_3$ solution (1.4 per cent) when required.

4. Processing

To a healthy culture, add 0.5 ml 0.005 per cent pre-warmed colchicine solution, incubate for 2–4 h, prepare cell suspension with trypsin as given for first sub-culture. Centrifuge at 500 rev/min for 10 min, discard supernatant and re-suspend cells in pre-warmed Hank's BSS. Centrifuge at 500 rev/min for 10 min, discard supernatant, re-suspend cells in pre-warmed 0.95 per cent sodium citrate solution and keep 20 min in 37 °C. Again centrifuge at 500 rev/min for 10 min, discard supernatant, re-suspend cells in small quantity of fluid left, add acetic–ethanol (1 : 3) drop by drop with agitation. Keep in excess of fixative from 30 min to overnight.

5. Preparation of slides

Centrifuge at 500 rev/min for 10 min, discard supernatant, add fixative and again centrifuge at 500 rev/min for 10 min. Discard supernatant and re-suspend in a few drops of 75 per cent acetic acid. Place a few drops on a wet, pre-cooled slide, heat over a flame to dry, cool and stain in 2 per cent acetic–orcein for 2–3 h at 37 °C. Dehydrate in cellosolve, treat in euparal essence for 2 min, and mount in euparal.

This schedule, with slight modifications, has been used by Fox and Zeiss (1961, Nasjleti *et al.* (1975) and Harnden *et al.* (1976) from different tissues.

Plasma clot culture method (Turpin and Lejeune, 1969)

1. Biopsy

For surgical cases, remove under general anaesthesia, a tissue about 4 × 4 × 4 mm in measurement. Wrap in a sterile square of gauze, place in a wide-necked flask 4 cm in diameter. Add 5 ml of sterile physiological saline, seal the flask and store for 24–36 h at room temperature, if necessary. For skin biopsy, after thorough cleansing with soap and sterile water, and sterilisation in ethanol (twice) and ether, pinch the skin between the jaws of a 'Coprostase' clamp, keeping a piece protruding above it. Anaesthetise locally with ether, remove with a scalpel a piece 3–4 mm long, place in a sterile square of gauze and treat as for surgical biopsy. Disinfect and close the suture with band aid.

2. Explant (Lejeune, Turpin and Gautier, 1960)

Wash the tissue in physiological saline and cut into pieces 1–2 mm square. Place a sterilised cover slip in the distal depression of a Leighton tube. Spread a drop of CP over the cover slip. Place the bits of tissue (2–3 per cover slip) on the plasma. Add a drop of CEE to coagulate the plasma and fix the

tissues to the glass. Close the tube with a rubber stopper, incubate for several hours or overnight at 37 °C. Add culture medium containing per tube: human AB, five drops; Hanks' solution with 200 μm/ml penicillin, 50 μg/ml streptomycin and 5 μg/ml chloramphenicol, five drops, and embryonic extract, two drops. Incubate.

3. Sub-culture

After development of a crown of fibroblasts around the explants in 4–6 days, transfer the explants to other tubes following the method described in step 2. Replace the medium in the tubes with cover slips with fresh medium. Incubate.

4. Processing

After 36 h incubation, add three drops of CEE to the medium in each tube. Incubate again for 16 h to obtain a large number of mitosis due to change in the substrate. Place the cover slip with a curved tip pipette, with the cells uppermost, in a mixture of sterile human or mammalian serum, 1 part; neutral water 5 parts and hyaluronidase 2.5 per ml (used to hasten absorption) of mixture. Incubate at 37 °C for 35 min. Transfer the cover slips to Carnoy's fixative (chloroform–acetic–ethanol, 3 : 1 : 6) and treat for 45 min.

5. Preparation of slides

Take out the cover slip and dry in open air. Hydrolyse in N HCl for $7\frac{1}{2}$ min at 60 °C. Rinse in neutral water, stain in Unna's blue for 10 min (1 part Unna's blue solution, 4 parts neutral water). Rinse in neutral water, dry for 5–10 min in open air, pass through toluene and mount in canada balsam.

Liquid medium method (Turpin and Lejeune, 1969)

This has been applied to surgical biopsies, mainly of tumours.

(1) Biopsy is similar to the above schedule.
(2) Cut into small bits, wash three times in Dulbecco PBS solution (with calcium). Transfer to Erlenmeyer flask, add trypsin solution in PBS buffer (25 mg/l), seal and agitate in a magnetic shaker at 37 °C from 10–20 min. Replace trypsin solution every 10–15 min with continued agitation, continuing up to 1–4 h according to the tumour studied. Transfer each change of trypsin solution to a centrifuge tube in cold. Centrifuge for 5 min at 800 rev/min. Wash three times in a solution of casein hydrolysate or a culture medium. Re-suspend sediment in 1–2 ml casein hydrolysate or the culture medium. Place the culture in test tubes with cover slips containing: casein hydrolysate or synthetic culture medium (like 199), 2 parts and human AB serum (1 part to have a concentration of 5×10^5 cells/ml). Incubate at 37 °C after adjusting pH. Replace the medium every three days. Cell multiplication depends upon the nature of the tumour.
(3) Processing and preparation of the slides are similar to the schedule given for blood cultures.

Several alternative schedules are in practice, combining or altering different

stages in the representative ones described here. For metaphase arrest in cultures grown on cover slips, they can be treated directly with colchicine in culture medium (0.1 g/ml) for 18–24 h (Axelrad and McCulloch, 1958) or colchicine can be added to the culture medium to give a concentration of 0.0025 per cent (Swanson and McKee, 1964). A saturated solution of Abopon in 0.2 M phosphate buffer at pH 7.0 can be used as a suitable mounting medium after acetic–orcein staining and rinsing in water (Hrushovetz and Harden, 1962).

Application in other human materials

Variations of the above schedules have been developed for cytogenetic investigations on human abortus material (Tjio and Puck, 1958; Basrur, Basrur and Gillman, 1963; Makino, Sasaki and Fukushima, 1963; WHO group, 1966). Some of the commoner ones are outlined in brief:

Method A

Cut out eight explants from material, approximately 3 mm in diameter. Place in 5 ml of Waymouth's medium enriched with 20 per cent calf serum; place in sloping position so that half of the specimen is in the medium. Incubate at 37 °C. After 4–7 days, primary outgrowths of histocytes and spindle cells are seen, these are followed by round cells which are in turn replaced by fibroblasts. Trypsinise the primary outgrowths for 9–14 days. Sub-cultures and change of medium are maintained as described in previous schedules. Sufficient cells are obtained by the third or fourth sub-culture. Thirty-six hours after sub-culturing, add 1 ml colcemid (80 μg/ml) and keep for 8 h. Trypsinise cells till freed (5 min), add TC 199, centrifuge, re-suspend in 1.12 per cent sodium citrate, incubate at 37 °C for 7 min. Centrifuge and fix in acetic–methanol (1:4) and stain as usual.

Method B

Expose tissue to 0.25 per cent trypsin solution for 30 min and shake in magnetic stirrer at low speed. Centrifuge resultant cell suspension at 600 rev/min for 10 min, remove supernatant, re-suspend button in Waymouth's medium and seed on to cover slips or petri dishes. Incubate at 37 °C in CO_2 enriched medium.

Method C

Sandwich explants 2 mm in diameter between cover slips and incubate in petri dishes at 37 °C in CO_2. In both methods B and C, transfer explants to fresh cover slips and grow for 48 h. Add 0.25 ml colcemid (80 μg/ml solution) and keep for 4 h. Remove medium, add hypotonic solution, incubate at 37 °C for 12 min and then fix and stain as usual.

The tissue culture technique can also be used for prenatal chromosome analysis from chorionic tissue, fetal skin or placental amnion (*see* Klinger and Miller, 1968), human endometrium (Rask-Maden and Philip, 1970), amniotic fluid (Nadler, 1968; Knörr-Gärtner and Harle, 1972) and umbilical cord blood (Robichaux, Davis and Lavor, 1973).

Application in other vertebrates

The schedules, with suitable variants, have been employed for the study of tissues from different parts of the body of different animals, as well as human subjects (Penrose and Delhanty, 1961; Vafai, 1977). Chromosomes have been studied successfully in cell cultures from kidney tissue of primates (Chu and Giles, 1957; Bender and Mettler, 1958; Rothfels and Siminovitch, 1958b; cf. Bender, 1965). Chu and Swomley (1961) obtained satisfactory preparations from skin cultures of lemurine lemurs, Klein (1973) from shank skin of *Ardea cinerea*, Dubey, Sarkar and Shah (1975) from embryonic tissue, Sasaki and Takagi (1974) from feather pulp culture of the ibis, Fraser, Paton and Barnes (1975) from rabbits derived from eggs fertilised *in vivo* and Chen and Ebeling (1975) from gill culture. In an agar-fixation procedure, developed by Pacha and Kingsbury (1962), trypsinised cells from the culture are suspended in Hanks' medium and then transferred to an agar surface containing 1.5 per cent agar and 0.5 per cent sucrose for 10–15 min. An agar square is cut out, processed and stained as usual. Both change of medium, and addition of colchicine, were adopted to obtain a large number of metaphase plates in opossum, followed by double staining in 2 per cent acetic–orcein and Harris's haematoxylin (Shaver, 1962). For feather pulp, inject 0.05 per cent colcemid (IP) at 0.8 ml/kg body weight, incubate for 1 h, pluck out feathers, transfer pulp to 0.45 per cent (w/v) sodium citrate solution for 15–20 min, fix in 50 per cent acetic acid for 30 min, squash (Wang and Schoffner, 1974).

Direct preparations

Originally developed for karyotype study, are modifications of the different procedures discussed previously. They usually involve breaking up the tissue after biopsy and studying it after a series of treatments, including hypotonic solution, colchicine, fixation and staining, but omitting the culture procedure. It can be used for materials which already contain a good number of cells undergoing mitosis, like fetal cells, cornea, etc. A schedule developed for fetal mammalian tissue is outlined (Ford, E. H. R. and Woollam, 1963). Inject 0.3 ml 0.025 per cent colcemid into 14 days pregnant mice. Kill after 1 h. Break up livers of the fetuses in 0.1 per cent colcemid in phosphate-buffered 0.85 per cent NaCl and treat for 1 h. Centrifuge, suspend in one per cent sodium citrate for 20 min, centrifuge and fix in acetic–ethanol (1 : 3) for 30 min, re-suspend twice in 45 per cent acetic acid, air-dry and stain in lactic–acetic–orcein.

Regenerating rat liver can be suspended in 1.12 per cent sodium citrate solution by aspirating, followed by high-speed centrifugation and squashing in 2 per cent acetic–orcein solution (Sparano, 1961). The corneal epithelium of mammals yields good mitotic figures. The entire eye can be fixed in an orcein–acetic–ethanol mixture followed by dissection and mounting (Gay and Kaufmann, 1950). The anterior portion may be fixed in acetic–ethanol (1 : 3) for 24 h followed by hydrolysis and staining by Feulgen. The epithelium is dissected out and mounted in glychrogel (Howard, 1952). Otherwise, the whole eye can be kept in 0.7 per cent sodium citrate solution at

37 °C for 30 min, fixed in 50 per cent acetic acid and N HCl (9 : 1) for 5 min and stained in 2 per cent acetic–orcein for 2 min. Some of the corneal epithelium is scraped off and squashed (Fredga, 1964).

Chromosome preparations from mouse embryos during early organogenesis have been made as follows (Wroblewska and Dyban, 1969): Treat in a glass vessel in 1 per cent sodium citrate at 37 °C for 20–25 min, depending on age. Fix from 3 h to overnight at 4 °C in acetic–ethanol (1 : 3), stain in 2 per cent acetic–orcein for ½–1 h. Disperse in 1–3 drops of glacial acetic and 50 per cent lactic acid mixture (1 : 2 to 3 : 2) for several minutes to 1 h, till cloudiness is produced. Place a small drop of the suspension on a slide, followed by a larger drop of the fixative. Air-dry and stain in lactic–acetic–orcein. It is suitable for embryos between the 7–11th day of pregnancy.

To study chromosomes in rodents without sacrificing the animal, a microchamber charged with an antigen is placed in the abdominal cavity for eight days; it is extracted 3 h after injecting colchicine and metaphase spreads prepared as usual (Bianchi, Merani and Bianchi, 1975). Pachytene chromosomes have been utilised for karyotype analysis in human and other materials (Ford, L. *et al.*, 1968, 1969). Testicular materials obtained by biopsy are cut into bits (Rowley and Heller, 1966) and kept in distilled water for 30 min. An equal volume of acetic acid is added and the material retained in it for several hours. Then a piece of tubule is squashed in a drop of fixative on a slide under a mechanical press. The cover slip is then floated out in 45 per cent acetic acid and the slide is treated in Carnoy's fixative for 20 min, followed by air-drying and staining in lactic–acetic–orcein solution (Welshons, Gibson and Skandlyn, 1962).

SEX CHROMATIN STUDIES

The sex chromatin, as seen in the interphase nuclei, has been used in the detection of errors of sex development, to determine the number of X chromosomes in the complement of an individual, and in studies requiring the indication of the sex chromosome complex of a particular tissue, especially in cases of homologous tissue transplants where donor and recipient do not have the same sex. The different sex chromatin techniques are based on the fact that the X chromosome may show the property of heteropycnosis in interphase nuclei and may form a distinctive chromatin mass or chromocentre. It is a female characteristic in all mammals, except the opossum, which shows such masses in the cell nuclei in both sexes. The presence of a female-specific chromocentre was first demonstrated in the nerve cells of the cat by Barr and Bertram (1949), leading to the term 'Barr body'. A long series of publications has established sex chromatin analysis as an effective diagnostic tool for sex chromosome studies, according to the rule that the maximum number of sex chromatin masses is one less than the number of X chromosomes present in the individual studied. The evidence obtained for genetic inertness of the X chromosome that forms the sex chromatin and the possibility of a mosaicism in mammalian females, the paternal X being active in some cells, and the maternal X in others, has opened new lines of research (Ohno, 1961; Lyon, 1961, 1972; Beutler, Yeh and Fairbanks, 1962; Grumbach and Morishima, 1962).

The proportion of nuclei with demonstrable sex chromatin masses varies with the type of preparation and the tissue, ranging from less than 60 per cent in buccal smears to almost 100 per cent in thick sections of nervous tissue. The sex chromatin mass shows a feulgen-positive reaction due to its DNA content and stains with chromosomal dyes like cresyl violet, fuchsin, gallocyanin, haematoxylin, thionine and particularly with orcein. It has an affinity for methyl green in pyronin methyl green staining and persists after mild acid or ribonuclease treatment (*see* Barr, 1965). It may be studied from buccal smears, sections of tissues and peripheral blood neutrophiles.

(1) *The buccal smear* technique for studying sex chromatin mass from buccal mucosa is the simplest one and is most widely used for clinical studies of sex determination. A simple schedule is given below.

Label clean slides with the subject's reference number and side of the body. Draw the edge of a metal spatula firmly over the buccal mucosa. Discard the material; scrape the mucosa gently a second time to obtain healthy epithelial cells from a deeper layer. Spread over a small area of an albuminised slide, using separate slides for smears from right and left sides. Do not spread too thinly. Immerse inversely in fixative (95 per cent ethanol) for 15–30 min, treat successively in absolute ethanol for 3 min, and 2 min in a 0.2 per cent solution of Parlodion in ethanol–ether mixture (1 : 1) to attach the cells firmly. Dry in air for 15 s, pass through 70 per cent ethanol (5 min), two changes of distilled water (5 min each) and stain. Alternative fixation can be carried out in ethanol–ether mixture (1 : 1), immediately after smearing, for periods ranging from 12 h to two weeks, followed by gradual hydration.

Staining may be done in 1 per cent aqueous cresyl violet solution or acetic–orcein solution (Sanderson, 1960) to get successful preparations. Barr (1965) suggests staining 5–10 min in working solution of carbol fuchsin followed by differentiation for 1 min in 95 per cent and absolute ethanol successively. (Stock solution of carbol fuchsin: 3 g basic fuchsin in 100 ml of 70 per cent ethanol. Working solution: stock solution 10 ml; 5 per cent carbolic acid in distilled water, 90 ml; glacial acetic acid, 10 ml; 37 per cent formaldehyde, 10 ml. Keep for 24 h before use.) Double staining, with biebrich scarlet as chromatin stain and fast green as counterstain, has been suggested by Guard (1959). Dehydration and clearing are carried out as for other squash schedules.

In interpreting the results of buccal smears, certain observations are significant, such as that the nuclei with sex chromatin masses in newborn females reach their normal number only on the fourth day after birth and that the size of the mass has been found to decrease after oral administration of certain antibiotics (Sohval and Casselman, 1961; Taylor, 1963).

(2) *Sex chromatin studies from tissues* have a much more limited application, being restricted mainly to tissues obtained during operation or post mortem (*see* Barr, 1965). A recommended fixative is: 37 per cent formalin, 20 parts; 95 per cent ethanol, 35 parts; glacial acetic acid, 10 parts, and distilled water, 30 parts. After 24 h fixation, tissues are transferred to 70 per cent ethanol. Paraffin blocks are prepared after dehydration through ethanol and xylol grades, sections 5 μm thick are cut. Staining is carried out in Harris's haematoxylin, counterstained with eosin, or in

other chromosomal stains like Feulgen, thionin or gallocyanin, following the usual procedures.

Sex chromatin can also be studied from a monolayer of cells growing *in vitro*, or skin biopsies (Moore, Graham and Barr, 1953), or leucocyte cultures, by omitting treatment with hypotonic solution during processing.

Prenatal sex chromatin analysis is useful in detecting male conceptuses with sex-linked recessive hereditary disorders when pedigree data are available. It can be carried out by concentrating cells from fluid samples by centrifugation, fixing on a slide and staining by thionin or Feulgen.

(3) *Studies from peripheral blood neutrophiles:* A drumstick-shaped nuclear appendage, which stains with Wright's, Giemsa or haematoxylin schedules, is observed in occasional neutrophile leucocytes in normal females, but never in the male, and is thought to contain sex chromatin. The number of neutrophiles per drumstick varies in different females. They can be studied from relatively thick blood smears, drawn on cover slips or slides, and followed by staining. Both buccal smear and neutrophile methods should be used simultaneously for the detection of sex chromosome mosaics.

Other methods for the study of differential chromosome segments

In subsequent methods, observations under the light microscope after Giemsa staining have been correlated with banding patterns of chromosomes obtained with Caspersson's fluorescence technique (*see* Sharma and Talukder, 1974; Yunis, 1974). For details, *see* Chapter 13.

Extensive work has been done on somatic cell fusion techniques, allowing genes to be mapped on the human chromosomes. In the *molecular hybridisation* method, to localise chromosome segments, e.g. satellite DNA on the basis of differential gene action, the principle of hybridisation at the molecular level *in situ* has been applied successfully by Pardue and Gall (1970); *see* Chapter 22.

CONCLUSION

An outline of the techniques, their application and advantages in human and animal chromosome methodology, as here depicted, is a clear index of the tremendous enthusiasm evinced in this branch of chromosome science. In spite of this explosion of research within the last few years, there is very little reason for complacence in view of the intricacies of the problems still unsolved. Glaring inadequacies are still present in the technology. For example, most of the outstanding achievements are based on culture technique—a method with certain inherent disadvantages. Scepticism has often been expressed regarding the accuracy of the *in vitro* culture data and the extent to which they represent *in vivo* conditions. In plants, it has been demonstrated that even treatment in distilled water exerts an appreciable effect on chromosomes (Sharma and Sen, 1954; Sharma and Sharma, 1960).

The elaborate composition of the human chromosome culture medium calls for a simplification of the procedure.

With relation to the initiation of leucocyte division in the peripheral blood culture, the discovery of the plant product, phytohaemagglutin in (PHA), should no doubt be considered as a landmark in the evolution of technology. But even then, to all workers in human chromosome analysis, the failure of certain batches of PHA to act is a common experience. It is often attributed to contamination, and in the absence of the latter, the cause is cited to be the physiological set-up of the tissue. It is not unlikely that the genetic constitution of the individual concerned controls its response to PHA, as in the case of leukaemic cells, which do not require this compound for the initiation of division. In order to meet the requirements arising out of the diversities in genetic and physiological make-up, many more effective chemicals like PHA are needed, to provide a wider choice. Exploration of this property in extracts from other beans, allied to *Phaseolus vulgaris*, undertaken in our own laboratory but not so far published, shows considerable promise. Moreover, the application of organic compounds like kinetin, gibberilin, ascorbic acid and other hormones—some of which are known to initiate division in nuclei in other biological objects—on human and mammalian tissue, may give valuable results in this direction.

In addition to leucocyte culture, it is necessary that for every pathogenic tissue, highly simplified and rapid schedules should be evolved, which would make human chromosome analysis a routine clinical practice.

The necessity for further advancement in the study of the details of chromosome morphology cannot be over-emphasised. Though to some extent, initial work on the details of chromosome structure from pachytene, specific fluorescence banding and karyotype analysis of human chromosomes has been started, yet the progress compares unfavourably with that achieved in other organisms. Extensive use of a range of pre-treatment agents of established value may solve this problem to an appreciable extent. An exhaustive analysis of the chromosome morphology, from both normal and abnormal individuals, and localisation of genes by somatic cell hybridisation technique, would bring complete mapping of the genes on human chromosomes within the realms of possibility. Such a genetic mapping would pave the way, ultimately, for the prevention of congenital disorders.

These possibilities of further research on human chromosome methodology in no way minimise the tremendous achievements in this direction made within the past few years (*see also* McKusick and Ruddle, 1977). With further refinements in technology as envisaged above, the judicious handling of the human chromosome, if not the genes, from the pre-natal to the adult phases, may perhaps successfully aim at the betterment of the human race.

NUTRIENTS FOR ANIMAL TISSUE CULTURE
(*see* White, 1954, 1959; Paul, 1959)

Balanced salt solutions (g/1000 ml) for animals

The ingredients, given in *Table 11.1*, are all dissolved successively in distilled water. $NaHCO_3$ and phenol red are dissolved separately in water, filtered

through a selas candle and saturated with CO_2, bubbling through a plugged and sterile pipette. Before use, the two solutions are mixed.

White's nutrient medium (White, 1954)

It contains 70 ml of sterile water and 15 ml of the mixture of White's inorganic salt solution, $Fe(NO_3)_3$ solution and sugar buffer given in *Table 11.1*. To this are added in succession 5 ml each of amino acids, stock, AC stock, B stock and B_{12} stock to prepare the final nutrient with pH 7.4 and a pale red colour.

The ingredients are:

(1) Inorganic salt solution, $Fe(NO_3)_3$ solution and sugar buffer are described in *Table 11.1*.

(2) Amino acid stock, containing (mg/80 ml of water):

l-Lysine-HCl	312 mg	*dl*-Isoleucine	208 mg
dl-Methionine	260 mg	*dl*-Phenylalanine	100 mg
dl-Threonine	260 mg	l-Leucine	312 mg
dl-Valine	260 mg	l-Tryptophane	80 mg
l-Arginine–HCl	156 mg	l-Glutamic acid	280 mg
l-Histidine–HCl	52 mg	l-Aspartic acid	120 mg
l-Proline	100 mg	l-Cystine	30 mg
Glycine	200 mg	0.01% phenol red	10 ml

(3) AC stock, containing:

Group A	Carotene	10 mg
	Vitamin A	10 mg
	Ethyl alcohol	100 ml
Group B	Ascorbic acid	10 mg
	Glutathione	20 mg
	Cysteine HCl	20 mg
	Water	100 ml
		Filter.
Group C	0.01% aq. phenol red	100 ml

Mix 2 ml of A, 10 ml of B, 2 ml of C and 86 ml of water and maintain at pH 7.4 by adding 0.1 N NaOH.

(4) B stock, containing:

Group B		*Group FA*	
Thiamine HCl	10 mg	Folic acid	10 mg
Riboflavin	10 mg	$NaHCO_3$	10 mg
Ca-pantothenate	10 mg	Water	100 ml
d-Biotin	10 mg		
Pyridoxin HCl	10 mg	Sterilise and filter	
Nicotinic acid	10 mg		
Inositol	10 mg		
l-Alanine	10 mg		
Choline	100 mg		
Water	100 ml		

(5) B_{12} stock containing 0.015 per cent aqueous vitamin B_{12} solution, sterilised.

Chromosome analysis from malignant tissues

INTRODUCTION

Cancer represents an unchecked, malignant form of rapid growth, perpetuated through several cell generations and probably originating from several causes, both internal and external, including transformation by viruses (*see* Klein, 1966). Hueper and Conway (1964) have made a detailed review of carcinogenesis in man in relation to occupational exposure to chemical substances. The problem has been aggravated further by the discovery of the carcinogenic properties of aflatoxins produced from *Aspergillus flavus* infecting groundnuts and cereals under storage (Roe and Lancaster, 1964 and *see* Raven and Roe, 1967). Irrespective of its mode of origin, cancerous tissue is always characterised by distinct cytological features (Seshachar and Nambiar, 1955; Hansen-Melander, Kullander and Melander, 1956; Ishihara, Kikuchi and Sandberg, 1963; Koller, 1963; Lubs and Clark, 1963; Stich, 1963; Wakonig-Vaartaja, 1963; Atkin, 1964; Springs, 1964;Wakonig-Vaartaja and Kirkland, 1965; Richart and Wilbanks, 1966; Miles, 1967a, b; Talukder and Sharma, 1968; Lampert, 1971). Although Bauer (1949) claimed that the frequency of mitosis is a symptom but not a specific sign of cancer, chromosomal abnormalities, and especially numerical variation, have been found to be conspicuous features of cancer cells (Koller, 1956; Makino, Ishihara and Tonomura, 1959). Variability is, however, low in tumours derived from single cell culture (Hauschka and Levan, 1958) whereas diploid cells are more common in primary tumours (Koller, 1960). Makino (1957) suggests that this irregularity shows that every tumour has its own stemline number which occurs at maximum frequency in that particular tissue. This hypothesis has found wide acceptance, particularly in relation to rat ascites tumours and the later phases of human tumours. Several authors have shown, however, that two or more stemlines may also characterise human neoplastic tumours (Ishihara, Kikuchi and Sandberg, 1963; Sandberg and Yamada, 1966; Sharma, G.P., Mittal and Sharma, 1969). Mitotic instability and chromosomal unbalance, associated with lack of differentiation, are therefore the universal features of cancerous cells. However, no cancer is unquestionably characterised by specific chromosomal changes, except chronic myeloid leukaemia, where a structural alteration in chromosome G(Ph′) has been found to be a common feature. Several, as yet unconfirmed, reports of other such associations are also available (*see* Nowell

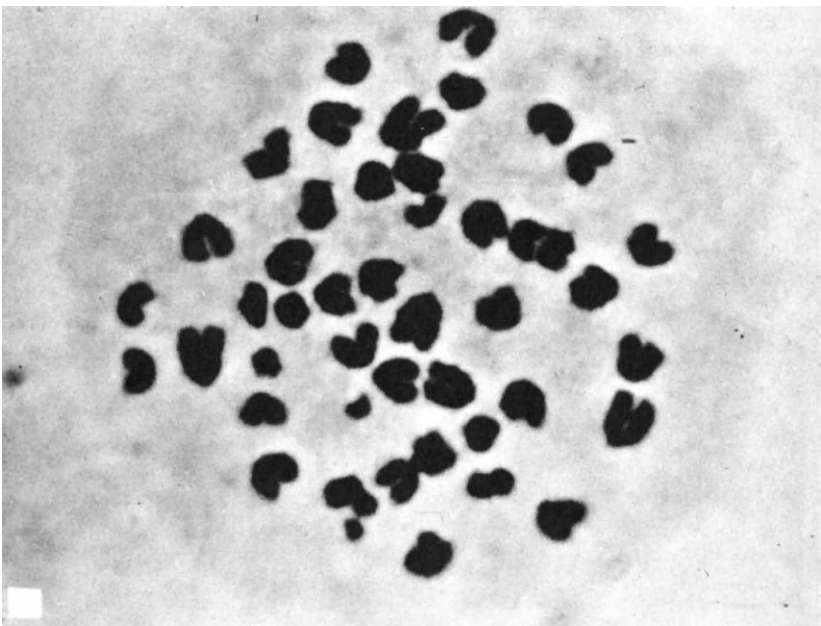

Plate 12.1
Landschütz ascites in a ♀♀ CBA mouse with 44 chromosomes, including five markers, one metacentric, one with a secondary constriction and 3 min from preparations made by intraperitoneal injection of colcemid soln followed by the usual orcein–air drying schedule (courtesy of Dr. P. C. Koller and Dr. C. Talukdar)

and Hungerford, 1960; Turpin and Lejeune, 1969). Discovery of the origin of the malignant growth, as well as its prevention, require an intimate knowledge of the cytology of cancer cells. Both growth and its cessation are related to the mechanism of the nuclear division.

The development of techniques for the study of cancer chromosomes and their behaviour was principally stimulated by the discovery that certain human abnormalities or diseases, such as mongoloid idiocy, can be correlated with certain chromosomal irregularities, and since then various techniques have been developed for the study of cancer chromosomes from tissues extracted from individuals, or after growing them in culture (Yunis, 1965; Turpin and Lejeune, 1969). Needless to say, tissue or cell culture has become an important tool in cancer cytology.

Even though the study of cancer chromosomes has been pursued for several years, data on their cytology was mostly nebulous until the discovery of the *ascites tumours* and a method for their observation. The single cells, or groups of cells, suspended in the body fluid are convenient for cytological observation, and the methods of study have undergone so much improvement that solid tumour tissue can now ultimately be converted into ascites tumours for facilitating cytological study.

The importance of tissue culture methods in relation to the study of cancer chromosomes is demonstrated in the discovery of Levan and others. This discovery shows that normal cells, during their transformation into adult

cells, show mitotic instability in tissue culture, thus attaining a genetic heterogeneity parallel with the cancer cells. Moreover, such cells, when inoculated into normal tissue, can induce tumour growth. Techniques have been devised to study the comparative cytology of cancerous and normal cells under culture conditions and their behaviour following cell fusion *in situ*.

MATERIALS SUITABLE FOR STUDY

Though cancer is the principal unsolved medical problem in human beings, the latter cannot, for obvious reasons, be utilised for detailed experimental purposes. In addition to blood and bone marrow, only biopsies for studying the chromosomes can be taken from patients suffering from cancer in various organs. In carrying out extensive experiments, using different chemical agents and testing the effect on the development and nuclear behaviour of cancerous tissue under laboratory conditions, inbred strains of white rat, mouse, guinea-pig and rabbit are mainly employed. The incidence of cancer can also be studied in other animals, which can be bred in the laboratory on a standard diet under standard conditions, depending upon their availability.

METHODS OF INDUCTION

In addition to the development of spontaneous cancers, different chemical agents, termed *carcinogens*, can be used for their artificial induction. The different types of carcinogens available in the market belong to the coal-tar derivatives; principally, the hydrocarbons, azodyes and others. A list of some of the common carcinogens, which have been tested for their carcinogenic activity on various animals, is given below. In addition, ultraviolet rays have also been employed to induce neoplasia in animals (*see* Allfrey and Buffa, 1979; Haret *et al.*, 1977).

Hydrocarbons

(1) Derivatives of benzanthracene: methyl 1,2-benzanthracene; dimethyl 1,2-benzanthracene; specially 5,6-dimethyl and 9-10-dimethyl 1,2-benzanthracene.
(2) Cholanthrene derivatives: methyl and ethyl cholanthrene.
(3) 3,4-Benzpyrene.
(4) Dibenzcarbazole.
(5) 3,4-Dibenzacridine.
(6) Dibenzfluorene.

Azodyes

Derivatives of *o*-aminoazotoluene and dimethyl aminoazotoluene (Butter Yellow):—2,2′-azonaphthalene.

Mustard derivatives

(1) Nitrogen mustard—β, β'—dibromodiethyl sulphide, sulphone-sulphoxide and its dichloro and di-iodo derivatives.
(2) Ethyl carbamate or urethane.

Steroids

(1) Stilbene derivatives, e.g. 4,4′ dihydroxy, α-β-diethylstilbene.
(2) Testosterone derivatives.
(3) Gonadotrophins.

Others

(1) Aerosol, alkaloids, *o*-aminotoluene, calcium gluconate, carbon tetrachloride, chloral hydrate, chloroquinone and benzoquinone chloroacetone, nitrosamines—dimethyl and diethyl, *n*-nitrosomorpholine, potassium thiocyanate, sulphonamides.
(2) For different viruses which can induce tumours, *see* Dalton and Haguenau (1962), Klein (1966) and Dulbecco (1969).

In plants, crown galls show similarities to animal cancer in the rapid rate of cell growth, mitotic instability, and lack of differentiation. Several species of bacteria, especially *Bacterium tumafaciens* and *Agrobacterium tumafaciens*, can induce crown gall in several plant species belonging to leguminous and other groups. The leaf or other plant surfaces can be abrased with carborandum powder and the inoculum applied in the damaged plant, resulting in the development of gall (Sharma and Nandi, unpublished). Species of *Vicia*, mainly *V. faba*, and *Solanum* are extremely susceptible. Several carcinogens have been tried on plant cells (Nandi, 1969) and certain plant extracts have also been shown to induce tumours in plants (Sharma, A., 1959).

The different methods by which a carcinogen can be administered into tissue to induce cancerous growth in animals are: (a) feeding—applied in a specific dose in the food; (b) intraperitoneal injection; (c) subcutaneous injection and (d) rubbing into the skin. These are applied with different solvents like water, olive oil, sesame oil, lard, glycerine, benzene, acetone, etc. and they are administered in specific doses for a prolonged period, at regular intervals. For example, tumours can be induced with intraperitoneal injections of 3,4-benzpyrene and methyl cholanthrene in rats within 3–6 months. For inducing multicentric hepatoma, *n*-nitrosomorpholine can be administered to inbred rats in drinking water (20 ml daily for six days), the dosages being 6 mg per cent solution for up to 34 weeks, 12 mg per cent up to 12 weeks, and 20 mg per cent up to 7 weeks (Druckrey, Schmähl and Müller, 1961; Bannasch, 1968).

In established mouse fibroblast cell cultures, to study the effect of carcinogens, methyl cholanthrene at 1 μg/ml of medium can be administered for a prolonged period (one to several weeks). The behaviour of loss of

contact inhibition can be detected even after 2–3 days exposure to either methyl cholanthrene or to 3,4-benzpyrene (Berwald and Sachs, 1963). When the treated culture is injected into C_3H mice, maximum tumour production was obtained with 6-day treated cultures.

The two terms *carcinoma* and *sarcoma* are applied, depending on the type of origin. The latter type represents tumorous growth initially originating from the mesoderm, whereas all other types are included within the category of carcinoma. Cancerous growth involving blood cells may result in *leukaemia*. Cancers represented in the small islands of cells in the body fluid are known as *ascites* tumours. Specific names are given to growths in the different organs, based on the organ affected and detailed cytological studies have been carried out on almost all kinds of human cancer, including maxillary, mammary, uterine, pulmonary, hepatic and skin carcinomas, reticulosarcoma, postauricular tumour, etc. to mention a few. After induction of cancer in the body of the subject, cells are maintained in culture and chromosomes can be studied in them through the methods outlined for the study of mammalian chromosomes.

In order to inhibit the cancerous growth, different dosages of x-rays, as well as different types of anticarcinogens, can be applied in the medium. Vincaleucoblastine, podophyllin, α- and β-paltatin, quercelin, etc. are some of the anticarcinogenic agents used. Podophyllin (Makino and Tanaka, 1953) is dissolved in isotonic glucose solution and applied to rats through peritoneal injections at room temperature. Three applications of a concentration up to 0.1 per cent (1ml/100 g of body weight) given every seventh day produced regression of the ascites tumour, associated with a loss of mitotic instability.

STUDY OF CANCER TISSUE IN CULTURE

The rapid advance of research on cancerous materials has been responsible for the development of several techniques for culturing malignant cells *in vitro*. The chromosome studies of these materials form one of the principal sources of our knowledge of the genomic constitution of malignant tissues. To secure growth *in vitro*, methods for the culture of *tissue explants*, *monolayers* as well as *cell suspensions* have been devised. Most of these schedules have been discussed in detail in the chapters on mammalian and human chromosomes and tissue culture. Only the schedules specially modified for cancerous cells are discussed here.

Explant culture

Most methods for cancer tissue explant culture are identical with those described in the chapters for the study of mammalian chromosomes and tissue culture, including Carrel flask, Roller tube, Hanging Drop and Sandwiching processes (Basrur, Basrur and Gilman, 1963). Mammalian serum is one of the major constituents of the medium but plasma clot consisting of 50 per cent plasma in balanced salt solution and 50 per cent embryo extract in serum provide the most congenial medium for tissue growth. Walker and Wright (1961) successfully cultured several human tumour

tissues, namely, lymphoma, melanoma, carcinoma and tumour of the nervous system in TC 199 containing 20 per cent autologous or pooled human serum, in order to study the effect of vincaleucoblastine on the cultured tissue. Barski and Belehradek (mentioned in Easty, 1967) used a mixture containing 30 parts TC 199 (Morgan, Morton and Parker, 1950) as modified by Barski; 30 parts Hank's medium and 30 parts human serum, without complement, for successful growth of human tumour tissues. For inducing growth of primary human tumour tissues, the medium devised by Evans *et al.* (1956) has been quite effective (Ambrose *et al.*, 1962; Easty and Wylie, 1963) but the addition of insulin and folic acid (Prop, 1961) along with AB serum resulted in profuse growth of mammary gland tissue of mouse. Lumsden (1963) succeeded in obtaining cultures of human brain tumours. In addition to these, several reports have been published of explant cultures of human organs and the different media adopted for the purpose are modifications of those already mentioned.

Monolayer and suspension culture from cell effusions

Suspension cultures *in vitro* from cell effusions can be obtained most successfully from ascites tumour cells. De Bruyn (1956), De Bruyn and Hampe (1961) effectively applied the monolayer technique for culturing ascites cells and cell effusions obtained from human pleural and peritoneal fluids. In monolayer culture, it is observed that cancer cells do not exhibit contact inhibition, often manifested in closely adhering normal cells (Abercrombie and Heaysman, 1957; Abercrombie and Ambrose, 1958). Effusion cultures of cells from human ascitic fluid, obtained through centrifugation, were made by Moore and Koike (1964), who noted that adaptation—the primary requisite for growth in culture—is maximum in the triploid cells where the number of cells in culture reaches as high a count as of 100 000 cells/ml. Di Paolo (1964) has also observed growth *in vitro* of several cell effusions. Reports of successful culturing of tumour effusions are continually accumulating (*see* Hsu, 1965, and Ambrose, Easty and Wylie, 1967).

Cell suspensions from solid tissue

Of all the techniques evolved for cancer tissue culture, processing of cell suspensions from solid tissue is the most elaborate one. As with normal tissues, disaggregation of cells poses the principal problem, for which mechanical, chemical and enzymic methods have been adopted (for details *see* chapters on tissue culture and mammalian chromosomes). Of the several mechanical methods available, one (Snell, 1963) involves kneading very small pieces of tumour (1 ml by vol) in the medium with thin-walled rubber tubing and finally forcing the suspension through a metal sieve which gives a good amount of single cell suspensions. In another technique, cells were grown in test tubes with glass beads and after a period of growth, were dislodged by shaking (Leighton, 1958) and dispersed finally by aspirating several times through a pipette. Suspensions of rat liver cells could be obtained by dispersion with a rubber pestle inside a glass tube (Jacob

and Bhargava, 1962). Scraping of the layer with a rubber policeman often hampers viability of the cells but yields sufficient material for analysis (Magee, Sheek and Sagik, 1958).

Of the chemical methods, the most effective is the use of versene or EDTA (*see* chapter on tissue culture) and shaking in this medium may or may not be supplemented with homogenisation (Di Paolo and Dowd, 1961). Among the different enzymes tried for dispersion, trypsin is undoubtedly the most useful, both for HeLa cells and other malignant tissues. Trypsin, with a small amount of deoxyribonuclease, has been applied successfully in some cases, but this treatment is limited by the possibility of digestion of DNA (Boyse, 1960; Madden and Burk, 1961). Elastase and collagenese have also been employed—the latter especially in the adult organs. Morgan and Griffiths (1963) used fibrinolysin for disaggregating tissues from cancerous human colon.

The containers used for culturing are the same ones as those required for normal animal tissue cultures, such as, Carrel flasks, T-flasks, Erlenmeyer flasks, petri dishes, cover slips in test tubes, etc. Pulvertaft (1961) recommended the use of a small culture chamber, 3 mm deep, prepared of polytetrafluoroethylene (nontoxic plastic), the cover slips being fixed with silicon grease and sealed with wax. Ambrose, Easty and Wylie (1967) employed small glass tubes with stoppers, and with the aid of an inverted microscope, the monolayer at the bottom of the tube could be analysed.

Both natural extracts, like serum and embryo extract, and synthetic media are in use. All laboratory-adapted cell strains in culture grow profusely in Waymouth's (1956) simple medium M.B. 752/1. The optimum growth is generally seen at pH between 7.0 and 7.8, cell disintegration occurring at over 8.0 (Paul, 1959; Taylor, 1962). Lymphocytes survive for long periods in hypotonic media (Trowell, 1963). A buffering system with bicarbonate, employing an atmosphere of 5 per cent CO_2 in air, or with tris-HCl in air, or atmospheres containing 2 per cent carbon dioxide, gives good growth and pH control (Martin, 1964). Easty, Yarnell and Andrews (1964) have demonstrated that tissues differ with respect to their capacity for the uptake of macromolecules of serum proteins. Excess of oxygen is detrimental to proliferative growth (Pace, Thompson and Van Camp, 1962). When normal cells are grown continuously in an atmosphere containing nitrogen, they often become neoplastic (Goldblatt and Cameron, 1953).

Suspension cultures

These have been found to be very suitable for malignant cells. For such cultures, continued rotation of the drum containing the culture tubes, steady shaking, silicone-coating of the inner wall of the container to prevent adhesion, continuous stirring and automatic replacement of the medium through cryostat are all applied as in normal tissues (Paul, 1959; Björklund, Björklund and Paulsson, 1961).

After continued and repeated sub-culturing, *cell lines* can be secured containing a colony of cells showing a rapid rate of proliferation. Cell lines derived from different types of tissue often look alike and lose the morphological characteristics of the original parent line. The cytological basis of the origin of cell lines, that is, whether it is through mutation or

selection is not fully known. Just as normal cell lines often show neoplastic growth later, similarly cases have been reported where the malignant cell lines, after a certain period of growth, have become normal (Gey, Bang and Gey, 1954; Foley and Drolet, 1964). In any case, in spite of these limitations, due to the easy method of rapid culturing, several normal and malignant cell lines have now been standardised and are being maintained for use in cytochemical work.

Several schedules for isolated *single cells* have been evolved but in general, single cell cultures of HeLa cells are easier to prepare than cultures of *fibroblast* cells. Methods for obtaining clones from a single cell originally derived from suspensions are also identical with those described for other animal tissues. Aronson and Kessel (1960) devised a method for isolating single cells by making them adhere to wax-soaked glass beads. For HeLa *cells*, the schedule developed by Puck, Marcus and Cieciura (1956), involving the growth of dilute suspensions of single cells on x-ray irradiated feeder layer or on suitable media, has yielded excellent results (Foley, Kennedy and Ross, 1963). HeLa cells (so named after being derived from carcinoma of the cervix uteri of a patient, Helen Lane), represent an excellent example of adaptation to cultural conditions, and are maintained for innumerable generations.

The potentiality of hybridising mammalian cells in culture for the suppression of malignancy has been elucidated in the work of Harris *et al.* (1969). Hybrid cells in culture were first obtained by Barski and Cornefert (1962), followed by a number of workers who also used polyoma virus to induce malignancy in one of the parent cell lines (Defendi *et al.*, 1964, 1967; Scaletta and Ephrussi, 1965; Silagi, 1967). The fusion of malignant and non-malignant cell lines and the malignant properties of their respective progeny revealed the dominance of malignant characters. Human–mouse somatic cell hybrids have been obtained by Nabholz, Miggiano and Bodmer (1969) by the method introduced by Harris and Watkins (1965).

The technique for cell fusion, described later, was first outlined by Harris and Watkins (1965), aided by the Sendai virus through which they show that any mammalian cell can be hybridised in culture. Following this schedule, they have hybridised a non-malignant cell line and different malignant cell lines (Harris *et al.*, 1969; also *see* Ephrussi, Davidson and Weiss, 1969). The non-malignant cell line chosen was A9 mouse fibroblast—an azaguanine-resistant strain originally obtained from α-cell line of mouse (Littlefield, 1964). Three malignant ascites tumour lines selected were as follows.

(1) Ehrlich—originally derived from mouse mammary carcinoma (Hauschka, 1953);
(2) SEWA—obtained initially by subcutaneous injection of polyoma virus into a newborn A-SW mouse (Sjogren, 1964); and
(3) MSWBS—ascites sarcoma, original derivation by methyl cholanthrene injection in a hybrid mouse (A-SW $\times$ AF_1) (Klein and Klein, 1958).

The detection of these hybrid strains growing in culture did not present any difficulty, as the culture medium (Littlefield, 1964) and the container used did not permit the growth of any of the parent strains. Mixed suspension

of parent cells with inactivated sendai virus yielded a large number of hybrid clones. Chromosome analysis of these hybrid cells revealed the sum total of the parent complements, indicated both by the general number and the proportion of marker chromosomes.

Injection of hybrid cells intraperitoneally and subcutaneously in compatible mice was carried out to test the tumerogenic capacity of these hybrid cells. With A9–MSWBS hybrids, no tumours were obtained, whereas with the other two types, reversion to malignancy was noted in only a few cases. In the chromosome complement of such malignant tumours, derived from A9–Ehrlich hybrids, a loss of certain chromosomes was observed; evidently the segregants of the hybrid cells. These data have been claimed to indicate that malignancy can be suppressed by fusion with specific non-malignant cell lines, and also that reversion to malignancy is associated with loss of certain chromosomes. Such results, if later proved to be consistent, bristle with immense possibilities for evolving a cure for malignancy. Moreover, refinements in methods, leading to a further clarification of the structure of chromosomes responsible for tumour inhibition may reveal the ultimate basis of the genetic control of susceptibility to carcinogenic agents (*see* Kimball, 1979).

Lately, excellent work has been carried out on the virus-induced malignancy in animals. Under cultural conditions, oncogenic viruses cause changes in the host cells resulting in tumorous growth of the latter, the process being known as *transformation*. This behaviour is similar to that of neoplastic or malignant growth induced by different carcinogens. Both RNA and DNA viruses can cause transformation (Klein, 1966). The polyoma virus and the simian virus (SV 40) of the latter category have been studied in detail from this aspect (Westphal and Dulbecco, 1968; Dulbecco, 1969). Both of them have a typical circular DNA and a molecular weight of 3×10^6. Three different mammalian cell lines, namely: (a) BHK—hamster kidney fibroblasts (Macpherson and Stoker, 1962); (b) BSC–1, kidney line of African green monkey (Hopps *et al.*, 1963); and (c) 3T3—skin fibroblast of mouse (Todaro and Green, 1963), were used for this investigation on transformation.

Polyoma virus and SV 40 multiply and cause cell death of 3T3 and BSC–1 cell lines respectively. But BHK and 3T3 lines can be also transformed by both the viruses, though the characteristics of transformation differ, depending on the nature of the specific virus. Transformed cell lines can be distinguished in culture from normal cell lines by their rapid rate of multiplication, low serum requirement, ability to grow in suspension culture in agar, or methocel, and their growth patterns on glass or plastic (Macpherson and Montagnier, 1964; Todaro, Lazar and Green, 1965; Hakomori, Teather and Andrews, 1968; Holley and Kierman, 1968; Stoker, 1968; Benjamin, 1974; Miller *et al.*, 1971).

In the case of stable transformation, there is complete integration of viral DNA into the DNA of the transformed cells, as specially demonstrated in 3T3 cells. Evidence in support of this has been obtained through:

(1) their detection on membrane filters (Gillespie and Spiegelman, 1965);
(2) hybridisation of viral DNA in transformed cells with specific RNA of SV40 (Westphal and Dulbecco, 1968);
(3) restriction of this hybridising capacity to association of the virus with chromosomal DNA; and

(4) absence of any free viral DNA in transformed cells. Moreover, this virus can be detached from the chromosomal DNA by fusing the transformed lines with permissive cells by the method of induced cell fusion (Gerber, 1966; Koprowski, Jensen and Steplewski, 1967; Tournier *et al.*, 1967; Watkins and Dulbecco, 1967). (*See* Chapter 14.)

Even though the exact mechanism of this integration of viral genome into the host chromosomes is not fully understood, the importance of this discovery in relation to viral carcinogenesis cannot be overrated. This knowledge of integration, together with the capacity of detachment, may provide essential clues to a solution of the problem of neoplasia and its regulation in animal cells.

SCHEDULES FOR THE PREPARATION OF TISSUE FOR CYTOLOGICAL STUDY

Direct biopsies

Biopsies are taken directly from patients suffering from cancer of particular organs. The tissue is directly observed in acetic–orcein, acetic–carmine or acetic–dahlia after staining for a few minutes, preceded by treatment in hypotonic salt solution for a few minutes. If necessary, the fluid may be slightly warmed to facilitate staining and squashing. To secure well-scattered chromosomes, pre-treatment in aqueous coumarin solution for a few minutes, prior to acetic–carmine staining, yields excellent results (Manna, 1954, 1957). Therman and Timonen (1950) observed that fixation in 10 per cent formalin before staining brings out the structure of the spindle quite clearly. They applied acetic–ethanol fixation to biopsies prior to staining.

For solid tumours, slight trypsin treatment (2 per cent at 37 °C for 1 h) may facilitate squashing.

Ascites tumours

The peritoneal or pleural fluid can be taken out with the help of a hypodermic syringe or pipette and a drop of this can be stained directly on the slide with any of the above-mentioned dyes. The cells may be treated in a hypotonic salt solution (preferably 1.12 per cent sodium citrate) before staining. To obtain a concentrated solution, the fluid is centrifuged. Makino (1957) observed that pre-treatment in a drop of water on the slide for 20–30 min prior to staining with acetic–dahlia yielded well scattered chromosomes. This method has been followed by Takayama and Makino (1961) and others. Propionic–sudan black B is also an effective stain (Tanaka and colleagues, 1955).

For fixing, squashing and staining the fluid directly in acetic–orcein, the material is pressed between specially prepared siliconed surfaces of slide and cover slip (*see* Levan and Hauschka, 1952).

Direct observation of bone marrow cells

The techniques for normal cells, as described in the chapter on mammalian and human chromosomes, can be followed.

Mitotic division of living cells in pleural fluid
According to the culture of ascites tumour, by modified hanging drop method —Makino and Tanaka, 1953.

(1) Fill the depression of a sterile grooved, or depression, slide with liquid paraffin above the level of its edge.
(2) Cut open a tumour-bearing rat. Draw out a small amount of tumour ascites fluid from the peritoneal cavity with a pipette. Place the fluid on a sterile dry cover slip without any medium.
(3) Invert the cover slip over the depression so that the ascites fluid lies in the liquid paraffin. Apply slight pressure and remove the excess liquid with a blotting paper. Seal and observe under a phase contrast, or light microscope.

Study from peripheral blood
The different techniques for studying chromosomes from peripheral blood cells, as described in the chapter on mammalian and human chromosomes, can be effectively used for cancer chromosomes as well.

Tissue culture in nutrient media

Biopsies are taken from solid or soft tumours and can be cultured in media as specified for explant cultures in the chapter on tissue culture. The cytological studies can be carried out as mentioned before for direct biopsies.

Levan and Hsu (1960) observed that if the original explanted tissue, e.g. solid mammary carcinoma of mouse, is trypsinised before transference to McCoy, Maxwell and Cruse's 5A medium (1959) for culture, convenient materials for cytological study can later be obtained. For chromosome analysis, they treated the tissue for 6 h with 0.05 γ/ml colchicine in the medium. Culture of ascitic fluid too, in sterilised pleural fluid can be made similarly *in vitro* after extracting the primary ascitic fluid from injected rats with a pipette. The chromosome studies in cultured cells follow the same methods as those mentioned above.

Another device which is finding great application in the study of tumour cells and the method of their invasion into normal cells involves the provision of a three-dimensional matrix for growth (Leighton, 1951; Leighton, Kline and Orr, 1956). Cellulose sponge matrix, saturated with serum and embryo extract, has been found to allow the development of three-dimensional colonies, closely approaching the condition in the body. The disadvantages of this method are the necrosis of the central region and the difficulty of direct observation.

Cloning of HeLa cells

The dilution technique (Paul, 1959)
The materials necessary are:

(1) A strain of HeLa cells growing on a medium of pH7.4;

(2) A balanced salt solution (BSS) without Ca, Mg, or PO_4;
(3) 0.05 per cent trypsin dissolved in the BSS;
(4) medium containing 20 per cent human or calf serum and the remaining synthetic nutrient medium;
(5) A stainless steel or glass cylinder of approximately 5 mm diameter and 10 mm height;
(6) 60 mm petri dishes;
(7) CO_2 incubator;
(8) pasteur pipettes.

The steps are:

(1) Prepare a healthy culture of HeLa cells on a clean medium at a pH of 7.4. Examine to identify the strain.
(2) Drain off the nutrient medium from the container. Add a quantity of BSS and drain again.
(3) Add 0.05 per cent trypsin dissolved in the BSS to the culture and incubate at 30 °C for 5–10 min.
(4) Distribute nutrient medium, containing 20 per cent serum and the rest of the synthetic medium, into petri dishes and test tubes, putting 5 ml into the former and 4.5 ml into the latter. Keep the petri dishes in a CO_2 incubator.
(5) Suspend the cells in the medium by shaking the container gently. Aspirate the suspension in and out of a pipette several times. After all cells have been suspended, add to the suspension half its quantity of growth medium to stop the action of trypsin. With a haemocytometer, determine the number of cells in a known volume of suspension. Add 0.5 ml of the suspension to 4.5 ml of the medium in the first one of the series of test-tubes. Shake well and add 0.5 ml of the fluid from this test tube to 4.5 ml of the medium in the next one, and so on along the set of test tubes until, on counting, a suspension yields 1000–2000 cells/ml.
(6) Pipette out 0.5–1 ml of the final suspension on to one of the petri dishes containing the medium, to give 100 cells per dish. Treat the other dishes similarly and keep them in the CO_2 incubator at 37 °C for 1 week. For counting the colonies, drain off the medium and stain.
(7) For further isolation, outline on the outer glass surface of the petri dish, with a glass pencil, the location of a particular colony. Coat the bottom edge of a glass cylinder with silicon grease. Drain out the medium and place the glass cylinder on the petri dish so that it encloses the colony to be isolated and is attached to the petri dish by the silicon grease. Pour a few drops of BSS into the cylinder, drain and add a few more drops. Drain out this solution, washing the culture within the cylinder. Add a few drops of trypsin solution and incubate at 37 °C for a few minutes. Disperse the cell suspension thoroughly by aspirating in and out with a pipette. Draw out the suspension and inoculate a fresh nutrient in another vessel for sub-culture.
(8) This method is effective for isolating single colonies but it cannot confirm whether the colony has developed from a single cell or a small group of cells.

The isolation technique (Paul, 1959)
The materials needed, in addition to those for the dilution technique, are:

(9) Liquid paraffin saturated with the medium, prepared by adding 10 ml of medium to 100 ml of liquid paraffin, shaking, and incubating at 37 °C for some days.
(10) Micropipettes prepared by drawing out the capillary area of a fine Pasteur pipette on the flame of a microburner to form a capillary point with a diameter of approximately 50 μm. It can be coated with silicon if necessary. The microburner can be prepared by attaching the rubber tubing of a gas burner to a hypodermic needle. The micropipettes are washed in BSS before use.

The different steps of the technique are:

(1) Pour a little ether on the bottom half of a petri dish. Allow it to evaporate. Dry completely by flaming. Fill the dish with liquid paraffin saturated with the medium.
(2) Pipette out the medium and put 10 drops around the dish containing the paraffin at approximately equal distances, about 1 cm from the edge. The drops penetrate the paraffin and spread out at the bottom of the dish. Pick up a few drops of the cell suspension (prepared as in the dilution technique) with a pipette and place in the centre of the medium–liquid paraffin mixture.
(3) Place the petri dish on the stage of a dissecting microscope. Attach a micropipette to a mouth tube. Focus the microscope on the drops of cell suspension at the centre of the petri dish. Take the micropipette in the right hand and guide its tip to the cell suspension at the centre of the petri dish. By observing through the microscope, guide the tip to an isolated cell and draw it into the pipette by sucking cautiously. Now move one of the drops of medium into the field of vision; guide the pipette into it and eject the cell into it gently. Inoculate similarly all the 10 drops, cover the petri dish and incubate in a CO_2 incubator at 37 °C. Observe after 24–48 h.
(4) Each cell develops into a colony within the drop. For transferring the colony add, with the pipette, a drop of trypsin in BSS inside the drop of medium containing the colony and aspirate it out as a suspension with a micropipette.

Study of chromosomes from sub-cultures *in vivo*

To study the behaviour of chromosomes and cell division in different sub-cultures obtained from the primary tumours, the following methods may be applied.

Ascitic fluid
Ascitic fluid may be taken from an affected rat and injected into the peritoneum of a normal rat. Oksala (1956) inoculated ascitic fluid, suspended in buffered physiological saline (1 : 9), in a dosage of 0.2 ml per mouse. The concentrated filtrate of ascites tumour can be obtained through Seitz EK

apparatus (after Hamazaki and colleagues, 1953), if necessary. The behaviour is studied at intervals, taking the peritoneal fluid of the sub-cultured rats (Makino and Tonomura, 1955).

Single cell sub-culturing from ascitic fluid (Makino and Kano, 1955; Sasaki and Hishida, 1958; Hansen-Melander, 1958)
This is applicable to cases in which the chromosomal behaviour of a cancer cell colony derived from a single cell of a heterogeneous population has to be studied. The inherent heterogeneity in the chromosome behaviour of every cancer cell has been substantiated from such studies.

In this method:

(1) Tumour ascitic fluid with tumour cells is first removed from rats.
(2) These are then diluted in the diluting fluid in a proportion of 1 : 20 000, the diluting fluid being prepared by injecting 15–20 ml of physiological saline with a sterilised syringe into the peritoneum of rats weighing about 100–120 g. With the same syringe, the peritoneal fluid is taken out from the treated rats after 15 min and centrifuged at 3000 rev/min for several minutes. The supernatant can serve as the diluting fluid provided it is cellfree on microscopical examination.
(3) With a sterilised pipette, a drop of the diluting fluid containing tumour cells is taken on a clean cover slip.
(4) A microscopic droplet containing a single cell is sucked into the micropipette.
(5) The droplet is ejected into the peritoneum of a normal rat.
(6) Cytological observations of the sub-culture following the method discussed above can be carried out after a few days.

Sub-culturing of solid tumours
Solid extracted tumours can be mashed in a homogeniser or tissue press and the tissue suspension can be inoculated subcutaneously or intraperitoneally into normal animals. Kikuchi (1960), while dealing with CBA mice mammary tumour, inoculated 0.2 ml into the normal animal. The remaining procedure for cytological study has been described before.

Ascites developed from solid neoplasms (Goldie and Felix, 1951)
This technique is very important in the study of cancer cytology, because solid tissues, which are otherwise difficult to observe, can conveniently be converted into free tumour cells suspended in the body fluid. The steps are:

(1) Intraperitoneal inoculation of sarcoma or lymphoma cells in mice is performed.
(2) Week-old subcutaneous implants of the subsequent tumour are taken and ground in a tissue press and a suspension in 0.85 per cent NaCl solution is prepared.
(3) The number of viable tumour cells in the mashed suspension is first determined by separating the tissue fragments and cell clumps from the suspension by sedimentation and decantation; a suspension sample is then placed in a haemocytometer previously coated with 0.02 per cent solution of neutral red in ethanol, and cells coloured with neutral red are con-

sidered dead. This step is necessary to find out the amount of dilution required to obtain the requisite number of viable tumour cells 0.1 mm^3. Mitotic activity can be counted with acetic–orcein staining.

(4) The suspension, after proper dilution of 1 : 10 or 1 : 20, is then inoculated into another mouse intraperitoneally.

(5) Growth characteristics, cell division, etc. can be studied from the peritoneal exudate after a few days.

Identification of the chromosomes may be made following the different banding pattern schedules (*see* Chapter 13). For example, O'Neill and Miles (1974) observed specific C bands in continuous human lymphoblastoid cell lines and Lin and Goldstein (1974) in three cell lines.

A list of the more common tumours induced artificially in laboratory mammals

Hirosaki sarcoma—originated spontaneously in a Japanese stock rat (Usubuchi *et al.*, 1955).

MTK-sarcoma I and MTK-sarcoma II—first produced in male and female Wistar rats respectively by Tanaka and Kano (1951) through the action of *o*-aminoazotoluene and *p*-dimethylaminoazobenzene.

MTK-sarcoma III—produced in a male Wistar rat by Tanaka (1952, unpublished, referred by Makino 1957), through the action of *p*-dimethylaminoazobenzene.

MTK-sarcoma IV—formed by the action of *o*-aminoazotoluene and *p*-dimethylaminoazobenzene on a Wistar rat (Tanaka, 1954 unpublished, referred by Makino, 1957).

Takeda sarcoma—originated spontaneously in a stock rat (Takeda *et al.*, 1952).

Usubuchi sarcoma—first produced in a stock rat by administering methylcholanthrene (Usubuchi *et al.*, 1953).

Watanabe ascites hepatoma—first induced in a stock rat by Watanabe and Matsunaga (1954) by repeatedly injecting water at 72 °C into the peritoneal cavity.

Yoshida sarcoma—produced by Yoshida, Muta and Sasaki (1944) in a stock rat through injection of *o*-aminoazotoluene and by painting the skin with potassium arsenite solution.

Ehrlich tumours—originally derived from a mouse mammary carcinoma (Hauschka, 1953).

SEWA—derived initially by subcutaneous injection of polyoma virus into newborn A-SW mouse (Sjögren, 1964).

MSWBS—ascites sarcoma formed originally through methylcholanthrene into a (ASW × AF_1) hybrid mouse (Klein and Klein, 1958).

Study of banding patterns of chromosomes

BANDING PATTERN TECHNIQUES

Differential banding patterns of chromosomes, usually observed at specific regions on particular levels, were initially developed for the analysis of human chromosome segments. These bands are made visible through low and high intensity regions under the fluorescence microscope or as differentially stained areas under the light microscope (*see* Lubs *et al.*, 1973; Houghton, 1974; Miller, Miller and Warburton, 1974; Sharma, A. and Talukder, 1974; Yunis, 1974; Vagner-Capodano, Noel and Stahl, 1975; Borgaonkar, 1976; Pearson and Van Egmond-Cowan, 1976; Schwarzacher, 1976; Proceedings of Leiden and Helsinki Chromosome Conferences, 1974 and 1977; Szabo and Papp, 1977 for review.) These methods were then extended first to different animals and later to plant chromosomes.

The advent of molecular hybridisation, which revealed the functionally different segments in a eukaryotic chromosome, led to the banding pattern technique. It is based on the principle that single strands of RNA or DNA are able to recognise and pair with their complementary base sequences. A denatured DNA duplex, on renaturation, undergoes pairing at complementary sequences. Highly repeated sequences show rapid rate of reannealing. The reassociation kinetics give an indication of sequence complexity of DNA. The presence of segments rich in repetitive DNA sequences, in addition to unique sequences which are not repeated (Pardue and Gall, 1970; Jones, 1973; Sharma, 1975), has been shown in different biological systems. This protocol for molecular hybridisation, that is, denaturation at the cytological level, if followed by renaturation and staining with different dyes, particularly Giemsa, gives intensely positive reaction at similar segments of chromosomes which otherwise show repetitive DNA. Obviously such treatment is capable of revealing repetitive segments in chromosomes. This banding, following denaturation–renaturation, Giemsa staining, is termed *C*-banding (Hsu, 1973; Arrighi, 1974).

Earlier, Caspersson and his colleagues had recorded differential fluorescence of different chromosome segments following staining with various fluorochromes and observation under the ultraviolet microscope and had successfully employed it in formulating a banding pattern analysis of the human karyotype (Caspersson, Lomakka and Zech, 1971; Zech, 1973; Paris Chromosome Conference, 1972). Such bands were referred to as *Q*-bands

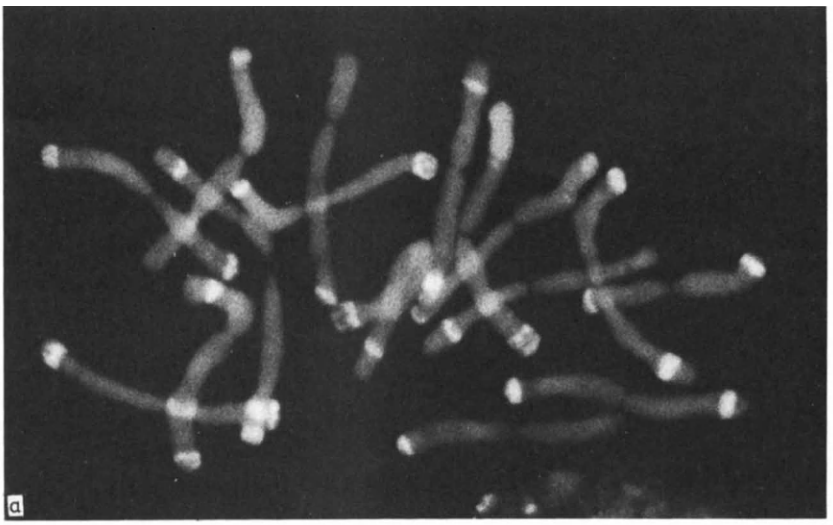

Plate 13.1
(a) and (b) *Quinacrine fluorescence and Giemsa stained bands in* Allium pulchellum (courtesy of Dr. C. G. Vosa, Botany School, Oxford)

Other fluorochromes produce banding patterns as well, e.g., Hoechst 33258 similar to *Q* and ethidium bromide the reverse (Unakul and Hsu, 1973; Hecht, Wyandt and Megenis, 1974).

A later observation showed that mere saline treatment, followed by Giemsa staining, gave a set of patterns, similar in relative staining intensities to the *Q*-bands. Such bands—known as *G*-bands, did not require any denaturation–renaturation (Drets and Shaw, 1971; Schnedl, 1973; Hansen-Melander *et al.*, 1974). Since then *G*-banding has been obtained following treatments in a variety of chemicals like standard saline, NaOH/HCl before incubation, NaOH, trypsin, etc. (Seabright, 1972; Sumner, Evans and Buckland, 1973; Hecht, Wyandt and Megenis, 1974) and even mere heating (Lomholt and Mohr, 1971).

The *R* banding or reverse banding, where the pattern is opposite to that of *Q* and *G* bands, was obtained by Dutrillaux (1973) following controlled heating. Acid extraction has been employed for *N*-banding for the nucleolar-organising region (Matsui and Sasaki, 1973; Stack, 1974; Funuki, Matsui and Sasaki, 1975). A *CT*-banding procedure produces bands in the telomeric and centromeric regions alone (Scheres, 1976). Orcein-staining after incubation in XSSC results in *O*-banding, which is similar in general to the *G*-band pattern (Sharma, 1975, 1977).

Various causes have been ascribed to the occurrence of the chromosome bands. Of them, four factors appear to be of particular importance, namely, the occurrence of repetitive DNA, and differences in the base composition of DNA, in the protein components and in the degree of packing of DNA or DNP-complex (*see* Britten and Kohne, 1971; Walker, 1971; Comings, 1972; Pardue and Gall, 1972; Schwarzacher, 1976). Some of the factors will be discussed later under the respective techniques.

The different banding patterns have been employed in locating marker segments of chromosomes, particularly those with repetitive DNA sequences, in plant and animal systems. They were, with the exception of *O* and *Hy* banding, developed initially for human chromosomes and have been successful in establishing standard human karyotypes and in ascribing certain syndromes to changes in bands on specific chromosomes (*see* Paris Conference, 1972; Caspersson and Zech, 1973; Sharma and Talukder, 1974; Yunis, 1974; Schwarzacher, 1976). The techniques were later extended first to other mammalian chromosomes and then to other animal systems, with modifications. In plant system, even though *G*, *C* and *Q* banding have been applied by various authors (Dobel, Rieger and Michaelis, 1973; Vosa, 1973, 1976, 1977; Marks and Schweizer, 1974), yet success has been less marked. *O*-banding has a relatively wider application (Sharma, 1975, 1977) while Feulgen-stained bands have been attempted by some workers. The chemical principle underlying *Q*-banding has been well worked out. With quinacrine mustard (QM), the fluorescent amino-acridine nucleus becomes intercalated within the double helix of DNA. The basic nitrogen atoms form ionic bonds with DNA phosphate and the alkylating side group binds covalently with guanine from DNA (Modest and Sengupta, 1973). Quinacrine dihydrochloride or atebrin does not form a covalent link due to the absence of alkylating side group. Thus the primary *Q* binding with both compounds has been suggested to be through intercalation of the acridine nucleus in the double helix. The chemical basis, or otherwise, of the other types of banding patterns is not

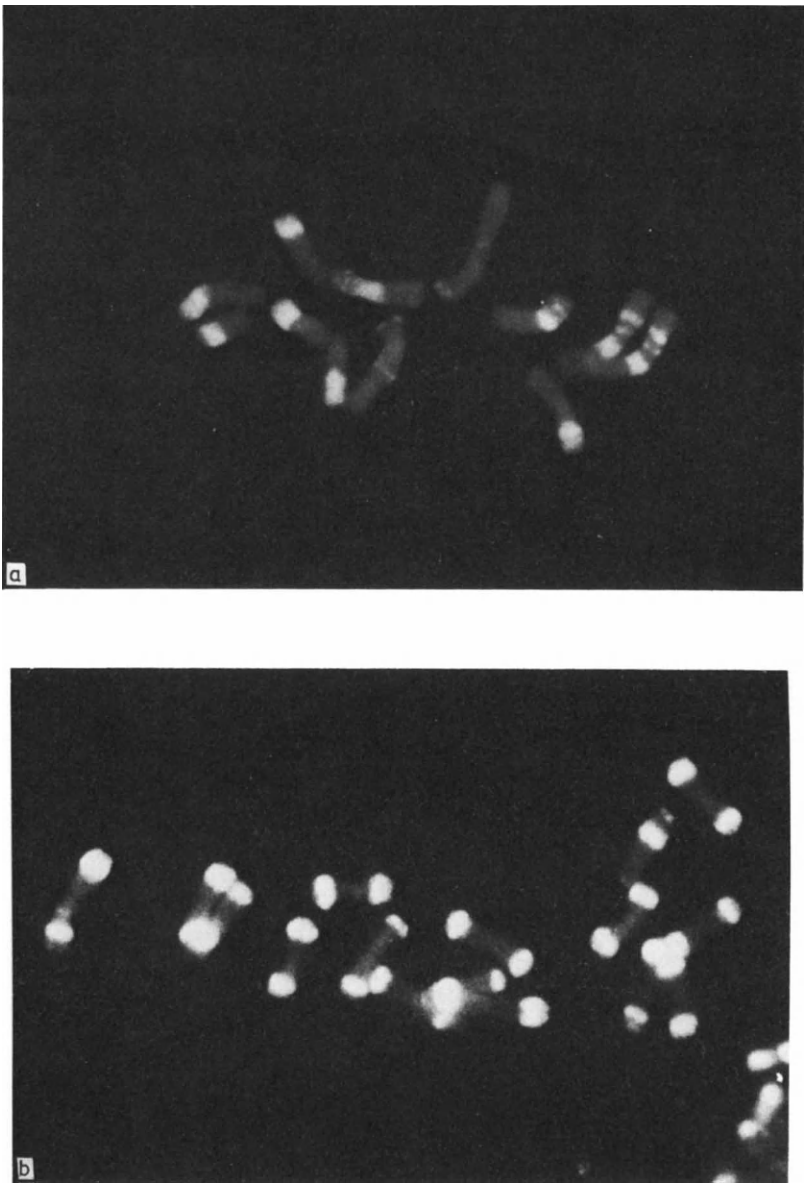

Plate 13.2
(a) and (b) *Quinacrine fluorescence bands in* Ornithogalum oliganthum *and* Allium stamineum (courtesy of Dr. C. G. Vosa, Botany School, Oxford)

yet fully clear (*see also* Deaven and Peterson, 1973; Comings and Drets, 1976).

FLUORESCENT BANDING OR *Q*-BANDING

Comings *et al.* (1975) have suggested that quinacrine mustard binds to chromatin by intercalation of the three planar rings with the large group at position nine lying in the small groove of DNA. Most pale staining regions are caused by a decreased binding of *Q*, predominantly due to non-histone proteins. DNA-base composition influences the fluorescence by correlation with G–C bonding at lower *Q*:DNA ratios and by conversion of dyes bound near G–C bases into energy sinks at higher ratios. Chromosomal proteins possibly have a much less pronounced effect (Latt, Brodie and Monroe, 1974).

With quinacrine mustard (QM) or quinacrine dihydrochloride (Q)

Schedule for human chromosomes (Caspersson, Lomakka and Zech, 1971; Zech, 1973; Sehested 1975)
Transfer air-dried chromosome preparations (fixed in acetic acid–methanol, 1 : 3) to absolute ethanol and bring down to water. Soak in McIlvaine's or Sörensen's phosphate buffer (pH 4.1 to 7.0) and stain either in Q (5 mg/ml) or QM (50 μg/ml) solution for 20–30 min at 20 °C. Wash in three changes and mount in buffer of same pH. Observe under phase contrast to mark out suitable metaphase plates, transfer to ultraviolet microscope and photograph immediately since the fluorescence fades progressively under ultraviolet light.

