For the measurement of protein nitrotyrosine by competitive ELISA, antibody dilution and the amount of nitro-BSA used for plate coating may have to be optimized. To achieve this, first titrate the amount of nitro-BSA needed to coat the plate versus a constant, high concentration of anti-nitrotyrosine antibody. Plot the absorbance values and select the lowest level that yields a strong signal. Next, coat the plate with this amount of nitro-BSA and vary the concentration of antibodies. Plot the obtained values versus antibody dilution and select a level of the antibody that is within the linear portion of the curve. Optimal dilution for the secondary antibody can also be obtained by similar titration. In addition, in most of the competitive ELISA assays, the first antibody (here anti-nitrotyrosine) may bind preferentially to the coating antigen because the latter on the plate is highly localized. Therefore, to ensure a thorough competition, samples to be analyzed should always be premixed with the first antibody and incubated overnight before the actual ELISA measurement.

Analysis of isoaspartate formation

When protein isoaspartate is measured by PIMT-catalyzed methyl transfer reaction, the protein solution must not contain any detergent such as SDS or chaotropic reagents such as guanidine-HCl, as these will denature the PIMT enzyme. Moreover, for an unknown protein or peptide, as a first step, it is useful to determine whether the protein has any isoaspartate residues. The protein can be diluted to several different concentrations and then analyzed. If the concentration of isoaspartic acid is not protein concentration-dependent, it is most likely that there is little or no isoaspartic acid present in the protein or peptide.

Some proteins, when not denatured, may contain isoaspartate residues in domains that make them poor substrates for PIMT. In such cases, the PIMT methylation reaction may not be complete and isoaspartate concentration may be underestimated. If so, proteins may need to be fragmented by proteolysis before they are used for isoaspartate determination. To determine if proteolysis is necessary, process a sample of undigested protein along with a digested sample. If the amount of isoaspartate measured in the intact protein is similar to that in the digested protein, the protein need not be fragmented for isoaspartate quantification. If a protein should require digestion by protease, the sample buffer used for blank reactions should contain the same protease and buffer components existing in the digestion, but without the protein sample. This will exclude any isoaspartate residues that may be present in the protease.

Anticipated Results

When performed correctly, protein carbonyl content of native proteins, such as BSA and human plasma, should be around 1 nmol/mg protein (usually 0.5 to 1.5 nmol/mg protein). Literature values for carbonyl content in normal tissues are usually between 1.5 and 2.0 nmol/mg protein (Reanick and Packer, 1994). If immunoblot is performed, immunostaining of protein carbonyls should be differential, which means protein oxidative damage does not occur equally in all proteins. Protein carbonylation analyzed by the use of tritiated borohydride is highly dependent on the source of tritiated borohydride, but for the same batch of the chemical with the same concentration, results are generally reproducible. If protein carbonyls derivatized with tritiated sodium borohydride are to be quantitated by a gel electrophoretic technique (see Support Protocol 2), radioactivity counts for each individual band in a protein mixture (<20 μg loaded), are usually less than 300 cpm if no more than one band is solubilized in a single vial.

For protein thiol groups measured by gel electrophoresis of iodoacetamide-treated proteins (see Basic Protocol 3), results of autoradiographic intensities should show a highly differential pattern for each individual protein. If a band exhibits the highest intensity among all the proteins resolved by SDS-PAGE, the protein would have the least loss in its thiol groups. In contrast, if a protein band exhibits a very weak intensity following autoradiography, it should have a maximal loss in its thiol groups. Depending on what proteins are being studied, results of liquid scintillation counting of an excised individual band may range from 500 cpm to 2000 cpm.

For mass spectrometric quantification of dityrosine (see Basic Protocol 4), the concentration of protein dityrosine is usually expressed as the ratio of dityrosine to tyrosine. In mouse, dityrosine concentration has been found to be around 0.3 to 0.6 mmol/mol for heart, 0.1 to 0.3 mmol/mol for skeletal muscle and brain, and 0.2 mmol/mol for liver (ter Steege et al., 1998). Nitrotyrosine, when determined by competitive ELISA and expressed as nitro-BSA equivalents, is about 0.12 μM in human plasma.

Isoaspartate concentration in proteins, usually expressed as pmol/mg protein, is 200 pmol/mg protein in murine brain and heart, and <50 pmol/mg protein in liver with no detectable isoaspartate residues in the plasma (Kim et al., 1997).

Time Considerations

Without the consideration of preparation of protein samples, for a small number of samples (<20), spectrophotometric quantitation (see Basic Protocol 1) can be finished within one day after the DNPH treatment. If a large number of samples are involved, the washing step may take a longer time, but one can always leave the protein pellet in the ethanol/ethyl acetate solution with the tubes capped lightly and stored under a hood.

Immunoblot detection of protein carbonyls (see Support Protocol 1), starting from SDS-PAGE, can be finished within 48 hr. The time can be shortened to 12 hr if the PVDF membrane is incubated for 1 hr each, with both primary and secondary antibodies.

The quantitation of protein carbonyls by electrophoresis (see Support Protocol 2) may require one week. Most of the time is spent on gel solubilization and liquid scintillation counting.

Gel electrophoretic analysis of protein thiol groups labeled with [^{14}C]iodoacetamide (see Basic Protocol 3) will take at least 2 weeks. Generally, radiolabeling of the protein samples and gel analysis can be finished within 2 days. The rest of the time is used for the exposure of X-ray film to the Whatman 3MM filter paper onto which gels have been dried.

Quantification of protein carbonyls by tritiated borohydride labeling (see Support Protocol 2) typical requires 2 days for ~20 samples. Labeling is generally accomplished in the first day, while the second day is left for scintillation counting.

Quantitation of protein dityrosine by mass spectrometry (see Basic Protocol 4) usually takes up to 1 week. Sample preparation, including tissue hydrolysis, can take 3 days; the actual quantitation by mass spectrometry can be finished within 2 days. Preparation of dityrosine standard (see Support Protocol 3) may take up to 1 week and the time used for lyophilization steps is flexible. In addition, the lyophilized samples can be stored at −80°C for several months before further analysis.

Competition ELISA measurement of nitrotyrosine (see Support Protocol 4) usually takes 2 days. Day one is allotted for sample preparation, plate coating and preincubation of the samples or nitro-BSA with anti-nitrotyrosine antibodies. Day two is used for antibody incubation, plate washing and data collection.

Enzymatic analysis of isoaspartate formation (see Basic Protocol 5), up to the step of liquid scintillation counting, can be finished in one day. After the addition of scintillation cocktail, the samples can be counted at any time. Gel electrophoretic analysis of isoaspartate formation (see Support Protocol 5) may require a week with most of the time spent on gel solubilization and liquid scintillation counting.

ACKNOWLEDGEMENTS

The authors thank Dr. Christiaan Leeuwenburgh for his help on the procedure for dityrosine quantification by GC/MS.

Radioiodination of Cellular Proteins

Radioiodination with ^{125}I is a useful method for the labeling of cellular proteins. Protocols describing the radioiodination of proteins expressed on the surface of live cells (Basic Protocol 1), proteins in subcellular fractions including membrane-solubilized proteins (Basic Protocol 2), and soluble proteins (Basic Protocol 3 and Alternate Protocol) are described below. Support Protocols 1 and 2 describe methods for preparing solubilized membrane proteins.

SAFETY PRECAUTIONS FOR WORKING WITH ^{125}I-LABELED COMPOUNDS

As with all radioactive isotopes, the experimenter should work only in areas designated for radioactive materials and should follow the guidelines set by the local radiation safety officer. Because ^{125}I is avidly taken up by the thyroid gland, safety guidelines often include a urine test and/or thyroid scan after the procedure.

Because of the risk of exposure to γ radiation, special care should be taken whenever ^{125}I is used. Therefore, a number of extra precautions need to be followed:

1. It is strongly recommended that this procedure be performed by two researchers. This allows one experimenter to do the labeling while the other provides the equipment needed and continually surveys for contamination with the appropriate sodium iodide crystal detector.

2. Vials containing unbound ^{125}I should always be opened in a fume hood designated for use with radioactive materials and equipped with an activated charcoal filter. This should protect the experimenter from the ^{125}I, which is extremely volatile and particularly hazardous to the thyroid gland.

3. All work should be carried out behind a set of lead bricks to block the γ radiation. A double row of standard 4-cm-thick bricks should be sufficient to provide protection from the ^{125}I.

4. When ^{125}I or radioiodinated cells are moved from the protective lead bricks to the fume hood, they should be encased behind lead shields to limit exposure of fellow researchers. Moreover, ^{125}I-labeled cells should be kept within a lead box in a designated incubator.

5. All subsequent processing with radioiodinated cells or proteins should be carried out behind lead shields while wearing protective clothing and gloves, using air monitoring devices, and working with extreme caution.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety officer (also see *UNIT 7.1* and *APPENDIX 1D*).

CELL SURFACE LABELING WITH ^{125}I USING LACTOPEROXIDASE

BASIC PROTOCOL 1

In this procedure, cell surface proteins are labeled by adding Na[^{125}I] to cells in suspension. The cells are then pulsed with hydrogen peroxide and lactoperoxidase, which catalyzes the oxidation of ^{125}I and converts it to a reactive species. Care should be given to the use of proper concentrations of cells, radioiodine, and lactoperoxidase. The cells must be checked for viability after labeling to ensure that they have tolerated the procedure.

Contributed by Steve Caplan and Michal Baniyash
Current Protocols in Cell Biology (2002) 7.10.1-7.10.13

Materials

$0.5–1 \times 10^8$ cells in suspension
PBS (*APPENDIX 2A*), azide free and ice cold
Na[^{125}I] (0.1 mCi/µl; NEN Life Science Products, Amersham Pharmacia Biotech, or ICN Biomedicals)
Lactoperoxidase enzyme solution (see recipe)
30% (v/v) hydrogen peroxide stock solution
Lactoperoxidase buffer (see recipe), ice cold
10 mM NaI in PBS (*APPENDIX 2A*), ice cold

Fume hood with double row of 4-cm-thick lead bricks
γ counter and appropriate counting vials

Prepare cells and reagents

1. Centrifuge $0.5–1 \times 10^8$ cells in suspension 5 min at $500 \times g$, 4°C, to pellet cells.
2. Wash cells three times with 25 ml ice-cold PBS by centrifuging as above.

   It is critical that there be no sodium azide in the PBS, as this impairs peroxidase activity.
3. While centrifuging, thaw Na[^{125}I] and lactoperoxidase enzyme solution. Dilute 30% hydrogen peroxide stock solution 1:1000 in ice-cold lactoperoxidase buffer. Keep all reagents and solutions on ice.
4. Resuspend cells in 1 ml ice-cold lactoperoxidase buffer. Keep suspended cells on ice.

Radiolabel cells

5. While working in a fume hood, add 20 µl Na[^{125}I] to the cells (2 mCi/ml cell suspension). Mix gently with pipet tip. Keep cells on ice throughout the entire reaction.
6. Add 100 µl lactoperoxidase enzyme solution to cells. Mix gently with pipet tip.
7. Add 25 µl diluted hydrogen peroxidase solution to the cells. Mix gently with pipet tip. Incubate cells 3 min on ice.
8. Add 50 µl lactoperoxidase enzyme solution to cells and mix gently with pipet tip.
9. Add 25 µl diluted hydrogen peroxidase and mix gently with pipet tip. Incubate cells 3 min on ice.
10. Pulse cells with an additional 50 µl diluted hydrogen peroxidase and incubate 3 min on ice. Repeat this step three times, incubating cells for 3 min on ice after each addition.
11. Wash cells three times with 10 ml ice-cold 10 mM NaI in PBS.

    This will terminate the incorporation of ^{125}I.

    These washes will contain extremely high levels of unincorporated ^{125}I, so great care must be taken to avoid contamination.

Determine ^{125}I incorporation

12. Suspend cells in 10 ml of 10 mM NaI in PBS and transfer a 10-µl aliquot to a counting vial and count the γ radiation using a γ counter. Pellet the cells.

    Whereas this reading is not a measure of specific activity, it does give a preliminary indication of the intensity of the label and can be used for comparisons with subsequent labeling experiments. It is also possible to estimate the general specific activity by first lysing the cells and then precipitating a sample of the protein by trichloroacetate. The

amount of protein and γ radiation can then be measured to attain the radioactivity per milligram protein.

It is also possible to count the number and percentage of live cells after the label with trypan blue staining (UNIT 1.1), in which unstained cells (i.e., those that exclude trypan blue) are counted as live cells. However, extreme caution must be exercised to avoid contamination.

13. Process and analyze pelleted cells.

It is also possible to freeze cell pellets at −70°C. However, the experimenter should bear in mind that the half-life of ^{125}I is ~60 days and some radiolysis may occur upon prolonged storage. Iodianted cell surface proteins are useful when there are no available antibodies directed at the extracellular regions of the proteins of interest. They can also be used to determine surface expression and topology of iodinated proteins by SDS-PAGE analysis. Peptide mapping can also be performed on cell surface–iodinated protein.

RADIOIODINATION OF MEMBRANE-SOLUBILIZED PROTEINS

BASIC PROTOCOL 2

This protocol uses lactoperoxidase beads to catalyze the iodination reaction. The entire radioiodination procedure should be carried out in a fume hood located in a room designated for radioactive work with ^{125}I.

Materials

1 ml membrane-solubilized proteins from 2×10^8 cells (see Support Protocols 1 and 2)
Lactoperoxidase beads in 50% suspension (Worthington Biochemical)
Na[^{125}I] (0.1 mCi/µl; NEN Life Science Products, Amersham Pharmacia Biotech, or ICN Biomedicals)
3% (w/v) dextrose
Triton X-100 lysis buffer (see recipe) with 0.02% (w/v) BSA

PD-10 columns (10-ml columns prepacked with Sephadex G-25 resin; Amersham Pharmacia Biotech)
γ counter and appropriate counting vials

1. Add the following to 1 ml membrane-solubilized proteins from 2×10^8 cells:

20 µl lactoperoxidase beads in 50% suspension (or follow manufacturer's instructions)
20 µl Na[^{125}I] (2 mCi)
150 µl of 3% dextrose.

Using immobilized lactoperoxidase prevents radioiodination of the enzyme and contamination of the desired labeled proteins with labeled lactoperoxidase. Dextrose is added for the generation of hydrogen peroxide in vitro.

To later estimate the specific activity of the iodinated membrane-solubilized proteins, it is advisable to calculate the protein concentration prior to the labeling procedure. This may be done using the Bradford assay or any other method (APPENDIX 3B).

2. Incubate 30 min on ice, mixing well every 10 min.

3. Wash a PD-10 column three times with 10 ml Triton X-100 lysis buffer with 0.02% BSA.

BSA saturates the column so that the small amount of radiolabeled material is not lost nonspecifically on the column.

4. Add the contents of the labeling tube to the column and collect 1-ml fractions until no more fluid drains out.

The labeled sample may be spun down prior to its loading on the column to separate the lactoperoxidase-coated beads. Alternatively, the entire sample may be applied to the column, and the lactoperoxidase-coated beads will be stacked at the top of the column, without interfering with the separation.

5. Add 9 ml Triton X-100 lysis buffer with 0.02% BSA and continue collecting 1-ml fractions until eight fractions are collected.

   It is important to add the lysis buffer when there is no more sample above the Sephadex resin to avoid dilution of the labeled sample.

6. Transfer a 1- to 10-µl aliquot from each fraction to a counting vial and measure its radioactivity using a γ counter.

7. Estimate the specific activity (cpm/mg protein) of the peaks.

   Usually the main fractions containing the labeled proteins are tubes 3, 4, and 5, and free Na[^{125}I]–containing fractions are in tubes 7 and 8. Based on the protein concentration obtained for the nonlabeled membrane-solubilized proteins, the specific activity may be estimated. This assumes a similar loss of protein by the end of the time the labeling is carried out, but the method is useful for comparing the equality of the labeling reaction from one experiment to the next.

8. Pool the desired fractions in a 15-ml conical centrifuge tube.

   The radiolabeled sample can be used for immunoprecipitation, as a probe for far western analysis (UNIT 17.2), and other applications. It can be stored in 0.05% (w/v) sodium azide at 4°C or in 50% (v/v) glycerol at −20°C for ~2 months, taking into consideration the 60-day half-life of ^{125}I.

MEMBRANE PREPARATION

The isolation of membranes serves as an important purification step because it removes cytosolic proteins and nuclei prior to solubilization of membrane proteins. This procedure enables the efficient solubilization of membranes and cytoskeleton-associated proteins without causing high levels of viscosity as a result of chromatin release from the cell nucleus.

NOTE: All steps in these protocols should be carried out at 4°C or on ice.

SUPPORT PROTOCOL 1

Membrane Preparation by Homogenization

This protocol utilizes a glass-glass (Dounce) homogenizer, which has proven useful for a number of different cell types. The exact conditions, including the number of strokes required for optimal cell disruption without breakage of nuclei, must be determined for each cell type. This can generally be accomplished by monitoring the procedure with the use of a phase-contrast microscope.

Materials

Cells grown in culture or from dissected organs
PBS (*APPENDIX 2A*), ice cold
Dounce buffer (see recipe)
10× phosphatase inhibitors (see recipe), optional
Tonicity restoration buffer (see recipe), ice cold
0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
Triton X-100 lysis buffer (see recipe)

Phase-contrast microscope
Glass-glass (Dounce) homogenizer with pestle B, ice cold

10-ml conical centrifuge tube, prechilled
Ultracentrifuge, Beckman TLA100.3 rotor or equivalent, and ultracentrifuge tubes, 4°C

Additional reagents and equipment for cell counting (*UNIT 1.1*)

Prepare cells

1. Harvest the required number of cells.

   Cells may be harvested from either tissue culture (UNIT 1.1) or organs by standard procedures. Cells in suspension are centrifuged, whereas it is necessary to collect adherent cells with a cell scraper prior to centrifuging. The number of cells to harvest depends on both the application and the cell type used. Typically, solubilized membranes from 2×10^8 cells are labeled. However, for particularly small cells, such as splenocytes or thymocytes, more cells may be used.

2. Wash cells twice with ice-cold PBS.

3. Count the cells (*UNIT 1.1*), keeping a sample of the intact cells to compare with the ruptured cells using a phase-contrast microscope.

4. Resuspend cells at $1–5 \times 10^8$ cells/ml in Dounce buffer with 1× phosphatase inhibitors if needed.

   Cell concentration is generally $1–5 \times 10^8$/ml, depending on the cell size. The Dounce buffer induces cell swelling and facilitates homogenization. The Mg^{2+} concentration in the buffer stabilizes the nuclear envelope, but is also a co-factor for a number of proteases. The lowest Mg^{2+} concentration at which nuclear integrity is maintained during the homogenization process is recommended. Nuclear integrity can be monitored using a phase-contrast microscope.

   If phosphorylated proteins are studied, tyrosine phosphatase inhibitors should be included in all solutions containing protease inhibitors.

5. Incubate cells 10 to 15 min on ice.

   The cells swell during this incubation.

Homogenize cells

6. Transfer cells to an ice-cold, tight-fitting glass-glass (Dounce) homogenizer.

7. Apply 30 to 50 strokes with pestle B in a straight up and down position.

   The number of strokes varies, depending on the lability of the cell membrane. This will have to be determined for each cell type by monitoring membrane disruption using the phase-contrast microscope.

8. Add ice-cold tonicity restoration buffer to a final concentration of 150 mM.

   Check to ensure that the cell membranes are ruptured using the phase-contrast microscope and compare them to the sample of intact cells. Tonicity restoration will maintain the integrity of the nuclei.

   An additional method for cell disruption is the shearing of cells through a 25-G needle. Whereas this also generally works well, the needle has a tendency to clog, and care must be taken to avoid contamination.

Collect membranes

9. Transfer cells to a prechilled 10-ml conical centrifuge tube and centrifuge 5 min at $500 \times g$, 4°C, to spin out nuclei. Save the supernatant, which contains the membranes, and use the cell pellet to check the results of the Dounce homogenization under the microscope.

The membrane fraction will appear turbid and the nuclear pellet will be white when compared to an intact cell pellet.

10. Add 0.5 M EDTA to supernatant to a final concentration of 5 mM.

    EDTA is added to chelate Mg^{2+} and subsequently decrease the activity of magnesium-dependent proteases.

11. Transfer supernatant to an ultracentrifuge tube and ultracentrifuge 1 hr at 100,000 × *g* (~50,000 rpm), 4°C, in a Beckman TLA100.3 rotor or equivalent.

12. Transfer the pellet, which contains the membranes, to a 1.5-ml microcentrifuge tube.

    After ultracentrifugation, a pellet containing the membranes will be seen whereas the supernatant should remain clear. The supernatant obtained after ultracentrifugation contains the cytosol and free lipids. Free lipids will float near the top of the tube.

Solubilize membranes

13. Resuspend membranes at 2×10^8 cell equivalents/ml in Triton X-100 lysis buffer for 20 to 45 min at 4°C with frequent, gentle vortexing.

    If a large amount of membrane is prepared (e.g., from 5×10^8 small cells, such as lymphocytes), resuspend the membranes first in lysis buffer without Triton X-100 and then add Triton X-100 to a final concentration of 0.5% (v/v).

14. Centrifuge 15 min at 12,000 × *g*, 4°C, to pellet insoluble material.

15. Save the soluble membrane extract in a small microcentrifuge tube.

    Membrane extracts can be frozen at –70°C until needed. However, freezing and thawing extracts may affect protein-protein interactions.

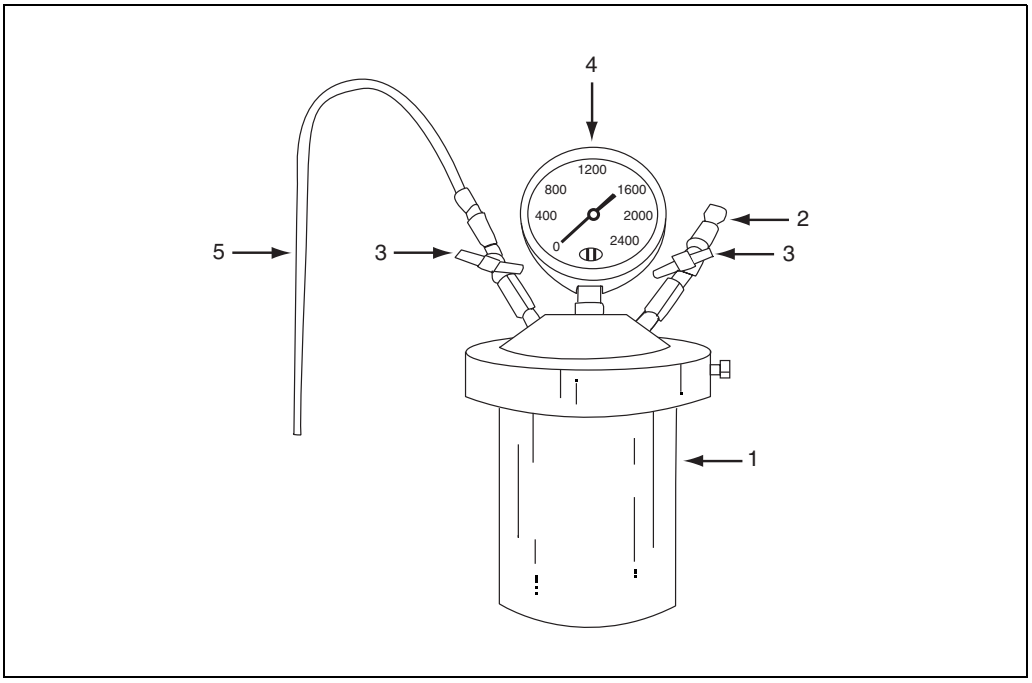

Figure 7.10.1 Nitrogen cavitation device. 1, High-pressure vessel (nitrogen bomb); 2, nitrogen filling tube; 3, valves regulating the flow of nitrogen to and from the vessel; 4, pressure gauge; 5, discharge tube.

Membrane Preparation by Nitrogen Cavitation

SUPPORT PROTOCOL 2

This is an alternative approach for membrane preparation. Nitrogen gas is dissolved in a high-pressure vessel (Fig. 7.10.1). Upon decompression, bubbles form and burst the cells. This technique is fast, easy, uniform, and reproducible. The efficiency should be determined by monitoring the samples with a phase-contrast microscope. A nitrogen cavitation device with a nitrogen gas tank is required, however, and this equipment is not inexpensive.

Additional Materials *(also see Support Protocol 1)*

Nitrogen cavitation device (e.g., Cell Disruption Bomb, Parr Instrument; Fig. 7.10.1)
Nitrogen gas tank

1. Harvest and swell cells as described (see Support Protocol 1, steps 1 to 5).
2. Place cells in a nitrogen cavitation device attached to a nitrogen gas tank and pressurize to 100 psi for 10 min at 4°C.

   Before the cavitation device is used, it should be pressurized and checked for leaks.

   This level of pressure is good for many cell types; however, the pressure, time of incubation, and rate of release from the nitrogen cavitation device should be optimized for each cell type.
3. Transfer cells to a prechilled 10-ml conical centrifuge tube.
4. Restore tonicity and collect membranes as described (see Support Protocol 1, steps 8 to 15).

RADIOIODINATION OF SOLUBLE PROTEINS

Raadioiodinated soluble proteins have been used extensively in cell biology and biochemistry, particularly for receptor binding and internalization assays. The high specificity by which radioiodination targets tyrosine residues (3.6% of the total amino acids in proteins) renders this technique less likely to impair antibody function than nonradioactive methods, such as biotinylation.

Lactoperoxidase-Catalyzed Radioiodination of Soluble Proteins

BASIC PROTOCOL 3

Soluble proteins can be radioiodinated by the lactoperoxidase-catalyzed or chloramine-T methods. The lactoperoxidase-catalyzed reaction is milder than the chloramine-T method and causes less protein denaturation. However, the specific activity of the radiolabeled proteins obtained by the lactoperoxidase-catalyzed method will be lower than that obtained with the chloramine-T method. Soluble proteins, such as immunoglobulins and protein A, can be radiolabeled using this protocol.

Materials

10 mg/ml BSA in PBS
PBS (*APPENDIX 2A*), ice cold
30% (v/v) hydrogen peroxide stock solution
0.025 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*), ice cold
1 mg/ml protein sample in PBS
Na[^{125}I] (~0.1 mCi/µl; NEN Life Science Products, Amersham Pharmacia Biotech, or ICN Biomedicals)
1.5 mg/ml lactoperoxidase enzyme (Sigma or Calbiochem) in PBS (*APPENDIX 2A*), stored in aliquots at −70°C or prepared fresh
15 mM NaI in PBS, prepared fresh and ice cold

PD-10 columns (10-ml columns prepacked with Sephadex G-25 resin; Amersham Pharmacia Biotech)
γ counter and appropriate counting vials

Set up column

1. Load a PD-10 column with 1 ml of 10 mg/ml BSA in PBS and then wash the column with 20 to 30 ml ice-cold PBS.

   The BSA saturates the column so that the small amount of radiolabeled material will not be absorbed nonspecifically to the column, which reduces recovery yields. Other carrier proteins such as fetal calf serum or ovalbumin can be used at the same concentration.

Label proteins

2. Immediately before use, dilute 30% hydrogen peroxide stock solution 1:1000 in ice-cold 0.025 M sodium phosphate buffer to a final concentration of 0.03%.

3. To 10 µl of 1 mg/ml protein sample, add the following:

   0.5 mCi Na[^{125}I]
   10 µl of 1.5 mg/ml lactoperoxidase enzyme
   2 µl of 0.03% hydrogen peroxide.

   Incubate 1 min at room temperature with continuous mixing.

   Because lactoperoxidase activity is inhibited by azide and sulfhydryl reagents, these should be avoided when the sample is prepared for labeling.

4. Repeat the addition of 2 µl of 0.03% hydrogen peroxide three more times at 1-min intervals.

5. Add 0.5 ml of 15 mM NaI in PBS.

   This serves to compete with the labeled NaI and terminate the reaction.

Isolate labeled proteins

6. Use a disposable pipet to layer the sample onto the PD-10 column (step 1) at room temperature and collect 1-ml fractions until no more fluid drains out.