Modifications

(1) The ethanol grades for progressive hydration of the slides may be prepared by using the buffer instead of distilled water. McIlvaine's disodium phosphate/citric acid buffer, pH 7.0, is very effective. The staining solution is prepared by adding an aliquot of aqueous QM solution to the buffer to give a final concentration of 50 μg/ml. This solution can be used repeatedly.
(2) In an alternative schedule, air-dried slides are kept for 5 min in 0.005 per cent QM solution in glass distilled water. A few drops can also be inserted inside the cover-glass. The slides are washed in distilled water for 25 s three or four times, mounted and observed in distilled water before the chromosomes get swollen (Manolov, Manolova and Levan, 1971).
(3) Vinblastine sulphate (0.0075–0.015 μg/ml) for 1 h may be used as a pre-treating chemical instead of colcemid. After fixation and air-drying the slides are stained in 0.5 per cent atabrine (Q) solution for 5 to 10 min, rinsed (2 min) in three changes of isotonic salt solution and mounted in the same solution. It has been used for studying chromosomes from malignant tissues (Fleischmann *et al.*, 1972).
(4) To analyse the human Y chromosome, air-dried slides are stained in a

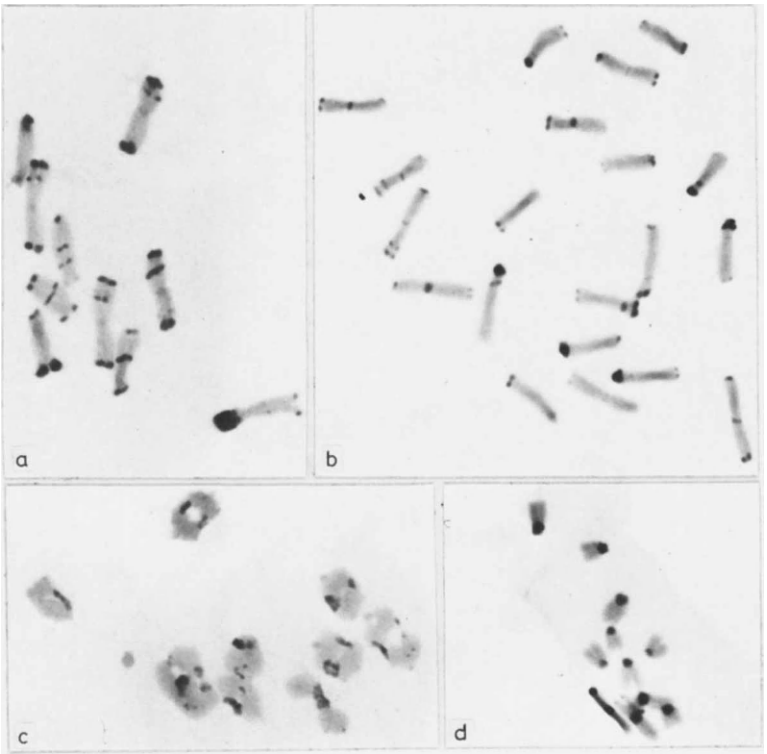

Plate 13.3
(a)–(d) *Giemsa stained bands in species of* Commelinaceae (courtesy of Professor Keith Jones, Jodrell Laboratory, Royal Botanic Gardens, Kew)

solution of 5 mg QM in 100 ml phosphate buffer (pH 7.0) for 30 min, rinsed and mounted in the same medium.

(5) HeLa cell preparations are stained with 2 per cent Q solution containing 0.1 per cent thymol, washed in running water, differentiated and mounted in McIlvaine's buffer (Czaker, 1973). This method is used extensively in various primates (Brumback, 1975), rhinoceros (Hansen, 1976), amphibian embryos (Bailly, 1976) and also in assessing human newborn for chromosomal disorders (Lin *et al.*, 1976).

Schedule for plant chromosomes

Grow plants in cold greenhouse. Pre-treat root tips in aqueous colchicine (0.05 per cent), fix in acetic–ethanol (1:3) overnight, squash directly in 45 per cent acetic acid and stain in 0.5 per cent aqueous quinacrine dihydrochloride for 10–15 min. Rinse in water and mount in distilled water (Vosa, 1976). Alternative stains are H33258 (0.02 per cent) and ethidium bromide.

With Hoechst 33258

Hoechst 33258 (2-[2-(4-hydroxyphenyl)-6-benzimidazolyl]-6-(1-methyl-4-piperazyl)-benzimidazole), a bibenzimidazole derivative, shows enhanced

Plate 13.4
Sister chromatid exchange in human chromosomes (courtesy of Dr. M. Ray, Children's Hospital, Winnipeg)

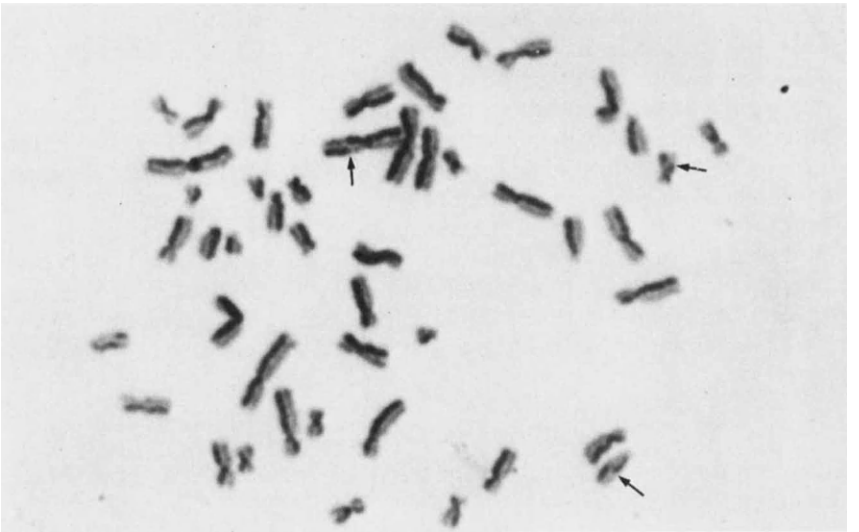

Plate 13.5
Giemsa stained bands in human chromosomes showing translocation in chromosomes (courtesy of Dr. Marina Seabright, General Infirmary, Salisbury, UK)

fluorescence with both AT and GC-rich DNA. However, enhancement of AT-rich DNA is greater (Weisblum and Haenssler, 1974) and it can be used as a probe for identifying all types of AT-rich regions in chromosomes, including those which are not demonstrable with quinacrine (Rowley and Bodmer, 1971; Hilwig and Gropp, 1972; Seth and Gropp, 1973). Its interaction with DNA and chromatin is characterised by changes in absorption and circular dichroism measurements (Latt and Wohlleb, 1975). Comings (1975) suggests that H33258 binds by an attachment to the outside of the double DNA helix interacting with base pairs. This binding allows greater sensitivity to the base composition than found with intercalating agents. It may be used as a 2×10^{-6} M solution in 0.1 XSSC in mammals and probably acts during the S phase (Rocchi *et al.*, 1976). It has been employed in the study of spontaneous and induced chromosome aberrations (Raposa and Natarajan, 1975) and in mouse–human heterokaryon analysis as an alternative to autoradiography (Moser, Dorman and Ruddle, 1975).

Schedule 1 Enhanced Hoechst fluorescence by heating in plants (Filion *et al.*, 1976)

Fix root tips, after pre-treatment in colchicine (4 h), in acetic–ethanol (1:3). Treat 1-day old slides in barium hydroxide/saline mixture (Filion, 1974) and stain in H33258 (40 μg/ml) in McIlvaine's buffer, pH 4.1, for 10 s. Rinse and mount slides in same buffer and seal. Heat the sealed slides for about 6 s on a hot plate 120 °C) and cool them rapidly by placing them, cover-glass down, between two slabs of dry ice.

The chromosome banding increases markedly in fluorescent intensity as compared with control. This method however is not applicable to all plants. A combination with Giemsa banding has been employed in rye (Vosa, 1974).

Schedule 2 In Drosophila chromosomes (Holmquist, 1975)
Dissect out ganglia in Ringer's, incubate 45 min at 24 °C in Schneider's cell culture medium with 0.05 μg/ml colcemid.

Keep in 1 per cent trisodium citrate for 10 min, 0.5 per cent trisodium citrate for 5 min, fix in three changes of acetic–methanol (1 : 3) for 30 min. Warm to 50 °C in a drop of 60 per cent acetic acid. After 30 s, cells dissociate from the mass of tissue and adhere to the glass at the edge of droplets. Add a drop of (1 : 3) fixative to warm slide.

Rinse slides for 10 min in PBS (0.15 M NaCl, 0.03 M KCl, 0.01 M Na phosphate pH 7.0), stain 10 min with a 1/100 dilution of stock 33258 Hoechst in PBS, rinse 10 min in PBS, rinse 4 min in water, drain and store for less than 12 h. Mount in McIlvaine's buffer pH 4.0 and observe in fluorescence microscope.

Reverse fluorescent banding with chromomycin and DAPI (Schweizer, 1976)

Two DNA binding guanine specific antibiotics, chromomycin A_3 (CMA) and closely related mithramycin (MM) are used as fluorescent dyes. Metaphase chromosomes in roots were sequentially stained with CMA or MM and the DNA-binding AT-specific fluorochrome 4′-6-diamidino-2-phenylindole (DAPI). Non-fluorescent counterstain may be used—methyl green with CMA and actinomycin D (AMD) with DAPI. In plant species, *Vicia faba*, *Scilla sibirica* and *Ornithogalum caudatum*, nucleolar organiser regions show bright fluorescence with CMA and MM. In general, C-bands which are bright with CMA and MM, are pale with DAPI and *vice versa*. Human metaphase chromosomes show a small longitudinal differentiation in CMA fluorescence, which is reverse that of AMD/DAPI double staining banding but of a lower contrast. CMA-banding appears to resemble *R*-bands.

However fluorochromes do not give qualitatively identical staining with certain types of heterochromatin (Hilwig and Gropp, 1972) and a general association of brightness with A–T richness is still in doubt (Comings and Drets, 1976). The anthracycline antibiotics daunomycin and adriamycin produce bands on human chromosomes (Lin and Van de Sande, 1975). The fact that both AT and GC specific fluorochromes are available and that sequential fluorescent staining of chromosomes (Holmquist, 1975) and counterstaining with non-fluorescent DNA ligands is feasible, means that suitable combinations may facilitate analysis of molecular mechanism.

Schedule
Treat root tips with colchicine (0.05 per cent, 3–6 h), fix in acetic–ethanol (1 : 3, overnight), squash in 45 per cent acetic and air-dry after removing coverslip by dry ice. Air-dried human or mammalian chromosome preparations can also be used.

CMA staining
Pre-incubate slides in McIlvaine citric acid—Na_2HPO_4 buffer (pH 6.9–7.0), containing 10 mM $MgCl_2$ for 10–15 min. Stain slides in buffer containing

10 mM $MgCl_2$ and 0.12 mg/ml CMA ('reinst', Serva, Heidelberg) or 0.11 mg/ml MM ('rein', Serva) for 5–10 min, wash and mount in McIlvaine's buffer (pH 6.9–7.0) and seal with rubber solution.

For counterstaining, pre-incubate slides in McIlvaine's buffer (pH 4.9) for 10–25 min, stain for 5–15 min in a buffered solution (pH 4.9) of 0.1 per cent methyl green GA (Chroma, Stuttgart), from which methyl violet has been removed with chloroform extractions. Rinse in buffer (pH 4.9) and in neutral buffer containing 10 mM $MgCl_2$, stain in CMA as described before.

Sequential staining with CMA and DAPI

Observe and photograph CMA or MM fluorescence as for *Q*-banding. Remove coverslip by dry ice or rinsing in buffer and then acetic–methanol and methanol successively. Remove chromosome-bound CMA or MM by extracting with pyridine for 2–3 days (Holmquist, 1975). Stain and observe DAPI fluorescence following Schweizer and Nagl (1976).

AMD + DAPI double staining

Dissolve AMD ('rein', Serva) in small amount of methanol and make up to 0.25 mg/ml with McIlvaine's buffer (pH 6.9–7.0). Pre-incubate human chromosome slides in buffer for 5 min and stain with AMD for 15–20 min, rinse with McIlvaine buffer (pH 6.9–7.0). Stain in DAPI at concentrations between 0.1 to 0.4 μg/ml (McIlvaine's buffer, pH 6.9–7.0) for 5–10 min. CMA and MM fluorescences fade rapidly and can be slightly stabilised by ageing the preparation and the solution.

DAPI fluorescence is observed with excitor filters UG 1, BG 3 and TK 300 (dichroic mirror of Leitz Ploem epi-illuminator) and barrier filters K-400 of the epi-illuminator and K-470, K-490 or K-510.

D-bands with antibiotics

Of the anthracycline group of antibiotics, daunomycin (Cerubidine-HCl) and adriamycin (Doxorubicin-HCl) give well defined and reproducible orange-red fluorescent banding patterns on human chromosomes (Lin and de Sande, 1975). The concentrations are 0.5 mg for daunomycin and 0.2 mg for adriamycin per ml in 0.1 M sodium phosphate buffer (pH 4.3) and the staining period 15 min. The schedule and pattern are similar to *Q*-bands. The G–C specific DNA binding antibiotic—olivomycin—produces reverse fluorescence banding patterns in human, bovine and mouse chromosomes (de Sande, Lin and Jörgenson, 1977).

Ethidium bromide as counterstain for quinacrine
(Hollander, Litton and Liang, 1976)

Fix cellular smears, in case of plants in 95 per cent ethanol. Use air-dried preparations for animal materials. Keep in 95 per cent and 70 per cent ethanol

for 3 min each; distilled water, 3 min; citric acid phosphate buffer (0.01 M, pH 5.6), 3 min; staining solution (50 μg/ml QM in citric–phosphate buffer, 0.01 M, pH 5.6, containing 0.5 per cent zinc sulphate), 10 min; two changes of 6 min each in pH 5.6 buffer; 5 per cent zinc sulphate solution, 5 min; two changes in distilled water of 4 min each; ethidium bromide solution (2 μg/ml EB in 7.0 pH phosphate buffer, 0.01 M), 5 min; 7.0 pH phosphate buffer (0.1 M), two changes of 2 min each, 7.6 pH phosphate buffer (0.01 M), two changes of 4 min each, mount in same buffer and seal.

With this counterstain, cytoplasm fluoresces pale green, nuclei pale orange and interphase fluorescent bodies appear as bright yellow spots, as also do the brightly fluorescing bands in metaphase chromosomes.

The mechanism of the counterstaining by EB is not yet clear. Presumably the brilliant areas contain AT-rich DNA binding firmly with QM, and EB removes, replaces or obscures the quinacrine in weakly stained areas, so that densely stained chromatin, by contrast, seems more prominent.

Chromosome banding has been observed in early meiotic prophase of male Chinese hamster by injecting ethidium bromide and actinomycin D intratesticularly for 4 h and making acetic–orcein squash preparations from minced testicular tissue (Unakul and Hsu, 1973).

Banding with acridine orange (AO)

Acridine orange reverse banding (RFA) is more useful than *Q*-banding for characterising variations in certain acrocentric human chromosomes but does not give any results consistent with *Q*-banding (Verma and Lubs, 1975). Terminal bands or *T*-bands were obtained by controlled denaturation of chromosomes at 87 °C using Giemsa and AO in diluted buffer (Dutrillaux, 1973).

Other chemicals

Other chemicals have been observed to give quinacrine-like fluorescence as well. These include alcoholic extracts of the alkaloids from fresh roots of eight genera of Papaveraceae and Fumariaceae (Vosa *et al.*, 1972) as also from *Chelidonicum majus*, *Macleaya cordata* and *Glaciumflavum*. Of limited use are sarcolysinoacridine (Iordanskiy *et al.*, 1971), berberine sulphate (Moutschen, Degraeve and Moutschen-Dahmen, 1973) and 2,7-di-*t*-butyl proflavine DBP (Disteche and Bontemps, 1974).

GIEMSA OR *G*-BANDING

Giemsa is a complex mixture of thiazine dyes and eosin. Of them, methylene blue and Azure A, B. and C alone give good banding. Thionin, with no methyl groups, gives poor banding while eosin has no effect. Thiazine dyes are strongly metachromatic and their adsorption spectra and extinction coefficients change with increase in dye concentration or on binding to positively charged chromotropes (Comings, 1975). Dye concentration, according to

Walther, Stengel-Rutkowski and Murken (1974) is more important than trypsin digestion or denaturation.

The surface topography of the human chromosomes at each stage of the *ASG* banding, observed with electron microscopy, shows that chromosomes collapse with 2 XSSC treatment at 60 °C for 1 h and, on subsequent staining with Giemsa, fibrillar appearance and transverse ridging of chromatids are observed. The banded patterns under light microscope may be due to the ridges absorbing more dye than other parts of the chromosome (Ross and Gormley, 1973; Blakey and Filion, 1976). With trypsin and QM, the collapse occurs before staining and with Q, it occurs during washing after staining. The collapse is pH-dependent (Gormley and Ross, 1976). The band and interband regions may reflect the concentration or compaction and arrangement of nucleoprotein fibres (Bahr, 1973; Takayama, 1976).

On the other hand, Khachaturov *et al.* (1975) suggest that differential staining due to Q, QM and G is due to their binding with various acid mucopolysaccharides.

Strong banding is favoured by presence in stain of high concentrations of methylene violet and its immediate homologues. Chromatography shows that only small amounts of these dyes occur in dry Leishman and Giemsa powders. However, additional active dye may be generated during preparing solution from dry powder, if the methanol used is not contaminated with formic acid and the period of heating is not too brief (Curtis and Horobin, 1975). Heated Giemsa solution produces more consistent bands on mammalian chromosomes (Vass and Sellyei, 1972, 1973).

According to Matsui and Sasaki (1975) during *G*-banding, macromolecules like DNA and proteins are lost, leading to an uneven distribution of chromatin. The amount of macromolecules residual after *G*-banding approximates 2 morphological bands. Non-histone proteins of relatively larger molecular sizes are removed by banding methods. The residual proteins in the *G* bands are relatively small molecules containing a large number of *S–S* bands and possibly contain more stabilised DNA. Thus the *G*-positive bands represent relatively thermostable chromatins consisting of smaller non-histone protein molecules. At the same time polylysine, polyarginine and histones H1, H2A, H2B and H3 inhibit *G*-staining and chromosome banding by binding to DNA and preventing side stacking of the positively charged thiazine dyes to the negatively charged phosphate groups on DNA. The binding is nonspecific and does not provide evidence for the role of histones in *G*-banding (Holmquist and Comings, 1976). The relative extraction of proteins was tested by staining with dansyl chloride, which conjugates with amino groups in polypeptides to emit bright fluorescence under ultraviolet light. It was observed that chromosomal proteins, particularly acid-insoluble ones, are partially lost during pre-treatments for *G*-banding (Matsukuma and Utakoji, 1976). Some chemical carcinogens, at concentrations producing transformation *in vitro*, can induce *G*-bands in human and hamster chromosomes after 24 h treatment, possibly due to non-specific toxicity (Di Paolo and Popescu, 1974). Similar bands were observed in mouse bone marrow chromosome preparations after injections *in vivo* of DNA alkylating agents (Kitchin and Loudenslager, 1976).

In plants

Schedule 1a For root tip (Filion, 1974)
Grow roots at 10 °C; pre-treat in 0.05 per cent colchicine in the dark for 4 h at room temperature, fix in acetic–ethanol (1 : 3) for 48 h and store in 70 per cent ethanol at 4 °C.

Hydrolyse root tips for 8 min in 1 N HCl at room temperature, squash in 45 per cent acetic acid, remove cover slips by dry ice method, dip in absolute ethanol, air-dry and store in desiccator for 5 days.

Treat with aqueous 0.064 M $Ba(OH)_2 8H_2O$ for 50 min at room temperature, wash in two changes of deionised water for 5 min, incubate in 2 XSSC (pH 7.0) at 60 °C for 40 min, rinse in two changes of deionised water and air-dry.

Stain in fresh Giemsa stock solution, diluted 50 times with M/15 Sörensen phosphate buffer, pH 6.8 for 5–8 min at room temperature, rinse in deionised water and mount in Permount.

Schedule 1b (Marks and Schweizer, 1974 and Schweizer, 1973)
Pre-treat root tips with colchicine (0.1 per cent for 1 to 2 h or 0.05 per cent for 2 to 3½ h), fix in acetic–ethanol (1 : 3) for 3 h, store overnight in 90 per cent ethanol; squash in 45 per cent acetic acid on slides 'subbed' with Haupt's adhesive.

Remove cover slips with dry ice, rinse in ethanol, air-dry and incubate in hot $Ba(OH)_2$, varying between 15 min at 50 °C in 5 per cent $Ba(OH)_2$ to 20 min at 60 °C in 6.5 per cent.

Rinse in distilled water, incubate in 2 XSSC at 65 °C for 1 to 2 h, rinse, stain in Giemsa (Gurr's R66 improved stock solution diluted with 50 times M/15 Sörensen buffer pH 6.9) for 3 to 24 h.

Wash in distilled water, air-dry and mount in DPX. Modifications of the BSG techniques have been employed with varying degrees of success in several angiosperms (Weismarck, 1974; Hadlaczky and Kálmán, 1975; Singh and Röbbelen, 1975; Taniguchi *et al.*, 1975; Mok and Mok, 1976; Tikhonovich and Fadeyeva, 1976; Vosa *et al.*, 1972; Vosa, 1976).

Schedule 2 For flower-buds
Fix buds for 24 h in Pienar's fixative (6 : 3 : 2, methanol, chloroform, propionic acid); store at 4 °C for 1 week in 90 per cent ethanol.

Squash in 45 per cent acetic acid, remove cover slip with dry ice and air-dry.

Immerse slides in 45 per cent acetic acid for 20 min at 60 °C, wash for 15 min in tap water. Rinse finally in distilled water.

Place in fresh saturated aqueous $Ba(OH)_2$ for 5 min at room temperature, wash in tap water for 1 h.

Incubate in 2 XSSC at 60 °C for 1 h, rinse in distilled water, stain in 2 per cent Giemsa (GT Gurr's R66 improved stock solution diluted 50 times with M/18 Sörenson phosphate buffer pH 6.9) for about 1 h.

Rinse rapidly in distilled water, air-dry, rinse in Euparal essence and mount in euparal (Marks, 1974).

Schedule 3 Kinetochore staining in meiosis
Immerse in air-dried slides for 5 min in 2 XSSC (pH 7.0) at 90 °C, 1 h in 2 XSSC at 60 °C, stain in Giemsa.

Or keep air-dried slides for 10 min in 90–94 °C potassium phosphate buffer (pH 6.8, 0.12 M); 15 s in ice-cold phosphate buffer quinch; 1 to 24 h in 60 °C phosphate buffer; 15 s in ice-cold phosphate buffer quinch and stain in Giemsa.

Kinetochore takes up stain (Stack, 1975). These methods were tried in *Triticale* (Lelley, 1975), wheat-rye hybrids (Mettin *et al.*, 1976) and *Secale* (Kranz, 1976).

In human chromosomes

Schedule 1 Acetic–saline–Giemsa (ASG) technique (Evans, Buckton and Sumner, 1971)
Incubate air-dried preparations for 1 h at 60 °C in 2 XSSC (0.3 M NaCl + 0.03 M trisodium citrate), stain at room temperature in Giemsa for $1\frac{1}{2}$ h (Gurr's Giemsa R66 1 ml to 50 ml buffer, pH 6.8), rinse, blot, soak in xylol and mount in DPX.

The pattern is similar to the *Q*-bands but more stable. Sumner, Evans and Buckland (1973) regard banding as due to an interaction of the dye with DNA. In an alternative schedule, staining may be carried out in pre-heated Giemsa solution for 2 min at 40–45 °C (Vass and Sellyei, 1973). In a modification by Ridler (1971), the slides are processed for 90 min at 65 °C in XSSC followed by two changes in 70 per cent ethanol and staining with 1/20 Giemsa in pH 7.0 buffer for 5 min. XSSC may be replaced by Sörensen's phosphate buffer (pH 6.8, 62 °C, incubation for 24 h) followed by direct staining in Giemsa (7 ml stock, 20 ml Sörensen's buffer and distilled water up to 100 ml) at pH 6.8 for 5 to 10 min and differentiation in 10 to 20 per cent ethanol (Chaudhuri *et al.*, 1971). This method has been successfully applied on other animal groups, including Lepidopteran insects (Bigger, 1975), gekko (King and Rofe, 1976), Macaca (De Vries, De France and Schevers, 1975), rodents (Bianchi, Vidal-Rioja and Bianchi, 1976) and triatomine bugs (Maudlin, 1974).

Schedule 2 Alkali treatment (Schnedl, 1971)
Immerse air-dried slides in 0.07 N NaOH at 20 °C for 90 s, wash in 70 per cent ethanol, transfer to 96 and 100 per cent ethanol and dry; incubate for 24 h in Sörensen's buffer at pH 6.8 at 59 °C and stain with buffered Giemsa solution (pH 7.0) for 20 min. The concentrations of NaOH may be varied between 0.002 and 0.007 and periods of incubation in buffer between 12 to 18 h. 2 XSSC may be used instead of Sörensen's buffer (Schnedl, 1973).

Both ASG and alkali denaturation techniques are applicable to human chromosomes at prophase (Bigger and Savage, 1975) and from fibroblast and amniotic fluid cells when combined with H33258 technique (Epplen *et al.*, 1975, 1976). Minor modifications have been used for spider mites (Pijnacker and Ferwerda, 1976), carnivores (Wurster-Hill and Gray, 1975), hamsters (Gamperl, Vistorin and Rosenkranz, 1976) and dogs (Selden *et al.*, 1975). Prophase human chromosomes from synchronised cells permit a high degree

of resolution (Bigger and Savage, 1975; Yunis and Sanchez, 1975; Yunis, 1976). Band mapping in human chromosomes is possible also from other phases (Drets, 1975; Kim, Johanssman and Grzeschik, 1975).

Schedule 3 Enzymic digestion of proteins

Add 10 ml sterile isotonic saline (0.85 per cent NaCl) to a phial of bactotrypsin (Difco Cat. no. 0153–59). Dilute further 1 ml with 9 ml of isotonic saline. Immerse air-dried slides in this solution for 8–10 s at 18–21 °C. Rinse slides in two changes of isotonic saline; shake to remove excess saline and stain with Leishman (BDH) diluted 1 : 4 with buffer tablets, pH 6.8 (Gurr) for 3 to 5 min; wash in two changes of the buffer and blot. Rinse in xylol and mount in DPX. More consistent patterns are obtained by treatment with hydrogen peroxide before trypsinisation (Seabright, 1973). Other proteolytic enzymes, like ficin, bromelin, papain, give similar results (Howard, Stoddard and Seely, 1973; Seabright, 1971, 1972) in other animals as well, like birds (Takagi Sasaki, 1974). Pronase (5 mg/100 ml distilled water) or α-chymotrypsin may be used for digestion (3–6 min at 37 °C) followed by rinsing and staining with Giemsa (Dutrillaux *et al.*, 1971; Finaz and De Grouchy, 1971; Dutrillaux, 1973). Slides heated up to an optimum of 120 °C yield better *G*-bands after trypsinisation (Birner and Wiener, 1975). A combination of warm phosphate solution with Giemsa-trypsin mix may be used (Sun, Chu and Chang, 1974).

In *modification for G-banding in male human meiosis* immerse fragments from testes in 0.44 g per cent hypotonic KCl solution for 8–10 h at room temperature. Treat in acetic–methanol (1 : 3) for 12–18 h and dilacerate in it. Resuspend in 5 ml 45 per cent acetic acid, centrifuge at 800 rev/min for 5 min, air-dry on pre-cooled slides. Keep slides at room temperature for 15 days, keep for 2 h in 2 XSSC at 40 °C. Rinse and cool, treat with 0.25 per cent trypsin solution for 10 s at 18 °C. Rinse and stain in Giemsa solution (Giemsa Biolyn: 1.5 ml; citric acid 0.1 M, 2 ml; Na_2HPO_4 0.2 M, 4 ml, pH adjusted to 6.7) (Luciani, Morazzani and Stahl, 1975).

For *G*-banding in *Heteropeza pygmaea*, remove embryos from mother in 0.9 per cent sodium citrate and keep for 5 min. Transfer to a subbed slide and remove sodium citrate. Cover with 45 per cent acetic acid. Squash under a cover slip. Remove with liquid N_2, rinse in absolute ethanol, air-dry. Incubate slides in 2.5 per cent trypsin solution in Ca- and Mg-free Hanks basic salts solution, pH 7.2, for 3 to 5 min at 37 °C. Wash in 70 per cent and absolute ethanol and air-dry. Stain in Giemsa diluted 1 : 20 (v/v) with 0.1 M phosphate buffer, pH 7.0 (Fantes and Camenzind, 1975).

In another modified method (Wang and Federoff, 1972), treat one part of slide with trypsin solution (0.025 to 0.05 per cent in Ca- and Mg-free BSS) or with trypsin-versene (one part each of 0.025 to 0.05 per cent trypsin and 0.02 per cent EDTA at pH 7.0) for 10–15 min at 25–30 °C. Keep other part as control. Rinse in two changes each of 70 and 100 per cent ethanol, air-dry, stain for 1–2 min in Giemsa (5 ml stock, 50 ml distilled water and 1.5 ml 0.1 M citric acid solution adjusted to pH 7.0 with 0.2 M Na_2HPO_4), rinse twice in distilled water, air-dry and mount. Reduced trypsin treatment and hot salt solution have been employed for rat karyotypes (Gallimore and Richardson, 1973).

Trypsin may hydrolyse the protein component of nucleoproteins denatured by fixation, thus allowing Giemsa to act on exposed DNA. Trypsin treatment should be kept at minimum since longer periods lead to *C*-banding as well (Lubs *et al.*, 1973). Chiarelli (1973) suggests that trypsin acts first as a denaturing and then as a hydrolysing agent. Electron microscope studies have shown such bands in trypsin treated hamster cell chromosomes with or without staining (Burkholder, 1974). Trypsin results in swelling while Giemsa induces an irreversible change in chromosome structure (Schuh, Korf and Selwen, 1975). Extraction with 5 per cent TCA (95 °C, 30 min) and then 0.1 N HCl (60 °C, 30 min) followed by staining in Giemsa for 90 min gives reproducible bands as well (Matsui, 1974).

Schedule 4 Protein denaturation and oxidation treatments

Immerse slides in a mixture of 3 vol urea (8 M) and 1 vol Sörensen's buffer (pH 6.8) at 37 °C at 10 min, wash in water and stain with Giemsa diluted 50 to 70 times with Sörensen's buffer for 5 to 20 min at room temperature (Shiraishi and Yosida, 1972). Other protein denaturing substances used are—two strongly anionic detergents (sodium lauryl sulphate and sodium deoxycholate, both 1.25 per cent); a nonionic detergent, Nonidet P-40, 5 per cent (Shell Canada Ltd); a commercial detergent for cleaning glassware, '7X', 1 per cent and mixtures of urea and detergents (Lee, Welch and Lees, 1973), dissolved or diluted in deionised water and applied to air-dried slides for 10–20 min. The patterns are similar to those obtained with proteolytic enzymes.

Incubate air-dried slides for 20–40 min in 10 mM potassium permanganate solution prepared in 33 mM phosphate buffer (pH 7.0) and containing 5 mM magnesium sulphate in an ice-bath. Wash in running water for 30 s, soak in absolute methanol for 5 min and air-dry. Stain with Giemsa (diluted 1 : 100 phosphate buffer, pH 7.0) for 5 min and seal with Enkitt containing 1 per cent butyl hydroxytoluene as anti-oxidant. This staining after oxidation may be associated with sulphydryl or disulphides in the chromosome (Utakoji, 1972, 1973). Peracetic acid and cupric sulphite reagent give similar patterns.

A combination of trypsin–urea banding yields reproducible results in birds (Stock, Arrighi and Stefos, 1974; Stock and Mengden, 1975) and invertebrates (Price, 1974). Centromere polymorphism regarding Giemsa staining has been observed in different species of *Nigella* (Marks, 1975).

Schedule 5 G-banding at different pH

Giemsa-9 banding (Patil, Merrick and Lubs, 1971)

Stain air-dried slides for 5 min in Giemsa solution (2 ml Harleco Giemsa stock solution : 2 ml of 0.14 M $Na_2HPO_4 12H_2O$ prepared by adding 5 g to 100 ml distilled water : 96 ml of distilled water adjusted to pH 9.0). Wash in cold running water for 1 min and air-dry. In a modification by Sehested (1975), staining may be carried out in glycine–NaOH–Giemsa (pH 8.8 to 9.1) or piperazine–HCl–Giemsa (pH 8.9–9.05).

Giemsa-11 (Gagne and Laberge, 1972)

Stain air-dried slides for 5 min with 2 per cent Giemsa in 0.1 per cent

$Na_2HPO_412H_2O$, adjusted at pH 11.6 with NaOH. Rinse, dry and mount. Heterochromatic segments at the centromere of chromosome 9, stain red-purple. Giemsa stain at pH 11.0 gives slightly different bands (Bobrow, Madan and Pearson, 1972).

Modifications of* G-*banding

Reagents were studied for producing bands in Chinese hamster cells after Giemsa staining (Kato and Moriwaki, 1972). Acids did not produce bands. Many salts induced bands in alkaline pH. Strong bases were more potent. Bands were mainly obtained by staining with Giemsa diluted either with NaCl solution or phosphate buffer (PB–Giemsa). Treatment for 10 min in collagenase (50 μg/ml) solution in Ca- and Mg-free Hanks' solution (pH 6.5) of mitotic slides from leucocyte cultures, followed by Giemsa staining, gives *G*-bands (Trusler, 1975).

Fresh air-dried preparations of leucocytes obtained following the micro-method (*see* Chapter 11) may be immediately banded by either of the following methods (Yunis and Sanchez, 1975).

(1) Immerse in 4 per cent formalin for 5 min, rinse in running tap water for 5 min and stain in Giemsa solution (R66 Gurr diluted 1/100 water) for 30 to 40 min; *or*
(2) Keep in absolute methanol for 5 to 10 min, air-dry and stain for 30 min with 1/80 Giemsa solution in 0.13 M phosphate buffer, pH 6.7, *or*,
(3) Dehydrate slide for 1 to 2 h in vacuum. Stain for 20 min in 1/100 dilute Giemsa solution.

Giemsa has been regarded to stain the protein remaining at the intercalary A–T rich sites after various pre-treatments (Lam-Po-Tang and Daniel, 1973). Both diluted stains and absence of pre-treatment do not affect the quality of the bands (Sanchez, Escobar and Yunis, 1973).

Stains other than Giemsa may produce *G*-banding after the usual banding schedule.

For Feulgen staining (Mittwoch, 1974), treat the banded slide, before staining, with N HCl at room temperature for 20 min and keep in Feulgen solution for 40 min in dark. Wash in two changes each of tap and distilled water, dehydrate through successive grades of 70, 80 and 95 per cent ethanol and xylol and mount in Cargille oil R.I. 1.556. The banding, though slight, is distinct and may be enhanced by contrast photography. It has been used in family and linkage studies (Scheres and Merkx, 1976).

For Alcian blue staining (Labelle and Briere, 1971), incubate the slide for 3 h at 37 °C in a solution containing 0.9 per cent NaCl, 0.05 M sodium EDTA, 0.075 M phosphate buffer, pH 6.7 and 10 USP units/ml sodium heparin. Wash in running water for 5 min and stain for 30 to 60 min in Alcian blue 8GX (Allied Chemical: 1 per cent in 3 per cent acetic acid at pH 1.07).

In the study of meiosis in mammalian male, air-dried preparations, after three days, may be stained for 30 s in carbol fuchsin, followed by BSG banding schedule of Sumner (1972), described earlier (Szemere and Chandley, 1976). Stock, Burnham and Hsu (1972) studied meiosis from solid tissues as well. For the study of lampbrush chromosomes, the dissected ovaries of *Triturus marmoratus* may be fixed in ethanol vapour and stained in 4 per cent

Giemsa in 0.01 M phosphate buffer at pH 7.0 for 20 min, followed by washing in distilled water and air drying prior to banding (Batistoni, Nardi and Pilone, 1974).

Methylene blue results in preferential staining pattern of *Vicia* chromosomes similar to *G*-staining and therefore may be substituted for three-cationic thionine derivatives contained in the original dye. It binds to nucleic acids and interacts weakly mainly as outside binding with chromatin. Interaction increases after alkaline pre-treatment (Lober *et al.*, 1973).

Human meiotic and mitotic chromosomes may be stained with N–N′ diethyl pseudoisocyanine (PIC) stain. With Budr or denaturation before staining in PIC, numerous banding techniques can be adopted. Cytochemical studies show a certain PIC affinity for DNA though the possibility of PIC reaction with proteins is not excluded (Vagner-Capodano, Pinna-Delgrossi and Stahl, 1976). Human chromosomes can be stained with PIC either directly or after esterification and oxidation. The bands are visible in ultraviolet light by fluorescence and in ordinary light by intensity of colour. The most suitable wavelength is 579 nm (Stahl and Vagner-Capodano, 1974).

Metrizamide is another medium for banding the chromosomes according to the buoyant density (Wray, 1976). Whole mount electron microscopy of Chinese hamster chromosomes, banded by exposure to actinomycin D during G_2, indicates that differential condensation of chromatin plays a role in banding by this technique. Pachytene chromosome study suggests that chromatin of the chromomeres may also have a higher density of attachment sites to the lateral element of the synaptonemal complex and probably to the nuclear membrane in interphase cells (Comings and Okada, 1975).

Feulgen-bands

Feulgen staining has been employed in lieu of Giemsa in producing *G*-bands as described earlier.

Prolonged hydrolysis and Feulgen staining in species of *Chilocorus* produce banding patterns opposite to *Q*-banding (Ennis, 1975).

Schedule for plants

Store pre-treated fixed root tips in 70 per cent ethanol at 4 °C for at least four days. Hydrolyse in 10 per cent HCl at 60 °C, wash thoroughly, stain in leucobasic fuchsin solution, wash and stain in aceto–carmine for 5 min. Squash in a drop of aceto–carmine and heat over a steambath for 1 to 2 min (Merritt, 1974). This process has, however, limited application.

C-BANDING

C-banding techniques were discovered as a byproduct of the *in situ* RNA/DNA hybridisation procedure (Pardue and Gall, 1970). *C*-bands apparently contain a large number of repeated DNA sequences, which are revealed following denaturation and reannealing in Giemsa staining (Hsu, 1973; Arrighi, 1974). The methods were initially devised for mammalian chromosomes but have been found to be effective in different degrees in other systems as well.

Schedule 1 Acid treatment for mammalian chromosomes (Arrighi and Hsu, 1971)

The principal steps are treatment with HCl to remove histones and other non-acidic proteins with ribonuclease to extract chromosome associated RNA and then treatment *in situ* with sodium hydroxide, and incubation for 18 to 24 h in 2 X or 6 XSSC at 65 °C, followed by staining in Giemsa.

Harvest lymphocyte or fibroblast cultures after colcemid and hypotonic solution pre-treatment (*see* schedule for culture, Chapter 11).

Fix cells in 50 per cent acetic acid. Prepare 'subbed' slides by coating clean slides with a mixture of gelatin (0.1 per cent) and chrome alum (0.01 per cent) solution. Dry. This step can be omitted for the usual flame or air-dried preparations or air-dried squashes.

Treat slides with 0.2 N HCl at room temperature for 30 min, rinse several times in distilled water and air-dry.

Treat with pancreatic ribonuclease (100 μg/ml in 2 XSSC) at 37 °C in a moist chamber for 60 min. The enzyme should be heated in a boiling water-bath for 5 to 10 min during preparation to eliminate contamination by deoxyribonuclease.

Rinse slides again in 2 XSSC, 70 and 95 per cent ethanol and air-dry. Treat with 0.07 N NaOH for 2 min, rinse immediately again in several changes of 70 and 95 per cent ethanol to remove NaOH completely.

Incubate in 2 XSSC and 6 XSSC at 65 °C overnight and rinse successively in 70 and 95 per cent ethanol several times.

Stain for 15 to 30 min in Giemsa solution (5 ml stock; 1.5 ml methanol; 50 ml distilled water; 1.5 ml 0.1 M citric acid, pH adjusted with 0.2 M Na_2HPO_4 to 6.8 to 7.2). Rinse with distilled water, air-dry and mount in Permount. Strictly neutral pH (6.8–7.2) and freshly prepared slides give good results.

In a modified schedule for a shorter duration, treat air- or heat-dried slides with 0.07 N NaOH for 1 min; rinse in 70 and 95 per cent ethanol; air-dry; incubate in 2 XSSC at 60 °C for 16 h; rinse and air-dry as before; stain in Giemsa for 1 h at pH 6.8 (1 ml stock Giemsa in 9 ml buffer); rinse in distilled water and air-dry; rinse in xylol and mount in neutral medium.

Modifications

In Chen and Ruddle's (1971) version, *non-subbed* air-dried slides are treated as given in the detailed schedule earlier. The slide is subbed with a solution of 0.5 g gelatin, 1.0 l distilled water and 0.5 g potassium alum after denaturation in NaOH and before staining. Merritt and Burns (1974), however, have shown such bands without any denaturation or renaturation in *Nicotiana otophora*.

The *C*-banding techniques have been utilised in studying the karyotypes of Orthopteran insects (Shaw, Webb and Wilkinson, 1976) and wheat (Gill and Kimber, 1974). In *Ceratitis capitata*, more *C*-bands are seen in sex chromosomes at prophase (Southern, 1976).

Schedule 2 Alkali treatment for mammalian chromosomes (Drets and Shaw, 1971)

Treat air-dried slides for 30 s in 0.07 N NaOH in 0.112 M NaCl (2.8 g

NaOH and 6.2 NaCl in 1 l distilled water, pH 12.0) at room temperature; rinse thrice in 12 XSSC (pH 7.0) for 5 to 10 min each; incubate in 12 XSSC at 65 °C for 60 to 72 h; pass through three changes each of 70 and 95 per cent ethanol, keeping 3 min in each; air-dry; stain in buffered Giemsa solution (pH 6.6) for 5 min, rinse briefly in distilled water, air-dry and mount in Permount.

Alternatively, NaOH can be used at 0 °C or room temperature for 0 to 180 s. Incubation may be carried out in 2 X, 6 X, 12 X and 24 XSSC for intervals between 15 min and 136 h. Periods of Giemsa staining may vary from 5 to 90 min with or without pre-treatment of chromosomes. Treatment in dibasic sodium phosphate (pH 11.8 to 12.0) for 10 to 30 min followed by 5 to 90 min in Hanks solution and Giemsa staining gives *C*-bands (Chuprevich *et al.*, 1973).

Schedule 3 Heat treatment for mammalian chromosomes (Yunis *et al.*, 1971)
Denature air-dried preparations for 10 min at 85–100 °C in 0.06 M phosphate buffer (pH 6.8), fast cool at 0 °C, reassociate with same buffer at 65 °C for different intervals and stain with Giemsa.

In a modified version (Lubs *et al.*, 1973), treat *heat*-dried slides in 0.02 N HCl for 15 to 20 min, incubate for 24 h in SSC, stain at pH 7.0.

In a modification by Bosman and Schaberg (1973), air-dried slides are incubated in buffered NaCl (900 mg NaCl; 220 mg Na_2HPO_4 and 32 g NaH_2PO_4/l, pH 7.5) at 20–22 °C for 1 h, rinsed in distilled water, incubated in buffer pH 6.8 at 20–22 °C for 5 min, stained in Leishman solution (1 ml stock in 3 ml buffer pH 6.8), rinsed twice in distilled water and air-dried.

Best *C*-banding is observed in one-day old slides. The dots are sometimes united to form a band, due to differential annealing of pericentric heterochromatin, which comprises several kinds of repetitive DNAs (Abe, Morita and Kawai, 1975).

Schedule 4 C-banding in newt chromosomes (Rudak and Callan, 1976)
Anaesthetise and remove 50 ml of the liver of *Triturus cristatus*, stitch up and rear the animal for 14 days at 18 °C.

Inject intraperitoneally with 0.25 ml aqueous 0.5 per cent colchicine solution. After 16 h, sacrifice the animal, cut liver in small pieces, place in distilled water for 10 min.

Fix in acetic–methanol (1 : 3), store at 4 °C.

Place small portion in a drop of 45 per cent acetic acid on a siliconised cover slip, tap and remove debris, squash over a subbed slide, remove coverglass by dry ice, dehydrate and harden in ethanol.

The method is similar for larvae and spermatogonia.

Digest in pancreatic RNase (100 μg/ml) dissolved in 2 XSSC for 1 h at 37 °C; rinse twice in 2 XSSC, 70 and 96 per cent ethanol, air-dry; keep for 2 min in 0.07 N NaOH at room temperature, rinse twice in 2 XSSC, 70 and 96 per cent ethanol, air-dry; then 18 h in XSSC at 65 °C, rinse in 70 and 96 per cent ethanol, air-dry, finally stain in Giemsa.

Schedule 5 C-banding in insects (Blackman, 1976)
Dissect out embryo in 0.75 per cent KCl solution, fix in acetic methanol

(1 : 3) and squash in 45 per cent propionic acid. Remove cover slip with dry ice and stain in 10 per cent Giemsa in phosphate buffer at pH 6.8.

For *C-banding* (technique by Brown, A. K.), denature for 2 min in 2 XSSC at room temperature with pH adjusted to 12.0 with NaOH and reassociate in 2 XSSC at 65 °C for 2 h.

Oviparae can be fixed in Bouin, Sections 6 μm thick can be stained with Heidenhain or Feulgen.

C- and *G*-banding have however been found to be less effective in Caledia (Orthoptere) (Shaw, Webb and Wilkinson, 1976).

Schedule 6 C-banding in mosquito (Newton, Southern and Wood, 1974)
Prepare air-dried squashes on 'subbed' slides, remove the siliconised cover slips.

Treat in 0.2 N HCl for 1 h at room temperature, then 3 min at 50 °C in 5 per cent $Ba(OH)_2$. Wash and incubate for 1 h at 60 °C in modified Hank's solution, a mixture of salts excluding Ca and Mg.

Stain in 2 per cent Giemsa (R66) buffered at pH 6.8, air-dry, pass through xylene and mount in euparal. It is applicable to B-chromosomes of Orthoptera as well (Gallagher, Hewitt and Gibson, 1973).

***Schedule 7 C-banding in* Gryllus argentinus** (Drets and Stoll, 1974)

Protocol 1 (meiosis)
Dissect testicles in BSS and separate seminiferous tubules with a needle, transfer to trypsin (Difson 1 : 250, 0.25 per cent in BSS), pipette to detach cells. Remove supernatant and wash by resuspending in 5 ml BSS without trypsin. Repeat last two steps two to four times.

Centrifuge at 800 rev/min for 5 min, reduce supernatant to 0.5 ml. Add 5 ml to 1 part of BSS and 1 part glass-distilled water. Allow to stand for 10 min. Resuspend and add 0.5 ml acetic–methanol (1 : 3), mix gently. Centrifuge, discard supernatant. Add 5 ml fresh fixative, keep for 10 min, repeat three times. Centrifuge and remove supernatant down to 0.2–0.4 ml. Flame, dry, stain in Giemsa and mount in Permount.

Protocol 2 (mitosis)
Inject colchicine 0.05 μl (0.05 mg/ml diluted in sterile BSS) intra-abdominally. After 18 to 24 h cut out a leg at the coxa. Remove a drop of haemolymph appearing at the wound with a siliconised pipette. Drop the cells and disperse in 5 ml BSS. Centrifuge. Reduce supernatant to 0.5 ml. Re-suspend in 5 ml BSS (2 + 1 part distilled water). After 5 min, add 0.5 ml fixer, mix and then treat as in Protocol No. 1 for *C*-band and stain in Giemsa.

Schedule 8 C-banding in plants
Pre-treat root tips in 0.05 per cent colchicine for 4 h, fix in acetic–ethanol for 12–15 h, hydrolyse in 1 N HCl at 60 °C for 25 s, squash in 45 per cent acetic acid with albuminised cover slips. Separate cover slips in absolute ethanol or by CO_2 freezing, dry at 60 °C, denature in saturated $Ba(OH)_2$ for 5 min at room temperature. Rinse in running distilled water, dry, incubate in 2 XSSC for 1 h at 60 °C, rinse and dry again.

Stain in 0.5 per cent Giemsa at pH 6.8 for 5–15 min, wash in distilled water, dry, dip in xylol and mount in canada balsam or DPX (Verma and Rees, 1974; Elgadi and Elkington, 1975; Linde-Larsen, 1975; Yen and Filion, 1976). Modifications involve changes in time of incubation and temperature (Sumner *et al.*, 1971; Sumner, 1972; Sarma and Tandon, 1974; Friskeesjö, 1974).

Schedule 9 C-banding in Pinus ovules (Borzan and Papes, 1977)
Fix ovules in acetic acid–ethanol (1 : 3) for 24 h; keep for 1 week in 90 per cent ethanol at 4 °C; squash in 45 per cent acetic acid after gentle heating. Remove cover slip by dry ice and air-dry slides. Incubate in 45 per cent acetic acid at 60 °C for 20 min. Wash for 15 min in tap water and rinse in distilled water. Incubate in 5 per cent $Ba(OH)_2 8H_2O$ at 54–56 °C for 15 min, rinse in distilled water and wash in tap water for 1 h.

Treat in 2 XSSC (pH 7.0) at 60 °C for 1 to 2 h. Rinse in distilled water. Stain in 2 per cent Giemsa (Merck) solution, diluted with M/15 Sörensen's buffer (pH 6.9) for 1 h. Wash in distilled water, air-dry overnight and mount.

Combinations of *C*- and *G*-banding have been tested in various groups for analysing karyotypes. In locust embryos, trypsin for *G* and $Ba(OH)_2$ for *C*-banding are effective (Webb, 1976, 1977).

Interstitial *C*-band sites, observed in polytene chromosomes of *Simulinum* spp. (Diptera) are regarded as euchromatic against the current opinion that *C*-banding is diagnostic for constitutive heterochromatin (Bedo, 1975). Treatment with deoxyribonuclease followed by Giemsa staining demonstrated clearly the constitutive heterochromatin of Indian muntjac chromosomes (Kato, Tsuchiya and Yosida, 1974). Ageing of preparations gives fine centromeric bands in addition to *C* and intercalary bands in amphibians (Ruiz and Becak, 1976).

CT-banding

CT-banding is a further amplification of *C*-banding techniques. In human material, treat air-dried preparations with $Ba(OH)_2$ solution at 60 °C, incubate in 2 XSSC at 60 °C and stain in cationic dye 'Stains All' (Scheres, 1976; Scheres, Hustinx and Rutten, 1974). The bands are of *C*- and *R*-types, located mainly at telomeric regions.

Cd-banding

Cd-banding reveals two identical dots (centromeric dots *Cd*) at the centromeric region, one for each chromatid (Eiberg, 1974). Store mammalian air-dried preparations for one week at room temperature. Incubate in Earle's BSS medium (pH 8.5 to 9.0) at 85 °C for 45 min. Stain in 4 per cent Giemsa in 1/300 M phosphate buffer (pH 6.5).

Combined method

In general, more than one banding pattern is utilised in assessing relationships between taxa. For example, combined *C* and *G* techniques have been effective in checking homology in bat genera (Stock, 1975), *Q*- and *G*-banding

in primates (Garcia *et al.*, 1976), and *C*-banding and autoradiography in cell line of kangaroo rat (Bostock and Christie, 1974). In the dinoflagellates, no *Q*, *G* or *C* bands could be recorded, indicating their primitive nature (Haapala and Soyer, 1974). A combination of *G*-banding and *in situ* hybridisation with *r*-RNA was tried in white banded gibbon *Hylobatus lar* (Warburton, Henderson and Atwood, 1975). A comparison of *G*, *Q* and *EM* banding patterns has been made in Indian muntjac (Green and Bahr, 1975) and of *Q*, *G* and *C*-banding in *Miaster* sp. (Diptera) (Bregman, 1975). Mouse chromosomes show an almost exact reversal of Giemsa 11 banding pattern for human chromosomes. In man–mouse hybrid, this method, associated with *Q*-banding, serves to identify human chromosomes against mouse chromosome background (Bobrow and Cross, 1974).

REVERSE BANDING OR *R*-BANDING

It was initially developed for human chromosomes (Dutrillaux and Lejeune, 1971; Carpentier, Dutrillaux and Lejeune, 1972; Dutrillaux, 1973), in which the pattern is opposite to *Q* and *G*, obtained following controlled heat treatment.

Schedule

Immerse air-dried preparations in phosphate buffer at pH 6.5, molarity 20 mM at 87 °C for 10–12 min. After cooling to 70 °C, wash the slides and stain with Giemsa dye, diluted with the same buffer at room temperature. Examine after 10 min in contrast medium.

Alternatively, treat air-dried slides with Earle's medium at 87 °C for 10–20 min, rinse in tap water and stain with Giemsa.

It is used as a primary tool in human chromosome identification in several laboratories (Stoll, 1975; Verma and Lubs, 1975) and has been tried in other animals, including birds (Comings and Wyandt, 1976).

O-BANDING OR ORCEIN BANDING

It was developed primarily for use in plant chromosomes (Sharma, 1975, 1977), since in plants, *G*, *C* and *Q* bandings have relatively limited application. The inherent disadvantages are the securing of air-drying of solid tissues and the comparatively lower response to Giemsa reaction. The technique principally involves an elimination of denaturation and consists of pre-treatment of the tissue, fixation in acetic acid–ethanol, treatment in a strong concentration of XSSC at room temperature (27–28 °C), washing, staining in acid–orcein and mounting in 45 per cent acetic acid. Orcein-positive bands appear in different segments of chromosomes, including the centromeric and intercalary ones. The mechanism of reaction possibly involves the DNA-protein linkage, since orcein is an amphoteric dye, capable of staining both DNA and protein. The gradual removal of non-histone protein through SSC treatment is principally responsible for *O*-banding at the sites of stronger DNA-protein linkage. As the removal of protein by SSC application is gradual, mild treatment results in intercalary bands com-

parable to *G*-banding whereas strong prolonged treatment ultimately shows only *C*-bands where the linkage is strong due to highly homogeneous repeats. The method therefore allows localisation of major and minor reiterated sequences in chromosomes.

Schedule

Pre-treat the tissue in 0.2 per cent colchicine for 2 to 3 h at 12 to 14 °C and then wash in water for 5 min. Other pre-treatment chemicals may also be used. Fix in acetic acid–ethanol (1 : 2) for 2–12 h. Treat in 45 per cent acetic acid for 5 min. Wash in water. Treat in a mixture of 1 M sodium chloride and 0.1 M sodium citrate (1 : 1) at 27–28 °C for 2–3 h. Wash in water. Warm for a few seconds at 90 °C in a mixture of 2 per cent aceto–orcein solution and N HCl (9 : 1). Keep in the mixture at 27–28 °C for 1 h. Squash under a cover slip in 45 per cent acetic acid and seal.

N-BANDING

N-banding has been employed principally in the localisation of nucleolar organising regions. It has been suggested that these bands represent certain structural non-histone proteins specifically linked to nucleolar organisers in different eukaryotic chromosomes.

Schedule 1 For human chromosomes (Matsui and Sasaki, 1973)

Incubate air-dried slides in 5 per cent aqueous trichloracetic acid for 30 min at 85–90 °C; rinse in water; reincubate for 30–45 min at 60 °C in 0.1 N HCl; rinse in tap water and stain for 60 min with phosphate buffered Giemsa, pH 7.0. Deoxyribonuclease (100 μg/ml for 60 min at 37 °C and pH 6.6) and pancreatic ribonuclease (pH 7.0) can be used instead of TCA.

Schedule 2 For animal and plant chromosomes (Funuki, Matsui and Sasaki, 1975)

Incubate air-dried slides at 96 $\pm$ 1 °C for 15 min in 1 M NaH_2PO_4 solution (pH 4.2 $\pm$ 0.2 adjusted with 1 N NaOH). Rinse in distilled water, stain in Giemsa (diluted 1 in 25 in 1/15 M phosphate buffer, pH 7.0), rinse in tap water and air-dry.

An earlier schedule by Stack (1974) gives differential Giemsa staining of both kinetochore and nucleolar organiser heterochromatin in mitotic chromosomes of higher plants by incubating air-dried slides of root tips (obtained by squashing fresh root tips in 45 per cent acetic acid and removing cover slip with dry ice) at 90 °C in potassium phosphate buffer (pH 6.8, 0.12 M) for 10 min. These slides are kept successively in phosphate buffer for 30 s at 0 °C and 1 h at 60 °C and stained in a 9 : 1 mixture of phosphate buffer and Giemsa stock solution at room temperature for 20 min. The slides are washed in distilled water and air-dried. A modification of this method gave two new types of staining regions in cattle (Diamond, Dunn and Howell, 1975). It has been applied with minor modifications to *Drosophila melanogaster* chromosomes, obtained from larval neuroblast and salivary gland cells treated with 0.075 N KCl, fixed in 1 : 3 acetic acid–methanol and flame-dried (Matsui, 1974).

Schedule 3 Ammoniacal silver III Technique (As-SAT) for satellite III DNA regions on human chromosomes (Howell and Denton, 1974; Howell, Denton and Diamond, 1975)

This method selectively stains those regions in which satellite III DNA has been localised, which include the secondary constriction region of human chromosome 9 and some centromeric regions of the acrocentric D and G group chromosomes.

Dissolve 8 g of silver nitrate into a mixture of 10 ml distilled water and 10 ml concentrated ammonium hydroxide to give a colourless solution of pH 12.0 to 12.5. Filter twice. Pipette four drops of the solution prepared on to a slide containing air-dried preparation. Add four drops of 3 per cent formalin (neutralised with sodium acetate) to develop the AS III stain. Mix the solutions on the slide surface with a glass rod, add cover-glass and observe under phase contrast.

The cytochemical basis is possibly the same as Giemsa-chromosome banding (*see* Jones *et al.*, 1974). Both in this and the *Ag-As* method, silver stained NORs appear as black spherical bodies on yellow brown chromosome arms. It has been also effectively used for mitotic chromosomes in Urodela (Ragghianti, Bucci-Innocenti and Mancino, 1977). The NORs are marked as subterminal black dots and correspond to sites of genes for 18 s and 28 s rRNA determined by *in situ* molecular hybridisation (Barsacchi Pilone *et al.*, 1976; Nardi *et al.*, 1974). This method has been used to locate nucleolar organisers in *Drosophila hydei* (Hennig, Link and Leoncini, 1975) and fishes (Arcement and Rachlin, 1976).

The As-Ag method has been employed in banding chromosomes of the Hominidae (Tantravahi *et al.*, 1976), after initial *Q*-staining.

Pre-treatment of human metaphase chromosomes with NaOH at pH 8.5, followed by staining with silver nitrate, differentiates both the nucleolar organising regions and kinetochores (Denton, Brooke and Howell, 1977). In *Trillium* sp. ammoniacal silver reaction gives brown stains for histones and prominently black stains for non-heterochromatic regions (Utsami and Takehisa, 1974). *N*-bands were, however, not observed on some nucleolar organising chromosomes in wheat (Gerlach, 1977).

Schedule 4 Modified silver technique Ag-As (Goodpasture and Bloom, 1975)

Prepare three solutions: (a) A pre-treatment (Ag) solution of 50 per cent aqueous silver nitrate; (b) an ammoniacal silver (As) solution prepared by dissolving 4 g silver nitrate in 5 ml distilled water and 5 ml concentrated NH_4OH (pH 12–13); (c) a developing solution of 3 per cent formalin first neutralised with sodium acetate crystals and then adjusted to pH 5 to 6 with formic acid.

Pipette the Ag solution on to slides containing air-dried preparations, cover with a cover-glass. Place slide about 25 cm below a photo flood (2800 °K bulb) for 10 min. Rinse off cover-glass with distilled water. Develop slide by adding four drops of *As* solution followed by four drops of developing solution. Cover with a cover-glass and monitor staining under microscope. When chromosomes turn golden-yellow, rinse slide in distilled water, dehydrate in ethanol series, soak in xylene and mount in Permount.

This method has been applied to several mammalian cell lines in culture and stains selectively the same chromosome areas (NORs) displaying heavy

labelling by *in situ* RNA/DNA hybridisation for 18 s and 28 s ribosomal cistrons (Pardue and Hsu, 1975). The available cytochemical data suggest that the Ag-As reaction stains the chromosomal proteins at the NOR rather than the rDNA itself.

Schedule 5 Negative silver staining in A-T and satellite DNA rich regions of human chromosome (Howell and Denton, 1976)

Place two drops each of fresh ammoniacal silver solution and absolute methanol on air-dried slide. Mix the solution and cover with a cover-glass. Place slide on a hot plate kept at 67 °C for 3 min. Wash off cover-glass quickly with absolute methanol, immerse slide in methanol for 1 min. Add two drops each of 3 per cent formalin (neutralised with sodium acetate) and the ammoniacal silver solution to wet surface of slide, cover with cover-glass and observe under microscope. In 5 min, the preparation stains golden yellow to brown. Wash the slide and make permanent.

The secondary constrictions of chromosomes 1, 9 and 16 and distal Yq do not take up stain. The negative silver binding is due to preferential removal or alteration of non-histone proteins associated with these regions.

HY-BANDING

HY-banding was initially applied to somatic chromosomes of some members of the Liliflorae. Root tips, fixed in acetic–ethanol (1 : 3), on treatment with 0.1 or 0.2 N HCl between 60 and 80 °C and staining with aceto–carmine, gave banded chromosomes (Greilhuber, 1973, 1974, 1975). Heterochromatic regions stain differentially, mentioned as Hy^+ and Hy^- bands but do not always coincide with *G*-bands.

REPRESENTATIVE SCHEDULES FOR COMPARATIVE STUDY OF DIFFERENT BANDING PATTERNS

Schedule 1 Combined autoradiography and Q staining for human chromosomes (Ganner and Evans, 1971)

Incubate leucocyte cultures at 37 °C for 72 h with colcemid (0.002 per cent), being present for 3 h in continuously labelled cultures and for the last 1 h in pulse labelling. In most cases H^3-thymidine (0.2 μCi/ml of culture medium; sp. act. 24 Ci/mM) is added to the culture 4 h before fixation to label cells in the latter part of S phase. Pulse-label a few cultures (30 min in H^3-thymidine at 0.2 μCi/ml, sp. act. 24 Ci/mM), change with a 100 times higher concentration of cold thymidine 10 h before fixation to label cells in early S phase. Prepare air-dried slides as usual.

Stain the slides in 0.5 per cent aqueous atabrine for 6 min, wash in running water for 3 min, rinse and mount in distilled water, observe and photograph for fluorescence.

Remove cover slip, restain slide in carbol fuchsin, cover with AR 10 Kodak stripping film, expose in dark at 4 °C for six days and develop with Kodak 19B. Almost all cells selected for fluorescence photography give positive autoradiographs.

Schedule 2 Comparative banding with heating, QM and proteolytic digestion for human chromosomes (Dutrillaux *et al.*, 1972)
Use air-dried preparations. For controlled heating, treat slides with 20 mM phosphate buffer for 10 min at 87 °C, rinse in tap water and stain in Giemsa. For QM staining, immerse slides in a solution of 5 mg QM in 100 ml distilled water and rinse thrice in McIlvaine's buffer pH 7.0. For proteolytic digestion, treat slides with 5 mg pronase (Calbiochem) in 100 ml distilled water for 3 to 6 min at 37 °C, rinse and stain with Giemsa.

The strongly stained bands after heating correspond to the weakly fluorescing ones of QM and to the unstained but swollen ones after proteolytic digestion and vice versa. The exceptions are the centromeric regions which are stained only after enzymatic digestion; the secondary constriction regions which remain unstained throughout; the short arm and satellite of acrocentric chromosomes which appear clear and swollen after proteolytic digestion but are variable with the other techniques and the variable Y chromosomes.

Schedule 3(a) Combined* Q *and* G*-banding for human chromosomes (Aula and Saksela, 1972; Evans, Buckton and Sumner, 1971)
Stain air-dried preparations for 6 min at room temperature in 0.5 per cent (w/v) solution of atabrine in deionised water; wash in running water for 3 min; rinse in deionised buffer, drain, cover with thin cover slip and seal with a rubber solution. Observe and photograph. QM solution in buffer (50 μg/ml) may be used instead of atebrine.

Wash slides in water, incubate for 1 h at 60 °C in 2 XSSC, stain in Giemsa for 1½ h (Gurr's Giemsa R66, 1.0 ml/50 ml buffer, pH 6.8), rinse, blot dry, treat in xylol and mount in DPX. The same plates may be observed to match the banding patterns. The *G*-banding can also be done prior to *Q*-banding.

For a list of such combined *Q*-*G* techniques, *see* Nilsson (1973). *Q*-banding of human chromosomes after BudR and BCdR treatment gives two separate patterns (Bühler, Jurik and Bühler, 1977): (i) an X-type pattern in which *Q* and *G* bands are both reversed; and (ii) Y-type pattern, in which *Q* banding remains conventional but *G* banding is reversed. Such combined methods have been employed successfully in different animals, including Coleopteran insects (Ennis, 1974).

Schedule 3(b) Combined* Q *and* G*-banding for urodele chromosomes (Schmid and Krone, 1976)
Inject intraperitoneally 0.05 ml 0.3 per cent colchicine solution, 5 h before sacrificing. Remove and mince testes finely. Resuspend cells with pasteur pipette in 20 ml isotonic cell culture medium (Wolf and Quimby, 1964) or hypotonic solution for 45 min. Intestine, kidney, liver, spinal cord, vas deferens or oviduct may be treated the same way.

Denature for 15–20 s in 0.07 N NaOH; incubate in 2 XSSC at 65 °C for 17 h and stain with Giemsa for *C*-banding.

Stain in fresh aqueous Q (5 mg/ml) or H33258 (0.3 μg/ml) directly for 10 min or after pre-treatment with DNAse (incubation in 200 μg/ml DNAse dissolved in 1 mM $MgCl_2$ pH 7.0 at 37 °C for 20–30 min).

Wash in phosphate buffer (0.067 M, pH 5.5) and mount in saturated saccharose solution

Schedule 4 Combined* Q *and* C *banding (Chen, 1974)
Treat leucocyte or cancer air-dried preparations with 1 : 3 acetic–methanol again for 15 min, air-dry, dehydrate through standard ethanol grades.

For *Q*-bands, treat slides with 0.05 per cent QM or Q aqueous for 5–7 min, rinse in distilled water for 7 min. For ASG, incubate slides in 2 XSSC (6.8 to 7.0) for 3 h at 65 °C, stain for 60 to 90 min in dilute Giemsa (0.8 to 1 per cent in vol of stock Giemsa) in phosphate buffer. it is called *Q-C* procedure since the resulting banding pattern by ASG is *C*, not *G*, as expected.

For consistent staining, Giemsa stain made by Humason's method (1967) must be stored in the cold for three months before use.

Schedule 5 Comparative* Q, G *and* C*-banding in human chromosomes (Disteche *et al.*, 1972)
Stain air-dried preparations in 0.1 per cent aqueous QM for 5 min, rinse and mount in phosphate buffer (pH 5.0) or McIlvaine's buffer (pH 4.1). Observe and photograph for *Q* banding.

Hydrolyse slides in 0.2 N HCl for 5 min, denature in 0.07 N NaOH for 75 s, incubate in 2 XSSC (pH 7.0) for 30 h at 60 °C and stain in Giemsa at pH 6.8.

For *G*-banding, incubate fresh slides in 2 XSSC (pH 7.0) for 20 min at 56 °C and stain with Giemsa at pH 6.8.

Such comparative banding techniques, together with photoelectric measurement for *Q*-bands, have been used effectively to identify translocations in cattle chromosomes (Gustavsson, Hageltorn and Zech, 1976). A combined QM and *C*-banding technique has also been applied in *Voria ruralis* (Diptera) maggots (Wake and Ward, 1975), as also karyotypes of gibbons (Dutrillaux *et al.*, 1975), mink (Mandahl and Fredga, 1975). In lemurs, *Q* and *G* banding are similar but *C*-bands are highly variable (Sasaki *et al.*, 1975).

Schedule 6 Antibody binding methods for human chromosomes

Anti-adenosine antibody binding method (Dev *et al.*, 1972; Erlanger *et al.*, 1972)
Base specific antinucleoside antibodies react with specific nucleoside bases in single-stranded DNA *in vitro*. They attach to chromosomes on being treated with denaturating agents like NaOH, giving a banding pattern similar to *Q* and *G* banding.

Prepare anti-adenosine (anti-A) antibodies by immunising rabbits to adenosine monophosphate conjugated to bovine serum albumin. Antibodies to rabbit gamma globulin are induced in sheep and fluorescin-tagged (for details, *see* Beiser and Erlanger, 1966).

Denature air-dried leucocyte preparations by heating for 1 h at 65 °C in 95 per cent formamide solution in XSSC, adjusted to pH 7.2 with concentrated HCl. Dilute the previously prepared anti-A antibody to 1 : 10 with phosphate buffered saline (PBS). Wash slides twice in 70 per cent ethanol, once in 95 per cent ethanol and air-dry. Keep in PBS for 5 min. Layer the

anti-A over the slides and maintain at room temperature for 45 min in a moist chamber. Wash in PBS, add the fluorescin-tagged anti-rabbit gamma-globulin (1 : 50 in PBS) and keep for 45 min in moist chamber. Rinse, mount in PBS and examine under fluorescence microscope.

Antiguanosine, anticytidine and antithymidine, after heating in formamide, give similar bands.

Combined chemical and immunochemical procedure for human chromosomes (Schreck *et al.*, 1973)

Photo-oxidise air-dried leucocyte preparations in a solution containing 33.4 μM methylene blue in 0.1 M Tris-HCl buffer (pH 8.75) by placing the slides in a coplin jar in 50 ml of the dye solution and bubbling oxygen through it for 10 min.

Seal the jar, place in a glass water bath at 25 °C 15 cm away from a 150 W Sylvania flood lamp at an illumination of about 64 600 lx overnight.

Rinse the slides in PBS (phosphate buffered saline containing NaCl, 20 g; 0.25 M Na_2HPO_4, 85 ml and KH_2PO_4, 15 ml in 2400 ml distilled water at pH 7.2 to 7.4). Layer with anti-C, prepared in rabbits (diluted 1 : 10 with PBS) and keep at 25 °C for 30 min.

Rinse slides in PBS, layer with fluorescin-labelled antibody, prepared in sheep against rabbit immunoglobin G (diluted 1 : 50 with PBS), incubate at 25 °C for 30 min, rinse and mount in PBS. Alternatively, the slides can be treated directly in QM after photo-oxidation. Observe under fluorescence microscope.

The photo-oxidation in presence of methylene blue destroys guanine residues in DNA. The chromosomes, on reaction with cytosine-specific antibody, reveal a fluorescent banding pattern identical with *R*-banding and reverse to the anti-A antibody binding method and QM and *G*-banding patterns described earlier. This pattern thus appears to reflect the DNA-base composition.

Simultaneous *G* and *C* banding have been evolved as modifications of the original schedules in several animals, including primates (Mandahl, 1976).

Schedule 7 Combined* C *and* R *banding (Kanda, 1976)

Treat air-dried preparations with 0.1 N HCl for 30 min at room temperature; denature in freshly prepared 3 per cent aqueous solution of $Ba(OH)_28H_2O$ for 10 min at 50 °C.

Rinse the slides, incubate for 1 h at 60 °C in 2 XSSC and stain with Giemsa.

R, *T* and *C* bands correspond to a progressive distinction of chromosome structure maintained by barium hydroxide solution.

Schedule 8* R *and* Q *banding of human chromosomes using a BrdU treatment (Dutrillaux *et al.*, 1976)

BrdU incorporation

(a) Continuous Add BrdU to culture medium (TC199 supplemented with AB serum, heparin and PHA) at 50 μg/ml for 2 to 24 h before fixation.

(b) Discontinuous (i) treat 4 h by BrdU added to medium, rinse in saline and incubate in standard medium with or without thymidine for 7–9 h at G_2 and last part of S; or, (ii) treat twice with BrdU, at early and late S-phase. In between, rinse by incubation in usual medium; or (iii) brief 1 h discontinued treatments by BrdU between 3 and 17 h before fixation.

Prepare air-dry smears and stain with acridine orange.

CONCLUSIONS

The banding pattern techniques have brought a revolution in the study of karyotype insofar as they permit precise identification of individual chromosome segments, with far-reaching consequences. The schedules have multiplied rapidly within the last five years. Not all of them are reliable and certainly none can be applied to *all* organisms. However, alterations in the basic steps can be devised for individual taxa. In general, the major types, *C*, *G*, *Q*, *O* and *N* give repeatable results.

The importance of locating the DNA sequence through banding lies in the fact that in this technique there has been a merger between molecular and cellular methodology. In the higher biological systems, the regulatory mechanism is highly complex, involving an initiation at the molecular level, mediation through a series of cellular reactions, ultimately culminating in expression at the organismic level. The limitations of the available methodology do not permit the observation of the life process as a whole, but keep the domains of molecules, cells and the organism as clearly demarcated.

Recent technological advances are, however, gradually removing the barriers between the molecular, ultrastructural and structural levels leading to an understanding of the phenomenon.