7. Add 10 ml PBS and continue collecting 1-ml fractions.

   It is important to add the PBS when there is no more sample above the Sephadex resin to avoid dilution of the labeled sample.

8. Transfer a 1- to 10-µl aliquot from each fraction to a counting vial and measure its radioactivity using a γ counter.

9. Determine the specific activity (cpm/mg protein) of the peaks.

   The first peak should contain radioiodinated proteins, whereas the second should have unincorporated (free) radioiodide.

10. Pool the desired fractions in a 15-ml conical centrifuge tube.

    The radiolabeled sample can be used for immunoprecipitation (UNIT 7.2), as a probe for far western analysis (UNIT 17.2), and other applications. It can be stored in 0.05% (w/v) sodium azide at 4°C or in 50% (v/v) glycerol at −20°C for up to 2 months, taking into consideration the 60-day half-life of ^{125}I.

Chloramine-T-Mediated Radioiodination of Soluble Proteins

ALTERNATE PROTOCOL

As described above (see Basic Protocol 3), the chloramine-T method is not as mild as lactoperoxidase-catalyzed radioiodination. It does, however, result in radiolabeled proteins with a higher specific activity.

Additional Materials *(also see Basic Protocol 3)*

0.5 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
Chloramine-T (Sigma)
Sodium metabisulfite (Sigma)

1. Prepare a PD-10 column as described (see Basic Protocol 3, step 1).
2. To 10 µl of 1 mg/ml protein sample add 10 µl of 0.5 M sodium phosphate buffer.

   The phosphate buffer provides additional buffering capacity required to neutralize the Na[^{125}I], which is supplied in 0.1 M NaOH.
3. Immediately before use, prepare 2.25 mg/ml chloramine-T and 7 mg/ml sodium metabisulfite each in 0.5 M sodium phosphate buffer.

   The chloramine-T and sodium metabisulfite should be weighed in separate tubes and then dissolved in the proper volume of phosphate buffer immediately before use.

   CAUTION*: Wear gloves when handling these reagents because they are both toxic.*
4. Add 0.5 mCi Na[^{125}I] and 10 µl of 2.25 mg/ml chloramine-T to the protein sample (step 2). Incubate 1 min at room temperature.

   Chloramine-T is a potent oxidant that converts iodine into its reactive I^+ state.
5. Add 10 µl of 7 mg/ml sodium metabisulfite (step 3) to the mixture to stop the radioiodination reaction. Wait 1 min and then add 50 µl of 15 mM NaI in PBS.
6. Layer the sample onto the PD-10 column and isolate the labeled proteins as described (see Basic Protocol 3, steps 6 to 10).

REAGENTS AND SOLUTIONS

Use deionized water, preferably filtered, in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers see* ***SUPPLIERS APPENDIX****. It is recommended that all solutions be prepared using sterile reagents.*

Dounce buffer

10 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.5 mM $MgCl_2$ (*APPENDIX 2A*)
Store up to 1 year at 4°C
Immediately before use add:
10 mg/ml aprotinin (Boehringer Mannheim–Roche)
10 mg/ml leupeptin (Sigma)
1 mM PMSF (*APPENDIX 2A*; Sigma)
1.8 mg/ml iodoacetamide (Sigma)

PMSF should be added immediately prior to use, as it undergoes hydrolysis in aqueous solutions.

Lactoperoxidase buffer

Mix 16.8 ml PBS (*APPENDIX 2A*); 1 ml 0.5 M NaH_2PO_4, pH 7.6 (see recipe); and 2.2 ml water. Store indefinitely at 4°C, but ensure it is not contaminated and check the pH after prolonged storage and adjust as needed.

This buffer is a PBS-based buffer with additional sodium phosphate.

Lactoperoxidase enzyme solution

Dissolve 1.5 mg lactoperoxidase (Sigma or Calbiochem) in 1 ml lactoperoxidase buffer (see recipe). Store in 50- and 250-µl aliquots at −70°C and thaw only once before use

NaH_2PO_4, 0.5 M, pH 7.6

Add 6.9 g NaH_2PO_4 to 100 ml water. Adjust pH to 7.6 with 0.5 M $NaHPO_4$. Store indefinitely at 4°C.

Phosphatase inhibitors, 10×

4 mM sodium orthovanadate
4 mM EDTA, pH 8.0 (*APPENDIX 2A*)
100 mM NaF
100 mM sodium pyrophosphate
Adjust pH to 7.6 and freeze aliquots at −20°C

Tonicity restoration buffer

10 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.5 mM $MgCl_2$ (*APPENDIX 2A*)
0.6 M NaCl (*APPENDIX 2A*)
Store up to 1 year at 4°C
Immediately before use add:
10 mg/ml aprotinin (Boehringer Mannheim–Roche)
10 mg/ml leupeptin (Sigma)
1 mM PMSF (*APPENDIX 2A*; Sigma)
1.8 mg/ml iodoacetamide (Sigma)

PMSF should be added immediately prior to use, as it undergoes hydrolysis in aqueous solutions.

Triton X-100 lysis buffer

150 mM NaCl (*APPENDIX 2A*)
50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.5% (v/v) Triton X-100
Store up to 1 year at 4°C
Immediately before use add:
10 mg/ml aprotinin (Boehringer Mannheim–Roche)
10 mg/ml leupeptin (Sigma)
1 mM PMSF (*APPENDIX 2A*; Sigma)
1.8 mg/ml iodoacetamide (Sigma)

PMSF should be added immediately prior to use, as it undergoes hydrolysis in aqueous solutions.

COMMENTARY

Background Information

The process of radioiodination occurs when ^{125}I (or ^{131}I) is introduced at the positions *ortho* to the hydroxyl group on tyrosine residues. This reaction may be carried out by either chemical or enzymatic oxidation activity. In most cases, ^{125}I is chosen for radioiodination; despite ^{131}I having about 7-fold greater specific radioactivity, the isotopic abundance of ^{131}I is usually <20% (due to ^{127}I contaminants). Moreover, the half-life of ^{131}I is only 8 days as compared to 60 days for ^{125}I.

Cell surface radioiodination

Cell surface labeling is an important tool to detect the presence of proteins on the cell surface. This technique is particularly useful for labeling surface membrane proteins for which there are no available antibodies directed against their extracellular domain. Such pro-

teins cannot be detected by simpler methods, such as the sorting of fluorescence-labeled cells or immunostaining. It can also be utilized to determine whether an unidentified protein that co-immunoprecipitates with a known protein is expressed on the cell surface membrane. Another application of cell surface labeling is to follow the kinetics of cell surface–expressed proteins. For example, cells can be stimulated and then surface labeled at various time points. Alternatively, cell surface proteins can be labeled, and then the labeled cells can be cultured without further labeling (i.e., chased) to determine the kinetics of the loss of labeled proteins from the cell surface.

Two commonly used cell surface labeling procedures are radioiodination and biotinylation. Lactoperoxidase-catalyzed radioiodination (Basic Protocol 1) almost exclusively labels tyrosine residues, whereas most methods of protein biotinylation primarily target lysine residues. This is an important consideration in choosing which type of cell surface label to utilize. Whereas the average frequency of tyrosine in proteins is only 3.6% of the total amino acids, lysine occurs with a frequency of 7%. However, one advantage of radioiodination is that it is unlikely to impair the ability of the protein to be recognized by a specific antibody during immunoprecipitation or immunoblot analysis. In contrast, conjugating proteins with biotin has been known to impede antibody binding if the biotinylated lysine residue happens to be within the epitope recognized by the antibody. Moreover, due to the high frequency of lysines in proteins, multiple biotinylation often occurs within the same protein. Each biotin that is conjugated adds an additional 500 Da to the molecular weight of the protein, and as a result, the resolved protein product often displays a range of molecular weights, depending on the number of conjugated biotin moieties. Interpreting these results can be confusing, especially when combined with assays to detect phosphorylated proteins, which often display an upshift in their apparent molecular weight.

Cell surface labeling of proteins by a lactoperoxidase-catalyzed reaction results in the covalent attachment of ^{125}I to accessible tyrosine residues (reviewed by Morrison, 1980). Because of the size of the enzyme, this reaction occurs exclusively on the outside of the plasma membrane. As the reaction and all reagents are kept on ice, limited internalization of radioiodinated surface proteins is expected.

There are various other methods for iodinating cell surface proteins, including the IODO-Beads reagent (Pierce) and the use of lactoperoxidase-coupled beads (rather than free lactoperoxidase), which can reportedly reduce background for certain applications (Koch and Haustein, 1976).

Preparation of membranes

Membrane preparation must precede iodination of membrane-solubilized proteins (Basic Protocol 2). Membrane preparation by homogenization (Support Protocol 1) utilizes one type of homogenizer that consists of a cylindrical glass homogenization vessel, in which either a rod-shaped Teflon-coated pestle or a glass pestle with a ball-shaped tip is inserted. Differences between the use of the two are summarized by Kinne-Saffran and Kinne (1989). The Teflon-glass homogenizer is advantageous for the homogenization of tissue fragments with a lower content of connective tissue, whereas the glass-glass homogenizer is more appropriate for tissue with a higher content of connective tissue and for single cells.

Membrane preparation by nitrogen cavitation (Support Protocol 2) allows quantitative disruption of cells in an inert atmosphere without danger of local heating. This method is mainly used for single cells in suspension or for cells grown in culture.

Radioiodination of soluble proteins

Labeling soluble proteins with radioiodine has been a standard laboratory procedure for many years. The techniques are simple, inexpensive, and reliable. Although different labeling techniques have been developed over the years, such as biotinylation and enzyme- or fluorescein-coupling, the use of radioiodinated proteins has some advantages when compared to these other labeling procedures. For example, samples containing radioiodinated proteins can be exposed to films for a longer time so that the signals emitted accumulate over time on autoradiographic film. (The ^{125}I half-life is 60 days.) Proteins labeled by other methods may provide limited levels of signal. This is particularly important when small amounts of a specific protein are tested. The radioiodination protocols presented here are those that are most commonly used (Morrison 1980). They depend on the availability of tyrosine residues, but in most cases, some histidine residues are also radiolabeled. Other labeling techniques are reviewed in Hubbard and Cohn (1976).

The use of immobilized lactoperoxidase as the catalyst for oxidation allows the easy removal of the enzyme itself, which can often

cause much background due to its own radioiodination. The column allows the removal of free radioiodine.

Critical Parameters

Safety precautions for working with ^{125}I are described at the beginning of this unit.

Cell surface radioiodination

The conditions suggested for this protocol have been optimized for a system in which immunoprecipitation is commonly the method of analysis. The number of cells used in this protocol is appropriate for cells of relatively small size, such as lymphocytes. For larger cells, such as fibroblasts, it may be advisable to radioiodinate $1–2 \times 10^7$ cells. It is important to test the viability of the cells after the procedure; if the cells have not tolerated the [^{125}I]Na labeling, there is likely to be a higher level of background (i.e., ^{125}I-labeled intracellular proteins). Typically, 95% viability should be anticipated. If lower levels of viability are encountered, the amounts of diluted hydrogen peroxide solution may be lowered.

Preparation of membranes

Success of membrane preparation depends upon the careful optimization of the conditions used for each cell type. For Dounce homogenization, the exact conditions, including swelling time and the number of strokes required for optimal cellular disruption without breakage of nuclei, must be determined. This can generally be accomplished by monitoring the disruption using a phase-contrast microscope. In the case of nitrogen cavitation, shearing and breakage of intracellular organelles is minimal if the pressure and time of equilibration are properly adjusted. It is important that the lysis is relatively rapid (to preserve transient associations of proteins), and that the pressure is high enough to ensure complete disruption of the cells and thereby prevent contamination of the nuclear fraction with intact cells. However, the pressure must be low enough to prevent excessive fragmentation of cell membranes.

Protease inhibitors should be used throughout the procedure and if phosphorylated proteins are of interest, phosphatase inhibitors should be used as well. Iodoacetamide is included with the protease inhibitors but it is added primarily because it blocks free sulfhydryls. This is required because after solubilization, disulfide bonds may be formed between polypeptides that are not normally bound covalently, leading to artifactual results.

Magnesium salts are used during cell breakage to stabilize the nuclear envelope; however, as magnesium is a co-factor for many proteases, these should be removed by chelation with EDTA after removal of nuclei.

Radioiodination of soluble proteins

Radioiodination of proteins may induce protein denaturation and inactivation, and therefore the labeling conditions for a specific protein should be determined. The use of lactoperoxidase beads for labeling membrane proteins, which are solubilized in lysis buffer, enables the researcher to perform the radioiodination by adding a minimal volume of beads and dextrose instead of the addition of lactoperoxidase solution and hydrogen peroxide periodically. Thus lysis buffer is not diluted and ratios between the Triton X-100 and the membrane lipids are maintained throughout the entire labeling procedure. Solubilized membrane proteins can be labeled in a manner similar to soluble proteins, utilizing lactoperoxidase and hydrogen peroxide. For the success of the labeling procedure, care should be taken to use proper concentrations of proteins (soluble or membrane-bound), radioiodine, and catalysts. For sensitive proteins such as IgE for example, a lower concentration of lactoperoxidase or chloramine-T and metabisulfite should be used.

Iodinated proteins should be stored in 0.05% (w/v) sodium azide at 4°C to inhibit bacterial contamination. Alternatively, aliquots may be stored at −20°C with 50% (v/v) glycerol. The presence of a carrier protein such as serum or albumin also helps prevent breakdown of protein due to radiation damage during storage.

Anticipated Results

Cell surface radioiodination

A typical cell surface radioiodination experiment should yield ~95% viable cells. A moderately expressed surface protein (with accessible tyrosines) should be detectable by immunoprecipitation and autoradiographic exposure of dried SDS-PAGE gels or of nitrocellulose membranes in 1 to 4 days. Highly expressed surface proteins, or proteins with multiple tyrosines may be detectable in exposure times of hours. An enhancing screen in the exposure cassette and storage of the cassette at −70°C will expedite results.

For many applications, an important control for surface-labeling experiments is testing the level of leakiness, or the level of intracellular proteins labeled by this procedure. One possi-

bility is to immunoprecipitate an entirely intracellular tyrosine-containing protein, such as actin or tubulin. Although these are highly abundant proteins, little or no label should be expected.

Preparation of membranes

Purification of membranes prior to solubilization results in a 5- to 10-fold purification over total cell extracts, but also in a variable decrease in yield. This will vary depending on the procedure used for cell breakage. In preparing membranes, as the efficiency of cellular disruptions increases, so does the degree of nuclear damage.

Membranes may also be isolated from specific intracellular organelles. Isolation of intracellular organelles is described in Chapter 3 of this book.

Radioiodination of soluble proteins

Radiolabeled soluble proteins can be used for immunoprecipitation (*UNIT 7.2*), immunoblotting (*UNIT 6.2*) and far western analysis (*UNIT 17.2*). Autoradiographic exposure time of dried SDS-PAGE gels or of nitrocellulose membranes can range from 1 to 7 days, depending on the levels of the labeled proteins. An enhancing screen in the exposure cassette and storage of the cassette at −70°C will expedite results.

Time Considerations

Once the cells have been harvested, the procedures described here should take <3 to 4 hr. For radioiodination of solubilized membrane proteins, membrane preparation takes an additional 2 to 3 hr.

CHAPTER 8
Cell Cycle Analysis

INTRODUCTION

The cell cycle is the ordered set of processes through which cells divide, producing two daughter cells possessing the same set of genetic information (Murray and Hunt, 1993). To pass successfully through the cell cycle, all cells must complete three essential tasks: replicate their DNA, faithfully segregate their chromosomes to the daughter cells, and separate the daughter cells from each other. In most cases, cells must also grow during each cell cycle so that the daughters are of sufficient size. One of the most fundamental decisions cells make is whether to progress through the cell cycle. Frequently, this decision is closely linked with choices of cell fate, such as whether to undergo differentiation or programmed cell death.

The last ten years has witnessed a dramatic growth in our understanding of the fundamental mechanisms that regulate the cell cycle. It has become clear that the cell cycles of all eukaryotes are regulated by a family of cyclin-dependent kinases (CDKs). As described in *UNIT 8.1*, these kinases drive both chromosomal DNA replication (S phase) and mitosis (M phase). These kinases are in turn controlled by phosphorylation and by the regulated proteolysis of their cyclin subunits. Orderly progression through the cell cycle is assured by regulatory mechanisms (frequently called checkpoints; Hartwell and Weinert, 1989) that inhibit advancement to the next phase of the cell cycle until necessary functions in the current phase are complete—e.g., by blocking the activation of mitotic CDKs and chromosome condensation until DNA replication is complete.

To address questions related to the cell cycle, it is essential to have clear markers for the cell-cycle state of cells. While mitosis is accompanied by clear morphological changes, biochemical markers are required to determine the state of cells during interphase. Since chromosomal DNA replication occurs during S phase, it is possible to assay directly whether individual cells are in S phase by measuring their capacity to incorporate nucleotide analogs, such as bromodeoxyuridine (BrDU), into DNA (*UNIT 8.2*). DNA content is a general diagnostic marker for whether cells have undergone DNA replication in S phase (thereby doubling their DNA content) or cell division in M phase (thereby reducing their DNA content by half). DNA content can also be monitored by flow cytometric analysis (*UNIT 8.4*). Finally, since different CDKs are active at different phases of the cell cycle, the activities of members of the CDK family also serve as a clear diagnostic marker for the cell-cycle state of cells (*UNIT 8.2*). A combined approach may be used for a more detailed description of the cell-cycle state, monitoring both the abundance of cyclin subunits and the DNA content of cells by flow cytometric analysis (*UNIT 8.4*).

The capacity to obtain populations of cells that are uniform with respect to their cell-cycle state is also essential for cell-cycle studies. Cultured cells can be arrested at various stages of the cell cycle through manipulation of their nutritional status or through treatment with inhibitors that block their progression through S phase or mitosis (*UNIT 8.3*). Alternatively, M phase cells can be obtained from adherent cultures through "mitotic shakeoff", taking advantage of the decreased attachment of cells to the culture vessel during mitosis (*UNIT 8.3*). Since a relatively small proportion of cells in an exponentially growing culture are in mitosis at any given time, mitotic shakeoff is frequently combined with some

Contributed by Mary Dasso
Current Protocols in Cell Biology (1999) 8.0.1-8.0.2

inhibitor treatment or nutrient manipulation. Prolonged arrest in response to nutritional manipulation or drug treatments can frequently perturb cell metabolism. In cases where this is undesirable, it is possible to make use of the fact that cell size is directly correlated with cell cycle stage. Centrifugal clutriation (*UNIT 8.5*), which separates cells on the basis of size, can be employed to obtain synchronous populations of cells from different cell cycle phases without drug treatments.

Overview of the Cell Cycle

Inductive signals from the environment and a variety of intracellular signals determine whether a cell enters the mitotic cell cycle and proliferates or withdraws from the mitotic cycle to meet with a nonproliferative fate. These signals influence the activation of cyclin-dependent kinases (CDKs), which lie at the heart of the intrinsic cell cycle machinery responsible for integrating cell division with developmental and environmental stimuli. A better understanding of these CDKs is expected to provide insight into the diverse processes that involve signal transduction, differentiation, senescence, apoptosis, development, and tumorigenesis.

THE BIOLOGY OF THE CELL CYCLE

A typical cell cycle proceeds with alternating rounds of DNA replication, which takes place during S phase, and nuclear and cytoplasmic division, which take place during M phase. DNA synthesis and mitotic division are separated by the intervening gap phases, G_1 and G_2, during which checkpoint controls are superimposed to preserve the accurate transmission of genetic information. Checkpoints achieve this by monitoring cell cycle events, such as DNA replication and spindle assembly, and generating signals in response to errors in these processes so that cell cycle progression can be halted until repairs are complete (Murray, 1994). These controls ensure that cell cycle events occur in the appropriate sequence and that cell cycle arrest will occur if these events are not carried out in the correct order. Checkpoint controls are responsible, therefore, for ensuring that cells enter S phase only after successful completion of the previous mitosis, attainment of adequate cell size, and repair of any spontaneous or environmentally induced DNA damage. Alternatively, checkpoints induce apoptotic pathways for damaged cells as a way of preventing them from giving rise to mutant progeny. For example, the tumor suppressor protein p53 plays an important role in DNA damage–induced cell death (Lowe et al., 1993) and G_1 phase arrest (Kuerbitz et al., 1992). Signals regulating checkpoints and controlling cell proliferation interact very closely with each other.

After each mitotic cycle, cells traversing G_1 phase receive signals from the extracellular environment, as well as intracellular cues dictated in part by checkpoints, before continuing in the cell cycle to replicate their DNA and divide once again. Extracellular signals that promote entry into S phase or the beginning of a new mitotic cycle include growth factors, mitogens, nutrients, and cell-substratum interactions. Alternatively, in the absence of mitogenic signals or in the presence of mitogenic antagonists, differentiation inducers, and certain spatial cues, cells withdraw from the cell cycle with unduplicated DNA and meet with alternate, nonproliferative fates, such as quiescence (G_0 phase) or differentiation. Some cell types may transiently undergo cell cycle arrest and then undergo apoptosis because the growth factors required for their proliferation may also be necessary for their continued survival.

A cell's "decision" either to commit to or withdraw from the mitotic cycle occurs at the restriction point late in G_1 phase, after which mitogenic growth factors are no longer required for cells to complete division (Pardee, 1989). In other words, cells that pass the restriction point, which occurs 1 to 3 hr prior to the onset of replication, proceed through the remainder of the cell cycle independently of environmental signals. The restriction point encompasses the critical regulatory mechanism that enables a cell to monitor its external and internal environment as well as the integration of these environmental cues to control the switch between alternative cellular fates, such as proliferation, temporal cell cycle arrest, quiescence, and differentiation. Passage through the restriction point and entry into S phase is determined by the phosphorylation status of the retinoblastoma tumor suppressor protein Rb, which is essentially governed by the activities of the CDKs.

THE CELL CYCLE ENGINE

The CDKs

The division cycle of a eukaryotic cell is currently understood (Morgan, 1995) to be a series of phases or transitions in which temporal order is imposed first by the sequential assembly and activation of the CDKs, and second by their proteolytic inactivation (Fig. 8.1.1). CDKs are enzymes composed of a catalytic subunit (the CDK) and an essential activator subunit (the cyclin). In mammalian cells,

Contributed by Michele S. Park and Andrew Koff

Current Protocols in Cell Biology (1998) 8.1.1-8.1.9

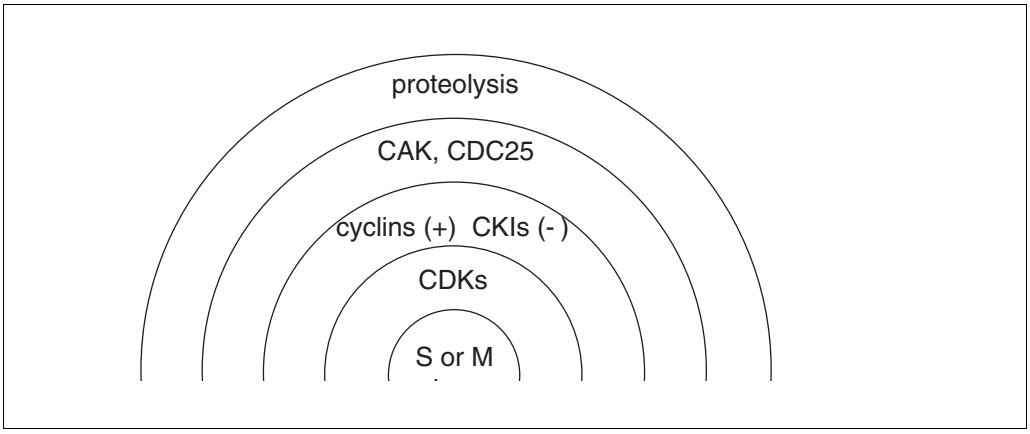

Figure 8.1.1 Peeling back the layers of proliferation control. This "onion" model of proliferation indicates the relationship of each cell cycle component to proliferation or cell division. Cyclin-dependent kinase (CDK) activity, which is absolutely required, depends upon physical interaction with positive regulatory subunits (cyclins) and can be prevented by physical interaction with negative regulatory subunits, called CDK-inhibitory proteins (CKIs). The activation of CDKs also requires phosphorylation by an activating kinase (CAK) and dephosphorylation of phosphates in the ATP-binding motif by members of the Cdc25 family. The entire mechanism can be regulated by proteolysis, because many cyclins and CKIs are targeted by ubiquitin-dependent degradation.

a succession of kinase subunits (CDK4, CDK6, CDK2, and Cdc2) is expressed along with a succession of cyclins (D, E, A, and B) as cells progress from G_1 to M. Cdc2 forms complexes with cyclins A and B to regulate entry into the M phase of the cell cycle.

CDK4/6 and CDK2, whose regulatory partners are the D-type cyclins (D1, D2, and D3) and cyclin E, respectively, represent two distinct classes of G_1 phase–specific CDKs whose activation is required for entry into S phase (Koff et al., 1992; Lew et al., 1991; Xiong et al., 1991). Cyclin D–dependent kinase activity is first detected in mid-G_1 phase as cells approach the G_1/S boundary. Cyclin D–dependent kinases have a distinct substrate preference for the retinoblastoma protein Rb (Matsushime et al., 1992, 1994; Meyerson and Harlow, 1994). Rb binds to and negatively regulates the activities of transcription factors such as E2F-DP1 heterodimers, whose functions are critical for the G_1/S phase transition (reviewed in Nevins, 1992). Under conditions favoring proliferation, the inactivating phosphorylation of Rb by the CDKs in mid- to late-G_1 phase results in liberation of E2F and other Rb-bound transcription factors, which then activate the transcription of S-phase genes. The phosphorylation of Rb is thereby modulated during the cell cycle, in that Rb is present in a hypophosphorylated, active state in G_0 and early G_1 and becomes hyperphosphorylated, and thereby inactive, in late G_1.

Cyclin E–associated kinase activity, although not required for phosphorylation of Rb, is rate limiting for entry into S phase. Cyclin E is expressed periodically at maximum levels near the G_1/S phase transition (Dulic et al., 1992; Koff et al., 1992) and is essential in *Drosophila* for completion of G_1 and progression into S phase (Knoblich et al., 1994). Cyclin E apparently regulates a transition different from that promoted by the D-type cyclins, because cyclin E, but not cyclin D1, is essential for entry into S phase in mammalian cells lacking functional Rb. Inactivation of any of the G_1 CDKs leads to cessation of proliferation and withdrawal from the mitotic cycle.

The activation status of the CDKs is regulated by many mechanisms reflecting both the diversity of the signals they integrate and the central importance of their roles in cell cycle control (Fig. 8.1.2). In general, these regulatory mechanisms act on the synthesis and degradation of the cyclin proteins, formation of cyclin-CDK complexes, positive and negative modification of kinase subunits by phosphorylation, and inhibitory constraints on kinase activity exerted by at least two families of CDK inhibitory proteins (CKIs).

Regulation of CDK activity by cyclins

The primary modulator of CDK activity is the cyclin subunit. Cyclin function is primarily controlled by changes in cyclin levels, which oscillate characteristically throughout the cell

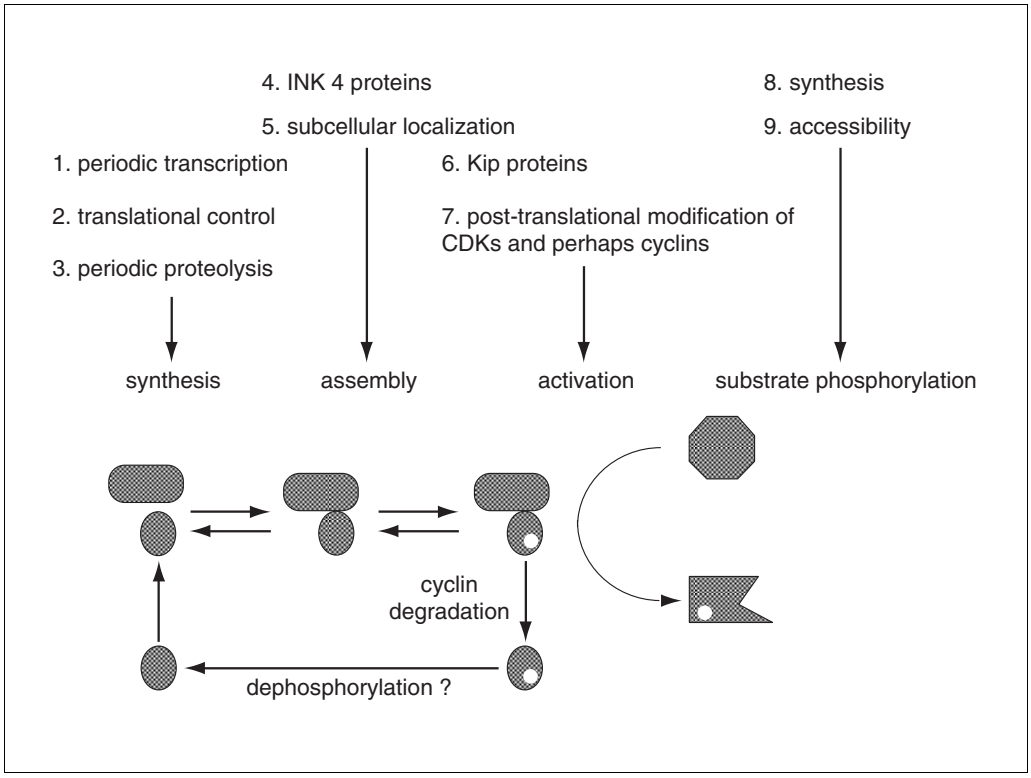

Figure 8.1.2 Activation (and inactivation) of cyclin-dependent kinases (CDKs). This schematic representation shows the five-step pathway (synthesis, assembly, activation, substrate phosphorylation, and cyclin degradation) that leads to CDK activation and proteolytic inactivation. The cyclin is oval, the CDK is round, the substrate is hexagonal, and activating phosphorylation is indicated by the inclusion of a white circle. Phosphorylation of the substrate may affect its structure, as shown here, or may only change the substrate's activity or make it a more attractive binding target for other proteins. Mechanisms that interfere with each step are listed above the step. Abbreviations: INK4, inhibitor of CDK4; KIP, CDK-inhibitory protein.

cycle. In the early *Xenopus* embryo, oscillations in cyclin B levels are mainly controlled by changes in the rate of cyclin degradation. Constant synthesis of cyclin B during the cell cycle provides a roughly linear increase in cyclin concentration until mitosis, at which point cyclin B degradation increases abruptly, resulting in a rapid decline in cyclin levels. Cyclin degradation seems to involve the ubiquitin-dependent proteolytic machinery, which requires the destruction box sequence motif near the N terminus of mitotic cyclins (Glotzer et al., 1991). The trigger for the initiation of cyclin B degradation is not entirely clear, but the proteolytic pathway is well defined.

Regulation of cyclin levels at the transcriptional level occurs in mammalian cells and yeast. In mammalian cells, sequential, periodic oscillations in the levels of the major cyclins largely reflect changes in messenger RNA levels (Pines and Hunter, 1989, 1990), but little is known about the mechanisms that generate these waves of gene expression. These mechanisms have been determined more comprehensively in the yeast *Saccharomyces cerevisiae*, where G_1 cyclins (CLNs) and M cyclins (CLBs) cooperate in overlapping feedback loops to ensure the properly timed execution of their transcription and degradation programs (Amon et al., 1993, 1994). Cyclins may act further to regulate CDK activity by targeting the bound CDK to specific substrates or subcellular locations.

Activation of CDK activity

Because cellular CDK levels tend to remain in constant excess throughout the normal cell cycle, most of the regulatory controls on catalytic activity are post-translational. In addition to cyclin binding, complete activation of the CDK requires phosphorylation at a conserved threonine residue (Thr-160/161). The enzyme responsible for this activating phosphorylation is itself a CDK and has been designated CAK for CDK-activating kinase. CAK is a multisubunit enzyme composed of a catalytic sub-

unit (CDK7 or MO15) and a regulatory subunit (cyclin H; Fisher and Morgan, 1994). CAK is capable of activating all of the major CDK-cyclin substrates involved in vertebrate cell cycle control. During a normal cell cycle, activation of phosphorylation at the threonine residue by CAK tends to oscillate in parallel with cyclin binding.

Changes in phosphorylation are probably not caused by changes in CAK activity, which remains relatively constant throughout the cell cycle. It is possible, therefore, that cyclin binding may stimulate CDK activation, perhaps by inducing conformational changes that permit CAK-mediated phosphorylation. CDK7, like its substrates, harbors a potential site of phosphorylation at a conserved threonine residue. Mutation of this residue greatly reduces kinase activity, suggesting that activation of CAK itself may require phosphorylation at this site (Fisher and Morgan, 1994). Therefore, although CAK activity is not rate limiting during normal cell proliferation, its regulation by other kinases or additional subunits may be critical under different environmental growth conditions.

Inactivation of CDK activity

Negative regulation of cell cycle progression by inactivation of CDK activity occurs during development, differentiation, senescence, and cell death. These negative controls most likely play a crucial role in preventing tumorigenesis, and an understanding of the balance between negatively and positively acting signals on CDK activities will be of utmost importance in future studies of the cell cycle.

A cyclin-CDK complex can be inactivated by a decrease in the synthesis or an increase in the degradation of cyclins, and through inhibitory phosphorylation at two sites near the N terminus (Thr-14 and Tyr-15 in human Cdc2 and CDK2). Phosphorylation of these two residues is particularly important in the control of Cdc2 activation during mitosis. Phosphorylation of Thr-14 and Tyr-15 parallels the rise in cyclin B levels that occurs as cells approach mitosis. The Cdc2–cyclin B complex is maintained in an inactive state until dephosphorylation of Thr-14 and Tyr-15 at the G_2/M border activates Cdc2 (Krek and Nigg, 1991).

The kinase responsible for phosphorylating Tyr-15 is Wee1, originally identified in *Schizosaccharomyces pombe* (Parker et al., 1991, 1992). Thr-14 and Tyr-15 are both dephosphorylated by the dual-specificity phosphatase Cdc25. Near the onset of mitosis, the Cdc25 protein undergoes a marked elevation in phosphatase activity that coincides with extensive phosphorylation of the protein in its N-terminal region. During mitosis, the kinase responsible for this phosphorylation is activated and the corresponding phosphatase is inhibited. The Cdc25-stimulatory kinase may be Cdc2 itself, creating an elegant positive-feedback loop to induce the mitotic dephosphorylation and activation of Cdc2.

Negative regulation of CDK activity occurs also through the actions of CKIs. Two families of these proteins exist that antagonize CDKs by binding to and inhibiting their kinase activity (reviewed in Sherr, 1994; Sherr and Roberts, 1995). The INK4 group (inhibitor of CDK4), whose members include p15, p16, p18, and p19, selectively compete with the D-type cyclins for binding to CDK4/6 to inhibit their kinase activity (Hannon and Beach, 1994; Serrano et al., 1993). The KIP family of inhibitors, which includes p21 (El-Deiry et al., 1993; Gu et al., 1993; Harper et al., 1993; Xiong et al., 1993), p27 (Koff et al., 1993; Polyak et al., 1994a,b; Toyoshima and Hunter, 1994), and p57 (Lee et al., 1995; Matsuoka et al., 1995), is defined by a conserved domain that is sufficient for stable binding to cyclin-CDK complexes and inhibition of their kinase activity. The KIPs have been described as promiscuous inhibitors because they can bind to and inhibit each of the G_1 CDKs essential for G_1 progression and S-phase entry.

The CKIs seem to function as stoichiometric inhibitors by setting an adjustable threshold for cyclin-dependent activation of the CDKs. In the presence of growth inhibitory stimuli or antimitogenic signals the levels of CKIs in the cell increase. High levels of these proteins prevent proliferation by establishing an inhibitory threshold that cannot be suppressed by the steady-state levels of cyclin-CDK complexes present in the cell. Conversely, mitogenic signals lower the inhibitory threshold to below the level of cyclin-CDK complexes, permitting CDK activation and cell cycle progression. The decision to proliferate or not to proliferate relies, therefore, on a balance of growth-inhibitory and growth-stimulatory signals transduced from the extracellular environment and modulated by CDK activity and the antagonizing effects of the CKIs.

Proteolysis

CKIs have been shown to prevent cell proliferation by negatively regulating cyclin-CDK complexes. Recent findings suggest that the converse may be true as well, i.e., that cyclin-

CDK complexes may inhibit CKI function (Sheaff et al., 1997). Cyclin-CDK complexes in yeast and in mammalian cells seem to promote cell cycle progression through degradation of CKIs by the ubiquitin-proteasome pathway. This pathway also regulates the turnover of certain cyclins, thereby determining their periodic expression as well as their rapid proteolytic inactivation in response to growth factor deprivation.

The ubiquitin-proteasome pathway is involved in protein degradation in mammalian cells and is responsible for the tightly regulated selective turnover of intracellular proteins. Experimental evidence has implicated the ubiquitin system in the degradation of mitotic cyclins, oncoproteins, the tumor suppressor protein p53, several cell surface receptors, transcriptional regulators, and mutated and damaged proteins. Some of these proteolytic events occur throughout the cell cycle, whereas others occur following cell cycle–dependent posttranslational modifications (such as site-specific phosphorylation) of the target proteins. Although the signals that designate proteins for degradation are still being elucidated, the enzymes of the ubiquitin-proteasome proteolytic pathway have been well characterized.

Degradation of a protein by the ubiquitin pathway involves two distinct steps: targeting of the protein by covalent attachment of multiple ubiquitin molecules and degradation of the targeted protein. Conjugation of ubiquitin to proteins destined for degradation generally occurs in a three-step process involving three specific classes of enzymes called E1, E2, and E3. E1 is the ubiquitin-activating enzyme that catalyzes the ATP-dependent activation of ubiquitin to produce a high-energy thiol ester intermediate. Following activation, the E2 ubiquitin-carrier (or ubiquitin-conjugating) proteins transfer ubiquitin from E1 proteins to the E3 ubiquitin–protein ligase. Finally, the E3 ligase catalyzes the formation of an isopeptide bond between the ubiquitin polypeptide and the protein substrate. While E1 is a general factor that does not seem to be cell cycle dependent, many E2 and E3 proteins, whose expression might be regulated in a cell cycle–dependent manner, are yet to be identified.

Although the signals responsible for directing the ubiquitin-proteasome machinery to specific target proteins are still being elucidated, recent findings on the turnover of cyclins D1 and E have revealed exciting evidence for phosphorylation-dependent promotion of proteolysis. Unlike cyclins B1 (Brandeis and Hunt, 1996) and A, which are targeted for degradation by the ubiquitin-mediated pathway through a proteolysis targeting signal (known as the destruction box) located within their sequence, cyclins D1 and E are targeted for degradation by an alternative mechanism. Cyclin E degradation by the ubiquitin-proteasome system is regulated by both CDK2 binding and CDK2 catalytic activity (Clurman et al., 1996). The binding of cyclin E to CDK2 protects it from ubiquitination, while CDK2-activated pathways abrogate this protective effect.

Site-specific phosphorylation as a mechanism for substrate targeting in ubiquitin-mediated degradation is further supported by recent reports on the degradation of cyclin D1. It has recently been reported that cyclin D1 turnover is governed by ubiquitination and proteasomal degradation, which are positively regulated by cyclin D1 phosphorylation on Thr-286 (Diehl et al., 1997). Furthermore, this site-specific phosphorylation does not appear to be dependent on CDK4 catalytic activity, suggesting the existence of another kinase that can phosphorylate cyclin D1 to accelerate its destruction by the ubiquitin-proteasome machinery.

Significant findings on the ubiquitin-dependent degradation of CKIs in yeast as well as in mammalian cells (Pagano et al., 1995) have recently been reported. CDK-dependent phosphorylation seems to play a critical role in the targeting of cyclins and certain CKIs for degradation by the ubiquitin-proteasome degradation machinery. The two CKIs that have been identified in the budding yeast *S. cerevisiae* ($p40^{Sic1}$, which regulates entry into S phase by inhibiting the Cdc28p-Clnp kinases, and Far1p, which is specifically required to arrest the cell cycle in G_1 in response to pheromones) are degraded by a common ubiquitination system. The components of this G_1-S ubiquitination system in *S. cerevisiae* are Cdc34p, Cdc4p, Cdc53p, and Skp1p.

Henchoz et al. (1997) have shown that Far1p is regulated by this ubiquitination system and that an important determinant of the recognition signal for ubiquitination is specific phosphorylation of Far1p by the Cdc28p-Clnp kinase. A similar pathway has been proposed for controlling degradation of the CKI $p40^{Sic1}$ (Feldman et al., 1997). Analogously to Far1p, an essential requirement for ubiquitination and degradation of $p40^{Sic1}$ appears to be phosphorylation by the Cdc28p-Clnp kinase, thereby ensuring that S phase cannot be initiated before the G_1-specific Cdc28p-Clnp kinase has been activated.

The two components of the yeast ubiquitin machinery responsible for recruitment of phosphorylated substrates (in particular $p40^{Sic1}$) for degradation are Cdc4p and Skp1p. The interaction between Cdc4p and Skp1p is mediated by the F-box, a newly recognized structural motif that seems to be required for Skp1p association (Bai et al., 1996). Skp1p connects many cell cycle regulators to the ubiquitin proteolysis machinery through the F-box motif. It seems likely that Skp1p association may designate active CDKs as targets of the proteolysis machinery.

Ubiquitin- and phosphorylation-dependent degradation may serve as a general mechanism to regulate CKIs. Evidence for the operation of this mechanism in mammalian cells has been provided by reports on the phosphorylation-dependent degradation of the CKI p27 by the ubiquitin-proteasome machinery. Mutations that affect putative sites of phosphorylation by associated cyclin E–CDK2 kinase stabilize p27 in vivo (Clurman et al., 1996; Sheaff et al., 1997; Vlach et al., 1997), demonstrating that p27 is an inhibitor as well as a biologically relevant substrate of cyclin E–CDK2 kinase activity. Ubiquitin-dependent degradation triggered by phosphorylation is a conserved mechanism to regulate the activity of CKIs and cyclins throughout the cell cycle and in response to extracellular signals.

TARGETS OF THE CELL CYCLE MACHINERY

The molecular networking of the CDKs and CKIs seems to affect the fundamental cell cycle regulator Rb. The intricate nature of multiple regulatory systems designed to modulate the activation status of CDK proteins reflects the importance of the substrate protein Rb as a functional unit that controls G_1 phase and as an obligatory oncogenic target (Bartek et al., 1996). Rb is unique as a prototypic member of the "pocket-protein" family, whose members include p130 and p107. All three proteins share structural homology, bind to oncoproteins of small DNA tumor viruses, interact with the E2F transcription factors, and suppress proliferation when overexpressed in cell culture.

Rb is functionally different from p130 and p107 in several important ways, however. Rb-knockout mouse embryos die at embryonic day E14.5 (Jacks et al., 1992; Lee et al., 1992), while certain strains of mice lacking p130 or p107 are viable and fertile, and display no obvious developmental abnormalities (Cobrinik et al., 1996; Lee et al., 1996). Furthermore, heterozygous Rb mice all develop and eventually succumb to specific tumors, while neither heterozygous nor homozygous p130- or p107-mutant mice exhibit increased tumor incidence.

Rb is, therefore, a bona fide tumor suppressor protein whose upstream regulators and downstream effectors comprise a multicomponent biochemical pathway that serves as the molecular mechanism underlying cell cycle control. A better understanding of the functional relationship between Rb and its negative and positive regulators will provide greater insight into the control of cell proliferation and tumorigenesis.

Some targets for CDK activity reside in the replicative machinery, and a brief discussion of the role of CDKs in replication follows. This aspect of control is not yet clearly understood, however, and any discussion at this time will be incomplete.

Activation of a replication origin is controlled at two levels. First, a protein-DNA complex termed the prereplicative complex (pre-RC) forms at the origin; this complex forms only in G_1 phase. Second, the pre-RC is converted into a replicative complex; this occurs only during S phase (reviewed in Stillman, 1996). This control must ensure that origins fire only once per cell cycle; therefore, origin activation must be coordinated with cell cycle progression, presumably by CDKs. Proteins that participate in origin activation have been identified in yeast and *Xenopus*, and, more recently, mammalian homologs (pre-RCs) have been described. Briefly, pre-RCs form only in cells in G_1 phase and are activated at the G_1/S transition. An origin of replication complex (ORC) binds to the origin of replication and acts as a foundation upon which the pre-RC is assembled in G_1 cells. Assembly of the pre-RC occurs with production of Cdc6 and recruitment of MCM (minichromosome maintenance mutants) proteins. After it is assembled, the pre-RC is activated first at the G_1/S boundary, and later throughout S phase for late-firing origins. This event requires the activation of the Cdc7-dbf4 kinase complex. Phosphorylation by this complex stimulates the dissociation of Cdc6 and MCM from the ORC, and replication ensues.

Mitogens and their downstream effectors, the CDKs, can affect this process by regulating the expression of Cdc6 at both the transcriptional and post-transcriptional levels. Oscillations of CDK activities also prevent the formation of the pre-RC. For example, G_2-phase cells cannot support pre-RC formation even when

provided Cdc6 (Piatti et al., 1996). Thus, one active research area is to determine how a cell coordinates the activation of CDKs, the conversion of a pre-RC to a replicative complex, and ultimately does this once, per cell cycle.

A PARADIGM OF CELL CYCLE ANALYSIS

Researchers with little experience in cell cycle studies may benefit from use of the following analytical paradigm, distilled from the literature, which addresses the mechanism of cell cycle arrest following drug/cytokine treatment or arrest-inducing conditions (also see Table 8.1.1). This analysis should take approximately 3 months to complete. Subsequent units in this chapter will describe in detail some of the techniques that can be used.

First, it is necessary to establish that the cell is arrested in a particular stage of the cell cycle under arrest-inducing conditions. Second, the amount of CDK activity in treated and untreated cells is measured. This can be accomplished in a G_1 cell by determining the extent

Table 8.1.1 A Beginner's Guide to the Cell Cycle Engine[a]

Protein	Activity
Positive regulators of CDKs participating directly in the cell cycle	
Cyclin A	Required for G_1/S transition and progression through S-phase; a role in G_2/M transition
Cyclin B	The mitotic cyclin; essential for G_2/M transition
Cyclins D1, D2, D3	Not required in the absence of Rb; cell type–specific patterns of expression
Cyclin E	Required for G_1/S transition
Essential CDKs participating directly in the cell cycle	
Cdc2	Binds to cyclin B and cyclin A; essential for mitosis
CDK2	Binds to cyclin E and cyclin A; may associate with cyclin D1; essential for entry into S phase
CDK3	Unknown partner; essential for entry into S phase
CDK4	Binds to D-type cyclins; cell type–specific pattern of expression
CDK6	Binds to D-type cyclins; cell type–specific pattern of expression
Regulators	
CAK	Complex composed of cyclin H and CDK7 with or without a novel protein MAT1
Cdc25	Three isoforms with patterns of expression that suggest one works at G_1/S and the others in G_2 and M
CIP/KIP family (p21, p27, p57)	Inhibit activity of all G_1 CDK complexes by forming a ternary complex and either blocking activation by CAK or by inhibiting the active complex
INK4 family (p15, p16, p18, p19)	Inhibit activity of cyclin D–CDK4 and cyclin D–CDK6 complexes either by forming a ternary complex or by competing for the CDK subunit
Most frequently used targets of the engine	
Cdc6	Accumulation may be regulated by phosphorylation
E2F (1-5), DP (1-2)	Heterodimeric family of transcription factors that interact with Rb family members
Lamins	Phosphorylation by B-type cyclins correlates with dissolution of the lamin structure at mitosis
Rb, p107, and p130	Phosphorylation by CDKs generally correlates with inactivation
RFA, human SSB	One subunit of the trimeric single-stranded binding protein is phosphorylated by CDKs
Histone H1	One of the first-identified substrates of the CDKs and a convenient in vitro substrate

[a]Abbreviations: CDK, cyclin-dependent kinase; CAK, CDK-activating kinase; CIP, CDK-inhibitory protein; KIP, CDK-inhibitory protein; INK4, inhibitor of CDK4; Rb, retinoblastoma; RFA, replication factor A; SSB, single-stranded DNA binding protein.

of phosphorylation of histone H1 by CDK2 and of glutathione-*S*-transferase-linked Rb by CDK4 and CDK6. These results can be correlated with the phosphorylation and expression of the various CDK substrates (i.e., Rb). Third, it is important to develop a steady-state expression profile of the cyclins, CDKs, and CKIs by immunoblotting as well as by northern blotting (if desired) to measure mRNA levels. Fourth, the formation of active CDK-cyclin complexes is investigated. If no kinase activity is detected, it may be interesting to determine whether this absence is due to CKI binding, post-translational modification of the ATP-binding cleft of the kinase, aberrant localization of one of the cyclins or CDKs, or other events. Finally, it may be relevant to determine whether cyclin-CDK complexes form at all. Are the components in the right place? Are the INK proteins sequestering CDK4 in the cytosol? Is cyclin D1 in the nucleus? These questions may provide insights into the mechanism of cell cycle arrest and may be a source of ideas for future research. If all the results indicate that the cell should not be, but is, in an arrested state, congratulations! You may be on your way to elucidating a novel mechanism. Good luck!

Assays for CDK Activity and DNA Replication in the Cell Cycle

The somatic cell cycle is normally divided into four phases: S phase, during which DNA is replicated, M phase (mitosis), when chromosomes and cells divide, and the periods in between—G_1 phase (after M and before S) and G_2 phase (after S and before M). Progress through the cell cycle is regulated by a complex formed by a cyclin subunit and a cyclin-dependent kinase (CDK). The catalytic subunit (the CDK) is activated by binding to the cyclin subunit.

In mammalian cells, three different cyclins—denoted cyclins A, B, and E—are primarily involved in regulating the cell cycle. These bind to one of two different CDKs, CDK1 (often called cdc2) and CDK2, such that specific cyclin-CDK complexes are present and active at particular phases of the cell cycle (see below). The amount of protein kinase activity of these cyclin-CDK complexes indicates, therefore, where a cell is in the cell cycle. This is useful for analyzing effects on cell proliferation and on cell cycle arrest. Whether a cell is in S phase can be inferred by determining the activation status of specific CDK complexes, but it can also be assayed directly by the incorporation of nucleotide analogs into DNA, which can also show how many cells entered S phase in the course of the experiment. As well as marking particular cell cycle stages in normal cells, the behavior of some cyclin-CDK complexes is perturbed in some transformed cells; therefore, assays for cyclin-CDK activity are often informative in studies on cellular transformation. This unit outlines how to assay cyclin-CDK activity (see Basic Protocol 1) and how to detect DNA replication by incorporation of 5-bromodeoxyuridine (BrdU) into DNA (see Basic Protocol 2).

Particular stages in interphase can be identified according to which cyclin-CDK complexes are present and active as follows:

Cyclin E–CDK2 activity appears in late G_1 stage and disappears in early S phase.

Cyclin A–CDK2 activity appears in early S phase and disappears in early M. In some cell types, cyclin A–CDK1 activity appears in G_2 phase and also disappears in early M.

Cyclin B–CDK1 activity marks the end of G_2 phase and disappears at mid-M.

MEASURING CDK ACTIVITY

BASIC PROTOCOL 1

Cyclin-CDK activity is assayed by a protein kinase assay using either a peptide substrate or, more usually, histone H1. Histone H1 can also be phosphorylated by a number of other protein kinases, notably cAMP-dependent protein kinase (PKA). For this reason cyclin-CDK assays using histone H1 should be carried out in the presence of a PKA inhibitor. A sharp increase in the histone H1 kinase activity in a whole cell lysate can be measured during mitosis, which is a gross indication of cyclin B–CDK1 activity, the major mitotic kinase. To measure the activity of other cyclin-CDK complexes, however, or to assay specific B-type cyclin-CDK complexes, one must first isolate a specific cyclin-CDK complex by immunoprecipitation.

Alternatively, proteins of the cyclin-dependent kinase subunit (Cks) family can be used as an affinity matrix. These proteins, which include the $p13^{suc1}$ protein from the fission yeast *Schizosaccharomyces pombe* and the $p9^{Cks}$ proteins from *Xenopus* and from humans, bind a number of cyclin-CDK complexes in cell lysates—notably cyclin B–CDK1—with high affinity. Cks proteins covalently linked to Sepharose beads are commercially

Current Protocols in Cell Biology (1998) 8.2.1-8.2.11

available from a number of companies and are often used as a quick and easy way to measure the increase in cyclin B–CDK1 activity at mitosis. They should not be considered specific for cyclin B–CDK1, however, because they bind other cyclin-CDK complexes as well as related kinases, such as MAP kinase.

In choosing an antibody before embarking on the immunoprecipitation and the protein kinase assay, there are two considerations that must be taken into account.

1. Because many CDKs are able to bind more than one cyclin, using an antibody directed against the cyclin will give a more precise indication of the stage of the cell cycle than using one that recognizes the CDK. Unfortunately, most anti-cyclin antibodies are fairly species specific, probably because the primary structure of the cyclins is much less well conserved than that of the CDKs.

2. Some domains of the cyclin and of the CDK are masked in the active complex (Jeffrey et al., 1995). Antibodies raised against the PSTAIRE motif for the conserved part of the CDK) of a CDK will recognize only the unbound, inactive kinase and, therefore, are useful only for immunoblotting, not for the kinase assay. Similarly, antibodies raised against the C terminus of the cyclin should not be used because these often only recognize the monomeric protein.

Basic Protocol 1 will give a good indication of cell cycle stage because it works well for cyclins A, B, and E, with their partner kinases CDK1 and CDK2. Complexes between cyclin D and CDK4 or CDK6 cannot be assayed in this manner, however, because they do not phosphorylate histone H1 and may be sensitive to some detergents. (See Background Information for references to more appropriate procedures.) Depending on the equipment available, the results can be assayed using a scintillation counter to measure the incorporation of radiolabeled phosphate into a substrate, or by SDS–polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 6.1*) followed by autoradiography (*UNIT 6.3*) or phosphorimaging.

Materials

Cells grown in 6-cm tissue culture dishes
1× PBS (*APPENDIX 2A*), ice cold
Lysis buffer (see recipe), ice cold
Protein A– or protein G–Sepharose conjugate (Amersham Pharmacia Biotech) or formaldehyde-treated *Staphylococcus aureus* cells (Pansorbin, Calbiochem)
Anti-cyclin antibody, anti-CDK antibody, or Cks–Sepharose bead conjugate (Upstate Biotechnology)
Kinase buffer (see recipe), ice cold
Histone H1 solution (see recipe) or consensus cdc2 peptide (New England Biolabs)
1 mM ATP (diluted from 100 mM ATP [see recipe] in distilled H_2O)
2000 Ci/mmol [γ-^{33}P]ATP or 3000 Ci/mmol [γ-^{32}P]ATP
100 mM EDTA (*APPENDIX 2A*)
2× SDS sample buffer (*UNIT 6.1*)
PKA-inhibitory peptide: 1 mM of peptide (Sigma) in 10 mM sodium phosphate, pH 7.2 (see *APPENDIX 2A* for buffer recipe; store peptide solution up to 1 year at –20°C)
50 mM roscovitine *or* 100 mM olomoucine (both from Calbiochem) in DMSO (store both solutions in aliquots up to 1 year at –20°C, and thaw only once; store olomoucine in the dark)
Negative control: immunoprecipitated preimmune serum or anti-IgG antibody
Positive control: purified cyclin B–CDK1
75 mM phosphoric acid (7.5 ml of 1 M phosphoric acid + 92.5 ml distilled water; store up to 2 years at room temperature)
96% ethanol

15% to 20% SDS-polyacrylamide gel (*UNIT 6.1*)
Coomassie blue G-250 staining solution (see *UNIT 6.1*)
Destaining solution: 10% (v/v) acetic acid

1-ml syringes and 21-G needles, prechilled to 4°C
1.5-ml microcentrifuge tubes, prechilled to 4°C
1-ml pipet tips, prechilled to 4°C
Phosphocellulose units (Pierce) *or* 1.5-cm squares of phosphocellulose P81 filter paper (Whatman)
Microcentrifuge, 4°C
End-over-end rotator or rotating wheel
Whatman 3MM filter paper
Phosphorimager (optional)

Additional reagents and equipment for SDS-PAGE and Coomassie brilliant blue staining (*UNIT 6.1*) and for autoradiography and densitometry (optional; *UNIT 6.3*)

Immunoprecipitate

1. Place 6-cm tissue culture dish containing cells on a glass plate on ice, preferably in a cold room. Remove culture medium with a Pasteur pipet, add 3 ml ice-cold PBS, and let stand for 1 min on ice. Tip the dish and remove PBS with a Pasteur pipet. Repeat wash with ice-cold PBS and carefully remove as much PBS as possible by draining the dish.