Chromosome banding technique, in its present form, is a synthetic procedure permitting the visualisation of molecular sequences at the cellular, *vis-à-vis* microscopic level. A quantitative assessment of the chemical constituents, through microphotometric analysis of bands at different phases of development and differentiation, may lead to an understanding of the basic mechanism of genetic regulation underlying plant, animal and human systems.

SISTER CHROMATID EXCHANGE

The experiments of Taylor, Woods and Hughes (1957) demonstrating DNA segregation according to the semi-conservative model of DNA replication, gave a uninemic interpretation of DNA organisation within chromosomes (Comings, 1974). The technique involved incorporation of tritiated thymidine (H^3-Thd) during one cell cycle, of normal Thd during the next and subsequent autoradiography. The resolution power was, however, low.

The initiation of banding pattern methodology led to the recent improvements in differentiating sister chromatids. It was initiated by incorporating bromodeoxyuridine (BrdU) during one or two successive replications and staining with fluorochromes afterwards (Dutrillaux *et al.*, 1974; Latt, 1974, 1977). Alternatively the slides were stained with Giemsa after treatment with a fluorochrome, exposure to light or storing and heating. This method is referred to as FPG (fluorescence plus Giemsa—Korenberg and Freedlander, 1974; Perry and Wolff, 1974). This technique permits the identification of two chromatids of each chromosome on the basis of differential staining intensities. The chromosomes of *somatic tissues* show the formation of sister chromatid exchanges (SCEs) by this method. These exchanges are spontaneous (Kato, 1974) and can be accelerated artificially (Kato, 1974, 1977; Kihlman, 1975). Such exchanges have been recorded mainly in animal tissues (Dutrillaux *et al.*, 1974; Kato, 1974; Korenberg and Freedlender, 1974; Latt, 1974; Perry and Wolff, 1974; Wolff and Perry, 1974; Bloom and Hsu, 1975;

Carrano and Wolff, 1975; Goto *et al.*, 1975; Natarajan and Klasterska, 1975; Bostock and Christie, 1976; Hsu and Pathak, 1976; Schnedl *et al.*, 1976; Sugiyama, Goto and Kano, 1976). Reports on plant chromosomes are relatively fewer (Kihlman and Kronborg, 1975; Scheid, 1976; Schvartzman and Cortes, 1977; Vosa, 1977), mainly due to difficulties in the incorporation of BrdU in plant DNA, which can, however be improved by inhibiting synthesis of thymidilic acid in root meristems (Haut and Taylor, 1967). Fluorodeoxyuridine (FdU), known to inhibit thymidilate synthetase (Cohen *et al.*, 1958), has at the same time, adverse effects on RNA synthesis and cell division. It was therefore suggested by Kihlman and Kronborg (1975) that uridine (Urd) be added to counteract the effect of FdU on RNA synthesis.

The mechanism for SCE banding with Giemsa after BrdU incorporation is still not absolutely clear due to the technical modifications adopted by different workers to obtain the most suitable preparations. Kihlman and Kronberg (1975) have shown clear differentiation between unifilarly substituted and non-substituted chromatids while Perry and Wolff (1974) observed differentiation between unifilarly and bifilarly substituted ones. Protein modification has been regarded by some authors to be responsible for differential staining with Giemsa (Wolff and Perry, 1974). Goto *et al.* (1975) and Sugiyama, Goto and Kano (1976) suggest, on the other hand, that the disorganisation of BrdU-substituted chromatids by photolysis results in a differential affinity for some dyes. Ultraviolet irradiation and trypsin treatment gave a preferential disintegration of the BrdU-substituted chromatids, suggesting that fluorochromes are not essential (Scheid, 1976). Dutrillaux (1975) observed various types of banding with asymmetry following treatment with BrdU, suggesting that BrdU is incorporated *anywhere*. Schvartzman and Cortés (1977), from a comparative analysis of the different techniques for differential chromatid staining, suggest the following general mechanism.

(1) BrdU-substituted chromatids are spontaneously capable of photolysis under certain conditions, but need previous sensitisation in others. Fluorochromes may act as such sensitisers.
(2) Such chromatids start to disorganise immediately after exposure to light or ultraviolet irradiation. In some cases, however, a consistent preferential disorganisation is obtained only after treating the slides at high temperature (Korenberg and Freedlander, 1974), storage (Kihlman and Kronborg, 1975) or exposure to enzyme digestion (Scheid, 1976).
(3) Although not all nuclear dyes can discriminate between differentially BrdU-substituted chromatids, the major factor appears to be the degree of chromatid disorganisation.

Another set of methods, allied to the above, utilises BrdU-Giemsa staining to identify late DNA-replicating sites by pale colour or dot formation (Wang, 1976). Dotted chromosomes may also be produced with sodium phosphate solution supersaturated with $NaHCO_3$ (Wang and Mukerji, 1976). A combination of *G*-banding and autoradiography has been employed by Smyth and Evans (1976) to map sister chromatid exchanges in human chromosomes.

BrdU-dye techniques provide a new approach to study both structural and

functional properties of metaphase chromosome bands. Incorporation of BrdU for an entire cycle followed by 33258 Hoechst staining does not give marked bands but its incorporation for only part of one S phase differentiates between early and late replicating chromosome regions, the latter corresponding to the *Q* and non-centromeric *C*-band positive chromosome segments. After two cycles of BrdU incorporation, sister chromatids can be identified. The random assortment of sister chromatids of homologues may be observed after a third cycle. Baseline sister chromatid exchanges (SCEs)—spontaneous or BrdU-induced—are more frequent in *Q*+ bands. They are sensitive indices of DNA damage by alkylating agents and light (Latt, 1977).

This method has been used in detecting *in vivo* exchanges in mammalian systems as a test for environmental mutagens (Allen and Catt, 1976,; Vogel and Bauknecht, 1976), for studying chromosome structure (Wolff and Perry, 1975) and in identifying active and inactive X chromosomes (Mikkelson, 1974; Takagi and Sasaki, 1975), and also DNA replication patterns under high resolution (Crossen, Pathak and Arrighi, 1975).

FLUORESCENCE PLUS GIEMSA (FPG) TECHNIQUE

Protocol 1 For animal tissue (Perry and Wolff, 1974)

Culture chinese hamster ovary (CHO) cells in McCoy's 5A medium supplemented with 13 per cent fetal calf serum. Treat the exponentially growing cells with BrdU (final concentration 10 μm) for 24 h, during which two rounds of replication take place.

Keep the cultures in dark to minimise the number of sister chromatid exchanges caused by the photolysis of BrdU-containing DNA. Add colcemid (final concentration 2×10^{-7} M), keep for 2 h and collect the mitotic cells by shaking. Treat the cells for 8 min with 0.075 M KCl to spread the chromosomes and fix in acetic–methanol (1:3).

Place cells in fixative on slides and allow to dry. Stain in Hoechst 33258 (0.5 μg/ml deionised water) for 12 min. Rinse briefly in deionised water. Mount the preparations in water and ring cover-glass with rubber solution. Sister chromatids exhibit differential fluorescence under ultraviolet light.

Allow the same preparations to age for 24 h. Remove the cover-glass. Incubate for 2 h at 60 °C in either 2 XSSC (0.3 M sodium chloride, 0.03 M trisodium citrate) or water. Stain for 30 min in 3 per cent Giemsa solution (Gurr's R66, pH 6.8). The bands are permanent and do not fade.

This method has been applied to fish by Kligerman and Bloom (1976). 0.5 mg BrdU in Hanks' BSS (Ca and Mg free)/g body weight of fish is injected intraperitoneally. After two to ten days inject 0.25 mg colcemid/g fish, keep for 6 h; sacrifice; treat scales, intestine, gill and kidney in 0.4 per cent KCl for 20 min, fix in acetic–ethanol, prepare slides and follow steps (3) and (4). Three-day old chick embryos can be similarly treated after exposure to BrdU (12.5–50 μg) in ovo for 26 h (Bloom and Hsu, 1975). This method has aided the visualisation of exchange aberrations in human chromosomes (Fischer and Kim, 1975; Kim, 1974).

Protocol 2 For plant tissue (Kihlman and Kronborg, 1975)

Expose lateral roots to aqueous solution containing 100 μM 5-BrdUrd, 0.1 μM 5-FdUrd and 5 μM (Urd) for 22 h. The treatment solution of Schvartzman and Cortés (1977) contains 10^{-7} M FdU, 10^{-4} M BrdU and 10^{-6} M Urd. Transfer to aqueous solution containing 100 μM thymidine (dThd) and 5 μM Urd for 21 h. Treat in 0.05 per cent colchicine for 3 h, fix overnight in acetic–methanol cold (1 : 3) in dark at 20 °C.

Rinse in 0.01 M citric acid–sodium citrate buffer (pH 4.7), incubate for 75 min at 27 °C with 0.5 per cent pectinase, dissolved in same buffer. Squash in 45 per cent acetic acid, coat with a mixture of 10 : 1 gelatin and chrome alum.

Remove cover slip by dry ice and bring preparation to water through descending ethanol grades. Incubate in moist chamber for 60 min at 27 °C with RNAse (1 mg RNase in 10 ml 0.5 XSSC) 200 μl. Cover.

Rinse in 0.5 XSSC, stain 20 min in H33258 (1 mg dissolved in 100 ml ethanol; 0.1 ml of this solution added to 200 ml 0.5 XSSC). Rinse and mount in 0.5 XSSC.

Store over distilled water for four days at 4 °C, incubate for 60 min at 55 °C in 0.5 XSSC.

Rinse in 0.017 M phosphate buffer, pH 6.8, stain for 6–7 min in 3 per cent Giemsa (R66) solution in same buffer.

Rinse in phosphate buffer, then water, air dry, pass through xylene and mount in Canada balsam.

ACRIDINE ORANGE STAINING METHOD (Kato, 1974)

Grow Chinese hamster cell line D-6 in dark in culture medium containing BudR at concentrations ranging from 0.1 to 40 μg/ml for two cell cycles and fix as usual for chromosome preparation. Stain slides with 0.125 mg/ml acridine orange in phosphate buffer, pH 6.0 for 5 min, wash for 15 min and mount in same buffer. Sister chromatids are clearly demarcated, one brightly and the other faintly stained. AO fluorescence may be quenched partially due to BUdR as reported for 33258 Hoechst fluorescence.

4′-6-DIAMIDINO-2 PHENYLINDOLE STAINING (Lin and Alfi, 1976)

Grow mouse cells in modified Eagle's MEM supplemented with 10 per cent fetal calf serum. Incubate the cells in dark and grow in a medium containing 10^{-5} M BrdU for 18–20 h or 30–32 h (one or two cycles of DNA replication. Add colcemid (0.1 μg/ml) to culture, harvest after 2 h by trypsinisation and prepare usual air dry smears.

Stain with 1 μg/ml of 4′-6-diamidino-2 phenylindole (DAPI) in phosphate buffered saline (pH 7.0) for 10 min, rinse in deionised water, mount in 0.2 sodium phosphate (pH 11.00). Observe chromosome fluorescence with Zeiss Microscope with HBO 200 W/4 Hg lamp, dark field illumination, a BG 12 exciter filter and a 470 nm barrier filter.

GIEMSA STAINING METHOD

Protocol 1 (Wolff and Perry, 1974)

Expose exponentially growing Chinese hamster ovary cells to BrdUrd for 24 h. Add colcemid (2×10^{-7} M) for 2 h. Collect cells by mitotic selection, centrifuge. Resuspend pellet in 0.1 M sucrose for 3 min or 0.075 M KCl for 8 min. Recentrifuge, fix in acetic–methanol (1 : 3), air dry. Immerse slides in 0.5 μg/ml Hoechst 33258 in deionised water for 12 to 15 min, rinse in deionised water and dry. The slides may be mounted in deionised water with a cover-glass or sealed or placed in a moist chamber. Expose slides for 24 h to daylight, remove cover slip, incubate for 2 h at 62.5 °C in 2 XSSC or water. Stain in 3 per cent Giemsa (Gurr R66, pH 6.8), rinse in water, dry, pass through xylene and mount in DPX.

Protocol 2 (Korenberg and Freedlender, 1974)

Grow Chinese hamster ovary cells for two generations in CS-F10 (calf serum) containing 10^{-4} M BrdU in place of thymidine, with 0.1 μg/ml colchicine for last 2 ml of culture. Shake culture bottles and centrifuge suspension at 90 × g for 5 min at 4 °C. Resuspend the pellet with approximately 10^7 cells in 4 ml hypotonic buffer at 37 °C, fix in cold acetic–methanol (1 : 3), air dry.

Grow human peripheral leucocytes for 72 h in F10 medium with 15 per cent fetal calf serum, PHA, 10^{-4} M BrdU and for the last 3 h, colcemid at 0.08 μg/ml. Centrifuge cell suspension at 70 × g for 5 min, resuspend and incubate at 37 °C for 8 min in 0.075 M KCl. Fix the pellet in acetic–methanol (1 : 3) and air dry.

For staining, heat slides, at least one day old, at 87–89 °C for 10 min in 1.0 M NaH_2PO_4, pH 8.0, rinse in distilled water at 23 °C, stain with Giemsa for 2 to 10 min (2.5 ml Harleco Giemsa to 50 ml distilled water, rinse, air dry and mount in Permount. Chromatids singly and doubly substituted with BrdU acquire differential Giemsa stain affinities after treatment at 88 °C for 10 min in 1.0 M Na-phosphate buffer (pH 8.0).

COMBINED SCD STAINING AND *G*-BANDING (Pathnak, stock and Lusby, 1975)

Treat monolayer mammalian cell cultures with BUdR (5 μg/ml) for two cell cycles. For human lymphocyte culture, add BUdR 24 h after initiation and reincubate for an additional 48 h. Grow cultures in dark. Apply a 2 h colcemid treatment (0.05 μg/ml) before harvesting for usual air-dried preparations.

Protocol 1 Trypsin treatment

Dilute the trypsin solution used in routine cell cultures and Hanks' balanced salt solutions (without Ca and Mg) to 20 per cent of its original

strength. Treat slides—two days to two months old—with this solution for 1 to 2 min, rinse successively in Hanks' BSS, 70 and 95 per cent ethanol and air dry. Stain in 2 per cent Giemsa solution in 0.01 M phosphate buffer (pH 7.0) for 2 min and rinse in deionised water.

This procedure gives both sister chromatid differentiation (SCD) and *G*-banding. Short treatment produces SCD; a slightly longer one yields *G*-bands on the bifilarly substituted chromatid and longer treatment gives bands on both chromatids. Continued treatment obliterates SCD pattern and only *G*-bands are seen.

Protocol 2 Urea treatment

Prepare an 8 M urea solution, mix with M/15 Sörensen's buffer (3 : 1) and keep at 37 °C. Treat slides in this solution for 5–15 s, rinse and stain in Giemsa as given in protocol 1. The SCD pattern is formed at first and is replaced by *G*-banding. Alternatively, *G*-banding may be induced first by urea treatment and later SCD induced in the same cells by the technique of Korenberg and Freedlender (1974).

'REVERSE' STAINING METHOD (Scheres *et al.*, 1977)

Prepare chromosome slides from cultures continuously labelled with BrdU (5–10 μg/ml final concentration). Incubate in trypsin solution (0.1 per cent in PBS, pH 7.2) for 2 s or more, and rinse.

Stain in basic fuchsin solution for 4 min. The solution consists of 0.1 per cent (w/v) of basic fuchsin (UCB Bruxelles) in water : formamide : 0.1 N NaOH (1 : 1 : 1), adjusted to pH 10.2 with the aid of HCl.

Rinse, dry and examine.

Metaphases treated in this way show one heavily stained and one pale chromatid. The pattern is the reverse of that obtained with Giemsa methods for differential staining of sister chromatids. Use diluted enzyme solutions or staining solutions with reduced pH for preparations which are very sensitive to trypsin. The method has been successfully applied to fresh as well as to 7 month old preparations.

BrdU-33258H ANALYSIS OF DNA REPLICATION (Latt, Willard and Gerald, 1976)

Cell growth

Culture peripheral lymphocytes at 37 °C in Eagle's MEM with 20 per cent fetal bovine serum, 2 mM L-glutamine and saline extract of red kidney beans (PHA).

To find late-replicating regions in S-phase, grow cells for 44–46 h in medium containing 10^{-4} M 5-BrdU, 4×10^{-6} M 5-fluorodeoxyuridine (FdU) and 6×10^{-6} M uridine (U). Replace it 5–9 h before harvest by Ham's

F-10 medium containing 20 per cent fetal bovine serum and thymidine (dT), 0.6 or 1.2×10^{-5} M. In some cases the thymidine is tritiated (0.8 μCi/ml). In most cases, duration of the terminal thymidine pulse is 5–7 h.

To suppress fluorescence of regions last to complete DNA synthesis, a converse 'B-pulse' protocol may be used, in which nearly three days of growth in control medium is followed by a 5–7 h pre-harvest pulse of BrdU, FdU and U at same concentration as above. A modification of both protocols is the addition of 10^{-4} M deoxycytidine (dc) together with the BrdU.

Cell harvest

Centrifuge 2 h after adding colcemid (0.1 μg/ml) and treat successively with 0.075 M KCl + acetic–methanol (1 : 3).

Stain slides with 0.5 μg/ml 33258H in 0.14 M or 0.40 M NaCl, 0.004 M KCl, 0.01 M phosphate, pH 7.0 and mount in 7.0 or 7.5 pH McIlvaine's buffer for fluorescence microscopy.

Incubate the same slides, not subjected to autoradiography, to 30 min at 65 °C in 2 XSSC (pH 7.0) and stain 20–30 min in 20 per cent Gurr's R66 (pH 6.8).

For autoradiography dip the slides in Kodak NTB-2 emulsion : water (1 : 1), expose for two to three weeks and develop with Dektol.

DOT FORMATION ON CHROMOSOMES (Wang, 1976; Wang and Mukherji, 1976)

Dotted chromosomes are produced in both BrdU and non-BrdU-substituted Chinese hamster cells after treatment with 1.0 M Na-phosphate solution (pH 9.0), with a supersaturated amount of $NaHCO_3$ at 80–95 °C. *The temperature needed for dot formation is always slightly higher than that needed for differential staining of chromatids.*

Grow Chinese hamster cells in monolayer for 24 h in McCoy's 5A medium supplemented with 10 per cent fetal calf serum.

Add BrdU at a final concentration of 10 μM and incubate in dark at 37 °C for 20 h for twice replication in BrdU without photolysis.

Two hours before harvesting, add colcemid at a final concentration of 0.03 μg/ml. Collect arrested metaphase cells by shaking culture bottles or by gently pipetting medium over monolayer for 5 min; treat with 0.075 KCl for 10 min at 37 °C, fix in acetic–methanol (1 : 3), air dry.

Heat 1.0 M NaH_2PO_4 in distilled water to 90 °C, add solid $NaHCO_3$ for supersaturation (pH 9) with $NaHCO_3$ precipitate. Treat slides in this solution for 3–4 min at 30–95 °C, rinse in distilled water, stain for 3–5 min in Giemsa (2 ml Fisher Scientific in 40 ml Sörensen buffer at pH 6.8); rinse in two changes of distilled water and air dry.

G-banding and SCD appear prior to dot formation. The late DNA-replicating sites become unifilarly BrdU-substituted and are identified by pale colour or dot formation.

Somatic cell fusion

INTRODUCTION

Cell fusion was first reported by Barski, Sorieul and Cornefort (1960) on the basis of their observation that two different cell lines of mouse, when grown together, result in the production of a nucleus containing chromosomes of both parents. A virus SV_5 was found to be the main agent responsible for fusion (Barski, 1968). Ephrussi and others (1964) and Yatsuyanagi and Ephrussi (1974) later obtained several such fusions and loss of chromosomes from fused cells was recorded. Littlefield (1964) devised a biochemical method of detecting hybrid cells in culture. Harris and Watkins (1965) demonstrated that fusion induced by Sendai virus, inactivated by ultraviolet light (Okada, 1962) or β-propiolactone (Neff and Enders, 1968), can be utilised to secure viable hybrid cells involving widely different groups. The lipoprotein envelope of the Sendai virus is essential for fusion and the inherent infectivity of nucleic acid is lost by ultraviolet treatment. It has been suggested that (*see* Harris, 1970) the envelope of the virus fuses with the apposed surfaces of the two adhering cells, forming an intercellular bridge between the two cells. Since the discovery of Sendai virus as a fusion inducing agent, several other viruses as well as chemicals have been shown to induce or promote somatic hybridisation (Pontecorvo, 1975; Ahkong, Tampion and Lucy, 1975).

FUSION BETWEEN ANIMAL CELLS

Schedule for somatic fusion between malignant cell lines derived from different mammalian species using Sendai virus (Harris and Watkins, 1965)

Take two cell types in quantity, as suspensions of single cells, namely HeLa cells from suspension cultures and Ehrlich ascites tumour cells from the peritoneal cavity of Swiss mice. (The virus selected in this case was a strain of Sendai virus supplied by Dr. H. G. Pareira of the National Institute for Medical Research, Mill Hill.) This member of the para-influenza I group of myxoviruses was chosen since one strain of these viruses (HVJ) was found to induce rapid fusion in suspensions of Ehrlich ascites cells *in vitro*.

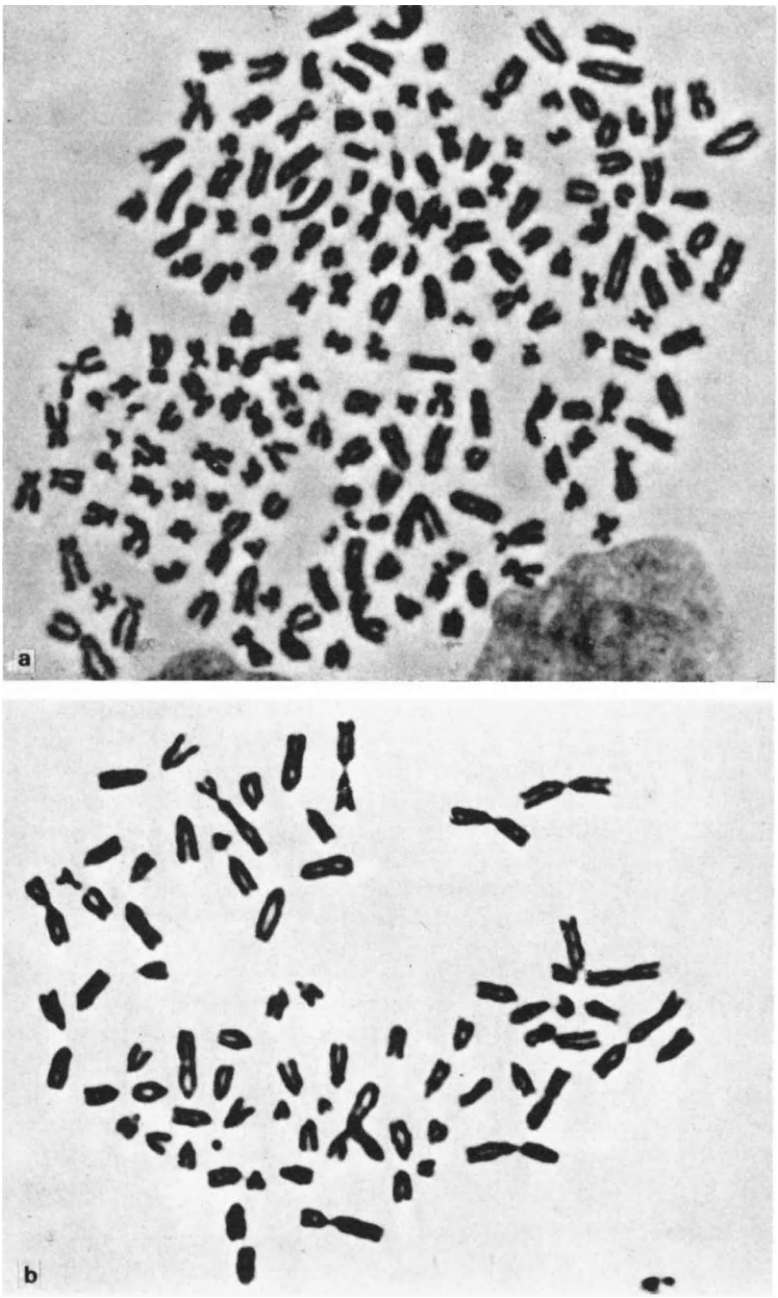

Plate 14.1
(a) *Man-mouse hybrid cell showing human metacentric and mouse acrocentric chromosomes, prepared following Sendai-virus mediated cell fusion method of Harris and Watkins* (courtesy of Prof. H. Harris and the Editors of the *Journal of Cell Science*). (b) YACIR (*Moloney virus induced lymphoma in A/Sn mice having* 40 *acrocentric chromosomes*) *and MSWB* (*methyl cholanthrene induced sarcoma in ASW mice having* 29 *chromosomes*) *hybrid cell showing* 69 *or* 70 *chromosomes, prepared following the above-mentioned method* (courtesy of Dr. F. Weiner)

Propagation of the virus

Dilute infected allantoic fluid (8000 haemagglutinating units/ml) with phosphate-buffered saline to 1 in 10^4 dilution. Inject 0.1 ml of the diluted fluid into the allantoic cavity of 10–11 day old fertile hens' eggs and incubate them at 37 °C for three days. Transfer to 4 °C, keep for 12 h and draw out the allantoic fluid. Centrifuge and accumulate fluid at 400 × g for 10 min and count the titre of haemagglutination in the supernatant. Centrifuge the supernatant at 30 000 g for 30 min. Remove the supernatant and re-suspend the cells at the bottom in one-tenth of the original volume in Hank's solution without glucose and store in 1 ml lots at −70 °C. Determine the haemagglutination titre. For the experiments, use the stored solution, diluted in Hank's medium.

Determination of haemagglutination titre

This is carried out in Salk-pattern haemagglutination trays. Prepare doubling dilutions of the virus in 0.5 ml phosphate-buffered saline. Add to each cup 0.05 ml of this solution containing about 2.5×10^7 guinea-pig erythrocytes in suspension. One haemagglutination unit (HAU) is the smallest amount of virus which produces complete haemagglutination after 2 h at room temperature.

Inactivation of virus

(1) Expose 1 ml of the concentrated Sendai virus suspension for 3 min (in a watchglass) to ultraviolet light on the surface of the membrane (from a Philips 15W18 in germicidal tube, with an intensity of 3000 ergs/ml/s). Mix the suspension by pipetting after each min. To test the infectivity of the irradiated virus, incubate pieces of chorioallantoic membrane with it in TC 199 medium in a tray. After 3 min of ultraviolet treatment, a drastic reduction is seen in the ability of the virus to multiply in the membrane, but its capacity to induce cell fusion *in vitro* remains intact.

(2) Inactivation can be carried out by β-propiolactone as well. Prepare a 10 per cent solution of β-propiolactone and dilute in 1 per cent saline bicarbonate (1.68 g $NaHCO_3$ and 0.5 ml phenol red in 100 ml isotonic saline). Treat the virus suspension (4 °C) with β-propiolactone (9 : 1), shake the mixture for 10 min in ice bath, incubate at 37 °C for 2 h with stirring at every 10 min and incubate at 4 °C overnight for hydrolysis of β-propiolactone (Poste, 1973).

Cell fusion with Sendai virus (Okada, 1962)

(1) Centrifuge and separate out HeLa cells from a suspension culture. Re-suspend in Hank's solution to a concentration of 2×10^7 cells/ml. Draw out Ehrlich ascites cells from the peritoneal cavity, wash by centrifugation in Hank's solution and re-suspend in it at a concentration of 2×10^7 cells/ml.

(2) Draw out 0.5 ml of each cell suspension with a pipette and transfer to a chilled inverted T-tube. Add 1 ml of the virus, and dilute, if required, with Hank's solution. The cells clump together and the size of the clumps

depends on the quantity of the virus added. Keep the tube with the mixture at 4 °C for 15 min and then shake in a water bath at 37 °C for 20 min at the rate of 100 oscillations/min. The cells in the clumps undergo various degrees of fusion during this period.

(3) Transfer 1 ml cell suspension of 5 ml culture medium, with the help of a pipette, into a 6 cm diameter petri dish containing 15 cover slips, each 1 cm in diameter. The culture medium contains: 20 per cent calf serum and 1 per cent tryptose, both in TC 199 with 100 units/ml penicillin and 100 μg/ml streptomycin. Incubate the petri dishes at 37 °C in a gas mixture of 5 per cent CO_2 in air. Transfer the cover slips to fresh medium after one day and again after four days. Multinucleate cells are observed adhering to the cover slips 4 h after introducing the suspension into the petri dishes. Within 24 h, most of them flatten out on the glass. Cell counts show that about 10 per cent of the original single cells in suspension adhere as multinucleate cells to the cover slip. Each multinucleate cell contains about two to 20 nuclei of two morphological types.

Modified schedule for somatic fusion between malignant and non-malignant cell lines (Engel, McGee and Harris, 1969)

This method, basically the same as that of Harris and Watkins (1965), was used to secure cell hybridisation between two cell lines, one malignant and the other non-malignant. The materials used were A9 and B82 mutants of Earle's L line of mouse. The first mutant cells were deficient in inosinic acid phosphorylase while the latter lacked thymidine kinase. When a medium containing aminopterin was used, neither of these lines could grow due to blocking of the endogenous biosynthesis of purines, and of thymidylic acid. This principle was followed in developing a medium containing 4×10^{-7} M aminopterin, 3×10^{-6} M glycine, 1.6×10^{-5} M thymidine and 1×10^{-4} M hypoxanthine (Littlefield, 1964). The parent cell lines were unable to grow in this medium but the hybrid line, derived by cell fusion, could grow in it. The cells of the two mutant lines were fused together by exposure to Sendai virus following the technique described before (Harris and Watkins, 1965) and the hybrid strain was isolated by growing the mixed population in the medium here described. In the experiments by Engel, McGee and Harris (1969), two sub-populations were raised, one (A) from cells fused together by 6000 HAU of inactivated virus and grown in the selective medium as a mixed culture, and another (B) derived from a single colony of hybrid cells isolated 25 days after the primary fusion, using 4000 HAU of the inactivated virus.

In non-malignant man/mouse somatic hybrid cells, where chromosomes are eliminated under normal conditions, Miller *et al.* (1971) recorded specific retention of human chromosome number 17 in the hybrid cell if grown in HAT selection medium with thymidine kinase.

Successful enzyme study and gene localisation from somatic cell hybrids have also been carried out by different authors (Siniscalco, 1970; Siniscalco, Klinger and Eagle, 1969; *see* Meera Khan, 1971).

Cell fusion with other viruses

In addition to Sendai virus, cell fusion can be induced by several other viruses including arboviruses all of which have the common property of having envelopes (Dijnawi and Olson, 1973; Poste and Waterson, 1975). Olson (1976) prefers Germiston virus because of the convenience in preparation, easy removal of infectivity by chloroform and protamine as well as capability of rapid and efficient induction of fusion. The only limitation is that it is infectious to man for which proper precaution must be taken. The stock of Germiston virus is normally prepared in cell cultures or suckling mouse brain (Olson, Sithisarn and Dijnawi, 1975), the LD_{50} concentration of stock being 10^6–10^7. After harvesting from the brain the virus can be homogenised or stored at −70 °C. Prior to homogenisation, the frozen sample is to be thawed with agitation at 37 °C. Suspension is prepared at 20 per cent w/v in phosphate-buffered saline (pH 7.2) with fetal bovine serum or bovine serum albumin inactivated at 56 °C for 30 min, at a final proportion of 2 per cent (FBS) and 0.4 per cent (BSA) and kept at 0 °C. The suspension is to be homogenised at maximum speed in Omnimixer for 3 min in ice bath cup followed by centrifuging at 350 × g for 30 min at 4 °C. The supernatant contains 10^8–10^9 infectious Germiston virus in 0.1 ml. It can be stored at −70 °C in aliquots after freezing.

To remove the infectivity, the suspension is to be mixed with chloroform in the proportion of 9 : 1, shaken vigorously and centrifuged at 500 × g for 15 min at 24–26 °C. The top aqueous layer can be used directly to induce fusion of cells grown from monolayers or suspension. The most important factor affecting fusion is that the medium should be free from serum as far as practicable. Before mixing, the virus and the cell cultures should be kept at 4 °C for 1 h, incubated at 42 °C for 2 h. At 37 °C fusion may be accomplished even at 3 min with 300 : 1 virus cell suspension ratio. Hybrid cells can be stained in Wright stain or grown in selective medium.

Virus induced fusion mediated by lectin

As virus induced cell fusion is associated with virus cell surface interactions, plant lectins, which often bind strongly with cell membrane have been explored in this connection. A number of plant lectins are known to inhibit fusion by viruses (Poste, 1975; Rott *et al.*, 1975). Phytohaemagglutinin (PHA), a plant lectin obtained from red kidney bean (*Phaseolus vulgaris*), accelerates fusion to a significant extent (Poste *et al.*, 1974; Sullivan *et al.*, 1975; Yoshida and Ikeuchi, 1975) (for its properties and constitution please refer to Chapters 2 and 11). The capacity of PHA to accelerate fusion has been attributed to its agglutinising property causing close cell to cell contact. It does not affect the binding of the virus to cell surface receptors. Of the two major biological fractions of PHA (Miller *et al.*, 1973), α-PHAP, which has a low erythroglutinin but potent leucoagglutinin activity, is claimed to be responsible for enhancing cell fusion (Poste, Alexander and Reeve, 1976). The technique of PHA accelerated cell fusion is outlined below (Poste, Alexander and Reeve, 1976).

(1) Take egg grown cultures of Sendai virus or (NDV) Newcastle disease virus and inactivate in β-propiolactone as mentioned in earlier schedules.
(2) Take thymidine kinase deficient (CI-IID) mouse cells (Dubbs and Kit, 1964) and hypoxanthine guanine phosphoribosyltransferase deficient (WI-18Va2) human cells (Weiss, Ephrussi and Scaletta, 1968) in equal numbers (5×10^6) of each and suspend in 1.0 ml serum free Eagle's basal medium with PHA (100 μg/ml).
(3) Adjust the pH to 8.00.
(4) Incubate for 90 min at 37 °C.
(5) Add 2000 HAU-inactivated Sendai virus or 2000 (EID_{50}) egg infectious disease of NDV and incubate for 1 h at 37 °C.
(6) Inoculate mixed cell suspensions on cover slips and incubate for 16 h at 37 °C.
(7) Fix and stain as usual with Giemsa or test hybridity by culturing in HAT medium.

Use of lipid vesicles in cell fusion

In order to eliminate the toxic properties of lysolecithin (Kataoka and Koprowski, 1975) the undesirable effects of Sendai virus, i.e. interference in the release of transforming virus (ter Meulen *et al.*, 1972), alteration in the surface properties and metabolic pathways (Harris *et al.*, 1966; Hand and Tamm, 1973; Okada *et al.*, 1975), and chromosomal aberrations (Stenman and Saksela, 1971), lipid vesicles prepared from phospholipids (Papahadjopoulos, Poste and Schaeffer, 1973; Martin and MacDonald, 1974; Poste and Papahadjopoulos, 1976) have been utilised to fuse mammalian cells of different lines.

A brief outline of the technique (Poste and Papahadjopoulos, 1976) for securing interspecific mammalian cell hybrids is described.

(1) Prepare unilamellar (small vesicles with single lipid bilayer, 25–50 nm) vesicles in the following way.
   (a) Disperse 10–20 μM of lipid phosphate in 2–4 ml aqueous buffer with 100 mM NaCl, 2 mM N-tris methyl-2-aminoethane-sulphonic acid (TES) and 0.1 mM EDTA, pH 7.4 and shake for 10 min at 37 °C (above the transition temperature of the lipid) in Vortex mixer.
   (b) Sonicate with nitrogen for 1 h (for natural phospholipids, 24–26 °C is suitable).
   (c) Equilibrate the vesicles at 24–26 °C after sonication for 1 h.
   (d) Dilute the vesicles in phosphate-buffered saline for use to secure 10^2–10^8 vesicles per cell for fusion; (1 μM of sonicate contains 2×10^{14} vesicles).
(2) Take two different cell types, thymidine kinase (TK) deficient C1-1D mouse cells (Dubbs and Kit, 1964) and hypoxanthine guanine phosphoribosyltransferase-deficient (HGPRT) WI-18Va2 human cells (Weiss, Ephrussi and Scaletta, 1968), and suspend equal number of cells (5×10^6) of each in 1.0 ml serum free Eagle's basal medium (pH 8.0).
(3) Incubate with vesicles (10^4 per cell) for 2 h at 37 °C.
(4) Take a drop of the mixed cells and inoculate on cover slip, incubate

for 16–24 h at 37 °C fix in methanol and stain in Giemsa to observe fused cells.

(5) Inoculate the rest of the cell mixture in 2.0 ml HAT medium (pH 8.0) in 35 mm plastic petri dishes (1×10^6 cells per dish) and incubate as usual.
(6) Replace the medium by fresh medium after 1, 3, 6, 9 and 12 days.
(7) After 14 days, fix and stain the cells following the usual procedure or follow starch gel electrophoresis to study enzyme activity of hybrid cells as expressed in HAT selective medium (Shows, 1974).

It has been shown that efficiency of phospholipid vesicles in fusion at 37 °C is dependent on its fluid consistency (Papahadjopoulos *et al.*, 1974; Kantor and Prestegaard, 1975). Fusion of charged vesicles as well as their penetration in cells through mixing with plasma membrane have been regarded as responsible for cell fusion (Poste, Papahadjopoulos and Vail, 1976).

Use of lysolecithin in cell fusion

In view of the fact that several lipolytic agents affect the cell membrane, lysolecithin; a phospholipid; was used by Croce *et al.* (1971) to induce cell fusion. Several lypophilic molecules have later been shown to have the same capacity (Lucy, 1974). But in general, it is claimed that the recovery of viable cells through these methods is significantly lower than those treated with viruses because of the cell damage caused by lipolytic agents (Keay, Weiss and Wildi, 1972; Kataoka and Koprowski, 1975; Papahadjopoulos and Poste, 1975). However, this damage can be minimised by using it in bovine serum albumin (Koprowski and Croce, 1973) or in lipid emulsion.

Lysolecithin solution can be prepared in different ways (Ahkong *et al.*, 1972). In order to have lipid emulsion, egg lysolecithin is dissolved in chloroform and the latter is removed in an atmosphere of nitrogen. The lysolecithin after drying, is exposed to a mixture of 0.9 per cent NaCl and 0.15 M sodium acetate buffer (3 : 5) pH 5.6, or Dulbecco medium pH 7.2, for 15–30 min for swelling. A stream of nitrogen is then passed through the compound in a sonicator to disperse the phospholipid and within 10 min lysolecithin is to be utilised.

There are different methods for the preparation of aqueous solution. Ahkong *et al.* (1972) preferred dissolving lysolecithin (70–560 μg) in a mixture of 1.7 ml 106 mM NaCl and 44 mM sodium acetate pH 5.7 whereas Poole, Howell and Lucy (1970) suggested dissolving the compound directly in Hank's balanced salt solution. Croce *et al.* (1971) suggested initial dissolution of lysolecithin in absolute ethanol (1 mg/ml), heating aliquots of stock solution in stoppered tubes at 60–70 °C for 20 min or 70–80 °C for 5–10 min, then passing nitrogen through the opened tubes to evaporate ethanol, and finally to keep the sterile LL powder in 0.5 ml of absolute ethanol at 50–60 °C. It is used in Eagle's minimal essential medium (MEM) or phosphate-buffered saline (pH 7.2) with bovine serum albumin 5 mg/ml (BSA) (Croce, Koprowski and Eagle, 1972; Koprowski and Croce, 1973), the final concentration of ethanol not exceeding 1 per cent in the protein solution. The techniques (Croce *et al.*, 1971; Koprowski and Croce, 1973) are outlined below.

For somatic cells

(1) Mix H^3 thymidine labelled 5×10^6 CV-1 (African green monkey kidney continuous line) with unlabelled 5×10^6 F5-1 cells (hamster line transformed by SV_{40}) in 1 ml Hank's solution.
(2) Centrifuge at 24–26 °C for 5 min at 160–180 × g.
(3) Treat the pellets (0.5 to 1×10^7) with 0.1 ml of LL solution in BSA for 1 min at the required pH (pH 8.0) and concentration, and shake the tubes to secure maximum exposure of cells to LL by detaching the pellets from the bottom.
(4) In order to neutralise the action of LL, add 1 ml MEM containing 30 per cent fetal calf serum (FCS) inactivated for 30 min at 56 °C.
(5) Centrifuge the samples for 5–6 min at 160 × g for 5–10 min at 24–26 °C, discard the supernatant, add 1 ml MEM on the pellets.
(6) Incubate at 37 °C for 15–20 min.
(7) Re-suspend the pellets in MEM containing 10 per cent FCS.
(8) Seed the culture (one million cells or so) in petri dishes or flasks.
(9) After 18–22 h of seeding, for observation, wash the cells three times in the medium, fix in methanol for 5 min and stain in Giemsa.

For use of LL in lipid emulsion, a slightly different method is to be followed. In this case, monolayers of cells in petri dishes (10^3) are to be treated for 5 min at 24–26 °C with 0.8 ml LL in lipid emulsion in serum free Dulbecco's medium and shaken, emulsion to be removed, and cells washed twice with the same medium. The cells to be fused are to be added in suspension in the same medium to the monolayer, kept for 7 min and shaken, the non-fused cells removed, and the monolayer washed twice with 2.5 ml FCS and cultured in selective medium.

For gametic cells

(1) Take spermatozoa from rabbits and wash three times in Hank's balanced salt solution.
(2) Centrifuge at 180 × g for 5 min at 24–26 °C.
(3) Treat pellet (5×10^7 motile cells) with 0.1 ml LL (1.2 mg/ml) for 1 min to stop motility.
(4) Add 45 ml MEM and centrifuge.
(5) Mix the pellet (5×10^7) with somatic cells (5×10^6) of a different line and centrifuge the mixture at 180 × g for 5–10 min at 24–26 °C.
(6) Follow the procedure as in steps 3–8 for somatic cells.

Use of polyethylene glycol in cell fusion

Polyethylene glycol [$HOH_2C(CH_2OCH_2)_nCH_2OH$], normally used for inducing cell fusion in plants (Kao and Michayluk, 1974), has been effective in mammalian systems as well (Pontecorvo, 1975). Davidson and others (Davidson, O'Malley and Wheeler, 1976; Davidson and Gerald, 1977) have developed a comparatively simple, quick and inexpensive method of securing mammalian cell hybrids with the use of PEG. It gives consistent results

with different batches of the compound, an advantage not often met with other fusion inducing agents including Sendai virus.

The solution of PEG is prepared in the Eagle's medium on a 1 : 1 basis, i.e., 10 g in 10 ml of medium bringing the strength to 50 per cent. Initially PEG is to be autoclave sterilised and Eagle's medium without serum is to be added to the hot PEG solution. The molecular weight of PEG varies from almost 200–6000, and the higher molecular weight. PEG often solidifies which can be liquefied by raising the temperature to 70 °C and then stored at 26–28 °C.

The technique for fusion of cells is outlined below (Davidson and Gerald, 1977).

For monolayers

For fusion experiments, mouse fibroblast (3T34E) a bromodeoxyuridine resistant line and rat glial cells (RG6A-TgA), an azaguanine resistant line may be chosen.

(1) In 60 mm Falcon tissue culture dishes, take Dulbecco's modified Eagle's medium supplemented with 10 per cent fetal calf serum (E-10FCS), and inoculate with 2.5×10^6 3T3 and 2.5×10^5 RG6 cells.
(2) Incubate for 24 h at 37 °C.
(3) Remove the medium by aspirating first, and then tilting the dish to drain off the residual medium and aspirating again.
(4) Add PEG solution (1000 at 50 per cent) at 26–28 °C or room temperature sufficiently to cover the cells and keep as such without disturbing for 1 min.
(5) Remove quickly the PEG by aspirating and wash the dishes thrice with Eagle's medium (Dulbecco's modification).
(6) Cover the cells with 5 ml E-10FCS medium and incubate for 24 h at 37 °C.
(7) Trypsinise the cells and harvest.
(8) Plate the cells in E-10FCS medium containing hypoxanthine, aminopterin and thymidine (E-10 HAT) (Littlefield, 1964). Addition of these compounds does not allow the parental cell lines to grow because of enzyme deficiencies associated with drug resistance, but the hybrid lines can grow and as such can be selected.
(9) Renew this medium every four to five days.
(10) After seven days, fix the dishes containing the cells in methanol and stain with Giemsa and count colonies.

The PEG concentration (1000) at 50 per cent seems to give the optimum result as below it, there is less fusion, and increased concentration results in decreased viability of cells (Davidson and Gerald, 1977). Normally the frequency of hybridisation is maximum at pH 6 and minimum at pH 9 but the effect of change is rather small. PEG 1000 at 50 per cent is chosen because of high rate of fusion and its least sensitivity to dilution effects.

For suspensions

For cell lines in suspension, for one partner, Chinese hamster (Wg 3H) or mouse (RAG), and for the other, human peripheral leukocytes (WBC) or mouse peritoneal macrophages may be chosen.

In order to secure cells of Wg 3H or RAG, cell lines can be grown in Eagle's medium (Dulbecco's modification) supplemented with 5 per cent fetal calf serum (E-5 FCS). For plasma suspension of WBC, sedimentation for 1–2 h in a mixture of equal volumes of heparinised whole blood and dextran solution (3 g of dextran of molecular weight 100 000–200 000, in 100 ml of saline), is to be followed by washing thrice with Hank's balanced solution before use.

(1) Mix 5×10^6 WBC and 5×10^6 Wg3H cells in a conical centrifuge tube.
(2) Centrifuge the mixture and remove the supernatant by aspirating, with 0.05 ml still remaining in the tube.
(3) Mix 1 ml PEG by pipetting and keep for 1 min.
(4) Add 9 ml of Eagle's medium, centrifuge and again remove the supernatant by aspirating.
(5) Suspend the cells again in 5 ml E-5 FCS medium and divide the suspension in the same medium in five 60 mm falcon culture dishes.
(6) After 24 h at 37 °C follow the same procedure as 7–9 above and after 14 days, fix the dishes containing cells with methanol, stain with Giemsa and count colonies.

In order to secure optimum yield of hybrid colonies, absolute removal of PEG is needed after use.

Use of microcells for cell fusion

As mentioned already in mammalian somatic cell hybrids, chromosome elimination of the human cells is one of the common phenomena from fused cells with mouse or Chinese hamster. This has been extensively utilised in the mapping of genes (*see* Ruddle and Creagan, 1975; Ringertz and Savage, 1976). As the elimination of chromosomes is a rather slow process and occurs in an erratic way, several authors have tried to use deficient cells with single or a few chromosomes as one of the partners in fusion, so that genes can be conveniently mapped (Pontecorvo, 1971; Burch and McBride, 1975; Goss and Harris, 1975; Wilecke and Ruddle, 1975; Wullems, van der Horst and Bootsma, 1975). The use of irradiated cell which has already suffered chromosome damage and loss has been utilised by Pontecorvo (1971, 1974; *see* Burgerhout, 1974). Induction of premature chromosome condensation in interphase leading to chromosome break and loss in one of the fusing cells has been adopted by certain authors (Schwartz, Cook and Harris, 1971; Matsui, Weinfeld and Sandberg, 1972).

One of the effective methods applied by Ege and Ringertz (1974) involves the use of subdiploid cell fragments termed 'microcells' containing small genetic material as one of the partners in fusion. Such microcells have a small deficient nucleus with surrounding cytoplasm and wall. These are ultimately produced from micronucleate cells often induced by colcemid as well as other microtubular poisons (Cremer *et al.*, 1976). Ege *et al.* (1974, 1977) have used cytochalasin B and centrifugation for the production of

microcells prior to enucleation needed for cell fusion from monolayers as well as from cell suspension. The method is outlined below.

(1) Remove cultured growing cells to small round (25 mm diameter) plastic discs punched from tissue culture dishes and allow to grow for 12–24 h.
(2) Add colcemid or vinblastine at a final concentration of 1–3 μg/ml and incubate for 72 h.
(3) After micronucleation, remove the medium and place the cells facing downwards in centrifuge tubes containing 4 ml of phosphate buffered saline (PBS).
(4) Stabilise the position of the plastic disc in the tube with plastic plugging.
(5) Centrifuge at 10000 rev/min for 10 min in a centrifuge at 37 °C to remove loosely attached cells.
(6) Transfer the discs to fresh centrifuge tubes containing PBS with 10 per cent calf serum and 10 μg cytochalasin B per ml.
(7) Centrifuge at 14000 rev/min for 20 min at 37 °C.
(8) Re-suspend the pellet, pool and centrifuge at 400 rev/min for 5 min.
(9) Remove the supernatant, wash and re-suspend the pellet in Eagle's MEM without serum for fusion experiment.

From cells in suspension (Wigler, Neugut and Weinstein, 1976)
With use of cytochalasin, discontinuous Ficoll gradient has been employed for separation of nucleated and anucleated cell fragments. This method is quite rapid as it allows enucleation of almost 6×10^7 cells in a 10 ml gradient.

The production of microcells can also be secured through cold treatment (Johnson, Mullinger and Skaer, 1975; Schor, Johnson and Mullinger, 1975). The method involves initially the mitotic arrest by N_2O of synchronised cells at 5 atm followed by treatment for 9 h at 5 °C. The cells are then to be incubated at 37 °C for 2 h to induce abnormal chromosome segregation and cytokinesis resulting in bunches of microcells which can be separated by shearing. The microcells can also be separated through Ficoll gradient or 5 μm nucleopore filter.

FUSION BETWEEN PLANT CELLS

In plants, the principal limitation of securing somatic hybridisation is the presence of cell wall and middle lamella which are to be digested by specific enzymes acting on cellulose and pectin. Following such digestion, the protoplast can be isolated and cultured, convenient for somatic hybridisation. Isolation and culture of protoplasts have been dealt with in chapter on Tissue Culture.

For protoplast fusion in plant system, in contrast to viruses in animals, several inducing agents such as polyethylene glycol, sodium nitrate, etc. are needed to bring the protoplasts of different species or varieties in contact with each other. Electron microscope analysis has revealed that adherence followed by membrane fusion in certain areas are caused by these agents (Withers and Cocking, 1972; Burgess and Fleming, 1974). Ultrastructural analysis of intergeneric heterocaryons (Fowke, Gamborg and Constabel,

1975) have revealed occurrence of tight adhesion between agglutinated plasmalemma in localised areas which gradually become dispersed in the cytoplasm. Occasional spontaneous protoplast fusion during enzyme treatment at an intraspecific level has been recorded (Usui, Maeda and Ito, 1974). Mechanical means such as micromanipulators have also been employed (Schenk and Hildebrandt, 1971; Diacumacos, 1975) in some species including legumes to secure protoplast fusion.

As compared to animal species, selection systems in plants are quite different for the detection of hybridity or heterocaryon nature. Refined chromosome techniques are essential for checking fusion. Carlson, Smith and Dearing (1972) utilised nutritional requirements as selection criteria of *Nicotiana glauca* and *N. langsdorfii* which are rather unusual as compared to other plant species. Chlorophyll deficient mutants have been used as markers in varieties and mutants of *Nicotiana* by certain authors (Melchers, 1975; Melchers and Labide, 1974; Gleba, Butenko and Sytnik, 1975). In *Sphaerocarpos*, Schieder's method (1975) of utilising auxotrophic mutants is analogous to the method adopted in animal system. In maize, mutant strains have been used (Giles, 1974). Sensitivity to drugs, such as actinomycin D, by Cocking and others (1974) has also been proved to be an effective marker. The advancements in the method of banding pattern analysis of chromosomes may ultimately lead to an effective method of detection of somatic hybridity. Application of refined techniques for chromosome analysis, already available, has immense potential in the identification of hybrids.

The different techniques for cell fusion in plants are outlined below.

(1) Sodium nitrate method (Power, Cummins and Cocking, 1970)
   (a) Suspend isolated protoplasts in a mixture of 5.5 per cent $NaNO_2$ in 10 per cent sucrose solution for 5 min at 35 °C.
   (b) Centrifuge at 200 × g for 5 min.
   (c) Transfer the pellet to a water-bath and keep for 30 min.
   (d) Slowly replace the supernatant (mixture) with Murashige and Skoog's medium with an addition of 0.1 per cent $NaNO_2$.
   (e) After some interval, wash twice with the medium and plate.

(2) Calcium ion method (Keller and Melchers, 1973)
   (a) Isolate protoplasts and centrifuge in a mixture containing 0.05 M $CaCl_2,2H_2O$, in 0.4 M mannitol, pH 10.5 at 50 × g for 3 min.
   (b) Keep the tubes in a water-bath for 40–50 min at 37 °C, when fusion can be noticed in a maximum of 50 per cent protoplasts.

(3) Polyethylene glycol method (Kao and Michayluk, 1974)
   (a) Mix two types of protoplasts in equal quantities.
   (b) Take a few microdrops (100 μl each) on petri dishes (preferably on cover slips placed at the centre of petri dishes, Bajaj, 1977).
   (c) Keep for 5–10 min at 24–26 °C.
   (d) Add 2–3 drops of PEG (50 μl) to the periphery and incubate for 30 min. Addition of calcium in PEG accelerates fusion.
   (e) Replace the PEG in the suspension by culture medium by gradually washing the protoplasts.
   (f) Plate and stain to note fusion.

The concentration of PEG needed should be determined initially, as

differential sensitivity has been noted with different species (Bajaj, Reinert and Gosch, 1975).

Cocking and his group (Power *et al.*, 1976) have been successful in securing regeneration of plants from somatic hybridisation of protoplasts of *Petunia hybrida* and *P. parodii* both with 2n = 14 chromosomes. So far such clear case of regeneration into mature plant was known only for interspecific somatic hybrids of *Nicotiana* (Carlson, Smith and Dearing, 1972). In order to identify the hybrids after fusion in *Petunia*, the growth characteristics and sensitivity to drugs (Cocking *et al.*, 1974; Power and Cocking, 1977) have been used as markers. *P. parodii*, in Murashige and Skoog's medium, does not grow beyond the colony stage and is unaffected by the presence of actinomycin D in the medium whereas *P. hybrida* cultivar 'Comanche' produces callus in the same medium and the growth is completely stopped in presence of actinomycin D. The positive test of hybridity is therefore formation of callus in presence of actinomycin D due to complementation.

The method as followed by Power *et al.* (1976) to secure somatic hybrid is outlined below (viability and fusion control set-ups are to be maintained as usual).

(1) Isolate leaf protoplasts of *P. parodii* and *P. hybrida* as outlined in chapter on tissue culture.
(2) Suspend the protoplasts in 9 per cent (w/v) mannitol solution containing inorganic salts (Cocking and Peberdy, 1974). The use of calcium ions at pH 8.5 is also recommended (Reinert and Bajaj, 1977).
(3) Keep the samples in screw-capped 8 ml tubes and use equal volume of each species for fusion.
(4) Centrifuge the tubes at 80 × g for 10 min and remove the supernatant.
(5) To induce fusion, add 2 ml 15 per cent (w/v) polyethylene glycol (molecular weight 6000), 4 per cent (w/v) sucrose and 0.01 M $CaCl_2$ in the tubes.
(6) Re-suspend protoplasts and keep at 25 °C for 10 min.
(7) Add after every 5 min, M/S medium 0.5, 1.0, 2.0, 2.0, 3.0 and 4.0 ml, continually re-suspending the protoplasts after each addition.
(8) Centrifuge at 60 × g for 15 min.
(9) Remove the supernatant and add 8.0 ml M/S medium in each tube.
(10) Keep the tubes for 1 h before plating. (A sample count may be taken at this stage which shows nearly 4 per cent of the nuclei in a fused state.)
(11) Culture the protoplasts on liquid agar medium in the following way.
  (a) Take 9 cm plastic petri dishes and add 8 ml M/S medium with actinomycin D (1.0 μg/ml) solidified with agar (0.5 per cent w/v).
  (b) Add 4 ml M/S medium with actinomycin D (2.0 μg/ml) and 4 ml protoplast suspension (2.0 × 10^5/ml) in M/S medium without actinomycin D on the surface of the agar. After this dilution the concentration of actinomycin D on the liquid becomes 1.0 μg/ml at a protoplast density 1 × 10^5/ml.
(12) Keep the cultures at 27 °C using daylight fluorescent tubes for 28 days.
(13) Transfer the cultures to M/S medium with 3 per cent mannitol solidified with 1 per cent agar, without actinomycin.

(14) After 60 days, transfer the cultures to M/S medium without mannitol for the formation of callus.
(15) After 10 weeks, transfer the fused hybrid calluses to M/S medium with IAA (2.0 μg/ml) and 6-benzylaminopurine (1.0 μg/ml) for shoot regeneration.
(16) After shoot formation, transfer to M/S medium with NAA (0.1 μg/ml) and 0.3 per cent agar.
(17) After the formation of plantlets of suitable size, transfer to pots to grow till maturity.

Following this method, hybrids of *P. parodii* and *P. hybrida* were obtained with purple flowers and chromosome numbers ranging between $2n = 28$ and $2n = 24$ showing tetra and hypotetraploid constitution.

FUSION BETWEEN PLANT AND ANIMAL CELLS

In order to secure fusion between plant and animal cells, both polyethylene glycol (Ahkong *et al.*, 1975) and Sendai virus (Lima de Faria, Eriksson and Kjellen, 1977) have been employed. The technique employed by Ahkong *et al.* (1975) is as follows.

(1) Prepare hen erythrocytes and suspend in modified Eagle's basal salt solution buffered at pH 7.4 with 20 mM HEPES buffer (6×10^8 cells/ml).
(2) Prepare yeast protoplasts with the use of helicase from exponentially growing cultures *Saccharomyces cerevisicae* strain NCYCO263B. Centrifuge the protoplasts at 1000 × g for 15 min in Ficoll (400) gradient dissolved in osmotic stabiliser (0.7 M sorbitol 0.01 M citric acid, pH 6.5). Prepare the gradient in the following way.
   (a) Prepare a layer of 8 per cent w/v Ficoll (8 vol).
   (b) Over (a) pour another layer of 5 per cent w/v Ficoll (8 vol).
   (c) Layer osmotic stabiliser on (b) above.
(3) Re-suspend the sedimented protoplasts in the osmotic stabiliser (6×10^8 protoplasts/ml).
(4) Centrifuge the protoplast preparation for 3 min at 1000 × g and remove the supernatant.
(5) Add erythrocyte preparation on the protoplast pellet (1 : 50 or 1 : 250) and centrifuge for 5 min at 800 × g and remove the supernatant.
(6) Re-suspend the preparation and mix with 1 ml 40 per cent w/v PEG (molecular weight 6000) in the HEPES buffered Eagle's medium, pH 7.4.
(7) Incubate at 37 °C for 15 min which will allow the formation of aggregates.
(8) Dilute 1 ml of the incubate with 5 ml of buffered Eagle's salt solution at 37 °C.
(9) Centrifuge at 800 × g for 5 min and re-suspend 1 ml solution at 37 °C.
(10) With continued incubation, note the swelling of erythrocytes and observe cell fusion under light microscope. For electron microscopy glutaraldehyde fixation may be employed.

Lima de Faria, Eriksson and Kjellen (1977) utilised Sendai virus for fusing

tritium and uridine labelled human cells with *Haplopappus gracilis* (n = 2), a member of the plant family Compositae. The fused cells were cultured in modified MEM (human culture medium) at 37 °C. Autoradiography and carbol fuchsin staining were adopted to check fusion. Heterocaryons with cell wall containing one human and one plant nucleus were recorded in 12 per cent of cells and the human chromosomes could be detected to undergo mitotic division in the plant cytoplasm.

CONCLUSION

The significance of cell fusion in biological systems is manifold (Astrin, 1979). One of the fundamental researches in which cell fusion is now widely applied is the mapping of genes in human chromosomes through chromosome elimination. Since the initial success of Weiss and Green (1967) of locating gene for thymidine kinase in human chromosomes through somatic hybridisation between fibroblasts of human embryonic lung, and thymidine kinase deficient aneuploid mouse, it has become a routine method in several laboratories (*see* Harris, 1970). Pearson *et al.* (1977), de Grouchy, Finaz and Cong (1977) have utilised primate-rodent cell hybrids to ascertain the origin of several of the human chromosomes and their relationship with gorilla, orang-utan and chimpanzee. Microcell hybrids (Ringertz and Ege, 1977) provide a comparatively more precise tool for chromosome mapping and analysis of gene complementation.

In oncological research, cell fusion technique is proving to be of immense value. There are several tumour viruses such as Simian virus 40 (SV 40) and Rous sarcoma which cause malignant transformation in susceptible cells by the incorporation of their genetic substance into the DNA of the host chromosome. Such transformed lines do not show the infective virus in the host cytoplasm. Through virus induced cell fusion of the transformed line with a permissive line which allows the multiplication of the virus in the cytoplasm it has been possible to secure the release of the virus from the chromosome (Gerber, 1966; Watkins and Dulbecco, 1967; Koprowski, Jensen and Steplewski, 1967). In addition to above, Harris *et al.* (1969) recorded that fusion of highly malignant Ehrlich ascites tumour cells with low malignant mouse cell line results in non-malignant hybrid cells. All these researches have generated constructive approaches towards cancer therapy.

In the field of plant cell fusion, such parasexual hybridisation has resulted into heterocaryons at an intergeneric level, such as *Digitaria*, barley, corn and pea with soybean (Giles, 1972; Kao *et al.*, 1974; Kartha *et al.*, 1974) and carrot with *Petunia* (Dudits *et al.*, 1976; Reinert and Gosch, 1976) and possibilities have been indicated in several other genera (Tempe, 1975) as well. Plant regeneration has however been successful only in case of *Nicotiana* and *Petunia* as mentioned above. The possibilities are now open for regeneration of intergeneric parasexual hybrids or amphidiploids. Such an attempt may ultimately lead to the success of parasexual hybridisation between a cereal and legume resulting in transference of nitrogen fixing property to the hybrid cereal.

It is hardly difficult to estimate the far reaching significance of fusion between plant and animal *vis-à-vis* human systems. A projection of its

application would depend on the extent to which the technical refinements would allow the two systems to remain viable and divide after fusion even under culture. It is true that the universality of the genetic code may permit the two organisms to complement each other in protein synthesis. On the other hand, their widely divergent status in the hierarchy of evolution and the loss of totipotency in one may prevent their symbiotic survival even *in vitro*. In spite of these basic differences, the results so far achieved show promise of success, in the foreseeable future, though to a relatively limited extent of their complementary survival. This feat of genetic engineering may ultimately lead to an understanding of the steps in evolution, correction of deficiencies and incorporation of desired attributes in plant and mammalian systems.

Effects of physical and chemical agents on chromosomes

The discovery of x-ray-induced mutation in *Drosophila* by Müller in 1927, followed by Stadler in maize in 1928, provided the necessary impetus for research on the effects of outside agencies on chromosomes. The result of this enthusiasm led to the discovery of the mutagenic property of chemicals, by Oehlkers (1943) and Auerbach and Robson (1946), followed by a host of others, and in the meantime, the polyploidising action of colchicine and its effective application on plants had been disclosed through the works of Blakeslee and Avery (1937) and their collaborators. The need for refinements in methods for the intensive investigation of the effects of these and other physical and chemical agents on chromosomes, both from utilitarian and fundamental standpoints, had been realised, and new avenues of research opened up.

In spite of the fact that the initiation of this line of investigation dates back to quite an early period, the standardisation of a method for a systematic attempt to explore the properties of different chemical agents was first made by Levan (1949) and his collaborators. The technique applied by them is known as the Allium test, in which the experimental materials consist of bulbs of *Allium cepa*, the common onion. The advantage of using onion as the experimental material lies in the fact that it is; (a) inexpensive, (b) easy to handle and (c) it yields a fresh crop of roots in tap water, thus providing meristems for study, every two or three days. The chemicals to be tested are prepared in solution and kept in wide-mouthed jars. A bulb with roots intact is then placed over the mouth of the jar so that its roots dip in the solution—the jars may be covered with black paper to allow healthy growth of the roots. After treatment for a desired period, the roots can be excised, fixed, stained and observed directly or kept for recovery in water or nutrient solution under similar conditions before fixation, staining and observation.

The above method is applicable only to root meristems, however, and for meiotic cells or pollen grains the entire inflorescence is generally treated by dipping the stalk in water. But the mode of treatment with these materials may vary and, if necessary, the anthers may be dipped in the fluid directly. For animal materials, the usual technique of application is through feeding or injection, and for post-treatment cultures, the organ can be dissected out or cultured in artificial medium, or the animals can be reared in cages with natural feeding. In tissue cultures, colchicine is generally added to the

medium (for details, please see chapters on tissue culture and mammalian chromosomes).

For physical agents such as x-rays, ultraviolet rays, etc., both plant and animal materials are placed in front of the source and the required dosage is applied, the subsequent process of culture being the same as that with chemical agents. The exact purposes for which physical and chemical agents are applied, and an outline of the methods of their application, are given below.

CHEMICAL AGENTS

Metaphase arrest

In the majority of plant and animal materials, the nuclear division within the different cells is not synchronous, with the result that the meristematic or the dividing zone represents a heterogeneous mass of cells, in which the nuclei are at different stages of division. The difficulty of such a medium is twofold: (a) metaphase stages—the best nuclear phase for chromosome analysis—cannot be obtained in high frequency, and (b) with regard to the analysis of an effect, the exact stage affected cannot be ascertained. A large number of cells, showing induced synchrony in division, is therefore necessary. This aspect of induced synchrony has been dealt with in detail by Zeuthen (1964) and Padilla and Cameron (1968).

The most suitable chemical for the purpose of securing a large number of metaphase plates is colchicine as it causes metaphase arrest by inhibiting the operation of the spindle mechanism; the principle underlying spindle arrest being outlined in the chapter on pre-treatment (Chapter 2). To secure metaphase arrest, the organs can be treated directly with aqueous colchicine solution for a required period, being added to the medium in tissue culture or injected into tissue or added to the food, which has been described in Chapter 11 on mammalian chromosomes. Its property of arresting the metaphase has made it an essential prerequisite for procedures on cell synchronisation. Before harvesting the cells in leucocyte cultures, the addition of colchicine or colcemid is essential for securing a large number of metaphase plates. The concentration needed to secure this effect may vary from a very dilute concentration, 0.01 per cent, to even 2 per cent, and the period of treatment from 10 min to 16 h in some amoeba materials. The mitotic stage, at which colchicine is effective at very low concentrations, is late prophase (Eigsti and Dustin, 1957; also Deysson, 1968; Wagner, 1969). In *Allium cepa*, spindle in root tips can be arrested by just $1\frac{1}{2}$ h treatment in 0.2 per cent colchicine solution, but before fixation and observation, a thorough washing in water for at least 15–20 min is necessary to remove any superficial deposits of this alkaloid, which may hamper staining. In leucocyte cultures, application of colchicine 10–20 h before harvesting, is desirable. The characteristic appearance of metaphase stages, showing clear euchromatid segments, is otherwise known as colchicine-mitosis or *c*-mitosis.

In addition to colchicine, a number of other compounds such as gammexane, chloral hydrate, acenaphthene, actidione, etc., are all applied for metaphase arrest. Their mode of action and effect on viscosity have also been

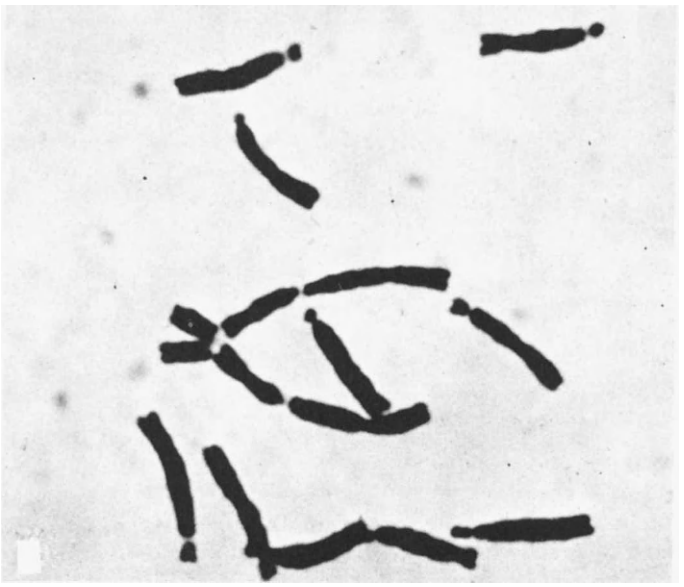

Plate 15.2
Localised chromosome exchange induced by hydroxyurea in Vicia faba (courtesy of Prof. B. A. Kihlman)

worked out in detail (Sharma and Chaudhuri, 1961; Sharma and Bhattacharyya, 1962; Sharma and Sarkar, 1963; Sharma and Talukder, 1965; Sharma and Ghosh, S., 1969). The efficacy of colchicine is markedly superior to that of the others. The effective concentrations of these chemicals are given in *Table 2.1* (page 26).

Polyploidy

The importance of polyploidy in agricultural and horticultural practices is well known. The increase in gene dosage resulting from multiplication of chromosome sets brings about giganticism in all characters in general. Enhancement of tolerance and adaptability are also added characteristics of polyploids. Moreover several interspecific and intergeneric crosses have been made fertile through polyploidy. All these facts taken together have made the induction of polyploidy an effective tool in the hands of agriculturists and horticulturists (*see* Gottschalk, 1978).

The properties of arresting metaphase and the induction of polyploidy are inter-related. Polyploidising chemicals like colchicine inhibit the formation of the spindle within the two poles and confine the chromosomes within one nucleus though their division remains unhampered. Levan (1949) has classified colchicine action under narcosis, as the narcotic action allows the tissue to recover as soon as the influence of the chemical is removed. Evidently

polyploid cells, which are formed by colchicine action, divide normally and give rise to polyploid shoots.

As an agent for inducing polyploidy, colchicine is more active in plants than in animals, though reports of animal polyploids, induced through colchicine, are available. Colchicine is applied in the following ways.

On seeds and young seedlings

The seeds may be immersed for 2–48 h in concentrations of colchicine solution varying from 0.02–0.1 per cent before sowing. Just-germinating seeds can be treated with similar concentrations of colchicine solution for 12–48 h with the plumules dipped in the solution, or the entire germinating seedling can be immersed completely in colchicine solution, but the former method is preferable as the root system remains unaffected, allowing the plant to grow normally.

On mature seedlings

(1) Colchicine is added in the form of soaked cotton plugs on the growing shoot, the period of treatment varying from 2–4 h, and the range of concentrations used being the same as given in the previous schedule. Cotton plugs, placed over the growing tip, should, however, be moistened at regular intervals by adding drops of colchicine solution with a brush, and after the treatment, the plug should be removed and the tip washed by brushing with water. The same method can be followed for treating young inflorescences.

(2) In the form of a paste mixed with lanolin or with glycerin. This method has been found to be effective where the growing point lies within the plumules, as in monocotyledonous plants.

On pollen grains and animal tissues in culture

Colchicine may be added in the agar medium meant for pollen tube growth (2 ml of 0.2 per cent colchicine in 8 ml of agar medium or in culture medium for other tissues, as described in the chapter on mammalian chromosomes). Other chemicals such as chloral hydrate, gammexane and acenaphthene, which cause metaphase arrest, can also be applied for the induction of polyploidy. In the authors' laboratory, 0.5 per cent caffeine solution in water has been found to be very effective, especially in leguminous plants, but in the present state of knowledge, for commercial purposes it is always safe to rely on colchicine.

After the induction of polyploidy, especially in seeds or seedlings, there are different methods by which success or failure of the experiment can be detected before the plant reaches maturity and starts blooming. These are:

(1) The chromosome number of young shoots, leaf tips and root tips can be counted, following acetic–orcein or Feulgen squash (for technique, *see* Chapter 7), but it is preferable not to rely too much on the chromosome counts from root tips, as polyploid cells, though present in roots, may be eliminated from the shoot apex.