   Adjust the volumes appropriately for other size dishes. Ideally samples should be assayed in duplicate.

2. Add 1 ml lysis buffer and leave dish on ice for 20 min. Tip the dish and scrape the lysate to one edge with a rubber policeman or cell scraper.

   The lysis buffer, also known as RadioImmunoPrecipitation Assay (RIPA) buffer, is a fairly stringent buffer that removes some of the more weakly associated proteins from the cyclin-CDK complex. It is an appropriate buffer to measure the basic level of cyclin-CDK activity, although any modulation by weakly associated proteins will be lost. A variety of other lysis buffers have also been used to assay cyclin-CDK complexes, using the same basic procedure.

3. Take up the lysate through a prechilled 21-G needle attached to a prechilled 1-ml syringe, and transfer to a prechilled 1.5-ml microcentrifuge tube. Draw up the lysate through the needle three times to shear the DNA. Alternatively, sonicate the tube, keeping the lysate cold at all times.

4. Add 10 µl protein A– or protein G–Sepharose, or 100 µl formaldehyde-treated *S. aureus* cells, to the lysate. Cap the tube and microcentrifuge 20 min at 10,000 × *g*, 4°C, to clear lysate. Remove lysate (~900 µl) with a prechilled 1-ml pipet tip, being careful not to disturb the pellet.

   At this point, the lysate can be frozen in liquid nitrogen and stored at –80°C. Samples should be thawed only once and not refrozen.

5. Add lysate (~900 µl) to anti-cyclin antibody, anti-CDK antibody, or Cks-Sepharose beads in a prechilled 1.5-ml microcentrifuge tube on ice. Incubate 1 hr to overnight at 4°C, with continuous mixing on an end-over-end rotator or rotating wheel for Cks-Sepharose beads.

   The amount of antibody will vary depending on the titer. Most available anti-cyclin or anti-CDK polyclonal antibodies are used at 1:1000 or less. Most monoclonal antibodies are used at 0.1 to 1 µg/ml, which will be ~1 µl monoclonal or polyclonal antibody per 6-cm dish of cells.

   The tube does not need to be continuously mixed if antibodies are being used.

6. Microcentrifuge the tube 5 min at 10,000 × *g*, 4°C. Transfer lysate to a fresh prechilled 1.5-ml microcentrifuge tube containing 30 to 50 µl of a 50% mixture of protein A– or protein G–Sepharose in ice-cold lysis buffer. Mix on an end-over-end rotator or rotating wheel for 30 to 45 min at 4°C.

   When using protein A–Sepharose and a mouse monoclonal antibody, adding 1 µg of a rabbit anti–mouse antibody often increases the efficiency of immunoprecipitation, because some subtypes of mouse IgG do not bind well to protein A. In general, mouse monoclonal antibodies bind better to protein G–Sepharose than to protein A–Sepharose. See Harlow and Lane (1988) for a more detailed discussion and Table 7.2.1.

7. Microcentrifuge 5 sec at maximum speed, 4°C. Remove lysate with a 1-ml pipet tip or 21-G needle attached to an aspirator. Add 700 µl ice-cold lysis buffer to pellet and microcentrifuge 5 min at 10,000 × *g*, 4°C. Repeat microcentrifugation three times with 700 µl ice-cold lysis buffer each time.

Perform kinase reaction

8. Remove supernatant, add 1 ml ice-cold kinase buffer to pellet, and microcentrifuge 5 min at 10,000 × *g*, 4°C.

   For SDS-PAGE analysis, transfer the Sepharose beads in the last wash solution to a screw-cap microcentrifuge tube.

9. Prepare kinase assay cocktail:

   80 µl kinase buffer
   4 µl 1 mM ATP (40 µM final)
   4 µl 10 µCi/µl [γ-^{33}P]ATP (2000 Ci/mmol) *or* [γ-^{32}P]ATP (3000 Ci/mmol)
   0.5 µl 10 mg/ml histone H1 (50 µg/ml final)
   2 µl 1 mM PKA-inhibitory peptide (20 µM final)
   9.5 µl double-distilled water.

   Either ^{33}P- or ^{32}P-labeled ATP can be used. ^{33}P may be preferable, because it emits β particles of a lower energy, and is therefore less harmful to the researcher and requires less shielding to use.

10. Remove as much of the last wash from the pellet as possible without leaving it completely dry. Add 20 µl kinase assay cocktail to the immunoprecipitate or Cks-Sepharose beads on ice and incubate 30 min at 30°C. Add 20 µl kinase assay cocktail to negative control immunoprecipitate and positive control as well.

    The amount of protein kinase in an immunoprecipitate should always be compared with that of a negative control. Purified cyclin B–CDK1 to be used as a positive control can be purchased from a number of different suppliers.

    As a further test for the specificity of the assay, one can inhibit a parallel set of immunoprecipitates with chemical inhibitors of the cyclin-CDKS. The cyclin-CDK complexes can be inhibited by several different chemicals. Thus far the most specific inhibitors have proved to be roscovitine (use at a final concentration of 5 µM) and olomoucine (use at a final concentration of 10 µM). Either of these inhibitors can be added to a separate reaction to indicate whether the bulk of the protein-kinase activity is due to a cyclin-CDK complex.

Assay for kinase activity

Assay by scintillation counting

11a. Add 100 µl of 100 mM EDTA to the samples to stop the reaction. Set up phosphocellulose units in a rack and apply samples to phosphocellulose units using a pipet, being careful not to touch the membrane with the pipet tip. Alternatively, spot samples on 1.5-cm squares of phosphocellulose P81 paper in a glass dish.

Phosphocellulose units and P81 paper are negatively charged; therefore, the substrate must have some positively charged residues. This makes them appropriate to assay either histone H1 or a consensus cdc2 peptide.

12a. Microcentrifuge phosphocellulose units 30 sec at 10,000 × *g*, room temperature. Add 500 µl of 75 mM phosphoric acid and spin again. Transfer phosphocellulose units to fresh microcentrifuge tubes, add 500 µl 75 of mM phosphoric acid, and spin again. Alternatively, rinse P81 squares three times with 5 ml of 75 µM phosphoric acid, and one time with 5 ml 96% ethanol.

13a. Transfer phosphocellulose units or P81 filter papers to scintillation vials, add 2 to 10 ml scintillation fluid, and count on the ^{32}P channel if using ^{32}P, or on the ^{35}S channel if using ^{33}P.

Assay by SDS-PAGE

11b. Add 10 µl of 2× SDS-PAGE sample buffer to the samples to stop the reaction. Boil samples 3 min in a screw-cap microcentrifuge tube to reduce the risk of vaporizing radioisotope.

12b. Run the samples on a 15% to 20% SDS-polyacrylamide gel (*UNIT 6.1*).

13b. Place the gel in a flat container, add 500 ml staining solution, and let stand 15 min at room temperature. Remove staining solution and add 500 ml destaining solution for 20 min. Repeat destaining three times with 250 ml destaining solution for 15 min each time.

14b. Place the gel on Whatman 3MM filter paper, cover with plastic wrap, and dry the gel in a gel dryer for 1 hr at 80°C. Expose the gel in a phosphorimager or to X-ray film.

Phosphorylated histone H1 can usually be detected on the dried gel with a hand-held β counter. If using ^{32}P, place a lead screen with a hole punched in it over the gel to assess the amount of radioisotope in individual lanes. If using ^{33}P, use another piece of X-ray film to block the signal from the other lanes.

15b. Measure the amount of incorporated label using a phosphorimager or by densitometry of the exposed film.

The labeled histone H1 will appear as a doublet of bands running at ~30 kDa.

Given the limited linear response of X-ray film, densitometry is an inaccurate way to measure the incorporation of label. It will provide only a rough guide to the relative amount of kinase activity in each sample.

MEASURING DNA REPLICATION USING INCORPORATION OF BrdU

BASIC PROTOCOL 2

This protocol describes how to use the nucleotide analog BrdU to label and detect cells in the process of DNA replication. BrdU freely diffuses into cells and therefore can simply be added to the culture medium. Cells are grown on poly-L-lysine-coated coverslips, which allows them to be visualized using high-resolution optics on an epifluorescence microscope. The cells are then fixed on the coverslips and the DNA is denatured to expose the BrdU epitope to an anti-BrdU antibody. If BrdU is added for a short time, this method can be used to identify only those cells undergoing DNA replication. Alternatively, a continuous pulse of BrdU will identify all the cells whose DNA was replicated during the experiment. Anti-BrdU antibodies can be either unconjugated, in which case a secondary antibody labeled with a fluorophore must also be used, or conjugated to a fluorophore, in which case the antibodies can be visualized directly by fluorescence microscopy. Conjugated antibodies are generally less sensitive but are sufficient for most purposes, except for the very short pulses of BrdU that are used to visualize individual DNA replication foci.

Materials

1 mg/ml poly-L-lysine: 20 mg poly-L-lysine (average mol. wt. 400,000)/20 ml dH_2O; filter sterilize through 0.45 μm filter and store at –20°C for 3 months
Cell culture medium
Cell suspension: 10^5 cells/ml in PBS (*UNIT 1.1*; see *APPENDIX 2A* for PBS recipe)
10 mg/ml BrdU (see recipe)
1 mg/ml 5-fluorodeoxyuridine (FrdU; see recipe)
PBS (*APPENDIX 2A*)
Blocking solution: 3% (w/v) BSA in PBS
50% methanol/50% acetone (fixative; prepared fresh); *or* formaldehyde solution (cross-linking agent; see recipe) and Tris·Cl/$MgCl_2$/Triton X-100 (TSM; see recipe)
*Eco*R1 exonuclease and exonuclease III, *or* HCl/Triton X-100 (see recipe)
Anti-BrdU antibody, conjugated; *or* unconjugated anti-BrdU antibody and fluorophore-labeled secondary antibody (Amersham)
Slide-mounting solution containing antifade agent

Grade 1 (0.15-mm) glass coverslips, cleaned and sterilized with dry heat
Cytocentrifuge (optional)
Humidified chamber: e.g., inverted petri dish with dampened filter paper in lid

Prepare and seed cells onto coverslips

1. Incubate clean, dry heat–sterilized coverslips for 5 to 15 min at 37°C in poly-L-lysine solution in a 10-cm tissue culture dish. Wash the coverslips with water and air dry at room temperature.

   To handle the coverslips, use fine watchmakers forceps with one of the tips bent to ~20° angle.

2. Place coverslips in 6- or 10-cm tissue culture dishes and add enough cell culture medium to cover the surface of the dish (3 to 5 ml). Pipet in the cell suspension. Spin down suspension cells onto coverslips in a cytocentrifuge, or simply incubate them as a 10^5 cell/ml suspension in PBS with poly-L-lysine coverslips for 10 min at 37°C.

   The amount of cells added will depend on the experimental design, but cells should not be confluent after they have reattached to the dish. Note that cells often adhere better to coverslips than to plastic, so they will tend to be a little denser on the coverslip than in the rest of the dish.

   Seed cells at least 3 to 4 hr before staining to allow them to adhere properly. Some cell lines may require a different incubation temperature.

Label S-phase cells with BrdU

3. Add BrdU to the cell suspension at a final concentration of 25 to 100 μM. Incubate at 37°C for 15 min to several hours.

   Use higher concentrations for shorter times. For labelings >2 hr, FrdU can be added to a final concentration of 0.4 μM. This inhibits thymidylate synthetase, reducing endogenous pools of thymidine and increasing the effective concentration of BrdU in the cell.

4. Remove BrdU and wash coverslips three times with 5 ml PBS each time. Transfer coverslips to a glass petri dish containing 5 to 10 ml PBS. Proceed to either fixation or permeabilization of cells.

5a. *Fix/permeabilize cells with methanol/acetone:* Rinse coverslips once with 5 ml PBS and drain off the PBS. Carefully add enough fixative to cover the coverslips (3 ml) and incubate 2 min at room temperature. Remove fixative and rinse coverslips with 5 to 10 ml PBS.

   Other fixatives include 100% methanol or 100% acetone. Fixation can also be done at –20°C. If methanol or acetone is used, the permeabilization step is not necessary (go to step 6).

5b. *Fix cells with formaldehyde, then permeabilize with TSM:* Rinse the coverslips once with 5 ml PBS and drain off PBS. Carefully add enough formaldehyde solution to cover the coverslips (3 ml) and let stand for 2 to 5 min at room temperature. Carefully rinse the cells twice with 5 ml PBS. Drain off PBS, add enough TSM to submerge the coverslips (3 to 5 ml), and let stand for 5 to 10 min at room temperature. Drain off TSM and wash three times with 5 to 10 ml PBS for 2 min each.

An optional step is to wash once in 50 mM glycine in PBS after removing the TSM to quench the cross-linking reagent. This is not usually necessary unless there is a very high autofluorescent background at the end of the procedure.

6. Place a piece of Parafilm on top of the dampened filter paper in the humidified chamber and pipet ~25 µl blocking solution onto the paper. Drain the excess PBS from the coverslip by touching the edge to a Kimwipe. Lay the coverslip cell side down on top of the drop of blocking solution and leave for 15 to 30 min. Proceed to denaturation of DNA by either acid or nuclease treatment.

Nuclease treatment is easier to combine with other antibodies in double-immunofluorescence experiments; acid denaturation is sometimes more sensitive.

7a. *Denature DNA with acid:* Place coverslips in a glass petri dish, add 5 to 10 ml HCl/Triton X-100, and let stand 10 min at room temperature. Remove coverslips to a fresh petri dish and wash twice with 10 ml PBS for 5 min each to neutralize the acid.

In dual-labeling experiments, the sample should be incubated with the second primary and the secondary antibodies and then fixed again before acid treatment. The first secondary antibody should be labeled with Texas red or TRITC, not FITC, because FITC is sensitive to acid pH.

7b. *Denature DNA with nuclease:* Dilute *Eco*RI and exonuclease III in their recommended buffers according to the manufacturers' instructions. In the humidified chamber, place the coverslip cell side down on a drop of ~150 U/ml of *Eco*RI and incubate for 30 min at 37°C. Then place the coverslip on a drop of 300 U/ml exonuclease III and incubate 30 min at 37°C.

Some commercially available kits contain a cocktail of EcoR1, exonuclease III, and anti-BrdU antibody, or DNase I and anti-BrdU antibody, which will denature the DNA and stain with the antibody in a single step.

Incubate coverslips with antibodies

8. Dilute anti-BrdU antibody in blocking solution according to manufacturer's instructions. Place coverslips cell side down on a drop of anti-BrdU antibody. Incubate coverslips with anti-BrdU antibody for 30 to 60 min at room temperature.

Usually 2 to 5 µg/ml is a good dilution for monoclonal antibodies.

9. Lift the coverslip off the Parafilm with forceps and place cell side up in a petri dish with 5 ml PBS. Wash the coverslips four times in 5 ml PBS for 5 min each time.

Coverslips stained with anti-BrdU antibody conjugated to a fluorophore can now be mounted on slides (step 12).

10. Dilute fluorophore-labeled secondary antibody in blocking solution according to manufacturer's instructions. Remove coverslips from PBS with forceps and place cell side down on a drop of fluorophore-labeled secondary antibody. Wash the coverslips four times in 5 ml PBS for 5 min each time.

Antibodies and fluorophores vary in their affinity and brightness, so there is no universally appropriate dilution. Most suppliers give a recommended dilution; otherwise it will have to be determined empirically—1:200 to 1:5000 is usually appropriate. Higher dilutions will result in less background staining.

Mount coverslips on slides

11. Dip coverslips in a beaker of water to remove any salts and then drain the water off by holding the edge of the coverslip to piece of Kimwipe.

12. Place each coverslip cell side down onto a small drop of mounting solution containing antifade agent on a good-quality, clean microscope slide. Remove any excess mounting solution from around the edge of the coverslip with a Kimwipe, being careful not to dislodge the coverslip. Seal the coverslip around the edge with a small amount of nail polish.

    Commercial mounting solutions are readily available. All mounting solutions should be adjusted to pH 8.5 or greater, because FITC fluorescence is pH sensitive. Mounting solutions containing Gelvatol or Mowiol harden overnight, after which they do not need to be sealed.

    Slides can be stored in the dark up to 3 months at 4°C or −20°C.

13. View the slides under epifluorescence using the appropriate filter set for the fluorophore on the primary or secondary antibody.

    It is helpful to first locate the optical plane with the cells using transmitted light and then visualize the anti-BrdU staining by epifluorescence.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ATP, 100 mM

Dissolve ATP lithium salt (Boehringer Mannheim) in water. Adjust pH to 7.0 with 1 M NaOH. Store in aliquots at −20°C for 1 year.

Bromodeoxyuridine (BrdU), 10 mg/ml (27 mM)

Dissolve 100 mg BrdU in 10 ml water. Filter sterilize through 0.45-µm filter. Divide into aliquots and store up to 6 months at –20°C.

5-Fluorodeoxyuridine (FrdU), 1 mg/ml (4 mM)

Dissolve 10 mg FrdU in 10 ml water. Filter sterilize through 0.45-µm filter. Divide into aliquots and store up to 6 months at –20°C.

Formaldehyde solution

3.7% (v/v) formaldehyde
2% (w/v) sucrose in PBS (see *APPENDIX 2A* for PBS recipe)
Prepare fresh

HCl/Triton X-100

17.4 ml of 11.5 N HCl (2 N final)
0.5 g Triton X-100 (0.5% final)
82 ml double-distilled H_2O
Prepare fresh

Histone H1 solution

10 mg/ml histone H1 from calf thymus (Boehringer Mannheim)
10 mM $NaPO_4$, pH 7.2
Store in aliquots up to 1 year at −20°C

Kinase buffer

250 µl of 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*; 25 mM final)
300 µl of 5 M NaCl (*APPENDIX 2A*; 150 mM final)
100 µl of 1 M $MgCl_2$ (*APPENDIX 2A*; 10 mM final)
100 µl of 0.1 M dithiothreitol (DTT; *APPENDIX 2A*; 1 mM final)
Store in aliquots up to 6 months at −20°C

Lysis buffer

30 ml of 5 M NaCl (0.15 M final)
12 ml of 0.5 M Na_2HPO_4
8 ml of NaH_2PO_4
10 ml of 0.5 M EDTA (5.0 mM final)
10 ml Nonidet P-40 (1.0% v/v final)
10 g sodium deoxycholate (1.0 % w/v final)
1 g SDS (0.1% w/v final)
2.1 g NaF (50.0 mM final)
1.8 g $NaVO_4$ (1.0 mM final)
10 ml aprotinin (1.0% v/v final)
928 ml double-distilled H_2O
Filter through a 0.45-µm membrane
Store up to 1 month at 4°C

Final sodium phosphate concentration is 10.0 mM and final pH is 7.2. This buffer is also known as RIPA buffer.

Tris/sodium/magnesium detergent (TSM)

0.5 g Triton X-100 (0.5% v/v final)
2 ml of 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*; 20 mM final)
1 ml of 5 M NaCl (*APPENDIX 2A*; 50 mM final)
0.3 ml of 1 M $MgCl_2$ (*APPENDIX 2A*; 3 mM final)
96.2 ml double-distilled H_2O
Filter sterilize through 0.45-µm filter
Store up to 6 months at room temperature

COMMENTARY

Background Information

A number of markers can be used to assess the progress of a cell through the cell cycle. Cells in mitosis (M phase) are easily recognized under a phase contrast or differential interference contrast (DIC) microscope by their condensed chromosomes, and DNA replication (S phase) was first recognized many years ago by the incorporation of radiolabeled nucleotides into DNA. The long periods between mitosis and DNA replication were defined simply by the absence of any assayable event (except growth), as is signified by the name given to these periods, G_1 and G_2 (the gap phases). With the advent of flow cytometry, all four cell cycle phases can be easily recognized by the replication state of the DNA. G_1-phase cells have a diploid ($2n$) content of DNA, G_2- and M-phase cells have completed DNA replication and therefore have a tetraploid ($4n$) DNA content, and S-phase cells have an intermediate content.

Much more is understood now about the molecular events underlying progress through the cell cycle than when the phases were named. Progress is controlled by sequential waves of cyclin-dependent kinase (CDK) activity (Fig. 8.2.1). Precisely where a cell is in the cell cycle can be determined by which cyclin-CDK complex is present and active. Cyclin E–CDK2, cyclin A–CDK2, and cyclin B–CDK1 are particularly useful in this respect. The D-type cyclins, with their associated kinase subunits CDK4 and CDK6, are affected by a number of parameters in addition to the stage of the cell cycle. For example, D-type cyclins rapidly disappear when growth factors are removed (Matsushime et al., 1991). The D-type cyclin–CDK complexes must be assayed under different conditions from A-, B-, and E-type cyclin–CDKs because they recognize only a very limited set

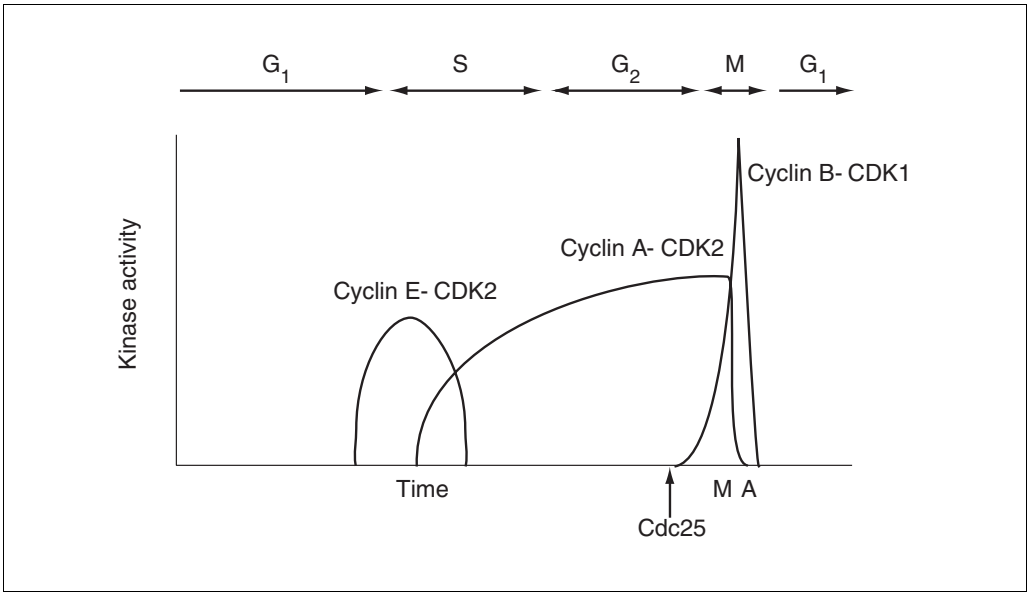

Figure 8.2.1 Appearance and disappearance of specific cyclin-cell-dependent kinase (CDK) activities through the cell cycle. The arrow marks the end of G_2 phase, at which point cyclin B–CDK1 is activated by the Cdc25 phosphatase. The relative kinase activities are not to scale. Abbreviations: M, metaphase; A, anaphase.

of substrates, which does not include histone H1. Of these, the retinoblastoma protein (Rb) is the best characterized (see Phelps and Xiong, 1997, for a more detailed discussion).

The amounts of CDK1 and CDK2 do not vary through the cell cycle, and therefore their activity is regulated by the levels of their cyclin partners. Cyclin levels are regulated both by their synthesis (effectively controlled at the level of transcription) and by their destruction. This is just the first level of regulation, however. Once the CDK has bound its partner cyclin, the complex must be phosphorylated on the T-loop threonine to generate a fully active and stable protein kinase complex. This step is performed by a specific enzyme, CDK-activating kinase (CAK), which in animal cells is itself another cyclin-CDK complex, cyclin H–CDK7, and is sometimes associated with a third protein, MAT1 (reviewed in Morgan, 1995). The phosphorylated cyclin-CDK complex can in turn be regulated by binding a member of a family of specific inhibitor proteins, and by phosphorylation of a threonine and/or tyrosine residue in the ATP-binding region of the kinase (reviewed in Lew and Kornbluth, 1996). These phosphorylation events alter the mobility of the CDK on SDS-PAGE. The final activation of a cyclin-CDK complex is performed by a specific family of phosphatases that dephosphorylate Tyr-14 and Thr-15. This event is responsible for the rapid activation of a preformed pool of cyclin B–CDK1 that drives cells into mitosis. The cyclin B–CDK1 complex is the most active histone H1 kinase in the cell, and its rapid activation is responsible for the peak of histone H1 kinase activity found in whole cell lysates when cells enter mitosis.

Critical Parameters and Troubleshooting

With the exception of the D-type cyclin–CDK4/6 kinases, the cyclin-CDKs are fairly robust kinases. Active cyclin-CDKs can be isolated from cell lysates that have been frozen immediately after isolation, although the kinases are not stable to repeated rounds of freeze/thaw. Cyclin-CDKs can be inactivated if the phosphate is removed from the T-loop threonine, however, and phosphatase inhibitors must be included in the lysis buffer. Okadaic acid is a poor choice as a phosphatase inhibitor, because it can prematurely activate cyclin B–CDK1 (Yamashita et al., 1991). Another phosphatase inhibitor, β-glycerophosphate, seems to have a stabilizing effect on cyclin-CDK complexes.

Negative results in CDK assays are more likely to be caused by failure to immunoprecipitate the kinase than by denaturation of the protein, which underlines the importance of choosing the correct antibody. If there is no detectable activity in samples that should contain a particular cyclin-CDK, the immunoprecipitates should be immunoblotted with anti-CDK and anti-cyclin antibodies. The anti-

PSTAIRE antibody, which recognizes a conserved alpha helix in CDKS with the sequence PSTAIRE in the center, is useful in this respect because it recognizes both CDK1 and CDK2 on immunoblots. Because the CDKs migrate at between 30 and 34 kDa, a normal reducing SDS-polyacrylamide gel can be used for immunoblots. Cyclins A and E migrate close to the heavy chain of the antibody in an immunoprecipitate, however, and can be masked if the secondary antibody binds to the heavy chain. This problem can be ameliorated by using antibodies from different species for the immunoprecipitation and the immunoblot; by cross-linking the antibody to the Sepharose beads; or by using *N*-ethyl maleimide or iodoacetamide in place of β-mercaptoethanol in the SDS-PAGE sample buffer.

A lack of signal in BrdU labeling is generally caused either by loss of cells from the coverslips during too-vigorous washing (especially before fixation) or by addition of the solutions to the wrong side of the coverslip. Check that there are cells on the slide at the end of the protocol by phase contrast or DIC microscopy. If the coverslips are dropped, it is very difficult to tell which side the cells are on. If the cells are dense enough, try scraping a small area with a needle and looking under a microscope to see if cells have been scraped away. Other problems are usually caused by defective antibodies (e.g., the fluorophore of the secondary antibody) or by defective enzymes in the nuclease method.

Anticipated Results

The cyclin-CDK complexes differ in their activity against histone H1 in the order: cyclin B–CDK1 > cyclin A–CDK1 = cyclin A–CDK2 >> cyclin E–CDK2. The amount of histone H1 kinase activity in any individual immunoprecipitate will vary, therefore, according to which cyclin-CDK is being measured and the stage of the cell cycle. Moreover, some transformed cells have altered levels of different cyclin-CDKs (e.g., cyclin E–CDK2 is overexpressed in a variety of cancer cell lines); therefore, results may differ between cell types.

The length of S phase will depend on the cell type being studied; S phase is ~6 to 8 hr long in many common human and mouse cell lines. When detecting DNA replication using BrdU, the number of positive cells will depend on the length of time for which BrdU is added to the medium and the proliferation state of the cells. With short pulses of BrdU, the sites of DNA replication will appear as distinct dots in the nucleus of the cell. They are easily seen with a ≥40× magnification lens. The number and size of the dots will depend on whether the cell is in early S phase (many small dots) or late S phase (fewer, bigger dots, more around the edge of the nucleus).

Time Considerations

Assuming a 1-hr incubation with the primary antibody, it should take ~3 hr to perform the steps from cell lysis through the kinase assay, and 90 min more to load the samples in the scintillation counter. Analysis of the samples by SDS-PAGE will take another 3 hr before the gel is exposed to X ray film.

For Basic Protocol 2, it should take ~3.5 hr from the time the coverslips are removed from the labeling medium until it is possible to view the slides under the microscope.

Methods for Synchronizing Cells at Specific Stages of the Cell Cycle

The protocols presented here describe procedures used to synchronize cells in various stages of the cell cycle (Fig. 8.3.1). Synchronization is particularly useful for investigating a particular cell cycle–regulated event or preparing cells for extraction of transient factors whose expression is dependent on cell cycle stage. Exponentially growing cultures are generally asynchronous; i.e., each cell progresses through the cell cycle independently of the cell cycle stage of its neighboring cells. Cells that are synchronized are artificially induced to cycle in a homogeneous manner. The ability to continue cycling is an important distinction between a homogeneous population of cells created by synchronization and one created by blocking cells from cycling. Blocking cells from cycling may also result in a homogeneous population of cells at a particular stage of the cell cycle, but often results in death of the cell. In contrast, the purpose of synchonization is to create an enriched population of cells at a single stage of the cell cycle; these cells will then be able to continue through the cell cycle with as little disruption of normal events as possible. For a comprehensive review of events and explanation of the salient features of each of these stages see Pines (1995), Hartwell and Kastan (1994), *UNIT 8.1,* and the chapter introduction.

Techniques will be presented for synchronizing cells in the G_1, S, and M phases of the cell cycle. These techniques include a selection of methodologies that capitalize on the biology and biochemistry of eukaryotic cells, such as selective nutrient depletion (e.g., isoleucine deprivation, see Alternate Protocol 3; and serum withdrawal, see Basic Protocol 2), feedback control through addition of excess nutrients (e.g., thymidine, see Basic Protocol 4), morphological differences (e.g., mitotic shake-off, see Basic Protocol 1), or the use of chemical agents to reversibly arrest cells at a particular cell cycle stage (e.g., lovastatin, see Basic Protocol 3; mimosine, see Alternate Protocol 4; and nocodazole, see Alternate Protocol 2). The protocols can be modified to enhance for mitotic cells (see Alternate Protocol 1) or to provide sequential G_1/S blocks (see Alternate Protocol 5). Methods are provided for determining the mitotic index (see Support Protocol 1) and for measuring DNA synthesis by trichloroacetic acid (TCA) precipitation of [^{3}H]thymidine-labeled DNA (see Support Protocol 2).

STRATEGIC PLANNING

Prior to selecting a method of synchrony there are several factors to consider.

Stage of Analysis Versus Stage of Synchrony

In general, it is best to synchronize cells as close to the start of the cell cycle phase to be studied (Fig. 8.3.2). In most cases, cells will not maintain a high degree of synchrony through several rounds of cell division. In order to follow the expression of factors as a function of progression through a cell cycle phase, it is usually best to synchronize cells in the phase prior to the actual phase to be investigated. For example, to investigate the S phase–specific expression of a G_1/S phase–cyclin protein (Gong et al., 1995), it may be necessary to synchronize cells in G_1 or at the G_1/S boundary using isoleucine deprivation or isoleucine deprivation coupled with aphidicolin treatment, respectively. The most difficult phase in which to investigate events related to both entry into and exit from is G_1, mainly because of the high degree of variability in G_1-phase progression.

Degree of Uniformity

Inherent in the strictness of this requirement is the specificity of the event to be analyzed. Ideally, cell cycle events that exhibit a broad window of action or expression would not require a high degree of synchrony, and measurements could be made over a longer period of time. In contrast, investigations of rare events with a short window of detection are often the most difficult, requiring a high degree of synchrony in the cell population in order to detect differences.

Number of Cells Required

This is determined in part by the sensitivity of the detection method selected. Cost and time are typically inversely related to the number of cells and degree of synchrony required. In cases where a large number of synchronized cells are required for biochemical

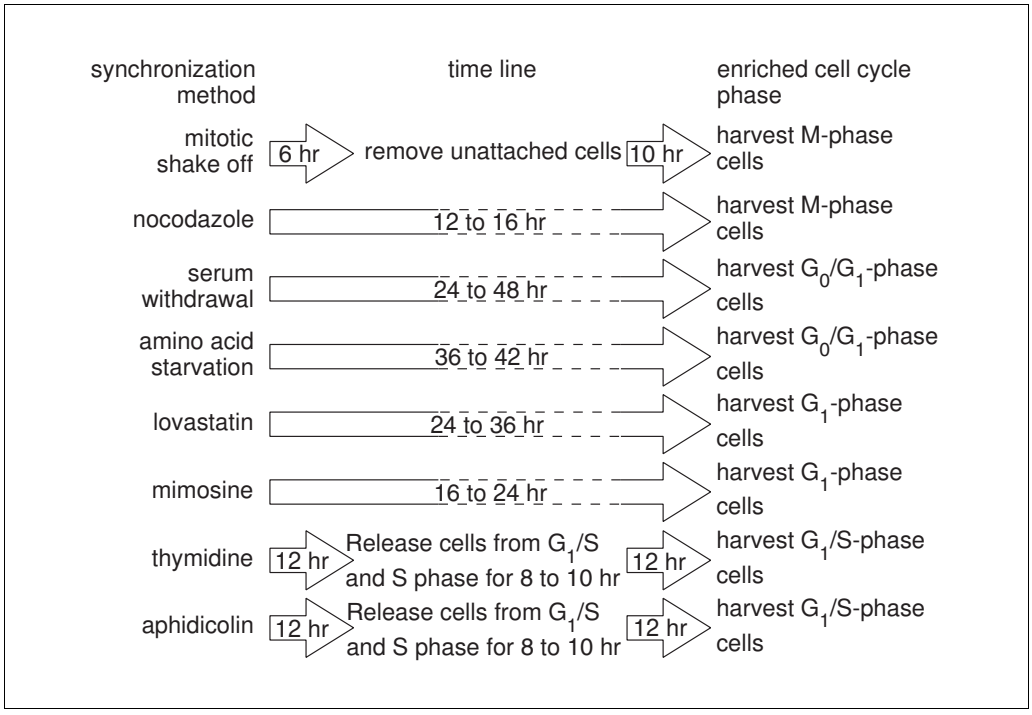

Figure 8.3.2 Quick reference guide to synchronization methods. Indicated times are for cultures with 24 hr doubling time.

characterization of a rare cell cycle event, some procedures, such as double aphidicolin exposure (see Alternate Protocol 5), can be expensive, while the same procedure may be an inexpensive and time-efficient means of obtaining a few hundred highly synchronized cells for analysis by immunofluorescent microscopy.

Doubling Time

All of the protocols discussed here are recommended for cells with doubling times <30 hr. Some may be used for cells with longer doubling times, but the efficacy of the protocol will depend on the specifics of the cells used. While all synchrony methods result in a population of cells enriched in a particular cell cycle phase, cell synchronization is relatively transient, producing synchronous populations for a single cycle. Synchrony generally diminishes each time cells pass through G_1 phase, since this is the most temporally variable stage of the cell cycle. Within a population of cells, G_1 phase averages between 8 and 16 hr for most rapidly dividing cell lines. Progression through S phase requires ~8 hr, through G_2 ~2 additional hours, and completion of M phase occurs 0.5 to 1 hr later.

Chemical Inhibitors

Chemicals that inhibit cell cycle progression are advantageous for synchronization because they are effective in a large variety of cell types, require no special equipment, and lend themselves to applications that require large numbers of cells. Indeed, chemical inhibitors are often the primary method of synchronizing cells at a particular stage of the cell cycle. There are two main disadvantages to chemical synchronization: (1) chemical treatment has been linked to the possible disruption of normal cell cycle regulatory processes (Schimke et al., 1991; Gong et al., 1995), and unbalanced cell growth induces an apoptotic phenotype in some cell types; and (2) chemicals may have more than one target in cells, some of which may not be fully known. With any experiment, however, careful design of controls is of greatest importance when using chemical synchronization.

Assessment of Synchronization

Assessment of the quality of synchronization is dependent on the equipment available. The best method for following overall changes in the distribution of cycling cells is flow cytometry. The most up-to-date benchtop versions of flow cytometers, such as the Becton Dickson FACScan/FACSCaliber and the Coulter Epics, are relatively simple to use, and the preparation of material for analysis is both rapid and inexpensive. If no flow cytometer is readily available, there are biochemical ways to determine cell synchrony. The first method measures the progression of cells through S phase. Short pulses of [^{3}H]thymidine in control and synchronized cultures are compared over time to monitor for peaks in [^{3}H]thymidine incorporation as an indicator of active replication and the maximum number of cells in S phase. This method can also be adapted to the fluorescent microscope using bromodeoxyuridine (BrdU)-labeled cells rather than [^{3}H]thymidine (*UNIT 8.2*). All cells that were in S phase during the pulse of BrdU can be followed through the cell cycle by labeling them with FITC. The second method measures the expression or sequential activation of cyclin-dependent kinases as an indicator of cell cycle stage. As demonstrated by Hunter, Pines and others (Minshull et al., 1989; Pines, 1995; Hunter and Pines, 1994; Brandeis and Hunt, 1996), cyclins are sequentially expressed and/or stabilized as cells move from G_1 into M phase (Table 8.3.1).

Immunoblotting (*UNIT 6.2*) for the various cyclins or in vitro kinase assays following cyclin-specific immunoprecipitation (*UNIT 8.2*) can be used to assess cyclin expression or activity. One caveat to this methodology is the fact that a large number of transformed cell lines inappropriately or constitutively express one or more cyclins (Buckley et al.,

Table 8.3.1 Characteristic Cyclin Expression Profiles and Activation as a Function of Cell Cycle Stage[a]

Cell cycle stage	Cyclin	Kinase activated
Early G_1	D-type	CDK4, CDK6
Mid-late G_1	E	CDK2
gc S phase	A	CDK2
G_2/M	A, B	cdc2

[a]Abbreviations: CDK, cell-dependent kinase; cdc, cyclin-dependent kinase.

1993; Keyomarsi and Pardee, 1993; Leach et al., 1993). This should be evaluated prior to using this method of assessment of cell cycle progression and synchronization. Finally, the mitotic index (a morphological evaluation of cell synchrony) can be used to compare asynchronous controls and synchronized cells for the appearance of rounded cells with condensed chromatin (O'Connor et al., 1993). This method has the advantage that no special equipment is required, although the evaluation of ≥500 events per sample is somewhat labor intensive and does not lend itself well to evaluating early G_1 synchronization.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

BASIC PROTOCOL 1

ENRICHMENT OF MITOTIC CELLS BY MITOTIC SHAKE-OFF

Mitotic shake-off is one of the oldest and perhaps easiest methods for obtaining mitotically enriched populations of cells (Morla et al., 1989; Pines and Hunter, 1989; Pagano et al., 1992). This method is based on the observation that as cells progress into metaphase during mitosis they become rounded and have fewer points of attachment with the culture vessel (Elvin and Evans, 1983; Zwanenburg, 1983).

This procedure is applicable to most monolayer cells. Collection of pure populations of mitotic cells allows the measurement of cell cycle–related events during the M/G_1/S phase transitions. Each cell type requires some characterization to determine the most suitable times at which cells should be harvested following release.

This procedure has several advantages. This technique is based on normal cellular processes rather than extrinsic control by experimental manipulation and does not require special equipment or reagents other than those commonly available in the average cell culture facility. However, this procedure is not applicable to suspension cultures or weakly adherent cultures, such as some neuronal cell types. Only a small proportion of the cells, 1% to 5% of the typical exponential asynchronous culture, may be in mitosis at any one time; therefore, a limitation of the procedure is the low yield of mitotic cells obtained from exponentially growing cultures. To overcome this drawback and preenrich for mitotic cells, one can carry out short incubations with mitotic inhibitors, and/or release cells from G_1/S-phase synchronization using the procedures described below, and capture cells by shake-off as they progress into M. Although this procedure is used for following the progression of cells into G_1, the same degree of synchrony is not maintained as cells progress through subsequent S and G_2 phases.

The following protocol describes mitotic shake-off using the adherent HT-29 colon cell line. It has also been used with CHO cells, HeLa cells, and a number of other colon and breast cell lines.

Materials

Human colon carcinoma cell line (HT-29 cells), grown in 162-cm^2 tissue culture flasks
RPMI-15: RPMI 1640 supplemented with 15% (v/v) heat-inactivated fetal bovine serum (FBS; *APPENDIX 2A*), prewarmed to 37°C
RPMI 1640 medium (*APPENDIX 2B*), prewarmed to 37°C
0.5× trypsin solution (see recipe)

Additional reagents and equipment for trypsinizing and counting cells (*UNIT 1.1*)

1. Trypsinize (*UNIT 1.1*) subconfluent cultures of HT-29 cells and replate in prewarmed RPMI-15 at one-half to one-third maximum density. Incubate at 37°C until 70% to 80% confluent.

   This ensures that the maximum number of cells will be replicating in the culture.

2. Remove the growth medium and wash cells once with prewarmed RPMI 1640. Add 3 ml of 0.5× trypsin solution and incubate cells 5 min at 37°C.

3. Tap the flasks on the bench to shake off any loosely attached rounded cells and add 20 ml prewarmed RPMI-15. Transfer cell suspension to 15-ml centrifuge tubes and centrifuge 5 min at 500 × *g*, room temperature.

4. Discard supernatant, resuspend pellet in 20 ml prewarmed RPMI-15, and centrifuge 5 min at 500 × *g*, room temperature. Discard supernatant and resuspend pellet in 20 ml prewarmed RPMI-15.

5. Count cells (*UNIT 1.1*) and adjust concentration to 2.5 × 10^5 cells/ml in prewarmed RPMI-15.

6. Transfer 20 to 40 ml of cell suspension to 162-cm^2 flasks and incubate 6 hr at 37°C. Observe the cultures to see if cells have reattached.

7. Shake flasks, swirl medium over the flask surface, and pipet off the medium. Repeat wash twice with 20 ml prewarmed RPMI-15 each time. Add 20 ml fresh, prewarmed RPMI-15 and incubate 10 hr at 37°C.

   The washing step removes any unattached cells.

8. Observe the cultures for evidence of cell rounding. Gently shake or tap the flasks on the bench and swirl the medium around the flask. Remove the medium, which contains mitotic cells.

9. Pool the medium from several flasks and centrifuge 5 min at 500 × *g*, room temperature, to pellet the mitotic cells.

10. Resuspend cells in RPMI-15, count cells (*UNIT 1.1*), and adjust cell density to 5 × 10^5 cells/ml in RPMI-15. Analyze cells by flow cytometry, Giemsa staining for mitotic chromatin condensation, or phase-contrast microscopy for rounded cells.

    For Giemsa staining, submerge an air-dried slide in 0.1 to 0.2 mg/liter Giemsa (Sigma, Life Technologies) for 10 min. Gently rinse stain away by dipping in 1× PBS and air dry the slide.

ALTERNATE PROTOCOL 1

PRE-ENRICHMENT OF EXPONENTIAL CULTURES FOR MITOTIC CELLS

Short incubations with S phase–synchronizing agents, such as excess thymidine (see Basic Protocol 4), will increase the proportion of cells in M phase. Release cells from this block by thoroughly washing and collecting them ~10 hr later, when significant numbers of rounded cells are observable in the culture. Alternatively, add 0.4 µg/ml nocodazole 5 to 6 hr before shake-off to arrest cells as they progress through M phase.

ALTERNATE PROTOCOL 2

ENRICHMENT OF MITOTIC CELLS BY NOCODAZOLE ARREST

Nocodazole chemically interferes with the organization of microtubules in cells. Microtubule formation is an important structural feature of cells as they enter mitosis. Several drugs, including vincristine and colcemid, are similar to nocodazole in that they interfere with microtubules and cause arrest in G_2/M. Unlike nocodazole, however, the effects of these agents may not be completely or readily reversed.

Nocodazole arrests both suspension and adherent cells in a prophase to pseudo-metaphase state. Interpretation of results and discernment of mitotic figures may be more difficult when nocodazole is used since nocodazole disrupts microtubules. Microtubules are required for the condensation of chromatin and alignment on the metaphase plate. This procedure has been used to obtain large amounts of activated cyclin B-cdc2-dependent kinases.

Nocodazole is inexpensive and specific in acting on cells in the post-replicative period. It can be added to actively growing cultures without residual effects on other cell cycle stages. Nocodazole is useful for obtaining large numbers of highly synchronized cells. Some cell lines are defective in sensing disruption of the microtubular network and will not arrest in G_2/M, but will instead continue to cycle and undergo abnormal mitosis. Nocodazole can exhibit toxicity at concentrations close to its effective concentration for some cell lines, so the optimal concentration should be determined prior to preparing large amounts of material. The concentration used in this protocol works well with CA46 cells, but lower concentrations may be used with other cell lines. Effective concentrations range from 10 to 400 ng/ml. High concentrations of nocodazole notably diminish cell synchrony following reentry into the cell cycle.

The use of the suspension cell line, CA46, is described in this protocol. Other lymphoma cell lines, breast cell lines, colon cell lines, and HeLa cells have also been used.

Materials

CA46 cells, grown in 75-cm^2 tissue culture flasks
0.4 mg/ml nocodazole (diluted from 4 mg/ml nocodazole; see recipe)
RPMI-15: RPMI 1640 supplemented with 15% heat-inactivated FBS (*APPENDIX 2A*), prewarmed to 37°C

Additional reagents and equipment for counting cells (*UNIT 1.1*)

1. Grow CA46 cells to subconfluency (0.5 to 1.0 × 10^6 cells/ml). Count cells (*UNIT 1.1*) and adjust concentration to 5 × 10^5 cells/ml in 20 ml prewarmed RPMI-15.

   At this dilution, the maximal number of cells should be replicating within the culture.

2. Add 0.4 mg/ml nocodazole to cultures at a final concentration of 400 ng/ml.

3. Incubate cells 12 to 16 hr at 37°C.

4. Centrifuge cells 5 min at 500 × *g*, room temperature, discard supernatant, and resuspend pellet in 20 ml fresh, prewarmed RPMI-15. Repeat centrifugation and addition of 20 ml prewarmed RPMI-15.

5. Transfer cell suspension to fresh 75-cm^2 tissue culture flasks and incubate 4 hr at 37°C. Monitor cultures during this next 4-hr period for an increase in cell number.

An increase in cell number indicates progression into G_1 phase. Mitotic index, due to the effect of nocodazole on microtubules, may be more difficult to measure if nocodazole is used. The mitotic figures seen following release from nocodazole are sometimes aberrant and less distinct (these probably result from cells trapped in mitosis at the time of application). In addition it is easier and faster to merely count cells than to perform mitotic index measurements if progression through M phase is being measured.

ENRICHMENT OF CELLS AT G_0/G_1 BY SERUM STARVATION

BASIC PROTOCOL 2

This protocol describes enrichment of cells at G_0/G_1 by serum starvation (Campisi et al., 1984). Although some fibroblasts begin entering G_0 within 1 hr (Pardee, 1989), it may take 24 to 48 hr for an entire population to respond to serum withdrawal. Before using this technique, it is important to determine the confluent/maximum cell density the cells will achieve (cells/ml or cells/cm^2).

The method described below is for monolayer cultures, although the procedure can be adapted to suspension cultures. This procedure has been used in many cell cycle–related studies, including analysis of the cell cycle–dependent reversible tyrosine phosphorylation of cdc2 (Morla et al., 1989) and regulation of cyclin A (Girard et al., 1991; Carbonaro-Hall et al., 1993). This simple method for obtaining G_0 cells requires no special equipment or reagents and is effective on cell types that do not respond to confluence arrest. Serum withdrawal may require extensive optimization of both the amount of serum withdrawn and the length of withdrawal. Withdrawal of serum for extended periods will actually reduce the synchronicity of the restimulated population. For some cell types, serum starvation is not a viable method of synchronization, because cells permanently arrest in G_0, do not arrest, or undergo apoptosis.

The use of 3T3 cells, a fibroblastic cell line, is described in this protocol. This procedure has also been shown to be effective in producing a G_0-like state in myoblasts (Puri et al., 1997), CHO fibroblasts (Tesfaigzi and Carlson, 1996), and MOLT-4 leukemia cells (Dbaibo et al., 1995).

Materials

NIH-3T3 cells, grown in 100-mm tissue culture plates
1× trypsin (Life Technologies)
DMEM (*APPENDIX 2A*), prewarmed to 37°C
DMEM-0.5: DMEM supplemented with 0.5% (v/v) heat-inactivated FBS (*APPENDIX 2A*), prewarmed to 37°C
DMEM-10: DMEM supplemented with 10% (v/v) heat-inactivated FBS, prewarmed to 37°C

Additional reagents and equipment for trypsinizing and counting cells (*UNIT 1.1*)

1. Trypsinize (*UNIT 1.1*) exponentially growing NIH-3T3 cells grown in 100-mm tissue culture plates, using 1× trypsin.

2. Transfer detached cells to 15-ml conical centrifuge tubes and centrifuge cells 5 min at 500 × *g,* room temperature. Discard supernatant, resuspend pellet in 10 ml prewarmed DMEM, and repeat centrifugation. Repeat wash.

3. Plate cells at 30% to 40% of their confluent density in 15 ml DMEM-0.5 and incubate 24 to 48 hr at 37°C.

   A 24- to 48-hr period of serum starvation allows cells time to sequester into a G_0-like state. This time period gives cells that have passed the restriction point (Pardee, 1974, 1989) the opportunity to proceed through the remainder of the cell cycle and arrest upon reentry into G_1 of the next cell cycle.

4. Remove DMEM-0.5 and add 15 ml DMEM-10. Incubate at 37°C.

   The addition of medium containing 15% FBS stimulates the cells to reenter the cell cycle. NIH-3T3 cells progress into S phase ~12 hr after stimulation; this time will vary depending on the cell type.

ALTERNATE PROTOCOL 3

ENRICHMENT OF CELLS AT G_0/G_1 BY AMINO ACID STARVATION

A large number of synchronous G_0 cells can be obtained by amino acid starvation (Tobey and Crissman, 1972). Omission of isoleucine, an essential amino acid, from the medium causes cells to sequester in a G_0/G_1-like state. Methionine depletion has also been successfully used to synchronize cells (Sallot et al., 1996). In some tumor cell lines, however, this treatment may produce a late S/G_2-phase arrest (Hoshiya et al., 1996). In the author's experience, depleting both isoleucine and methionine does not result in greater synchronization, but rather increases the likelihood of irreversible G_1 arrest and cell death. Before using this technique, it is important to determine the doubling time of the exponentially growing culture.

This procedure can be used with suspension or adherent cell lines to follow the progression of early G_1 cells into the cell cycle. Cells cycle synchronously upon release (addition of complete medium) for an entire cell cycle through cytokinesis. This method does not require exogenous chemicals to cause cell cycle arrest but makes use of the intrinsic biology of the cell. Notably, not all cell types will become synchronous with this procedure. Some transformed cells lines are defective in nutrient checkpoint control and will continue through the cell cycle irregularly. In other cell types, nutrient deprivation induces cell death or partial differentiation rather than transient arrest.

Materials

CA46 cells, grown in 162-cm^2 tissue culture flasks
Isoleucine-free minimal essential medium (e.g., Select-Amine Minimal Medium, Life Technologies), prewarmed to 37°C
Dialyzed FBS (Life Technologies)
RPMI-15: RPMI 1640 supplemented with 15% (v/v) heat-inactivated FBS (*APPENDIX 2A*)

1. Centrifuge exponentially growing CA46 cells 5 min at 500 × *g*, room temperature. Discard supernatant, resuspend pellet in 50 ml prewarmed isoleucine-free minimal essential medium without serum, and centrifuge again. Repeat wash.

2. Resuspend cells at 35% to 40% of their confluent density in (4×10^6 cells/ml) isoleucine-free minimal essential medium/10% dialyzed FBS, transfer to appropriate size tissue culture flasks, and incubate 36 to 42 hr at 37°C.

   This time period is equivalent to one and one-half to two cell cycles for CA46 cells. This time should be appropriately adjusted for each cell type.

   Prolonged culture under these conditions will lead to increased toxicity, genetic aberrations, and, in some cases, irreversibility of the arrest.

3. Transfer cells to 50-ml centrifuge tubes and centrifuge 5 min at 500 × *g*, room temperature. Discard supernatant and resuspend pellet in RPMI-15 at a final cell density of 0.5×10^6 cells/ml.

   Avoid rough or unnecessary handling of the cells following the starvation procedure because the cells may be more fragile than exponentially growing cells.

   Adherent cells should be treated cautiously as they may not be as tightly attached to the plate and may be dislodged by the removal of the isoleucine-free medium or addition of the fresh complete medium.

ENRICHMENT OF G_1-PHASE CELLS USING LOVASTATIN

BASIC PROTOCOL 3

Lovastatin inhibits HMG-CoA reductase (3-hydroxy-3-methylglutaryl-coenzyme A reductase), resulting in the depletion of mevalonate, which is an essential precursor of cholesterol synthesis and a requirement for isoprenylation of substrate molecules, including p21 ras (Wejde et al., 1993).

Lovastatin has been demonstrated to block a variety of cell types, including adherent and suspension cells, in very early G_1 phase rather than in G_0, as defined by the presence of the proliferation-specific antigen Ki-67 (Keyomarsi et al., 1991). Lovastatin has been effectively used to synchronize breast cancer cells (Bonapace et al., 1996; Wilcken et al., 1997) and Jurkat cells (Martel et al., 1997). Lovastatin is a convenient and rapid inhibitor of early G_1 cells, requiring a single cell cycle to induce a G_1 block. Lovastatin is not effective with all cell types, and in some cell types it also induces a partial arrest of cells in G_2/M (Jakobisiak et al., 1991). Lovastatin is more expensive than some other methods described for generating G_1 populations, and it requires careful optimization of concentration and timing in order to obtain maximal synchronization.

This protocol describes a method by which lovastatin can be used to synchronize breast cancer cells in G_1 phase.

Materials

MCF-7 cells, grown in 100-mm tissue culture plates
1× trypsin (Life Technologies)
DMEM-10: DMEM supplemented with 10% (v/v) heat-inactivated FBS (*APPENDIX 2A*), prewarmed to 37°C
10 mM activated lovastatin (see recipe)
DMEM-10 containing 5 mM mevalonate (Sigma)

Additional reagents and equipment for trypsinizing and counting cells (*UNIT 1.1*)

1. Trypsinize (*UNIT 1.1*) exponentially growing MCF-7 cells using 1× trypsin and replate in 15 ml DMEM-10 at a cell density equivalent to 30% to 35% of maximum.

   This prevents growth arrest due to confluence.

2. Add 10 mM activated lovastatin to the culture medium at a final concentration of 40 µM and incubate 24 to 36 hr at 37°C.

   This incubation should last for at least one doubling time; times may vary according to the cell type.

   Effective concentrations of lovastatin vary according to the cell type and should be optimized; concentrations ranging between 10 and 60 µM have been reported (Keyomarsi et al., 1991).

3. Trypsinize cells in 3 to 5 ml 1× trypsin. Add 5 ml prewarmed DMEM-10 to cells and centrifuge 5 min at 500 × *g*, room temperature. Discard supernatant, resuspend pellet in 10 ml prewarmed DMEM-10 and repeat centrifugation. Repeat wash.

4. Resuspend cells at 35% to 40% of their confluent density in 15 ml DMEM-10 containing 5 mM mevalonate.

   The mevalonate concentration should be ~100-fold the concentration of lovastatin used. Key regulatory proteins that require isoprenylation for activity will be modified following release of the cells from the lovastatin block.