(2) In case of scarcity of materials, where only one or two samples from their external appearance appear to have been polyploidised, it is

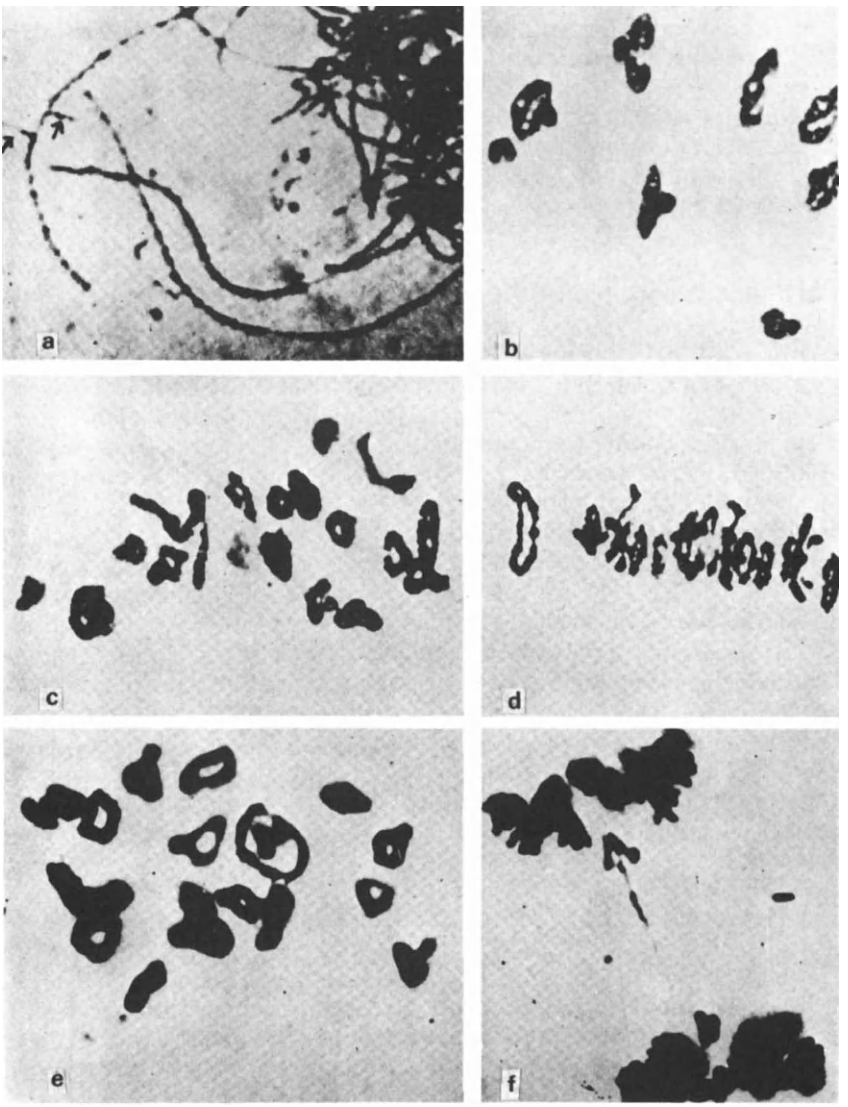

Plate 15.3

S. Swaminathan and the Editor, *Stain Technology*)

desirable not to remove the shoot apex or injure roots for chromosome counting but to study the anatomical characteristics from a portion of the mature leaf to obtain an indication of the success of the experiment. In general, it has been found that polyploidy is associated with an increase in stomatal size and decrease in stomatal frequency per unit area of the leaf, so the lower epidermis of the mature leaf of the polyploid can be peeled off and mounted in 50 per cent glycerin solution. Stomatal size and frequency per unit area can be noted and the result can then be compared with that of diploids obtained following a similar procedure adopted for a control diploid plant. Post-treatment with x-rays of colchicine-treated plants results in better survival of polyploids as x-rays are more effective against diploid cells, causing them to be eliminated in selection.

Chromosome fragmentation and other effects

The capacity of inducing chromosome breakage is a property of several chemical agents. The study of chromosome breakage is beset with immense possibilities. Firstly, fragmentation followed by translocation of some fragments may bring about a new patterning of chromosome segments resulting in heritable phenotypic difference. Its importance in the evolution of new species and desirable varieties is obvious. Secondly, the chromosome breaking property of chemicals has an important bearing on the chemotherapy of cancer. Incidentally it may be mentioned that the biological basis of the radiation treatment of cancer is the induction of extensive fragmentation of chromosomes which ultimately leads to the cessation of nuclear division. As some chemical agents, which are otherwise known as radiomimetic chemicals (simulating radiation effects), are endowed with the same property, their application in cancer therapy needs no elucidation. The bactericidal effect of ultraviolet rays is also well known.

Lastly, the study of chromosome fragmentation by chemicals has a special significance in bringing out the differential nature of chromosome segments. Several chemical agents such as 8–ethoxy caffeine induce chromosome breaks at certain specific loci (Kihlman, 1966). This differential break can be taken as an index of the different chemical nature of susceptible segments from the rest of the chromosome parts (*see* Sharma and Sarkar, 1963; Sharma and Sharma, 1964).

The modes of action of different chemical agents causing chromosome breaks vary. Some of them affect sulphydryl groups of proteins whereas others act through their influence on hydrogen bonds of nucleic acids. Guanidine cross linkages are held to be involved with mustard compounds. Some agents may affect the oxidation–reduction system within the nucleus. The relationship between deoxyribonucleotide synthesis and chromosome breakage has been discussed in detail by Kihlmam (1964, 1971; also *see* Taylor, 1963). Kaufmann, Gay and McDonald (1960) suggested that localised chromosome breakage in constriction segments of *Vicia faba* by maleic hydrazide (McLeish, 1953) may be due to some specific reaction with RNA. Taylor, Haut and Tung (1962) noted the effect of fluorodeoxyuridine on chromosome breakage and reunion. Maleic hydrazide (1,2, dihydro-3,6-pyridazinedione) may interfere with the RNA ratio to such an extent that

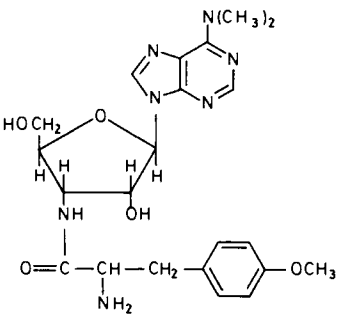
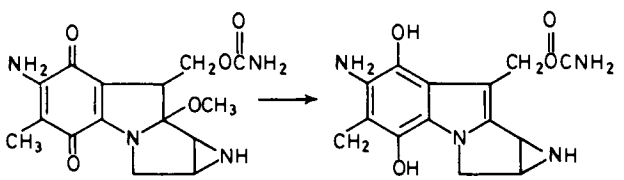
Streptomycin



Puromycin

breakage occurs in segments involved in its metabolism (*see also* Evans and Bigger, 1961; Evans, 1962). Sharma and Sharma (1960) reviewed the different theories in detail and suggested that the final upset of the nucleic acid metabolism ultimately results in hazards in protein re-duplication causing chromosomes to break at different loci. The effects of different chemical agents and their modes of action have been dealt with in detail by several workers (Sharma, Chaudhuri and Chakraborti, 1963; Bell and Wolf, 1964; Sharma and Chatterji, 1964; Lawley and Brookes, 1965; Michaelis, Schoneich and Rieger, 1965; Rao and Natarajan, 1965; Sharma and Ghosh, 1965, 1969; Adams, Abrams and Lieberman, 1966; Kihlman, 1966, 1971; Rasmussen and Painter, 1966; Turner, Abrams and Lieberman, 1966; Adams and Lindsay, 1967; Glass and Marquard, 1967; Ito *et al.*, 1967; Young *et al.*, 1967; Zimmerman and Schwaier, 1967; Kihlman and Hartley, 1968; Moutschen *et al.*, 1966, 1968; Wagner *et al.*, 1968; Drake, 1969; Alam, Corbeil and Chagnon, 1974; Ashwood-Smith and Grant, 1976). From our laboratory,



Mitomycin C Activated form

Nandi (1969) studied the effects of several carcinogens on plant cells. Several plant products, such as, pigments (Sharma and Gupta, 1959; Sharma and Chaudhuri, 1963; Sharma and Sarkar, 1967); oils (Swaminathan and Natarajan, 1957) as well as alkaloids (*see* Deysson, 1968), which may even add to the soil mutagenicity, have been shown to influence chromosome breakage. Viral and bacterial infections as well as some proteolytic enzymes (De and Maity, 1975), have also been observed to affect chromosome breakage and other irregularities (*see* Halkka, 1967).

A number of antibiotics, cycloheximide and cyclic AMP with a profound influence on the replication of DNA, transcription and protein synthesis (Collins, 1965; Gautsch, Young and Cleaver, 1973; Korinek, Spelsberg and Mitchell, 1973; Sobell, 1974), have been widely used in the study of the structure and behaviour of chromosomes. These compounds were originally tried out on bacteria and the knowledge gained thereby has frequently been applied on higher organisms, especially in cancer research. In view of their wide applicability, a short account of their properties is given here. Several other antibiotics have also been applied but their mode of action is not yet clear (Sharma and Bhattacharyya, 1967).

Mitomycin C

Hata *et al* (1956) studied its anti-tumour action. It inhibits DNA replication but transcription is not affected for a certain period (Smith–Kielland, 1964). It acts possibly by linking two polynucleotide strands of DNA (Iyer and Szybalski, 1963; Pricer and Weissback, 1964). On activation, a mitomycin C molecule loses a methanol (Schwartz, 1962) and the ethylamine group acts as an alkylating agent, linking it with one of the DNA strands.

Actinomycin D

This cytostatic and anti-tumour compound checks transcription but allows replication of DNA to continue for a certain period (*see* Kirk, 1960; Reich *et al.*, 1962). It is supposed to form a reversible complex with double-stranded DNA (Haselkorn, 1964; Reich, 1964; Sobell, 1974). Of all the antibiotics affecting chromosome behaviour, actinomycin D has been most widely employed, both in plants and animals. It has been found to be effective even for the suppression of meiosis (Jain and Singh, 1967).

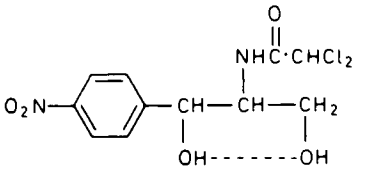
Streptomycin

Protein synthesis is checked by this antibiotic, possibly by hampering the transfer of amino acids from transfer RNA to the growing polypeptides (Mager, Benedict and Artman, 1962; *see* Kogut and Lightbown, 1964). Davies, Gilbert and Gorini (1964) indicated that cell lethality occurs because of gross misreading of the messenger RNA, resulting in non-functional proteins.

Puromycin

This chemical, which is similar to streptomycin, also hampers protein synthesis and interferes in the transfer of amino acids to the growing

polypeptide. It is considered to act as an analogue of amino-acyl t-RNA, due to the similarity between the two (Yarmolinsky and Haba, 1959 and *see* Darken, 1964). In fact, it has been detected attached to the released polypeptide in *E. coli* cells treated with puromycin (Nathans, 1964).



Chloramphenicol

Chloramphenicol

The inhibition of protein synthesis by this compound is affected through action at the ribosomal level. It has been claimed that the binding may be at the same location as puromycin but it checks the binding of the messenger RNA and not that of the transfer RNA (Rendi and Ochoa, 1962; Gale, 1963; Brock, 1964; Jardetzky and Julian, 1964; Kucan and Lipmann, 1964; Traut and Monro, 1964; Vazkuez, 1964).

Chemical agents that can cause chromosome breaks are listed in *Table 15.3*. Two methods are outlined below, one for the demonstration of random breakage and the other for localised breakage.

Schedule of treatment

For random breakage

(1) Place a healthy bulb of *Allium cepa*, with root tip intact, on top of a jar containing 0.005 m/l solution of pyrogallol. Keep the jar in a temperature of 25–30 °C.
(2) After 4 h, cut a few roots, fix in acetic–ethanol mixture (1 : 2) for 30 min, and follow the usual method of orcein squashing or Feulgen staining for root tips. Mount in 1 per cent acetic–orcein solution or 45 per cent acetic acid and count the number of random fragments in metaphase and anaphase stages.
(3) Continue the treatment of roots in pyrogallol solution up to 24 h and observe at regular intervals to study the increase or decrease in the frequency of fragments.

For localised breakage

(1) Place germinated seeds of *Vicia faba* on a sieve fixed over a jar containing 0.075 M 8-ethoxycaffeine solution, in such a way that the roots passing through the sieve remain dipped in EOC solution. Continue the treatment for 6 h at 10 °C.

(2) Allow the roots to recover in tap water at 20 °C for 24 and 48 h.
(3) Cut the root tips and follow the same schedule for observation as in (2) for random breakage.

In the study of the effect of chemical agents on chromosomes, the technique employed for observation should be taken special care of, due to the fact that chromosome breaks may result during slightly prolonged heating with acetic–orcein–HCl mixture (Sharma and Roy, 1956), which is an essential step in the procedure for orcein squashing. Similarly, chromosome breaks have also been observed through mere water treatment by Sharma and Sen (1954). The schedules for the demonstration of chromosome breakage by acetic–orcein and water are outlined below (*see* also chapter on stain).

Schedule for demonstration of orcein breakage

(1) Treat excised root tips of onion in 0.002 M solution of 8–oxyquinoline for 2 h at 16–18 °C.
(2) Fix in acetic–ethanol (1 : 2) for 30 min.
(3) Heat the root tips gently over a flame in a mixture of 2 per cent acetic–orcein and normal hydrochloric acid mixed in the proportion of 9 : 1 for 30 s.
(4) After a few minutes, mount and squash in 1 per cent acetic–orcein and observe.

Fragments can be observed in metaphase and anaphase stages, but if the heating is prolonged for a few seconds more, the frequency of fragments shows an increase. High frequency of fragments can also be obtained if acetic–ethanol fixation is omitted. In view of the above results, it is always desirable to keep a check on the period of heating, not exceeding 10 s in the procedure for orcein staining.

This schedule may be applied to animal tissues as well.

Schedule for the demonstration of chromosome breakage induced by water treatment

(1) Treat young healthy roots of *Crinum asiaticum* in tap water at 30 °C for 2 h.
(2) Follow the usual procedure of fixation and orcein staining. Fragments can be detected both in metaphase and anaphase.

In the study of the effect of chemical agents on chromosomes, a control experiment should be set up with water treatment alone in cases where water is used as the solvent of the chemical agent.

Detailed reviews are available on the modes of application and effects of chemical mutagens on living systems, particularly animals (*see* Hollaender, 1976; Hollstein and McCann, 1979).

Division in differentiated nuclei

Division in adult nuclei, when otherwise the nuclei have ceased to undergo apparent division, can also be induced with the aid of chemical agents. The importance of this line of investigation was realised after the demonstration of the endopolyploid constitution of differentiated nuclei by Huskins (1947), Huskins and Steinitz (1948), and Geitler (1948). Until these works were published, the mechanism of differentiation which is principally operative in adult cells was supposed to be obscure. It is well known that gene action is controlled by specific enzymes, the synthesis of which is again dependent on genes. Manifestation of a trait is the ultimate result of a series of chemical reactions, set up initially at the gene level, and every step in this metabolic path requires the presence of enzymes. If differentiation, which involves the manifestation of diverse characters, is a process controlled by genes, then the latter, it was thought, must reduplicate in adult nuclei for the synthesis of specific enzymes. However, as the nuclei and, consequently, chromosomes of the adult cells do not show any apparent division, the extent to which genes influence the process of differentiation remains questionable. The above-mentioned authors implied that gene action and duplication are interrelated.

The above authors first claimed that the adult nuclei, though apparently non-dividing, undergo endomitotic re-duplication of the chromonemata, thus exerting control over the process of differentiation: normally they lie in a polytenic condition. Huskins and Steinitz (1948), with the aid of a special technique using hormones, as outlined later, induced division in the adult nuclei, thus permitting the chromosomes to complete the nuclear cycle; during this division their polytenic and polyploid constitution was revealed. Afterwards other chemicals were worked out having the same property (D'Amato, 1952). Sharma and Sen (1954) induced division in such cells by nucleic acid treatment, while Sharma and Mookerjea (1954) demonstrated that of the nucleic acid, the sugar constituent alone can induce division, and claimed that the polytenic condition of the adult nuclei is due to deficiency in nucleic acid. Later, other compounds were also shown to induce division (Sharma and Bhattacharyya, 1956; Sharma and Datta, 1956). Even the effect of irradiation on adult nuclei has been studied (Sharma and Mukherjee, 1965). Torrey (1961) used a different method which involves the use of kinetin (6-furfuryl-amino-purine) for the induction of division in endomitotic plant cells. A considerable amount of work has been carried out in our own laboratory on the induction of division in adult nuclei. With the aid of 2,4-dichlorophenoxyacetate as well as indolylacetic acid, division could be induced even in the vascular zone (Sen, 1970). Both diploid and polyploid nuclei have been recorded within the differentiated zone. The occurrence of diploid chromosome numbers in adult nuclei in the differentiated zone can easily be explained on the basis of the fact that transcription of RNA responsible for gene action does not depend on replication of DNA, and one strand of DNA is active in this respect. But the occurrence of polyteny may possibly suggest that there is a limit for continued transcription of a strand after which replication is necessary for the production of a fresh strand to be used in transcription (Sharma, 1978).

The chromosomal control of differentiation has been well illustrated in the puffing pattern in salivary gland chromosomes of diptera at different phases of development. Excellent reviews on this aspect of differentiation have been published by different authors (Pavan, 1965; Schultz, 1965; Stebbins, 1965; Clever, 1965; Nescovic, 1968; Padilla and Cameron, 1968; Pavan and Da Cunha, 1969).

Schedule for the induction of division in differentiated nuclei

(1) Take cuttings or seedlings of *Rhoeo discolor* and remove all the roots.
(2) Allow them to grow in jars containing the following culture solution:

	mg/l		*mg/l*
$Ca(NO_3)_2.4H_2O$	95	Mn	0.5
NH_4NO_3	129	Cl	1.9
$MgSO_4.7H_2O$	180	B	0.5
KH_2PO_4	133.5	Cu	0.02
$K_2HPO_4.3H_2O$	7.35	Zn	0.01
$Fe_2(C_4H_4O_6).H_2O$	5.0		

Use distilled water and adjust the pH to 5.7. Fix the cuttings in such a way that a portion of the stem dips in water. Cover the jar with black paper and keep in a temperature of 22–24 °C. Keep the materials in the jar until freshly generated roots, 3–10 cm long, are obtained.
(3) Transfer the materials to a similar jar containing 50–100 ppm indole-3-acetic acid and keep for 24–72 h.
(4) Re-transfer the materials to fresh culture as in (2) and keep for a maximum of 72 h.
(5) Take out the materials after every 24 h. Remove about 4 mm from the root tip, which is meristematic, then cut 1–2 mm.
(6) Follow the usual procedure for fixation in acetic–ethanol and orcein squash technique for root tips.

Polyploid cells can be seen in metaphase in the differentiated region.

Control preparations should be set up allowing the roots to grow in culture solution, in which no division will be found in the similar zone of the root tip.

The properties of different cytokinins have been dealt with by Srivastava (1967).

Somatic reduction

The possibility of the occurrence of reductional separation of chromosomes (Metz, 1926; Hughes-Schrader, 1927; Berger, 1938; Christoff and Christoff, 1948) and its experimental induction (Nemec, 1904) in tissues, other than the gonadal ones, though pointed out by different authors, did not receive serious consideration until Huskins (1947) demonstrated the process on slides prepared by his associates and by Kodani. He claimed that by treatment with sodium nucleate, reductional separation of chromosomes can be initiated in root-tip cells. The significance of this finding from both the technical

and theoretical points of view was immense because of its direct bearing on the Precocity Theory of Darlington (1937), in which synapsis and reductional separation of chromosomes are held to be initiated because of the single-thread nature of chromosomes in early prophase of meiosis.

The objection to the technique of Huskins that observations based on squash preparation may show artificial separation of chromosomes has also been overruled, as similar behaviour has been observed in sectioned materials as well. Since the work of Huskins was published, reports of somatic reduction in plants have emanated from different centres, including the author's laboratory, where both induced and spontaneous occurrence has been observed (Sharma and Bhattacharjee, 1953). Spontaneous occurrence has also been reported in sea urchin embryo by Lindahl (1953). However, there is no universal evidence yet available that somatic reduction in plants, though occurring rarely, is associated also with interchange of segments. In *Haplopappus* species in culture, such pairing has been recorded (Mitra and Steward, 1961).

Somatic reduction, through treatment with sodium salts of ribose nucleic acid, evidently suggests that the balance of the nucleic acid within the cell is at least one of the principal controlling factors of mitosis and meiosis. The induction may therefore be considered as based on the principle that increase in the proportion of RNA, by its direct application or by application of certain factors which may enhance its synthesis, may cause somatic reduction. Huskins and Cheng (1950) induced reduction by low temperature treatment, and though no method has yet been standardised for this, the original method is now given, which may help in its further refinements.

Schedule of treatment for the induction of somatic reduction

(1) Take a healthy young bulb of *Allium cepa* (onion), denude it of roots and let it grow in a jar containing tap water until a fresh crop of roots germinates.
(2) When the roots are just 2–3 mm long, fit the bulb on top of a jar containing 0.1–0.2 per cent sodium nucleate solution in water. Sodium nucleate supplied by Schwartz Laboratories, Inc., New York (S.N.4509), yields good results. Place the bulbs in such a way that the roots dip into the sodium nucleate solution. Treat the bulbs for 6–12 h.
(3) Cut the tip portion of the root (meristematic region) and follow the usual method of fixation and Feulgen or orcein squashing.

Reductional separation of chromosomes can be observed in a few per cent of the cells. Each chromosome unit with two chromatids intact moves as it is to either of the poles, so that the distribution of 16 chromosomes is equally divided between the two poles, i.e. eight at each (Huskins and Cheng, 1950). For inducing somatic reduction through temperature treatments, onion bulbs may be kept growing in tap water at 5–6 °C for 5–64 days. At every seven or eight day interval, healthy young root tips may be fixed, stained and observed after the usual procedure. In all cases of reductional grouping in somatic cells, it is preferable to confirm the observation from materials sectioned from paraffin blocks.

PHYSICAL AGENTS

Principle

X-rays are at present employed for effectively altering chromosome structure, both at microscopic and ultramicroscopic levels. In addition, other types of radiations are used, such as α-rays, β-rays, γ-rays, fast neutrons, ultraviolet and infrared rays. The biological action of these agents depends on their ionising and non-ionising properties, and as such they are classified under two categories, ionising and non-ionising rays. The term 'ionisation' implies the conversion of an atom into an ion. An atom consists, as is well known, of a positively charged nucleus surrounded by negatively charged electrons, the charges being so balanced as to maintain an electrically neutral state. Ionising radiations dissipate energy during their passage through matter, by ejecting electrons from the atom through which they pass. The ionised atom, losing the negative balance, becomes positively charged and is known as an ion. The result of ionisation is a chemical change of the molecule concerned. Whenever a binding electron between the two molecules is affected, serious after-effects ensue.

Non-ionising radiations, such as ultraviolet rays, infrared rays, etc., cause dissipation of energy within the tissue by molecular excitation, the principal biological action being attributed to the absorption of energy by particular cellular constituents, the most important one being nucleic acid. The recent works on the chemical basis of ultraviolet action have been discussed later.

Effect and scope

The production of gene mutation is no doubt one of the most important uses of the physical agents. In Darlington's words, 'One can compress a millennium of variation within a few seconds'. In addition to gene mutation, fragmentation of chromosomes is another outstanding effect of these agents, and as such breakage may involve both the chromatids of the chromosome or a single chromatid, depending on the stage in which the nucleus has received the radiation. When the chromosome is already split, either one or both chromatids may break, depending on the path of the rays (for details, *see* Lea, 1955), the breaks being either immediate or delayed (Davidson, 1958). The subsequent effects of chromosome breakage are translocation, deletion, inversion, rejoining as well as stickiness, pyknosis and polyploidy, and can all be studied in treated materials.

Radiation in the production of useful mutations in plants was reviewed elaborately by Gustafsson (1954), Singleton and colleagues (1956) and Smith (1958). A prominent case of translocation in barley, induced by x-rays, was demonstrated by Tjio and Hågberg (1951). The comparative effects of radiation and hybridisation in plant breeding have been assessed by Gregory (1956), Gaul (1967) and Swaminathan (1969).

Another important use of x-rays in agriculture and horticulture is the experimental induction of parthenogenesis. If a species is pollinated with irradiated pollen, haploid plants may result through parthenogenesis. The best examples are *Triticum*, *Nicotiana*, etc. (Kihara and Yamashita, 1938;

Smith, 1946). Effects of cosmic rays in plants were studied by Nizam (1969).

The importance of irradiation, either through x-rays or other agents, in working out the time of chromosome reproduction as well as the structure of chromosomes, has been amply realised (*see* review by Taylor, 1962). Results of radiation breaks are considered as good indices of timing of chromosome reproduction. Treatment, followed by a study of the successive cycles and the scoring of chromosome or half-chromatid aberrations, provides significant clues in this direction and aids the understanding of the effects occurring at G_1, S and G_2 phases.

In animals and human beings the most important use of x-ray is its application in the treatment of cancer. The production of excessive chromosome breaks, followed by the loss of acentric fragments into the cytoplasm, thus causing a disturbance leading to the death of the cell, forms the biological basis of radiation treatment of tumours. The smear technique in cytology has considerably helped not only the diagnosis of malignancy in tumours but also the discovery of the actual dose of x-rays needed for its cure or prevention.

To meet all the above problems, methods have been devised for the application of different physical agents under different conditions on the chromosomes, but before undertaking any work on the effects of physical agents on chromosomes certain factors, which control their sensitivity, should be considered.

Regarding the different factors, it has been found that x-irradiation is more dependent on environmental factors than other types of radiation, especially the thermal-neutron radiation. Four important factors of the organism itself have to be taken into account, namely, its genotype, age of the tissue, divisional stage receiving the radiation and number of chromosomes. Species, or even strains of the same species, vary with regard to their response to irradiation (Lamprecht, 1956; *see* Smith, 1958; Sharma and Chatterji, 1962; Sharma and Chatterjee, 1963). Aged seeds are more susceptible (Nilan, 1956). Evidence so far gathered also indicates that meiotic cells are more sensitive than mitotic ones (Sparrow and Singleton, 1953). Sparrow (1951) observed that late prophase to metaphase is the most susceptible stage with regard to chromosome breakage. Fox (1966) studied the effect of x-rays on embryos. Polyploids are more resistant to a majority of physical agents as compared with diploids (MacKay, 1954). Heterochromatic segments may be more susceptible to x-rays as compared to euchromatin (Keyl, 1956; Bhattacharyya, 1958). Randomness of x-ray break has been noted by different authors (*see* Heddle, 1965). With regard to environmental factors, the most important ones are moisture content, oxygen concentration and temperature, and in most cases, an increase in moisture content and oxygen concentration accelerates the response (Nilan, 1956; Sharma and Talukder, 1964). Similarly, an increase in temperature has an accelerating effect on chromosome breakage during irradiation (Nybom and colleagues, 1953; *see* Evans and Sparrow, 1961; Konzak *et al.*, 1961; Riley and Miller, 1966; Wolff, 1967). The comparative action of different rays and chemicals has also been dealt with by different authors (*see* Ghosh and Sharma, 1968). The importance of nucleic acid and protein in the manifestation of chromosome breaks has also been studied (Sharma and Sharma, 1960, 1961, 1962, 1964).

Mode of action

Regarding the mode of action of the physical agents, particularly the x-rays, opinions differ, but on the basis of the target theory, the x-rays affect the chromosomes directly, without the intervention of any intermediaries (Lea, 1955). Upholders of the chemical theory hold that the x-ray effect on chromosomes is indirect and is principally conveyed through the cytoplasm (Koller, 1948). Some evidence, including the similar effects of radiomimetic chemicals, oxygen, etc., points to the plausibility of the chemical theory. The dissociation of water molecules into H and OH ions by x-rays and the later formation of HO_2 or H_2O_2 are considered to be the main effects of x-rays, these chemicals ultimately bringing about chromosome breakage (Nilan, 1956). X-rays have also been thought to affect the hydrogen-binding of nucleic acids (Butler, 1954) or $-SH$ groups of proteins (Dustin, 1949). Extensive reviews on this aspect are available (Moutschen, 1967; Drake, 1969, Gottschalk, 1979).

In explaining the effects of ultraviolet rays, it is suggested that the linkage between adenine and thymine undergoes a breakage and two adjacent thymines of a single strand of the nucleic acid undergo union, forming a thymine dimer, which causes difficulty in replication and chromosome breakage (*see* Setlow and Carrier, 1964; Hanawalt and Haynes, 1967). If the organisms are brought to light, there is photoreactivation of the repair enzyme complex and the frequency of the effects decreases (*see* Setlow, 1968; Witkin, 1969).

Research on this aspect, carried out in this laboratory (Sen, Golechha and Sharma, 1967; Sen, 1969), has shown that histone acts as repressor for the repair complex and the digestion of histone accelerates the ultraviolet-induced breaks.

Schedules for treatment with different types of agents

X-rays

Apparatus
Consists in the simplest form of an x-ray tube with attached rectifier, transformer, control and dosimeter.

Dosage and period
Depends on the material, the stage of development, and the purpose of the treatment. For an entirely new material, the dosage and time should be fixed by a series of trials with different dosages combined with different periods of time.

Application on plant materials

Seeds
Place dry seeds, spread in a single row, in a petri dish. Expose to x-rays at 30 000 R. Germinate in moist sawdust. Remove root tips when about 1 cm

long, treat in acetic–ethanol mixture (1:3) for 30 min and squash following orcein or Feulgen schedule. If soaked in water before irradiation, the effect is usually greater and may become drastic.

Seedlings and bulbs with root tips
Place young seedlings on a petri dish with their radicles pointing in the same direction. For bulbs, take healthy ones with a tuft of healthy roots about 2 cm long and place them with the root tips facing the source. Expose to x-rays for the desired period. Transfer them to sawdust or to nutrient medium, as the case may be. For immediate effect, remove root tips at regular intervals of an hour, fix for 30 min in acetic–ethanol (1:3), followed by staining by Feulgen or orcein squash methods. For prolonged effect, study the root tips similarly at intervals of 24 h.

Inflorescences
Grow the plants in flower-pots. Expose the young inflorescences to x-rays by bending them to face the source. For immediate effect, select a flower bud of suitable size and observe the pollen mother cells after smearing in acetic–carmine solution. Allow the inflorescence to develop and observe meiotic stages at intervals of 24 h. Endosperm and pollen grain mitosis can be studied in a similar manner.

In tissue culture, different agents have been tried on tissues growing in culture.

Application on animal materials

For small animals
Place the animals to be irradiated inside a tube and expose to the x-rays. Transfer them to their normal conditions. At regular intervals, dissect out the gonads in a drop of Ringer's solution, stain with acetic–carmine and observe.

Other ionising rays

Alpha rays
The sources of α-rays are certain radioactive elements like radon and polonium. The rays are formed of particles having a low penetration and a high ion density. They may be used on both root tips and inflorescences of plants.

Beta rays
The radiation emitted is formed of charged particles with low penetration. They can be obtained from special generators and applied in the same way as x-rays. Alternatively, radioisotopes like ^{3}H, ^{32}P, ^{14}C, etc., also emit β-particles (Cronkite *et al.*, 1959). The material can be treated by immersion in or injection with a known quantity of radioiosotope solution of accepted

concentration. The isotope can also be applied in known quantities in the food or tagged with certain essential constituents of nucleic acid and protein, thymidine, uridine (for RNA), different amino acids, etc.

Gamma rays

Gamma rays are obtained as electromagnetic radiations either from radium itself or from the isotope ^{60}Co. The material can be exposed to these rays by placing it within a ^{60}Co field for known periods. The rays are more penetrating. The material can be fixed and stained as usual for observation.

Table 15.1 Effects of radiation resulting in chromosome breakage in some animal tissue

Radiation	*Material used*	*Effective dosage*	*Author*
(1) Beta rays	*Drosophila*, larva	^{32}P in food at 1 mg per fly approx. 1000 nm approx. 72, 144 and 216 h preceded and followed by 2000R x-rays	Bateman and Sinclair, 1950
(2) Near infrared	*Drosophila*, sperm	1000 nm approx. before and after 3000R x-rays	Kaufmann and Gay, 1947
(3) Neutrons	*Drosophila*, whole fly, male	Different dosages	Giles, 1943
(4) X-rays	*Drosophila*, whole fly	1000–5000R	Müller, 1940; Kaufmann, 1946
	Drosophila, egg	500R, 105R	Ulrich, 1957
	Drosophila, embryo	5000R	Geyer-Duszynzka, 1955
	Locusta, testes	500R approx.	White, 1935
	Chortophaga, embryo	4–8000R	Carlson, Harrington and Gaulden, 1953; Carlson and Harrington, 1955

Other radiations

Other radiations like fast neutrons can be obtained from special generators or from cyclotrons or atomic piles.

Non-ionising radiations

Ultraviolet rays

The apparatus consists, in simpler forms, of a mercury lamp or a quartz mercury arc in conjunction with a monochromator.

The method of treating the material, both plant and animal, is similar to that followed with x-rays. Bajer and Molé Bajer (1961) irradiated endosperm chromosomes during division with ultraviolet rays with microbeam apparatus constructed by Uretz and Perry (1955), the ultraviolet source being a mercury green lamp (*see also* Chapter 9 on ultraviolet microscopy).

Table 15.2 Effects of radiation resulting in chromosome breakage in some plant tissue

Radiation	*Material*	*Dosage*	*Author*
(1) Alpha rays	*Tradescantia*, pollen tube	Different dosages	Catcheside and Lea, 1943
	Tradescantia, pollen grain	Inflorescence treated in radon solution	Kotval and Gray, 1947
	Vicia faba, root tips	Treated in radon solution, 7–8 units	Thoday and Read, 1947
(2) Beta rays	*Tradescantia*, pollen grain	^{32}P plaque, externally	Kirby-Smith and Daniels, 1953
	Tradescantia, anthers	(a) ^{14}C from ammonium carbonate at 0.9–8.2 μCi/ml for 4–8 days	Kirby-Smith and Daniels, 1953
		(b) ^{32}P from sodium hydrogen phosphate at 1–10 μCi/ml for 1–9 days	Giles and Bolomey, 1948
		(c) ^{3}H-thymidine 1 μCi/ml for 8–56 h	Wimber, 1959
(3) Gamma rays	*Tradescantia*, pollen grain	(a) 5/min for 100–2000 min	Koller, 1953
		(b) ^{60}Co. 100–400R	Kirby-Smith and Daniels, 1953
		(c) ^{60}Co: 1.1–1.3 MeV in air and nitrogen	Swanson, 1955
(4) Near infra-red	*Tradescantia*, pollen grain	(a) 1000 nm approx. for 3 h before and after 107R x-rays	Swanson, 1949
		(b) 1000R approx. for 3 h before and after 90 and 350R x-rays	Yost, 1951
	Tradescantia, meiosis	1000 nm approx. for 3 h	Snoad, 1955
(5) Neutrons	*Tradescantia*, pollen grains	Different dosages	Thoday, 1942
(6) Ultraviolet	*Tradescantia*, pollen tube	(a) 254 nm at 2×10^{-3} ergs/mm^2 for 60 s	Swanson, 1943
		(b) 253.7 nm before and after x-rays	Swanson, 1944
	Zea mays, pollen grain	253.7 nm at 546 000 ergs/cm^2	Fabergé, 1955
(7) X-rays	*Hyacinthus*, root tip	150–1000R	La Cour, 1956
	Lilium, p.m.c.	150R	Sauerland, 1956
	Scilla, endosperm	50R	La Cour and Rutishauser, 1954
	Tradescantia, p.m.c.	18R and 360R	Haque, 1953
	Tradescantia, anther	150R	Sax, 1938
	Tradescantia, pollen grain early	(a) 360R	Darlington and La Cour, 1945
		(b) 30–300R	Lane, 1951; Sax, King and Luippold, 1955
	Tradescantia, pollen grain late	180R, 250R	Catcheside and Lea, 1943; Bishop, 1954

Radiation	*Material*	*Dosage*	*Author*
	Trillium, root tip	5–45R	Darlington and La Cour, 1945
	Trillium, p.m.c.	50R	Sparrow, Moses and Dubow, 1952
	Trillium, pollen grain	45–375R	Darlington and La Cour, 1945
	Uvularia, p.m.c.	90R	Darlington and La Cour, 1952
	Vicia, root tip	50–200R	Thoday, 1953; Davidson, 1958
	Zea mays, pollen grain	800–1500R	Catcheside, 1938

Infrared rays

The apparatus generally consists of special types of tungsten lamps used for rapid drying. In some later models, arcs, for the production of both ultra-violet and infrared rays, have been built within one source with separate controls. The unwanted rays are screened off with suitable filters.

The method of application is similar to that of x-rays.

TREATMENT OF TISSUE WITH BOTH PHYSICAL AND CHEMICAL AGENTS

It may sometimes be necessary to treat the tissue with both physical and chemical agents, either singly or in a combined form. Radiation effects and the consequent cytological irregularities have often been found to be much minimised in the absence of oxygen or in the presence of certain chemicals (Riley, 1952, 1957; Riley, Giles and Beatty, 1951). As the effects of radiation on the organism as a whole are mostly deleterious, such chemicals are referred to as 'protective chemicals', against radiation damage. Their study is considered as one of the most important aspects of radiobiology, as it has opened up possibilities of affording protection against the destructive effects of radiation to human beings.

Protective chemicals can be applied before, after, as well as during, the time of radiation, the procedure varying according to the type of chemical and the nature of the radiation. From a cytological aspect, protection is afforded against chromosome breakage and inhibition of cell division. The mechanism through which protection is afforded is not clear in all cases, but in the absence of oxygen it can, however, be explained on the basis of the fact that lack of oxygen does not allow the formation of hydrogen peroxide. Similarly, some of the protective substances may act as *oxygen acceptors* removing the dissolved oxygen from the solution. Therefore, protective substances must be oxygen acceptors (Riley, 1954; Sharma and Sharma, 1964). On this basis, glucose, sodium nitrite, ferrous sulphate and stannous chloride are all to be considered as protective chemicals.

The principle of protection afforded by certain sulphydryl compounds such as BAL (2,3-dimercaptopropanol), cysteine and glutathione, is not yet

Table 15.3 Some other chemicals which induce chromosome breaks and show other mutachromosomic properties (Sharma and Sharma, 1960)

fully clarified, but it has been suggested that they may affect the target itself, thus operating against the direct action of radiation. It is also possible that reaction following irradiation of water may be modified or the availability of oxygen necessary for the effect may also be reduced.

In addition to the compounds mentioned above, propene, magnesium chloride, diethyl ether (Nybom *et al.*, 1953), hydrogen sulphide, mercapto-acetic acid, cysteamine, i.e. β-mercaptoethylamine, histamine and other amines (Bacq and Herve, 1951), carbamyl choline, thiourea, cobalt, etc., may also be used. It is, however, very necessary to have protective chemicals with selective action, otherwise, along with other parts of the body, the radiation treated area may also develop radio-resistance, and so nullify the purpose of radiation treatment. A number of critical reviews have been published regarding chemical protection as well as repair and recovery from chromosome damage (Riley, 1954; Evans, 1966, 1968).

Another purpose for which both the agents are often applied to the tissue is to secure a high number of metaphase stages for treatment with x-rays.

Schedule of treatment

(1) Place young denuded bulbs of *Allium cepa* in jars containing tap water and allow the roots to germinate till they are 1–3 cm long.
(2) Place the bulbs horizontally in large glass petri dishes filled with a solution of the chemical compound whose protective action is to be studied. For this purpose, 4×10^{-3} M sodium thiosulphate may be used. Treat for 30 min in this solution.
(3) Irradiate the bulbs in the same solution of sodium thiosulphate with an x-ray dose of approx. 150R at an output of 30–40R/min. The x-ray machine may be operated at 200 kV peak and 15 mA.
(4) After irradiation, keep the bulbs in the fluid for another 10 min. Transfer the bulbs to beakers containing tap water where they can be kept for 4–5 days for immediate observation and for observation of the root tips at regular intervals.
(5) Cut healthy young root tips, treat in 0.5 per cent colchicine solution for 1 h to secure a large number of metaphase stages necessary for the study of chromosome interchanges and deletions.
(6) Fix in acetic–ethanol (1 : 3) and follow the usual procedure for orcein or Feulgen staining of root tips and observe the interchanges and deletions at the metaphase stages.
(7) To measure the protection afforded by the chemical, set up a control experiment in which all the above steps are followed, substituting distilled water in place of the chemical compound. The difference in the frequency of interchange and deletions between the two sets will give a measure of the protection afforded by the chemical.
(8) For animal and plant tissues in culture, the tissue is irradiated *in vitro* and treated with chemicals added to the medium.

Synchronisation of division through physical and chemical agents

In a logarithmically growing cell population, several methods of analysis present serious problems due to non-synchrony of cell division (Zielke and Littlefield, 1974; Probst and Maisenbacker, 1975; Savage and Popworth, 1975; Dickermann and Goldman, 1976). No doubt, cells in certain cases show natural synchronous division, such as, eggs at the time of cleavage, or p.m.c.s. in the anthers of *Lilium*. Induced synchrony becomes essential for accurate analysis of several aspects of the cell cycle. The principle involved in induced synchrony is to allow all the cells to start DNA replication simultaneously.

The different schedules for inducing synchrony fall under two categories —physical and chemical (Zeuthen, 1964). The former has, however, not been found to be very useful. Of the physical methods, shock treatment like chilling at 4 °C for 1 h and subsequent removal to 37 °C has been found to be successful in HeLa cell cultures (Newton and Wildy, 1959 and cf. Miura and Utakoji, 1961). In others, it is of limited success (Lesser and Brent, 1970; Badger and Cooperland, 1976). Even irradiation with x-rays has been utilised for synchronisation.

The chemical methods appear to be more promising in inducing synchronisation as specially noted in the case of mammalian cells. With this object in view, methods have been devised to cause thymine deficiencies, thus blocking DNA replication. A folic acid analogue, amethopterin (4-amino—N^1o-methyl folic acid), has yielded successful results. As long as the culture contains this analogue, DNA-replication remains suspended and it can be resumed on the addition of thymidine and the cell population is doubled within a few hours (Rueckert and Mueller, 1960). However, even here, synchronisation cannot be considered as complete, due to the differential susceptibility of the different phases. After treatment, the cells in G_1 remain in the same phase while those in the later phases complete their cycle and are blocked prior to the succeeding *S* phase. Cells in the *S* phase, on the other hand, are heterogeneous in the sense that a few per cent of the cells are at the beginning, some at the middle, and some at the end of the *S* phase. They are all blocked in their respective positions. As soon as the synthetic activity starts after the addition of thymidine, the cells lying at the different stages of the *S* phase resume the activity from their respective points and become non-synchronous, while all other cells start from the *S* phase and show synchrony.

In monolayer cultures of HeLa cells, it has been noticed that interphase cells are not attached to the surface as the mitotic cells. As such, the intermitotic cells can be separated out from the mitotic ones and synchrony can be induced in the latter (Terasima and Tolmach, 1963). An antibiotic which also checks DNA replication is mitomycin C. This compound permits RNA synthesis to continue, checking only the synthesis of DNA. Cells treated with mitomycin C show the two polynucleotide strands being linked together. Because of the cross linkage, replication, which requires separation of the strands, is obstructed (Pricer and Weissbach, 1964).

In cultures, mitomycin C as such is ineffective, but if activated through chemicals or cell extracts, it can be used *in vitro* (Iyer and Szybalski, 1963).

The alkylating action of the ethylene amine group of mitomycin C is responsible for linking it to a DNA strand. Its possibility in synchronisation in higher organisms is yet to be thoroughly studied.

Similar inhibiting effects on replication have been obtained with fluorodeoxyuridine (FUDR) (Eidinoff and Rich, 1959, Littlefield, 1962). It is also widely applied, though there is a possibility of chromosome breakage through its incorporation in the DNA molecule, as obtained with BUDR (bromodeoxyuridine) and hydroxylamine. Hydroxyurea has been used as a DNA-synthesis–inhibiting agent as well (Kihlman and Hartley, 1968; Plagemanne, Pickey and Erbe, 1974).

Several other chemical agents have so far been used for achieving synchronisation in cultures. In all cases, the principle in general is to block synthesis of DNA or arrest metabolic activity of mitosis. Other chemicals used are thymidine (Xeros, 1962), colcemid (Stubblefield, 1967), a combination of cytosine arabinoside and colcemid (Verbin *et al.*, 1972) and vinblastine (Pfeiffer and Tolmach, 1967). The induced deficiency of certain metabolites such as leucine (Everhart and Prescott, 1972), isoleucine (Tobey and Ley, 1971) as well as isoleucine and glutamine (Ley and Tobey, 1970) may also lead to synchrony.

There are some serious limitations of the use of chemical agents for induction of synchrony such as the chromosome damage and toxicity often caused by those chemicals (Yu and Sinclair, 1968; Comings, 1971; Nelson and Krunv, 1972).

Wheatley (1974, 1976) suggested an effective technique with the use of hypotonic solution inducing synchrony by hypertonic arrest in metaphase (SHAM). Ooka (1976) described a method utilising selection of postmitotic cells through combination of techniques for detaching cell monolayers (Terasima and Tolmach, 1963) and gravity sedimentation on a column of culture medium (Shall and McClellan, 1974).

The schedule is outlined below (Ooka, 1976).

(1) Grow mammalian cells in suspension (2×10^5 cells/ml in suitable medium (Eagle MEM).
(2) Seed suspension culture cells in Roux bottles (8×10^6 cells per bottle).
(3) Remove the old medium after 48 h (with elimination of dead cells and add 30–50 ml of fresh medium.
(4) Shake horizontally.
(5) Recover the detached cells (20–30 per cent) by centrifugation at 500 rev/min for 10 min.
(6) Resuspend in 3 ml of serum free medium.
(7) Carefully deposit with pipette 70×10^6 cells suspension in serum free medium on the top of a sterile glass column (2.6×19 cm) containing 90 ml of medium.
(8) Incubate and allow to settle at 37 C for 40 min.
(9) Pipette out the upper third of the cells in medium (30 ml), mix with 170 ml of medium and incubate at 37 C to obtain synchronised cell populations.
N.B. Wider columns can be used (4.4×28 cm) if more cells (500×10^6) are necessary.

Introduction

The development of the present concept of the chemical make-up of chromosomes affords an excellent example of the extent to which refinements of methods aid in understanding its fundamental natures. The earliest attempt towards analysing the chemical nature of the hereditary substance was made by Miescher (1874) by isolating 'nuclein' from the nuclei of various animals through a standard biochemical method of isolation. In fact, 'nuclein'—the invariable constituent of the cell nucleus—was later known to be nucleoprotein, on which vigorous research is at present being carried out in different centres. Even with considerable modifications and alterations in the outlook with regard to the chemical nature of chromosomes in recent years, the fundamental principle involved in Miescher's discovery still remains undisputed, although Miescher himself was unaware of the implications of his findings. It has been the work of research teams of the present century to correlate the findings of those engaged in different disciplines of biological science, namely, that of Strasburger on 'mitosis', of Mendel on 'hereditary factors' and of Miescher on 'nuclein'. Through this synthesis, the 'nuclein' of Miescher is established as the constituent of the gene substance, the behaviour of which in heredity Mendel analysed, and which takes part in the cell division that Strasburger followed.

From the time of Miescher up to 1924, there was a blank phase in the study of chromosome structure, during which period no significant improved method was devised. The year 1924, however, represents a landmark in the science of cytogenetics due to the outstanding work of Feulgen and Rossenbeck in devising a special technique, based on Schiff's reaction for aldehydes, for the detection of deoxyribonucleic acid *in situ* in chromosomes. The basis of the Feulgen staining and the validity of the test have already been discussed (Chapter 5).

The impetus given through the work of Feulgen and Rossenbeck led to the analytical methods of Kossel (1928), Levene and Bass (1931), Behrens (1938) and Gulick (1941), which established the polynucleotide structure of the DNA molecule in association with the protamines, histones, etc., of chromosomes. Gradually, the study of chromosome structure was shifted from a purely cytogenetical level to chemical and histochemical analysis, which has given an understanding of the pattern of organisation, even at the submicroscopic level. In chemical terms, the chromosome is now visualised as a giant complex molecule made up of several but less complex molecules, the

physicochemical units—the genes responsible for hereditary stability. Within the last 30 years tremendous advances have been made in the study of chromosome structure due to the cooperative efforts of workers engaged in different branches of science, namely genetics, cytology, biochemistry and biophysics. The critical methods evolved by them have demonstrated that the chromosome cannot be visualised as simply a deoxyribonucleic acid during functional phases as in procaryotes, but is to be considered in higher plants and animals as composed of at least two types of nucleic acids, namely RNA and DNA, as well as two types of proteins—the histone and an acidic protein rich in tryptophane. The former includes five principal types.

The clarification of the complex constitution of chromosomes has been aided through biochemical methods of isolation of the chromatin matter, cytochemical tests meant for the localisation of constituents *in situ*, molecular hybridisation, ultrastructural study as well as methods for quantitation including extraction. For the latter purpose precise tests for nucleic acids and for proteins in general, and amino acids in particular, are available. One of the most important inventions is the method for the differential localisation of RNA and DNA by pyronin and methyl green (Brachet, 1940; *see* Talukder and Sharma, 1968). This work is aided by highly critical controlled tests, including digestion through specific enzymes like deoxyribonuclease and ribonuclease for the respective nucleic acids, and pepsin, trypsin and chymotrypsin for the digestion of different types of proteins. Similarly, methods for nucleic acid extraction through trichloracetic acid and perchloric acid have aided in finding out the precise seats of occurrence of the two acids, when applied in conjunction with specific tests. These techniques for localisation and control are not free from limitations. Nevertheless, in spite of these limitations, the conclusions arrived at from different aspects of study are nearly identical, indicating that the conclusions with regard to the chemical nature of chromosomes are not far from the truth. Moreover, spectrophotometric methods, based on ultraviolet absorption at 265 nm of purine components of the nucleic acid, devised originally by Caspersson and modified later by Pollister, Leuchtenberger and others (Leuchtenberger, 1958; Vendrely *et al.*, 1958, Pollister, Swift and Rasch, 1969), provide confirmatory evidence. These methods along with the study of ultrastructure, have also helped in ascertaining whether the chromosome undergoes any cyclic change in structure. Quantitative estimation of the different constituents has been aided through chromatography as well (Chargaff and Davidson, 1955). Studies on x-ray and electron diffraction patterns have also aided in deducing the relationship between nucleic acids and proteins within the chromosomes.

The knowledge that has been gained with the aid of the above methods suggests that RNA and DNA lie in active connection with the proteins (Chargaff and Davidson, 1955; Nurnberger and Gordon, 1958), but confirmation is lacking. Chargaff (1953) stated that lipoid is present in the chromosome in the form of a protein complex. Vendrely *et al.* (1958) suggested the presence of a pre-formed distinct nucleohistone part within the chromosome, merely on the basis of certain data relating to the constancy of chemical composition. That there is a distinct nucleoprotein complex within the chromosome in the living cell was proved unequivocally by Kaufmann and his colleagues (Kaufmann, 1953; Bal and Kaufmann, 1959; Dutt and Kaufmann, 1959) in their works, involving the use of deoxy-

ribonuclease on unfixed cells of *Tradescantia*, grasshopper, *Drosophila* and of trypsin on the fixed cells of *Drosophila*. Moreover, taking recourse to deoxyribonuclease and ribonuclease treatments, together with Feulgen and pyronin–methyl green staining, not only the presence of RNA in the chromosome was confirmed but it has also been shown that the chromosome chain may be composed of both RNA and DNA (Kaufmann *et al.*, 1958; Kaufmann, McDonald and Gay, 1951; cf. Wolstenholme, 1965). The latter contention has, however been much debated (Kaufmann, Gay and McDonald, 1960; cf. Das, Luykx and Alfert, 1964).

Even when RNA may be considered as a constituent of the chromosome, opinions still differ as to whether it is associated with the histone or the non-histone protein (Sharma and Roy, 1956; Sharma and Sharma, 1958). Mirsky and Ris (1947), on the basis of their technique for the isolation of chromosomes, suggested that RNA remains principally in association with the non-histone protein and DNA with the histone. On the other hand, other workers (Kaufmann, Gay and McDonald, 1960), through cytochemical tests involving ribonuclease treatment and specific acid extraction of different proteins followed by staining, claimed that RNA remains in association with the histone. They demonstrated that dilute HCl (0.02 N) hydrolysis can remove histone but not acidic protein. DNA remains in combination with both histone and non-histone (Mirsky and Ris, 1951; Bernstein and Mazia, 1953; Bloch and Godman, 1955; Bloch, 1958; Kaufmann, Gay and McDonald, 1960; *see* Dupraw, 1970; Bonner, 1977; Lima de Faria, 1975). RNA of chromatin is bound both with DNA and histone. Walters (1968) noted the appearance of ribonucleoprotein structures during meiotic prophase, associated with the release of synthetic products. The importance of histones in gene regulation has been amply realised (Busch, 1965; Georgier, 1969). Chromosomes in the extended and active phase may contain non-histones and also histones whereas the stage of inactivity and condensation has been marked by the presence of histones mainly. Residual complexes of calf thymus chromatin have been shown to be made up of DNA and histone, and transcribing activity is associated with the gradual loss of histone (Georgier, Ananieva and Kozlov, 1966; Paul and Gilmour, 1966; Clever, 1968; Sonnenbichler, 1969). Relevant to this observation is the finding made by Gall (1966) whose spreading technique of chromosome fibre enabled him to demonstrate that in *Triturus*, 25–30 nm thick inactive fibres are made of nucleohistone and owe their origin to the coiling of those thinner fibres which are actually involved in protein synthesis. This gradual deproteinisation associated with gene action is an index of regulation of genetic activity by histone.

Further complexity in chromosome structure was introduced by the demonstration of the possible presence of lipids in the chromosomes (Brock, Stowell and Couch, 1952; Chayen, La Cour and Gahan, 1957; Serra, 1959; Idelman, 1958). Unfortunately, as lipids share many of the chemical properties of other substances, it is very difficult to locate them in the chromosomes. Indications of their presence have been observed in root tips, anthers, salivary glands, etc. The modification of the phospholipid test is no doubt an important achievement (Serra, 1959), but the study of lipids has been much neglected (Deane, 1958). In all probability, lipids are present in the form of lipoprotein complexes, with specific sulphydryl proteins and, as pointed out

by Kaufmann, Gay and McDonald (1960), they may have some correlation, as yet unexplored, with the nucleic acid components of the chromosomes.

One of the significant developments in the study of the structure and function of chromosomes is the discovery of multiple copies of similar DNA sequences (Crick, 1971). Since its discovery, it has been found in varying amount in different organisms from plant to human system reaching a value of even 70–75 per cent of total DNA (Arrighi and Saunders, 1973; Lee and Thomas, 1973, Vosa, 1977; Ohno, 1974, Tartof, 1975). High homogeneous repeats or satellite DNAs have been located in different organisms. The presence of repeated sequences has been noted in centromeres, secondary constrictions and telomeres (Panitz, 1978). The chromosome structure has been visualised as representing a linear array of potentially independent replicons terminated by a short palindromic or inverted repeat sequences (Cavalier-Smith, 1976), having major repeats at one locus and minor repeats interspersed throughout the chromosomes. This interspersed nature of the repeats may allow flexibility of uniques or may serve as loci of accumulation of mutations (*see* Schwarzacher, 1976).

The presence of such repeated sequences and in general, sequence complexity of DNA has been demonstrated through advancements in the molecular hybridisation technique both at the *in situ* chromosome level as well as *in vitro*. Refinements in extraction techniques coupled with molecular hybridisation have led to the identification of functionally differentiated segments of chromosomes.

In addition to ribosomal RNA, the role of 5S RNA and its mode of origin has been elucidated. Nearly 450–650 copies of 18S and 28S types are found in the haploid genome of *Xenopus laevis* which occur in clusters in the nucleolus organising regions. Both 18S and 28S rDNAs have been observed in the nucleolar organising region of different biological systems (Evans, Buckland and Pardue, 1974; Pardue, 1975; Hsu, Spirito and Pardue, 1975). In the genetic system in eukaryota in general, and plant systems in particular, it has been shown that there is an inbuilt mechanism of addition of genetic elements which may serve as controlling units or regulators, as spacers, for performing some generalised function or may serve as loci for mutations (Cattanach, 1975; Sharma, 1978a). It has no doubt been well established that the regulated mechanism of differentiation is controlled by the repression and depression of an operon—the operating unit in a chromosome. The concept, as worked out in prokaryote, can no doubt explain the mechanism of differentiation where the gene structure is a simple DNA molecule and differentiation involves only certain physiological properties, capacity of infection and patterning of the protein layer. But in the higher organisms, where growth and development are sequential and phasic, and where even intrachromosomal relationships are often manifested, especially in relation to euchromatin and heterochromatin, the functional operon may not be the same as in procaryotes. Even if the existence of operons in higher organisms is accepted, then it must be admitted that such operons are the constituents of much more complex operational units. It has been rightly suggested that in higher organisms, the chromosomes may constitute innumerable nucleotides, which function autonomously during development, as noted in puffing in *Diptera*, and each such chromomere is comparable to an entire phage chromosome (Beermann, 1967; and *see* Whitten, 1969a, b; Ashburner,

1972). No doubt the operon concept provides a basic background to account for differentiation, but to explain the phasic pattern of development characteristic of higher plants and animals, a complicated mode of operation has to be visualised embracing translocation effects, interchromosomal relationship in the rhythmic functioning of the cell metabolism and triggering of the different development phases (Sharma, 1978b).

The technical achievements, as noted above, are no doubt principally responsible for bringing out the complex constitution of chromosomes, but even then no precise understanding has been obtained as to the pattern of their arrangement and the exact relationship between nucleic acids and protein (*see* Willey, 1978). The difficulty encountered in obtaining this knowledge may be attributed to the complexity of the chromosome strand and DNA molecule and the changes in their relationship during different phases of development. Ris (1957, 1967), Kaufmann, Gay and McDonald (1960) and others, through ultrastructural studies by electron microscopy, have demonstrated the complex constitution of the chromosomes, but there is still the question, what is the chemical basis which causes the constituents to adhere to one another? This has not yet been precisely solved. Mazia (1954) suggested that bivalent cations, like calcium and magnesium, serve as bridges between the macromolecules of chromosomes, which was later supported by others. The necessity of hydrogen bonding in maintaining the structural integrity, and the importance of protein linkers were suggested (*see* Ris, 1967; Sharma, 1978b).

Though DNA is considered to be the basic substance in the chromosome, it is yet to be found whether it exists in the form of a continuous strand throughout the length of the chromosome or is interrupted or attached at certain segments. Its uninemic multireplicon nature has been claimed by various authors (*see* Prescott, 1977). Callan and MacGregor (1958) demonstrated that deoxyribonuclease treatment disintegrates isolated but unfixed lampbrush chromosomes, suggesting that DNA forms a continuum throughout. In addition, 5′-fluorodeoxyuridine (FUDR), which is a pyrimidine base analogue capable of inhibiting synthesis of thymine in DNA replication, if applied in low concentrations before DNA replication, induces chromosome breakage (Taylor, 1962). Ultraviolet radiation at 200 nm is also effective in causing chromosome breakage (Bloom and Leider, 1962; and *see* Moses, 1968). In spite of Watson and Crick's discovery of the double helix nature of DNA, refinements in cytochemical and ultrastructural methods are needed to effect a reconciliation between the structural complexity of DNA and the other constituents of chromosomes, as worked out cytochemically. Several models of chromosome structure have been proposed by Taylor (1959, 1969). Dupraw (1970), De (1964), Hamilton (1968) and Bahr (1975). The importance of RNA in gene activity, if regarded as a possible constituent of the chromosome, is also not yet clear. McMaster-Kaye and Taylor (1958) and Kaufmann *et al.* (1959) suggested that crossing over and recombination may be controlled by RNA. Marinozzi's observations (1964) further confirm the role of RNA in the formation of synaptonemal complex during synapsis (*see also* Menzel and Price, 1966). On the other hand, it has been suggested that the presence of RNA during this phase should await further ultrastructural and cytochemical evidence (Moses, 1968). The structure of the synaptonemal complex has been dealt with in detail by different workers (Moens, 1979;

Smith and King, 1968; Gassner, 1969; Moses, 1969; Sen, 1969; Sheridan and Barnett, 1969; Stern and Hotta, 1969; Westergaard and Wettstein, 1970). Mazia (1961) regarded RNA as responsible for chromosome movement. It does seem likely that all the components of the chromosome are responsible for the maintenance of structural integrity and form an interconnected system. Kaufmann, Gay and McDonald (1960) stated that the pattern of this complex fibril changes with metabolism. The dynamicity in structural patterning of chromosomes is exhibited in its association with histones in the body cells, being replaced by protamines in the germinal line.

Diversity in the nature of chromosomal histones has also been recognised. Lysine-rich histone has been demonstrated to combine with DNA, forming cross-linking with double helix, whereas histones rich in arginine are linked with the phosphoric acid groups along the double helix (Littau *et al.*, 1965). The heterogeneity of the DNA molecule and its consequent modifications, while combining with proteins, has been emphasised as well (Wake, Ochiai and Tanifugi, 1968). Sharma (1974) questioned the feasibility of proposing a universal model for chromosome structure in view of its dynamicity in different phases of development and growth. Chromosomes for transmission, as in spermatozoa, or meant for replacement of parts, as in crossing over, may have a structural difference from chromosomes of the somatic nucleus. The futility of proposing a universal model from a single phase of development is apparent. Simultaneously, with the evolution of chemical complexity of chromosome structure, there has been ample evidences to indicate emergence of variability in chemical make-up of chromosomes during organogenesis, maintaining the basic genetic structure (Sharma, 1974, 1976, 1978). Such dynamic nature of the chromosome is indicated by its varying DNA content from organ to organ in plant and animal systems (Pelc, 1972; Cook, 1973; Essad, Vallade and Cornu, 1975; Banerji and Sharma, 1979; Scarano, 1973; Sager and Kitchin, 1975). Similar variation has been recorded in the protein content of the chromosomes (Bloch and Hew, 1960; Ruderman, Baglioni and Cross, 1974; Innocenti, 1975) and in the association of histone and non-histone with the chromosome structure (Klimenko, Malayshev and Nikitin, 1975; Sin, 1975; Holmgren *et al.*, 1976; Khesin and Lukovitch, 1976; Sevalijevic, Krtolica and Konstanlinovic, 1976).

All these evidences clearly indicate the dynamic change in chemical nature of chromosomes during development and differentiation. No universal model of chromosome structure embracing all phases of differentiation is feasible. Complexity of mechanism of differentiation in eukaryota demands a dynamism in structure which the chromosomes fulfil in all respects.

The above resume of our knowledge of the chemical nature of chromosomes, as aided through the different techniques, reveals the gaps still to be filled. However, with so much technical background already prepared, and refinements in methodology attained within the last few years, exact knowledge of the pattern of association of the nucleic acids and proteins, in maintaining the structural integrity of the chromosome, does not seem to be far off. The correlation of chromosome components, in quality and quantity, with phases of development and growth, would lead to a better understanding of the chemical basis and initiating mechanism of each genetically controlled reaction.

17
Nucleic acid and its components

Since nucleic acid is composed of three principal constituents—namely sugar, bases and phosphoric acid—the majority of chemical tests are based on the identification and localisation of any one of these constituents. The principal procedures, limitations and advantages of the different techniques are outlined in the following text.

TESTS FOR SUGAR

There are certain methods (Turchini, Castel and Kien, 1944) through which both the deoxyribose and the ribose sugars can be tested, but at the same time there are certain specific tests for the deoxy sugar, of which the Feulgen procedure is considered to be the most important. For the demonstration of aldehydes through fluorescence—Schiff's reagents, like acridine orange (Kasten, 1959; Joshi and Korgaonkar, 1959; Paolillo, 1964; Rigler, 1964; Roschlau, 1965), please see chapter on fluorescence microscopy. Stoward (1963) employed salicylyl hydrazide sequence instead of Schiff dyes.

Feulgen reaction

The Feulgen reaction is based on Schiff's reaction for aldehydes whereby, by acid hydrolysis, the liberated aldehydes of the deoxy sugar are allowed to react with fuchsin–sulphurous acid to yield a typical magenta colour reaction. For details of this reaction and its discussion, please refer to the chapter on staining.

The Feulgen test is not only specific for the localisation of DNA in chromosomes, but at the same time the intensity of the reaction may be considered to be an index of the amount of DNA present in the cell. Several authors (Pollister and Ris, 1947; Pollister, 1950; Pollister, Himes and Ornstein, 1951; Pollister, Swift and Alfert, 1951; Pollister, 1952; Mellors, 1955; Freed and Benner, 1964; Mendelsson, 1966; Wied, 1966; *see* Freed, 1969) have employed spectrophotometric methods for measurement of the intensity of Feulgen colour for the quantitative estimation of DNA in the fixed nuclei. On the basis of the quantitative estimation, the DNA content of cells is inferred to be a constant factor and is proportional to the number

of chromosomes present (Vendrely and Vendrely, 1948; Ris and Mirsky, 1949; Pasteels and Lison, 1950; Swift, 1950; and *see* Pearse, 1972). Stowell and Cooper (1945) modified the Feulgen reaction, and coupled with photometric recordings, measured mean amounts of DNA per unit volume per cell and correlation was brought about between morphological data and other results. Caspersson (1947) utilised the ultraviolet absorption technique and the Feulgen reaction and developed the concept that nuclear-associated chromatin plays a significant role in the nucleoprotein synthesis of malignant cells. for further details, please see Chapter 9.

Feulgen–naphthoic acid hydrazide reaction

This schedule is meant for testing the presence of deoxyribonucleic acid. Danielli (1947) utilised 2,4-dinitrophenylhydrazine for staining chromosomes yellow. This method avoided the difficulty of mild hydrolysis in revealing aldehydes and the use of Schiff's reagent. Pearse (1951) similarly secured good results by using 2-hydroxy-3-naphthoic acid hydrazide. This compound not only combines with aldehydes but with ketones as well, and if the resulting dark yellow compound is coupled with diazotised *o*-dianisidine in alkaline solution, a purple blue compound will be obtained. As the hydrazide reagent combines with tissue proteins as well, to produce protein hydrazides, the cytoplasmic details also are maintained; however, this reagent acts as an acidic dye as compared to the basicity of the basic fuchsin.

2,4-Dinitrophenylhydrazine

This was used by Danielli (1947) in three different methods which are briefly outlined below.

(1) Hydrolyse squashes of salivary glands of *Drosophila* with N HCl for 15 min. Treat with 2,4-dinitrophenylhydrazine. The chromosomes take up very little colour.
(2) Treat the squashed tissue at 0 °C with a saturated solution of dinitrophenylhydrazine in 2 N HCl or with a saturated solution, 0.5 N in HCl, in 75 per cent ethanol, cover and observe. The bands take up colour.
(3) Hydrolyse a suspension of deoxyribosenucleic acid at 60 °C by N HCl for 15 min. Allow it to react with 2,4-dinitrophenylhydrazine and the solution will slowly become cloudy. Keep for 30 min at room temperature, then cool to 0 °C and place the squashes in the solution. The final concentration of HCl is 0.02 N. Remove the squashes after 1 h. The chromosomes take up light stain.

The stain, in general, is fainter than that obtained after fuchsin staining.

Feulgen–naphthoic acid hydrazide test

Reagent a

2-Hydroxy-3-naphthoic acid hydrazide	0.1 g
50% ethanol	100 ml
Glacial acetic acid	5 ml

Reagent b

Tetrazotised *o*-dianisidine	0.1 g
Veronal buffer solution pH 7.4	100 ml

(1) Bring the sections (originally fixed in alcoholic or formalin fixatives) down to water. Rinse in N HCl. Hydrolyse in N HCl at 60 °C for 6–15 min, depending upon the tissue and fixative.
(2) Rinse successively in cold N HCl, distilled water and 50 per cent ethanol.
(3) Immerse for 1–3 min in reagent b at 0 °C. Wash in distilled water.
(4) Dehydrate through ethanol and xylol grades and mount in DPX.
(5) DNA takes up bluish purple stain. Cytoplasm and other proteins may be stained red.

Dische reaction (Dische, 1930, 1944)

The Dische reaction was considered for a long time to be a specific test for the deoxyribose sugar of the chromonucleic acid. Dische employed five reactions including the carbazole and the diphenylamine. The carbazole reaction is specific for pyrimidine-bound aldehyde DNA (Schneider, 1948) and is carried out in strong sulphuric acid solution, heating to 100 °C. In the diphenylamine reaction a blue coloration is obtained by the addition of diphenylamine to the tissue similarly treated with hot acid.

The Dische test is often employed for the quantitative estimation of DNA from isolated nuclei by subjecting them to the test and observing against a colorimeter. The matching of colour with the known samples of nucleic acid solutions gives an estimate of the amount of DNA present.

For cytochemical localisation of DNA *in situ*, this test cannot be applied; moreover, the specificity of the Dische reaction has been questioned (Stacey, 1950; Dische, 1955) on the ground that under strongly acid conditions 2-deoxypentoses become converted to laevulinic acid which gives no colour with the reagent, but an intermediate compound ω-hydroxylaevulinic aldehyde yields colour with diphenylamine. As other deoxysugars, e.g. deoxyxyloses, also yield laevulinic aldehyde, the validity of the results remains questionable if not supplemented by other control experiments.

Several tests are in vogue for RNA. They involve the use of orcinol, phloroglucinol, cysteine and sulphuric acid. Dische (1955) suggested that the orcinol reaction of Bial (1903), Dische and Schwartz (1937) and Dische (1953) is comparatively more sensitive than the latter two, and the replace-

ment of orcinol by phloroglucinol (Dische and Borenfreund, 1957) yields even better results. In this method, the minimum concentration of ribose and its esters can be much more precisely determined than that obtained through the use of orcinol. Specificity is accentuated by the fact that it is not affected by the presence of other sugars.

Dische's schedules for colour reactions with DNA

The experiments have all been carried out on extracted nucleic acids. For extraction schedules, the reader is referred to the chapter on extraction.

Schedule of reaction with diphenylamine

Reagents

Extracted aq. DNA	50–500 μg/ml of solution
Diphenylamine	1 g (twice crystallised from 70% ethanol or ether)
Glacial acetic acid	100 ml
Conc. H_2SO_4	2.75 ml

For preparing the reaction mixture, dissolve the diphenylamine in the acetic acid and add sulphuric acid.

Procedure

(1) Mix together one volume of DNA solution and two volumes of the reaction mixture.
(2) Heat at 100 °C for at least 10 min.
(3) For control, heat a quantity of water separately with the reaction mixture.

Observations

Observations show that the DNA solution takes up a blue colour, which persists for hours. An absorption curve drawn with a Beckman spectrophotometer shows a maximum at 595 nm. The colour is maximum after 10 min heating, but shorter periods up to 3 min may give enough coloration for qualitative purposes. The blue colour is produced by 2-deoxypentoses and not only 2-deoxyribose.

Schedule of reaction of DNA with cysteine and concentrated H_2SO_4 (Dische, 1949)

Reagents

Extracted DNA solution with 50–500 μg/ml DNA	1 ml
Conc. H_2SO_4	4 ml

Procedure

(1) Add together the DNA extract and H_2SO_4 under cooling. Keep for 1 h.
(2) Add 1 ml 3 per cent solution of cysteine hydrochloride. Shake thoroughly. Keep the mixture for 24–48 h at room temperature.
(3) Measure absorption with a Beckman spectrophotometer.

Observations

These show a sharp absorption maximum at 375 nm, which is reached after 48 h.

Modified schedule of reaction with indole HCl
(Ceriotti, 1952)

Reagents

DNA solution containing 2.5–15 μg/ml DNA	2 ml
0.04% indole C.P. solution in distilled water	1 ml
Conc. hydrochloric acid	1 ml
Chloroform—purified by extraction with conc. H_2SO_4, followed by water extraction and storage over $CaCl_2$ for 48 h	

Procedure

(1) Add the other reagents to the DNA solution.
(2) Immerse the test tube for 10 min in a boiling water bath.
(3) Cool to room temperature under running water.
(4) Extract three times with 4 ml chloroform. Separate water from chloroform by centrifuging.

Observations

Observations show that the water phase gives a yellow colour which persists for several hours. The chloroform phase shows a faint pink colour. The absorption curve, by a Beckman spectrophotometer, has a sharp peak at 490 nm and a smaller constant peak at 460 nm. The reaction is regarded as being produced by only the purine nucleotides of DNA (Dische, 1955).

Hydrazine—benzaldehyde Schiff reaction

The principle of separating pyrimidines through anhydrous hydrazine at high temperature (Takemura, 1958) has been adapted by Smith and Anderson (1960) for nuclear DNA. Benzaldehyde is applied for complete removal of pyrimidine bases. This method may even be used for quantitation (*see* Pearse, 1972).

Dische's schedule for colour reactions with RNA (Dische, 1955)

Schedule on orcinol reaction (Dische and Schwartz, 1937)

Reagents

Extracted solution of RNA	1.5 ml
Reaction mixture, prepared by dissolving 0.1 g of ferric chloride in 100 ml hydrochloric acid and adding 3.5 ml of a 6% solution of orcinol in ethanol	3 ml

Procedure

(1) Mix the RNA extract with reaction mixture.
(2) Heat in a waterbath for 3 min.
(3) Cool to room temperature under running water.
(4) Measure the optical density with a Beckman spectrophotometer against a blank containing water and the reagent.

Observations

These show an optical density at 665 nm. The specificity of the reaction is rather low as not only RNA, but also 2-deoxyribose, DNA, methylpentose and hexuronic acids give a green colour with an absorption maximum around 670 nm.

Various modifications of this schedule are available.

Schedule on phloroglucinol reaction (Euler and Hahn, 1946)

Reagents

Extracted solution containing:

2 mg of RNA	1 ml

Reagent mixture containing:

0.1% solution of ferric chloride in a mixture of conc. HCl and glacial acetic acid (1 : 6)	8 ml
25% phloroglucinol solution in a mixture of conc. HCl, water and glacial acid (1 : 1 : 2)	1 ml

Procedure

(1) Add the reagent mixture to RNA extract and stir.
(2) Immerse the tube in a boiling water bath for 50 min.
(3) Cool to room temperature under running water.
(4) Add 1 ml phloroglucinol solution and keep for 20 min at room temperature.

(5) Immerse the tube in a boiling water bath for 4 min.
(6) Cool down to room temperature and keep for 2–24 h.

Observations

Observations show that the maximum intensity of the colour appears after 10 h and the adsorption maximum is at 680 nm. DNA does not give any coloration, as prolonged heating might have destroyed the sugar of the purine nucleotides of DNA.

Schedule of reaction with cysteine and H_2SO_4

The schedule is similar to those described under reactions for DNA (*see* page 512). The reading is taken 15 min after the addition of cysteine when the maximum absorption produced by pentoses is observed. The peak of absorption curve is observed at 390 nm.

Schedule for observing aldopentose in presence of other saccharides (Dische and Borenfreund, 1957)

Reagents
Extracted RNA solution containing:

4–40 μg/ml pentose	0.4 ml

Reaction mixture (freshly prepared) containing:

Glacial acetic acid	110 ml
Hydrochloric acid	2 ml
0.8% glucose	1 ml
5% phloroglucinol	5 ml

Procedure

(1) Add 0.4 ml of RNA extract to 5 ml of the reaction mixture.
(2) Shake, immerse for 15 min in a vigorously and uniformly boiling water bath.
(3) Cool to room temperature under tap water.

Observations

Observations show that all aldopentoses produce an intensely red colour with a sharp absorption maximum at 552 nm. The optical density of the colour produced by ribose or its phosphate esters is proportional to the concentration of the compounds. This reaction is not affected by the presence of other sugars.

Tryptophane–perchloric acid condensation method

Cohen's (1944) method involves freeing of deoxyribose sugar from the bases by treatment with hot perchloric acid. The liberated groups of the sugar are then allowed to condense with the secondary amine of tryptophane to

give the colour reaction. The reaction is very slow and carried out in a test-tube. No *in situ* localisation is possible as perchloric acid quickly extracts DNA.

Schedule

Add 0.2 ml 1 per cent tryptophane solution and 1.2 ml 60 per cent perchloric acid to 1 ml of a solution containing 100–500 μg of extracted DNA. Boil in a water bath for 10 min, cool in tap water and observe under a spectrophotometer. A purple colour is obtained and an absorption maximum is observed at 500 nm. An aldehyde intermediate probably causes the colour reaction.

TESTS FOR THE BASES

No specific chemical test is, in fact, at present available to test purine and pyrimidine components of nucleic acid. The only reliable method of their identification is measurement through ultraviolet absorption originally devised by Caspersson (1947). A strong absorption can be obtained at 265 nm of the purine and pyrimidine components of the nucleic acid. However, this method takes for granted that all the purine and pyrimidine components are located in the nucleic acids. Moreover, it is also necessary to find out how far the absorption is affected by neighbouring compounds.

Danielli (1947) utilised tetrazotised benzidine for staining chromatin of the chromosome. Mitchell (1942) employed it for demonstrating cytoplasmic ribonucleoprotein. He claimed that tetrazotised benzidine reacts not only with tyrosine, tryptophane and histidine (*see* Chapter 11) but also with the purine and pyrimidine groups. For specific chromatin staining, the method involves the treatment of the sections in acetic anhydride (10 per cent solution in dry pyridine, treated for 1 h at 100 °C) or in benzoyl chloride (10 per cent in dry pyridine, for 20 h at room temperature), which are termed blocking agents, prior to application of tetrazotised benzidine. The basic principle of this method is to allow the tissue to react with a reagent which will not allow a number of tissue components to undergo any reaction with tetrazotised benzidine. By using such blocking reagents as acetic anhydride or benzoyl chloride, tryptophane, tyrosine and histidine are apparently eliminated and, as such, the components resistant to benzoylation and reacting thereafter with tetrazotised benzidine are the purines and pyrimidines. However, Danielli stated that other substances may react with diazonium salts.

Pearse (1953, 1960, 1972) stated that tetrazonium reaction involves the protein part of the DNA protein as purified DNA, free from protein, does not give any reaction whatsoever. It has been claimed that even after benzoylation, the reaction is due to the amino acids of the protein which remain protected from benzoylation due to the physical state of nucleoprotein. Bernard and Danielli (1956) also suggested later that, after benzoylation, the reaction is due to histidine residues in nucleoprotein fraction. As such, this test should not be used to demonstrate purine and pyrimidine components of nucleic acids.

Schedule for the coupled tetrazonium reaction

Main schedule

Reagents

Reagent a

(1) Benzidine base	0.5 g
Conc. HCl	5 ml
Dist. water	20 ml
(2) 2% aq. sodium nitrite solution	10 ml
(3) 5% aq. ammonium sulphamate	10 ml
(4) Anhydrous sodium carbonate	28 g
Dist. water	95 ml

Prepare first reagents (1) and (4) separately. To 20 ml of reagent (1) at 0–5 °C, add slowly, a few drops at a time, 7 ml of 2 per cent $NaNO_2$ solution from a chilled pipette, for a period of 10–15 min. Agitate rapidly but do not allow the temperature to rise above 10 °C. Keep the mixture in cold to attain a temperature of about 5 °C or below. Add 3.5 ml of 5 per cent aqueous ammonium sulphamate solution. Add 34 ml of reagent (4) and stir. As effervescence ceases and the solution becomes alkaline, it changes to a clear dark yellow. Add enough distilled water to make the volume up to 150 ml.

Reagent b

Veronal acetate buffer pH 9.2

Reagent c

8-Aminonaphthol-3,6-disulphonic acid (H acid)	0.5 g
Veronal acetate buffer pH 9.2	25 ml

Procedure

Paraffin sections (fixed previously in formalin, alcohol or freeze dried) are used.

(1) Bring down the sections to water.
(2) Immerse them in fresh diazotised benzidine (reagent a) at 4 °C for 15 min.
(3) Wash in water and three changes of veronal acetate buffer at pH 9.2 (reagent b) for 2 min in each change.
(4) Immerse in a saturated solution of H acid in veronal acetate buffer at pH 9.2 (reagent c) for 15 min.
(5) Wash in distilled water for 3 min.
(6) Dehydrate in ethanol, clear in xylol and mount in DPX or Canada balsam.

Alternative for step (2) is 0.2 per cent aqueous solution of Fast blue B salt in tris buffer at pH 9.2, for 5 min at room temperature.

Observations

Most of the tissue components are stained reddish brown, showing the

presence of tyrosine, tryptophane and histidine. The colour produced is stable and remains for several months.

Precautions
The tetrazotised benzidine solution (reagent a) should be prepared freshly before use.

Schedule with benzoylation

Procedure

(1) Bring down sections to water and then gradually to absolute ethanol.
(2) Immerse these sections or paraffin sections in petroleum ether for 3 min.
(3) Remove and dry in air.
(4) Heat the dried sections to 60 °C in an incubator or to 80 °C on a warm plate for 5–10 min. This step is optional, depending on the material.
(5) Treat the dried sections in 10 per cent benzoyl chloride in dry pyridine for 10–16 h at room temperature. The period of treatment is shorter for alcohol-fixed tissues and longer for formalin-fixed ones.
(6) Rinse in absolute acetone.
(7) Immerse in absolute ethanol.
(8) Bring down the sections, through decreasing ethanol grades, to water.
(9) Next follow the coupled tetrazonium reaction, from step (2) in the previous schedule, to demonstrate the presence of bases.

Precautions
Keep the benzoyl chloride solution away from moisture, as it rapidly loses strength on contact with water. In controlled humidity, the solution lasts for about a month. Dry pyridine by distillation over barium sulphide. As mentioned already, this test is not specific for bases.

Schedule with acetylation

Procedure

Steps (1), (2), (3) and (4) are the same as those of the previous schedule.
(5) Immerse the sections in 10 per cent acetic anhyride in dry pyridine and heat for 4–8 h at approx. 100 °C, under a reflux condenser.

The later steps are similar to the previous schedule.

TESTS BASED ON THE REACTION WITH PHOSPHORIC GROUPS

Tests for phosphoric groups of nucleic acids are not so precise as those meant for detecting the sugar components. Though it is generally considered that phosphate dye linkage is in the form of a salt, later works indicate the role of hydrogen bonding in the reaction (*see* Pearse, 1972). However, one of the principal staining schedules, based on the use of methyl

green and pyronin, involves reaction with phosphoric groups. It will be discussed under methods for differentiating DNA and RNA in tissues.

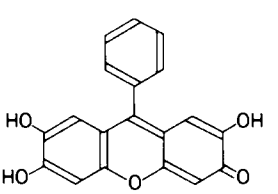
Serra and Lopes (1945) demonstrated phosphorus *in situ* in deoxyribonucleic acid in tissues, and photographs presented by them reveal clearly the presence of phosphorus in chromosomes. However, as phosphorus is an essential constituent of many compounds, the test should always be applied in two sets of tissue, one undergoing digestion with nuclease prior to the test and serving as the control. Without this control measure it is not possible to differentiate phosphorus of nucleic acid from that of other constituents.

This method involves, in principle, the treatment of the tissue in the hydrochloric acid–molybdic reagent for hydrolysis and precipitating phosphomolybdate for 2–3 weeks at a low temperature of 4–10 °C. The phosphomolybdate, when formed through ammonium molybdate, is demonstrated by means of acetic benzidine and sodium acetate, whereby it takes a blue colour. The method has, however, two serious limitations. In the first place, the sensitivity of phosphomolybdic reagent, which is often not very sharp, should be properly assessed. Secondly, all the shortcomings of precipitation tests are inherent in this method. Pearse (1972) has objected to the test on the basis that prolonged acid hydrolysis may lead to diffusion of phosphate ions causing artefacts.

METHODS FOR THE SIMULTANEOUS DETECTION OF DEOXYRIBOSE AND RIBOSE NUCLEIC ACIDS

Several methods are at present available by which both types of nucleic acids can be detected simultaneously. These techniques can be divided into two categories, those based on reaction with sugar moiety and those based on reactions with phosphoric groups.

The most important technique falling under the first category is that of Turchini, Castel and Kien (1944). These authors first introduced fluorones for critical differentiation of DNA and RNA in the cell. The technique is based on the condensation of deoxyribose and ribose sugar with 9-phenyl-2,3,7,trihydroxy-6-fluorone, or more precisely xantheonone, having the structure:

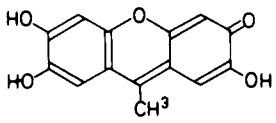


This should be 9-phenyl 2,3,7-trihydroxy 6-oxoxanthene
OR 9-phenyl 2,6,7-trihydroxy 3-oxoxanthene
(OR ------ xanthen-6-one and xanthen-3-one respectively)

Therefore, prior to this reaction, uncovering of sugars by acid hydrolysis is an essential step in the technique. It differs from the Feulgen reaction in the fact that both the sugars react, deoxyribose giving blue to violet and ribose yielding yellow to red coloration. As strong acid hydrolysis may cause extraction of RNA, the choice of a proper fixative is needed to prevent this extraction. The authors have recommended fixation with chromic or picric compounds. Moreover, for different types of organisms, different fixatives have been recommended and the period of hydrolysis has been varied.

Pearse (1972) used a variety of fixatives containing ethanol as well as formalin on human tissues, but in none of the cases could he secure any differentiation excepting a general pale rose to pink colour of the nuclei. Moreover, as the shades of colour often vary, even for DNA alone, it is not proper to utilise this method for quantitative estimation (Kurnick, 1955a, b).

Backler and Alexander (1952) used methyl substituted derivatives of fluorone and this modification of Turchini's method yielded successful results. The compound used by them is 9-methyl-2,3,7-trihydroxy-6-xantheonone having the chemical structure:



They obtained violet to blue black colour in DNA and yellow to red colour in RNA, but in this method also, similar to Turchini's, the fixative and period of hydrolysis are important factors which should be varied in order to secure reproducible results in a variety of tissues in different organisms. Because many factors control the reaction, the method is not considered as critical for quantitative and qualitative assessments for the nucleic acids as other methods in vogue, which are discussed later in this chapter. The only advantage of this method is that selective staining of the two nucleic acids can be obtained with the use of only one type of xantheonone compound.

Schedules

Method of Turchini, Castel and Kien (1944)

Reagents

Nucleic acid reagent	Dissolve 80 mg of 9-phenyl (or methyl)-2,6,7-trihydroxy-3-fluorone in 100 ml of 95% ethanol containing 15 drops of conc. sulphuric acid
Hydrochloric acid	1 N (alternatively 25%) conc. HCl in 90% ethanol
Aq. sodium carbonate	1% solution

Procedure

(1) Fix the tissue in Bouin's fluid.
(2) Prepare and cut paraffin sections. Bring down to water.
(3a) For treatment with methyltrihydroxyfluorone reagent: Hydrolyse the sections in 1 N HCl at 60 °C for 5 min, wash with water, rinse in absolute ethanol and treat for 5–10 min with nucleic acid reagent. Wash with several drops of 90 per cent ethanol, then with 1 per cent sodium carbonate solution. Rinse in water. Dehydrate through ethanol and xylol grades and mount in balsam.
(3b) For alternative treatment with phenyltrihydroxyfluorone reagent: The procedure is similar except that hydrolysis is carried out in cold temperature in alcoholic solution of 25 per cent HCl for 3–5 min.

Method of Backler and Alexander (1952)

This method has been used on human autonomic ganglia fixed in Bouin's fluid, rat tissues fixed in Bouin's, Zenker's, formol and formol–saline fixatives, and mouse liver, frozen and dried.

Reagents

(1) 9-methyl-2,3,7-trihydroxy-6-fluorone containing:

1,2,4-Triacetyltrioxybenzene	1 mole
Paraldehyde	1.25 mole
Ethanol	5 times the combined weight of the above reagents
Sulphuric acid	5–10% (v/v)

Mix the chemicals together and add sulphuric acid. Allow to stand for 18–24 h at room temperature. Add 30 volumes of distilled water. Allow to remain for 24 h when a reddish orange precipitate of the dye settles out. Filter and discard the filtrate. Dry the residue at 37–40 °C in an oven. Dissolve the precipitate in the minimum quantity of ethanol needed and filter. Add 30–60 volumes of water to the filtrate and allow it to stand for 24 h. Filter and dry again as before. The product will be a reddish orange powder, decomposing at 319 °C, moderately soluble in alcohol and practically insoluble in water.
(2) Sulphuric acid.
(3) Hydrochloric acid 1 N.
(4) 1 per cent solution of sodium carbonate in distilled water.

Procedure

(1) Deparaffinise and bring down paraffin sections to water.
(2) Immerse the slides in 1 N HCl for 2 min at 60 °C for partial hydrolysis.
(3) Transfer immediately, without washing, to 80 per cent ethanol and keep for 15 s.
(4) Transfer the slides directly to a mixture containing:

9-Methyl-2,3,7-trihydroxy-6-fluorone	1 g
Sulphuric acid	1 ml
95% ethanol	100 ml

Keep for 20 min in this solution.
(5) Keep in 1 per cent aqueous sodium carbonate solution for 2 min.
(6) Immerse the slides in distilled water for 2 min for rinsing.
(7) Keep in acetone and distilled water mixture (1 : 1) for 3 min.
(8) Transfer to pure acetone for 3 min.
(9) Keep in acetone and xylol mixture (1 : 1) for 2 min.
(10) Give two changes of pure xylol, $1\frac{1}{2}$ min in each.
(11) Mount in piccolyte. RNA takes up yellow to red stain and DNA stains violet to blue black.

Note

(1) Use the staining mixture for several weeks.
(2) Use fresh sodium carbonate solution for each set of staining.
(3) Use fresh distilled water for rinsing.
(4) For dehydration, use acetone instead of ethanol, as the dye is extracted by ethanol treatment.

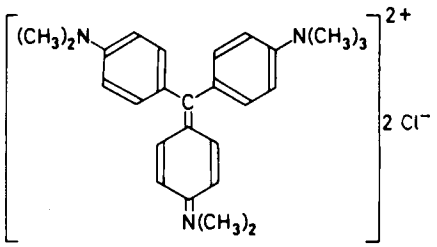
Pyronin–methyl green technique

Of all the methods employed for the differential localisation of RNA and DNA, the universally accepted standard technique is that of Brachet (1940–1942, 1958) based on Pappenheim (1899) and Unna's (1910) methyl green–pyronin G mixture. In this schedule, methyl green imparts a green colour to chromatin or, more precisely, DNA, whereas RNA present in the cytoplasm, nucleolus, etc., appears pinkish red with pyronin, in both cases the reaction involving the phosphoric groups of the nucleic acid moiety. The specificity of pyronin staining of RNA is also confirmed by staining a parallel slide originally digested with ribonuclease. The latter preparation, serving as the control, does not show the presence of RNA or pyronin staining, being exhausted of this nucleic acid by digestion through its specific enzyme. Another control set can be stained merely with 1 per cent toluidine blue (Kurnick, 1952) and the dye adheres only to RNA-containing areas.

Several modifications of the original technique have been adopted from time to time. In Brachet's schedule, the aqueous dye mixture is mixed with acetate buffer and acetone is used as the dehydrating agent. With low pH levels, pyronin is strongly positive, whereas at higher levels, methyl green yields the crisper colour. The optimum pH level for staining is considered to be 4.8. Kurnick (1955a, b), on the other hand, recommended pyronin (05564, Gurr) specifically for the purpose, and used tertiary butyl alcohol for dehydration. Bhaduri and Mukherjee (1961) secured good results in plants by using toluol as the final clearing agent.

Methyl green

It is correctly represented as 'Methyl Green OO', a basic dye of the triphenyl methane series. The structure can be represented as



It is slightly soluble in water and comparatively less soluble in alcohol.

Balbiani (1881) first utilised this dye to secure green colour in salivary gland chromosomes of *Chironomus*, followed later by Pappenheim and Unna, who employed it in combination with pyronin. In Unna's modification, phenol was a constituent of the mixture which evidently adjusted the pH for optimum staining with methyl green (Kurnick, 1950a, b). The selective staining DNA by methyl green was first demonstrated by Brachet (1942). Kurnick (1947) claimed that selectivity of DNA staining by methyl green is dependent on the polymerised nature of the DNA molecule, and he observed that depolymerised DNA could not be satisfactorily stained with methyl green, and also that histones competed with the dye for nucleic acid. The constant stoichiometry of the staining showed the formation of the chemical compound with the phosphoric group during staining. Kurnick and Mirsky (1950) asserted that one dye molecule combines with ten phosphoric groups of DNA, basing their observation on the stoichiometry of the reaction by dialysis, precipitation of stain–nucleic acid mixtures and staining of nuclei of known DNA content. This ratio of 1 : 10 was given by heptamethyl pararosaniline (CI 684) and the ratio 1 : 13 by hexamethyl pararosaniline (CI 685) (Pearse, 1960, 1972). Kurnick (1950a, b) and Errera (1951) claimed that stable binding of methyl green should involve at least two amino groups with two methyl groups of the dye. The stainability of methyl green is therefore controlled largely by different agents which under certain conditions may bring about depolymerisation (Kurnick, 1955a, b). In this connection Godman and Deitch (1957) claimed that, even with all possible precautions, there is no certainty that DNA is not depolymerised. For quantitative analysis of DNA through methyl green staining, certain conditions must however be satisfied—such as, avoiding depolymerising fixing agents, optically homogeneous preparation of nuclei, elimination of histones, as well as the use of stain in aqueous solution. Kurnick (1955a, b) further suggested that proteins other than histones or protamines may possibly be bound to DNA at sites other than the phosphoric acid so that their presence does not stand against methyl green stainability.

Alfert (1952) suggested that the blocking of stainable groups of RNA by protein is principally responsible for specific staining of DNA by methyl green. There is, however, no fundamental difference between Alfert's claim and Kurnick's observations (Kurnick, 1955a, b; Pearse, 1960). Taft (1951) depolymerised DNA by varying pH and temperature without affecting methyl green stainability. Pearse (1960) pointed out that such depolymerisation may principally involve rupture of hydrogen bonding (Gulland and Jordan, 1947) which may be a reversible process.

It was suggested by Vercauteren (1950) that, in the nucleic acid molecule,

the spacing of negatively charged phosphate residues corresponding to two positively charged sites on the methyl green molecule is the principal controlling factor in staining. Agents which cause breaking of weak bonds in the DNA molecule result in coiling of the molecule, thus causing alteration in spacing which is responsible for loss of methyl green staining. Rosenkranz and Bendich (1958) suggested that the double strand state of DNA is responsible for methyl green specificity.

Goldstein (1961) claimed that the explanation so far provided for methyl green staining of DNA is unnecessary, the chief factor being the weight of the dye cation, and he has suggested that dye cations, having a combined atomic weight between 350 and 500, can penetrate and adhere to unclear DNA whereas smaller cations adhere to denser molecules such as cytoplasmic RNA. Methyl green, having a cationic weight of 387, is specific for DNA. Heat or other agents may bring about alterations in the structure of DNA in such a way that it becomes denser and, as such, becomes stainable with pyronin. He confirmed this suggestion by studying the behaviour of a number of dyes with different cationic weights such as toluidine blue, malachite green, acridine red, celestine blue, etc. However, along with cationic weights, hydrogen ion concentration, mordant, solubility, etc., also control the stainability to a significant extent (Baker, 1958, 1966).

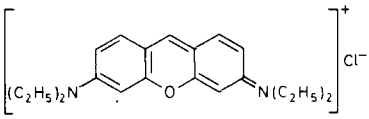
Van duijn (1962) criticised Goldstein's hypothesis of density difference being the basis of differential staining and suggested that more evidence was necessary to validate its cytochemical specificity. Cowden (1965) stained cytoplasmic RNA of oocytes with methyl green alone, while the same regions took up stain with pyronin Y in methyl green–pyronin mixture. Scott (1967), with the aid of his critical electrolyte concentration method, noted that the combination of both these dyes with polynucleotides is too strong to be explained only by electrostatic bonds. Planar dyes, such as pyronin, react with single-stranded RNA with accessible bases, whereas non-planar dyes like methyl green combine with double helical structures. The importance of the period of staining and dye concentration has been indicated; best results have been secured with staining for 16 h in 0.15 per cent methyl green and 0.25 per cent pyronin in 50 mM sodium acetate (pH 5.6) with 2 M magnesium chloride.

One of the principal steps which has a profound influence on staining is the purification of the dye, which is essential as methyl violet remains as an impurity with methyl green. Kurnick (1950a, b) and Leuchtenberger (1950) suggested purification before use by chloroform extraction. Taft (1951) performed purification by repeated chloroform extractions of a 0.5 per cent solution of methyl green in 0.1 M acetate buffer. Jordan and Baker (1955) recommended the extraction of freshly prepared 0.5 per cent aqueous methyl green with chloroform at least eight times, until all the impurities are removed and the chloroform becomes colourless.

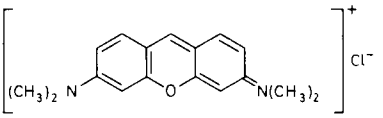
The above discussion reveals that methyl green staining may yield erroneous results unless all the different factors affecting the process are strictly controlled; discrepant results often noted are due to these variable factors. However, under strictly limited conditions, with a special check on purification of the dye, fixation without any depolymerising effect, and pH during staining, the method can be safely applied for localisation and quantitation estimation of DNA.

Pyronin

Pyronin is a basic dye of the xanthene group and is available in three different forms, 'pyronin B', 'pyronin Y' and 'pyronin G'. Pyronin Y (Michrome No. 339, Gurr) is a tetramethyl whereas pyronin B (Michrome No. 44, Gurr) is a tetraethyl compound.



Pyronin B



Pyronin Y

Both are, however, fairly soluble in water and sparingly soluble in alcohol.

Kurnick (1950a, b) first demonstrated that pyronin preferentially stains low polymers of nucleic acid, but stoichiometric studies did not reveal constancy in the binding of depolymerised DNA by pyronin (Kurnick and Mirsky, 1950). To secure selective staining, pyronin G or Y is suitable as pyronin B results in non-specific cytoplasmic staining. Evidently, methylation may have some connection with the staining property of pyronin.

The selectivity of pyronin staining of RNA, as already mentioned, is confirmed in Brachet's (1942) schedule through ribonuclease digestion. Kurnick (1955b), however, noted that if the dye is used alone, nuclei also stain red, indicating thereby that methyl green competes effectively with pyronin for polymerised DNA while used in a mixture. Kurnick (1952) noted that pyronin B or a number of pyronin Y preparations of American firms stain protein as well, and, as such, they are ineffective for quantitative analysis. On the other hand, pyronin Y of G. P. Gurr Ltd revealed specific RNA coloration, specially when used in an aqueous solution with methyl green, followed by rinsing in butyl alcohol. In any case, the pyronin Y of different firms can be used (Kurnick, 1955a; Kaufmann, Gay and McDonald, 1960; Pearse, 1960, 1972) if extracted repeatedly with chloroform, like methyl green. Paolillo (1964) has discussed in detail the specificity of different pyronins for plant tissues.

The choice of a proper fixative, as mentioned for methyl green, is also important for pyronin staining, as the use of fixatives which cause depolymerisation of nucleic acid results in pyroninophilia of DNA. For the same reason, nuclei of degenerating cells also stain with pyronin (Harris and Harris, 1950). Kurnick (1955a) has however pointed out that depolymerisation may be of different degrees, ultimately resulting in mononucleotides, but even before this ultimate stage is reached, DNA may become pyronin positive and lose methyl green stainability. It has also been pointed out that a mere rise in temperature, such as from 80–100 °C, may cause depolymerisation to the extent of pyroninophilia but not a loss of protein precipitability (Swift, 1953). If the depolymerisation is so severe as to dissolve DNA, no pyronin staining can be observed. Laverack (1955) recommended the staining for the study of nucleic acid in unfixed frozen sections.

Importance of the methyl green–pyronin method

Considerable advances have been made in the study of the chemical make-up of chromosomes and related structures of various organisms with the aid of the differential staining schedules. In addition to its application to various plant and animal cells, this method is finding wide application in cancer cytology, cytological studies from tissues cultured in artificial medium and bone marrow, as well as in peripheral blood smears (Brachet, 1942; Stowell, 1946; White, 1947; Perry and Reynolds, 1956; Hoffman, 1956; Arakaki and Sparkes, 1963).

Kaufmann, McDonald and Gay (1951) and Kaufmann, Gay and McDonald (1960) carried out intensive investigations on the identification of chromosomal components through enzymic digestion of fixed tissues and various staining procedures, including especially pyronin and methyl green. They showed that chromosomes contain both RNA and DNA in the form of chains, in addition to basic and non-basic proteins, and that both histone and non-histone proteins remain associated with DNA, whereas RNA is associated principally with histones. This latter finding is contrary to that of Mirsky and Ris (1947) who assumed RNA to be associated principally with tryptophane-rich protein in 'residual chromosomes', responsible for maintaining the structural integrity. Kaufmann considered that all the components form an interconnected system and no single component should be considered as essential for structural integrity (*see also* Dupraw, 1970).

During the active phase, DNA is associated with non-histone protein and 'genetic inactivity' is correlated with DNA–histone. Spermatozoa of certain organisms which do not contain either histone or protamine may be exceptions (Bernstein and Mazia, 1953; Ris, 1958). The shifting pattern in different phases of metabolism has been emphasised (Bloch, 1958). Evidence from studies involving differential localisation of DNA and RNA amply indicates that RNA exerts a significant influence in changing the properties of chromosomes during the course of mitosis (Kaufmann and Das, 1954; Kaufmann, McDonald and Bernstein, 1955; Davidson, 1957).

'Mobilisable' RNA may play a part in crossing over and recombination, especially as ribonucleoprotein has been found in attachment plates holding the synapsing chromosomes in *Tradescantia* (Kaufmann *et al.*, 1959; Kaufmann, Das and McDonald, 1960). RNA may play a role in chromosome movement, or chromosomes may simply be convenient carriers for RNA distribution (Mazia, 1961). In spite of the fact that DNA forms the essential genetic substance, the presence of RNA in chromosomes, as clearly evidenced through the methyl green–pyronin technique and ribonuclease digestion, has opened up new complexities in the study of chromosome behaviour and function, the unravelling of which is essential for understanding the genetic control of all vital activities.

The impact of Brachet's works has been amply felt in the ultimate analysis of the different types of RNA involved in transcription and translation—the essential steps in protein synthesis. All present concepts of gene action and regulation of differentiation may be at least traced back to the differential localisation of DNA and RNA in the cell through the method devised by Brachet.

Schedules for pyronin–methyl green staining

Modified schedule (Brachet, 1942 and 1953)

The recommended fixation time is for 4–16 h at pH 7.0 in 10 per cent aqueous formalin.

Reagents

(1) Methyl green Before use, wash methyl green repeatedly with chloroform or amyl alcohol to dissolve and remove the traces of methyl violet which are formed when methyl green is exposed to the atmosphere. Filter off the residual methyl green and dry it. Alternatively, shake an aqueous solution of methyl green with an excess of chloroform or amyl alcohol. The violet component is to be gradually removed. Allow to stand for 2–3 days. Remove the aqueous supernatant liquid for use.

(2) Pyronin Y or pyronin G In general, the bluish shades are more satisfactory.

(3) Ribonuclease Ribonuclease solution can be prepared by Brachet's method, as follows. Mince up finely 0.5–1 kg of ox pancreas by passing through mincer. Pound the minced meat into a smooth paste with mortar and pestle. Suspend the paste in an equal volume N/10 acetic acid for 24 h. Boil for 10 min, cool and filter. Bring the pH to 6.0. Filter again. Add a few thymol or camphor crystals as preservative and store in cold. The enzyme retains its activity for several months.

(4) Preparation of the required reagents
Pyronin–methyl green mixture

Methyl green (washed in chloroform and dried)	0.15 g
Pyronin Y	0.25 g
90% ethanol	2.5 ml
M/5 acetate buffer pH 4.7	97.5 ml

In an alternative method, modified from Trevan and Sharrock (1951, *see* Pearse, 1960) the solutions used are:

Solution (1)

5% aq. pyronin solution	17.5 ml
2% aq. methyl green solution (chloroform-washed)	10 ml
Dist. water	250 ml

Solution (2)

M/5 acetate buffer pH 4.8

Mix equal quantities of (1) and (2) in a staining jar. Do not use mixture after keeping for a week.

Ribonuclease

0.1% solution in dist. water adjusted to pH 6.0

This chemical has been used for control experiments in the original schedule by Brachet.

Procedure

Only a general schedule is given, which has to be modified according to requirements.

(1) Fix sliced tissue in Carnoy's or Zenker's fluid. Wash. Dehydrate as usual. Embed in paraffin. Cut paraffin sections. Deparaffinise in toluene and bring the sections down through alcohol grades to distilled water.
(2) Stain the sections in pyronin–methyl green mixture for 20 min.
(3) Wash them rapidly with distilled water.
(4) Differentiate in 95 per cent ethanol for 5–10 min.
(5) Dehydrate in absolute ethanol, clear in toluene and mount in DPX.
(6) For control experiments: (a) keep one set of slides, marked 'A', in distilled water pH 6.0 in an oven at 37 °C for 1 h. Then stain, differentiate, dehydrate and mount as described before; (b) keep a second set of slides, marked 'B', in ribonuclease solution in an oven at 37 °C for 1 h and then follow the staining schedule described before.

Observations

(1) In the normally stained tissue, RNA in nucleolus and cytoplasm takes up red colour, while DNA appears as green particles in the nuclear chromatin.
(2) In control experiment (a) no green colour is observed, showing that DNA has been removed by warm water.
(3) In control experiment (b), RNA is removed by ribonuclease, shown by the complete absence of red colour.

Methyl green–pyronin Y schedule by Kurnick (1955b)

The recommended fixative is Carnoy's fluid or freeze-drying.

Reagents

Pyronin Y	2 g
Methyl green	2 g

Dissolve 2 g of pyronin Y in 100 ml of distilled water. Add chloroform and shake the mixture in a separating funnel till the layer of chloroform becomes colourless. Separate the dissolved dye. Similarly prepare a 2 per cent solution of methyl green and extract it with chloroform. The solutions can be kept as stock. For use, mix together 12.5 ml of pyronin Y solution and 7.5 ml of methyl green solution and add 30 ml of distilled water.

Procedure

(1) Fix and embed the tissue. Bring down the paraffin sections to distilled water.

(2) Immerse the sections in the staining mixture for 6 min. Freeze-dried sections can be stained directly.
(3) Remove excess stain by blotting with filter paper.
(4) Transfer to *n*-butanol, keeping for 5 min and then treat in a further change of *n*-butanol for 5 min.
(5) Transfer to xylol and keep for 5 min.
(6) Transfer to cedarwood oil and keep for 5 min.
(7) Mount, preferably in Permount.

Observations

Chromatin is stained green while cytoplasm and nucleoli are bright red.

Alternatives

In an alternative schedule, increase the period of staining up to 10–30 min, rinse in distilled water, drain and blot, keep in two changes of *n*-butanol for 5 min each and mount directly in euparal (Darlington and La Cour, 1960).

Modification of Brachet's schedule (1955)

Reagents

(1) Methyl green extract is freshly prepared by treating 0.5 per cent methyl green solution in distilled water with chloroform repeatedly till the chloroform layer is colourless.
(2) Acetate buffer—prepared by mixing 119 ml of 0.2 M sodium acetate solution and 81 ml of 0.2 M acetic acid and maintained at pH 4.8.
(3) 0.15 per cent aqueous pyronin G solution.

For the final mixture, mix together:

0.5% aq. pyronin G solution	37 ml
0.5% aq. extracted methyl green solution	13 ml
0.2 M acetate buffer	50 ml

This mixture retains its capacity for at least four months (Jordan and Baker, 1955).

Procedure

(1) Bring down the paraffin sections to distilled water and blot to remove moisture.
(2) Immerse for 30 min in the buffered staining mixture.
(3) Wash in distilled water for a few seconds and blot again.
(4) Keep in pure acetone for 1 min.
(5) Transfer to acetone–xylol mixture (1 : 1) and then to pure xylol, keeping for 1 min in each.
(6) Mount in neutral balsam.

Observations

DNA takes up blue, blue green or green colour while RNA stains red.

Kay and Dounce's modification (Kay, 1953)

The staining mixture is prepared by using 0.37 per cent methyl green and 0.11 per cent pyronin B dissolved in glycerol, 20 ml; 2 per cent aqueous phenol, 100 ml; and rectified spirit, 25 ml. It can be used for fresh suspensions or dried smears of tissue homogenates.

Methyl green–pyronin and ribonuclease method for RNA (according to Brachet, 1942 and Trevan and Sharrock, 1951)

(1) Fix in 10 per cent formalin at pH 7 ± 0.2 for 4–16 h.
(2) Since commercially prepared methyl green is a mixture of methyl green and methyl violet, for purification, shake the aqueous solution of the dye with excess of chloroform or amyl alcohol. After 2–3 days, remove aqueous supernatant for use. Though the methyl green thus purified slowly breaks down into methyl violet, the process is so gradual as to be negligible.
(3) Prepare:
Solution A: 5 per cent aqueous pyronin 17.5 ml; 2 per cent purified aqueous methyl green 10 ml; distilled water 250 ml.
Solution B: 0.2 M acetate buffer, pH 4.8. It may or may not contain 30 ml 1 per cent orange G. Alternatively, an acid citrate buffer (pH 5.0), prepared by adding 51.5 ml 0.2 disodium hydrogen phosphate to 48.5 ml 0.1 M citric acid can be used.
Mix equal volumes of A and B. This mixture should not be kept for longer than a week.
(4) Bring down the sections to water.
(5) Stain in methyl green–pyronin solution for 10 min to 24 h.
(6) Rinse in distilled water for a few seconds.
(7) Blot and dehydrate rapidly in absolute acetone.
(8) Rinse briefly first in a mixture of acetone and xylene (1 : 1) and then in 10 per cent acetone in xylol.
(9) Clear in two changes of xylol and mount in a synthetic resin.
(10) The nuclear chromatin takes up green, bluish green or purplish green colour while the sites of RNA stain red.

Modified schedule for plant tissues (Bhaduri and Mukherjee, 1961)

Reagents

(1) Pyronin Y (No. 10779, Gurr) England—2 per cent solution in distilled water, purified by shaking with an equal quantity of chloroform in a separate funnel.

(2) Methyl Green Chroma (No. 50.07) Germany—purify 2 g by shaking twice with 50 ml of chloroform, filtering and drying the residue at room temperature in a desiccator. Prepare a 2 per cent solution in distilled water.

Prepare staining mixture by adding together:

2% aq. pyronin solution	50 ml
2% aq. methyl green solution	30 ml
Dist. water	10 ml
Chloroform	10 ml

Procedure

(1) Bring paraffin sections of tissues, previously fixed in Carnoy's fluid, down to distilled water.
(2) Shake the staining mixture before use. Then immerse the slides in it for 15 min at 20 °C.
(3) Blot excess stain with a filter paper and dip the slide in 50 per cent ethanol and pure *n*-butanol mixture (1 : 1) for 2 s.
(4) Immerse in *n*-butanol for 10 min.
(5) Keep in pure chloroform for 10 min.
(6) Again immerse in *n*-butanol for 5 min.
(7) Treat in toluol for 1 h.
(8) Mount in neutral balsam.

Observations

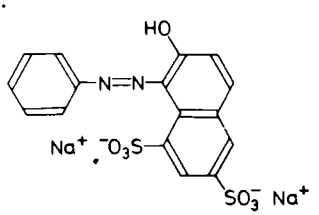
Chromosomes and nuclear chromatin stain bright green while nucleolar and cytoplasmic RNA stain pink to deep rosy red.

Sulkin's schedule (1951)

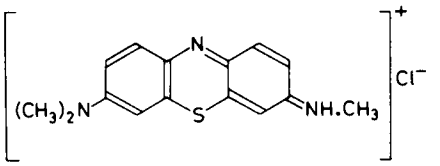
Fix tissues in 10 per cent formalin, Zenker's solution of 90 per cent ethanol, bring the paraffin sections to water and immerse, one lot in N/10 KOH for 45 min at room temperature and the other in water. Stain in toluidine blue, haematoxylin–eosin or phloxine–methylene blue. These dyes stain both DNA and RNA. Exposure to KOH inhibits the staining of RNA alone.

Trichome staining schedule

Another technique for the differential stain of the two types of nucleic acid was developed by Korson (1951). In this method, trichome staining combinations were employed—orange G for protein, methyl green for DNA and toluidine blue for RNA. All of them are used in a common mixture in aqueous solutions. Orange G (Michrome No. 411) is an acid dye of the azo group with the formula:



Toluidine blue (Michrome No. 404) is a basic dye of the thiazine group with the formula:



The fixative recommended is acetic–alcohol or acetone or even formalin-containing fixatives. Though normally methylene blue, toluidine blue, etc., stain RNA, it is difficult to distinguish the cytoplasmic RNA from the nuclear one. Following the trichrome technique, bright green coloration of chromatin is seen simultaneously with blue nucleolus and orange cytoplasm with blue-coloured structures embedded in it. The method involves staining to an 'end-point' and removing the excess dye through overnight treatment in butanol. Though the exact mechanism involved in the process is not clear, yet it is claimed to be a chemical reaction in which orange G combines with the proteins, leaving nucleic acids available for methyl green and toluidine blue staining. DNA combines with methyl green, and RNA is left over to react with toluidine blue. The specificity of this method has been claimed on the basis of control procedures. Extraction of RNA by cold perchloric acid removes those materials which stain in toluidine blue, whereas negative methyl green and toluidine blue reactions are obtained by extraction of both kinds of nucleic acids through hot trichloracetic acid. Similarly, the application of DNA and RNA before staining yields negative methyl green and toluidine blue reactions respectively.

This method, though recommended for the differential staining of DNA and RNA against a differentially stained cytoplasmic background, is not as widely applied as methyl green and pyronin, the latter method being particularly suitable for quantitative estimation. Moreover, the contrast is not very sharp when the green and blue coloration is used as the differentiating index of the two types of nucleic acids. One special advantage of this technique lies in its capacity to differentiate other cytoplasmic components from RNA positive bodies.

Several authors (Bradley and Wolf, 1959; Feder and Wolf, 1965; *see* Lamm, Childers and Wolf, 1965) have noted that metachromatic staining of DNA and RNA can be obtained with toluidine blue. Fixation in acrolein and embedding in ester wax have been recommended. Ghosh and Lettré (1969) worked out a schedule with toluidine blue and Feulgen reaction for double staining of DNA and RNA. The presence of DNA in nucleoli has also been demonstrated by Ebstein (1969), confirming the previous findings of Lettré and her colleagues.

Schedule for differential trichome staining of DNA and RNA (Korson, 1951)

The fixatives recommended are Carnoy's fixative or cold acetone. The tissues stained were rat liver, spleen, thymus, intestine, spinal cord and pancreas,

hepatoma and cholangioma and human thyroid and bone marrow. Marrow is smeared, air dried, fixed in absolute methanol for 3 min and dried again before use.

Staining solutions used

(1) Orange G—4 per cent solution in distilled water.
(2) Methyl green—purified by repeated washing in chloroform 0.15 per cent solution in distilled water.
(3) Toluidine blue O—0.1 per cent solution in distilled water.

Procedure

(1) Bring down the slides to water.
(2) Treat in orange G solution for 2 min.
(3) Dip in a jar containing distilled water to which a drop of orange G solution has been added.
(4) Treat in methyl green solution for 15 min.
(5) Immerse the slides in toluidine blue–methyl green mixture (1 : 1) for 5 min.
(6) Rinse in absolute tertiary butanol.
(7) Treat overnight in a change of absolute tertiary butanol.
(8) Clear in xylol and mount.

Observations

The nuclear chromatin stains bright green (DNA), the nucleolus blue (RNA) and the cytoplasm orange with a variable amount of blue staining structure (RNA).

Several control experiments were set up to verify the results obtained. The schedules and their observations are given below.

Experiment 1 Bring down sections to water. Incubate with crystalline deoxyribonuclease to remove DNA selectively at room temperature for 7 h. The solution used contains 0.1 mg of deoxyribonuclease/ml of McIlvaine's buffer pH 6.5. Sufficient magnesium chloride is added to a 0.2 M solution. Stain as usual.

In the final preparation, chromatin is colourless, nucleoli are blue and cytoplasm is orange with blue granules.

Experiment 2 Incubate sections for 1 h at 45 °C with crystalline ribonuclease (0.01 mg/ml solution) in McIlvaine's buffer pH 6.5 to remove RNA selectively. Stain as usual. Chromatin is found to be coloured green, nucleoli are colourless and cytoplasm is orange with colourless granules.

Experiment 3 Incubate the sections with deoxyribonuclease, followed by ribonuclease. Stain as usual. Both chromatin and nucleoli are colourless and cytoplasm is orange with colourless granules.

Experiment 4 Treat the sections with 10 per cent perchloric acid solution for 11 h at 4 °C for extracting RNA. Stain as usual. Chromatin stains green, nucleoli remain colourless and cytoplasm is orange with colourless granules.

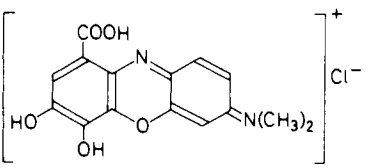
Experiment 5 Treat sections with 5 per cent hot trichloracetic acid at 90 °C for 15 min or with 10 per cent hot perchloric acid at 80 °C for 15 min for extracting both nucleic acids. Stain as usual. Both chromatin and nucleoli are colourless and cytoplasm is orange with colourless granules.

Acrolein–toluidine blue method for DNA and RNA (according to Feder and Wolf, 1965)

(1) Fix small bits of tissue in 10 per cent aqueous acrolein with 0.5 per cent calcium acetate.
(2) Dehydrate in a mixture of methanol and methoxyethanol (1 : 1), pass through ethanol and *n*-propanol grades and embed in polyester wax following the usual schedules.
(3) Cut sections 5 μm thick and mount on slides.
(4) Bring the slides down to water and stain for 8 min in 0.1 per cent toluidine blue in phosphate buffer to pH 4.2 at 22 °C.
(5) Dehydrate in tertiary butyl alcohol for 5 min, clear in xylol and mount in a synthetic resin.
(6) The sites of DNA take up a deep blue stain while those of RNA are pale purple.

Gallocyanin–chrome alum for differential staining of RNA and DNA

Einarson (1935, 1949, 1951) suggested the use of a lake formed by gallocyanin and chrome alum for the differential staining of DNA and RNA. Gallocyanin (Michrome No. 143) is a dye of the oxazine group with the formula:



and acts as a weakly acid stain in aqueous solution. It forms three salts with chrome alum [$K_2SO_4.Cr_2(SO_4)_3.24H_2O$], called by Einarson lake–cation [gallocyanin–$Cr(H_2O)_4$], lake–hydroxide [gallocyanin–$Cr(H_2O)_4OH$] and lake–sulphate [gallocyanin–$Cr(H_2O)_4SO_4$]. The lake–cation reacts with the phosphate groups of the nucleic acids to form combination dark-blue lake tissue salt. This reaction has been used for quantitative estimation of nucleic acid by Einarson. According to Sandritter, Diefenbach and Krantz (1954), 1 molecule of gallocyanin is bound by phosphorus atoms in 'polymerised' RNA and by 23 atoms in heated RNA. Diefenbach and Sandritter (1954) found the ratio of gallocyanin and DNA in their stoichiometric combination to be 1 : 3 : 7. Sandritter, Kiefler and Rick (1963) noted a proportionate increase in red colour with heating up to over 30 min. Harms (1965) suggested that chromium lake of gallocyanin is formed by complexing of two hydroxyl groups lying adjacent to each other.

The advantages of gallocyanin–chrome alum technique for qualitative staining of nucleic acids are:

(1) It is a progressive stain and is not washed out during dehydration and clearing.

(2) Though the highest specificity of staining is at lower pH levels, between 1.5 and 1.75, yet staining can be done at almost any pH between 0.8 and 4.3.

However, the chief drawback of this method for quantitative staining is, according to Pearse (1968), that information about the proportion of combination with nucleic acids and stoichiometric data is still incomplete. Stenram (1954) found that even after ribonuclease extraction, staining with gallocyanin–chrome alum at a pH up to 4.0 was observed in Nissl substance in nerve cells. De Boer and Sarnaker (1956) extracted from gallocyanin solution, a compound which stained Nissl bodies bright blue while the rest of the cytoplasm remained colourless. Non-specific staining is held to be due to the attachment of the lake–sulphate to acid groups in the tissues through its dimethylamine grouping. Mayersbach (1956) regarded this method as more specific than pyronin–methyl green technique. Pearse (1968), however, regarded it to be a highly specific method, but not of the same calibre as pyronin–methyl green schedule. This method evidently does not require specific fixation and, though suitable for qualitative observations, is not very successful for the quantitative study of differentially stained substances.

Einarson's schedule (Einarson, 1951)

Different fixatives have been recommended.

Reagents

Chrome alum	5 g
Gallocyanin	0.15 g
Dist. water	100 ml

Dissolve chrome alum in distilled water and add to it gallocyanin. Shake, and heat in a beaker on a flame and boil for 5 min. Remove the flame, allow the solution to cool to room temperature. Filter and collect the filtrate in a measuring cylinder. Add distilled water to the solution and filter until the filtrate measures 100 ml. This stock solution can be kept for about 1 month. The optimum pH is 1.64. If necessary, the pH of the solution can be adjusted by adding aqueous 1 N HCl or 1 M NaOH solution in the proportions shown in *Table 17.1*. If a precipitate is formed on adding NaOH, do not keep the solution for more than a week.

Procedure

(1) Bring down the paraffin sections to water as usual.
(2) Immerse and keep in dye–lake solution for 48 h at room temperature.
(3) Rinse in distilled water.
(4) Dehydrate through alcohol and xylol grades and mount in a suitable medium.

Observations

RNA and DNA take deep blue stain, the optimum pH with least non-specific staining being 0.83–0.94.

Table 17.1

Stock solution in ml	*pH needed*	*Amount of* N *HCl to be added in ml*	*Amount of 1* M *NaOH to be added in ml*
40	0.83	10	0
	0.90	9	0
	0.92	8	0
	0.94	7	0
	1.02	6	0
	1.10	5	0
	1.14	4	0
	1.18	3	0
	1.29	2	0
	1.44	1	0
	1.64	0	0
	1.84	0	1
	2.16	0	2
	2.90	0	3
	3.42	0	4
	3.76	0	5
	3.98	0	6
	4.07	0	7
	4.18	0	8
	4.27	0	9
	4.35	0	10

Modified gallocyanin schedule (De Boer and Sarnaker, 1956)

Various fixatives have been recommended for preparing paraffin blocks. Freeze-drying is employed after fixation in formalin.

Reagents

Gallocyanin	0.6 g
Chrome alum	10 g

Dissolve chrome alum in 200 ml distilled water. Shake the gallocyanin crystals in 200 ml distilled water for 1 min. Filter, and add the residue with the filter paper to chrome alum solution. Boil on a water bath for 30 min. Cool to room temperature. Filter, and add 1 per cent HCl to bring pH to 1.6.

Procedure

(1) Bring paraffin sections down to distilled water as usual.
(2) Immerse in the dye–lake for 24 h or more, the period being dependent on the tissue and the age of the stain.
(3) Wash in acidulated distilled water, acidified with HCl at a pH 1.6, for 1 min. Change the solution and wash again until excess dye is removed.
(4) Dehydrate as usual through ethanol and xylol grades and mount.

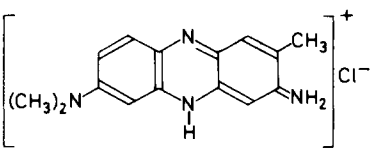
Observations
Deep blue colour is seen at the sites of nucleic acids.

Modified gallocyanin method for nucleic acids (according to de Boer and Sarnakar, 1956)

(1) Fix material in formalin and freeze-dry or fix in other fixatives and embed in paraffin.
(2) For preparing the dye, follow the procedure outlined in the previous schedule. Alternatively, following the method of Berube *et al.* (1966), mix 150 mg gallocyanin and 15 g chromalum in 100 ml distilled water, boil for 10–20 min, cool and filter. Bring filtrate to 100 ml by washing the precipitate with water. The filtrate can be used directly for staining, or to separate the chelate, add dilute ammonia to bring filtrate to pH 8.0–8.5. Filter with suction through a medium-porosity fitted glass funnel. Wash the precipitate with anhydrous ethyl ether, dry and store. Before use, prepare a 3 per cent solution in normal sulphuric acid.
(3) Bring down the sections to water.
(4) Immerse in gallocyanin–chromalum solution for 24 h or more, depending on the maturity of the stain.
(5) Wash for 1 min in distilled water acidulated with HCl at pH 1.6.
(6) Wash repeatedly till no more dye comes out.
(7) Dehydrate in ethanol, clear and mount in a synthetic resin.
(8) The nucleic acids take up a deep blue stain.

STAINING OF RIBONUCLEIC ACID

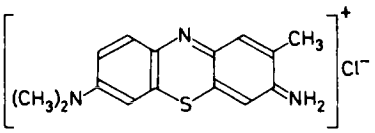
Supravital staining of RNA by neutral red has been claimed by Dustin (1947). Neutral red is a basic dye of the azine group, having the formula:



However, this stain is not widely applied as not all RNA in the cell is detected and chromosomal RNA cannot be studied through this method. Similar staining has also been noted with stilbamidine (Kurnick, Klein and Klein, 1950; Snapper *et al.*, 1951). No *in situ* localisation is possible in these methods as particles aggregating after diffusion may also take up the colour. Gram staining of bacteria is also dependent on its RNA (Stacey, 1947; Mitchell and Moyle, 1950).

In addition to toluidine blue (Hermann, Nicholas and Boricious, 1950), as mentioned above, methylene blue and several members of the thionin series

have been considered (Stowell and Zorzoli, 1947) as stains for RNA. Methylene blue is a basic dye of the thiazine group, having the structural formula:

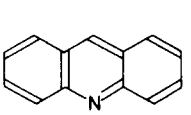


Pyronin is, however, more widely applied than any of these stains because of its superior specificity and capacity for yielding qualitative data.

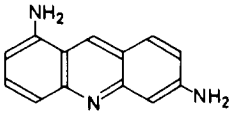
(1) Schiff-methylene blue staining (Spicer, 1961): Bouin's fluid fixation preserves RNA. RNA stains with 0.02 per cent thiazine dye in aqueous McIlvaine phosphate–citrate buffer between pH 3 and 4; 24 h fixation in Bouin's fluid hydrolyses DNA, which stains in Schiff's reagent without further acid hydrolysis. Thus, after fixation in Bouin's fluid, direct Schiff staining followed by 0.02 per cent methylene blue in phosphate–citrate buffer at pH 3.0–3.5 colours DNA magenta and RNA blue.
(2) Pyronin staining for RNA (Tepper and Gifford, 1962): Dehydrate fixed shoot or root tips in tertiary butyl alcohol series, embed, cut at 7 μm, and mount with Haupt's adhesive. Place sections in a 2 per cent aqueous solution of pyronin Y for 6 min, blot, differentiate twice for 5 min each in tertiary butyl alcohol, clear twice for 5 min in xylol and mount in Harleco synthetic resin. The dye had previously been extracted 5 times with equal volumes of chloroform and kept at a pH of 3.5.

OTHER STAINS OF DNA

Similar to methyl green, stoichiometric data are claimed to have been obtained with crystal violet for DNA by Kurnick (1950b). Staining with aminoacridines too is stated to be due to the polymerised nature of DNA (Irvin and Irvin, 1952; Lawley, 1956).

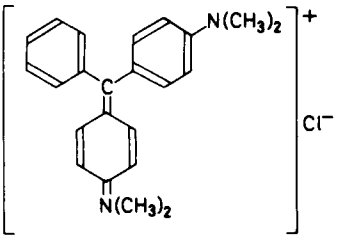


Acridine

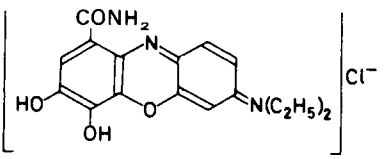


2,6–diamino acridine

De Bruyn and colleagues (1953) demonstrated that the spacing of amino groups in 2,8-diaminoacridines is appropriate for forming hydrogen bonding with phosphate groups of DNA, being 0.7–0.8 nm apart. Due to its polymerised nature, DNA staining has also been reported with quinolines (Parker, 1949), methyl green, malachite green (Kurnick, 1950a, b) as well as rosaniline (Lawley, 1956). Malachite green, a basic dye of the triphenylmethane group, has the structural formula:



With rosaniline, the dye has been found to compete with metal cations for binding sites in DNA. Acriflavine is regarded as a supravital stain for chromatin (De Bruyn, Robertson and Farr, 1951; Oster and Grimson, 1949) but its specificity for DNA is not yet known. Brenner (1953) suggested that, even with haematoxylin, specific staining for DNA can be obtained with alum mordant. Celestine blue is also considered as a specific DNA stain by Sanders (1946) and Davidson (1948) who have utilised this dye with pyronin for the differential staining of nucleic acids. However, its specificity is yet to be ascertained (Kurnick, 1955a). Celestine blue is a basic dye of the oxazine group, with the structural formula:



Sambucyanin has been considered as a stain for nucleic acids by Novelli (1954), which gives a red colour with both DNA and RNA.

Azure B staining has been so adjusted under appropriate conditions that DNA stains mainly orthochromatically and RNA metachromatically, so that DNA takes up a blue green colour, while cytoplasmic and nucleolar RNA are red purple (Flax and Himes, 1952).

Azure A can be used as a stain for nucleic acid if the dye is used in an aqueous solution and differentiation is carried out overnight in absolute ethanol. Its specificity has been confirmed by digestion with nucleases (Flax and Pollister, 1949).

Himes and Moriber (1956) stained paraffin sections successively in Feulgen reaction (azure A–Schiff reagent); periodic acid–Schiff (with basic fuchsin–Schiff reagent) and a 0.02 per cent solution of naphthol yellow S in 1 per cent acetic acid. It serves as a triple stain—blue green nuclei, red polysaccharides and yellow proteins.

Proteins

Within the nucleus, proteins remain chiefly in combination with nucleic acids, forming nucleoproteins. It is universally accepted that the relationship between proteins and the nucleic acids, RNA or DNA, is very intimate (Chargaff, 1955; Kaufmann, Gay and McDonald, 1960). Nucleolipidoprotein complexes are also possible (Serra, 1955, 1968). With the aid of special enzymic digestion methods, followed by tests for proteins and nucleic acids, evidence for the presence of two different types of proteins has been collected, one type being basic (e.g. protamine or histone), and the other acidic. The basic protein types are rich in arginine, lysine and occasionally histidine, and the acidic protein or the non-basic type is rich in tryptophane. However, several other kinds of proteins, and even non-individualised polypeptides, have also been found to exist. Histones may contain a number of amino acids whereas protamines may represent a special type of simplified protein of dibasic amino acids (Serra, 1942).

The two types of proteins can be analysed by ultraviolet spectrophotometry (Caspersson, 1940; Hyden, 1943) and the relative concentrations can be determined by chemical tests (Serra, 1946; Glenner and Lillie, 1957; Lillie, 1957). Isolated nuclei in 3 per cent aqueous sodium hydroxide solution can be fractionated by precipitation with mineral acids, permitting the basic proteins to remain in solution from which, in the presence of ammonium chloride, they can be precipitated out in 70 per cent alcohol (Mayer and Gulick, 1942; Serra, 1945).

Stedman and Stedman (1947, 1950) isolated from nuclei an acidic protein which they termed the 'chromosomin', an essential constituent of chromosomes. Mirsky and Ris (1947, 1951) separated nucleohistones from residual chromosomes, in which tryptophane-containing protein was found with RNA. Later work revealed the existence of a well defined nucleohistone complex in the chromosome (Vendrely and Vendrely, 1953; Vendrely *et al.*, 1958; Bal and Kaufmann, 1959; Dutt and Kaufmann, 1959), and direct relation between DNA and the arginine content of isolated nuclei has also been found (Vendrely and Vendrely, 1953). Dounce (1952, 1955) noted that DNA may also combine with non-histone proteins through its phosphate groups. By means of different cytochemical methods involving enzymic digestion, colour reaction, and extraction with dilute HCl for specifically removing histones, it has been concluded that DNA remains in the chromosomes in association with two types of proteins, histones and non-histones

Bernstein and Mazia, 1953; Bloch, 1958; Kaufmann, Gay and McDonald, 1960). Kaufmann and associates (1951) regarded RNA as associated with histone, while Mirsky and Ris (1947) considered it to be connected with tryptophane-containing protein.

Though the existence of at least two different types of proteins in chromosomes of higher organisms has been unanimously accepted, their exact pattern of association and function are to some extent still obscure. Mirsky and Ris (1947), from their study on isolated chromosomes, inferred that the residual chromosome, containing both DNA and RNA with non-histone protein, is responsible for maintaining the structural integrity even when the nucleohistone fraction is separated by sodium chloride treatment. Kaufmann, Gay and McDonald (1960) considered that all four components of the chromosome, that is, DNA, RNA, histone and non-histone proteins, form an interconnected system, and according to them, both nucleic acids and proteins are essential for retaining the chromosomal stability, thus no single component should be considered as an essential structural material.

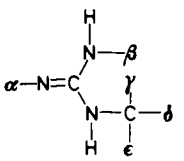
Regarding the functional aspects of proteins at the chromosomal level, the direct correlation between the amount of DNA and the amount of histone is worth consideration. The function of histones as gene repressors is being well recognised (*see* Zubey, 1964; Busch, 1965). McLeish (1959) found that the nuclear arginine and nuclear DNA show positive correlation in photometric tests. During the interphase, prior to mitosis, doubling of DNA is correlated with histone synthesis (*see* Bloch, 1958). According to him DNA histone complex predominates at the time of DNA-replication, whereas non-histone proteins are associated with DNA at the time of physiological activity. However, as sperms of certain organisms contain neither histones nor protamines, this generalisation is debatable (Bernstein and Mazia, 1953; Ris, 1958; Kaufmann, Gay and McDonald, 1960). The amount of residual or non-histone protein corresponds with the amount of RNA in the cell, which is evidently related to cytoplasmic activity. The protein, associated with RNA, whether histone or non-histone (as in residual chromosome), may be concerned with anaphase movement (Ris and Kleinfeld, 1952) or synapsis, as in *Tradescantia* (Kaufmann *et al.*, 1959).

No universally acceptable model of chromosome structure, reconciling the double helix model of DNA and protein, has yet been proposed, but one has been suggested by Freese (1958) and Taylor (1963, 1969) in which double helix DNA molecules are situated in a linear arrangement, linked by protein blocks, possibly of histone type. The role of divalent cations as linkers has also been suggested. However, this suggested model does not accommodate the longitudinal variations in the chromosomes, especially of the euchromatic and heterochromatic segments (Lewis and John, 1963; Van Holde *et al.*, 1979).

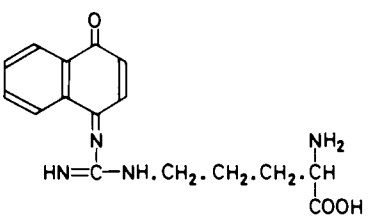
Disregarding the isolation procedures already considered, which do not allow the study of chromosomal proteins *in situ*, a number of chemical tests are at present available through which specific amino acids can be localised at the chromosomal level. They are the Sakaguchi reaction for arginine, tyrosine and tryptophane reactions, based mainly on the Millon's method, and sulphydryl tests for proteins by Barrnett and Seligman (1951).

ARGININE TEST

Of all the amino acid tests so far employed for the study of proteins in the chromosomes, that for arginine is the most important. The original Sakaguchi method (1925) has been modified by different workers (Serra, 1946; Baker, 1947; Thomas, 1950; Liebman, 1951), but is based on the principle (Baker, 1947) that a positive reaction can be obtained with compounds having the formula:



where $\alpha = \beta = H$ or CH_3; and $\begin{matrix} -\gamma \\ -\delta = \equiv N \\ -\epsilon \end{matrix}$ and the positions of γ, δ and ϵ may be taken by various atoms or by a single nitrogen of dicyandiamide. The guanidine group is involved in the reaction. The compound formed by the reaction of arginine with α-naphthol may have the structure shown below (Gurr, 1958):



Serra (1946) obtained positive arginine reaction in the meiotic chromosomes of both plants and animals. Sharma and Bhattacharyya (1957) noted an increase in the arginine content of the nucleus and cytoplasm following induced malignancy. The only limitation of this method is that the colour is unstable and fades rapidly. However, in Liebman's method the colour can be retained for about six months.

TYROSINE, TRYPTOPHANE AND HISTIDINE REACTIONS

Danielli's (1950) coupled tetrazonium reaction involving the use of tetrazotised benzidine gives positive results with all the above three protein-bound amino acid groups, but in order to locate each amino acid specifically, dif-

ferent blocking agents, namely benzoyl chloride, performic acid, 2,4-dinitrofluorobenzene, have been used prior to the addition of tetrazonium salts, these agents acting specifically on certain amino acids so that the reactions of these acids with tetrazonium salts are blocked. In this method, the application of a colour-producing agent is preceded by treatment with non-chromogenic reagents having a specific blocking capacity on certain amino acids. Of the various blocking agents, 2,4-dinitrofluorobenzene blocks reaction of tyrosine, while performic acid acts against tryptophane, and benzoyl chloride against all three (Barnard and Danielli, 1956; Barnard, 1961). For coupling, 8-amino-l-naphthol-3,6-disulphonic acid (H acid) has been used. The reactions can be interpreted as given on pages 546 and 548 (Gurr, 1958).

In place of tetrazotised benzidine, michrome blue salt 250 (tetrazotised *o*-dianisidine) can be used which is quite stable, and the colour produced is blue instead of red.

In addition to coupled tetrazonium reactions, methods are available through which the three amino acids can be separately demonstrated *in situ*. These are now described.

Trytophane reaction

This test is principally based on the indole reaction, which yields a blue or reddish violet colour (Ehrlich, 1901; Lison, 1936; Serra, 1946; Gurr, 1958). Gurr does not consider the test as specific unless confirmed through other methods, the process involving condensation of the reagent with phenols, amines or pyrrol derivatives, yielding coloured substance comparable with triphenyl–methane dyes (page 546).

In addition to the above principle, Glenner and Lillie (1957) employed the benzylidine condensation reaction for localising indole derivatives. Here, *p*-dimethylaminobenzaldehyde is used for the reaction and azotate of 8-amino-1-naphthol-5-sulphonic acid (S) is used for post-coupling. The method is based on the principle that the indole form resonates to an α-indolalin and a negative centre is produced at the carbon atom in position 2 of the indole ring. Following condensation of the carbonyl group of *p*-DMAB at the carbon 2 of the indole ring, a carbinol is formed. After dehydration, a purple violet coloured compound is produced (page 546).

The post-coupling reaction is applied to the condensation product to secure intensification of the colour, and in order to perform azo-coupling, under anhydrous conditions as far as possible, the post-coupling reaction with S acid is carried out in glacial acetic acid. A dark blue compound can be observed in the tissue. The reaction has been successfully employed by Sharma and Chatterji (1964) in the mitotic chromosomes of plants, where the mass of tissue, as such, is allowed to undergo the reaction before final smearing in 45 per cent acetic acid. The reaction is interpreted by Glenner and Lillie (1957) as:

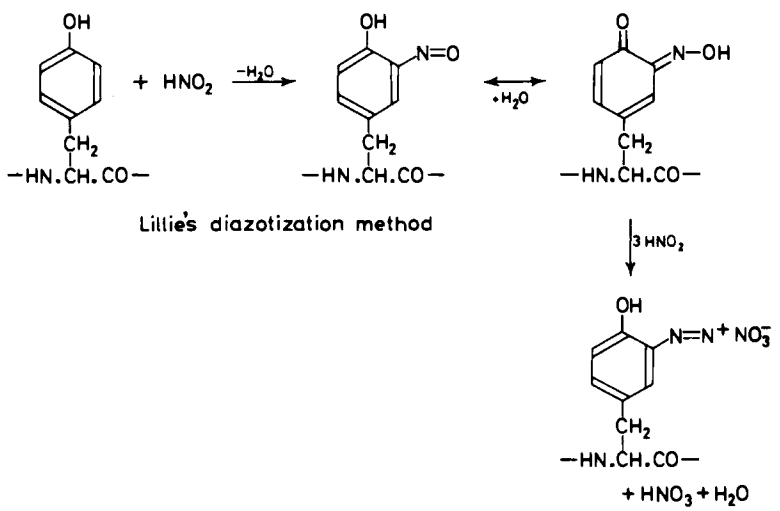
Glenner and Lillie's benzylidine condensation method

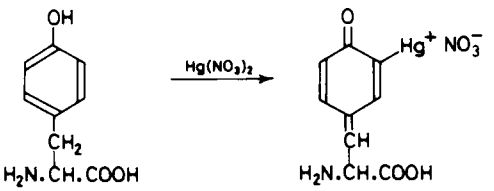
Tyrosine reaction

As adopted by Bensley and Gersh (1933), Serra (1946) and Gurr (1958), this test is principally based on Millon's reaction for proteins. Mercuric nitrate is used as Millon's reagent and the hydroxyphenyl group of tyrosine reacts with mercuric nitrate to produce an unstable coloured compound (Lugg, 1937; Gurr, 1958).



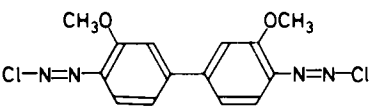
Lillie's diazotization method

Lillie (1957) applied protein diazotisation followed by coupling with a naphthol to localise protein bound tyrosine. The coupling reagent tried is S acid, 8-amino-1-naphthol-5-sulphonic acid. His method is based on Morel and Sisley's technique (1927), where the principle involves the formation of an *o*-C-nitrozation of tyrosine, followed by the formation of a quinone–oxine tautomer and, finally, the production of diazonium nitrate by reduction through more nitrous acid.



Histidine reaction

Protein bound histidine is best demonstrated in Landing and Hall's technique (1956) which is based on the principle of allowing histidine to react with michrome blue salt 250 with the structure

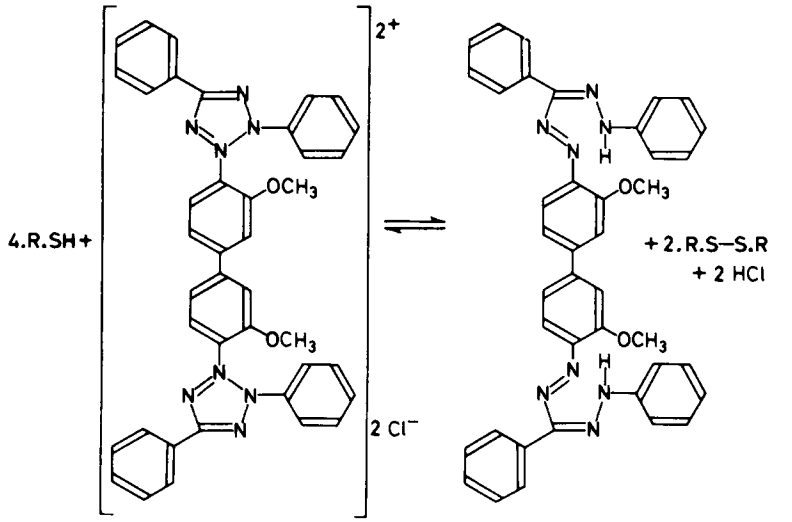


The reaction takes place with the imidazole group of histidine, and two weakly coloured compounds are produced which, following coupling with H acid (8-amino-1-naphthol-3,6-disulphonic acid), form a mixture of intensely coloured azo dyes of brick red or reddish brown appearance. The reaction is almost identical to that of the coupled tetrazonium test, except that here, instead of tetrazotised benzidine, michrome blue salt 250 is used.

REACTIONS FOR S—S AND S—H GROUPS OF PROTEINS

Of all the tests meant for the S—S and S—H groups of proteins, Barrnett and Seligman's technique (1954) is widely applied and is based on the use of tetrazonium salts, whose oxidising property is utilised at a higher pH. At the site of reducing groups, strongly coloured insoluble formazan is produced from colourless tetrazolium salts. The formazans may possibly be tagged with other structures as well (Nineham, 1955).

Hyde and Paliwal (1958) employed with success a modified schedule for



demonstrating chromosomal sulphydryl groups in onion root tips. In a separate method by Chevremont and Frederic (1943), the reaction involves the reduction of potassium ferricyanide by the sulphydryl groups within the tissue. The ferrocyanide thus produced, reacts with ferric sulphate to deposit insoluble prussian blue.

Test for chromosomal histones

In addition to the Sakaguchi reaction based on the arginine content of histones (McLeish, 1959), several other tests for nucleohistones are used. Of them, alkaline fast green (Alfert and Gerschwind, 1953) is the one most widely employed, giving the best results with tissues fixed in formalin, or formaldehyde vapour, or freeze-dried (Cowden, 1966; Pearse, 1972). The removal of nucleic acid is desirable before applying the test (Davenport and Davenport, 1965). Naphthol yellow S (Deitch, 1955), amido black 10B (Geyer, 1960), alkaline eosin or bromophenol blue (Bloch and Hew, 1960), Biebrich scarlet (Spicer, 1962), etc. have also been utilised in securing colour reactions. Jobst and Sandritter (1964) used metaphosphoric acid treatment, followed by gallocyanin, whereas the ammoniacal silver nitrate method has been applied by others (Black and Ansley, 1964).

Formaldehyde fixatives have been regarded as suitable for the preservation of histones (McLeish, 1959) while Davies (1954) regarded freeze-substitution in methanol as a superior method of preservation. De (1961) recorded better preservation after freeze-substitution in methanol than in ethanol. He further noted that FAA fixation retains both basic and non-basic proteins and renders the histone resistant to extraction by 1/100 N HCl at 25 °C, for 4 h. This resistance has been attributed to cross-linkage formation in the protein side chains. There are different methods for the isolation of fractions, including chemical fractionation, chromatography and electrophoresis, which have been dealt with in detail by Busch (1965).

SCHEDULES

Arginine reaction

Liebman's modification (1951) of Thomas's method (1950)

Reagents

(1) 1% α-naphthol solution in absolute ethanol	5 ml
Dist. water	95 ml

Mix together

(2) 1 N sodium hypochlorite solution	15 ml
1 N potassium hydroxide solution	5 ml
Dist. water	80 ml

Mix together

(3) Urea	10 g
Potassium hydroxide	5 ml
Dist. water	15 ml
Tertiary butanol	70 ml

Mix the first three chemicals together. Then add butanol.

Procedure

(1) Cut paraffin sections of materials (16 μm thick), previously fixed in Bouin's fluid, and mount on slides without the use of albumin. De-paraffinise by immersing successively in pure xylol and absolute ethanol. Dip in celloidin solution. Drain off excess celloidin and wipe the back of the slide. Before the celloidin solution has hardened completely, immerse successively in 90 and 70 per cent ethanol. Bring down to distilled water.
(2) Treat the slides with cold α-naphthol solution (1) for 15 min at 0–4 °C.
(3) Transfer immediately to cold hypochlorite–hydroxide mixture (2) and treat for 1½ min at 0–4 °C.
(4) Dip immediately in cold urea solution (3) and keep for 10 s with continuous stirring at 0–4 °C.
(5) Change over to fresh cold urea solution (3) and treat with stirring for 2 min at 0–4 °C.
(6) Immerse in anhydrous tertiary butanol for 10 s, stirring the solution with the slides.
(7) Treat in a change of tertiary butanol for 3½ min.
(8) Immerse in pure xylol with stirring for 10 s.
(9) Treat with two more changes of pure xylol, keeping 1–2 min in the first and 2–3 min in the second.
(10) Drain off xylol and mount in liquid paraffin seal.

Observations
Arginine and arginine-containing proteins take up an orange to reddish colour.

Precautions
(1) Steps (2)–(5) should be carried out at 0–4 °C and the remaining ones at room temperature.
(2) The reagents should be freshly prepared.

Serra's test for arginine (Serra, 1944)

Reagents

(1) Reaction mixture containing:

1% α-naphthol solution in 96% ethanol, diluted 1:10 with 40% ethanol	0.5 ml
Normal sodium hydroxide solution	0.5 ml
40% aq. urea solution	0.2 ml

Keep at 0–5 °C.

(2) 2 per cent sodium hypobromite solution, freshly prepared by pouring 0.7 ml of liquid bromine in 100 ml of 5 per cent NaOH, with stirring and cooling.