5. Monitor cells for progression through G_1 and S phases by flow cytometry, activation of cyclin E– or cyclin A–dependent kinases, or incorporation of labeled nucleotide precursors into DNA (see Support Protocol 2).

ALTERNATE PROTOCOL 4

ENRICHMENT OF G_1-PHASE CELLS BY MIMOSINE ARREST

Mimosine, a plant-derived amino acid whose cellular target is still unclear, blocks cells either in late G_1 phase (Lalande, 1990) or at the G_1/S boundary (Watson et al., 1991; Mosca et al., 1992), depending on the relevance of the recovery period to the timing of initial [^{3}H]thymidine incorporation. When used alone or in combination with prior isoleucine synchronization, mimosine arrests cells with a diploid DNA content (Mosca et al., 1992, Dijkwel and Hamlin, 1992). Mimosine is an effective inhibitor of S-phase entry in mammalian fibroblastic cell lines and human leukemic cell lines, and it inhibits DNA replication in *Xenopus* extracts (Gilbert et al., 1995). Mimosine is an inexpensive and stable inhibitor of cell cycle progression and is relatively non-toxic compared with other chemical inhibitors, such as aphidicolin. Unlike aphidicolin, however, mimosine requires several hours to inhibit cell cycle progression. Studies monitoring cell cycle progression indicate that replication is initiated 1 to 2 hr after release from mimosine-induced blockade.

There is some debate as to the target and position in the cell cycle at which mimosine arrests cells. It has been reported that mimosine inhibits enzymes involved with thymidine biosynthesis (Kalejta and Hamlin, 1997) and other enzymes involved with nucleotide biosynthesis (Gilbert et al., 1995). The lack of clarity as to the exact target and site of action of mimosine could complicate the use of mimosine to study defined events in nucleotide regulation or incorporation.

Materials

CA46 cells, grown in 75-cm^2 tissue culture flasks
RPMI-15/mimosine: RPMI supplemented with 15% (v/v) heat-inactivated FBS (*APPENDIX 2A*) and 400 μM mimosine (diluted from 100 mM mimosine; see recipe), prewarmed to 37°C
RPMI-15: RPMI supplemented with 15% (v/v) heat-inactivated FBS, prewarmed to 37°C

1. Centrifuge 5–25 × 10^6 exponentially growing CA46 cells or CA46 cells synchronized by prior isoleucine deprivation (see Alternate Protocol 3) 5 min at 500 × *g*, room temperature. Discard supernatant and resuspend pellet in prewarmed RPMI-15/mimosine to give a final cell concentration of 0.4 × 10^6 cells/ml.

   Effective concentrations of mimosine range from 100 to 400 μM.

2. Incubate cells 6 to 24 hr (exponentially growing cells) or 14 hr (isoleucine-deprived cells) at 37°C.

3. Centrifuge cells 5 min at 500 × *g*, room temperature. Discard supernatant, resuspend pellet in 10 ml prewarmed RPMI-15, and repeat centrifugation. Repeat wash and resuspend cells in prewarmed RMPI-15 at a cell density equivalent to 35% to 40% of their confluent density (0.4 × 10^6 cells/ml).

4. Monitor progression of cells into S phase by incorporation of labeled nucleotide precursors into DNA (see Support Protocol 2) or flow cytometry.

SYNCHRONIZING CELLS AT THE ONSET OF S PHASE BY DOUBLE-THYMIDINE BLOCK

Synchronization of cells at the G_1/S phase border is generally achieved by inhibition of DNA synthesis using chemical inhibitors, including aphidicolin, hydroxyurea, or excess thymidine (Tobey and Crissman, 1972; Thomas and Lingwood, 1975; Heintz et al., 1983).

Synchronization of cells with excess thymidine was the first reliable method to be widely used (Bootsma et al., 1964, Stein and Borun, 1972). The method involves two sequential exposures to high levels of thymidine, with each exposure separated by an interval determined from knowledge of the normal cell cycle distribution of the exponentially growing cells and the recovery time from the thymidine block. The method is most useful to measure S- and G_2/M-phase events. The procedure is good for one cell cycle passage; the cells lose synchrony rapidly thereafter.

Thymidine is an inexpensive and readily available inhibitor of the cell cycle. Unlike many inhibitors, the mechanism by which thymidine blocks the cell cycle is well understood and attributable to feedback inhibition of the nucleotide synthesis (Thomas and Lingwood, 1975). It may be difficult to accurately measure DNA synthesis by measuring [^{3}H]thymidine incorporation, because of the large pools of thymidine in cells, especially early in S phase. Prolonged disruption of the cell cycle with thymidine results in genetic aberrations presumably caused by misreplication events.

Before using this technique, it is important to determine the doubling time of the exponentially growing culture. The procedure described below is for the synchronization of HeLa cells based on a doubling time of 24 hr.

This protocol can be used for both adherent and suspension cells. The only requirement is that cells display a robust doubling time of less than 24 to 30 hr. Doubling times outside this range may require alterations in the timing of thymidine application and release (see Critical Parameters and Troubleshooting).

Materials

HeLa cells, grown in 162-cm^2 tissue culture flasks
DMEM-10/thymidine: DMEM supplemented with 10% (v/v) heat-inactivated FBS (*APPENDIX 2A*) and 2 mM thymidine (diluted from 100 mM thymidine; see recipe), prewarmed to 37°C
DMEM, prewarmed to 37°C
DMEM-10: DMEM supplemented with 10% (v/v) heat-inactivated FBS (*APPENDIX 2A*), prewarmed to 37°C
1× trypsin (Life Technologies)
1× PBS, pH 7.4 (*APPENDIX 2A*)

Additional reagents and equipment for trypsinizing and coating cells (*UNIT 1.1*)

1. Plate exponentially growing HeLa cells at 30% to 50% confluence in 15 ml DMEM-10/thymidine and incubate 12 hr at 37°C.

   This time period is equivalent to the progression through G_2/M and G_1 phases. During this period, the G_2/M cells will progress into G_1 and then with the original G_1 cells will achieve a biochemical state equivalent to G_1/S-phase border cells. Any cells in S phase when thymidine is added will become blocked in S phase.

2. Remove the the thymidine-containing medium with a pipet and rinse the dishes twice with 10 ml prewarmed DMEM each time.

   Thoroughly rinse all surfaces of the dish to prevent carryover of thymidine.

3. Trypsinize cells using 1× trypsin, resuspend in 10 ml DMEM-10, and count the number of cells in suspension (*UNIT 1.1*). Replate the cells at 30% to 35% of their confluent density in 15 ml prewarmed DMEM-10 and incubate 16 hr at 37°C.

   During this period, the cells will recover from the thymidine block (~1 to 2 hr), progress through the cell cycle, divide, and enter G_1 of the next cell cycle. If the cells are expected to progress through two more cycles, they should be plated at ~25% of their confluent density.

   Progression of cells through the first thymidine block can be monitored by determining cell number. Approximately 5 to 6 hr after removal of the thymidine, cells that were blocked at the end of S phase (the leading-edge cells) will enter G_1 of the next cell cycle and an increase in cell number will be detectable. Incubation in medium without added thymidine should occur ~8 to 10 hr later in order to give lagging-edge cells (those arrested at G_1/S in the first block) sufficient time to progress through S phase.

4. Remove medium with a pipet and replate with 15 ml prewarmed DMEM-10/thymidine and incubate 12 to 14 hr at 37°C.

   Cells in G_2/M or G_1 will progress and arrest at the G_1/S-phase border.

5. Remove the the thymidine-containing medium with a pipet and rinse the dishes twice with 15 ml DMEM-10 each time.

   Thoroughly rinse all surfaces of the dish to prevent carryover of thymidine.

6. Monitor the progression of cells into S phase by flow cytometry, into G_2/M by assembly and activation of cyclin B-cdc2-dependent kinase (*UNIT 8.2*), or through M phase by cell rounding, mitotic index (see Support Protocol 1), or increases in cell number.

ALTERNATE PROTOCOL 5

PERFORMING SEQUENTIAL G_1/S BLOCKS

Variations on the double thymidine–block strategy have evolved with time. A commonly used variant technique involves a first block with thymidine and a second block with aphidicolin (Heintz et al., 1983) or alternatively a double-aphidicolin block (O'Connor et al., 1993). Essentially the same basic principles as described in Basic Protocol 4 for the double-thymidine block apply to the use of aphidicolin. The use of thymidine and aphidicolin procedures for synchronizing cells at the G_1/S-phase border proved useful in determining the regulation of various cell cycle–related processes, including the regulation of histone gene expression (Heintz et al., 1983), regulation of cyclin B (Pines and Hunter, 1989), and effect of DNA damage on the formation and activation of cyclin A– and cyclin B–dependent kinases (O'Connor et al., 1993). Starvation methods paired with sequential aphidicolin treatment are particularly useful for obtaining highly synchronous populations of G_1/S cells (Heintz and Hamlin, 1982, Burhans et al., 1986).

Aphidicolin is a specific inhibitor of eukaryotic DNA polymerase (Heintz and Hamlin, 1982). Treatment of cells with aphidicolin prohibits S-phase cells from progressing through the remainder of S phase, while G_1 and G_2/M cells continue to cycle to the G_1/S boundary (Burhans et al., 1986). For this reason, a single aphidicolin block is not usually sufficient to obtain a highly synchronous culture. Aphidicolin can be substituted for thymidine during both blocks in Basic Protocol 4, by adding aphidicolin (see recipe) to exponentially growing cells at a final concentration of 0.1 μg/ml aphidicolin.

The point at which aphidicolin blocks the entry of cells into S phase is much better characterized and closer to the start of S phase than the point at which excess thymidine blocks. Incorporation of nucleotide precursors into DNA begins <15 min after release of cells from aphidicolin (Burhans et al., 1986); therefore, aphidicolin may be more appropriate for some studies examining S-phase progression. It is important to note that

aphidicolin blocks the replicative DNA polymerase but not other events related to replication such as unwinding of replication origins and assembly of replication complexes. For this reason, there is some controversy about the exact phase in which aphidicolin arrests cells from cycling. It is clear that aphidicolin blocks cells at a cell cycle phase before the incorporation of deoxynucleotides into long polymers of DNA at the very beginning of S phase.

Aphidicolin can be used in suspension cultures or adherent cell lines. While aphidicolin is rapid and dependable and produces a highly synchronous population of cells immediately poised to enter S phase, it is also more expensive to use than excess thymidine. In addition, prolonged treatment of cells with aphidicolin results in DNA fragmentation (Schimke et al., 1991).

DETERMINING MITOTIC INDEX

SUPPORT PROTOCOL 1

The mitotic index is used to monitor the progression of cells through M phase, when chromatin condensation occurs. This procedure is labor intensive, but it correlates well with the progression of cells through M phase and cytokinesis (O'Connor et al., 1993). This method is useful to monitor cell cycle progression into M phase in the presence of inhibitors of cell division, such as colcemid or vincristine, when observation of the progression of cells through a single cell cycle is desired.

This protocol is adaptable to attached cells that have been trypsinized or to suspension cells. When working with adherent cells it is important to guarantee that you are observing the entire population of cells and not a subset of easily detached cells. Adherent cells staged at certain phases in the cell cycle attach more tightly to their substratum (see previous protocol) and may detach more poorly than other cells in the same vessel. Therefore, to avoid an experimental artifact and overestimation of mitotic cells due to uneven detachment of cells, culture vessels should be carefully viewed after trypsinization and removal of cells to ensure that no or few cells are left behind. Mitotic index should be determined at several timepoints (see below). Elevation of the percentage of cells exhibiting mitotic figures relative to the asynchronous control is evidence that the cells are actively cycling and are synchronized.

Materials

Burkitt's lymphoma cell line (CA46 cells), grown in RPMI-15, synchronized and unsynchronized
RPMI-15: RPMI supplemented with 15% (v/v) heat-inactivated FBS
1× PBS, pH 7.4 (*APPENDIX 2A*), ice cold
0.5× PBS, pH 7.4 (*APPENDIX 2A*), *or* 75 mM KCl, ice cold
3:1 (v/v) ethanol/glacial acetic acid, ice cold
Giemsa stain (Sigma, Life Technologies; optional)

1. Stimulate $>1 \times 10^3$ CA46 cells for each timepoint to enter the cell cycle by the method indicated in the synchronization protocol or by changing to fresh RPMI-15.
2. At the appropriate timepoints, transfer cells to a 15-ml centrifuge tube and centrifuge 5 min at 500 × *g*, room temperature. Discard supernatant, resuspend cells in 2 vol ice-cold 1× PBS, and repeat centrifugation. Discard supernatant and resuspend cells in 0.5 ml ice-cold 0.5× PBS for 10 min or ice-cold 0.75 mM KCl for ≥20 min, on ice to permit swelling of the cells without rupture.

   This hypotonic swelling makes mitotic figures easier to distinguish. Alternatively, add 6 ml of 2% (v/v) 3:1 ethanol/glacial acetic acid and store overnight at 4°C.

   The number and frequency of timepoints depends on the experiment. For G_1- or S-synchronized cells, mitotic index can be monitored every 4 hr; for late S- or M-synchronized cells,

it should be monitored every 30 min. Unsynchronized cells should be analyzed at the same timepoints to assess the success of the synchronization protocol.

3. Centrifuge cells 5 min at 500 × *g*, room temperature. Discard supernatant and resuspend pellet in 0.5 ml of 3:1 ethanol/glacial acetic acid. Finger vortex gently while resuspending to avoid cell clumps.

   The final cell concentration should be 1-5× 10^3 cells/ml.

4. Drop ~100 µl cells onto glass slide, two to three slides per timepoint. Allow slides to air dry for 0.5 to 2 hr.

   Cells should not overlap, therefore, the optimal concentrations of cells to be placed on each slide can be determined empirically by dropping cells onto one or two slides and observing them for the distribution on the slide. To help cells spread evenly, the slide can be tilted at a slight angle to improve the spread of cells.

5. Stain cells with 0.1 to 0.2 mg/liter Giemsa stain for 10 min. Gently rinse Giemsa stain from slides by dipping in 1× PBS and air dry slides.

6. Observe slides under the microscope for the presence of cells with mitotic figures with condensed nuclear material and a lack of nuclear membrane. Represent the data as a percentage of mitotic cells in the total number of cells observed.

   Generally, 200 to 500 cells are scored for each timepoint.

SUPPORT PROTOCOL 2

MONITORING [^{3}H]THYMIDINE INCORPORATION INTO DNA BY TCA PRECIPITATION

Pulse-labeling of cells with [^{3}H]thymidine (Thomas and Lingwood, 1975) followed by TCA precipitation onto filters (Jackman et al., 1994) has been used to monitor synchronous cells for peak DNA synthesis (>3- to 4-fold increase over baseline incorporation of labeled nucleotides). Peak DNA synthesis reflects the point in time when the maximum number of cells are in S phase.

Materials

CA46 cells, released from synchronization
RPMI-15: RPMI supplemented with 15% (v/v) heat-inactivated FBS (*APPENDIX 2A*), prewarmed to 37°C
[^{3}H]thymidine (20 to 60 Ci/mmol)
1× PBS (*APPENDIX 2A*)
0.5× PBS (see recipe)
20% (v/v) TCA, ice cold
5% (v/v) TCA, ice cold
95% ethanol

Dry ice/methanol bath
Wet ice in bucket
Glass fiber filters
Vacuum manifold
Vacuum drying oven, 80°C

1. Following release of cells into the cell cycle by replacement of amino acids or growth factors (Basic Protocol 2, Alternate Protocol 3) or by removal of inhibitors (Basic Protocol 3, Basic Protocol 4, Alternate Protocol 4), transfer several aliquots of 1 × 10^5 CA46 cells to 15-ml plastic centrifuge tubes.

   The number of cells can be reduced 10-fold, if necessary

2. Centrifuge the cells 5 min at 500 × *g*, room temperature. Discard supernatant and resuspend pellet in an equivalent volume of prewarmed RPMI-15 supplemented with 5 µCi/ml [^{3}H]thymidine. Incubate 30 min at 37°C.

3. Centrifuge cells 5 min at 500 × *g*, room temperature, discard supernatant, and resuspend pellet in 5 ml ice-cold 1× PBS. Repeat PBS wash and resuspend pellet in 0.5 ml 0.5× PBS.

4. Place cells in tube rack in dry ice/methanol bath and let stand for 1 to 3 min. Allow cells to thaw for 3 to 5 min at 37°C. Repeat twice.

   The freeze-thaw process lyses the cells.

5. Place tubes containing cell lysates in bucket containing wet ice. Add an equal volume of ice-cold 20% TCA to the lysates and let stand 30 min on ice.

6. Moisten glass fiber filters with 5% TCA, then place in vacuum manifold and seal in place according to the manufacturer's directions.

   Label filters with pencil prior to wetting or, alternatively, label the caps of scintillation vials into which filters will be placed.

7. Transfer precipitates to glass fiber filters under vacuum. Wash each tube twice with 2 vol ice-cold 5% TCA and transfer this material also to the appropriate filter.

8. Wash filters three times under vacuum with 5 ml ice-cold 5% TCA and once with 5 ml ice-cold 95% ethanol.

9. Transfer filters to scintillation vials and set caps loosely in place. Place vials in 80°C vacuum oven for ~45 min.

   Include blank filters as a negative control for background.

10. Add 5 to 10 ml scintillation fluid to each vial. Place vials in scintillation counter and count on the ^{3}H channel for 5 min each. Average the cpms from multiple aliquots and plot against time from release.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Aphidicolin, 10 µM

10 µM aphidicolin (Sigma) in dimethylsulfoxide (DMSO)
Store <3 months at −80°C

Lovastatin, activated, 10 mM

Dissolve 52 mg lovastatin (Merck, Sharp, and Dohme Research Pharmaceuticals) in 1.04 ml of 95% ethanol. Add 813 µl 1 N NaOH. Adjust to pH 7.2 with 1 M HCl and dilute to 13 ml (4 mg/ml; 10 mM) with sterile-filtered, deionized H_2O or medium. Store <1 month at −20°C.

This preparation is "activated" lovastatin, which is ready for use.

Mimosine, 100 mM

100 mM L-mimosine (Sigma) in PBS, pH 7.4 (*APPENDIX 2A*)
Store <2 months at 4°C

Nocodazole, 4 mg/ml

DMSO in 4 mg/ml nocodazole (Aldrich)
Store <6 months at −20°C or <1 month at 4°C

Thymidine, 100 mM

100 mM thymidine (Sigma) in PBS, pH 7.4 (*APPENDIX 2A*)
Sterile filter or autoclave and store <3 months at −20°C or −80°C

Trypsin, 0.5×

Dilute 1× trypsin (Life Technologies) 1:1 with 50 ml 1× HBSS (*APPENDIX 2A*) supplemented with 1.25 ml of 0.5 M disodium EDTA and 1 ml of 0.5 M HEPES, pH 7.2. Store <3 months at −20°C or <1 week at 4°C.

COMMENTARY

Background Information

An essential task in the study of cell cycle–related processes is synchronization of cells into specific cell cycle phases. Synchronization improves the conditions by which an actual process under scrutiny can be studied and helps link the process to a particular cell cycle–phase transition. This unit provides methods that have proven effective in synchronizing mammalian cells into defined cell cycle phases. The advantages and disadvantages of each procedure are discussed and some key situations where such procedures have been employed successfully in the biochemical dissection of cell cycle–control processes are described. This unit focuses on the use of chemicals or growth-restriction conditions to synchronize exponentially growing cells.

An additional method for obtaining enriched populations of phase-specific cells, using centrifugal elutriation to obtain pure populations of cells, has been omitted from this unit. Centrifugal elutriation uses mechanical separation to isolate cells in different cell cycle phases. Centrifugal elutriation is often a superior method of synchronization: it allows one to obtain pure populations of cells without introducing potential artifacts of imbalanced growth, since no chemicals are employed and no transient arrests are induced. Its expense and specific requirements for optimization of the elutriator preclude the use of this methodology in most laboratories performing occasional synchronizations or just getting started in methods of cell cycle analysis. This method will, however, be described in a future unit.

Critical Parameters and Troubleshooting

The goal of cell synchronization is to create a completely synchronized population of cells that progress uniformly through the cell cycle. Achieving this task requires that (1) the cells be completely arrested at one defined point in the cell cycle, (2) the arrest procedure be completely reversible, and (3) the released cells recover and progress uniformly through the cell cycle. In the practical sense, the procedures currently available for cell synchronization aim towards, but do not entirely meet, these requirements. Problems arise in the degree of arrest obtainable and the uniformity with which the released population progresses through the cell cycle. For a cell line not yet characterized for synchronization, one may have to experiment with several different procedures to find the most suitable technique.

Mitotic shake-off: If cell lines are poorly adherent, synchrony obtained by this shake-off will be poor as well. Therefore, the time of trypsinization or the concentration of trypsin should be reduced. Care should be taken with more fragile cell lines not to damage their membranes during manipulation of cells, which might prevent their reattachment or reentry into the cell cycle.

Poorly growing cultures or cultures that are not in logarithmic growth will produce lower yields of cells than fresh, rapidly dividing cultures. If too few cells are obtained by this method despite optimal cell growth, removal of unattached cells to enhance synchrony should be omitted in favor of obtaining larger numbers of cells. Alternatively, this technique can be combined with nocodazole to enhance the number of cells and purity of the synchronized population.

Nocodazole: If an increase in cell number is not observed or a decrease in cell number is observed following release from nocodazole, the concentration of the drug is most likely too high, resulting in an irreversible block in G_2/M phase or causing cells to die. Reducing the concentration should alleviate this problem.

Increasing the concentration of nocodazole should prevent any leakiness of the G_2/M-phase block. In cell lines with doubling times >24 hr, 16 hr may not be sufficient time to accumulate the bulk of the cells in G_2/M. Caution should be used when extending the time of nocodazole

exposure, as longer exposure times may permit all cells to exit G_1 and S phases, but may be toxic to cells held for prolonged periods of time in G_2 and M phases. Finally, a number of tumor cell lines are defective in their ability to arrest at G_2/M. Nocodazole will not be an effective synchronizing agent for these checkpoint-defective cell lines.

Serum starvation: A range of reduced serum concentrations are effective (0.1% works well for most cell lines). Serum withdrawal can also be accomplished by complete withdrawal (0% serum) or performed with 1% serum, depending on the cell line. The optimal concentration must be determined for each cell line. In addition, plating cells too densely interferes with the ability of cells to fully arrest. Densely plated cells arrest as a result of confluence rather than nutritional depletion. If cells are overgrown following removal of serum, cells should be plated at a lower density prior to initiating serum withdrawal.

Amino acid depletion: Insufficient washing of the cells early in amino acid starvation will reduce the ability of the cells to become uniformly synchronized. It is very important to use dialyzed (not charcoal-treated) FBS rather than reduced serum concentrations of standard serum. Keeping cells below confluence is also important during amino acid depletion, as excess cell numbers can prevent maximum growth of synchronized cultures.

Low numbers of synchronized cells can result from toxicity of amino acid withdrawal. The unfortunate side effect of toxicity is that dying cells can provide a source of isoleucine, which will further reduce the quality of the synchrony. Toxicity can result if cells are exposed to amino acid–deficient medium for two or three cell cycles. Extended withdrawal times may also cause cells to remain in G_1 as statically arrested cells rather than transiently blocked cells.

Lovastatin: The results of synchrony obtained with lovastatin have shown some variation among cell types. Several fibroblastic cell lines have demonstrated strong G_1-arrest characteristics in the presence of lovastatin, while other tumor cell lines have demonstrated a persistent arrest in both G_1 and G_2. In those cases where cells show a significant G_2 rather than G_1 population of cells in the presence of lovastatin, it would be best to select another method of synchronization.

Mimosine: As mentioned previously, the site and mode of action of mimosine arrest has not been clearly defined. Therefore, it is not clear that mimosine inhibits cells from progressing into S phase or inhibits the progression of cells through S phase (Kalejta and Hamlin, 1997). If mimosine does, in fact, have two sites of action in the cell cycle, then a single mimosine treatment may produce populations contaminated with cells trapped in S phase. For this reason, it may be prudent to use mimosine as an adjunct to G_0/G_1-synchronizing protocols to obtain pure, late G_1/S–synchronized cultures.

Double-thymidine block: Timing is of the essence with this technique! With the procedure outlined in Basic Protocol 4, the leading-edge cells will be at the G_1/S phase border of the next cell cycle at the end of the sixteenth hour, while the lagging edge of cells will be in G_2/M at the end of the sixteenth hour. If thymidine is added too quickly, cells at the end of S phase will become trapped until released following the second thymidine block. If thymidine is added too late, cells already in S phase will become trapped in S phase during the block and may interfere with detection of early S-phase events.

Mitotic index: This is a relatively straightforward technique with few steps that require optimization. Gentle handling of the cells following resuspension and fixation with 3:1 ethanol/glacial acetic acid will improve cell yields and cell morphology.

[^{3}H]thymidine incorporation into DNA: Insufficient cell numbers, poorly growing cultures, and use of medium with a large pool of cold thymidine can all lead to poor labeling of DNA. Also insufficient washing of cultures synchronized by double-thymidine exposure can lead to a large pool of excess cold thymidine, which reduces the relative amount of [^{3}H]thymidine. If cell number is the problem, precipitating materials from increasing numbers of cells should demonstrate an optimum cell concentration for detection of labeled DNA. Alternatively, if cell numbers are limiting, the addition of 1 µg of cold carrier DNA or RNA to cell lysates may improve the recovery of labeled DNA. Poorly growing cultures are detectable by their reduced cell cycle time and failure to increase logarithmically in cell number with time. If the required medium for cell growth (e.g., some hematopoietic cell lines require the addition of hypoxanthine/thymidine to the medium), the medium used for labeling cells can be substituted for another medium with lower thymidine concentration (e.g., DMEM) during the 30-min labeling period with little or no effect on cell replication.

The lack of increase in DNA synthesis above background can be the result of insufficient washing of TCA precipitates, poor or ineffec-

tive synchronization of cells, or failure of cells to re-enter the cell cycle.

Failure of cells to re-enter the cell cycle can be determined by monitoring cell numbers. In cases where synchrony is poor, the cell number will increase uniformly rather than punctately, as occurs with synchronized cultures. Thorough and complete washing of cell precipitates is critical to the success and reproducibility of this protocol.

Anticipated Results

Mitotic shake-off: Cells obtained by mitotic shake-off should be enriched in G_2/M phase by at least 75%. Contamination of cells in M with cells in other stages is most often related to the stringency of trypsin treatment or rigor of shaking or tapping of the cultures. Pure populations of G_1 cells can be gained using the mitotic shake-off technique by placing the mitotic cells in a flask and incubating them for 2 hr at 37°C. The mitotic cells will re-attach to the flasks and flatten out as they enter G_1 phase. Mitotic laggards can be removed from the flask by gently swirling the medium over the attached cells and then decanting the medium. The remaining attached cells will consist of primarily G_1 cells, which can be confirmed by flow cytometry.

Nocodazole: It is possible to obtain nearly pure populations of G_2/M-phase cells (up to 95% with CA46 cells) by using nocodazole. It is necessary to confirm that the cell cycle block has been reversed by monitoring cell number. Nocodazole is generally used at 10 to 400 ng/ml (final concentration). Excessive concentrations or prolonged incubation times can be toxic. The authors have found that nocodazole-arrested lymphoma cells do not display the characteristic proportional increase in cell volume that is observed with other types of G_2-arrest agents, when evaluated using a Coulter counter and channelzyer. Therefore, methods that monitors changes in cell volume should be not be used to evaluate the effectiveness of nocodazole arrest.

Serum starvation: Over 90% of the population should be in G_0/G_1 following serum starvation. By 12 to 16 hr after addition of serum-containing medium, 40% to 60% of the population should enter S phase in a parasynchronous wave. Peak synthesis of DNA, as measured by [^{3}H]thymidine incorporation, should occur by 16 hr after restimulation.

Amino acid depletion: With this technique, >90% of CA46 cells will arrest in G_1 after two cell cycles. Following release into the cycle, >80% of these cells will re-enter the cell cycle and progress into S phase. The quality of the synchronization depends on obtaining maximal replication in cells prior to depletion of amino acids and thorough washing of cells prior to resuspension in isoleucine-free medium. Conditions that lead to extensive cell death during the procedure may interfere with this procedure, since lysed cells can act as a significant source of free isoleucine. Depending on the cell type, cells will enter S phase as a synchronous or parasynchronous wave within 8 to 12 hr. Starvation methods are useful when combined with other types of synchronizing agents, in particular, release from starvation in the presence of aphidicolin or mimosine to enrich for G_1/S cells (Heintz and Hamlin, 1982, Burhans et al., 1990, Dijkwel and Hamlin, 1992).

Lovastatin: Up to 80% reversible sequestration of cells in G_1 phase has been seen with the use of lovastatin (Wilcken et al., 1997). It is important to note that recovery from lovastatin does prolong the G_1 phase of many cell types (Keyomarsi et al., 1991).

Mimosine: Synchronization with mimosine produces late G_1/S populations of >70% purity. These cells initiate DNA synthesis <30 min after release from mimosine arrest.

Double-thymidine block: Cell populations treated in this manner can often be enriched to contain >65%, and sometimes as much as 80%, of the cells in S phase. The real trick to this procedure is to prevent the leading-edge cells from entering S phase of the next cell cycle while ensuring the lagging-edge cells have left S phase of the previous cell cycle. Most cells will progress into S phase within 1 to 2 hr following release from excess thymidine.

Mitotic index: As cells enter M phase, the number and percentage of mitotic figures observed in the cultures will increase.

[^{3}H]Thymidine incorporation: Peak DNA synthesis as reflected by an increase of at least 3-fold over background represents the point in time when the maximum number of cells are in S phase. The increase in peak DNA synthesis can be substantially >5-fold over background, depending on the culture conditions and the degree of synchrony obtained.

Time Considerations

Because these methods involve manipulations of cultures of cells, they required one or more days, although the hands-on time for any one day may be limited. For an estimate of the total time required for each synchrony protocol see Figure 8.3.2.

Determining Cell Cycle Stages by Flow Cytometry

The most common approach to determining the cell cycle stage is based on measurement of cellular DNA content. This allows one to discriminate between cells in the $G_{0/1}$ versus the S versus the G_2/M phases of the cell cycle (Fig. 8.4.1). DNA is generally stained with a fluorescent dye and cellular fluorescence is measured by flow, image, or laser scanning cytometry (Crissman and Steinkamp, 1990). A variety of fluorochromes can be used for DNA staining. The spectral properties of the dyes most frequently used for this purpose are presented in Figure 8.4.2. Following cell staining with one of these dyes, the intensity of fluorescence integrated over the analyzed cell is expected to be in stoichiometric relationship to DNA content, and thereby can be used to determine the cell cycle stage. Deconvolution of the DNA content frequency histograms, usually done using special computer software (Rabinovitch, 1994), reveals the percentage of cells residing in the respective phases of the cell cycle.

A plethora of techniques for DNA content measurement utilizing the fluorochromes depicted in Figure 8.4.2 have been published during the past two decades. Description of many methods, which are applicable to different cell systems including eukaryotes and prokaryotes, as well as to clinical samples, can be found in a separate monograph (Darzynkiewicz et al., 1994). The techniques differ primarily according to the mode of cell permeabilization (detergent versus fixation with alcohols) and composition of the stain solution. Four types of procedures are described in this unit. Relatively simple and rather universally applicable methods for staining ethanol-fixed cells are presented in Basic Protocol 1 and Alternate Protocol 1. Because cells may be stored in the fixative for extended periods of time and/or transported while in the fixative, these methods allow one to prepare and collect the cells without regard to the timing of their analysis. The methods presented utilize the two most commonly used DNA fluorochromes, propidium iodide (PI; see Basic Protocol 1) and 4′,6-diamidino-2-phenylindole (DAPI; see Alternate Protocol 1). The DAPI staining procedure, which does not require incubation with RNase A, is simpler and more rapid as compared to the one using PI. However, it requires a flow cytometer equipped with a UV excitation source.

The methods utilizing detergent to permeabilize cells are presented in Basic Protocol 2 and Alternate Protocol 2. These methods provide more accurate estimates of the DNA content, and therefore better discrimination of the cell-cycle phases as compared to measurement of fixed cells. This is due to the fact that exposure of live cells to detergents results in rupture of the plasma membrane and elimination of the cytoplasmic constituents, which contain components that are autofluorescent or that nonspecifically interact with DNA fluorochromes. Isolated nuclei are then stained rather than whole cells. It should be stressed that analysis of the detergent-treated cells may lead to an underestimation of M cells. Lacking a nuclear envelope, these cells may totally disintegrate into chromosomes or chromosome aggregates. In Basic Protocol 2 cells are stained with PI; in Alternate Protocol 2 they are stained with DAPI. As in the case of fixed cells, staining with of detergent-permeabilized cells with DAPI does not require incubations with RNase A. It should be stressed that fluorochromes other than PI or DAPI (Fig. 8.4.2) can be used in these protocols, provided that their fluorescence is excited and measured at appropriate wavelengths, as indicated in the figure.

A different approach is used for cell cycle analysis of live cells (see Basic Protocol 3). The main application of this method is for cell sorting, where cells that have been selected on the basis of their DNA content (cell cycle phase) can be cultured for analysis of their

Current Protocols in Cell Biology (1999) 8.4.1-8.4.18

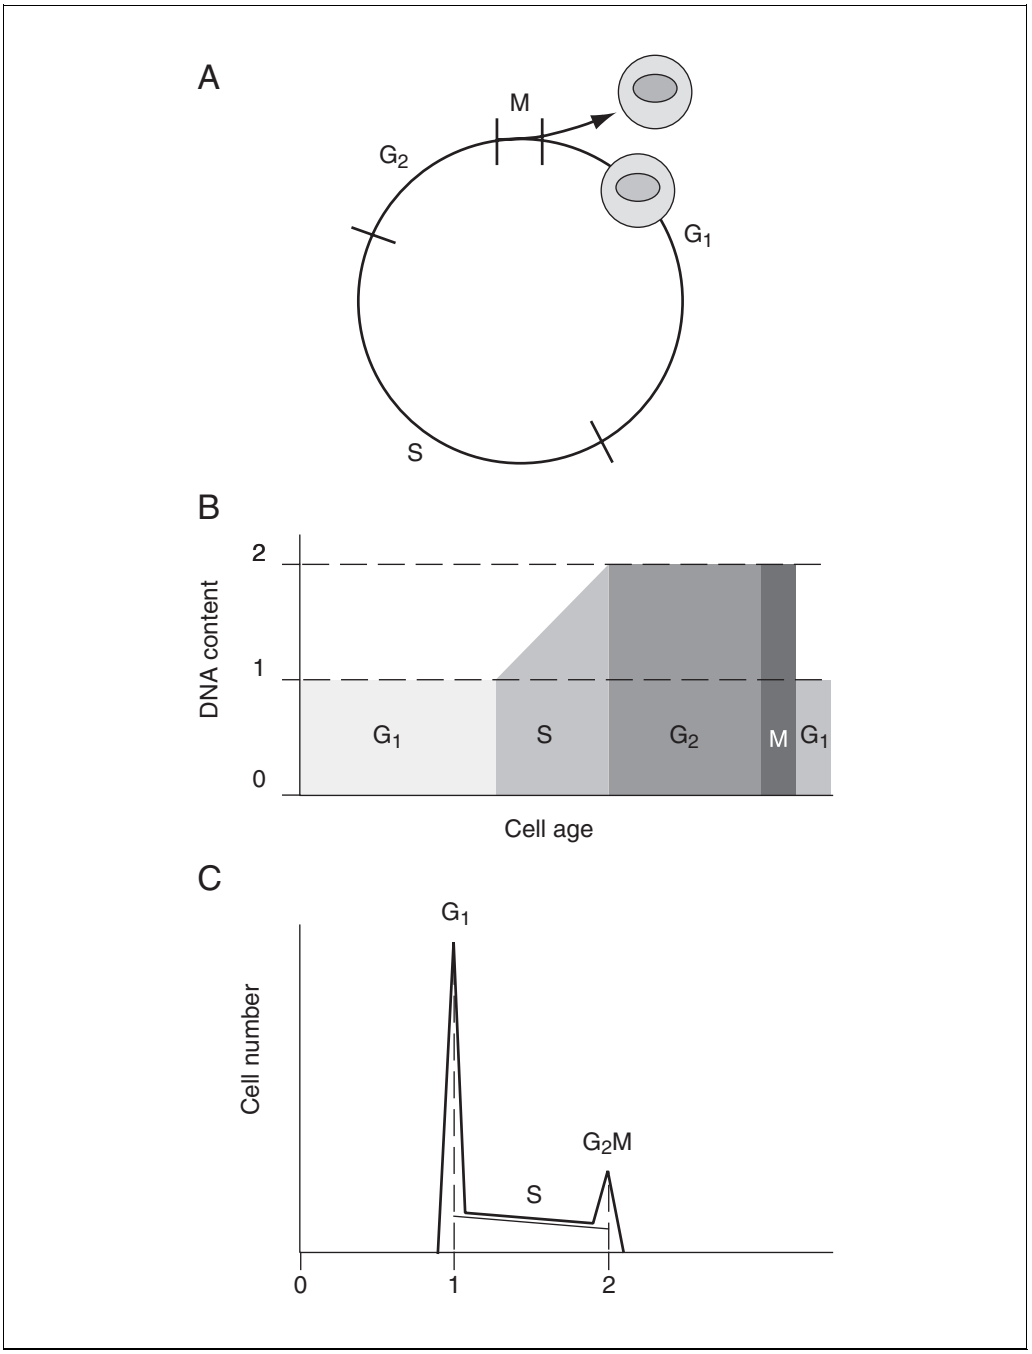

Figure 8.4.1 Relationship between DNA content and the cell cycle. (**A**) Stages of the cell cycle. (**B**) Estimation of cell position in the cell cycle based on DNA content measurement. Content of cellular DNA doubles during S, and therefore the cell age during S can be estimated based on the amount of replicated DNA (increase in DNA content). On the other hand, cells in G_1 and G_2/M are uniform with respect to DNA content, which is equivalent to the DNA ploidy index (DI) 1.0 (for G_1) and 2.0 (for G_2/M). (**C**) If DNA content could be measured with absolute accuracy, based on DNA-specific fluorescence, the G_1 and G_2/M cells would have uniform fluorescence values and be represented on the frequency histograms as the bars of a single channel width (dashed lines). Due to inaccuracy in DNA-content measurement, the actual data are in the form of G_1 and G_2/M peaks. Percentage of cells represented by these peaks, and in the S phase, are estimated by deconvolution of the histograms, using a variety of mathematical techniques (Bagwell, 1993; Rabinovitch, 1994). The interactive software based on these techniques deconvolutes the histograms and is available from several sources (see Background Information).

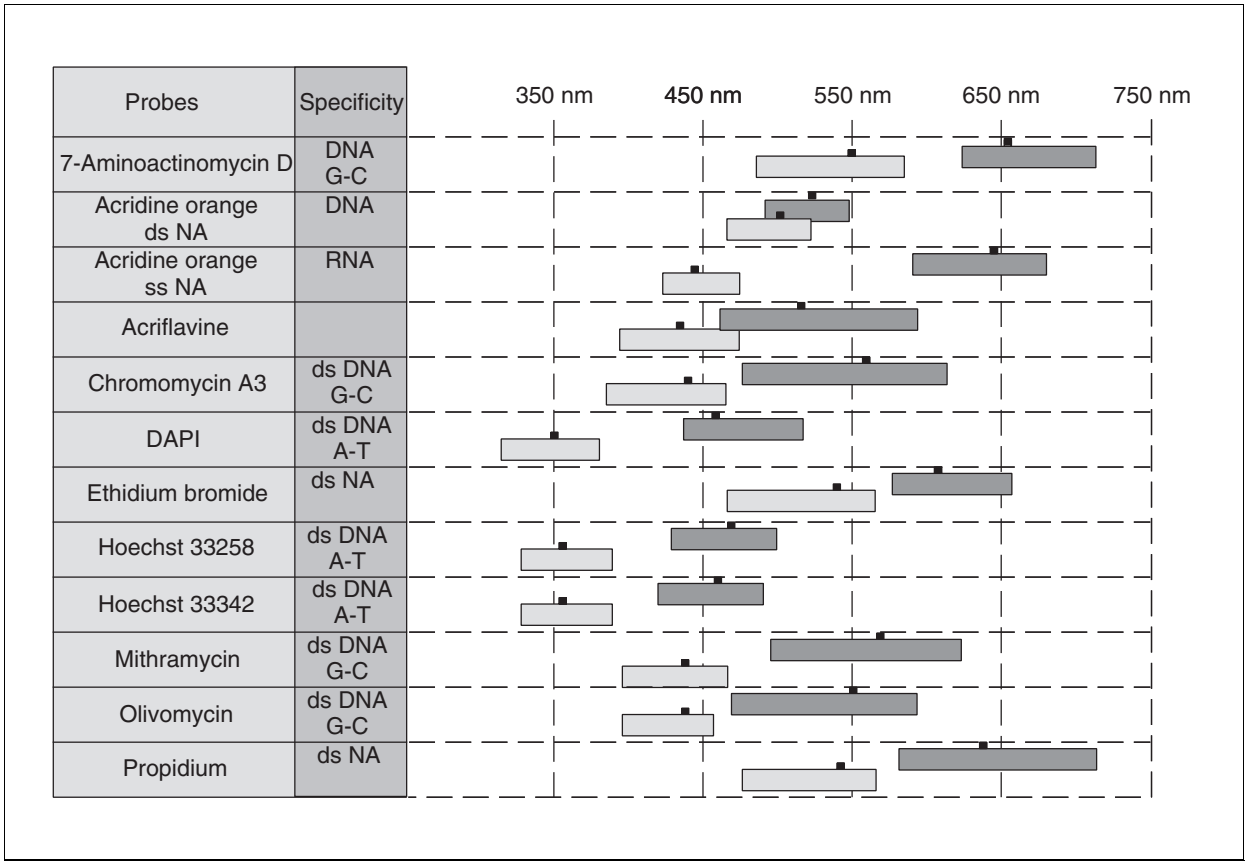

Figure 8.4.2 Fluorescence excitation (shaded bars) and emission (solid black bars) wavelengths of the most commonly used DNA fluorochromes. Abbreviations: ds, double-stranded; ss, single-stranded; NA, nucleic acid.

growth characteristics or sensitivity to drugs or for purposes of cloning or expansion. The method presented in Basic Protocol 3 is simple, based on cell staining with Hoechst 33242 fluorochrome, which, unlike PI or DAPI, is able to penetrate through the plasma membrane and stain DNA in live cells.

The final procedure combines analysis of cellular DNA content with expression of cyclins D, E, A, or B1. Cyclins are the key components of the cell cycle progression machinery and are expressed discontinuously during the cell cycle (see Background Information). Thus, the presence of a particular cyclin detected immunocytochemically within the cell, provides an additional marker of the cell cycle position. Simultaneous bivariate analysis of DNA content and expression of cyclins (Basic Protocol 4) makes it possible to distinguish additional stages of the cell cycle, which cannot be identified by analysis of DNA content alone (Darzynkiewicz et al*.,* 1996).

CELL CYCLE ANALYSIS OF FIXED CELLS STAINED WITH PROPIDIUM IODIDE

BASIC PROTOCOL 1

In this protocol, ethanol is used to fix and permeabilize cells to make them accessible to propidium iodide (PI). As mentioned above, the fixation step makes this protocol applicable in instances when samples have to be stored or transported before analysis. Following fixation, the cells are rinsed with PBS and stained with PI in a solution containing Triton X-100 and RNase A. Triton X-100 additionally permeabilizes the cells, and to some extent decreases cell loss resulting from electrostatic cell attachment to tubes. Because double-stranded sections of RNA also stain with PI, RNase A is included to digest these sections and thereby to increase specificity of DNA staining.

Materials

Cells to be stained
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Fixative: 70% ethanol
Propidium iodide staining solution I (see recipe)

Low-speed centrifuge
12 × 75–mm centrifuge tubes, preferably polypropylene or silanized
Flow cytometer with 488-nm argon-ion laser fluorescence excitation source
Software to deconvolute cellular DNA content frequency histograms (e.g., Multicycle from Phoenix Flow Systems)

Additional reagents and equipments for counting and trypsinizing cells (*UNIT 1.1*)

Prepare cell suspension for fixation

1a. *For cells growing in suspension or hematologic samples:* Rinse cells once by centrifuging 6 min at 200 × *g*, room temperature, with PBS. Count cells (*UNIT 1.1*) and thoroughly resuspend 1×10^6 to 1×10^7 cells in 0.5 ml of PBS.

1b. *For cells growing attached to tissue culture dishes:* Collect cells from flasks or petri dishes by trypsinization (*UNIT 1.1*) and pool the trypsinized cells with the cells floating in the medium (the latter consist of detached mitotic, apoptotic, and dead cells). Centrifuge the cell suspension 6 min at 200 × *g*, room temperature. Remove the supernatant and resuspend the pellet in medium containing serum (to inactivate trypsin), then centrifuge again and remove the supernatant. Count cells (*UNIT 1.1*) and thoroughly resuspend 1×10^6 to 1×10^7 cells in 0.5 ml of PBS.

Other means of trypsin inactivation, such as addition of protease inhibitors, may also be used.

1c. *For cells isolated from tissues (e.g., tumors):* Rinse free of any enzyme used for cell dissociation using the centrifugation technique described in step 1a, above, and thoroughly resuspend (well dispersed, not in aggregates) 1×10^6 to 1×10^7 cells in 0.5 ml of PBS.

Fix cells in ethanol

2. Prepare for fixation by adding 4.5 ml of 70% ethanol fixative to each of an appropriate number of 12 × 75-mm centrifuge tubes. Keep tubes on ice.

3. Using a Pasteur pipet, transfer 0.5-ml aliquots of cell suspensions prepared as in step 1a, 1b, or 1c into the appropriate tubes containing the cold 70% ethanol fixative and keep cells in fixative ≥2 hr on ice.

It is important to achieve a single-cell suspension. Fixation of cells that are in aggregates while suspended in PBS stabilizes the aggregates, which then become impossible to disperse. It is essential, therefore, to have a monodisperse cell suspension at the time that cells are mixed with ethanol.

Cells suspended in 70% ethanol can be stored at 0° to 4°C for several months if not years.

Stain cells with PI

4. Centrifuge the ethanol-suspended cells 5 min at 200 × *g*. Decant ethanol thoroughly.

5. Suspend the cell pellet in 5 ml PBS, wait 60 sec, then centrifuge again as in step 4. Decant supernatant

6. Resuspend cell pellet in 1 ml of propidium iodide staining solution I. Incubate either 15 min at 37°C or 30 min at room temperature.

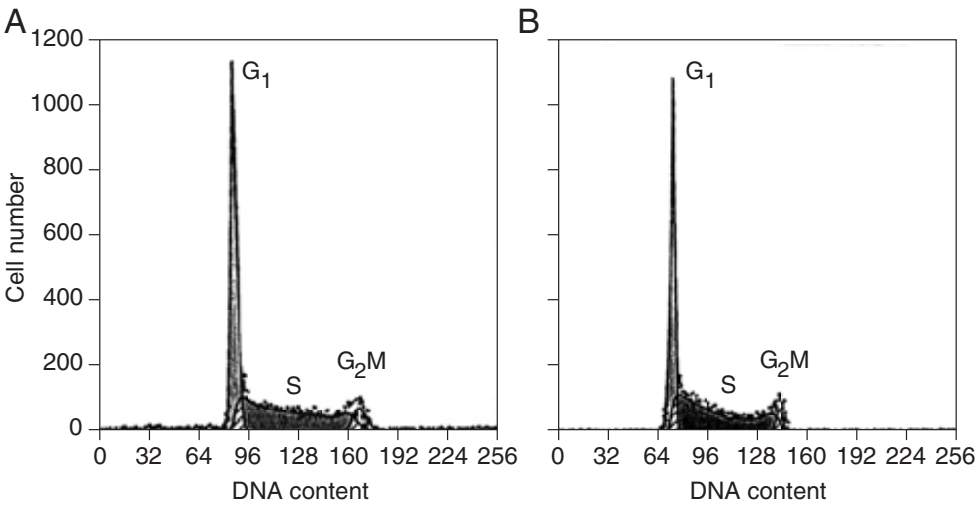

Figure 8.4.3 (**A**) DNA content frequency histograms of fixed HL-60 cells stained with DAPI (Alternate Protocol 1) and (**B**) detergent-permeabilized HL-60 cells stained with DAPI (Alternate Protocol 2). The histograms were deconvoluted using Multicycle software (Phoenix Flow Systems).

Measure cell fluorescence by flow cytometry

7. Set up and adjust flow cytometer for excitation with blue light and detection of PI emission at red wavelengths.

   For excitation, the 488-nm argon-ion laser line may be used. Alternatively use a BG 12 optical filter when the source of illumination is a mercury-arc or xenon lamp. A long-pass (>620-nm) emission filter is recommended.

8. Measure cell fluorescence by flow cytometry. Use pulse-width/pulse-area signal to discriminate between G_2/M cells and the cell doublets, and gate out the latter. Analyze the data (Fig. 8.4.3) using DNA content histogram deconvolution software (e.g., Multicycle from Phoenix Flow Systems).

CELL CYCLE ANALYSIS OF FIXED CELLS STAINED WITH DAPI

ALTERNATE PROTOCOL 1

This protocol is similar to Basic Protocol 1, except the cells are stained with DAPI rather than PI. Because DAPI does not stain RNA, there is no need to treat the cells with RNase A. Excitation of DAPI, however, requires UV light source, which is not universally available. Emission of DAPI is measured at blue wavelengths.

Additional Materials *(also see Basic Protocol 1)*

DAPI staining solution I (see recipe)
Flow cytometer with UV illumination source (e.g., mercury-arc lamp or laser tuned to UV at 340 to 380 nm)

1. Collect cells, fix in 70% ethanol, and wash (see Basic Protocol 1, steps 1 to 5).
2. Resuspend cell pellet in 1 ml DAPI staining solution. Incubate 30 min in the dark at room temperature.
3. Set up and adjust flow cytometer for UV excitation at 340 to 380 nm and detection of DAPI emission at blue wavelengths.

   For excitation, an UG-1 optical filter (short-pass, 390 nm) may be used when the source of excitation is a mercury-arc or xenon lamp. For detection of DAPI emission a band-pass filter at 470 ± 20 nm is recommended.

4. Measure cell fluorescence by flow cytometry. Use the pulse-width/pulse-area signal to discriminate between G_2/M cells and the cell doublets, and gate out the latter. Analyze the data (Fig. 8.4.3) using software that deconvolutes DNA content frequency histograms (e.g., Multicycle from Phoenix Flow Systems).

BASIC PROTOCOL 2

CELL CYCLE ANALYSIS OF UNFIXED, DETERGENT-PERMEABILIZED CELLS STAINED WITH PI

In this protocol the cells are lysed with detergent to aid in the staining of DNA for flow cytometric analysis. The cells in suspension are mixed with staining solution that contains Triton X-100, PI, and RNase A. DNA content of the stained nuclei is then measured by flow cytometry, using excitation with blue light. Because there is no fixation step, the procedure is simpler and more rapid, and because there are fewer centrifugations, there is less cell loss as compared to Basic Protocol 1

Materials

Cells to be stained: 1×10^6 to 5×10^6 cells/ml suspended in PBS (*APPENDIX 2A*) or culture medium
Propidium iodide staining solution II (see recipe)

Flow cytometer with 488-nm argon-ion laser fluorescence excitation source
Software to deconvolute cellular DNA content frequency histograms (e.g., Multicycle from Phoenix Flow Systems)

1. Mix 0.2 ml of cell suspension with 2 ml of propidium iodide staining solution II. Incubate 20 min at room temperature.
2. Set up and adjust flow cytometer for excitation with blue light and detection of PI emission at red wavelengths.

   For excitation, the 488-nm argon-ion laser line may be used. Alternatively use a BG 12 optical filter when the source of illumination is a mercury-arc or xenon lamp. A long-pass (>620-nm) emission filter is recommended.

3. Measure cell fluorescence by flow cytometry. Use pulse-width/pulse-area signal to discriminate between G_2/M cells and the cell doublets, and gate out the latter. Analyze the data (Fig. 8.4.3) using DNA content histogram deconvolution software (e.g., Multicycle from Phoenix Flow Systems).

ALTERNATE PROTOCOL 2

CELL CYCLE ANALYSIS OF UNFIXED, DETERGENT-PERMEABILIZED CELLS STAINED WITH DAPI

This protocol is essentially identical to Basic Protocol 2 except that the cells are stained with DAPI. As mentioned previously, there is no need for incubation with RNase A, which simplifies the protocol, but the procedure requires a flow cytometer equipped with UV light excitation source.

Additional Materials (also see Basic Protocol 2)

DAPI staining solution II (see recipe)
Flow cytometer with UV-illumination source (e.g., mercury-arc lamp or laser tuned to UV at 340 to 380 nm)

1. Mix 0.2 ml of cell suspension (1×10^5 to 1×10^6 cells suspended in PBS or culture medium) with 2 ml of DAPI staining solution II. Incubate 10 min at room temperature.
2. Set up and adjust flow cytometer for UV excitation at 340 to 380 nm and detection of DAPI emission at blue wavelengths

For excitation, an UG-1 optical filter (short-pass, 390 nm) may be used when the source of excitation is a mercury-arc or xenon lamp. For detection of DAPI emission a band-pass filter at 470 ± 20 nm is recommended.

3. Measure cell fluorescence by flow cytometry. Use the pulse-width/pulse-area signal to discriminate between G_2/M cells and the cell doublets, and gate out the latter. Analyze the data (Fig. 8.4.3) using software that deconvolutes DNA content frequency histograms (e.g., Multicycle from Phoenix Flow Systems).

STAINING OF LIVE CELLS WITH HOECHST 33342

BASIC PROTOCOL 3

Supravital staining of DNA offers the possibility of sorting live cells at different phases of the cell cycle, based on differences in their DNA content. The protocol uses Hoechst 33342 fluorochrome, which stains cellular DNA without a need for cell fixation or permeabilization with detergent. The actual procedure for cell staining is simple. Cells are suspended in culture medium or PBS and incubated in the presence of 2.0 to 5.0 μg/ml of Hoechst 33342 for 20 to 90 min. Cell fluorescence is then measured directly, without any additional treatments or centrifugations. Because Hoechst 33342 is excited at UV wavelengths, the procedure requires a flow cytometer with a UV light illumination source. It should be stressed, however, that accuracy of DNA content measurement and therefore the ability to discriminate cells at different phases of the cycle, is much lower with supravital cell staining as compared to staining of ethanol-fixed or detergent-permeabilized cells.

Materials

1 mg/ml Hoechst 33342 in H_2O (store up to several weeks at 4°C in dark or foil-wrapped bottles)

Cells to be stained: 1×10^6 cells/ml suspended in PBS (*APPENDIX 2A*) or culture medium

Flow cytometer with UV light illumination source (e.g., mercury-arc lamp or laser tuned to UV at 340 to 380 nm)

1. Add sufficient 1 mg/ml Hoechst 33342 to cells suspended in PBS or culture medium (1×10^6 cells/ml) to obtain a final fluorophore concentration of 2.0 μg/ml. Incubate 20 min at 37°C.
2. Set up and adjust flow cytometer for UV excitation at 340 to 380 nm, and detection of Hoechst 33342 fluorescence at blue wavelengths.
3. Measure cell fluorescence by flow cytometry. Use the pulse-width/pulse-area signal to discriminate between G_2/M cells and the cell doublets, and gate out the latter. Analyze the data (Fig. 8.4.3) using software that deconvolutes DNA content frequency histograms (e.g., Multicycle from Phoenix Flow Systems).

When intensity of cell fluorescence or resolution of cells in the cell-cycle phases is inadequate, prolong the staining time (up to 90 min) and/or increase Hoechst 33342 concentration in the medium (up to 5 μg/ml). The same sample may be reanalyzed after prolonged incubation and/addition of more staining solution.