Procedure

(1) Harden the pieces or sections in 10 per cent formalin solution for 12–24 h if the fixative does not contain formalin.
(2) Immerse the pieces or sections for 15 min in the reaction mixture at 0–5 °C.
(3) Add to the reaction mixture with tissue 0.2 ml sodium hypobromite solution. Keep for 3 min at 0–5 °C with stirring.
(4) Add another 0.2 ml 40 per cent urea solution to the mixture and stir.
(5) Immediately add 0.2 ml more of sodium hypobromite solution to the mixture with constant stirring.
(6) Remove the material after 3 min and pass successively through four pure glycerin baths, keeping to 2–3 min in each.

Observations
Arginine-containing areas give positive reaction but the rest do not.

Alternative
Immerse the tissue in NaOBr solution for 3 min after step (5). Then transfer to glycerin baths.

Sakaguchi dichloronaphthol reaction for arginine

According to McLeish *et al.* (1957); Deitch (1961); fixed material in acetic–ethanol, or by freeze-drying, followed by embedding in paraffin.

(1) Prepare immediately before use: 4 per cent filtered barium hydroxide; 1 per cent sodium hydrochlorite; 1.5 per cent 2,4-dichloronaphthol in tertiary butyl alcohol.
(2) Bring down slides to water, wash twice in distilled water. Blot and transfer to an empty staining jar.
(3) Add to a flask successively: barium hydroxide, 5 parts; sodium hypochlorite, 1 part; dichloronaphthol, 1 part, with shaking. Pour the mixture into the staining jar and keep the slide in it for 10 min at 22 °C.
(4) Pass the slides through three changes of tertiary butyl alcohol, shaking vigorously in each change.
(5) Keep in two changes of xylene containing 5 per cent tri-*n*-butylamine for 30–60 s in each.
(6) Drain and mount in Shillaber's Oil containing 10 per cent tri-*n*-butylamine. The presence of arginine is indicated by an orange-red colour.

Sakaguchi oxine reaction for arginine

Modified according to Carver, Brown and Thomas (1953).

(1) Bring down sections embedded in paraffin and fixed in Bouin, Carnoy's or formalin fixatives, to 70 per cent ethanol.
(2) Treat for 15 min at room temperature in 0.3 per cent 8-hydroxyquinoline in 30 per cent ethanol.
(3) Tranfer the slide immediately, without draining, to alkaline hypochlorite solution. (The solution of freshly prepared hypochlorite is standardised before use against 0.1 N sodium thiosulphate, employing 1 ml of the hypochlorite, 5 ml N-potassium iodine, 8 ml concentrated HCl and 50 ml of water. The fresh hypochlorite solution is used as stock. Prepare a 0.15 N stock solution of KOH. Before use, measure out suitable quantities of the two stock solutions in a 100 ml cylinder to make a final concentration of 0.15 N chlorine and 0.015 N KOH, taking the average chlorine content of fresh commercial hypochlorite to be 1.6 N.) Keep slides for 60 s without moving.
(4) Prepare alkaline urea solution by adding 15 g urea to 10 ml of 0.15 N KOH in a 100 ml cylinder. Dilute with water to 25–30 ml and mix until dissolved. Add 70 ml tertiary butyl alcohol and mix. Transfer the slide immediately, without draining to the alkaline urea solution, and agitate gently for 10 s. Transfer and keep in a fresh alkaline urea bath for 2 min.
(5) Treat slide in tertiary butanol for 4 min.
(6) Keep in aniline oil for 3 min.
(7) Wash in xylol for 10 s.
(8) Mount in a synthetic resin containing 0.025 ml aniline/100 ml.

Arginine sites are indicated by an orange colour.

Tyrosine reaction

Modification of Millon's reaction

Reagents

(1) Aqueous nitric acid solution, prepared by mixing:

303 ml conc. nitric acid with 202 ml dist. water and keeping for 48 h	100 ml
Mercuric nitrate	180 g
Dist. water	900 ml

Shake at intervals for a period of several days. Filter.

(2) Millon's reagent, prepared by mixing:

Sodium nitrate	1.4 g
66.6% aq. nitric acid solution (as described before)	3 ml
Mercuric nitrate solution in aq. nitric acid solution (solution (1) described before)	400 ml

(3) Distilled nitric acid, prepared by mixing:

66.6% aq. nitric acid solution (as described before)	100 ml
Dist. water	390 ml

Procedure

(1) Prepare and mount paraffin sections of formalin-fixed materials. De-paraffinise by passing through pure benzene and pure acetone grades. Dry by exposure to atmosphere. Frozen sections can be mounted directly on slides without water.
(2) Treat several slides simultaneously in the Millon's modified reagent solution (2) at room temperature. Remove one slide after every 15 min or 30 min interval from the reagent and treat as follows.
(3) Dip immediately in the distilled nitric acid solution (3).
(4) Rinse thoroughly in distilled water.
(5) Dehydrate quickly through 70 per cent and absolute ethanol grades, clear in xylol and mount in neutral balsam.

Observations

The areas which have tyrosine-containing proteins are coloured orange to brick red (Bensley and Gersh, 1933).

Precautions

(1) The optimum period of treatment in Millon's reagent is determined by removing the slides at fixed intervals.
(2) Incubation at 60 °C in Millon's reagent accelerates the reaction and it can be completed in 1 h instead of 3 h at room temperature.

Serra and Queiroz-Lopes's modified method (1945)

Reagents

(1) Reaction mixture containing:

Magnesium sulphate	7.5 g
Magnesium chloride	5.5 g
Sodium sulphate	7 g

Dissolve in 85 ml of distilled water, to which 12.5 g of concentrated sulphuric acid has been added. Dilute to 100 ml with distilled water.

(2) 1 M sodium nitrite solution, prepared by dissolving 6.9 g in 100 ml of distilled water.

Procedure

(1) Bring down the slides or pieces of tissue to water.
(2) Incubate in a few ml of the reaction mixture for 30 min at 60 °C in a stoppered jar.
(3) Cool the container in running water and leave at room temperature for 10 min.
(4) Add an equal volume of distilled water to the reaction mixture containing the tissue.
(5) Add to the mixture a few drops of sodium nitrite solution.
(6) After 3–4 min, place the tissues in free glycerin and either prepare squashes or mount as usual.

Observations

After 3 min treatment in $NaNO_2$ solution, the sites containing proteins with tyrosine take up colour, which lasts for several months.

Lillie's modification (1957) of the Morel–Sisley method for tyrosine (1927)

The fixative recommended is 4 per cent formaldehyde solution for 3–48 h.

Reagents

(1) Nitrosating mixture containing:

Sodium nitrite	6.9 g
Glacial acetic acid	5.8 ml
Make up to 100 ml with dist. water	

(2) Coupling mixture containing:

1-amino-8-naphthol-4-sulphonic acid (S acid)	1 g
Potassium hydroxide	1 g
Urea	2 g
70% ethanol	100 ml

Procedure

(1) Cut paraffin sections 5 μm thick. Mount and deparaffinise through xylol and alcohol grades and bring down to distilled water.
(2) Nitrosate at 3 °C in the nitrosating mixture for 18 h.
(3) Rinse in three changes of cold distilled water (0 °C), keeping 5 s in each.
(4) Couple in the coupling mixture for 1 h at 3 °C.
(5) Rinse in three changes of N/10 hydrochloric acid, keeping 5 min in each.
(6) Wash in running water for 10 min, dehydrate in ethanol, clear in xylol and mount in neutral balsam.

Observations
Areas containing tyrosine take up a pinkish red colour.

Dinitrofluorobenzene (DNFB) method for tyrosine, SH and NH_2

According to Danielli (1950) and Burstone (1955); material is freeze-dried or fixed in ethanol, acetone, formalin, etc.

(1) Bring down the sections to absolute acetone or ethanol, remove and dry in air.
(2) Treat with a saturated solution of DNFB in 90 per cent ethanol saturated with sodium bicarbonate for 2–16 h at room temperature.
(3) Wash in three changes of 90 per cent ethanol and finally in water.
(4) Treat with 5 per cent sodium hydrosulphate for 30 min at 45 °C.
(5) Wash in water.
(6) Immerse in nitrous acid, prepared by adding 1 vol of freshly prepared 5 per cent sodium nitrite to 4 vols of 2 N HCl at 0–4 °C for 30 min.
(7) Wash in water.
(8) Treat in a saturated solution of H acid in veronal acetate buffer at pH 9.4 for 15 min at 0.4 °C.
(9) Wash in water, dehydrate through ethanol grades, clear in xylol and mount in balsam or DPX. The sites of DNA attachment in the tissues appear as reddish-purple.

Tryptophane reaction

Indole reaction

Reagent
Ehrlich's indole reagent or *p*-dimethylaminobenzaldehyde.

Procedure

(1) Bring down frozen or paraffin sections to distilled water.
(2) Keep for 1–2 h at 60 °C in a partly filled stoppered jar.
(3) Bring down the jar and its contents to room temperature.

(4) Wash the sections with absolute ethanol, clear in xylol and mount in a suitable medium.

Observations

The formation of a bluish or reddish violet coloration at the sites containing tryptophane or other substances containing the indole group.

Glenner and Lillie's method for tryptophane (1957)

Reagents

(1) *p*-Dimethylaminobenzaldehyde	1 g
Conc. hydrochloric acid (sp. gr. 1.19)	10 ml
Glacial acetic acid	30 ml
(2) Fresh diazotate of 8-amino-1-naphthol-5-sulphonic acid (S acid), prepared by adding 240 mg of S acid to 3 ml of N HCl and 6 ml of distilled water, cooling to 4 °C, adding 1 ml of N $NaNO_2$ and stirring at 4 °C for 15 min	1 ml
Glacial acetic acid	40 ml

Procedure

(1) Fix tissues in 10 per cent calcium acetate formalin. Cut paraffin sections 5 μm thick, deparaffinise and bring down to absolute ethanol. Dry in air for 30 s.
(2) Immerse for 5 min in *p*-dimethylaminobenzaldehyde mixture (1) at 25 °C.
(3) Wash successively in three changes of glacial acetic acid for 30 min in the first change and 1 h in each of the other two.
(4) Treat for 5 min at room temperature in S acid mixture (2).
(5) Wash in two changes of glacial acetic acid, keeping for 30 s in each.
(6) Treat for 5 min at room temperature in 40 ml of glacial acetic acid containing 20 mg of new fuchsin.
(7) Wash in two changes of glacial acetic acid, keeping for 1 min in each, pass through acetic acid–xylol and then pure xylol grades and mount.

Observations

When counter-stained with new fuchsin, sites of indole derivatives stain pale purple to deep blue. Otherwise they colour pale to dark blue.

Eosin–light green method for tryptophane (Hřsel, 1957)

Treat with 4 per cent CrO_3 for 30 min, wash in running water for 20–30 min, rinse in distilled water, treat in 1 per cent phosphomolybdic acid for 20 min, rinse, stain for 30 min in 1 per cent eosin, rinse, stain in 1 per cent light green for 10 min, dry with filter paper, dehydrate through isopropyl alcohol grades, clear and mount. Eosin stains tryptophane-containing proteins; light green is bound to amino groups.

Tryptophane method for formalin-fixed tissues

According to Adams (1960). The material is fixed in formalin and embedded in paraffin following the usual schedule.

(1) Bring the sections down to absolute ethanol.
(2) Immerse the slides in a solution containing: glycerol, 5 ml; 60 per cent ferric chloride, 1 ml; conc. sulphuric acid, 5 ml; methylated alcohol, 80 ml. The solution can be stored for several months.
(3) Lift out slide with forceps, decant excess fluid, ignite in a small flame, holding the slide horizontal with the sections uppermost. Repeat three to six times.
(4) Wash in absolute ethanol
(5) Rinse until clean in glacial acetic acid–ethanol mixture (1 : 1). Clear in xylol and mount.
(6) The sites of tryptophane show a mauve coloration. Since the pigment is not stable, the slides must be examined within 24 h.

Histidine reaction

Landing and Hall's method (1956)

Reagents

(1) Gram's iodine	30 ml
Ammonia solution (sp. gr. 0.880)	2 ml
(2) Diazo mixture containing:	
Naphthanil diazo blue B (Michrome blue salt 250)	0.05 g
Veronal acetate buffer pH 9.16	50 ml
(3) H acid mixture containing:	
8-amino-1-naphthol-3,6-disulphonic acid (H acid)	1 g
Veronal acetate buffer pH 9.16	50 ml

Procedure

(1) Fix in 10 per cent formalin. Prepare paraffin sections as usual and bring down to distilled water.
(2) Treat in ammoniacal Gram's iodine solution (1) at room temperature for 24 h.
(3) Wash in distilled water.
(4) Wash in 95 per cent ethanol till the sections lose their yellow colour.
(5) Wash successively in distilled water and veronal acetate buffer pH 9.16.
(6) Treat in diazo mixture (2) for 15 min at 0–4 °C.
(7) Rinse in distilled water.
(8) Wash in three changes of veronal acetate buffer, keeping 2 min in each.
(9) Treat in H acid mixture for 15 min at 0–4 °C, stirring.
(10) Rinse thoroughly in water. Dehydrate through acetone or alcohol and xylol grades and mount.

Observations

The areas containing histidine stain brick red to reddish brown.

Metaphosphoric acid–gallocyanin for basic proteins

According to Jobst and Sandritter (1964). Air-dried smears may be used after alcohol or formalin fixation.

(1) Keep smears for 15 min in 5 per cent aqueous trichloracetic acid at 95 °C to remove DNA.
(2) Wash three times in 70 per cent ethanol, followed by water.
(3) Dissolve completely 0.8 g of crystalline metaphosphoric acid (HPO_3) in 100 ml distilled water, by shaking at 20 °C.
(4) Keep the slides in the above freshly prepared solution at 20 °C for 1 h.
(5) Rinse in distilled water three times, 1 min each time.
(6) Prepare gallocyanin–chrome alum solution by boiling 150 mg of gallocyanin for 10 min with 5 g chrome alum in 100 ml distilled water and restore to a final volume of 100 ml. Immerse the slides in the stain for 48 h at 20 °C.
(7) Wash in running water for 5 min.
(8) Dehydrate in ethanol, clear in xylol and mount in a synthetic resin.
(9) The sites of basic protein stain deep blue due to the combination of metaphosphoric acid with NH_2 and guanidine groups.

Naphthol–yellow S method for basic proteins of nuclei

According to Deitch (1955). The material can be post-fixed in ethanol after freeze-drying; or fixed in acetic–ethanol and then cut in the cold microtome; or embedded in paraffin after fixation in formalin or Carnoy's fluid.

(1) Bring down the sections to water.
(2) Immerse for staining 4–6 h in 0.5 per cent aqueous naphthol yellow S at pH 2.7.
(3) Wash in distilled water.
(4) Dehydrate in 95 per cent ethanol, clear in xylol and mount in a synthetic resin.
(5) The amount of yellow staining shows the number of available basic groups of protein. In the nuclei, if the nucleic acids have not previously been removed, only those basic groups not blocked by DNA will be shown.

Combined reaction for tyrosine, tryptophane and histidine

Danielli's coupled tetrazonium reaction (1950)

Reagents

(1) Benzidine solution containing:

Benzidine base	0.5 g
Conc. hydrochloric acid	5 ml
Dist. water	20 ml. Store at 0–5 °C

(2) H acid solution containing:

8-amino-1-naphthol-3,6-disulphonic acid (H acid)	0.5 g
Veronal acetate buffer pH 9.0	25 ml

Procedure

(1) Prepare paraffin sections from alcohol or formalin-fixed tissues. Bring down to distilled water.
(2) Add 7 ml cold 2 per cent aqueous sodium nitrite solution to 20 ml of cold benzidine solution (1) drop by drop at 0–5 °C, not allowing the temperature to rise above 5 °C. Chill the solution to 0 °C.
(3) Add to it 3.5 ml 5 per cent aqueous ammonium sulphamate solution, stirring, and then 34 ml aqueous sodium carbonate solution (28 g in 95 ml water). Stir well. After effervescence has stopped, make up to 150 ml with distilled water. This solution is tetrazotised benzidine and it decomposes after an hour.
(4) Treat the sections in tetrazotised benzidine solution for 15 min.
(5) Rinse thoroughly in distilled water.
(6) Wash in three changes of veronal acetate buffer (pH 9.0), keeping for 2 min in each.
(7) Treat in H acid solution (2) for 15 min.
(8) Rinse in running water for 3 min. Dehydrate through alcohol and xylol grades and mount.

Observations

The sites containing tyrosine, tryptophane and histidine stain reddish brown. The stain is stable. Blocking agents should be used prior to this test for specific localisation of each amino acid (*see* text).

Sulphydryl groups

Modified alkaline tetrazolium reaction

According to Deguchi (1964) for S—S and S—H groups.

(1) Prepare a 5 per cent KCN solution and adjust the pH to 8.4 with 0.2 M acetic acid. To 10 ml add 10 ml 0.2 borate buffer (pH 8.4) and 15 mg nitro-BT. Keep in a covered glass jar. Store at −20 °C.
(2) Bring down sections to absolute ethanol.
(3) Cover with 1 per cent celloidin and allow to dry.
(4) Immerse the slides in fresh 0.5 M thioglycollic acid, adjusted to pH 8.0 with 1 per cent NaOH for 2–3 h at 50 °C.
(5) Rinse successively in water, 1 per cent acetic acid, and again in water.
(6) Immerse in the nitro-BT reagent for 30–60 min at 37 °C.
(7) Wash in 1 per cent acetic acid and then in water.
(8) Dehydrate, clear and mount in a synthetic medium.

Protein-bound S—S and S—H give dark blue to red colour in the section.

Tetrazolium method for both S—S and S—H groups (Barnett and Seligman, 1954)

Reagents

(1) Trichloracetic acid	1 g
80% ethanol	100 ml
(2) Incubation mixture containing:	
10% aq. potassium cyanide solution	48 ml
1 N sodium hydroxide	2 ml
Blue tetrazolium chloride	0.025 g

Procedure

(1) Fix tissues in alcoholic trichloracetic acid solution (1) for 24 h.
(2) Prepare paraffin blocks. Cut sections 5–10 μm thick. Fix to slides with minimum quantity of albumin. Dry at 37 °C. Deparaffinise with xylol and bring down to absolute ethanol.
(3) Dip in 0.5 per cent celloidin dissolved in absolute ethanol and ether mixture (1 : 1). Drain and dry.
(4) Treat in 90 and 70 per cent ethanol, keeping 2 min in each. Bring down to distilled water.
(5) Treat in incubation mixture (2) at 37 °C for 8–12 h, till the sections take up a blue colour.
(6) Rinse thoroughly in water. Mount in glycerin jelly.

Observations

The sites of sulphydryl groups are indicated by the blue colour.

Alternative

Neotetrazolium chloride may be used in place of blue tetrazolium. The incubation period is 2–3 h and the colour developed is purplish red.

Test of chromosomal histone (Black and Ansley, 1964)

Squash salivary glands in 45 per cent acetic acid, make air dry preparations, fix in 10 per cent acetate buffered neutral formalin (15 m), rinse in water, place in A–S solution (fresh aqueous 10 per cent $AgNO_3$ added to concentrated NH_4OH till turbid), agitate for 5–6 s, wash in water, develop in 3 per cent formalin (2 m) wash in water, dehydrate and mount, A–S reacts with DNA-bound histone.

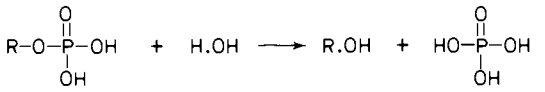
Enzymes

ALKALINE PHOSPHATASE

Of all the tests employed for the *in situ* localisation of enzymes in chromosomes, the technique for the demonstration of alkaline phosphatase activity is the most important, the term 'alkaline phosphatase' being loosely used for histochemical purposes, which is precisely 'phosphomonoesterase I'. This enzyme can act at an alkaline pH of 9.2 to 9.6 and is specific for monoesters of *o*-phosphoric acid.



Phosphate ester *ortho*Phosphoric acid

The demonstration of the enzyme activity in the cell, and especially in the chromosome, can be carried out principally through two different methods: (a) calcium phosphate deposition; and (b) azo dye methods.

Calcium phosphate method

The calcium phosphate precipitation technique was first developed independently by Gomori (1939) and Takamatsu (1939), and was based on the principle that if a tissue containing the enzyme is incubated at 37 °C in a medium containing phosphate salt as the principal constituent at an alkaline pH (9.4), the liberated phosphoric acid can be deposited at the site of the enzyme as an insoluble phosphate precipitate if a calcium salt is present as one of the components. The visualisation of calcium phosphate can be done by converting it into silver sulphate and then to metallic silver or into cobalt phosphate through a cobalt salt and finally to a black precipitate of cobalt sulphide through ammonium sulphide. The method as modified at present (Danielli, 1950; Gomori, 1946, 1952) contains in the medium magnesium sulphate or chloride as activator (Kabat and Furth, 1941). A barbiturate solution is used to buffer the medium between 9.0 and 9.4 and a citrate buffer is often used to remove preformed calcium salt. The way through which magnesium activates the enzymes is not fully explained. Three alternative

modes of action are possible (Pearse, 1960, 1972): (a) the metal may form an essential part of the active centre of the enzyme; (b) it may bind the enzyme with the substrate; or (c) the activation may be caused by changing the surface charge of the protein and, consequently, its electrokinetic potential.

Several phosphate salts have been used as substrates, such as α, β-glycerophosphate, fructose diphosphate, adenosine triphosphate, sodium dihydrogen phosphate, etc., but the most commonly used one is sodium-β-glycerophosphate. Substrate specificity has been observed in a number of cases and alkaline phosphatase is found to represent a large number of enzymes (Gould, 1944; Glick and Fischer, 1946; Zorzoli and Stowell, 1947; Dempsey, 1949; Sharma, Mookerjea and Ghosh, 1953; Dixon and Webb, 1964). Moss (1964) recorded the presence of alkaline phosphatases in different human tissues, differing in electrophoretic and enzymatic properties (Raichoudhuri *et al.*, 1976). Eaton and Moss (1966) demonstrated that alkaline phosphatase and pyrophosphatase are identical.

A number of factors influence the activity of the enzyme. Fixation has a profound effect, and the most effective fixation is freezing, but as there are a number of disadvantages in this procedure. Chilled alcohol or acetone (4 °C) has been found to be quite suitable as it does not cause any loss of activity. Cold neutral formalin-fixation also gives successful results (Seligman, Chauncey and Nachlas, 1951). However, even with a metallic fixative, Sharma and Roy (1956a) secured satisfactory results in plant chromosomes.

In addition to fixation, the temperature for embedding in paraffin and for mounting or storage also affects the activity to a significant extent. Embedding in a mixture of paraffin waxes of m.p. 42 and 55 °C yields excellent results (Dalgaard, 1956). In no case should a temperature higher than 37 °C be used for drying slides (Ruyter and Newmann, 1949; Pearse, 1960).

As the enzyme is effective in an alkaline medium, the maintenance of proper pH (9.2–9.8) is necessary. Moreover, the calcium phosphate becomes soluble at a low pH and, as such, the problem of diffusion may result; Robbins (1950), Cacioppo and colleagues (1953) and Sonnenschein and Kopac (1953) dealt with this aspect in detail. The problem of activation is also important. In addition to magnesium, ascorbic acid, salts of bile acids, zinc, etc., have been found to act as activators (Cloetens, 1941; Newman, Kabat and Wolf, 1950; Sadasivan, 1952; Hoare and Delroy, 1955). The choice of proper substrates is a major factor, and though sodium glycerophosphate is the most commonly used substrate, phenyl phosphate is more easily hydrolysed at an alkaline pH (Hill, 1956; Pearse, 1960).

Activity of alkaline phosphatase in nuclei and chromosomes has been demonstrated by several workers (Krugelis, 1942; Danielli and Catcheside, 1945; Brachet and Jenner, 1948; Sulkin and Gardner, 1948; De Nicola, 1949; Bhattacharjee and Sharma, 1951; Chevremont and Firket, 1953; Sharma, Mookerjea and Ghosh, 1953; Sharma and Roy, 1956a, b). Danielli and Catcheside (1945) observed phosphatase-positive areas in the bands of the salivary gland chromosomes of *Drosophila* and compared them with the Feulgen-positive areas. Bhattacharjee and Sharma (1951) demonstrated greater activity in meiotic cells of plants than in the mitotic ones. Sharma, Mookerjea and Ghosh (1953) correlated the phosphatase activity in chromo-

somes, throughout the divisional cycle, with the Feulgen stainability. Sharma and Roy (1956a) obtained positive phosphatase reaction in chromosomes and nucleoli, even after nucleic acid extraction, and attributed this residual activity to phospholipoid complexes. These authors (1956c) also noted changes in phosphatase activity after treatment with x-rays.

The validity of the test has, however, been questioned on two grounds:

(1) The possibility of the diffusion of the enzyme from the site of its occurrence and its adsorption at a different site (Feigen, Wolf and Kabat, 1950; Newman *et al.*, 1950).
(2) Diffusion of calcium phosphate and its adsorption at a different site (Cleland, 1950; Novikoff, 1955).

Several authors claimed that a positive phosphatase reaction may not indicate high activity at that particular site (Martin and Jacoby, 1949; Novikoff, 1952, 1955). Danielli (1947) suggested the reliability of this technique for *in situ* localisation of the enzyme. Lison (1948) also agreed, to a major extent, with Danielli's observations. Sharma, Mookerjea and Ghosh (1953) performed a number of control experiments, including inactivation of the enzyme through different methods, and claimed the validity of the test for *in situ* localisation (*see* Serra, 1955).

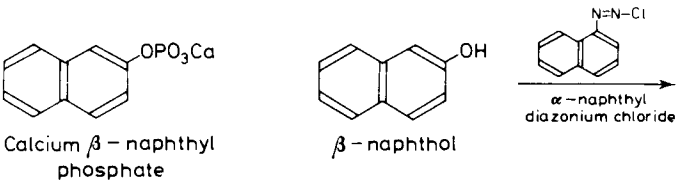
In any case, in view of the problem of diffusion and adsorption raised by certain authors (Pearse, 1972), several modifications have been suggested to eliminate these limitations. Deimling (1964) suggested the use of lead ions to combine with phosphoric acid, avoiding calcium and cobalt, but the membrane effect of lead is a limitation. Gomori (1951), in his schedule, increased the concentration of calcium ions in the substrate mixture. Martin and Jacoby (1949) suggested the elimination of magnesium salt from the medium, and also stated that if the slides are coated with celloidin and dried in air for a few minutes, reproducible results may be obtained. Maengwyn-Davies and Friedenwald (1950) prepared the incubation medium saturated with calcium phosphate. Even incubation in the substrate medium before the removal of paraffin (Goetsch, Reynolds and Bunting, 1952) was suggested. Novikoff (1955) considered that such procedures may all lead to the reduction of enzyme activity (*see* Osawa, 1951). According to him, if these measures can be adopted without reducing enzyme activity, the Gomori–Takamatsu technique can then be applied for *in situ* localisation. Fishman, Green and Inglis (1963) and Watanabe and Fishman (1964) noted the inhibition of intestinal alkaline phosphatase activity by L-phenylalanine. Thomas and Aldridge (1966) recorded a similar inhibition by Be ions.

Gomori (1950) suggested that the alkaline phosphatase technique can be applied for quantitative estimation. Danielli (1950) stated that quantitative results can be estimated on the principle that the sites of highest activity appear before those of less activity. Several methods for the quantitative estimation of alkaline phosphatase activity, with the aid of spectrophotometry, radioactivity as well as interferometry, have been developed (Doyle, Omoto and Doyle, 1951; Barka and colleagues, 1952; Barter, Danielli and Davies, 1955; Shugar, Szenberg and Sierakowska, 1957; cf. Pearse, 1972).

Azo dye method

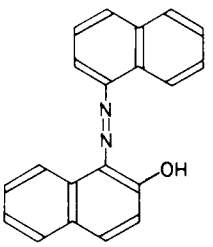
Coupling methods

The azo dye technique is based on the principle of precipitating the alcoholic part of the phosphate ester instead of the phosphoric acid. The method was originally developed by Menten, Junge and Green (1944). They used β-naphthyl phosphate as the substrate and the liberated β-naphthol, after hydrolysis, is reacted upon *in situ* by diazotised α-naphthylamine at pH 9.4, whereby a red precipitate is obtained (*see* reaction as outlined). It can be applied to both fresh and formalin-fixed tissues.



Calcium β – naphthyl phosphate

β – naphthol

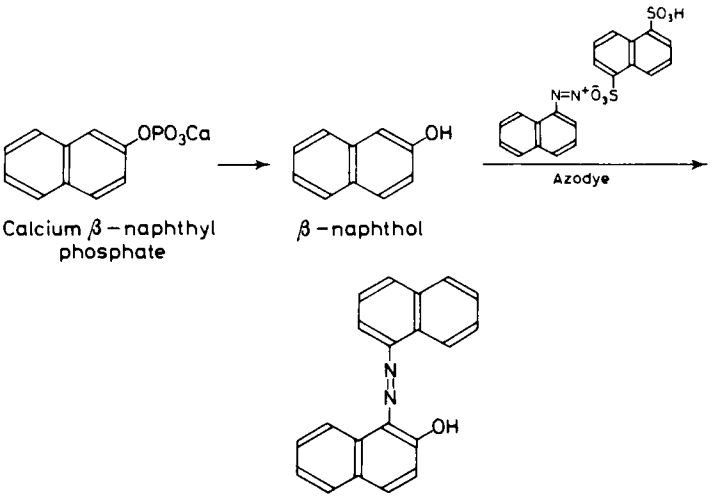


Red insoluble dye

Danielli (1946) suggested the use of phenyl phosphate and β-naphthyl phosphate to obtain the reaction. Mannheimer and Seligman (1948) used magnesium ion as activator and modified the procedure and used α-naphthyl-diazoniumnaphthalene-1,5-disulphonate for coupling. The purplish red dye, which precipitates out, has been found to be insoluble.

This method has the added advantage over the original technique of Menten, Junge and Green (1944), in that the coupling reagent used here is stable as compared to the diazonium salt used by them. In fact, in acetone-fixed paraffin sections, the phosphatase-rich areas can be observed within 1 min. The low temperature (usually 10 °C) and short period of incubation reduce the background staining to a significant extent. In Mannheimer–Seligman's method (1948), development of the pigment can be controlled, as desired. In Gomori's modification of the original method (1951), sodium α-naphthyl phosphate has been used instead of calcium β-naphthyl phosphate, as the sodium salt is relatively less soluble (Friedman and Seligman, 1950). It does not cause any haziness or false adsorption. In order to avoid blurring, he has suggested that a non-optimal pH and temperature should be used, which would cause the naphthol to be liberated at a slower rate. That α-naphthyl salts are suitable as a substrate has also been confirmed by King (1952), Novikoff (1955) and Goessner (1958).

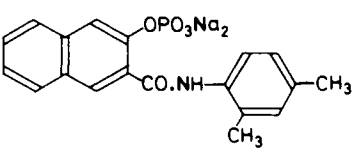
However, diazonium salts have certain disadvantages, namely, (a) several



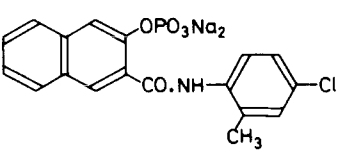
of them cause inhibition of enzyme activity, which may be eliminated by using a very low concentration of the solution, and (b) non-specific staining of tissue may result from their breakdown products (Pearse, 1972). When diazotised *o*-dianisidine is used as the diazonium compound, it has been found that the precipitation of colour varies with the pH. At a higher pH, both ends of the molecule are available for reaction, whereas at a lower pH, only one end undergoes coupling (Lojda, Vecerek and Pelichova, 1964). Loustalot (1955) noted that, following storage, enzyme activity was observed in residual substrate, but these storage artefacts can be eliminated by treatment through Lugol's iodine treatment. However, Gomori's modification has so far been found to be quite reliable and is much simpler than other techniques (Gurr, 1958). The most important advantage of Gomori's schedule is that the process can be carried out in higher temperatures, which results in good enzyme activity. Pearse (1972) made a detailed study of the diffusion, if any, of reaction products.

Another application of the coupling azo dye technique involves the use of substituted naphthol phosphate (Burstone, 1958a, b, 1962; Rutenberg and colleagues, 1958, etc.). Phosphate esters of several complex arylides of 2-hydroxy-3-naphthoic acid were used by Burstone. They are all highly stable esters and their reaction products are sparingly soluble. Several esters while used in 2 per cent dimethyl formamide at an alkaline pH have been found to be suitable, such as

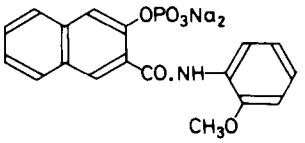
(a) Naphthol-AS-MX



(b) Naphthol-AS-TR



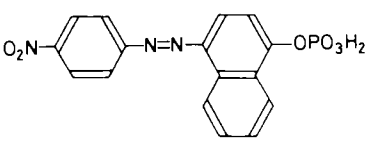
(c) Naphthol-AS-BI



For coupling, fast blue RR, fast red RC, fast violet, etc., have been applied. The method has been widely used on freeze-dried tissues as well as to study leucocyte phosphatases in blood smears, bone marrow, the low solubility of the reaction products making precise localisation possible (Ackerman, 1962; Kaplow, 1963; Wetzel, Horn and Spicer, 1963, Wulff, 1967). Hexazotised bases were introduced by Davis and Ornstein (1959), using hexazonium para rosaniline (HPR) with naphthol AS substrate (Barka and Anderson, 1962). Similarly, Lojda, Vecerek and Pelichova (1964) used tetrabromofuchsin and Stutte (1967) applied New Magenta (triaminotritolylmethane chloride). Moreover, being stable esters, their stock solutions can be stored for a long time. The limitation of this method lies in the facts that: (a) being sparingly soluble in water, the required concentration is scarcely obtained, (b) being composed of large molecules, access to the enzyme is not adequate, and (c) the low coupling capacity of hydroxy naphthoic arilides often hampers visualisation of the precipitate (Defendi and Pearse, 1955; Pearse, 1972).

Non-coupling methods

In order to avoid the instability of the diazonium salts, their inhibitory effects and the use of low temperature, Loveless and Danielli (1949) used the phosphorylated azo dye technique which involves the application of a coloured phosphate ester which yields an insoluble coloured base on hydrolysis. *p*-Nitrobenzene, azo-4-naphtholphosphate.



has been used for the purpose. It does not inhibit the activity of the enzyme and undergoes ready hydrolysis. According to Pearse (1972), the free base is slightly soluble in water and, as such, diffusion occurs. This method has yet to be standardised for application in the study of chromosomes.

In addition to the above methods, post-coupling azo dye techniques (Danielli, 1946) with sodium phenolphthalein phosphate have been used. Indoxyl phosphate has also been used as a substrate for the demonstration of enzyme activity (Holt, 1954; Seligman, Heymann and Barrnett, 1954). For criticisms, the reader is referred to Defendi's work (1957) and Pearse (1972).

ACID PHOSPHATASE

This enzyme, which is actually 'phosphomonoesterase', acts on monoesters of phosphoric acid at a pH of 5.0 to 5.3. Gomori (1941) originally devised

the techniques, based on the same principle as alkaline phosphatase. As in acid pH, calcium salts are soluble in water, lead nitrate is used here instead of calcium salts and finally visualisation is brought about through the deposition of brown lead sulphide precipitate. It does not require magnesium as an activator and fluoride salts inhibit its action (Moog, 1943).

Several workers have, however, criticised the technique, claiming non-specific deposition of the precipitate (Moog, 1943; Wolf, Kabat and Newman, 1943; Hard and Lassek, 1946; Lassek, 1947). Newman, Kabat and Wolf (1950), Lovelock (1954) and Clarkson and Kench (1958) have discussed the details of the procedure and the different factors controlling it. Newman, Kabat and Wolf suggested that this method, with glycerophosphate as the substrate, yields reproducible results, provided control experimental sets are maintained. Novikoff (1955) stated that any procedure which minimises diffusion with alkaline phosphatase holds good for acid phosphatase as well.

Several modifications of the procedure were later published, and of these the more important ones are those of Gomori (1950), Goetsch and Reynolds (1951) and Tandler (1953). Gomori suggested that the precipitation may not be homogeneous due to patchy fixation as well as due to other causes. In his modified schedule, the substrate concentration has been raised and phosphates, which undergo more rapid hydrolysis than glycerophosphate, have been tried. The role of the buffer concentration has been emphasised. Moreover, rinsing in 1–2 per cent acetic acid, as suggested by Gomori (1952), is not recommended at present (Barka and Anderson, 1963; Bitensky, 1963; Goldfischer, Essner and Novikoff, 1964; Ruyter, 1964; Janigan, 1965; Lake, 1965; Pearse, 1972), since Desmet (1962) demonstrated that acid rinsing may result in complete loss of precipitate.

Goetsch and Reynolds (1951) emphasised the procedure for mounting and deparaffinisation as important factors controlling the process, and according to them, the temperature during the entire procedure should not be raised above 38–40 °C (*see* Woodward, 1951). Egg albumen was regarded as having an inhibitory influence. Best results were obtained when the slide was not dewaxed at all. Ruyter (1964) did not record any such inhibition but recommended chilled 80 per cent acetone fixation.

Tandler (1953) used cobalt ions in place of lead, but at a lower pH; the precipitation of phosphate with this ion is incomplete. For better and non-diffusible precipitation through acid phosphatase activity, other metallic salts should be tried (Pearse, 1960). In another schedule, suggested by Takeuchi and Tanoué (1951), the pH level has been raised together with other modifications. For a comparative discussion of the different schedules, the reader is referred to Grogg and Pearse (1952).

With the aid of Gomori's method, the activity of acid phosphatase in nuclei has been reported by several authors (Wachstein, 1945; Rabinovitch, 1949). In plant chromosomes, the entire phosphatase cycle, during nuclear division, has been studied by Sharma and Roy (1956b). Sharma and Bhattacharyya (1957) analysed acid phosphatase activity in the chromosomes of malignant cells of plants, induced through different agents. Several authors (Avers, 1961; Beneš, Lojda and Horavka, 1961; Harrington and Altschul, 1963; Poux, 1963; Beneš and Opatrna, 1964; Gahan, 1965) have demonstrated acid phosphatases in different plant organs. In animals, it is distributed profusely in spleen and liver. Its presence has been shown in fungi and protozoa as

well (Atkinson and Shaw, 1955; Klamer and Fennell, 1963), and also in lysosomes (Novikoff, 1961; Wolman, 1965; Herveg, Beckers and De Visscher, 1966; Wolman and Bubis, 1966; Gahan, 1965, 1967). More than one acid phosphatase has also been recorded (Connor and MacDonald, 1964; Elliot and Bak, 1964; Arsenis and Touster, 1967; Goodlad and Mills, 1967).

Seligman and Mannheimer (1949) used coupling azo dye technique for the demonstration of acid phosphatase activity. As in acid pH, β-naphthol does not couple satisfactorily with diazonium salts, α-naphthyl phosphate has been used as the substrate. Anthraquinone-1-diazoniumchloride, being a stable diazonium compound, has been employed and sodium chloride is used to check diffusion. Similar to alkaline phosphatase, a number of modifications have been proposed, using naphthol AS phosphate and hexazotised fuchsin as diazonium compound, and for details the reader is referred to Burton (1954), Rutenberg and Seligman (1955), Gomori (1956); Goldberg and Barka (1962); Lojda (1963); Lojda, Vecerek and Pelichova (1964); Meany, Gahan and Maggi (1967); Pearse (1972).

CYTOCHROME OXIDASE

Another enzyme, the activity of which needs analysis, in connection with processes related to chromosome metabolism, is cytochrome oxidase. The method for its demonstration is outlined in the schedules.

SCHEDULES

Detection of acid phosphatase

Lead nitrate method for acid phosphatase (Gomori, 1950)

Reagents

(1) Incubation mixture containing:	
3% aq. sodium-β-glycero-phosphate solution	50 ml
M/20 acetate buffer, pH 5.0	500 ml
Lead nitrate	0.6 g
(2) Concentrated ammonium sulphide solution	10 ml
Distilled water	40 ml

Mix together

(3) 2% aq. eosin solution	50 ml

Procedure

The fixative recommended is chilled acetone for 24 h for paraffin or celloidin sections, 10 per cent cold formalin for frozen sections and post-fixation in Wolman's fluid for 1–2 h.

(1) Cut frozen sections 10–15 μm thick and mount on slides. Dry thoroughly at room temperature for adherence to the slides. For materials fixed for

paraffin sectioning, cut paraffin sections 4–8 μm thick at 4 °C. Mount and post-fix in cold acetone for 1–2 h.
(2) Bring down to water.
(3) Incubate in the incubating mixture for 30 min to 16 h at 37 °C. The optimum period is usually 4 h.
(4) Bring down to room temperature, wash first in distilled water, then in 1–2 per cent acetic acid and then again in distilled water, giving a few dips in each.
(5) Treat with yellow ammonium sulphide solution for 1–2 min.
(6) Rinse in water.
(7) Immerse in eosin solution for 2–5 min.
(8) Wash in water and mount in glycerin jelly.
(9) For permanent preparations, omit step (8), dehydrate through alcohol and alcohol–xylol grades and mount in DPX.

Observations
A deposition of black precipitate at the sites of phosphatase activity.

Alternative
In step (4), rinsing with acetic acid can be omitted.

Modified lead nitrate method for acid phosphatase
(Takeuchi and Tanoué, 1951)

Reagents

(1) Incubation mixture containing:

2% aq. sodium-β-glycero-phosphate solution	20 ml
0.1 M acetate buffer (pH 5.0–6.0)	10 ml
2% aq. lead acetate solution	10 ml
1–5% aq. magnesium chloride solution	3 ml

(2) Ammoniacal silver nitrate solution, prepared by adding 28 per cent ammonia water drop by drop to 5 per cent aqueous silver nitrate solution, with shaking, until the precipitate just dissolves.
(3) 5 per cent aqueous sodium thiosulphate solution.

Procedure
The earlier steps are similar to the previous schedule.

(1) Bring down the sections to distilled water.
(2) Incubate the sections at 37 °C in the incubating mixture for 30 min to 2 h.
(3) Wash in distilled water.
(4) Immerse in ammoniacal silver nitrate solution for 30 min.
(5) Treat in 5 per cent sodium thiosulphate solution for 5 min.
(6) Mount directly in glycerin jelly, or for permanent preparations dehydrate through ethanol and ethanol–xylol grades and mount in DPX or a suitable medium.

Observations
A deposition of brown precipitate at the sites of acid phosphatase activity.

Coupling azo dye method for acid phosphatase

Reagents

(1) Incubation mixture: Dissolve 10–20 mg of sodium-α-naphthyl-phosphate in 20 ml 0.1 M veronal acetate buffer at pH 5.0. Dissolve in it 1.5 g polyvinyl pyrrolidone with stirring. Add 20 mg of the stable diazotate of *o*-aminoazotoluene or diethyl-sulphamino-*o*-anisidine. Stir and filter.
(2) Mayer's aqueous haemalum solution.

Procedure
The recommended fixative is 10 per cent formalin at 4 °C for 10–16 h for frozen sections, later cut 10–15 μm thick, mounted and dried thoroughly at room temperature. Alternatively, cold microtome sections can be used after mounting on cover slips and post-fixing in cold acetone or Wolman's fixative.

(1) Bring the sections down to distilled water.
(2) Incubate at 37 °C in the incubation mixture. The period of treatment ranges from 30 s to 1 min for dog prostate, to 30–60 min for rat liver.
(3) Rinse thoroughly in water.
(4) Immerse in Mayer's haemalum solution for 4–6 min.
(5) Rinse thoroughly in running water.
(6) Mount directly in glycerin jelly or after dehydration in neutral balsam.

Observations
Sites of acid phosphatase activity are reddish brown while the nuclei are deep blue.

Alternative
0.1 M acetate buffer can be used instead of veronal acetate buffer in the incubation mixture.

Naphthol AS-BI phosphate method

The initial steps are similar to the previous schedules (Burstone, 1958a, b).

Reagents

(1) Incubation mixture containing, 4 mg of naphthol AS–BI phosphate dissolved in 0.25 ml dimethyl formamide and added to 25 ml 0.2 M acetate buffer (pH 5.2–5.6). Add to it 35 mg of red violet LB diazonium salt and two drops of 10 per cent aqueous manganese chloride solution. Shake and filter.
(2) Mayer's aqueous haemalum solution.

Procedure

(1) Bring down the sections to water.
(2) Incubate in the incubation mixture for 30 min to 6 h at 37 °C. (3), (4), (5) and (6) are similar to the same steps in the previous schedule.

Observations
The sites of acid phosphatase activity take up various shades of red, while nuclei are blue.

Alternative
AS–TR and AS–MS phosphates can be used instead of AS–BI phosphate. For frozen sections, the amount of dimethyl formamide used is 0.1 ml.

Post-coupling method for acid phosphatase

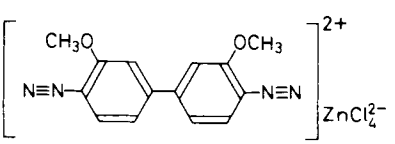
Recommended fixatives are the same as in the previous schedules. Free-floating frozen sections and cold microtome sections, mounted and unfixed. can also be used (Rutenberg and Seligman, 1955).

Reagents

(1) Incubation mixture containing:
Sodium-6-benzoyl-2-naphthylphosphate—Prepare by dissolving 14 g of 6-benzoyl-2-naphthol and 8.6 g of phosphorus oxychloride in 100 ml dry benzene and heating under reflux. Add 5 ml of pyridine and heat for 30 min. Allow to cool. Filter. Distil the filtrate on a water pump at 70–80 °C till a thick syrupy liquid is formed. Keep in a desiccator in low vacuum over saturated aqueous KOH solution for a few days. Separate out the crystals of acid phosphate. Dissolve in a mixture of methanol and sodium methoxide in methanol (1 : 1). Suspend the crystals in water, filter, wash with methanol and ether and dry.

Dissolve 25 g of sodium-6-benzoyl-2-naphthylphosphate in 80 ml distilled water Add 20 ml 0.5 *m*-acetate buffer (pH 5.0). Add 2 per cent sodium chloride solution.

(2) Aqueous solution of diazonium salt (preferably fast blue *β-o*-dianisidine), made alkaline with sodium bicarbonate with the formula:



Procedure

(1) Bring down sections to water and wash successively in 0.8, 1.0 and 2 per cent aqueous sodium chloride solutions.
(2) Incubate at 37 °C for 30 min to 2 h in case of fixed sections or for 10–60 min for fresh sections in the incubation mixture.

(3) Rinse in several changes of distilled water. Use cold saline solution for fresh sections.
(4) Treat for 3–5 min in cold aqueous diazonium salt solution.
(5) Rinse in three changes of cold saline.
(6) Mount in glycerin jelly or dehydrate as usual, clear and mount in balsam. In case of fresh unfixed sections, fix in 10 per cent cold formalin for 2 h before mounting.

Observations
The acid phosphatase sites are marked by a blue or reddish blue precipitate.

Mathers and Norman's method (1956)

This method has been applied for the study of acid phosphatase activity in malignant and benign tumours of the prostate glands.

Reagents
Incubation mixture containing M/10 aqueous sodium glycerophosphate solution, buffered to pH 4.9 with acetate buffer containing 0.12 per cent lead nitrate solution.

3% aq. acetic acid solution
2% aq. ammonium sulphide solution
1% aq. light green solution

Procedure

(1) Prepare 10 μm thick frozen sections and bring to water.
(2) Incubate in the incubation mixture at 37 °C for 5–15 min.
(3) Wash in 3 per cent acetic acid solution.
(4) Treat with fresh ammonium sulphide solution for 2 min.
(5) Rinse thoroughly in water.
(6) Stain with light green solution.
(7) Rinse again in distilled water.
(8) Mount in glycerin jelly or dehydrate and mount in neutral balsam.

Observations
Dark brown or black precipitate is formed at the sites of acid phosphatase activity.

Detection of alkaline phosphatase

Calcium cobalt method for alkaline phosphatase (Gomori, 1946)

Reagents

(1) Incubation mixture containing:

3% aq. sodium-β-glycerophosphate soln	10 ml
2% aq. sodium diethylbarbiturate	10 ml
Dist. water	5 ml
2% aq. calcium chloride solution	20 ml
5% aq. magnesium sulphate solution	1 ml

(2) 2 per cent aqueous cobalt nitrate or acetate solution.
(3) Aqueous dilute yellow ammonium sulphide solution (about 50 drops of concentrated liquid in 20 ml water).

Procedure

(1) Preparation of paraffin sections—Fix in cold acetone at 4 °C with three changes for 24 h. Transfer through progressive alcohol grades to absolute ethanol, keeping 30 min in each grade. Treat with ethanol ether mixture (1 : 1) for 1 h and transfer to 1 per cent celloidin. Decant excess celloidin and treat successively in chloroform and benzene, keeping 1 h in each. Embed in paraffin. Cut sections 5 μm thick and mount on albuminised slides.
Dry at 37 °C and store at 4 °C.
(2) Bring down the slides in distilled water through immersion successively in petroleum ether and absolute acetone.
(3) Incubate in the incubating mixture at 37 °C for 30 min to 16 h, 4 h being the optimum period.
(4) Wash thoroughly in distilled water after bringing down the slides to room temperature.
(5) Immerse in 2 per cent cobalt nitrate solution for 3–5 min. Wash in distilled water.
(6) Immerse in yellow ammonium sulphide solution for 1–2 min.
(7) Rinse in distilled water. Stain with 1 per cent eosin solution for 5 min if required.
(8) Dehydrate and clear through ethanol and xylol grades and mount in neutral balsam.

Observations

A deposition of a black precipitate at the sites of alkaline phosphatase activity.

Alternatives

(1) For frozen sections, cut very thin sections and mount on slides without albumin. Dry at room temperature for 1–2 h. The remaining steps are similar to paraffin sections.
(2) In a later schedule by Gomori (1952), the incubation mixture contains:

3% aq. sodium glycerophosphate solution	20 ml
2% aq. sodium diethylbarbiturate solution	30 ml
2% aq. calcium chloride solution	4 ml
2% aq. magnesium sulphate solution	2 ml
Dist. water	30 ml

Cobalt chloride can be used instead of cobalt nitrate or acetate.

(3) Non-metallic fixatives give quite good results. The preparation of paraffin blocks can be done through the usual alcohol–chloroform grades.

Caution

(1) In no step, from fixation to mounting, should the temperature exceed 56 °C.

(2) The incubation mixture should be freshly prepared before use.

Fredericsson's modification of Gomori's method (1952, 1956)

The method is recommended for paraffin sections of materials fixed in alcohol.

Reagents

(1) Incubation mixture containing:

2% aq. sodium-β-glycerophosphate solution	25 ml
2% aq. sodium veronal solution	25 ml
2% aq. calcium nitrate solution	5 ml
0.8% aq. magnesium chloride solution	5 ml
Acetone	40 ml

(2) 2 per cent cobalt nitrate solution in 40 per cent acetone.

(3) Dilute yellow ammonium sulphide solution in 40 per cent acetone.

Procedure

(1) Fix tissues in 90 per cent ethanol at 22 °C for 24 h. Dehydrate through 96 per cent and absolute ethanol grades and then two changes of benzene, keeping 30 min in each. Embed in paraffin, cut sections 3–10 μm thick and mount without stretching in water. Deparaffinise through xylol and 40 per cent acetone grades. Bring down to distilled water.

(2) Incubate in the incubation mixture at 37 °C for 10 min to 1 h.

(3) Bring to room temperature and wash in 40 per cent acetone.

(4) Immerse in cobalt nitrate solution in acetone for 5 min.

(5) Wash again in 40 per cent acetone.

(6) Immerse in ammonium sulphide solution in acetone for 3 min.

(7) Wash in pure acetone.

(8) Dehydrate through alcohol and xylol grades and mount in neutral balsam.

Observations

The formation of black precipitate at the sites of alkaline phosphatase activity.

α-Naphthyl phosphate method for alkaline phosphatase
(Gomori, 1951)

Reagents

(1) Incubation mixture containing:

Sodium-α-naphthyl phosphate	0.05 g
5% aq. borax solution	10 ml
10% aq. magnesium chloride or sulphate solution	0.5 ml
Cold dist. water (20 °C)	100 ml
A stabilised diazonium salt	0.25 g

Either tetrazotised-*o*-dianisidine (michrome blue salt 250), 3-nitroanisole-4-diazonium chloride (michrome red salt 606), 4–chloroanisole-2-diazonium chloride (michrome red salt 612) or 3-nitrotoluene-4-diazonium-naphthalene-1, 5-disulphonate (michrome scarlet salt 618).

(2) Haematoxylin solution in water.

(3)

70% ethanol	99 ml
Glacial acetic acid	1 ml

Mix together.

Procedure

(1) For paraffin block preparations, fix thin cold slices of tissue at 4 °C for 24 h in three or four changes of acetone. Clear in xylol. Embed in paraffin rapidly. Cut sections and attach to albuminised slides. Deparaffinise as usual.
(2) Rinse three times in pure acetone and then in three changes of distilled water.
(3) Incubate in the incubation mixture at 37 °C for 10–30 min or more. Remove a slide at intervals and observe under the microscope until the correct brightness of colour is attained. Stir the mixture mechanically during incubation.
(4) Rinse thoroughly in distilled water after bringing the slides to room temperature.
(5) Immerse in haematoxylin solution for counterstaining.
(6) Treat with acetic–ethanol mixture for 5–10 min.
(7) Rinse thoroughly in water.
(8) Mount in glycerin jelly or dehydrate, clear and mount in neutral balsam.

Observations

The sites of alkaline phosphatase activity stain purplish black with michrome blue salt 250, purplish brown with michrome red salt 606 and reddish brown with michrome red salts 612 and 618.

Alternative

Sodium β-naphthylphosphate may be used instead of sodium-α-naphthyl-phosphate but α-salts yield a more specific and non-diffusible precipitate.

A modified coupling azo dye method for alkaline phosphatase (*see* Pearse, 1972)

For frozen sections

(1) Fix thin slices of tissue in 10 per cent neutral formalin in the cold for 10–16 h, or use fresh frozen cold microtome sections, mounted on cover slips.
(2) Cut frozen sections 10–15 μm and mount on slides without adhesive. Dry in air for 1–3 h.
(3) Dissolve 10–20 mg sodium-naphthyl phosphate in 20 ml 0.1 M stock tris buffer (pH 10). Add to it, with stirring, 20 mg of the stable diazotate of 5-chloro-*o*-toluidine. Cover the sections on the slides with the filtered solution and incubate at room temperature for 15–60 min.
(4) Rinse in running water for 1–3 min.
(5) Counterstain for 1–2 min in Mayer's haemalum.
(6) Rinse in running water for 30–60 min and mount in glycerine jelly.
(7) The sites of alkaline phosphatase activity appear brown with Fast Red TR and Fast Violet B or black with Fast Black B. The nuclei are dark blue.

For paraffin sections of material fixed in cold acetone

(1) Bring down the sections to water after passing successively through light petroleum and absolute acetone.
(2) Cover with freshly prepared filtrate of substrate-diazonium salt mixture as in previous schedule.
(3) Incubate for 30 min to 4 h for salt Fast Blue RR or for up to 2 h for salt Fast Red RC or for up to 12 h for salt Fast Red TR.
(4) Rinse in water, counterstain with haemalum as given in previous schedule, wash in running water and mount in glycerine jelly.
(5) Salt Fast Red TR gives the best results, the sites of alkaline phosphatase activity appearing reddish brown and the nuclei blue.

Detection of cytochrome oxidase

G nadi reaction

Reagents

(1) α-naphthol solution—Add 1 g of α-naphthol to 100 ml distilled water and boil till α-naphthol begins to melt. Add to it 40 per cent aqueous potassium hydroxide solution drop by drop till the mixture turns yellowish blue.
(2) Dimethyl-*p*-phenylenediamine base solution—Add 0.5 g of dimethyl-*p*-phenylenediamine from a sealed tube to 100 ml distilled water, breaking the tube inside the water. Keep for 24 h. Aid dissolution by occasional shaking.

(3) Gram's iodine solution.
(4) Carmalum solution.
(5) 0.5 per cent aqueous lithium carbonate solution—2 drops added to 100 ml distilled water.

Procedure

(1) Fix thin tissues in formol–saline for 3–5 h. Cut frozen sections and bring them down to water.
(2) Mix together equal volumes of α-naphthol and dimethyl-*p*-phenylene-diamine base solutions. Filter. Treat the slides in this mixture until the sections turn blue.
(3) Wash in distilled water.
(4) Treat with Gram's iodine solution until the sections turn brown.
(5) Keep in lithium carbonate solution for 15 min to 24 h until the sections again become blue.
(6) Rinse in distilled water.
(7) Immerse in carmalum for 2–5 min.
(8) Mount in glycerin jelly.

Observations

The nuclei take up pink and the oxidase granules take up blue colour.

Micrurgy

The isolation procedure is often adopted, not only for the chemical analysis of chromosomes but also for culturing the nuclei and chromosomes in natural or synthetic media. The latter procedure requires micrurgical operation of the cell without the use of any chemical. It allows a study of the initial steps in chromosome metabolism and of the mechanism of genetic regulation of differentiation. On the other hand, the chemical method of chromosome isolation, in which only non-injurious compounds are employed, is useful for the study of the chemical make-up of the chromosomes at different stages of development.

MICRURGICAL METHOD OF ISOLATION OF NUCLEI AND CHROMOSOMES AND THEIR CULTURE

The technique for micrurgical isolation has mainly been developed with respect to the salivary gland chromosomes of diptera, where puffing at different segments in different phases of development provides adequate proof of the genetic control of differentiation and the change of pattern following treatment with different agents. Short term *in vitro* culture can be carried out following the hanging drop method (as mentioned in the chapter on tissue culture), involving culturing in a drop of medium on the cover slip inverted over a depression slide, and sealed with oil, or on a slide covered with oil. Blowing through a pipette is recommended for adequate oxygen supply. The best medium for hanging drop culture is no doubt haemolymph but several other media, including TC 199 and Jones and Cunningham's medium (1961) for sciarids and chironomids, respectively, can also be used. Hadorn, Gehring and Staub (1963) devised a method for *in vivo* culture, in which glands, after explantation, were transferred to younger hosts by injection. One of the serious limitations of polytene chromosome culture is the fact that salivary gland cells have a strong ionic barrier against haemolymph, whereas owing to the presence of a special membrane, there is no such barrier between adjacent cells (Kanno and Loewenstein, 1964; Kroeger and Lezzi, 1966). Consequently, in the case of any cell leakage in haemolymph or lumen, there is a complete loss of ionic equilibrium, because all the cells are simultaneously affected. Therefore, when excising the gland, extreme care must be taken not to rupture, or shear, the ligaments adjacent

to it. Moreover, because of the low regeneration rate of glands after injury, this method allows a study of DNA synthesis and transcription only, not of the entire process of mitosis.

THE ISOLATION AND CULTURING OF NUCLEI IN MEDIUM UNDER OIL

The essential requisites are, (a) a suitable medium, (b) a suitable oil and (c) siliconised slides. A good dissecting microscope serves the purpose for observation. Of the media used, the egg contents of *Drosophila* have been found to be very satisfactory. They have to be diluted at the later stages and culture can be prolonged even up to 4 h (Kroeger, 1963, 1966; Lezzi, 1961, 1965; *see* Von Borstel, 1959). Sugar medium with synthetic compounds, having the following composition, gives very satisfactory results (Frenster, Allfrey and Mirsky, 1960; Sirlin and Schor, 1962; Rey, 1963; Lezzi, 1965; Kroeger, 1966):

Saccharose	64.1805 g
Glucose	3.3741 g
$MgCl_2$	1.7866 g
NaCl	1.6659 g

Tris buffer 0.5 l (3.025 g Tris + 20.7 ml 1/N HCl)

supplemented with polyvinylpyrrolidone or Luviskol-K90. The oil needed to cover the culture for checking against desiccation is hydrofluorocarbon oil (Kal-F No. 10) (Kopac, 1955), the viscosity of which can be adjusted by mixing with paraffin. Another oil, often employed, is a mixture of heavy mineral oil and Oronite Polybutane 128 (2 : 1).

The slide can be siliconised by dipping in a mixture of a few drops of silicone oil in 250 ml of acetone and drying for 24 h at 20–25 °C. If required, the time, temperature and concentration can be varied.

The schedule followed for isolation and culturing is given below (Kroeger, 1966).

(1) Cover the donor tissue with a drop of oil on a siliconised slide.
(2) From a second oil drop on the slide containing the culture medium, transfer two spheres of medium to the first oil drop containing the donor tissue. Of the two spheres, sphere A should be about one fifth to one tenth the volume of the other sphere, and B should be about 20 times larger in volume than the donor tissue. The transfer is carried out under a dissecting microscope, after bringing the medium in sphere A in contact with the donor tissue so that the medium in sphere A forms just a rim surrounding the donor tissue. The method is as follows:
    (a) For semi-isolation, gradually cut off and separate the cytoplasm and other extranuclear components from the nucleus in A, with the aid of a bent tungsten needle, leaving the nucleus surrounded by a very thin layer of cytoplasm. The tungsten needle must be sharpened previously by immersion in a hot mixture of potassium nitrate and sodium nitrite. Glass needles, drawn out in a gas micro-burner, can also be used. Draw the large droplet B and join it with A. Push the

nucleus into the larger sphere B and finally cut off the connection between the two spheres.

(b) Alternatively, for complete isolation, puncture the cell with a glass needle and squeeze out the nucleus and follow the procedure given in (a)

(3) For staining, after the incubation period, place a large drop of acetic–orcein solution on the material, avoiding conglomeration of cells, and stain for 20 min or more. Pass through acetone to remove the oil, rinse in water, blot off excess fluid, add a drop of acetic–orcein solution, wait for a few minutes and mount under a cover slip. Lactic–orcein solution, used alternatively, may be prepared according to Beermann's schedule, that is, boiling 2 g of orcein in a mixture of 50 ml each of acetic acid and lactic acid, shaking and filtering. If necessary, a contrasting stain may also be applied, prepared by mixing light green (FS) 0.1 per cent in 96 per cent ethanol, and orange G, 0.2 per cent in 70 per cent ethanol, in the proportion of 55 : 45, followed by adding 1–2 drops of acetic acid to bring to pH 5.0 (Clever, 1961). The method has also been extended to ultrastructure analysis from suspension culture (Lengyl, Spardling and Penman, 1975; Spardling, Singer and Penman, 1975).

Isolation of chromosomes

To secure fixed chromosome preparations, the method is quite a simple one. The chromosomes are fixed as usual in 45 per cent acetic acid and then removed from the cell with a needle.

To obtain unfixed chromosome preparations, the most convenient method is to puncture the salivary gland with a needle and squeeze out the chromosomes in sugar medium, as mentioned above (Lezzi, 1965). There are two other methods, one involving treatment of the gland with pronase followed by homogenisation and differential centrifugation (Karlson and Löffler, 1962) whereas in the other, the glands are dipped in 0.25 per cent solution of dried eggwhite for 2–3 h and then the stiffened chromosomes are isolated with needles (Buck and Malland, 1942). For studying ribonucleic acid metabolism, the required precursors and other factors have to be supplied to the medium (*see* Kroeger and Lezzi, 1966).

In *transplantation experiments*, a foreign cytoplasm is inserted within the host cell by piercing the cell without touching the nucleus, pressing the cytoplasm through the oil and then the slit with the help of a needle. Similarly, chromosomes can be donated to the host cytoplasm by taking out a chromosome, rolling it into a bundle and pushing it through the slit of the host cell. It is even possible to make a slit in the nucleus and transplant the chromosome inside the nucleus (Kroeger, 1966). The degree of perfection achieved in these procedures depends on experience, skill and steadiness of operation. Microsurgical methods have also been employed to secure mammalian somatic cell hybrids and their analysis and cloning (Diacumakos, 1975).

The main disadvantage of the microsurgical method is the difficulty in securing a long term culture and in performing an operation without injury to the tissue.

21

Isolation and extraction of nuclei, chromosomes and chromosome components

The primary requisite for the extraction of nuclei is to isolate them in normal condition in adequate amounts and to keep the chromatin in an undamaged state. Several factors control the success of isolation, of which low temperature, medium, method of homogenisation, pH and divalent cations are most important and should be suitably adjusted for each tissue (*see* Roodyn, 1972; Chrispeels, 1973).

Techniques may differ depending on the nature of the cell as well, which may range from easily disruptible membrane, and heavy cytoplasm loosely attached to the membrane, to old mature cells with tough nuclear membrane where cytoplasmic content is low and difficult to detach (Magliozzi *et al.*, 1971; Yasmineh and Yunis, 1974; Meistrich, 1977). In order to check the activity of autolytic enzymes, it is always necessary to keep the temperature between 2–4 °C, and use jacketing device wherever there is chance of excessive heat generation which is rather common during high-speed homogenisation (Busch, 1967). Rapid processing is also one of the essential requisites for preventing autolysis.

Isolation procedure may be direct or indirect. In the former, the nucleus is isolated directly from the cytoplasm with the aid of a micromanipulator and observed under the microscope (Edström, 1953). But the schedule has several limitations and cannot be applied conveniently to all tissues. Therefore for chemical analysis, indirect method of mass isolation is adopted.

In mass isolation technique, the general principle involves firstly, the disintegration of the cytoplasm through mechanical or chemical means keeping the nucleus intact, followed by filtration through mesh or cheesecloth, differential centrifugation in suitable liquids and sedimentation. The general specific gravity of the liquid lies between the range of 1.35 and 1.45 and centrifugation at 1000–6000 rev/min is needed for separation.

Initially, for isolation of nuclei from different organs such as brain, kidney or liver of mammals, it is necessary to cut the organs in small pieces in ice cold physiological saline solution or in powdered dry ice. Several washings in saline solution and continuous stirring are necessary prior to homogenisation. The initial step for fractionation is to break the cell wall or membrane either through gentle homogenisation or cutting with blender or razor blades. The choice of a suspending medium of proper tonicity is needed to keep the organelles intact. Both aqueous and non-aqueous media may be used for homogenisation and nuclear isolation. The non-aqueous medium (Busch,

1967) is not widely used and is necessary specially for retention of soluble proteins. The most widely used aqueous medium is sucrose which has the advantage of causing easy separation of cytoplasmic constituents (Noll, 1967a, b). The concentration needed for plant cells is rather high (0.40–0.50 M) as compared to that for animals (0.25–0.32 M). One of the most important steps is the addition of divalent cations in the medium, to check chromatin gelling and to maintain the chromosome structure. These are also responsible for stabilisation and hardening of the membranes. Unless these are added in optimal concentrations, nuclei may be too hardened to prevent further extraction of their components for analysis. In this respect, calcium, though exerting a stronger effect, for which it is widely used, is not suitable for some special types of cells such as tumours or transformed lines, where addition of even a very small amount may stand against proper disruption. In such materials, magnesium yields better results. The most widely used cations are calcium and magnesium though lead, zinc and even cadmium are also employed (Dounce and Ichowicz, 1970; Magliozzi *et al.*, 1971). In isotonic sucrose solutions, along with divalent cations for maintenance of nuclei, the addition of Triton X100 (0.4 per cent) or Nonidet P40 (0.5 to 0.05 per cent) help to preserve the nuclei selectively with the exclusion of other cytoplasmic organelles. The nuclei may later be separated either through differential centrifugation or discontinuous density gradient centrifugation.

Chevallier and Philippe (1975) suggested that in addition to mineral cations such as calcium or magnesium and potassium for stabilisation of chromatin and nuclei, the different intranuclear structures, including different chromatin fractions, can be best preserved through the addition of a polyamine such as spermidine or spermine. It is desirable to confirm the nature of isolated sample fractions from each step through cytological analysis and Feulgen staining. The nuclear fractions can be directly subjected to nucleic acid isolation technique or stored at $-20\,^{\circ}C$ in 70 per cent ethanol.

For quantitation through absorption analysis, extracted DNA or RNA may be diluted with 1 N perchloric acid and ultraviolet absorption studied at 260 nm. The normal ultraviolet value at 260 nm is considered to be 1.0 for 33 μg of DNA or RNA after hydrolysis. The other methods of quantitation through colour reactions are diphenylamine test for DNA (Burton, 1968) and orcinol test for RNA (Schneider, 1957).

SCHEDULES FOR ISOLATION OF NUCLEI

Animal cells

From S3 HeLa cells (Prescott, *et al.*, 1966)

(1) Grow monolayers of S3 HeLa cells in F-10 medium supplemented with 10 per cent calf serum, penicillin (50 units/ml) and streptomycin (50 μg/ml).
(2) Add 5 ml 0.25 per cent trypsin in saline D-2 at pH 7.0–7.4 (Ham, 1963). Incubate for 5–10 min at 36.7 °C and suspend in an additional quantity of 5 ml saline D_2.
(3) Centrifuge at 1000 × g at 0–2 °C for 5 min and remove the trypsin.

Wash thrice in 50 ml 0.154 M KCl and centrifuge at 1000 × g for 5 min.

(4) For lysing the cells and isolating the nuclei, re-suspend the cells (0.1 ml) in 4 ml 0.1 per cent (v/v) Triton X100 isolation medium (Rohm and Haas, Philadelphia) containing 0.001 per cent (w/v) spermidine phosphate trihydrate (spermine) dissolved in redistilled water. Agitate continuously by blowing through a micro-pipette to rupture cell membrane. After 2–4 min, fix a drop in Carnoy's fluid, stain with toluidine blue and observe under a microscope to find if the nuclei are completely freed from cytoplasmic contamination.

(5) After complete lysis, add 0.25 M sucrose with 0.001 per cent spermine to a final volume of 50 ml and centrifuge at 700 × g at 0–2 °C for 20 min. Re-suspend the sediment in 0.25 M sucrose with spermine and centrifuge. Repeat twice. Spermine prevents excess rupture of the nuclear membrane and saline D_2 with spermine is more satisfactory than sucrose.

From mammalian organs and other animal systems

(1) Immerse the dissected organ from physiological saline solution, in a cold mixture of 0.3 M sucrose–3 mM $CaCl_2$ solution. Remove connective tissues. The rest of the procedure should be carried out at 4 °C.

(2) Weigh 5 g of tissue and mince with scissors.

(3) Homogenise the tissues in a Teflon pestle tissue grinder with 7.5 ml 0.5 M sucrose, 3 mM $CaCl_2$, using ten strokes at 400 rev/min. Continue the process till nuclei reach the point of disruption.

(4) Add 20 ml 0.3 M sucrose and 3 mM $CaCl_2$ and filter through fine cloth.

(5) With 0.3 M sucrose and 3 mM $CaCl_2$ adjust to 42 ml.

(6) Take 40 ml of the sample and centrifuge at 1000 × g for 9 min and collect the pellet.

(7) Suspend the pellet in 20 ml 0.3 M sucrose, 3 mM $CaCl_2$ and 0.5 per cent Nonidet P40 to preserve the nuclei and grind continuously to avoid foaming.

(8) Take a centrifuge tube and prepare a layer of 10 ml suspension on 10 ml 1.8 M sucrose, 1 mM $CaCl_2$ and centrifuge at 40 000 × g for 15 min.

(9) Suspend the pellet in 0.7 ml 1.0 M sucrose, 3 mM $CaCl_2$ and add initially 1.0 ml 0.5 M sucrose, 3 mM $CaCl_2$, followed by 1.0 ml 0.3 M sucrose and 3 mM $CaCl_2$ through continuous stirring at least for 15 min.

(10) Make the solution up to 30 ml with 0.3 M sucrose and 3 mM $CaCl_2$.

(11) Centrifuge for 10 min at 1000 × g.

(12) Re-suspend the pellet in 10 ml 0.3 M sucrose and 3 mM $CaCl_2$ which forms the nuclear fraction.

(13) Precipitate with 2 vol of 95 per cent ethanol.

(14) Store at −20 °C.

Vendrely's schedule (1952)
This is suitable for animal material.

(1) Cool the fresh tissue to −25 °C.

(2) Chop into very small pieces and suspend in about 10 ml M/3 citric acid at 2 °C.
(3) Shake thoroughly in a shaker and filter.
(4) Centrifuge at 2 °C for 5 min at 3500 rev/min. Suspend the sediment in M/18 citric acid.
(5) Repeat step (4) four times, each time reducing the speed of centrifugation, and discarding the supernatant.
(6) A final centrifugation for 5 min at 1000–1200 rev/min gives a homogeneous suspension of nuclei

Yasmineh and Yunis (1974) suggest an alternative method in which the mammalian tissue from physiological saline is initially subjected to homogenisation in a 3–5 vol solution of 0.32 M sucrose–5 mM $MgCl_2$–0.2 mM $CaCl_2$ in a Potter–Elvehjem homogeniser (200 μg clearance, 50 ml capacity), Teflon pestle being mechanically operated with 1/15 HP, variable speed motor with a few strokes at nearly full motor speed till final and complete disruption of the nuclei. The homogenate is filtered through eight layers of gauze for removal of connective tissue, diluted four times with the same homogenising solution and then centrifuged at 1000 × g for 10 min, the pellet being taken, discarding the supernatant by aspiration. For further removal of the contaminants, such as erythrocytes, lipids, etc., the pellet is suspended again in 5 vol of 2.2 M sucrose–5 mM $MgCl_2$–0.2 mM $CaCl_2$, and after a few strokes in homogeniser, diluted further five times with the same solution and centrifuged at 15 000 × g for 1 h. The supernatants containing the contaminants are drained and the pellet finally contains purified nuclei. The method allows nearly 80 per cent recovery of the nuclei. For pachytene nuclei separation of Syrian hamster multilayered discontinuous sucrose gradient method has been adopted (Utakoji, 1970).

For dipteran ovaries, a different method has been adopted by Renkawitz and Kunz (1975) based on the method of Boyd, Berendes and Boyd (1968). In this technique, ovaries are suspended in a buffer mixture (0.1 M NaCl, 0.0019 M KCl, 0.001 M $MgCl_2$, 0.01 M tris, 0.4 per cent (w/v) Triton X100 of pH 7.2, slowly homogenised with a pipette, and suspension filtered through a gauze (69 μm). The process is repeated several times with the residue. The total filtrate is layered on a two step Ficoll (polymer of sucrose) gradient (5 and 20 per cent) and kept at 4 °C. By 15 h, the follicle cell nuclei form a small band between the buffer and 5 per cent gradient, and nurse cell nuclei accumulate at the interface or top of 20 per cent Ficoll. The bands are separated with pipette and pellets of nuclei can be obtained by slow centrifuging (50 × g for 4 min) at 4 °C.

From erythrocyte cells of birds

Laskowski's method (1942)

(1) Prepare isotonic salt solution, 0.1 M aqueous potassium dihydrogen phosphate solution and lysolecithin solution (prepared by mashing poison glands of 100 bees with an emulsion of 5 g lecithin in 30 ml of phosphate buffer at pH 7.0, digesting at 37 °C for 24 h and filtering through a Birkfield filter).

(2) Draw out fresh citrated blood, collect the erythrocytes by centrifuging and wash them repeatedly in fresh changes of isotonic salt solution by alternately suspending them in the fresh solution and then centrifuging.
(3) Take about 40 ml of the saline solution containing the final suspension of cells and add about 5–10 ml lysolecithin solution. Treat for 30–40 min at room temperature, observing at intervals.
(4) After complete haemolysis, wash the cells again in salt solution by alternate suspension and centrifugation several times in fresh solution.
(5) Store in cold as a suspension in normal saline solution or 0.1 M KH_2PO_4 solution. The nuclei take blue colour with aqueous methylene blue solution.

Modification
Bensley (*see* Glick, 1949) used a few drops of ether instead of lysolecithin solution.

Dounce and Lan's method (1943)

(1) Prepare 0.9 per cent aqueous sodium chloride solution, 0.11 M phosphate buffer (pH 6.8–7.0) containing 0.3 g of Merck's purified saponin.
(2) Similar to the previous schedule, wash the erythrocytes twice in sodium chloride solution.
(3) Suspend the cells in a quantity of saline solution equal to the amount of blood used and add one-tenth its vol of phosphate buffer. Treat for 5 min.
(4) Wash the nuclei repeatedly in saline solution and add each time 2–3 ml phosphate buffer to the nuclei just before adding the saline solution.

Stoneburg's method for rat tumour cells (1939)

(1) Prepare 5 per cent aqueous citric acid solution, 1 per cent hydrochloric acid, 0.8 per cent sodium chloride solution, pepsin (1/10000).
(2) Chop up the cleaned tissue in to small bits.
(3) Keep overnight in five times its volume of citric acid. Stir occasionally.
(4) Add an equal quantity of distilled water and filter through eight layers of cheesecloth.
(4) Add an equal quantity of water to the filtrate and keep for 3 h.
(5) Centrifuge in a cylinder lined with cellophane. Wash the nuclei repeatedly with water by centrifuging and suspending alternately.
(7) Treat the residue in equal volume of a mixture of HCl and NaCl with pepsin (1 : 1) for 4 h at 37 °C. Stir at intervals.
(8) Remove the nuclei settled at bottom and wash.

Dounce's method for rat liver nuclei (1952)

(1) Freeze freshly dissected rat liver.
(2) Add 100 g of it to 500 ml citrated water containing ice chips (1.05 ml 1 M citric acid in 100 ml water, pH 6.0–6.2) in a Waring blender while stirring continuously for 10–15 min.

(3) Filter once through two layers and then again through four layers of cheesecloth.
(4) Centrifuge for 20 min at about 2000 rev/min. Separate the sediment and make it up with water to 400 ml. Add a drop of caprylic alcohol to break up the foam.
(5) Centrifuge for 15 min. Suspend the residue in 400 ml distilled water and centrifuge for 10 min.
(6) Repeat washing the tissue and centrifugation four to five times, adding 200 ml water each time, centrifuging for periods decreasing from 10–13 min at slower revolutions and decanting the supernatant each time.
(7) Filter through four layers of cheesecloth.
(8) Keep the nuclei for 45 min in 100 ml distilled water. Decant. Centrifuge and re-suspend nuclei in a few ml distilled water.
(9) To prevent agglutination, add a few drops of 1 M citric acid to the washing water each time.
(10) This method can also be applied to tumour tissue, varying the amount of citric acid to get a final pH of 3.0.

Hoerr's modification of Lazarow's method for liver nuclei (1943)

(1) Occlude the inferior vena cava of the liver for 10–20 s/min, thus changing the hydrostatic pressure from 2–4 ft. Pass cold physiological salt solution simultaneously through the liver *in situ*, replacing the blood completely.
(2) Dissect out the liver and chill to 0 °C without freezing.
(3) Grind in 0.85 per cent sodium chloride solution and squeeze through bolting silk.
(4) Wash out in 0.5–0.7 per cent sodium chloride solution at a pH of 6.0–6.2.
(5) Separate and wash by successive centrifugation and suspension at a temperature of nearly 0 °C.

Gulick's modification of Behrens' (1939) method for thymus and lymph nuclei

(1) Dissect out the organ. Chop into small bits and freeze in liquid air.
(2) Dehydrate in changes of dry acetone at 20 °C followed by extraction in ether. Remove excess ether in a desiccator over concentrated H_2SO_4.
(3) Mash in power mill, suspend in benzene–carbon tetrachloride mixture (sp. gr. 1.25).
(4) Grind again in a ball mill with glass beads.
(5) Centrifuge at slow speed (30–50 rev/min) for one to two months.
(6) Suspend successively in pure benzene and benzene–carbon tetrachloride mixture, with increasing proportions of carbon tetrachloride, centrifuging after each change till no more powder settles.
(7) Then add benzene till the denser nuclear fraction comes down under centrifugation.
(8) Separate and store.

Schneider and Petermann's schedule
(1950, referred to by Serra, 1955)

This has been used for animal tissues. The experiment is carried out at 20 °C.

(1) Chop 50 g of fresh calf thymus into small bits.
(2) Mix in a Waring blender with 50 ml 0.5 M aqueous sucrose solution and 400 ml of a mixture of 0.25 M sucrose and 0.0018 M calcium chloride solutions for 4 min at 350 rev/min.
(3) Squeeze through a double layer of gauze and a single layer of flannelette.
(4) Centrifuge at 2000 rev/min for 10 min.
(5) Suspend the sediment in 90 ml of the mixed sucrose–calcium chloride solution and allow to settle for 10 min.
(6) Filter through a double layer of gauze.
(7) Centrifuge the filtrate at 2000 rev/min for 10 min.
(8) Collect the sediment containing the nuclei. Purify by washing in sucrose–calcium chloride solution and re-suspension.

For polytene nuclei of *Drosophila*

Several methods have been proposed for isolation of polytene nuclei of *Drosophila* and *Chironomus* (Ristow and Arends, 1968; Cohen and Gotchell, 1971; Zweidler and Cohen, 1971; Boyd, 1975a) including even mass isolation as they provide ideal materials for the study of gene action. Several of the methods are outlined below. The procedure in all of them is to be carried out at 0–4 °C.

Isolation of nuclei in aqueous medium (Boyd, 1975a)

(1) Isolate salivary glands in 1–5 ml isolation buffer consisting of 0.11 M NaCl, 0.002 M KCl, 0.01 M Tris (hydroxymethyl) aminomethane, 0.0025 M $MgCl_2$ (pH 7.2–20 °C), with 0.001 per cent spermidine.
(2) Reduce the suspension into small masses by drawing the suspension in and out of a pipette.
(3) Take a pipette with constricted tip and add 0.2 per cent Triton X100 and continue gentle pipetting for 5 min or more to secure 95 per cent of free nuclei without rupturing the wall.
(4) Filter through a nylon screen (53 μm opening), saturated with isolation buffer and held with the aid of a round two piece glass funnel (diameter 2.4 cm) forming a reservoir over the screen with the funnel below.
(5) Gently add additional 9 vol of isolation buffer through the tube and pipette slowly to free the nuclei completely from the associated tissue mass.
(6) Centrifuge the filtrate at 40 × g for 5 min at 4 °C and the pellet consists of nearly 95 per cent polytene nuclei.
(7) *If further purification is desired,* follow *discontinuous sucrose gradient* separation (Elgin and Boyd, 1975) of the pellet.
   (a) Suspend the pellet in isolation buffer containing 1.67 M sucrose (15 ml/g of gland).

(b) Prepare a layer of 2 ml isolation buffer 2.3 M sucrose under 10 ml nuclear suspension in the tubes.
(c) Slightly mix the interface and centrifuge 40 000 × g for 42 min at 4 °C (SW 40 rotor—Beckman α2–65B).
(d) Suspend the nuclear pellet by heavy agitation.
(e) Finally scrape off the nuclei from the bottom of the tube.

This method is suitable for small masses up to a maximum of 0.2 g of glands.

But *for large masses*, a slight modification has been proposed in the schedule of Helmsing and Van Eupen (1973). In this technique, the isolated glands in insect Ringer's solution (Hennig, 1972) are directly placed in a Dounce homogeniser (Clearance A, 20 ml stem capacity) and the solution is replaced by isolation buffer with spermidine (0.001 per cent) and 0.2 per cent Triton X100. After repeated and slow homogenisation in buffer (5 ml/g of gland) supernatant containing nuclear suspension in each case, the nuclear suspensions are all added together and brought to 0.5 per cent Triton X100, filtered in a 50 ml centrifuge tube through a 53 μg screen held by two pieces of glass funnel (5.5 cm diameter) as above. The screen is washed with isolation buffer containing 0.5 per cent detergent (NP 40) and the filtrate is centrifuged at 40 × g for 5 min. Nearly 80 to 90 per cent of polytenic nuclei can be obtained through this procedure from large masses.

Later (Mahr, Lezzi and Eppenberger, 1977), a modified method has been suggested for mass isolation of polytene nuclei of *Chironomus* salivary glands. The larvae initially are dried on filter paper, frozen immediately in liquid propane and stored either at −70 °C or liquid nitrogen. Two to three g of larvae are broken in 2–4 mm pieces using mortar and pestle filtered through 1000 μm mesh nylon grid, filtrate treated with pre-warmed (55 °C) SNKE (30 per cent sucrose w/v in NRE i.e., 100 mM NaCl, 5 mM KCl, 0.5 M EDTA, 10 mM tris maleate, pH 6.3, per g of frozen tissue), and immediately cooled in an ice bath. Just after cooling, the filtrate solution is introduced in a plastic syringe (30 ml) with an eccentric outlet and pressed through a specially prepared glass tube with six regularly spaced capillary constrictions. After allowing the particles to settle for 5–10 min in a conical glass tube, agitating at intervals, two-thirds of the supernatant is removed by suction, the residue mixed with 5 vol cold NKE and the glands are collected after dissection and kept in ice-cold NKME. After isolation, the glands are centrifuged (2500 × g) for 10 min, supernatant decanted, pellets suspended in 1 per cent digitoxin solution. Then 500 glands/ml in NKMC (80 mM NaCl, 5 mM KCl, 2.5 mM $MgCl_2$, 10 mM tris maleate, pH 6.3) are ruptured by passage through glass capillary (0.4 mm diameter), contaminants are removed and nuclei pelletted again (2800 × g) for 5 min.

Isolation of nuclei in non-aqueous medium

This method (Busch, 1967) is based on the principle of replacing the Ringer with liquid nitrogen and freezing.

(1) Homogenize slightly the gland masses in Ringer, and take the pellet, discarding the supernatant.
(2) Pour liquid nitrogen in the tube containing the pellet, against a dry ice acetone bath.

(3) After freezing the tissue, lyophilise and suspend in dried petroleum ether (boiling point 30–60 °C) in a Teflon glass homogeniser.
(4) Centrifuge for 10 min at 500 × g, pipette off the supernatant as far as practicable and allow evaporation of the rest.
(5) Resuspend the tissue this time in equal vol of dry cold benzene and carbon tetrachloride.
(6) Centrifuge for 15 min at 12000 × g.
(7) Dry the pellet and later hydrate the nuclei if necessary.

This method does not allow disruption of normal morphology of polytene chromosomes and because of lyophilisation, nuclei can be stored for indefinite periods.

For plant tissues

(1) Wash fresh, young roots or leaves in chilled water, remove the ribs in case of leaves, weigh 20 g and remove to 4 °C chamber where the rest of the procedure is to be followed.
(2) Transfer the tissue to a Waring blender containing 120 ml extraction buffer (0.25 M sucrose, 20 mM Tris HCl, pH 7.8, 10 mM NaCl, 1 mM $MgCl_2$, 2.5 per cent Ficoll and 5 per cent dextran 40) and continue blending for 15 s (at Variac Setting 50 volts).
(3) Take a flannelette of two layers, moisten with buffer and filter homogenate through it and adjust the final volume to 120 ml.
(4) Centrifuge for 10 min at 2500 × g.
(5) Separate the pellet and suspend in 10 ml extraction buffer.
(6) Slowly layer 5 ml of the suspension in a Corex tube (30 ml) on the upper surface of discontinuous sucrose gradient solution (7 ml 60 per cent, 7 ml 50 per cent and 7 ml 25 per cent sucrose).
(7) Centrifuge for 30 min at 8000 rev/min.
(8) Take the pellet which contains the nuclei only and suspend in 4 ml extraction buffer. This can be precipitated with 2 vol 95 per cent ethanol and fraction may be stored at −20 °C.

A modification of the above methods is also applicable to algae and even protozoa (Buetow, 1976).

Stern and Mirsky's schedule (1952)

This is suitable for plant materials.

(1) Extract 6 g wheat flour with petrol ether.
(2) Suspend in 300 ml fresh ether and grind for 46 h in a ball mill.
(3) Suspend in 500 ml of a mixture of cyclohexane and carbon tetrachloride, adjusted at a sp. gr. of 1.395. Centrifuge.
(4) Separate the supernatant. Add to it one-third its volume of ether and centrifuge. The sediment gives some nuclei with debris.
(5) Suspend the sediment from step (3) in cyclohexane and carbon tetrachloride mixture (sp. gr. 1.447), centrifuge at 6000 rev/min for 6 min.

(6) Collect the supernatant, suspend in petrol ether and again centrifuge. The supernatant contains now largely nuclei.
(7) The supernatant can be purified by repeating step (5) with 6000 rev/min and a mixture of sp. gr. 1.416 and then by repeating step (6).

For tumour and cultured cells

For tumours, cultured normal and abnormal cells, as well as for tissues from old animals, a slightly stronger method is to be adopted. For separation of nuclei from cytoplasm with least injury to nuclear membrane, low clearance homogenisers (50–77 μm) are necessary. Moreover several factors control the preparation of purified undamaged nuclei from such tissues, for example, nuclear swelling through the use of hypotonic medium, use of proper detergents namely Triton X100 NP40, Tween 40, Tween 80, sodium deoxycholate, etc., high pH and the use of citric acid in some cases (Muramatsu, 1970; Magliozzi *et al.*, 1971; Roodyn, 1972; Lengyal, Spardling and Penman, 1975; Spardling *et al.*, 1975). Yasmineh and Yunis (1974) recommend milder treatments and the method with hypotonic medium as adopted by them for transformed cell lines (SV 373-11-A8 Smith, Gells and Martus, 1972 or RSV B 77/3T4, Varmus, Vogt and Bishop, 1973, of mouse) is outlined below (de la Maza and Yunis, 1973).

(1) Take 300 falcon flasks (250 ml) or 25 roller bottles (0.59 gallon) containing at least 3×10^9 cells in culture.
(2) Pour off the original medium.
(3) Scrape the cells and collect in approx 1.0 l of reticulocyte standard buffer (RSB) (0.01 M NaCl, 0.01 M Tris, pH 7.4 and 1.5 mM $MgCl_2$).
(4) Centrifuge at $1000 \times g$ for 10 min.
(5) Resuspend the cells in 150 ml of 1 : 3 dilution of RSB and keep for 5–10 min to allow swelling. Make periodic observations through phase contrast microscopy to secure optimum swelling without bursting.
(6) Transfer the cells to a Potter homogeniser (77–100 μm clearance, 50 ml capacity) and completely disrupt the cells with eight to ten mechanical strokes with nearly full motor capacity.
(7) Centrifuge the homogenate at $1000 \times g$ for 5 min.
(8) Take the pellet of crude nuclei and unbroken cells, wash with 150 ml of 1.3 RSB and centrifuge again.
(9) To secure clear nuclear preparation, resuspend the pellet in 300 ml of 2.2 M sucrose–1.5 mM $MgCl_2$ by slight mechanical stroking in the Potter homogeniser (200 μm clearance).
(10) Centrifuge the suspension at $15\,000 \times g$ for 1 h in an angle centrifuge. The pellet at the bottom of the tube contains almost purified nuclei with slight cytoplasmic tags. The recovery of nuclei after this method is nearly 60–70 per cent.

The above method is a modification of the procedure followed by Penman (1969). The alternative method (Busch, 1967) involves citric acid, which has the disadvantage of cell and chromatin clumping with low recovery (40–50 per cent), but yields clearer nuclear preparations. It is necessary to have a

crucial pH for each type of cell, to free the nuclei from cytoplasmic adherents (Dounce, 1963). The method in brief may be outlined as follows:

(1) Follow the same procedure up to step (4) as above.
(2) Resuspend the cells in 150 ml of a solution containing 2.5 per cent citric acid, pH 2.5 and 0.8 M sucrose in a Potter homogeniser (50 to 100 μm clearance) with a few mechanical strokes in full motor capacity.
(3) Centrifuge the homogenate at 1000 × g for 10 min.
(4) Discard the supernatant.
(5) Resuspend the crude nuclear pellet in 300 ml 2.2 M sucrose–1.5 mM $CaCl_2$ in a Potter homogeniser (200 μm clearance) with a few strokes.
(6) Centrifuge at 15 000 × g for 1 h in an angle centrifuge.
(7) Collect the purified nuclear pellet from the bottom.

ISOLATION OF MITOTIC APPARATUS

Methods have also been developed for the isolation of mitotic apparatus for different organisms including mammalian systems. For isolation, the different steps principally involve synchronisation of mitotic cells, stabilisation of the mitotic apparatus, release through cell lysis, and fractionation of the suspension for separation of the released mitotic apparatus. Methods have been successfully applied to a wide variety of subjects namely HeLa, human amnion cell lines (Sisken, 1970), Chinese hamster cell cultures (Stubblefield, 1966; Wray, 1973a, b), etc. Hexylene glycol (HG) is used normally to stabilise the spindle, 2-*n*-morpholino sulphonic acid for a pre-lysis to rinse for washing off the medium at a higher pH and calcium for checking spindle shrinkage and securing chromosome contrast.

Technique I (Sisken, 1970)

(1) Centrifuge the cell suspension at 2000 rev/min for 2 min and discard the supernatant.
(2) Resuspend the cells by gentle pipetting in 1–2 ml of a mixture of 0.9 per cent NaCl, 10^{-4} M MES, pH 6.5–7.0.
(3) Transfer the suspension to 15 ml conical siliconed centrifuge tube and the mixture to make it up to 10 ml.
(4) Centrifuge the suspension at 1500 rev/min for 2 min.
(5) Discard the supernatant and resuspend the cells by gentle pipetting as in (2) in 4 ml of a mixture of 1 M HG, 10^{-3} M/MES, 10^{-4} $CaCl_2$, pH 6.9–7.2.
(6) Sediment the material quickly at 1500 rev/min for 2 min and resuspend in the same mixture as in (5).
(7) Sediment at 1500 rev/min for 2 min in 4 ml of a mixture of 1 M/HG, 10^{-3} M/MES, 4×10^{-4} M $CaCl_2$, pH 6.5–6.6 to stabilise the spindle at lower pH.
(8) Sediment the mitotic apparatus again in the same solution, fix or observe under the microscope.

Technique II (Wray, 1973a)

(1) Take exponentially growing cell cultures and add colcemid (0.06 μg/ml) and keep for 3 h, follow selective trypsinisation to secure a large number of mitotic cells separate from interphase cells.
(2) Remove CO_2 from the culture flask by purging with air to avoid change of pH of the isolation buffer.
(3) Remove the media, wash the culture twice with isolation buffer consisting of 0.1 M/HG, 10^{-3} M $CaCl_2$, 5×10^{-5} M PIPES (piperazine -*N*-*N*′ bis (2-ethane sulphonic acid) monosodium monohydrate). In this buffer the nuclei are stabilised but not fixed.
(4) Allow the cells to settle at room temperature in a minimal 5 ml buffer, till the cells are detached.
(5) Centrifuge the cell suspension at 1000 rev/min for 2 min and discard supernatant.
(6) Inactivate trypsin by suspending in media.
(7) Allow further formation of spindle by incubating for 20 min at 37 °C.
(8) Centrifuge for 2 min at 1000 rev/min.
(9) Wash in isolation buffer (1.0 M/HG, 0.5 mM $CaCl_2$, 0.05 mM, pH 6.5 PIPES) at 25 °C.
(10) Centrifuge at 2000 rev/min for 3 min and discard the supernatant.
(11) Suspend gently in isolation buffer medium as used in (3) at 25 °C.
(12) Rotate on Vortex mixer at high speed or gently syringe to cause cell lysis.
(13) Centrifuge at 3000 rev/min for 5 min and isolate mitotic apparatus.

For isolation of nuclei, the method is identical with that followed for mitotic apparatus, excepting (a) addition of colcemid in exponentially growing cultures is not needed; (b) in the isolation buffer, HG concentration is to be kept at 0.5 M and $CaCl_2$ at 1.0 mM. Also omit step (7), follow the syringe method in step (12) and centrifuge at 2000 rev/min for 3 min. The nuclei isolated are quite pure and unbroken.

ISOLATION OF CHROMOSOMES

For chromosome isolation, metaphase cell populations treated with colcemid are to be cooled at 4 °C in fresh medium to inactivate trypsin, dissolve mitotic apparatus and remove residual colcemid as well. It is also necessary to incubate the pellet in cold buffer after centrifugation at 37 °C for 10–15 min. This allows the cells to be broken easily and to equilibriate the chromosomes with the buffer so that they do not suffer a shock or stretching effect by the sudden difference in milieu after breakage (Wray, 1973a, b).

Hexylene glycol in the buffer prevents instability and disintegration. Similarly, the calcium concentration needs to be raised as otherwise there is dissolution of chromosomes. Another factor which requires deft handling is the syringing through a 22 gauge needle for rupturing the cell membrane, allowing the chromosomes to come out. For various cell lines, it is necessary to work out the number of times the solution is to be passed through the needle and the force necessary to secure the desired result. All steps are to

be continuously checked through phase contrast microscopy and the temperature should not be allowed to drop below 37 °C before cell breakage. After the chromosomes are liberated, the rest of the steps are to be carried out at 4 °C as usual. Isolated chromosomes can be stored in a stable condition without disintegration at 4 °C for several months (*see* Marushige and Marushige, 1978, for interphase chromatin isolation).

Technique 1

(1) Follow steps (1) to (4) as in technique 2 (for mitotic apparatus of Wray, 1973b) but in step (3), the isolation buffer should have the composition 1.0 M HG, 5×10^{-4} M $CaCl_2$, 10^{-4} M PIPES, pH 6.5. Prepare the buffer by 1 to 10 dilution of 5×10^{-3} M $CaCl_2$, 10^{-3} M PIPES and then adjust the pH to 6.5 by 1.0 N NaOH. Add hexylene glycol later and not before the above steps are carried out. With organic liquid otherwise, there may be sluggishness of the electrodes. For 0.1 ml vol of cell pellet, always use 15 ml centrifugation tubes.
(2) Centrifuge the cells at 1000 rev/min for 2 min.
(3) Suspend in fresh media.
(4) Keep at 4 °C for 20 min or more. Mitotic apparatus should be completely dissolved. Check in phase contrast microscope.
(5) Centrifuge the suspension for 2 min at 1000 rev/min and discard the supernatant.
(6) Wash in isolation buffer at 4 °C (1.0 M HG, 0.5 mM $CaCl_2$, 0.1 M PIPES, pH 6.5).
(7) Recentrifuge for 2 min at 2000 rev/min and discard the supernatant.
(8) Take the pellet and suspend at 4 °C in chromosome buffer prepared in step (3) and incubate at 37 °C for 10 min in a water bath.
(9) Use a 22 gauge needle (5 ml B-D, 1.5 inch) for gently syringing of the cells, causing disruption of walls and liberation of chromosomes; maintain the temperature as above and check through phase contrast microscope.
(10) Soon after the chromosomes are liberated, transfer to 4 °C and centrifuge for 5–10 min at 3000 rev/min and discard the supernatant.
(11) The pellet contains isolated chromosomes free from contaminants.

Technique 2

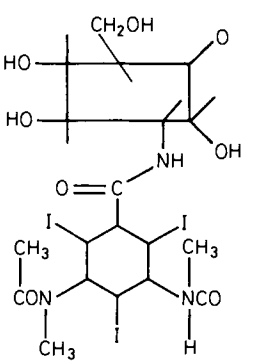
It has been demonstrated (Wray, 1973a, b) that most of the methods of chromosome isolation including that for electron microscopy by causing lysis of mitotic cells on air water interface as are described above, show degraded DNA when analysed through sucrose gradient technique and most of the DNA are degraded to smaller molecules. Hypotonic solution as well as even acid or neutral medium cause this degradation. The isolation procedure developed by Cory and Cole (1968) shows the presence of double stranded DNA of 2×10^8 daltons in Chinese hamster fibroblast system. In view of this fact, Wray (1973b) developed a method for isolating chromosomes at alkaline pH (10.5) to maintain high molecular weight DNA in chromosomes. The outline of this method is as follows.

(1) Take exponentially growing fibroblast culture of Chinese hamster, add 0.06 μg/ml colcemid, and keep for 3 h. Follow differential trypsinisation to keep only metaphase cells.
(2) Take the suspension and centrifuge at 1000 rev/min for 2 min, discard the supernatant.
(3) Inactivate trypsin by suspending in fresh medium.
(4) Keep at 4 °C for 20 min for dissolving the spindle.
(5) Recentrifuge at 1000 rev/min for 2 min and discard the supernatant.
(6) At 4 °C, wash thoroughly in freshly prepared isolation buffer (pH 10.5), composed of 1.0 M HG/2 $\times$ 10^{-3} M $CaCl_2$/1 $\times$ 10^{-3} M CAPS (cyclohexylamino propane sulphonic acid). Adjust pH before addition of HG.
(7) Centrifuge at 2000 rev/min for 3 min and discard the supernatant.
(8) Suspend at 4 °C in buffer.
(9) Incubate at 37 °C for 10 min in water bath.
(10) Follow gentle syringing as in technique 1 by a 22 gauge needle and observe under phase contrast microscope.
(11) Centrifuge for 5–10 min at 3000 rev/min.
(12) Discard the supernatant and the pellet containing isolated chromosomes.

This method allows separation of short and long chromosomes through fractionation on a 20 ml sucrose buffer gradient (8–40 per cent) and centrifugation for 30 min with a Sorvall HB-4 rotor at 2000 rev/min. Several fractions can be separated from the top containing large and small chromosomes respectively.

Isolation using metrizamide (after Wray, 1973)

During isolation of chromosomes, one of the difficulties often faced after centrifugation is the adherence of chromosomes on the walls and their separation as clumps. In order to avoid clumping Wray (1977) developed a method using metrizamide. It is tri-iodinated benzamido derivative of glucose: [(3-acetamido-metrizamide 5-*N*-methylacetamido-2,4,6 tri-iodobenzamido)-2-deoxy-2-glucose]. It is readily soluble in water and for dissolving a temperature higher than 55 °C is to be avoided. It can be used for isopycnic banding of chromosomes.



Metrizamide
(mol. wt. 789.1)

Wray used metrizamide for layering on a preferred gradient, gradually allowing it to rise till the buoyant density is reached. The method involves treatment of the tubes with siliclad (1 per cent), 1 per cent dimethyldichlorosilane in CCl_4, bovine serum albumin or bovine submaxillary mucin, and suspension of chromosomes in buffer containing 1 per cent siliclad, ethanol, isoamyl alcohol and disodium salt (*NDA:* 2-naphthyl-6-8-disulphonic acid). The method is outlined below (Wray, 1977).

(1) Treat the isolated mass for 5 min with 1 per cent dimethyl dichlorosilane in CCl_4 in 15 ml centrifuge tubes.
(2) Dry and treat in silicone in the tube at 140–160 °F for 24 h.
(3) Prepare chromosome suspension in 1 ml of chromosome isolation buffer containing 0.75 M metrizamide and 5 mM NDA.
(4) Centrifuge for 10 min at 10 000 rev/min using HB-4 rotor (Sorvall).
(5) Fractionate the gradients on the top in 0.25 ml aliquots.

Isolation of mamalian metaphase chromosomes by extraction from cell culture

As the majority of the techniques of cell isolation by chemical means result in a dissociation of nucleohistones (Busch, 1965) and chromosome aggregation, a very simple method was suggested by Maio and Schildkraut (1966a, b, 1969). The isolation is carried out at neutral pH utilising the high specific gravity of chromosomes, without the use of acid, alkali or enzyme. The method involves cell culture, metaphase arrest, homogenisation, preparation of crude chromosome suspension and finally purification of chromosomes. The method, claimed to yield stable and intact chromosomes, is outlined below.

(1) Grow suspension cultures of HeLa strain S3 cells, mouse strain L-cells, Chinese hamster cells, strain V-79-379A from the lung of a female and a strain of Syrian hamster cells transformed by SV-40 virus, in Eagle's medium supplemented with non-essential amino acids and 5 per cent fetal calf serum. The generation time for the Chinese hamster cell line is 12 h while those for the other cells lines vary from 22–24 h at 37 °C.
(2) Add to these logarithmically growing cultures, vinblastine sulphate (Eli Lilly and Co.) to obtain a final concentration of 0.01 μg/ml for HeLa and Chinese hamster cells, and 0.5 μg/ml for Syrian hamster and L-cells, incubate at 37 °C for 15 h and 8 h, respectively, for the two former strains and 11 h for the two latter strains. The HeLa cells give the highest frequency of metaphases (often as high as 90 per cent) and do not form any micronuclei, as against a frequency of 20–40 per cent in the other strains. However, the only disadvantage of HeLa cells is the uniformity of their chomosomes, which are difficult to identify. The selection of the optimum incubation period should be checked against the formation of micronuclei, because once formed, they are very difficult to separate from the chromosomes and the chromosome yield is thus lessened.
(3) For hypotonic treatment and homogenisation, harvest in each experiment for extraction, 4–12 l of cell culture containing 2×10^9 to 6×10^9 cells.

(4) Centrifuge at 500 × g for 15 min in the cold at 10 °C and wash the sedimented cells twice in Earle's balanced salt solution.
(5) Re-suspend in a mixture (TM) containing 0.0001 M of each of the chlorides of calcium, magnesium and zinc in 0.02 M Tris, maintained at pH of 7.0, in a proportion of cell suspension to medium (1 : 10) and keep for 20 min.
(6) Add 5 per cent filtered saponin solution to make a final concentration of 0.05 per cent and keep for 5 min.
(7) Transfer aliquots of the suspension to a 40 ml capacity Dounce homogeniser with pestle, and break up the cells with a few strokes to release the chromosomes.
(8) To prepare crude chromosome suspension, add twice the volume of TM, containing 0.05 per cent saponin, to the homogenate and transfer to centrifuge tubes.
(9) Fill about 3 cm of each tube and centrifuge for 5 min at 120 g. The resulting sediment contains most of the nuclei and unbroken cells.
(10) Decant the suspension liquid, containing the chromosomes, and store.
(11) Re-suspend the sediment in each tube by pipetting in TM solution to the original vol.
(12) Centrifuge and store the supernatant to extract the chromosomes left in the sediment.
(13) Repeat the process to extract most of the chromosomes; observing through a phase contrast microscope.
(14) To obtain a purified extract of chromosomes, centrifuge the collected suspension in an anglehead centrifuge at 2500 × g for 10 min.
(15) Wash the sediment in only 0.02 M tris containing 0.1 per cent saponin (pH 7.0), because the divalent metallic salts in the TM solution prevent the liberation of chromosomes from the debris and solution of the amorphous material.
(16) Re-suspend the sediment in 2.2 M sucrose in 0.02 M tris (pH 7.0) and 0.1 per cent saponin.
(17) Layer the suspension in cellulose nitrate in ultracentrifuge tubes over 10 ml of the dense sucrose solution (sp. gr. 1.28).
(18) Stir with a glass rod to mix the two solutions, leaving about 1 cm of the sucrose solution undisturbed at the bottom of each tube.
(19) Centrifuge at 50 000 × g for 1 h.
(20) Discard the supernatant and the sediment contains the chromosomes (sp. gr. approx. 1.35) plus the few nuclei that are left as contaminant.
(21) Re-suspend the sediment with purified chromosomes in TM and observe under phase contrast.
(22) If the chromosomes are still mixed with impurities, repeat the process of washing in Tris–saponin buffer and centrifuging in dense sucrose.
(23) Remove the sucrose by suspending the chromosomes in TM.
(24) Centrifuge at 2500 × g for 10 min.
(25) Repeat the procedure three times.
(26) Store the suspension containing chromosomes in the TM solution at 0 °C in ice buckets. Longer storage is recommended at −20 °C, after adding glycerol, to obtain a final concentration of 20 per cent.
(27) For experimental purposes, the chromosomes can be maintained both in a contracted state and in monodisperse suspension in a buffer containing

0.005 M calcium chloride and 0.05 per cent saponin in 0.02 M tris at a pH of 7.0. Dispersion may be achieved by aspirating repeatedly through a syringe with a No. 22 spinal tap needle.

From the HeLa metaphase cells, about 30–40 per cent of the chromosomes are recovered, as counted in a phase contrast haemocytometer. The average DNA content of isolated chromosomes from HeLa metaphase cells has been estimated to be 0.5 μg per chromosome and therefore less than 10 per cent of DNA is lost from the chromosomes during the isolation procedure.

For permanent mounts

(1) Add an equal volume of acetic–methanol (1 : 3) fixative to the suspension, mix thoroughly by aspirating through a pipette.
(2) Centrifuge at 2500 × g for 3 min.
(3) Resuspend the sediment in the fixative and centrifuge, the process being repeated several times.
(4) Redispose the final pellet in a small amount of fixative.
(5) Prepare air-dried slides by spreading a drop of the concentrated solution over a grease-free slide and allowing it to dry. The preparations may be stained using the usual stains for chromosomes (*see* Chapter 11).

Isolation of metaphase chromosomes from synchronised Chinese hamster cell lines (after Maio and Schildkraut, 1969)

For isolation of metaphase chromosomes from a large population of cells, Horikawa and Sakamoto (1977) developed a technique using combined colcemid and harvesting technique as adopted to some extent by Watanabe and Horikawa (1973) for HeLa S3 cell lines. The technique is outlined below.

(1) Take Chinese hamster cells (2×10^6) in Roux culture bottles containing 90 per cent Eagle's medium supplemented with 10^{-3} M sodium pyruvate, 2×10^{-4} M α-serine, 2×10^{-3} M α-glutamine and 10 per cent bovine.
(2) After 48 h incubate the cells in the medium containing 0.025 μg/ml colcemid for 6 h at 37 °C.
(3) Wash with Eagle's MEM to remove dead cells and debris and collect the mitotic cells by pipetting.
(4) Chill at 4 °C.
(5) To secure more mitotic plates, treat further the rest of the cells with 0.025 μg/ml, colcemid at 37 °C for 4 h.
(6) Mix this population with the chilled ones after washing with Eagle's MEM.
(7) Repeat the process once more to secure large frequency of metaphases as compared to control harvesting, without colcemid.

After each step, take cell counts in haemocytometer, chromosomes being fixed in methanol and stained in Giemsa.

Chilling, in general, decreases the plating efficiency from 4–8 h and there is a gradual increase in chromosome number. Addition of colcemid does not cause any damage or aberrations in chromosomes.

From such a synchronised population, isolation of metaphase chromosomes was carried out according to the method of Maio and Schildkraut (1969) with the following modifications.

(1) Repeat centrifugation in the horizontal head of a centrifuge at 100–150 × g with gradual increase for 8 min while removing nuclei and unbroken cells.
(2) Pool chromosomes from the supernatant and sediment by centrifugation in horizontal head centrifuge at 550 × g for 10 min.
(3) Wash pellets by resuspending in 0.02 M Tris (pH 7.0) with 0.1 per cent saponin.
(4) Centrifuge again at 550 × g for 20 min and collect purified chromosome populations.

The advantages of having isolated chromosomes for experimental work, as seen from Chinese hamster and HeLa cells, are as follows:

(1) The karyotype is usually maintained; there is little evidence of loss through breakage and the chromosomes are strongly Feulgen-positive.
(2) Phase contrast photographs show the chromosomes to be plump, refractive and rigid, possibly due to the adherence of histones which are generally lost in normal fixation procedure.
(3) The chromosomes can be studied with regard to changes in ionic environment and enzyme treatment.
(4) Isolated chromosomes of Chinese hamster cells can be separated into three classes by low-speed centrifugation at a steep sucrose gradient (Maio and Schildkraut, 1966b). The chemical composition of the morphologically distinguishable chromosomes can then be studied differentially.

The inherent disadvantages of the method include:

(1) selective loss or the possibility of loss, of small chromosomes during centrifugation; and
(2) absorption of the ribosomes on the chromosomes during extraction.

The future possibilities of the method and refinements suggested are:

(1) In addition to the divalent metal cations needed for maintaining the chromosome structure at a neutral pH during isolation, several polyamines and even histones may be used for the same purpose.
(2) The purity of the preparations depends on phase contrast observations, to exclude the presence of nuclei, membrane fragments and cytoplasmic debris, but extraneous materials may be adsorbed on the chromosomes or the chromosome constituents may get lost. Since they cannot be detected through phase contrast, refinements in this aspect are needed.

Claude and Potter's method (1943) for isolation of chromatin threads

The tissues used are spleen cells of leukaemic mice and liver cells of normal rats and guinea-pigs.

(1) Chill the tissue to 0 °C. Grind with an equal quantity of dry sand in a mortar for 3 min.
(2) Slowly add six times its quantity of distilled water or 0.9 per cent sodium chloride solution (pH 7.4).
(3) Centrifuge for 1 min at 1500 rev/min. Discard the residue.
(4) Centrifuge again the supernatant liquid for 10 min. Collect the sediment containing chromatin threads.
(5) Suspend the sediment in one and a half times its volume of saline solution.
(6) Centrifuge by alternately allowing the centrifuge to attain 1500 rev/min and then switching it off. Finally centrifuge at 1500 rev/min for 10 min.
(7) Repeat steps (5) and (6) again with supernatant fluid. The sediment contains white threads of chromatin.

Isolation of interphase chromatin

In order to isolate chromosomes or more precisely chromatin from interphase nuclei, the isolation of extremely purified nuclei is essential which has been described in previous sections. These isolated nuclei contain, in addition to chromatin, several intranuclear matter including nucleolus, soluble proteins etc. which are all to be removed through the use of adequate buffers (Zubay and Doty, 1959; Olins and Olins, 1974; Oudet, Gross-Belard and Chambon, 1975; Bakayev *et al.*, 1975). In spite of having several techniques (Tata, Hamilton and Cole, 1972; Hewish and Burgoyne, 1973; Noll, 1974) involving removal of chromatin from membrane, use of excising DNA with endogenous DNAse, etc., none of the techniques can be considered as of universal application. It is extremely difficult to maintain *in vivo* linear sequence of segments, and prevent interchain crosslinking. Hancock, Faber and Fakan (1977) have suggested a method for isolation of chromatin from cultured cells using solutions of very low ionic strength, without divalent cations and very low exposure to aerial oxidation. The schedule as tried with mouse cell line P815 (Schindler, Day and Fischer, 1959) is outlined below (Hancock, Faber and Fakan, 1977).

(1) Take exponentially growing cultures of the above cell line which may grow as suspension cultures*, add five times trypsin inhibitor (Calbiochem from egg white) followed by ice cold modified Eagle's growth medium (Dulbecco and Freeman, 1959) with 10 per cent calf serum. This ensures complete check of proteolytic activity.
(2) Centrifuge at 1500 × g for 7 min at 4 °C.
(3) Wash the pellet in growth medium without serum.
(4) Resuspend the pellets in 0.1 M sucrose in 0.2 mM phosphate buffer (pH 7.5) with a final concentration of 0.2 mM phosphate (prepared by titrating NaH_2PO_4 with KOH) in a rotary mixer till the suspension becomes homogeneous.
(5) Centrifuge the cells at 1500 × g for 7 min at 4 °C.
(6) Resuspend the pellet in the same solution as in step (4) (5 ml for 10^8 cells) and disperse by gentle rotary mixing.

* For cell lines other than P815, for detachment of cells, use 0.2 per cent trypsin in PBS with 1 per cent calf serum but without calcium or magnesium.

(7) Add an equal volume 0.5 per cent Nonidet P40 in 0.2 mM EDTA (pH 7.5—NP40 to be added dropwise to EDTA through vigorous stirring) 1 ml/min by gentle rotary mixing till there is loss of turbidity and the suspension remains opalescent. The chromatin structures undergoing sedimentation have a network of chromosome fibrils and there is an expansion of volume.
(8) Layer the cell lysate on solution used in step (4) but brought to pH 8.5 (NaH_2PO_4 with KOH liberated) as at a slightly alkaline pH the nonhistone nonchromatin protein can be removed. The volume of the solution should be 2 ml on 10 ml lysate for $5 \times 10^{6-7}$ or 5 ml on 35 ml lysate in four tubes for 5×10^8 cells.
(9) Centrifuge at 3000 rev/min for 15–20 min at 4 °C in a swinging rotor (22 cm). The pellet is translucent and consists of chromatin.
(10) Remove the surface to 1/2 of the supernatant by sucking through pipette.
(11) Wipe thoroughly the inside wall of the tube with absorbant paper.
(12) Remove the rest of the supernatant by suction.
(13) For purification repeat this process from step (8), if necessary to remove nonchromatin protein.

If necessary, the chromatin pellet can be fragmented and dissolved in proper medium in a Dounce homogeniser (15 ml) homogenising by 10–20 gentle strokes in 0.2 M EDTA (pH 7.2) which decreases the chance of interchain interaction because of divalent cations. The degree of homogenisation determines the length of the chromatin fragments.

Separation of DNA and protein after chromosome isolation

After chromosome isolation, the initial step for the analysis of components is the separation of DNA and protein. Of the proteins again, it is necessary to separate histone and nonhistone moieties. The methods earlier tried for separation of the protein components involved (a) use of dilute mineral acids, (b) quantitation with polyacrylamide gel electrophoresis, and quantitation after initially fractionating chromatin proteins through chromatography or Bio Rex-70 (Levy, Simon and Sober, 1972; Vanderbroek *et al.*, 1973), on Biogel (Ishitani and Listowski, 1975), hydroxyapatite (Paul, 1972), Sephadex (Elgin and Bonner, 1972; Richter and Sekeris, 1972) and cellulose (Yoshida and Shimura, 1972; Raeck, Simpson and Sobert, 1974). Meischer in 1871, first isolated nuclein by digesting pus cells with HCl and pepsin.

The principal limitation of the acid treatment which is based on the principle of solubilising histone protein and precipitating nonhistone with DNA (Bonner *et al.*, 1968) is that a part remains with nonhistone and thus bound to DNA even after separation. The complete solubilisation of histone, an essential requisite, is not often achieved. With polyacrylamide gel electrophoresis, a portion of the nonhistone may remain on the gel surface or may become mixed with buffer, thus causing serious error in the procedure. The inherent limitation of quick fading of colour sometimes cannot be avoided. The scanning of SDS gels also is difficult because of problems of separation of histones and nonhistones on the basis of molecular weights.

In view of these limitations Sonnebichler *et al.* (1975, 1977) have suggested a method for analysis of chromosomal proteins after complete separation of DNA and protein from chromatin through high speed centrifugation with salt and urea (*see* MacGillivray and Rickwood, 1978).

The outline of the method including the separation of DNA and protein is as follows.

Separation of DNA and protein

(1) Wash isolated chromosomes once with 0.024 M EDTA, 0.075 M NaCl (pH 7.0) and twice with 0.15 M NaCl.
(2) After washing, add 2 M NaCl, 5 M urea and 0.01 M $NaHSO_4$ (for checking protein degradation), transfer the chromosomes to centrifuge tubes, and centrifuge in an angle rotor at 100 000 × g for 35 h. The DNA forms a pellet and protein remains on the supernatant.
(3) Separate the pellet and the supernatant, and subject the pellet to the same procedure to free it completely from protein. *This pellet is now pure DNA.* (For small amount of nucleoprotein, separation can be achieved by density gradient centrifugation with 2 M CsCl and 5 M urea for 70 h at 100 000 × g. The DNA forms a pellet and protein remains on the supernatant.)
(4) Dialyse the supernatant for 3 h, reducing the salt concentration to 0.6 M and precipitate protein with 6 vol of acetone.
(5) Wash the protein with pure acetone.
(6) *The purified protein should be dried in vacuum.*

Separation of protein components

(7) Dissolve proteins in a concentration of 1 mg/100 ml 1 per cent acetic acid, 0.01 M β-mercaptoethanol, and 8 M urea.
(8) For electrophoresis use refrigerated teflon surface in a moist chamber (Heil and Zillig, 1970).
(9) Prepare 0.6 M ammonium borate buffer with 6 M urea, 0.01 M EDTA, 0.01 M mercaptoethanol (pH 10, though it comes down later to 9.3 due to CO_2 interaction). The presence of strong urea checks histone–non-histone overlapping during electrophoresis.
(10) Adjust the buffer with 25 per cent ammonia.
(11) Equilibrate cellogel strips (4 × 17 cm) with buffer, put in the chamber, neatly blot with filter paper to prevent the presence of air bubbles.
(12) Apply 1 mm of protein in 1 to 2 μl.
(13) Use electric power of 60 v/cm for 1 h, though for low resolution 15 min may be sufficient.
(14) Histones migrate towards the cathode and nonhistones in general move towards the anode or remain stationary. Slight nonhistones may move towards the cathode, but for their slow rate can easily be differentiated.
(15) Stain cellogel strips with 0.5 per cent amido black in 45 per cent methanol, 45 per cent water and 10 per cent glacial acetic acid.
(16) Remove excess dye with successive washing with solvent for 15 min.

(17) For quantitation, cut the coloured areas from blank cellogel strips, dissolve in glacial acetic acid. Measure the intensities at 630 nm on the basis of the standards prepared with known quantities of protein on cellogel strips.

The advantage of this method over acid treatment or column chromatography is that it does not allow any loss of protein and the analysis thus carried out gives an accurate assessment of protein composition. Moreover with low resolution electrophoresis, involving short duration, a series of samples can be analysed within a short period.

Separation of protein after chromosome isolation by electrophoresis

For separation of chromosome proteins Wray (1977) used the same method as (Wray, 1973) for Chinese hamster and HeLa tissue cell line isolation but the cells are broken by nitrogen cavitation in a pressure vessel using 250 psi and chromosomes are purified through sucrose buffer gradient centrifugation at 1500 × g for 30 min. The isolated chromosomes can also be studied for ultrastructure analysis in electron microscope following critical point drying (*see* Chapter 9 on electron microscopy).

For analysis of chromosome proteins, polyacrylamide gel method is as follows.

(1) Dissolve chromosomes in 3 per cent SDS (sodium dodecyl sulphate), 0.062 M Tris (pH 6.8) at 100 °C for 10 min and take observation in spectrophotometer.
(2) Analyse chromosome protein in 9 per cent polyacrylamide gel using Tris–glycine–buffered SDS system (Laemmli, 1970).
(3) Stain the gels with 0.05 per cent Coomasie blue in methanol–acetic acid–water (40 : 7.5 : 52.5).
(4) Destain by diffusion in 7.5 per cent acetic acid.
(5) (a) Analyse the protein bands in spectrophotometer.
    (b) For photography, develop in D-11 (Kodak) for 5 min at 20 °C.
    (c) Scan in a scanner.

ISOLATION AND SEPARATION OF HETEROCHROMATIN AND EUCHROMATIN OF CHROMOSOMES

Preparatory treatment of nuclei

In order to isolate chromatin, the prerequisite is the disruption of nuclei. This is best achieved through removal of outer membrane. Yasmineh and Yunis (1974) utilised a method based on the original technique of Frenster, Allfrey and Mirsky (1963) which removes even ribosomes and soluble proteins in the process of separation of nuclear membrane and cytoplasmic components. The method involves repeated suspension of nuclei in 0.01 M Tris buffer (pH 7.1), containing divalent calcium and magnesium, through stirring and centrifuging at 500 × g for 5 min. The quantity of buffer to be used is

100 ml/ml of nuclei. The treatment slightly differs with different tissues depending on the type and concentration of cations used in the initial homogenising medium and Tris buffer. While nuclei are initially extracted in the presence of magnesium, the procedure involves gently stirring in Tris buffer and microscopic observation of suspension. The suspension is to be prepared at least thrice and careful checking at each step is necessary as prolonged keeping may ultimately lead to liquefaction of chromatin along with membrane dissolution. But during homogenisation if only calcium or both calcium and magnesium are used, repeated suspensions with heavy stirring for 30 s each are necessary for removal of the outer membrane. It is always desirable to use in buffer the same cations originally used in homogenising medium. For example, in *Microtus agrestis*, Yasmineh and Yunis (1974) treated nuclei through four suspensions in Tris buffer 0.2 mM Ca–5 mM Mg with heavy stirring for 30 s in a plastic tube with the aid of a Potter homogeniser operated at 20 per cent output of Tri R motor (1 mm, clearance). But for nuclei prepared through hypotonic procedure as in transformed cells, four or more suspensions in Tris buffer with 1.5 mM magnesium are prepared, whereas for nuclei prepared through citric acid method, calcium may be used in place of magnesium in Tris buffer. In both cases, Potter homogeniser (200 line clearance with three to five strokes at 50 per cent motor output) is used for loose homogenisation and stirring. The use of tris buffer, in general, permits better disruption of fragile nuclei.

Breaking of nuclei for separation of chromatin

In order to disrupt the nuclei, and secure chromosomes and chromosome fragments for further separation through density gradient centrifugation, two methods are in vogue—sonication and passage through a French pressure cell. In both techniques, nuclei treated with Tris buffer are suspended on 0.25 M sucrose (25 vol) and stirred by means of Potter–Elvehjem pestle for 30 s in plastic tube (clearance 1 mm, 20 per cent output). In order to secure nuclear swelling, the optical density at 420 nm is adjusted to 1–3 with 0.25 M sucrose and stirred gently for 20 min in cold. Fibrous materials are to be removed by passing through two layers of flannelette. The nuclei are to be periodically observed to detect optimal swelling which is indicated by a typical spherical shape, hyaline nature and size almost twice that of the original one.

Sonication method

In order to secure sonication of nuclei, a sonifier is used (Yunis and Yasmineh 1972; Yasmineh and Yunis, 1974) such as Branson sonifier operating at 7 to 11A, generating sonic waves at 20 kc/s. The sample is to be kept at 0–4 °C, and overheating is minimised through discontinuous sonic bursts of not more than 15 s each. Nuclear suspensions in 15 to 18 ml aliquots are sonicated for 5 s bursts and the sonicate is periodically examined for disruption of all nuclei. If the nuclei are suitably prepared through proper cation concentration during homogenisation and adequate Tris buffer extraction, the disruption can be achieved by a maximum of 15 s sonication.

French pressure cell method

This technique is employed to cause disruption of nuclei by processing through a pressure cell. By differential centrifugation, the chromosomes can be separated from nucleoli. One of the limitations of the press technique is the difficulty in controlling the pressure so that often unbroken nuclei may come out (Muramatsu, 1970). The original method of Desjardins *et al.* (1963) has been modified by Liau, Craig and Perry (1968), which involves hypotonic shock treatment along with processing through French press. The technique in outline is as follows; the entire procedure being carried out at 2–4 °C.

(1) Homogenise the tissue in 10 vol of 0.25 M sucrose, with 5 mM NaCl and filter through several layers of cheesecloth and stir the filtrate gently with a magnetic stirrer.
(2) Take 40 ml of aliquot in a French pressure cell and apply pressure through the hydraulic press till up to 7000 psi.
(3) Slowly open the needle valve of the cell for the homogenate to come out of the orifice, without allowing the pressure to reach below 5000 psi.
(4) Take 20 ml of the pressate in 30 ml tubes (Spinco 25.1 rotor), follow a two layer system with different concentrations of sucrose and separate the nucleoli as pellet at 25 000 rev/min.
(5) Pipette out the upper layers and separate chromatin through high speed centrifugation.

Separation of euchromatin and heterochromatin

The chromatin suspension is to be filtered through two layers of flannelette and subjected to differential centrifugation for separation of chromatin fractions of different densities which are referred to as heterochromatin, intermediate chromatin and euchromatin. As the compaction and amount of heterochromatin are variable from species to species, the degree of centrifugation also differs. It has been suggested that centrifugation at different velocities, namely 500 × g/10 min, 1000 × g/10 min, 4000 × g/10 min, 6000 × g/10 min, 12 000 × g/10 min, 20 000 × g/10 min, 78 000 × g/30 min may be performed and sediments may be collected for each fraction. The euchromatin part of very low density should be obtained from the final centrifugation from the supernatant by making it 0.15 M with NaCl and precipitating with 2 vol of cold ethanol. The preparations can be periodically fixed with acetic–methanol and stained with Wright's stain.

In order to have a precise estimate of the amount of heterochromatin present in the fraction, it is preferable to extract the DNA from the fraction and its satellite or highly repeated content through CsCl or Cs_2SO_4–Ag^+ density gradient centrifugation. The distribution of satellite DNA in various fractions does not follow a set pattern and is species specific. For example, chromatin sonicate of liver nuclei (Yasmineh and Yunis, 1974), of mouse, guinea-pig and calf can be separated into fractions of high, intermediate and low densities by ethanol which can be further subjected to density gradient centrifugation. The results indicate that though satellite DNA content is 10 per cent of the total DNA in all the three species, it appears as a minor

peak on right side of the main peak, whereas in calf and guinea-pig, the presence is noted on two minor peaks one on each side of the main peak. In the light density fractions, rich in heterochromatin, the satellite DNA is nearly seven-fold in mouse whereas in guinea-pig and calf it is three- to four-fold and two- to three-fold respectively. The differences in satellite DNA content are quite distinct.

For isolation of different components of chromatin, Chevallier and Philippe (1975) follow a method in which isolation and sonication of mouse liver nuclei are carried out in a medium containing 2.2 M sucrose, 1 mM tris (pH 7.5), 25 mM KCl, 0.9 mM $MgCl_2$, 0.9 mM $CaCl_2$ and 0.14 mM spermidine. After sonication and differential centrifugation, two heavy fractions (1000 × g, 3500 × g) containing nucleoli, nucleolar associated chromatin and extranucleolar heterochromatin, one intermediate fraction (78 000 × g) containing nuclear membrane and other particles and a light fraction (105 000 × g) with euchromatin fibrils only, can be separated. This method thus allows a separation of euchromatin and heterochromatin.

EXTRACTION AND QUANTITATION OF NUCLEIC ACIDS FROM NUCLEI

Nuclei from either plant or animal cells can be subjected to quantitation of DNA and RNA. The technique is based on the principle of extraction through selective alkaline hydrolysis of RNA and acid hydrolysis of DNA. As the products are degraded during hydrolysis, it is not possible to analyse the components through this procedure. The steps involved in the technique are successive washing and extraction of the precipitate. So it is always desirable to homogenise the precipitate in a small volume of the solvent, the final volume of the solvent being added later.

(1) Take a sample (2–3 ml) in 2 vol of cold ethanol and centrifuge at 10 000 × g for 10 min and follow the same procedure with the precipitate. Wash finally in pure ethanol and centrifuge in the same speed. Centrifuging is to be done in the same speed in subsequent steps as well.
(2) Take the precipitate, add 7 ml of a mixture of absolute ethanol and ethyl ether (3 : 1) and boil for 3 min at 70 °C. Centrifuge and discard the supernatant.
(3) Wash repeatedly the pellet, centrifuging in 95 and 70 per cent ethanol respectively, and discard supernatant.
(4) Add 5 ml of 0.3 N NaOH and incubate for 30 min at 70 °C.
(5) Chill the suspension and slowly add cold 5.0 N perchloric acid, bringing the final concentration to 1.0 N.
(6) Centrifuge again and separate the supernatant which is pure RNA fraction.
(7) Wash and centrifuge the pellet twice in cold 0.2 N perchloric acid.
(8) Separate the pellet and add 2–4 ml of 1.0 N perchloric acid and incubate for 20 min at 70 °C.
(9) Chill the suspension and centrifuge.
(10) Separate the supernatant which is DNA fraction, the precipitate containing protein remaining among other constituents.

(11) Read the absorption of DNA fraction at 260 nm in the spectrophotometer.

In all systems, both the nucleic acids can be labelled by initially feeding with specific radioactive precursors and both autoradiography and scintillation counts can be taken for quantitation.

DIFFERENT METHODS OF EXTRACTION OF PURE NUCLEIC ACID

Extraction from tissues

Initially extraction of DNA from tissue involved a comparatively simple procedure, when strong salt solution and later chloroform–isoamyl alcohol were used to free the DNA ultimately from the protein (Gulland, Jordan and Threlfall, 1947). This procedure, which could be applied only in tissue with high DNA and less RNA content, such as thymus, testis, etc. suffered from serious limitations. The action of DNases as well as nickases or DNA breaking specific endonucleases, which might cause degradation of DNA during extraction, was completely overlooked. The procedure at that stage involved the following steps (Gulland, Jordan and Threlfall, 1947);

(1) mincing and suspending the tissue in an equal volume of 0.9 per cent NaCl and milling to form a fine suspension,
(2) resuspending the pellet twice in an equal volume of 0.9 per cent NaCl,
(3) suspending the pellet in 5 vol 10 per cent NaCl and stirring at 0 °C for 48 h,
(4) removal of the insoluble material by centrifuging at 6000 × g and precipitating the supernatant in an equal volume of methanol and washing the precipitate in methanol,
(5) vacuum drying at 25 °C,
(6) dissolving through stirring powdered nucleoprotein in 10 vol of 10 per cent NaCl,
(7) centrifuging the solution at 6000 × g,
(8) emulsifying through stirring after adding an equal volume of chloroform–isoamyl alcohol.
(9) centrifuging at low speed and re-extracting the aqueous layer with chloroform–isoamyl alcohol several times to remove protein,
(10) precipitating the DNA with an equal volume and washing with different concentrations of methanol, before finally drying the purified DNA.

The other widely used method had been the use of acid and alkali for extraction. As this method is even now used for crude extraction, the technique is outlined below.

(1) Homogenise the tissue in 5 per cent ice cold perchloric acid and discard the supernatant.
(2) Wash the residue with fat solvents like absolute ethanol, ethanol–chloroform or diethyl ether.
(3) Air dry the residue and later incubate at 37 °C for $3\frac{1}{2}$ h in 0.3 N NaOH for hydrolysis of RNA.

(4) Precipitate DNA and protein by 10 per cent perchloric acid and estimate RNA from supernatant.
(5) Heat the residue at 90 °C for 10 min with 10 per cent perchloric acid and centrifuge.
(6) Take the supernatant which is DNA and estimate.

Total protein can also be estimated by dissolving in 1 N NaOH. All the estimations may be carried out in a simple colorimeter like 'Spectronic 20' based on colour reactions for DNA, RNA and protein.

The above methods were gradually modified with the introduction of the use of sodium citrate for binding Mg to inhibit DNAse action, ribonuclease for removing RNA and amylase and pronase for removing polysaccharides, use of detergents for separating DNA and protein and also caesium chloride equilibrium centrifugation for isolating a small quantity of DNA from the bulk of cytoplasmic protein. The different methods now employed (Travaglini, 1973) are based on certain factors like (a) lysis, disruption and fractionation, (b) detergenation of cell organelles, (c) detergenation coupled with the use of extractants, and (d) density gradient and column separation involving use of enzymes as well.

In order to cause lysis and disruption of tissues prior to extraction of DNA, different methods are in vogue. For hard materials, such as plant tissues, insects, etc., often blender, mortar and pestle, or glass homogenisers, in media containing glycerol or sucrose, calcium or magnesium salts and Tris buffer (6.8–7.0) (*see* Stern, 1968) are used. After the tissue has been disrupted, screen or nylon mesh filtration is generally applied to get rid of cell particles and unbroken tissue. Other cell organelles along with polysaccharides, starch, extrachromosomal proteins are separated through various methods including the use of enzymes, detergents, etc. (Chun, Vaughan and Rich, 1963; Stern, 1968; Manning, Wolstenholme and Richards, 1972; Zweidler and Cohen, 1971; Tantvydas, 1971; Thompson and Cleland, 1971; Muramatsu, 1970; Ritossa and Spiegelman, 1965). For yeast (Blamire *et al.*, 1972), *Euglena* (Nass and Ben-Shaul, 1972) and slime mold (Sussman and Rayner, 1971) methods are slightly different.

The majority of eukaryotic cells can be disrupted and lysed after thawing by freezing or by homogenising in the extraction medium itself which may consist of sodium dodecyl sulphate (2 per cent), paraminosalicylate (6 per cent) and caesium chloride. Methods have been devised for different tissues such as mouse embryos (Williamson, 1969), liver, spleen and testis (Irving and Veazey, 1968; Okuhara, 1970), insect eggs and larvae (Travaglini, Petrovic and Schultz, 1973; Papaconstantinou *et al.*, 1972), starfish oocytes (Huez, Zampetti-Bosseler and Brachet, 1972), *Xenopus* (David, Brown and Reeder, 1970), *Ascaris* embryos (Bielka, Schultz and Bottger, 1968), ascites tumour and tissue culture cells (Harrison, 1971a; Cummings, 1972) with slight modifications whenever necessary (*see* Travaglini, 1973).

Use of detergents

The method originally devised by Marmur (1961) for prokaryota applies well in eukaryotic system (Williamson, 1969; Weintraub and Holtzer, 1972) because of the mildness of the technique. But in eukaryotes the presence of excessive proteins and polysaccharides requires, in addition, phenol or

caesium chloride equilibrium centrifugation for rapid deproteinisation. The procedure, in principle, involves the following steps (Travaglini, 1973).

(1) Suspend 2–3 g of cells in 25 ml STE (0.15 M NaCl, 0.05 M EDTA, 0.05 M Tris, pH 8) and 2 ml 25 per cent SDS.
(2) Incubate the mixture at 60 °C for 10 min and cool at 20–25 °C.
(3) Add 5 M sodium perchlorate to a final concentration of 1 M to the suspension, the whole mixture being shaken for 30 min with equal volume of chloroform–isoamyl alcohol.
(4) Centrifuge for 5 min at 3000–10 000 × g and separate the emulsion into three layers.
(5) Pipette out the upper aqueous layer and precipitate the nucleic acid by gently adding two parts of 95 per cent ethanol and slowly mixing it.
(6) Spool the nucleic acid fibres with the aid of a stirring rod.
(7) Dissolve the precipitate in 10–15 ml 1 XSSC (0.15 M NaCl and 0.015 M Na citrate).
(8) Repeat the same procedure for deproteinisation with chloroform–isoamyl alcohol several times, till no protein is noted at the interface.
(9) Precipitate the supernatant dissolved in the 1 XSSC (nearly two-thirds of the supernatant in volume).
(10) Add 50 μg/ml RNAase and incubate at 37 °C for 30 min.
(11) Deproteinise again with chloroform–isoamyl alcohol, and precipitate the supernatant with equal volume of ethanol.
(12) Dissolve the nucleic acids in 9 ml of 1 XSSC.
(13) Add 1.0 ml of 3.0 M sodium acetate, 0.001 M EDTA (pH 7.0).
(14) Stir the solution and while stirring, add 0.54 part of isopropanol dropwise.
(15) Precipitate DNA fibre.

Normally this is a useful method for extraction of DNA from eukaryotic nuclei (Weintraub and Holtzer, 1972) but for tissues with high protein or polysaccharide content, repeated deproteinisation with ethanol is substituted by combination with phenol of caesium chloride extraction methods.

Use of phenols

Nucleases are inactivated by phenols, and when the latter are saturated with a lipophilic salt such as *p*-aminosalicylate, separation from protein can be carried out much more effectively than with SDS-chloroform octanol. Several combinations of phenol and salt are in use and one of the most common methods is noted below (Kirby, 1957, 1965).

(1) Add 600 ml of sodium-*p*-amino salicylate to 75 g of tissue and homogenise and break in a high speed mixer for 45 s.
(2) Filter the mixture through a Buchner funnel, to remove the debris and quickly add 600 ml of 90 per cent phenol.
(3) Continue stirring for 1 h and centrifuge at 0 °C (300 × g) for 1 h and remove the aqueous layer containing nucleic acid by suction.
(4) Wash the phenol and insoluble part with 6 per cent sodium-*p*-amino-salicylate solution and separate the aqueous layer through centrifugation.

(5) Combine the two aqueous layers (400 ml), stir, and add an equal volume of 2-ethoxyethanol.
(6) Remove the fibrous precipitate with a glass rod and dissolve in 100 ml of water.
(7) Add 6 g of sodium-*p*-aminosalicylate to the DNA solution and precipitate DNA again with 100 ml of ethoxyethanol. The water–ethoxy ethanol mixture contains a flocculent precipitate of RNA.
(8) Dissolve quickly the DNA precipitate in 100 ml water, add 4 g sodium acetate and precipitate DNA again with 100 ml 2-ethoxyethanol.
(9) Dissolve DNA in 50 ml water, add 2 g sodium acetate and 1–5 mg ribonuclease in 1 ml water, and keep the mixture at 2 °C for 16 h.
(10) Precipitate DNA again with 50 ml 2-ethoxyethanol and remove the solvent after precipitation, and then dissolve the precipitate in 33 ml water for 15–30 min.
(11) Add 33 ml 2.5 M dipotassium hydrogen phosphate and 1.65 ml 33 per cent phosphoric acid followed by further addition of 33 ml 2-methoxy-ethanol. Shake the mixture and keep at rest for separation of layers.
(12) Pipette out the topmost layer and centrifuge at 10 000 × g for 1 h.
(13) Decant the clear organic layer, discarding the sediment, add a few drops of toluene and subject the mixture to dialysis twice against water and twice against sodium acetate taking 2 litres in each case.
(14) Remove the contents, centrifuge, make up to 4 per cent with sodium acetate (100 ml) and finally precipitate DNA with 100 ml 2-ethoxyethanol.
(15) Take out the fibrous precipitate, wash with ethanol : water (3 : 1) twice and finally with ethanol and allow it to dry on calcium chloride in a vacuum desiccator.

The complicated and elaborate procedure of DNA purification through 2-methoxyethanol may be substituted by RNAse and amylase.

Precaution is necessary to ensure that all cells are disrupted during homogenisation and the reagents used for extraction should be adequate. The latter step eliminates trapping of DNA at the saltphenol interface. Extraction temperature should in no case be above 25 °C. Moreover DNA is denatured even in presence of traces of phenol which lowers the *Tm* value. In cases where extraction of polymer is necessary, this method should be avoided as phenol saturated with salt solution dissolves poly dAT and other similar polymers (Smith, Martinez and Ratliff, 1970). The tissue injury arising out of shearing forces because of the use of blender and vigorous shaking is also another disadvantage of this technique. Some of these limitations can be overcome with the use of a method in which both phenol and detergents are applied.

Use of both phenol and detergents

The technique combining both phenol and detergents has been applied for nucleic acid extraction from tissues of different organisms namely insects (Kram, Botchan and Hearst, 1972), amphibia (Baker, 1972), mammals (Harrison, 1971b) and even plants (Manning, Wolstenholm and Richards, 1972).

The method used for *Drosophila* is as follows (Ritossa and Spiegelman, 1965).

(1) Suspend in 10 vol of buffer (w/v) at pH 7.6, Tris (0.05 M), KCl (0.025 M), Mg acetate (0.005 M), sucrose (0.35 M) and homogenise at 0 °C. in a mortar.
(2) Filter the homogenate through eight layers of gauze.
(3) Centrifuge the filtrate at 700 × g for 10 min.
(4) Suspend the pellet in 0.15 M NaCl, 2 per cent SDS and 0.1 M EDTA and adjust to pH 8 (35 ml for each 10 g of flies).
(5) Gently agitate (Travaglini, 1973) for 10 min at 60 °C as shaking may cause shearing of DNA.
(6) Follow subsequent procedures as mentioned above for *detergent method* using 1 vol of cold ethanol instead of 2 vol in the first step, to increase the yield.
(7) Collect the fibres in a glass rod.
(8) Centrifuge the residual flocculent DNA precipitate.
(9) Resuspend in 1 XSSC with the addition of 1 vol of ethanol.
(10) Collect the fibrous precipitate.
(11) Treat the fibrous DNA dissolved in SSC with RNase (150 μg/ml) at 37 °C for 4 h, to remove RNA.
(12) To remove polysaccharides, digest the preparation with α-amylase (250 mg/ml) for 45 min and with pronase (50 μg/ml) for 30 min both at 37 °C. Treatment with pronase also removes the interfacial protein as far as practicable.
(13) Add 1 per cent SDS to the digest and treat twice with phenol, at 25 °C.
(14) Deproteinise twice for 10 min each with chloroform–isoamyl alcohol for 10 min.
(15) Remove chloroform and phenol by shaking with ether.
(16) Precipitate DNA in 2 vol of ethanol.
(17) Collect the fibrous DNA and dissolve in 0.01 XSSC.

Density gradient centrifugation for extraction

The method is based on the principle of separation of cell fractions through density gradient centrifugation. Several media such as sucrose, caesium chloride, Ficoll (a sucrose polymer), dextran, potassium tartrate, sodium bromide as well as silica gel (Pertoft, 1966; Wray and Stubblefield, 1970; Wolff, 1975) have so far been used. The change in osmotic pressure as well as the induced chemical toxicity are often common problems met with these techniques.

For tissues, with heavy cytoplasmic content, caesium chloride method for DNA extraction (Travaglini, 1973) is suitable for separating different nucleic acids, polysaccharides and proteins. Homogenisation of cells followed by centrifugation results in pelleting of nucleic acids and polysaccharides. It has the advantage of forming a gradient due to density difference after equilibrium sedimentation in a constant centrifugal field. Moreover, in high concentrations, it inhibits nuclease action and causes separation of nucleic acids from proteins. Gradient extraction techniques are best suited for micro extraction from unmixed organelles. The method as followed for *Drosophila* embryo is outlined below.

(1) Homogenise embryos (2 ml/10 ml of CsCl) in 4 M CsCl (density 1.40 g/ml) at 4 °C.
(2) Centrifuge the homogenate at 40 000 rev/min for 24 h at 20 °C to equilibrium; polysaccharides and nucleic acids form a pellet.
(3) Separate the pellet and dissolve in 1 XSSC (9 ml SSC, to pellet from 2 ml egg white).
(4) Digest successively in the following enzymes for 1 h each at 37 °C: (a) 0.01 vol α-amylase (10 mg/ml), (b) 0.1 vol ribonuclease (0.01 mg/ml), (c) 0.01 vol pronase (50 mg/ml).
(5) Centrifuge initially at low speed to remove insoluble material and then at high speed (40 000 rev/min) for 1 h at 4 °C to pellet DNA.
(6) Dissolve DNA in 1 XSSC and store at −30 °C.

Due to the use of strong concentration of CsCl which inhibits the action of nuclease, the method does not allow enzymic degradation of DNA. It may sometimes be necessary as in sea urchin embryo to shake again with chloroform–isoamyl alcohol before the use of enzymes to remove all traces of nuclease.

Column methods for extraction

The methods are simple as compared to the previous procedures and involve preparation of the cell lysate and passing the lysate through a column for selective absorption from which the sample can later be eluted.

MUP method

This method (Britten, Päkich and Smith, 1970) utilises absorption on hydroxyapatite (HAP) for separation of DNA directly from lysates. Hydroxyapatite can be purchased or prepared in the laboratory as it is an alkalised mixture of Na_2HPO_4 and $CaCl_2$. The technique involves, in addition to buffer, the use of (a) urea, needed for disrupting the cell, denaturing chromosome proteins, and inactivating enzymes, the last two properties being shared also by (b) sodium lauryl sulphate (SLS) and (c) ethylene diamine tetraacetate (EDTA)—the chelating agent for binding bivalent and polyvalent metal ions. Of these, SLS is normally purified by recrystallisation from hot ethanol, dried after ether washing and stored as 25 per cent at 4 °C in a solid form. The only limitation of the technique is the limited capacity of HAP which can recover only a small amount of DNA from a large mass of tissue (Travaglini, 1973). The technique in outline is as follows.

(1) Suspend the tissue in a mixture of 8 M urea, 0.24 M phosphate buffer, 1 per cent SLA and 0.01 M EDTA and homogenise in a blender. For plant materials, add molar sodium chlorate to the lysing mixture, extract the lysate with an equal volume of chloroform–isoamyl alcohol, and take the supernatant after centrifuging.
(2) Pass the homogenate or supernatant as obtained above on HAP, and stir to check channelling.
(3) Wash HAP with heavy amount of urea buffer mixture (8 M urea, 0.02 M phosphate buffer).
(4) Wash with 0.14 M phosphate buffer to remove urea.
(5) Elute DNA with 0.04 M phosphate buffer.

Poly-1-lysine-Kieselguhr (PLK) method

Instead of hydroxyapatite, Kieselguhr columns (Ayad and Blamire, 1968) coated with poly-l-lysine may be used for extraction of DNA. Blamire *et al.* (1972) utilised this method for yeast cells which are now widely applied because the yield of DNA is quite satisfactory from small samples. The method for yeast is outlined below.

(1) Suspend 10 g of yeast cells in 10 ml mixture of 0.4 M NaCl, 0.02 M KH_2PO_4 (pH 6.8) and 0.1 M EDTA.
(2) Disrupt in a homogeniser.
(3) Centrifuge the lysate at 27000 × g at 4 °C for 30 min.
(4) Take out the supernatant, and treat with 50 μg/ml RNase for 30 min at 30 °C for removal of RNA.
(5) Add 0.4 M buffered saline and run through PLK column.
(6) Wash the column with 1.4 M NaCl–0.02 M KH_2PO_4.
(7) Elute DNA at 1.6 M NaCl.

Special methods for plant materials

From callus and callus buds

Isolation of DNA from callus or developing buds from callus base has been carried out by Doerschug, Miksche and Stern (1976). Such callus, grown in sterile cultures, not only provides profuse materials but is free from contaminating bacteria and fungi. The method may be outlined as follows.

(1) Prepare sterile cultures from the seeds in a suitable basal medium (Eriksson, 1965 and *see* chapter on tissue culture) supplemented with 10 ml/l myoinositol and 50 ml/l coconut milk.
(2) Expose the cultures (masses of buds at the base of the callus) to short photoperiods (10 h light/14 h dark) followed by long days (19 h light/8 h dark) which results in the profuse growth of buds, which are compact masses of cells.
(3) Collect the buds and follow the DNA isolation procedure (modification of Hotta, Passel and Stern, 1965) as outlined below.
(4) Grind the tissues in cooled ethanol (−20 °C) in a ground glass homogeniser till the homogenate becomes a mixture of cell clumps, single and broken cells.
(5) Wash twice with 70 per cent ethanol.
(6) Disrupt the cells by stirring in a mixture of 2 vol of 1 per cent sodium lauryl sulphate (SLS), 0.01 M ethylenediamine tetra-acetic acid (EDTA) and 0.05 M Tris buffer, pH 8.5.
(7) Keep the mixture at 65 °C for 20 min.
(8) Centrifuge and re-extract the pellet in the original extraction fluid.
(9) Add 2 vol of 95 per cent ethanol, centrifuge and collect the precipitate by centrifugation.
(10) Wash twice with 70 per cent ethanol.
(11) Redissolve the precipitate by slow stirring at 21–23 °C, in a mixture of 0.01 M Tris, pH 7.5, 0.01 M EDTA, 1 M NaCl, and 1 mg/ml pronase. Pronase should be pre-treated earlier at 65 °C for 10 min to remove contaminating deoxyribonuclease, if any.

(12) Incubate for at least 4 h.
(13) Deproteinise the solution twice in a mixture of chloroform and isoamyl alcohol (24 : 1).
(14) Spool out DNA by slowly adding 0.55 vol of isopropanol.
(15) Follow further purification as per Marmur's (1961) method through two ribonuclease treatments (50 μg/ml, 15 min, 37 °C) followed by pronase treatment (200 μg/ml, 2 h, 37 °C).
(16) Extract with chloroform and isoamyl alcohol till no precipitate is formed at the interface.
(17) Finally precipitate with isopropanol.
(18) Store the extracted DNA at −30 °C in 95 per cent ethanol.

From other plant tissues

Flavell and O'dell (1976) purified DNA from frozen aerial tissues of wheat according to the schedule of Smith and Flavell (1974). In this schedule, after treatment with amylase, ribonuclease and pronase, the DNA is to be continuously shaken with phenol saturated with 0.2 XSSC in the presence of 2 per cent sodium lauryl sulphate till no further precipitate appears at the interface on centrifugation. Dialysis of the final aqueous layer is carried out overnight against 0.1 XSSC at 3 °C and the DNA is recovered by ethanol precipitation or centrifugation at 120 000 × g for 8 h. Further purification can be carried out as per methods of analysis outlined below.

Extraction from subcellular samples

In order to extract purified DNA or RNA from the subcellular samples, fractions stored in 70 per cent ethanol at −20 °C are to be first centrifuged at 8000 × g for 10 min at 2–4 °C and the freed pellet is suspended through mixing in equal volume of 1 XSSC in the cold.

(1) Resuspend pellet in 2.5 per cent sarkosyl (sodium-*n*-lauryl sarcosinate-Geigy NL 97) and have it thoroughly dispersed.
(2) Heat at 70 °C for 20 min and repeat centrifuging at 8000 × g for 10 min at 2–4 °C.
(3) Decant the viscous supernatant and dilute it with 4 vol of 1 XSSC so that the final sarkosyl concentration is 0.5 per cent. After addition of T_1 ribonuclease (20 μg/ml) and DNAse free ribonuclease A (25 μg/ml)* keep at 37 °C for 30 min.
(4) Gradually add through mixing 0.2 vol of 5 M NaCl and then predigested pronase† (500 μg/ml) and heat at 60 °C for 1 h. This digested lysate can be used for density analysis or hydroxyapatite column filtration.
(5) In order to remove protein and precipitate DNA, add equal part of water saturated freshly distilled phenol to the lysate. Close tightly the tube with rubber stopper and mix it thoroughly by repeated inverting several times, per min. Add equal part for chloroform after 30 min. Shake thoroughly and centrifuge the mixture at 8000 × g for 10 min and remove

* Recrystallise ribonuclease A five times at 2 mg/ml in 1 XSSC to make it DNAse free. Heat the enzyme solution to 90 °C for 10 min and freeze for storing.

† Incubate B grade pronase at 2.5 mg/ml in 1 XSSC at 65 °C for 20 min to prepare predigested pronase and freeze for storing.

the top layer with pipette and repeat the above phenol–chloroform extraction method till no precipitate is found in the interface.

(6) Take the upper layer from the finally separated phase into a centrifuge tube through pipetting and add slowly an equal volume of 95 per cent ethanol in the DNA solution. Winding out the fibres at the interface may be necessary for high concentration of DNA followed by washing with 70 per cent ethanol, to remove excess phenol and finally excess ethanol. With low concentration of DNA, it would be necessary to mix the phases, chilling and centrifuging the solution at 10 000 × g for 10 min at 2–4 °C followed by washing the pellet with 70 per cent ethanol and later pouring off the excess ethanol.

(7) Take 2–4 ml of DNA and dissolve in 0.1 XSSC, keeping in a shaker for overnight at 2–4 °C.

(8) Test the purity of the preparation in a spectrophotometer where for pure DNA the ratio will be two in 260–280 nm.

Protein contamination is indicated in lower ratios and peak at 270 nm is indicated if phenol is not completely removed. In case of the presence of contaminants, the entire procedure from steps (3) to (7) is to be repeated.

Several modifications of the above procedure have been adopted by different authors, specially to avoid either loss of DNA or injury to its constituents during extraction.

For animal tissues

Renkawitz and Kunz (1975) adopted two methods for extraction of DNA from organs and nuclei from the brains and ovaries of species of *Drosophila*, *Calliphora* and *Sarcophaga*.

(1) In the first method as followed for extraction from tissues, the organs are ground in a homogeniser containing Tris-buffer (0.1 M EDTA, 0.05 M Tris HCl, pH 8.4), 0.5 per cent (w/v) sarkosyl, and 200 μg/ml pre-digested pronase E (Merck) and finally incubated for 3 h at 37 °C. Extraction is carried out four times with an equal volume of Tris–buffer saturated phenol, transferred to 0.15 M NaCl and final precipitation of DNA is obtained with 2 vol 96 per cent ethanol at −20 °C overnight. The precipitate is then centrifuged and after washing with aqueous saturated ethyl ether, dissolved in 0.1 XSSC or stored at −20 °C.

(2) In the other method, the homogenisation is carried out as above and the homogenates or isolated nuclei are incubated at 37 °C in sarkosyl tris buffer for 90 min at 37 °C. After addition of CsCl, the mixture is adjusted to a density of 1.349/ml, chilled for 1 h, centrifuged and protein precipitated. 2 ml of the supernatant, equal volume of CaCl (1.76 g/ml) is to be added for underlaying and the tube further centrifuged for 19 h at 26 000 rev/min in Beckman SW 56 rotor (Heermann *et al.*, 1975). After collecting the fractions, analysis is carried out at 254 nm with ISCO model 640 fraction collector attached with an absorption monitor US 5.

In the first method, which includes phenol treatment as well, there is a considerable loss of DNA during extraction but the hyperchromacity is rather high, i.e. 35–39 per cent whereas with the second method, due to omission of

phenol step, the yield of DNA is high but hyperchromocity is low (25–31 per cent).

But with both these methods, DNA fractions are further to be purified through repeated centrifugation in CsCl (1.685 g/ml) at 38 000 rev/min (Beckman 65 rotor) for 70 h or at 35 000 rev/min (Beckman Pi 60 rotor) for 80 h and further analysed and fractionated with ISCO system as above. Renkawitz and Kunz (1975) utilised these methods for rDNA analysis and molecular weights were calculated using Studier's (1965) formula.

Extraction of RNA

In view of the fact that RNA is associated actively with chromosome metabolism, a brief outline of the method of extraction of RNA is given below (Muramatsu, 1973).

(1) Homogenise gently the nuclear pellet in 20–40 vol 0.15 M NaCl, 0.05 M sodium acetate (pH 5.1), 0.3 per cent SDS mixture. The pH is kept at 5.1 in order to protect high molecular weight RNA.
(2) After dissolving, add an equal volume of phenol-*m*-cresol (70 : 10 : 20) mixture with 0.1 per cent hydroxyquinoline and stir at 65 °C for 8 min.
    Both phenol and SDS are very effective RNAse inhibitors and high temperature accelerates RNA extraction, suppressing the release of DNA.
(3) In order to secure full extraction, shake at 26–28 °C for 15 min.
(4) Centrifuge for 5 mins at 10 000 rev/min at 4 °C.
(5) Separate the phenol layer by pipetting so that the aqueous and interphase layers are left.
(6) Add additional 2/3 vol of phenol-*m*-cresol mixture and shake for 5 min at 26–28 °C.
(7) Centrifuge at 10 000 rev/min at 4 °C for 5 min.
(8) Repeat the procedure by transferring the aqueous layer to another tube and re-extraction and centrifugation in phenol-*m*-cresol mixture.
(9) Add 1.5 to 2 vol, of ethanol-*m*-cresol mixture (9 : 1) containing 2 per cent potassium acetate to precipitate the aqueous phase in a deep freeze for 2 h.
(10) Centrifuge the precipitate at 3500 rev/min for 30 min.
(11) Shake and centrifuge successively the pellet in 75 per cent ethanol containing 1 per cent potassium acetate, 95 per cent containing 1 per cent potassium acetate and finally 95 per cent ethanol.
(12) Keep the final pellet dissolved in 0.05 sodium acetate (pH 5.1) in deep freeze.

For differential extraction of RNA, stepwise extraction is needed. Normally ribosomal and transfer RNA are extracted in the aqueous phase at 24–26 °C following phenol extraction at neutral pH and nuclear RNA requires higher temperature (50–65 °C) (Georgiev and Mantieva, 1962).

The most interesting technique of the isolation of messenger RNA containing unique sequences is based on the finding of long polyadenylic sequences (poly A). Threads 150 to 200 nucleotides long remain linked with three termini of the coding sequence (Kates, 1970, 1973; Lee, Mendecki and Brawerman, 1971; Mendecki, Lee and Brawerman, 1972; Perri, Kelley and

La Torri, 1974; Puckett, Chambers and Darnell, 1975; Edmonds and Winters, 1976).

In this technique (Lee, Mendecki and Brawerman, 1971; Brawerman, 1973, 1976; Brawerman, Mendecki and Lee, 1972), the RNA, dissolved in 0.5 M KCl, 0.001 M $MgCl_2$, 0.01 M Tris–HCl (pH 7.6), is passed through a nitrocellulose filter such as Millipore filter under high ionic concentrations, resulting in adsorption of poly A sequence containing RNA whereas ether RNA passes through the filter. Glass fibre filter to which poly U has been coupled by ultraviolet radiation (Sheldon, Juvale and Kates, 1972), is also widely used. Several authors prefer methods based on interaction of poly A with oligo (dT) on cellulose or poly U on cepharose columns (Brawerman, 1973).

The recovery of poly A containing RNA is obtained by eluting with 0.5 per cent SDS in 0.1 M Tris–HCl (pH 9.0) at 0 °C or with lower concentration of SDS (0.1 per cent) in lower Tris–HCl (0.01 M), pH 7.6 at 24–26 °C (Mendecki, Lee and Brawerman, 1972; *see* Muramatsu, 1973).

The discovery of long poly A sequences in messenger RNA and its absence in mRNA coding for histones has opened up new possibilities in the analysis of unique sequences. The function of this additional sequence is not fully established but the very fact that such homopolynucleotide sequences may be of varying size suggest some specificity of function.

ANALYSIS OF DNA SAMPLES THROUGH EQUILIBRIUM SEDIMENTATION CENTRIFUGATION

In order to study and analyse the DNA, caesium chloride is often used for equilibrium density sedimentation. This method allows an analysis of its sequence complexity as well as single or double stranded nature. Gradients of CsCl are formed during centrifugation and in the linear gradient, the midpoint is the density of CsCl at the time of initiation. Centrifugation is continued till the isodensity position is reached. DNA molecules are equilibrated, the density at pH 8.5 of DNA in CsCl being approximately 1.700 g/ml. It has been noticed that there is a direct relationship between GC content and buoyant density and with increasing denaturation of DNA there is a regular increase of 0.015 g/ml of density. The linear relationship between density and GC content was worked out by Schildkraut, Marmur and Doty (1962) = 1.660 + 0.098 (GC).

For convenience of handling and to avoid a steep gradient, fixed angle rotors are used for CsCl in the preparative centrifuge. In order to secure effective column height (distance between minimum and maximum radii of sample) under variable rotor speed and steepness of the gradient, column height of the gradient is adjusted to a minimum. This ensures quick formation of the gradient and rapid movement of DNA to isodensity position. Normally for high molecular weight DNA, the time required for equilibration, according to Howell (1973), is 20–24 h at 44 770 rev/min in analytical centrifuge and 35–40 h at a lower rev/min of 35 000 with type 50 rotor in a preparative centrifuge.

A sample schedule for the analysis in CsCl gradient is mentioned below (Howell, 1973).

(1) Adjust the CsCl solution with sample to desired midpoint by adding solid CsCl to DNA solution or by diluting the stock CsCl solution with DNA. The determination of refractive index helps to adjust the density but for crude lysates, such determination is not applicable.
(2) Take 0.1 to 0.2 ml of crude lysage (e.g., *Chlamydomonas*) or purified DNA containing at least 10 000 acid precipitable counts/min in a graduated test tube. Add 2000–5000 acid precipitable counts/min of phosphorus labelled *E. coli* DNA as marker (0 = 1.710 g/ml). Bring the volume to 4.34 ml by adding 20 mM Tris–HCl (pH 8.5) and finally dissolve 5.75 g CsCl in it. For the purified DNA sample, adjust the refractive index to 1.404. Take 5 ml of the sample with a pipette in a cellulose nitrate centrifuge tube and fill it with mineral oil and cork tightly with metal cap with no air bubble in between. Fix the tubes in fixed angle rotors (40, 50 or 65 types) and centrifuge at 35 000 rev/min for 30 h at 20–25 °C.
(3) Collect samples after centrifuging by puncturing the bottom of the tube with a 24 gauge needle; from a 5 ml gradient, 20 drops give 35–40 fractions.
(4) Determine the refractive indices of a minimum of five fractions of the gradient.
(5) Work out the density of the CsCl in the fraction according to the formulae 25 °C = 10.8601 n 25 °C, 13.4974 and prepare a graph with refractive index as abscissa and density (25 °C) as ordinate.
(6) Add 0.1 ml of 2.5 mg/ml herring sperm carrier DNA and then 0.5 ml cold 10 per cent TCA to each sample. Filter the chilled samples individually, wash three times with 5 per cent TCA and then with 95 per cent ethanol. Take counts from the filters in scintillation counter.
(7) Against the individual fraction, tabulate the CsCl concentration, acid precipitable CPMs as well as absorption at 260 nm. The density may be compared with the reported values of different species (Borst and Kroon, 1969) and on the basis of the density, GC content can be worked out.

In case of *Chlamydomonas reinhardi*, 85 per cent of the total DNA has a density of 1.723 g/ml and 7–15 per cent represent minor satellites having a density of 1.695 g/ml.

ANALYSIS OF DNA THROUGH HYDROXYAPATITE COLUMN

This method is very useful for separation of DNA components and purification of DNA from crude lysate. Hydroxyapatite can distinguish between single and double stranded DNA at a wide range of temperatures (Bernardi, 1971). In view of this property, both thermal denaturation and reassociation kinetics analysis (*Tm* and *Cat*) are performed through the use of this column which essentially is $Ca_{10}(PO_4)(OH)_2$. The binding is not affected by the inclusion of solubilising agents such as urea and detergents, which is an added advantage.

A method is described here showing separation of double and single stranded DNA (*see* Bernardi, 1971; Howell, 1973).

(1) Take slurry of hydroxyapatite (Howell recommends Hypatite C—Clarkson Chemical Co) stored in refrigerator, warm to 22–24 °C and pour a column (2 × 2 cm). Wash with 40 ml 0.05 M phosphate buffer prepared through equimolar proportions of NaH_2PO_4 and Na_2HPO_4.
(2) Prepare a sample of 10 ml in phosphate buffer (0.05 M) of 50 000 acid precipitable counts/min of tritiated *Chlamydomonas reinhardi* DNA (crude lysate or purified form) and 10 000 counts/min of heat denatured phosphorus labelled *E. coli* DNA. For crude lysate, buffer should be prepared in 8 M in urea.
(3) Add sample to the column and run 25 ml of 0.05 M phosphate buffer through the column. For crude lysate, the first 5 ml of buffer should be 8 M in urea.
(4) Run a continuous gradient and elute DNA using 100 ml each of 0.05 M and 0.35 M buffer and collect in 5 ml samples. Store all fractions in chilled state.
(5) Count the refractive index (n) of all fractions for determination of salt concentrations and plot the refractive index against buffer concentrations (0.05 M and 0.35 M) for the stock solutions.
(6) Add to each fraction 0.2 ml of 2.5 mg/ml herring sperm DNA (carrier DNA) and then 2.5 ml cold 40 per cent PCA which would form an acid precipitate.
(7) Filter the samples individually in Whatman (F/C) glass fibre filters, wash thrice with a total of 15 ml 5 per cent TCA and lastly with 5 ml 95 per cent ethanol.
(8) Dry the filters and count in a scintillation counter.
(9) Plot the data on a graph with counts/min against fraction number and buffer concentration against fraction number. Elution profiles of single and double stranded DNA are quite distinct.

REMOVAL OF CHROMOSOME COMPONENTS FROM CHROMOSOMES

The importance of removal techniques in the study of chromosomes cannot be over-estimated. For the removal of nucleic acids and proteins, several techniques are employed and chemicals or digestion through specific enzymes are considered to be suitable for the purpose.

Removal through chemicals

Schneider (1945), following the method of Cohen (1944), first demonstrated that hot trichloracetic acid (CCl_3COOH) treatment (5 per cent treatment at 40 °C for 15 min) removes nucleic acids from the tissue, the method enabling the complete removal of both DNA and RNA from the cell. Several authors (White, 1950; Kaufmann *et al.*, 1951c; Sharma and Bhattacharjee, 1952) showed that this method of extraction leaves a protein part showing positive staining with acid dyes. Distinct protein staining was recorded, both in chromosomes and nucleoli. Atkinson (1952) effectively removed RNA without affecting DNA by using trichloracetic acid at 60 °C.

Sharma (1951) observed that heterochromatic regions of chromosomes can be sharply stained if acetic–alcohol fixed root tips are treated with 0.25 M trichloracetic acid at 60 °C for 40 min followed by hydrolysis at N HCl for 20 min, prior to Feulgen staining. Following this procedure, the metaphase chromosomes lose DNA from their segments, whereas heterochromatic segments adjacent to the centromere show positive Feulgen reaction. This procedure can, therefore, be applied for staining heterochromatic segments of chromosomes.

Boivin, Vendrely and Vendrely (1949) demonstrated that hydrolysis with 1 N HCl results in complete removal of RNA and depolymerisation of DNA. The same concentration can remove both types of nucleic acids if applied at 37 °C for 3 h (Dempsey *et al.*, 1947; Dempsey, Singer and Wislocki, 1950).

Perchloric acid was employed initially by Ogur and Rosen (1949) for extracting nucleic acids from root tips of onion. Erickson, Sax and Ogur (1949) as well as Sulkin and Kuntz (1950) suggested that specific extraction of RNA as performed through ribonuclease can be effectively substituted by perchloric acid. Cold perchloric acid treatment (10 per cent at 4 °C) for a period of 4 h or over has been used to remove RNA, and the application of 10 per cent acid at 70 °C for 20 min results in the complete removal of both DNA and RNA. Seshachar and Flick (1949) pointed out that the extraction of RNA by cold perchloric acid can be completed only under strictly limited conditions. Moreover, this procedure is associated with depolymerisation of DNA, though not apparently losing any Feulgen stainability. Following such a procedure, pyroninophilia of chromosomes increases rapidly, which evidently is due to the depolymerised nature of DNA. Pearse (1972) agreed with Seshachar and Flick and considered that digestion with ribonuclease cannot yield results parallel to perchloric acid because in addition to depolymerisation, various proteins, glyco- and lipoproteins, are also removed by the latter procedure. Kurnick (1955) showed that in unfixed and fixed tissue homogenates, 10 per cent perchloric acid treatment cannot be employed for quantitative separation of nucleic acids, though principally RNA is extracted at low temperatures. It has been suggested (Pearse, 1972) that perchloric acid can be employed for the specific extraction of RNA under limited conditions of fixation and staining and also depending on the type of tissue used (Koenig and Stahlecker, 1951, 1952; Atkinson, 1952; Wenderoth, 1953; Franz, Warden and Mayer-Arendt, 1954; Goessner, 1954). Aldridge and Watson (1963) noted that no protein is extracted following cold perchloric acid treatment in acrolein-fixed tissues, whereas after acetic–ethanol fixation, there was very little protein extraction but Kasten (1965) observed that post-washing in water causes displacement of protein.

In addition to acids, even alkali treatment was employed to remove nucleic acids from cells. Levene (1901) employed sodium or ammonium chloride solution for the purpose. Due to the depolymerising effect of salt solutions on nucleohistones, Mirsky and Pollister (1946) could separate ribonucleoprotein from deoxyribonucleoprotein from liver through 0.15 M and 1 M sodium chloride treatment. Complete removal of RNA from fixed materials was secured by Opie and Lavin (1946) by treatment with 0.17 M sodium chloride solution at 56 °C for 2 h. Chargaff, Crampton and Lipshitz (1953), following the analysis of bases after extraction by NaCl, demonstrated that DNA has

a constant mean composition within each species but varies from species to species. In addition to these acid and alkali extraction methods, a few others have also been employed by some authors. Caspersson, Hammersten and Hammersten (1935) employed malonic and formic acids for the extraction of nucleic acids. Brachet (1940) observed that treatment in water at 70 °C gradually removed RNA from tissues. A number of buffer solutions on the alkaline side was also found to remove RNA selectively (Stowell and Zorzoli, 1947). It is necessary to prepare and use depolymerising enzyme solutions in glass distilled water and at 37 °C so that the action of electrolytes and the effect of water can be eliminated.

Removal through enzymatic digestion

The principle of this method is based on the application of a specific enzyme to the cell and, on the basis of its digestive property, location of the particular substance in the tissue or the cell. Enzymes that are employed for the digestion of nucleoproteins from chromosomes belong to two categories, namely nucleases and proteases. The former, which bring about digestion of nucleic acids, are available in the form of deoxyribonuclease and ribonuclease, the name being derived from the medium on which they act. For the complete breakdown of nucleic acid and its components, at least three different types of enzymes are necessary, which are capable of breaking (a) the polymeric linkage into component nucleotides, (b) the ester linkage maintaining the nucleotide structure, and (c) the glycosidic linkage for maintaining nucleosidic structure, respectively. Nucleases, also known as nucleopolymerases, responsible for the first action are primarily applied in chromosome studies.

Proteases may be trypsin or chymotrypsin, which digest basic proteins, and pepsin, which degrades both histone and more acidic proteins (Daly, Mirsky and Ris, 1951; Kaufmann *et al.*, 1951c).

Ribonuclease is generally extracted from ox pancreas, spleen, or liver in crystalline form (Kunitz, 1940; Brachet, 1942; Ledoux and Brachet, 1955; Kaplan and Heppel, 1956). Its molecular weight is 15000 and the enzyme, on purification, is a soluble protein. It can resist very high temperatures (Pearse, 1972). Ribonuclease preparation has often been found to be contaminated with proteolytic enzymes (Mazia, 1941; Schneider, 1946; Kaufmann, 1950) so that it is always necessary to check the effect of the enzyme on protein structures. Brachet (1940) first employed ribonuclease for the critical detection of RNA in the tissue in his pyronine–methyl green schedule. In all the modern staining techniques for the detection of RNA and DNA, application of ribonuclease is always used as a control measure to check the site of RNA. Stowell and Zorzoli (1947) pointed out that electrolytes in solution and distilled water at 60 °C may remove RNA and, as such, the enzyme should be dissolved in glass distilled water and used at 37 °C (Kaufmann, 1950). The general procedure for destroying the proteolytic activity of ribonuclease is to boil the extract for 3 min in acid solution, prior to buffering in veronal acetate buffer at a pH of 6.75 (White, 1947). A similar purpose is served by heating at 80 °C for 10 min. The thermostable nature of ribonuclease does not harm its potency under such severe treatment.

Fixatives affect the activity of the enzyme to a significant degree. Chromic

acid itself, and fixatives containing it, prevent ribonuclease action. Results are also not satisfactory with Bouin or certain alcoholic fixatives (*see* Pearse, 1972). In general, formalin fixation is recommended for effective digestion with ribonuclease.

Several authors (Kaufmann, Gay and McDonald, 1950; Pollister *et al.*, 1950; McDonald and Kaufmann, 1954; *see* Kaufmann, Gay and McDonald, 1960) utilised specific staining procedures, combined with the use of ribonuclease. These experiments reveal that RNA forms one of the principal components of the chromosomes and, in all likelihood, is linked with an acidic protein rich in tryptophane.

Similar to ribonuclease, deoxyribonuclease is employed for causing digestion of DNA. It is a protein of the albumin type, containing both tyrosine and tryptophane. Methods were evolved for the preparation of an extremely pure form of deoxyribonuclease, free from proteolytic contaminants or ribonuclease (Kunitz, 1948, 1950; Kaufmann *et al.*, 1951a, b, c). The crystalline enzyme shows activation by magnesium ions and becomes inactivated by heat. If the enzyme preparation is available in a pure form, the complete loss of methyl green and Feulgen stainability is immediate following 1–2 h treatment at 37 °C (Brachet and Shaver, 1948; *see* Vercauteren, 1950; Kurnick, 1955, *see* Pearse, 1972).

In addition to the nucleic acid enzymes, as mentioned already, trypsin and chymotrypsin are applied for the digestion of the basic protein while pepsin removes both histone and more acidic proteins (Daly, Mirsky and Ris, 1951; Kaufmann *et al.*, 1951a, b and c; *see* Kaufmann, Gay and McDonald, 1950). In fact, the application of these two enzymes, combined with nucleases, has helped in the interpretation of chromosome structure as an interconnected system of two types of nucleic acids and proteins.

Even in view of the applicability of the enzyme digestion procedures, the limitations of these techniques cannot be ignored. It is also necessary to know how far an enzyme can penetrate through different barriers to the substrate. The acidity of the substrate, concentration of the electrolysing solution, temperature, inhibiting or activating factors, etc., should all be taken into consideration. Danielli (1947) emphasised the necessity of finding out the extent to which isolated enzymes represent their state *in vivo*, as they may undergo certain modifications during extraction. However, in spite of the limitations, the methods based on enzymatic hydrolysis have helped the cytologists to clarify the problems of chromosome structure, growth and differentiation to a significant extent.

CONCLUSION

The procedures for isolation as mentioned above are also not free from limitations. The principal disadvantage lies in the methodology for separation and the liquids needed for suspension. Even with weak solvents, there is the possibility of decomposition of sensitive compounds, adsorption of cytoplasmic contents by the nucleus and elimination or diffusion of some nuclear components. Even though the use of very low temperatures such as 4 °C minimises the chances of autolysis, the aqueous or non-aqueous solvents as such may lead to diffusion. In the former case, diffusion is very heavy

but even in the latter, lipoid components may diffuse out (Daly, Allfrey and Mirsky, 1952; Serra, 1955). Dounce (1952) noted that even physiological saline solution results in the extraction of nuclear components.

In spite of these limitations, isolation techniques enable a worker to handle nuclei and chromosomes directly in the laboratory, permitting correct analysis of components. With proper check on solvents used for separation and suspension, it is possible to secure purified nuclei, chromosomes and even chromosome complements (Chorhazy *et al.*, 1963). The latter allows a correct analysis of the direct correlation between sequence complexity of DNA, its RNA components and the production of functional proteins of different enzymes (Allfrey and Mirsky, 1962; Sibatani *et al.*, 1962; Pardue and Gall, 1975). The functional and structural relationship between different components of the nucleus and chromosomes is best analysed through isolation methodology.

Molecular hybridisation *in situ*

The study of chromosome structure and the localisation of functionally differentiated segments of chromosomes have been greatly facilitated through the application of molecular hybridisation technique at the chromosome level. In view of the linear sequence of genes in a chromosome, it is now theoretically possible to prepare a cytological map delineating the DNA sequences and precise locus of transcription of specific messengers through an *in situ* hybridisation technique on the chromosomes. This knowledge of the operational mechanism of chromosomes at the molecular level is due basically to the important advances in methodology, one involving the reannealing technique for analysing the sequence complexity of DNA and the other comprising hybridisation of RNA and DNA molecules (Britten and Kohne, 1967; Gillespie and Spiegelman, 1965). The principle of both techniques is that single strands of DNA can always recognise and pair with complementary base sequences of another strand of DNA or RNA (Marmur, Rownd and Schildkraut, 1963; Birnstiel, Sells and Purdom, 1972). With the aid of these methods, the eukaryotic chromosomes have been shown to comprise of not only unique sequences but also of highly repeated sequences present in multiple copies, coding for major RNA species such as ribosomal RNA. Both these methods are based on experiments carried out *in vitro* using isolated nucleic acids. The method of extraction and fractionation inherent in the procedure is yet to be fully perfected to allow undamaged representation of structures as in *in vivo* state. This is essential for chromosomes where spatial arrangement of genes plays a vital role in gene action.

The disadvantages of the *in vitro* technique are however eliminated in the *in situ* hybridisation method. The principle of the *in situ* technique is based on the use of pure labelled nucleic acid fractions obtained from the *in vivo* state or prepared from complementary DNA sequences *in vitro* and their hybridisation with previously denatured DNA of the chromosomes *in situ*.

The detection of a particular DNA sequence in a chromosome is dependent principally on two important factors; (1) the sensitivity of detection, and (2) the sequence complexity of DNA. The strength of detection depends on the amount of radioactivity and the sensitivity of autoradiographic procedure. The nucleic acid of high specific activity is always desirable for hybridisation. It has been noted 10^6 dpm/μg is the lower useful limit (Pardue and Gall, 1975). Regarding the spacing and sequence complexity, highly

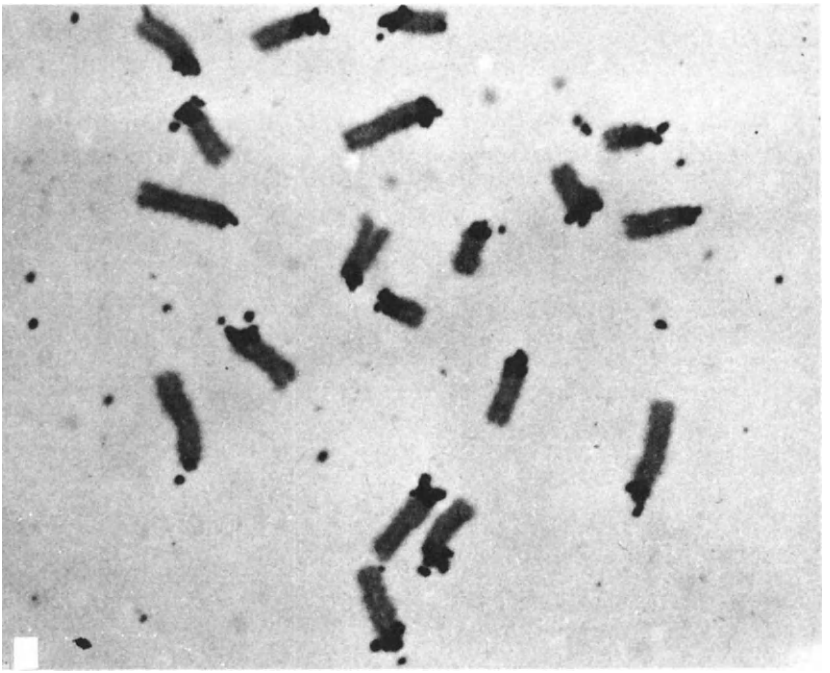

Plate 22.1
Hybridisation of mouse chromosome DNA with c-RNA synthesised from mouse satellite DNA-only centromeric heterochromatin labelled (courtesy of Prof. J. G. Gall and Dr. M. L. Pardue)

repeated sequences aggregated at one locus are ideal for *in situ* localisation.

It is desired here to present the fundamentals of denaturation and annealing of nucleic acid strands, the two essential protocols for both *in vitro* and *in vivo* studies, before dealing with the different steps of this technique.

The separation of the double helix into single strands of DNA, otherwise termed as *denaturation*, can be secured most effectively by heating the nucleic acid solution. Other alternative methods of treatment include strong acid, alkali or even some organic compounds such as formamide (McConanghy, Laird and McCarthy, 1969; Subirana and Doty, 1966). The separation can be detected by a rise in ultraviolet absorbance at 260 nm.

The term, melting temperature or *Tm* implies the temperature corresponding to the midpoint of the absorbance. The value of *Tm* is directly correlated with the GC ratio of DNA as it confers a higher stability against thermal denaturation than the AT component of the nucleic acid. Ionic concentrations have a significant influence on the *Tm* value (Marmur and Doty, 1962).

Reassociation of DNA, implying restoration of the duplex, is, in effect, the reverse process and requires a stronger salt concentration and lower temperature than that required for denaturation. In general, the temperature required for optimal effect is 25 °C below the *Tm* value, though for RNA/DNA hybrid duplex it is near the *Tm* value (Wetmur and Davidson, 1968). The salt concentration and temperature needed for reannealing have a significant effect on accurate base pairing (McCarthy and Church, 1970). The nature of

the DNA molecule, its homo- or heterogeneity, governs the reassociation kinetics. Repeated sequences associate more readily as compared with unique sequences. As a corollary, reassociation time is a direct index of its sequence complexity. There are various ways of measuring the rate of reassociation, the most convenient method being detection of fall in absorbance at 260 nm. Other methods include measurement of the amount of labelled DNA fragments immobilised on nitrocellulose filters or passing after reassociation through a hydroxyapatite (calcium phosphate) column which holds back the duplex (McCallum and Walker, 1967; Britten and Davidson, 1971). Britten and Kohne (1968) devised a method of comparing the rate of reassociation of samples of different concentrations at different periods. They introduced the term C_0t (C_0 denoting the initial concentration and t implying the period of treatment for reassociation) the value being expressed in terms of titre i.e. mol/s/l, and the midpoint of the data i.e. $C_0t\,\frac{1}{2}$ is termed as the value. The C_0t value has proved to be very effective in working out the sequence complexity of DNA.

PRINCIPAL STEPS IN THE SCHEDULE

Fixation and preparation of slides

The most convenient method is to fix the tissue in acetic–ethanol (1 : 3), followed by squashing in 45 per cent acetic acid and removing the slide by the dry ice method. This drying method has the advantage of removing much of the basic protein which otherwise may hamper hybridisation. The fixation itself causes slight denaturation. In general, formaldehyde fixation should be avoided as it may interfere with denaturation of DNA. On the other hand, protein subbed slides are also sometimes used so that the tissue and later photographic emulsion are kept intact on the slides. In practice, it has been noted that slides treated with gelatin and chrome–alum may help in the adhesion of the material but it stands against perfect scattering of chromosomes. In addition to the above method of fixation, often ethanol–chloroform (2 : 1) (Buongiorno-Nardelli and Amaldi, 1970) or even processing without fixation (John, Birnstiel and Jones, 1969) are adopted. One must however be extremely cautious in choosing fixatives as those with heavy metals like mercury or lead may cause chemographic damage whereas others like formalin and glutaraldehyde may have a desensitising effect on emulsion (Rogers, 1969; Jones, 1973).

Removal of RNA

Removal of pre-formed RNA both chromosomal and extrachromosomal, is desirable, as otherwise it may compete with the labelled RNA for hybridising with DNA. Gall and Pardue (1971) recommended pancreatic RNAse treatment and incubation for 2 h at 24–26 °C or at 37 °C for 1 h at a concentration of 100 μg/ml in 2 XSSC followed by thorough washing in 2 XSSC, to check subsequent hydrolysis of RNA. Pre-treatment with dilute HCl (0.2 per cent) for the removal of residual histone is also recommended. In order to free

this enzyme from DNAse, previous boiling in a solution of 1 mg/ml in 0.02 M sodium acetate (pH 5) for 3 min followed by rapid cooling in ice bath and diluting, has been suggested (Jones, 1973).

Denaturation

A perfect denaturation technique to secure optimum hybridisation has not yet been achieved. In *in situ* technique, the denaturation is carried out normally through solutions of low and high pH, high temperature, formamide, acids and alkalis. It can be performed at 0.2 N HCl (pH 0.8) at room temperature for 20 min (MacGregor and Kezer, 1971). For high pH, Gall and Pardue (1969; Pardue and Gall, 1975) applied 0.07 N NaOH for 2 min at room temperature. For different materials, concentration may have to be changed. Optimum effect with minimum injury to the tissue has been noted in the above concentration (Pardue *et al.*, 1970). Heat denaturation is generally accomplished at 100 °C (Jones, 1970; Buongiorno, Nardelli and Amaldi, 1970) in 0.1 XSSC for 5 min with subsequent quenching at 0 °C. Jones and Robertson (1970) adopted 60 per cent formamide in 3 XSSC treatment at 65 °C for denaturing DNA at lower temperature. Steffensen and Wimber (1972) used 90 per cent formamide in 0.1 XSSC for 2.5 h at 65 °C on salivary gland chromosomes of *Drosophila*.

Of all these methods, heat treatment followed by quenching does not yield more than 1 per cent reannealing. Along with heat, alkali treatment (NaOH or BaOH) causes chromosome damage. The swelling in NaOH is often counteracted to some extent by SSC treatment. The HCl method being comparatively mild with low pH value, maintains chromosome structure intact with good stainability, but in this procedure too some amount of depurination has been reported (Pardue and MacGregor, referred in Pardue and Gall, 1975).

In order to detect the degree of denaturation, Steffensen and Wimber (1972) recommended the use of fluorochromes, such as acridine orange and observation in fluorescence microscopy. The technique is based on the principle that double stranded structures fluoresce green as against red fluorescence of single strands after excitation. The removal of RNA by RNAse from chromosome is essential in order to secure green fluorescence (Wolstenholme, 1965). After denaturation through formamide treatment (Steffensen and Wimber, 1972), reannealing and consequent reversal to green fluorescence can be obtained by treating denatured unstained preparations in 2 XSSC at 65 °C for 20 min.

FORMATION OF HYBRID MOLECULES *IN SITU*

In principle, the conditions for *in situ* technique are the same as those applied for hybridisation with DNA fixed on nitrocellulose filters. It involves the application of tritiated complementary nucleic acid solution (method of preparation dealt with later) on the denatured preparation on an absolutely grease free, clean slide and incubation at requisite temperature in a moist chamber. The slide is covered with siliconised non-wettable cover-glass (taking precaution to keep it free from air bubble) and placed in pre-warmed

plastic petri dishes on glass rods. The same solution should be present in the petri dish in sufficient amount and the entire set is to be incubated at annealing temperature for the requisite period after sealing. Cleaning the slide with strong acids followed by distilled water washing, drying and final treatment with ether/ethanol before polishing the slide and cover-glass to be used, are essential. To detect alkali leaching by the cover glass, if any, it is better to have a control set up with hybridisation buffer plus phenol red under the cover-glass. In case of evidence of leaching during incubation, the cover-glass should be boiled in 1 N HCl and thoroughly washed in pH 7 buffer. The entire operation is to be carried out using plastic gloves and fluid is applied through a microlitre syringe.

There are several factors which control annealing. It is always desirable to add excess of non-radioactive non-competing nucleic acid to avoid non-specific binding of radioactive nucleic acid. The filter hybridisation studies have indicated that high concentration of cations leads to non-specific annealing by raising the melting temperature (McCarthy and Church, 1970). Steffensen and Wimber do not recommend more than 6 XSSC concentration for annealing. The temperature required for incubation is usually below the *Tm* value. This may not be true for all cases as for poly U the optimal temperature is 30 °C (Jones, 1973). But in cases where this value is not known, trial should be given around 60–65 °C. With organic solvents like formamide as *in vitro*, even 25–40 °C may serve the purpose. For hybridisation at high temperature, SSC or SNB (0.15 M NaCl, 10^{-3} M Tris, pH 7.0) buffer may be used depending on the need for sodium ions, for example 2 XSNB at 65 °C (Pardue and Gall, 1975). The same authors, for a reaction at low temperature, suggest the use of 40 per cent formamide in 4 XSSC at 37 °C. It is always safe to use lower temperature as otherwise the amino acyl bond, such as in tRNAs, may undergo cleavage.

For hybridisation with complementary RNA, competition between complementary strands of DNA is also to be taken into account. It is not possible with the existing techniques to immobilise completely the complementary strands as done in case of *in vitro* techniques. However, complementary single strands take nearly 20 min at 65 °C to form substantial amounts of DNA duplex. Therefore, it is desirable to secure reannealing within the first few minutes with optimal concentration and temperature. Varying concentrations of tritiated RNA with high specific activity, such as 3.0 μg/ml (John, Birnstiel and Janes, 1969), 0.2 μg/ml (Steffensen and Wimber, 1972), 2–3 μg/ml as well as 0.01 μg/ml (Gall and Pardue, 1971) have been used to secure such optimal effect. Complex unique sequences require considerably more time for reannealing than simple and particularly homogeneous repeated DNA. For *in situ* technique, in general, the ionic strength, nucleic acid concentration, temperature and period of incubation, should be determined for each material and the conditions are more or less identical to those needed for filter hybridisation.

REMOVAL OF NON-REACTIVE RNA

It is desirable to remove non-specific RNA from nuclear and cytoplasmic structures. For this purpose, after washing thoroughly in 2 XSSC, treatment

with RNAse is needed. As an RNA/DNA hybrid is quite resistant to such digestion, concentration of RNAse varies between 1 and 25 μg/ml in 2 XSSC for 15 min to 1 h at 37 °C. Jones and Bishop (referred in Jones, 1973) recommended the use of 20 μg/ml of the enzyme for 20–30 min at 37 °C and in the case of poly rU, the temperature required is 0 °C. For RNA/DNA hybrids too, non-specific bound DNA should be washed off by a few SSC washes at 55–60 °C. Final washing in 70 and 95 per cent ethanol is necessary before drying. In order to remove inaccurately matched hybrids, Jones (1973) has suggested an exposure of the *in situ* hybrid at a temperature just below the *Tm* value, so that ultimately specific hybrid duplexes are maintained. After non-specific complexes are removed, two to three brief changes in 2 XSSC followed by keeping at 4 °C with continuous stirring in excess of SSC is desirable prior to dehydration and air drying.

AUTORADIOGRAPHY

Principles of autoradiography have been discussed in detail in a previous chapter. Liquid emulsion procedure is generally applied in order to secure proper staining. Kodak NTB 2 or Ilford K2 diluted with equal amount of distilled water is suitable. It (Kodak NTB 2) is normally obtained in 4 oz bottles and is solid at 26 °C. For use, it is heated at 45 °C for nearly 30 min, and then 112 ml of warm distilled water is added slowly, avoiding bubble formation. The entire operation is to be carried out in total darkness or using a Kodak Wratten Series II. The fluid can then be distributed in small 10 ml aliquots in nylon vials, covered with aluminium foils and stored in a refrigerator. At the time of use, it is to be warmed again at 45 °C and the entire contents i.e., 10 ml, should be utilised which is adequate for at least 30 slides. A thick coating is not desirable, as β-particles do not have high energy to reach the surface of the film and may produce background grains of extraneous origin. After the required period of exposure in dark varying from a few hours to many days at 4 °C, the preparations are to be developed, rinsed, fixed in acid fixing bath, washed, stained as usual and observed.

An outline of the schedule is presented below though various other modifications have been published by various authors (Mauning *et al.*, 1975).

Schedule for *in situ* hybridisation (Pardue and Gall, 1975.)

(1) Take small pieces of fresh tissue, not more than 5 mm in diameter, tease and fix for 5–10 min in acetic–ethanol (1 : 3).

For cell suspensions, gently centrifuge cultured cells in medium, re-suspend cell pellet in 40 times vol of hypotonic solution (3 parts distilled water and 1 part medium), keep for 5 min at 26–28 °C, gently centrifuge again and replace hypotonic solution by equal vol of 50 per cent acetic acid on the pellet for fixation in ice chamber for 20 min. After fixation, give a fresh change in 50 per cent acetic acid and re-suspend the cells.

(2) Put a drop of 45 per cent acetic acid on a siliconised 18 mm cover slip (cover slip can be siliconised by dipping for a short period in 1 per cent

siliclad solution, rinsed in distilled water, and dried overnight at 26 °C and stored. Rinse in 95 per cent ethanol and dry before use.

(3) Transfer a small piece (maximum 1 mm) from the fixed and teased material to acetic acid on the cover slip and mince it thoroughly. Remove any large pieces, if present. Before transferring, the precaution may be taken to remove the fixative on the surface by mild drying to avoid violent stirring in 45 per cent acetic acid. For fixed cell suspensions, just transfer a drop to 45 per cent acetic acid.

(4) Take a subbed slide and put it on the cover slip and apply slight pressure so that the cover slip adheres firmly to the slide. Subbed slides can be prepared by dipping detergent washed, grease-free slides, for a few hours in subbing solution (composed of 0.1 per cent gelatin, dissolved initially in hot water to which 0.01 per cent chrome alum is added later) and dried for a few hours before use.

(5) Place the slide with the cover slip surface down on a filter paper and apply uniform pressure with the thumb to secure a well scattered monolayer smear, devoid of excess fluid.

(6) Keep the slide against dry ice for a few minutes for freezing and flip off the cover slip.

(7) Transfer the slide to ethanol for a few minutes, air dry and store, if necessary.

For Drosophila *salivary gland chromosomes* slight deviations from the above steps are: glands should be dissected in Ringer's solution before transferring to 45 per cent acetic acid on the siliconised cover slip. Before squashing on the subbed slide as above, mild pressure is to be applied with the needle back or fine sheet rod for chromosome spreading. Finally, after detaching the slide through dry ice technique, it is first to be kept in acetic–ethanol (1 : 3) for 2–3 min before transferring to ethanol and air drying.

(8) Transfer the slide (with squashes or cell suspensions) to a moist chamber, apply a drop of RNAse solution in 2 XSSC at a concentration of 100 μg/ml, cover the preparation with a cover slip and keep in moist chamber at 37 °C for 1 h or 26–28 °C for 2 h. This step is necessary to remove pre-formed endogenous RNA. (Moist chamber can be prepared with 4-inch plastic petri plates with the bottom lined with moist filter paper and containing 5–10 ml 2 XSSC. The slide can be suspended above the liquid by U-shaped glass rods or two rubber pieces. The medium inside the cover slip and in the petri plate should have the same ionic strength to avoid any shift in concentration. The advantage of plastic moist chamber is that the moisture accumulating on the plastic lid does not coalesce and drop on the preparation as in glass lids (Pardue and Gall, 1975).

(9) Remove the cover slip by dipping in a jar containing 2 XSSC.

(10) Give three changes of the slides in 2 XSSC and transfer first to 70 per cent ethanol and then to 95 per cent ethanol and air dry.

(11) *For denaturing DNA*, transfer the slides to 0.07 N NaOH at 26–28 °C and keep for 2–3 min.

(12) Give three changes in 70 per cent ethanol and subsequently two changes

in 95 per cent ethanol in a total period of 10 min each and air dry the slides.

(13) Take the slides for hybridisation and choose for incubation the SSC or SNB buffer depending on the need for sodium ions. For lower temperature (37 °C), 40 per cent formamide in 4 XSSC and for higher temperature (65 °C) 2 XSSC (0.15 M NaCl, 0.015 M sodium citrate; pH 7.0) may be used. Add excess of non-radioactive non-competitive nucleic acid to prevent non-specific binding.

Put a drop of radioactive nucleic acids to be hybridised (*see* Appendix A and B for preparation of complementary RNA and preparation of DNA) on the preparation cover with a cover slip and place the slide in a moist chamber (as prepared in step (8) above), seal the chamber and incubate in an oven in the required temperature, for example 10–15 h in 2 XSNB at 65 °C. The moist chamber must contain the same concentration of buffer as that under the cover slip.

(14) After hybridisation, remove the slide from the oven and (a) to remove non-specifically bound RNAs in RNA–DNA hybrids, dip in 2 XSSC when it is to be washed for 15 min at 26–28 °C. Incubate in pancreatic RNAse (20 μg/ml in 2 XSSC) for 1 h at 37 °C, and rinse twice in 2 XSSC for a total of 10 min, and (b) to remove non-specific bound DNA in DNA–DNA hybrids, dip in 2 XSSC at a temperature 5 ° below the incubation temperature. Give three more changes in 2 XSSC at the same temperature for a total period of 10 min.

(15) Pass through 70 and 95 per cent ethanol and air dry the slides.

(16) *For autoradiography*, carry out the entire operation in absolute darkness or safelight.

(a) Melt the emulsion (Kodak NTB 2 mixed in equal proportions with distilled water and kept in 10 ml vials as mentioned earlier) at 45 °C for 10 min and pour in a plastic dipping chamber held at 45 °C, taking care not to allow any air bubble to come in. Dip the slides in the chamber, gently withdraw, drain off the excess fluid and place vertically in a rack against an air drier for about 1 h for drying. Store the slides in sealed boxes (with silica gel inside for maintaining dryness) in the dark for a few hours to several days depending on the requirements.

(b) After exposure, develop the slides for 2–3 min in Kodak D-19 developer, rinse in distilled water, fix in Kodak fixer for 2–5 min and give several changes in distilled water.

(17) Stain in Giemsa (mix the stock solution K20 with 0.1 M phosphate buffer, pH 6.8 just before use) for a few minutes. Check at intervals to find out the exact period necessary for staining.

(18) Rinse in distilled water, air dry and cover with Permount under a coverglass.

APPENDIX A

Preparation of complementary RNA

The complementary RNA needed for *in situ* hybridisation may be obtained through *in vivo* labelled nucleic acids, *in vitro* transcription of nucleic acids

which is most widely applied and chemical labelling of pre-formed nucleic acids.

For *in vivo* transcription, adequate amount of nucleic acids can be obtained through cell lines cultured in medium containing tritiated nucleic acid precursors. If optimum conditions are satisfied then rapid turnover of nucleic acid fractions can be secured with radioactivity ranging from 10^6–10^7 dpm/μg (Pardue and Gall, 1975). Pardue *et al.* (1972) have also reported that sea-urchin embryos growing in sea water containing tritiated uridine in early cleavage stages yield highly labelled mRNA for hybridisation.

For *in vitro* transcription, *E. coli* RNA polymerase may be used for securing RNA copies from isolated specific DNA fractions. Similarly DNA copies from RNA are produced with the aid of *reverse transcriptase* (RNA dependent DNA polymerase, Verma and Baltimore, 1974) or *E. coli* DNA polymerases (Loeb, Tartof and Travaglini, 1973). As there are often preferential transcriptions of DNA sequences by these enzymes, it is always desirable to analyse the product carefully. In these experiments, consequently the radioactivity of transcribed RNA is completely dependent on the specific activity of the precursors used.

Chemical labelling of preformed nucleic acids is performed in cases where labelling cannot be performed by the previous two methods. Several authors (Commerford, 1971; Prensky, Steffenson and Hughes, 1973; Prensky, 1976) have now developed methods using radioactive iodine ^{125}I for labelling. The radioactivity may even be the same as for tritiated precursors (Attenburg, Getz and Saunders, 1975) but heavy iodinisation may often affect hybridisation index. This radioisotope being more energetic than tritium, with a short 60-day half-life, action is more rapid. It is claimed that *in situ* localisation on chromosome may be less precise (Pardue and Gall, 1975) than tritium labelling. Steffensen, Prensky and Dufy (1974), using ^{125}I labelling, have been able to localise 5S RNA cistrons in human chromosomes. In the iodination methodology (Attenburg, Getz and Saunders, 1975), the reaction mixture contains purified nucleic acid, $TICl_3$ and a mixture of Na ^{125}I and KI carrier. Constituents are mixed in acetate buffer (pH 5.0) at 0 °C and an ionic strength of 0.05–0.10 M (Na). The mixture is kept in sealed container at 60–80 °C for 15–20 min followed by chilling to 0 °C. A reducing agent is added at the termination point, the pH is raised to 8.5–9.0 and again heated for 20 min at 60 °C. The nucleic acid is thus iodinated and recovered through gel filtration chromatography and radioactivity counted through counter. The labelled nucleic acid may then be used for hybridisation on chromosomes.

Schedule for in vitro *transcription*

A schedule is outlined below for the preparation of complementary RNA through *in vitro* transcription which is widely applied and is the most successful of all the methods so far used.

The essential requirements of this preparation are the use of prolonged heat sterilised and siliconised glassware specially to avoid adhesion of contaminant ribonuclease, sterile double distilled water and chemicals free from heavy metals to secure desired specificity. The highly purified form of RNA polymerase is needed which can be obtained in commercial form or can be

prepared following the method of Chamberlain and Berg (1961). Special precaution is needed to ensure that it is free from the contaminant enzyme–polynucleotide phosphorylase which can synthesise homogenous polynucleotide chains from the necessary precursors. Similarly DNA serving as the primer and prepared following caesium chloride gradient method (*see* Chapter 21) should be subjected to rigorous dialysis to free from contaminants.

In order to carry out the reaction the following steps are to be adopted. Approximately 100 μCi each of all four labelled ribonucleoside triphosphates in equal molar concentration are to be mixed and lyophilised, to be followed by addition of buffer, primer and polymerase. The quantity of the reaction fluid is desired not to exceed 0.3 ml (Jones, 1973). The buffer is prepared of the following ingredients (a) 0.04 M Tris (pH 7.9 adjusted with HCl at 37 °C). 0.15 M KCl; 1.5 mM $MnCl_2$; 10 mM $MgCl_2$; 1.6 mM spermidine; 2 mM β-mercaptoethanol; 0.4 mM K_2HPO_4. The amount of primer may vary between 2 and 20 μg of DNA and RNA-polymerase between 4 and 20 units (Chamberlain and Berg, 1961), and the reaction is to be carried out at 37 °C.

The progress of reaction is to be studied at regular intervals 0, 5, 10, 15, 20 and 40 min by taking 5 μl samples and subjecting them to the following test.

(1) Place the samples on 2 mm cellulose acetate circles and dry.
(2) Wash three times in 5 per cent TCA at 0 °C.
(3) Rinse at least three times in cold 70 per cent ethanol for 2 min each.
(4) Take counts from the dried circles for 1 min, in liquid scintillator (toluene based).
(5) Plot acid precipitable counts and note the time for optimum reaction after which there is a fall in rate.
(6) After the optimal level, stop the reaction by transferring to chilled ice for extraction of complementary RNA through the following steps.
(7) Add pure DNAse (RNAse free) to the mixture to a final concentration of 40μg/ml and keep at 37 °C for 10 min to digest primer DNA.
(8) Add 50–100 μg of unlabelled carrier RNA (e.g. *E. coli* RNA) and make 0.2 per cent mixture in SDS (sodium dodecyl sulphate) and 0.1 M in NaCl and keep for 2 min at 37 °C.
(9) Shake at 22–26 °C for 10 min with equal volume of aqueous saturated phenol to remove protein.
(10) Centrifuge at 480 × g for 10 min.
(11) Remove the upper aqueous supernatant and keep it apart.
(12) Extract the lower portion with an equal volume of water and recentrifuge.
(13) Take the two samples of (11) and (12) and apply to 'Sephadex' G50 column (1.5 × 30 cm) equilibrated with 1/10 SSC.
(14) Wash the column with 1/10 SSC.
(15) Take 0.5 ml of 5 min fractions and take spectrophotometric data at 260 nm.
(16) Note the appearance of *C*-RNA and carrier RNA after approx. 2 h.
(17) Take similarly 5 μl fractions corresponding to absorbance data and count on filter circles as in (5).
(18) Collect the fractions showing radioactive peak and record the volume.
(19) Lyophilise the material.

(20) Work out the final concentration and specific activity on the basis of the specific activity of the labelled nucleoside phosphates used and the base composition of the primer.
(21) Add saline citrate buffer while using.

It is preferable to check the complementarity of RNA extracted by hybridising it with template DNA (Gillespie and Spiegelman, 1965). The latter is to be equilibrated on neutral caesium chloride gradient, denatured and filter hybridised with complementary RNA. The degree of pairing gives an indication of the buoyant density of the primer complementary to hybridised RNA and as such its specificity (MacGregor and Kezer, 1971).

APPENDIX B

Preparation of DNA

The basic steps involved in the preparation of DNA constitute initially the breaking, disruption or lysis of the cells without causing breakage of DNA molecules. Simultaneous solubilisation of the deoxyribonucleoprotein is carried out by breaking the cells in medium containing detergents or solutions having low or high ionic strength rather than the medium such as 0.4 to 0.8 M. During the process of extraction or purification, digestion of DNA through the microorganism's own nucleases is always to be prevented through denaturants like phenol, chloroform, etc., detergents or salt solutions. In all cases enzymes absolutely free from deoxyribonucleases, such ribonuclease, pronase are to be applied to make it free from RNA. Failure to get purified DNA of sufficient quantity is mainly due to incomplete lysis, low solubilisation and digestion of DNA. Once the deoxyribonucleoprotein is extracted, deproteinisation is performed mostly through phenols followed by slight shaking and addition of chloroform for separating aqueous and solvent phases. Lastly, extraction may be done through ethanol or even isopropanol. The latter however is particularly effective to remove RNA contaminant but is not suitable where amount to be extracted is rather low.

The detailed procedure for extraction and purification of DNA has been dealt with in Chapter 21. Two short representative schedules are given *in outline* here for DNA preparation for nucleic acid hybridisation *in situ* (Schwartz and Taylor, 1974).

For Chinese hamster ovary (For culturing – *see* Chapter 11 for method of Taylor, Adams and Kurek, 1973)

(1) Take labelled cells grown in culture in roller bottle, drain off the medium, rinse with distilled water.
(2) Add 15 ml solution for securing lysis (0.1 M sodium bicarbonate, 0.05 M EDTA, 0.3 per cent sarkosyl, Geigy chemicals) through shaking at pH 5.8.
(3) Make the solution 0.7 M in sodium trichloroacetate.
(4) Take 5 ml of lysate in centrifuge tube containing sodium perchlorate step gradient and centrifuge using SW 27 rotor (Beckman) for isolation

of long chain DNA molecules. (Prepare step gradients from buffered sodium perchlorate solution ranging from 2 M to 5 M.)

(5) Fractionate the gradients carefully with wide mouthed pipette.

(6) Pool the bottom fractions containing DNA of 65S or higher and dialyse in either 0.001 M Tris and 0.005 M EDTA at pH 10.0 at 2 °C and store at −20 °C after an addition of 10 per cent glycerol.

For plant sprouts

(1) Take cucumber or *Phaseolus* bean sprouts and remove cotyledons and seed coat, wash thoroughly in Micro Cleaning solution (International Products Corporation) and rinse.

(2) Homogenise in chilled grinding solution (for extraction *see* chapter 21, Sisken *et al.*, 1967) consisting of 1 M hexylene glycol, 0.5 mM calcium chloride, and 0.005 M CAPS at pH 10.4.

(3) Filter the homogenate through two layers of nylon net. Centrifuge for 5 min at 1 °C in a 9 RA head (Lourdes Instrument Corporation) at 1000 × g.

(5) Re-suspend the pellet thrice in grinding solution with 3.5 per cent Tween 80 (Sigma) and centrifuge.

(6) Suspend the nuclear pellet in the lysing solution as mentioned above for Chinese hamster ovary.

(7) Isolate nucleic acid following twice phenol chloroform extraction (*see* Chapter 21).

(8) Dialyse cucumber DNA in 0.05 M $NaHCO_3$ and 0.01 M EDTA at pH 10.0 and at 2 °C and prepare for density gradient centrifugation in poly-allomer centrifuge tubes.

(9) To the buffered DNA solution (27 μg/ml), add CsCl bringing the final density in each tube to 1.710 g/ml CsCl.

(10) Centrifuge the samples in ultracentrifuge (Beckman α-2, 65 rotor) for 48 h at 35 000 rev/min at 24 °C.

(11) Fractionate the tubes and follow spectroscopic determination of the position of the bands.

(12) For heavy satellite bands, centrifuge again for purification.

N.B. For sodium perchlorate step gradient centrifugation, instead of CsCl of *Phaseolus* bean DNA the following steps may be added before dialysis.

(1) Treat with 10 μg/ml ribonuclease A (Worthington Biochemical Corporation) for 1 h at 25 °C.

(2) Follow phenol–chloroform extraction again and dialyse into 0.1 M $NaHCO_3$, 0.01 M EDTA and 0.01 per cent sodium azide at pH 10.6 at 2 °C and follow the steps (4) to (6) as in Chinese hamster ovary using 0.01 M Tris and 0.01 M EDTA at pH 10.6 in step (6).

There are, no doubt, some inherent limitations of the technique so far discussed. In the eukaryotic systems, the complexity of the chromosome structure, especially the proteins (Gillespie and Spiegelman, 1965), may often stand in the way of proper hybridisation. This is one of the limiting factors as complete deproteinisation *in situ* results in loss of chromosome integrity. Most of the fixatives which are in use remove a considerable portion of

protein. The treatment with 45 per cent acetic acid or HCl may remove basic protein whereas NaOH application results in removal of non-basic protein (Dick and Johns, 1967; Hnilica, Kappler and Hnilica, 1965). Treatment with pronase may sometimes cause complete loss of chromosome integrity. As such all the methods have been evolved with the objective of retaining the DNA structure as far as practicable with some amount of protein being left to keep the chromosome intact. In the *in situ* technique, in general, as compared with filter hybridisation, some amount of protein remains associated with chromosomes. The extent to which this association affects hybridisation and facilitates non-specific binding is not known. The addition of excess non-radioactive, non-competing nucleic acids to hybridisation mixture reduces non-specific binding to chromosomal proteins (Pardue and Gall, 1975).

A rapid reannealing of complementary strands of denatured DNA is also disadvantageous to hybridisation (Stockert and Lisanti, 1972) which can only be avoided if the method for immobilisation is adopted (Pardue and Gall, 1975). It is therefore necessary to evolve a method through which complementary strands may be completely immobilised against reannealing, to facilitate hybridisation. Notwithstanding several limitations, the hybridisation technique is reasonably accurate as competition with unlabelled nucleic acids reveals the loss of labels from hybridised loci (Steffensen and Wimber, 1971). Different values of hybridisation efficiency in relation to 5S RNA, tRNA as well as 18 and 28 S RNA have been reported (John, Birnstiel and Janes, 1969; Wimber and Steffensen, 1970; Jones, 1970; Pardue, 1971; Birnstiel, Sells and Purdom, 1972). The shift in value may often be noted in addition to other factors to be due to self absorption of radioactivity by the preparations increasing sensitisation and consequent decline in emulsion specificity (Jones, 1973).

The other technical limitation is often incomplete denaturation, causing hindrance to hybridisation which however can be avoided through adequate procedures (*see* Spardling *et al.*, 1975).

Molecular hybridisation study *in situ* has been successfully employed to locate genes specially coding for 5S RNA (Pardue, Brown and Birnstiel, 1973; Steffensen, Prensky and Dufy, 1974), rRNA (Pero *et al.*, 1973) and even tRNA (Steffensen and Wimber, 1971). Highly repeated DNA sequences (the extraction procedure mentioned in Appendix B) offer convenient subjects for hybridisation as, because of their homogeneity, annealing is rather rapid. Gall and Pardue (1969) localised nucleolar organising DNA or rDNA in *Xenopus* followed by others in different organisms. The procedure requires either to hybridise tritiated rRNA at the chromosomal site or to separate the satellite DNA through caesium chloride gradient and use it for transcribing rRNA meant for hybridisation (Jones, 1970; Pardue and Gall, 1970; Rae, 1970; Avanti *et al.*, 1973; Ullman *et al.*, 1973; Evans, Buckland and Pardue, 1974). Such rDNA may be AT rich as in *Drosophila* or GC rich as in most other organisms. Homologous rDNA segments may exist even between widely different organisms such as *Xenopus*, an amphibian and *Drosophila*, an insect, suggesting possibly some evolutionary relationship. Such rDNA segments may be located near the centromere, tips of chromosomes or in other loci as well.

The approach later developed by several authors to identify chromosome segments through banding technique prior to *in situ* hybridisation

(Evans, Buckland and Pardue, 1974; Pardue and Gall, 1975) may help in localising repetitive segments to a significant extent. Refinements in methods are also leading towards the study of *in situ* DNA–RNA hybrids through indirect immunofluorescence under high resolution (Rudkin and Stoller, 1977).

Repetitive DNA is present in heavy amounts in all organisms including plant systems where it may occupy nearly 10 per cent as in mouse genome (Henderson *et al.*, 1974) or even 70 per cent as in rye (Ranjekar, Lafontaine and Pallotta, 1974). There may be highly repetitive, repetitive and non-repetitive or unique sequences (Cullis and Schweizer, 1974; Schwartz and Taylor, 1974).

The method has enabled detection of gene action in differentiated tissue and activity of structural genes in embryos and adult tissues of sea urchin has been demonstrated (Galau *et al.*, 1976). Ribosomal DNA constancy in different *Crepis* species and the suppression of nucleolar organiser in interspecific hybrids of their genes have also been reported (Doerschug, Miksche and Stern, 1976).

Following *in situ* technique, Wimber and Steffensen (1970) have shown that 5S RNA genes of the ribosomes are present in chromosome 2 at region 56 EF of *Drosophila* (Wimber *et al.*, 1974). Similarly, several sites have been localized in chromosomes 2 and X (Steffensen and Wimber, 1971), which hybridise with tRNA. In any case, precise localisation of tRNA genes and their relationship with associated DNA in a single band are yet to be ascertained as even allowing concessions for several repeats in tRNA, a significant amount of DNA in a band remains unaccounted for.

The possibility of localising unique sequences in polytene chromosomes through *in situ* technique has been suggested by Pardue and Gall (1975). In metaphase chromosomes of *Xenopus laevis*, 5S genes have been located containing 1000 copies of the sequence (Pardue, Brown and Birnstiel, 1973). In that case, a polytene band of 10^3 chromatids can easily provide a suitable substrate for localising a unique sequence through this method.

Leaving aside the possibility as mentioned for polytene chromosomes in *Drosophila*, hybridisation with mRNA, particularly those with unique sequences, is indeed rather difficult. The release of mRNAs from purified polysomes and their hybridisation with single copy mDNA in several stages of sea-urchin embryo have been successfully done (Galau *et al.*, 1976). The isolation of polysomes from various stages of development is one of the approaches. Later, the discovery of poly A sequences in messengers has made the task of extraction convenient (Perry, 1973).

In addition to delineating functional loci of chromosomes through DNA–RNA and DNA–DNA hybridisation, the latter is an efficient method of working out phylogeny and relationship of species on the basis of extent of base pairing. In the prokaryotic system, it has been extensively employed, but in the eukaryote it has a comparatively limited application because of the large number of chromosomes involved (Chooi, 1971). This objective has however been pursued more effectively in filter technique rather than in *in situ* hybridisation method.

Appendix 1
Culture Medium for *Drosophilia*

Materials

Corn meal	10 g
Treacle	13.5 ml
Agar-agar	1.5 g
Water	75 ml

A trace of a preservative, such as Nipagin and Moldex.

Preparation

Add the agar to the water and keep overnight, then boil to dissolve it completely. Add the remaining ingredients and mix thoroughly. Add a few drops of yeast suspended in water. Cool. Transfer a small quantity of the food to a bottle 3 in × 1 in and mate the flies at 25 °C in this bottle. After two days, transfer the flies to bottles prepared by placing a quantity of food about 1 in deep in each, together with a piece of folded sterilised crêpe paper. Stopper the bottles with cotton wool. After laying eggs for a day in a bottle, the parents must be removed to a fresh bottle. Keep at room temperature. When the larvae come out, give the cultures another yeasting. Keep the bottles at 18 °C in trays containing running water to slow down growth till the larvae are needed.

Appendix 2
Buffer solutions

M/5 BUFFERS

Stock solutions

For M/5 acetate buffer

Solution A

Glacial acetic acid	12.01 ml
Dist. water	987.09 ml

Solution B

Sodium acetate trihydrate	27.21 g
Dist. water—make up to	1000 ml

For M/5 borate buffer

Solution A

Aq. boric acid solution	1.24%

Solution B

Aq. sodium biborate solution	1.9%

For M/5 citrate buffer

Solution A

Aq. citric acid solution	4.2%

Solution B

Aq. sodium citrate solution	5.9%

For M/5 maleate buffer

Solution A

Maleic acid	46.4 g
1 N sodium hydroxide	400 ml
Dist. water—make up to	1000 ml

Solution B

1 N sodium hydroxide solution

M/10 BUFFERS

Stock solutions

M/10 phosphate buffers

Solution A: M/10 disodium hydrogen phosphate containing:

Disodium hydrogen phosphate, anhydrous 10% aqueous	141.98 ml
Dist. water	859.02 ml

Solution B: M/10 sodium dihydrogen phosphate containing:

10% aq. sodium dihydrogen phosphate solution	138.05 ml
Dist. water	861.95 ml

M/10 veronal buffers

Solution A

N/10 hydrochloric acid

Solution B

Sodium diethylbarbiturate powder, dried in an oven and dissolved in distilled water to give M/10 solution.

pH 5.2 to 8.6

Tris (Hydroxymethyl) aminomethane-maleate buffer.

Stock solutions: 0.2M-tris-maleate (24.2 g tris + 23.2 g nucleic acid, or 19.6 maleic anhydride, in 1 l of distilled water).

Stock 50 ml + x ml 0.2 M NaOH, made up to 200 ml.

Table A2.4

pH	*x*	*pH*	*x*
5.2	7.0	7.0	48.2

6.6	42.5	8.4	81.0
6.8	45.0	8.6	86.5

pH 5.0 to 7.4

0.2 M Cacodylate buffer.

For stock solution, dissolve 42.8 g of $Na(CH_3)_2.AsO_2.3H_2O$ in 1 l of distilled water. (Sabatini *et al.*, 1963)

Take 50 ml of cacodylate, add x ml of 0.2 M-HCl and make up to 200 ml.

Table A2.5

pH	*x*	*pH*	*x*

Addendum

In the eukaryotic system, the DNA in the chromosome is demonstrated to contain long intervening transcribable sequences between the contiguous genes which thus become noncontiguous and split in nature. The evidence is further provided by the difference in size of the primary and processed transcripts (*see* Darnell, 1978).

Evolutionary advance is also associated with increase in amount of DNA (Rees and Jones, 1972; Shapiro, 1976). The variety of repeated sequences, their possible functions as spacers and control elements have been well discussed (Davidson, Klein and Britten, 1977; Judd, 1979; John and Miklos, 1979; and *see* Golubovskaya, 1979).

In the fundamental thread of the chromosome, the uninemic multirepliconic constitution has been further confirmed (Peacock, 1979; Hand, 1979; Prescott, 1977). The presence of divalent cations in maintaining the structural complexity of the chromosomes (*see* Worcel and Benyajati, 1977; Varshavsky, Bakayev and Georgiev, 1976) and the role of protein linkers are claimed.

The relationship of nucleolar DNA with protein has also been clarified with the aid of spreading technique coupled with electron microscopy (Miller and Beatty, 1969; Scheer, Spring and Trendelenburg, 1977; Franke *et al.*, 1978; Busch *et al.*, 1978).

The function of the protein and specially of histones in genetic regulation has been elaborated (Weintraub and Groudine, 1976; Garel and Axel, 1976; Bacheler and Smith, 1976; Stein, Hochhauser and Stein, 1978). The groups of core histones associated with DNA, forming discrete units on nucleosomes on the primary fibre, have been analysed (Hozier, 1979; Rill, 1979) and their foldings at the higher levels of compaction ultimately determine the nature of the chromosome fibre in different forms (*see* Georgiev, Nedospasov and Bakayev, 1978; Tsanev, 1978; Woodcock, 1978; and *see* Ris and Korenberg, 1979).