This protocol is predominantly used for sorting live cells. However, because sensitivity of cells to Hoechst 33342 varies depending on the cell type (the dye also sensitizes cells to UV light), it is possible that viability and cell cycle progression of the sorted cells may be affected by the staining procedure.

BASIC PROTOCOL 4

BIVARIATE ANALYSIS OF DNA CONTENT AND EXPRESSION OF CYCLINS D, E, A, OR B1

A special category of methods for cell-cycle analysis combines measurement of DNA content and expression of the proliferation-associated proteins. The latter are detected immunocytochemically, using specific antibodies that are labeled with fluorochrome either directly, or indirectly via a secondary antibody. This protocol is devoted to cyclins, whose analysis provides an insight into the actual components of the cell-cycle progression machinery (see Background Information and *UNIT 8.2*). Because some cyclins are expressed transiently, at very specific time intervals in the cell cycle, their presence in the cell can be considered as a marker of this particular portion of the cycle. The protocol combines measurement of DNA content with expression either of one of the D-type cyclins, or cyclins E, A, or B1. Cells are fixed and labeled with anti-cyclin antibody followed by fluorescein isothiocyanate (FITC)-conjugated secondary antibody, and finally stained with PI for DNA measurement. If directly conjugated FITC-anti-cyclin antibody is available, secondary-antibody labeling (steps 8 and 9) can be omitted. This analysis is adapted to the most commonly used flow cytometers, such as those equipped with a single-laser (488-nm) illumination source.

Materials

Cells to be analyzed
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Fixative: 80% ethanol or absolute methanol, −20°C.
0.25% (v/v) Triton X-100 in PBS, pH 7.4 (store at 4°C)
Rinsing buffer: 1% (w/v) bovine serum albumin (BSA) in PBS, pH 7.4 (store at 4°C)
Anti-cyclin IgG1 antibodies: e.g., mouse monoclonal antibodies to cyclin B1 (clone GNS-1), cyclin A (clone BF-683), cyclin D1 (clone G124-326), cyclin D3 (clone G107-565), and cyclin E (clone HE12); all provided by PharMingen; antibodies to cyclin D1 may also be obtained from Immunotech/Coulter
Mouse IgG1 (isotypic control)
FITC-conjugated goat anti–mouse IgG
Propidium iodide staining solution III (see recipe)

15-ml conical tubes, polypropylene or silanized
Low-speed centrifuge
Flow cytometer equipped with 488-nm argon laser fluorescence excitation source

Additional reagents and equipment for collecting and preparing cells for fixation (see Basic Protocol 1, step 1a, b, or c)

Prepare and fix cell suspension

1. Collect cells and resuspend in PBS (see Basic Protocol 1, step 1a, b, or c).
2. Prepare for fixation by adding 10 ml of 80% ethanol or absolute methanol fixative to each of an appropriate number of 15-ml tubes. Keep tubes on ice (0° to 4°C).

   In addition to preparing a tube for each aliquot of cells to be tested with an anti-cyclin antibody, prepare an appropriate number of tubes for isotypic controls .

3. With a Pasteur pipet, transfer 1 ml of the each cell suspension into the appropriate tubes containing cold fixative. Incubate on ice.

   Time of fixation (storage) at 4°C may vary from 4 hr to several days.

   To minimize cell loss, all the subsequent steps should be done in the same tube.

Label cells with anti-cyclin primary antibody

4. Centrifuge fixed cells 5 min at 300 × *g*, room temperature. Remove alcohol, resuspend cells in 5 ml PBS, and centrifuge as before.

5. Remove supernatant and resuspend cell pellet (≤1 × 10^6 cells) in 1 ml of 0.25% Triton in PBS. Keep on ice for 5 min, then add 5 ml of PBS and centrifuge at 300 × *g* for 5 min at room temperature. Remove supernatant.

6. Dissolve each of the anti-cyclin antibodies of interest (primary antibodies) in rinsing buffer at 5 µg/ml. For each sample to be analyzed, take 100 µl of the 5 µg/ml anti-cyclin antibody solution. Also, prepare 100 µl of 5 µg/ml mouse IgG_1 (isotypic control) for each tube of control cells prepared.

7. Resuspend each cell pellet in 100 µl of rinsing buffer containing the appropriate primary antibody or isotypic control. Incubate 60 min at room temperature with gentle agitation or at 4°C overnight.

Label cells with FITC-conjugated secondary antibody

8. Add 5 ml of rinsing buffer to each tube and centrifuge 5 min at 300 × *g*, room temperature. Remove the supernatants.

9. Make a 1:30 dilution of the secondary antibody (FITC-conjugated goat anti–mouse IgG) in rinsing buffer. Resuspend each of the cell pellets in 100 µl of the diluted FITC-conjugated secondary antibody and incubate 30 min in the dark at room temperature with gentle agitation.

   If cyclin antibody that is directly conjugated to FITC is available, this protocol can be simplified by omitting steps 8 and 9.

Stain cells with PI

10. Add 5 ml of rinsing buffer to each tube and centrifuge 5 min at 300 × *g*, room temperature. Remove the supernatants

11. Resuspend each cell pellet in PI staining solution III. Incubate 20 min at room temperature in the dark before measurement.

Measure cell fluorescence by flow cytometry

12. Set up and adjust the flow cytometer for excitation with blue light (488-nm laser line). Use a 530 ± 20 nm band-pass filter for detection of FITC emission and 620-nm long-pass filter for PI emission.

13. Measure the cyclin-associated green fluorescence of FITC and DNA-associated red fluorescence of PI.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DAPI staining solution I

To 100 ml of 0.1% (v/v) Triton X-100 in PBS (*APPENDIX 2A*) add 0.1 mg 4′,6-diamidino-2-phenylindole (DAPI; Molecular Probes). Store up to 1 month at 4°C in the dark.

DAPI staining solution II

To 100 ml of PIPES buffer (see recipe) add 0.1 mg 4′,6-diamidino-2-phenylindole (DAPI; Molecular Probes). Store up to several weeks at 0° to 4°C in dark or foil-wrapped bottles.

PIPES buffer

3.02 g piperazine-*N*,*N*′-bis(2-ethanesulfonic acid (PIPES; Calbiochem; 10 mM final)
5.84 NaCl (0.1 M final)
406 mg $MgCl_2$ (2 mM final)
1 ml Triton X-100 (0.1% final)
H_2O to 1000 ml
Adjust to pH 6.8
Store up to 6 months at 0° to 4°C

Dissolve the dry ingredients and Triton X-100 in ~800 ml water, adjust pH with NaOH or HCl, and add water to 1000 ml.

Propidium iodide (PI) staining solution I

To 100 ml of 0.1% (v/v) Triton X-100 in PBS add 20 mg DNase-free RNase A and 2 mg of propidium iodide (PI; Molecular Probes). Store up to 2 weeks at 4°C in the dark.

If RNase is not DNase-free, boil a stock solution of RNase A (2 mg in 1 ml water) for 5 min, then use it to prepare the PI staining solution.

Propidium iodide (PI) staining solution II

Add 2 mg of propidium iodide (PI; Molecular Probes) to 100 ml of PIPES buffer (see recipe). Store up to several weeks in dark or foil-wrapped bottles at 0° to 4°C. Prior to use add DNase-free RNase A to 200 µg/ml final concentration.

Propidium iodide staining solution III

Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing:
5 µg/ml propidium iodide (PI)
200 µg/ml DNase-free RNase A
Prepare fresh

COMMENTARY

Background Information

Univariate cellular DNA content analysis

Choice of protocol: Choosing a particular protocol from among those presented in this unit depends on the sample type (i.e., determining whether fixed or unfixed cells should be used), availability of UV light illumination in the flow cytometer (which will dictate preference for DAPI over PI), or the need to identify and quantify apoptotic cells in addition to discrimination of the cell cycle phases. In the discussion that follows, characteristics and applicability of each of the methods is presented. Because a variety of different fluorochromes can be used to stain cellular DNA, and occasionally some of them may be preferred over DAPI, PI, or Hoechst 33342, the spectral properties of the most commonly used dyes are presented in Figure 8.4.2.

In Basic Protocol 1 and Alternate Protocol 1, DNA content is measured in prefixed cell samples. The preference for analysis of fixed cells often is dictated by the need to store or transport samples. Extended storage of unfixed cells, unless done at low temperatures following suspension of the cells in cryopreservative medium, leads to cell deterioration and DNA degradation. Fixed cells, on the other hand, often can be stored for months if not years without much deterioration. The fixative essentially has two functions: (1) it preserves the cells by preventing lysis and autolytic degradation, and (2) it makes the cells permeable and hence makes DNA accessible to the fluorochrome. For DNA-content analysis, the precipitating fixatives (ethanol, methanol, and acetone) are preferred over the cross-linking agents (formaldehyde, glutaraldehyde). It should be stressed, however, that damaged DNA, especially DNA having a large number of double-strand breaks (e.g., as are present in apoptotic cells) leaks out from the ethanol-prefixed cells during hydration and subsequent staining. This allows one to identify apoptotic cells as those with fractional DNA content ("sub-G_1 cell population"). Methods for detecting apoptotic cells are reviewed in Darzynkiewicz et al. (1997).

As mentioned, a variety of DNA fluorochromes can be used to stain DNA in the prefixed cells. Staining with dyes that react with DNA and RNA, such as PI, requires incubation of cells with RNase A. The enzyme is included in the staining solution; a 30-min incubation at room temperature in that solution is adequate to remove RNA from the subsequently measured cells. Since most flow cytometers use blue light (488-nm line of the argon ion laser) as the fluorescence excitation source, PI is a useful label.

Alternate Protocols 1 and 2 employ DAPI instead of PI. One advantage of DAPI is its greater specificity towards DNA, which often is reflected in lower coefficient of variation (CV) values of the mean DNA content of G_1 cell populations. Another advantage is that it does not require incubation with RNase A. However, not all flow cytometers are equipped with a UV-light illumination source, which is needed for DAPI excitation.

The major advantage of detergent-based methods (see Basic Protocol 2 and Alternate Protocol 2) is greater accuracy in DNA-content estimates. However, because the cells are lysed by detergents, mitotic cells, which lack a nuclear envelope, may disintegrate to such an extent that individual chromosomes or chromosome clusters are measured. This usually happens when the samples are vigorously pipetted or vortexed. Therefore, one has to be cautious in interpreting the data, because mitotic cells may not be detected by methods utilizing detergents or hypotonic staining solutions. This is of special importance in instances when a large proportion of cells are in mitosis—e.g., during incubations with mitotic blockers. Furthermore, the presence of chromosomes or chromosome aggregates in the sample may contribute to an increased frequency of detection of objects with low fluorescence values, generally classified as debris or apoptotic cells ("sub-G_1" cell population, see Darzynkiewicz et al., 1997). Likewise, the lysis of apoptotic cells, which have fragmented nuclei, releases several fragments from a single cell. Each such fragment may erroneously be identified as an individual apoptotic cell.

DNA staining in live cells (see Basic Protocol 3) is generally performed in combination with cell sorting to obtain cells synchronized at particular cell cycle phases. The fluorochrome for supravital cell staining is expected to be nontoxic and not alter the cell metabolism. Such a probe has yet to be developed. Most DNA fluorochromes are charged molecules that do not adequately penetrate the plasma membrane. Some uncharged Hoechst dyes that can pass through the membrane, though at a limited rate, are exceptions. The most frequently used supravital DNA fluorochrome is Hoechst 33342. The procedure of staining with Hoechst 33342 followed by sorting appears not to induce immediate cytotoxicity (Loken, 1980). Delayed toxicity attributed to Hoechst 33342 has been observed, however, especially when the cells were treated with some antitumor drugs or radiation subsequent to staining. Hoechst dyes photosensitize cells that have BrdU incorporated into their DNA, in particular to UV light at ~300-nm wavelengths. Viability of the sorted BrdU-labeled cells, counterstained with Hoechst dyes and illuminated with UV light laser, is expected to be impaired.

The intensity of supravital cell staining with Hoechst 33342 and the resolution of DNA content (i.e., possibility of discrimination of cells in different cell-cycle phases) varies among different cell types. This variability, to a large degree, is due to a rapid efflux of the dye from the cell generated by the P glycoprotein transport pump. Cells characterized by rapid efflux mechanisms (e.g., multidrug-resistant tumor cells or stem cells) stain poorly with Hoechst 33342. It has been observed, however, that agents that may impair the efflux function (e.g., calcium channel–blocking drugs such as verapamil), at least in some cell types, improve stainability with Hoechst 33342 (Krishan, 1987).

Cell cycle and kinetic parameters: All cells in $G_{0/1}$ have a uniform DNA content, as do cells in G_2/M. Under ideal conditions of DNA staining and measurement, the fluorescence intensities of all $G_{0/1}$ and G_2/M cells are expected to be uniform, and, after digitization of the electronic signal from the photomultipler, to have uniform numerical values with G_2/M cells having twice the fluorescence of cells in $G_{0/1}$. This, however, is never the case, and on frequency histograms the $G_{0/1}$ and G_2/M populations are represented by peaks of various width because of inaccuracy of the measurement. The coefficient of variation (CV) of the mean value of DNA-associated fluorescence of the $G_{0/1}$ population is a measure of the width. The CV value, therefore, is a reflection of the inaccuracy of the DNA estimate. Because of the inaccuracy there is an overlap between early S and $G_{0/1}$ as well as between late S and G_2/M cells on the histograms. Several mathematical methods of deconvolution of the DNA content frequency histograms have been developed to estimate the

percentage of cells in the respective phases of the cell cycle (Bagwell, 1993; Rabinovitch, 1994). The goal of these techniques is to evaluate the extent of the overlap and thereby to correct for the inaccuracy of the measurement. These methods provided the basis for development of software that allows one to estimate percentage of cells in particular phases of the cycle from the histograms, through simple interactions with the computer. Such software is generally provided upon the purchase of instruments or can be obtained separately from other vendors. The most common software programs used to deconvolute DNA content frequency histograms are provided by Phoenix Flow and Verity Software House.

It is often assumed that the cells in S and G_2/M represent the "proliferative" cell fraction and that their frequency reflects the proliferative potential of the cell population. While this indeed may be the case in some cell systems, the DNA content frequency histograms alone do not provide any direct information on cell kinetics. For example, the histogram cannot reveal whether the cell progression through the cycle is slowed down (e.g., compared to control) if the slowdown affects all phases of the cycle proportionally. Likewise, the histogram cannot show whether the cells are "frozen" in the cycle, which may happen during treatment with high doses of certain drugs, hyperthermia, or radiation. However, when the cell-proliferation rate (e.g., the cell-doubling time in culture) is measured in parallel with DNA content, it is possible, with certain assumptions and approximations, to estimate cell kinetics, including the duration of individual phases of the cycle. One of the assumptions is that the cells are in exponential phase of growth. In such a situation there are always twice as many daughter cells as mother cells, and the cell age distribution across the cycle is represented by the diagram shown in Figure 8.4.4B. Duration of a particular phase of the cycle (e.g., G_1) can then be estimated from the equation:

$$\frac{T_{G1}}{T_C} = \frac{\ln(F_{G1} + 1)}{\ln 2}$$

where T_{G1} is duration of G_1 phase, T_C is duration of the cell cycle, and F_{G1} is a fraction of cells residing in G_1. T_C is estimated from the cell growth curves—i.e., when the number of live cells is plotted as a function of time (cell number on exponential scale versus time on linear scale of the x and y coordinates), the exponential growth is reflected by a straight slope. The slope allows one to calculate the cell doubling time in culture. The latter, with generally acceptable approximation, equals T_C. A similar formula, of course, applies for estimating duration of phases of the cell cycle other than G_1. Thus, for example, when the duration of the cell cycle is 24 hr and the fraction of cells in G_1 is 0.5 (50%), the duration of G_1 (T_{G1}) is $1n(1 + 0.5) \times 24/1n\ 2 = (0.405 \times 24)/0.693 =$ 14.0 hr. The graphical approach for measuring duration of the cell-cycle phases from the DNA content frequency histograms is illustrated in Figure 8.4.4.

Bivariate analysis of DNA content and expression of cyclins D, E, A, or B1

Cyclins are the key elements of the cell cycle progression machinery. They combine with particular cyclin-dependent protein kinases (CDKs) forming the holoenzymes that phosphorylate different sets of proteins at consecutive stages of the cell cycle, thereby driving the cell through the cycle (Pines and Hunter, 1991; Draetta, 1994; Hartwell and Kastan, 1994; Sherr, 1994; Cardon-Cardo, 1995; Morgan, 1995; Bartek et al., 1997). The function of cyclins in these holoenzymes is to activate their partner CDKs and to target them to specific protein substrates whose phosphorylation is essential for traversing a particular section of the cell cycle.

Several cyclins, notably D-type cyclins as well as cyclins E, A, and B, are expressed transiently during the cell cycle. Cyclins D and E belong to the family of G_1 cyclins, whereas cyclins A and B are G_2 cyclins (also see Fig. 8.2.1). During unperturbed growth of normal, nontumor cells, the scheduled timing of synthesis and degradation of cyclins takes place at very specific points of the cycle. The periods of expression of these cyclins by the cell, therefore, can be considered landmarks of the cell cycle. These landmarks complement the traditional milestones of the cycle detected by DNA content measurement, namely mitosis and DNA replication.

The development of antibodies to cyclins made it possible to detect them immunocytochemically and to investigate their expression in individual cells by cytometry (Gong et al., 1994; Lukas et al., 1995; Urbani et al., 1995; Juan et al., 1997). Bivariate analysis of DNA content and cyclin expression provides a framework for subdividing the cell cycle into several subcompartments and for defining, with a greater precision than before, the point at which the cell cycle is arrested by some antitumor

drugs (Darzynkiewicz et. al., 1996). Furthermore, the differences in cyclin expression make it possible to discriminate between cells having the same DNA content but residing at different phases, such as in G_2 versus M or G_2/M cells of a lower DNA ploidy versus G_1 cells of a higher DNA ploidy.

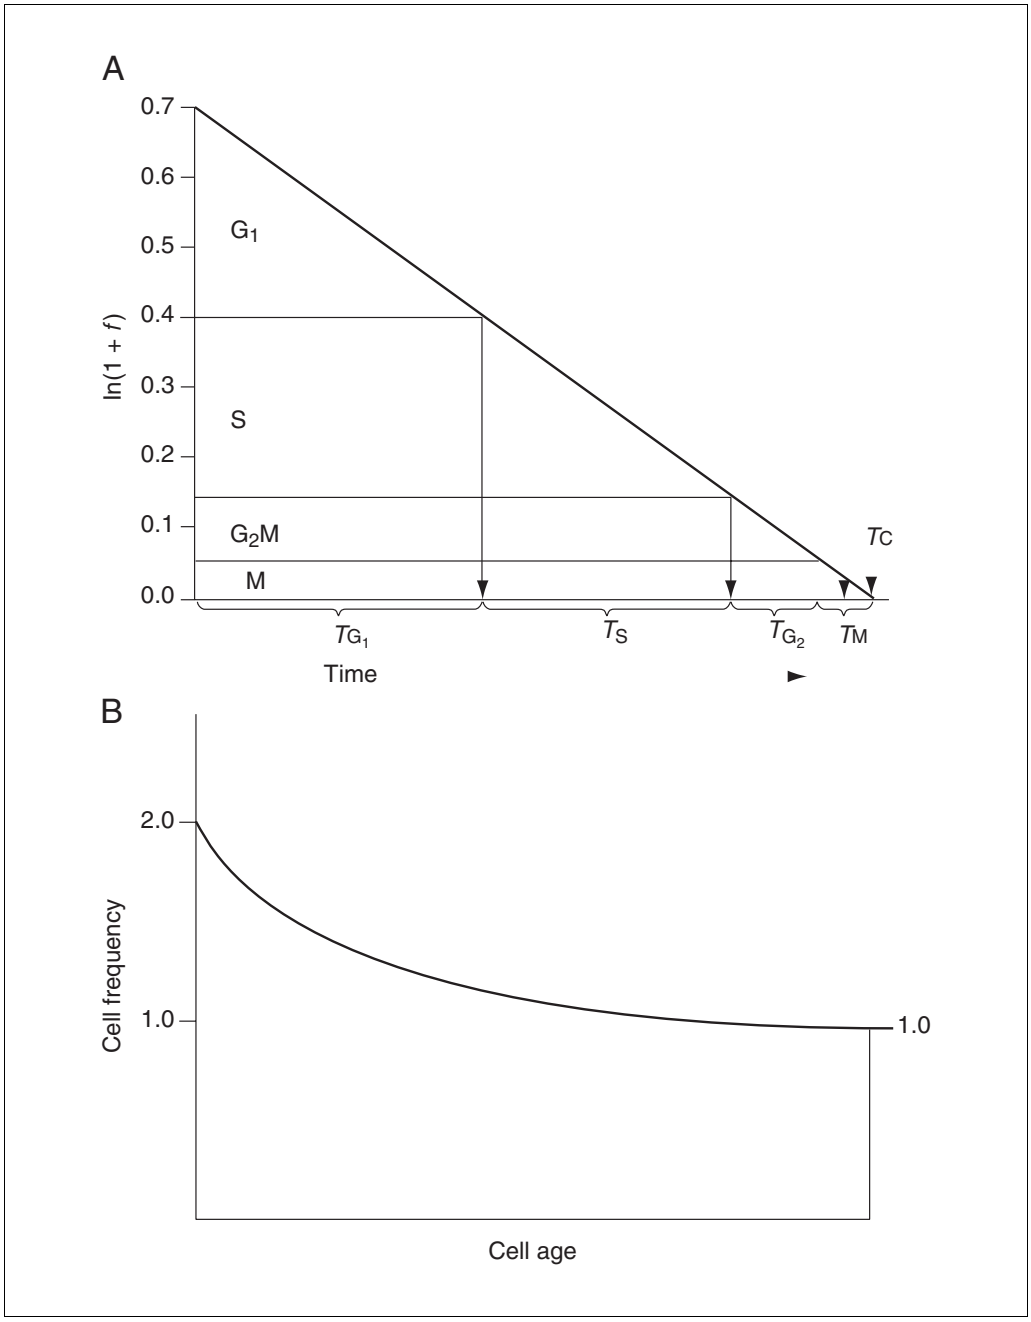

Figure 8.4.4 Graphical method for estimating duration of particular cell cycle phases (**A**) The method is based on the assumption that all cells are in the exponential phase of proliferation—i.e., that there are twice as many daughter as mother cells. (**B**) The proportions of cells in different phase of the cycle are obtained from DNA content frequency histograms (Fig. 8.4.3), and the value of T_C (cell generation, or cell cycle time), which is in turn calculated from the growth curves as the cell-doubling time in culture. T_C equals the cell-doubling time when all cells are in the proliferative cell pool—i.e., when the growth fraction equals 1.0. Fractions of cells in particular phases of the cycle (f) are plotted exponentially as ln(1 + f). T_C is then connected with ln 2 (0.693). The points of intersection of the line connecting ln 2 and T_C with the levels representing frequency of cells in particular phases of the cycle, projected on the time coordinate, represent the duration times of these phases, as shown.

The bivariate analysis of cyclin expression versus DNA content, unlike any other approach, detects the inappropriate ("unscheduled") expression of cyclins—i.e., the presentation of G_1 cyclins by cells in G_2/M and of G_2/M cyclins by G_1 cells—without the need for cell synchronization. Such unscheduled expression of cyclins B1 and A was seen when cell cycle progression was halted, e.g., after synchronization at the G_1/S boundary by inhibitors of DNA replication (Gong et al., 1995; Urbani et al., 1995). The unscheduled expression of cyclins B1 or E, representing a characteristic feature of a particular tumor phenotype, was also observed in some tumor cell lines when their growth was unperturbed (Gong et al., 1994). Likewise, while the expression of cyclins D1 or D3 in nontumor cells was restricted to an early section of G_1, the presentation of these proteins in many tumor cell lines was also seen during S and G_2/M (Juan et al., 1996). As specific markers of cell proliferation, cyclins are expected to reflect proliferative potential of tumors and therefore to be the key prognostic markers in neoplasia.

Critical Parameters

Univariate cellular DNA content analysis

The most critical issue in DNA content analysis is the accuracy of DNA content measurement. The accuracy, as mentioned (see Background Information), is reflected by the extent of variation in cellular fluorescence between the cells with identical DNA content, such as $G_{0/1}$ cells. The CV of the DNA-associated mean fluorescence of G_1 cells, therefore, is considered as an index of accuracy of DNA content measurement. High accuracy is required, in particular, in studies of DNA ploidy, to distinguish between DNA diploid and aneuploid cells, which may differ minimally in DNA content. High accuracy of DNA content measurement is also critical in analysis of the cell cycle distribution. Regardless of the type of the software used to deconvolute DNA frequency histograms, the accuracy in estimation of cell proportions in respective phases of the cell cycle directly correlates with accuracy of DNA content measurement. There is no formal consensus regarding the acceptable maximal CV value of the mean DNA content of $G_{0/1}$ cell population—i.e., maximal error in cellular DNA content estimate. Most researchers, however, would consider the accuracy to be poor and results unacceptable if CV values of $G_{0/1}$ populations of normal, nontumor cells exceed 6%.

A variety of factors can contribute to poor accuracy in DNA content analysis. The most common is inappropriate optical alignment (spatial position of laser beam with respect to sample flow and fluorescent light–collecting lenses) of the flow cytometer. When the instrument is optimally aligned, the measured cell passes precisely through the center of the laser beam, and at the same time, is in the focus of the fluorescence emission collection lenses. A minor adjustment of the sample flow or any of the optical parts leads to a loss in accuracy of DNA content measurement. Proper maintenance of the instrument, and careful adjustment with standard fluorescent beads of known uniformity prior to analysis of the experimental samples, is essential to achieve accurate DNA content measurements. Problems in sample preparation, either resulting in mechanical damage to the cells or involving incorrect composition of buffers and staining solutions, represent another common cause of poor resolution in DNA analysis.

It should be stressed that there may be situations when, in spite of good accuracy in DNA content measurement (in terms of proper instrument adjustments and sample staining), the CV of the mean DNA content of G_1 cell populations is relatively large. This may happen when significant numbers of dead or dying cells are present in the sample or when the cells were treated with drugs interacting with DNA. Many antitumor drugs are known to impair stainability of DNA with the fluorochromes used for flow cytometry. Furthermore, because of the nature of the tumor, which may either be multiclonal or have developed drug resistance by gene amplification mechanisms (e.g., as reflected by the presence of minute chromosomes), the tumor cell populations may have variable DNA content, and therefore intrinsically high CV values for the $G_{0/1}$ cell populations.

Bivariate analysis of DNA content and expression of cyclins D, E, A, or B1

The critical steps for immunocytochemical detection of intracellular proteins are cell fixation and permeabilization. These steps often have to be customized for particular antigens. The fixative is expected to stabilize the antigen in situ and preserve its epitope in a state where it continues to remain reactive with the available antibody. The cell has to be permeable to allow access of the antibody to the epitope.

Most studies on cyclins have employed precipitating fixatives such as 70% to 80% ethanol, absolute methanol, or a 1:1 mixture of methanol and acetone cooled to –20° to –40°C. Brief (15- to 30-min) treatment with 1% paraformaldehyde followed by 70% cold ethanol has been used for fixation of D-type cyclins although this cyclin can also be detected following fixation with cold methanol. The choice of fixative, thus, appears not to be a critical factor for cyclin detection and, although the absolute level of the immunofluorescence may vary, various fixation protocols yield essentially similar cyclin distributions with respect to the cell cycle position. Each fixative has some undesirable effects (e.g., increased cell clumping in the case of the ethanol/acetone mixture or cell autofluorescence and poor DNA stainability when formaldehyde is used), and one often has to compromise between these effects and the optimal detection of a particular cyclin. Fixation in 80% cold ethanol, as presented in this protocol, offers such a compromise.

Much more critical for the detection of cyclins is the choice of a proper antibody. Often an antibody that is applicable to immunoblotting fails in immunocytochemical applications, and vice versa. Likewise, the antibody may show nonspecific reaction with denatured proteins (i.e., reveal several bands on immunoblots), and yet be acceptable in immunocytochemical assays. These discrepancies may be due to differences in accessibility of the epitope or differences in the degree of denaturation of the antigen on the immunoblots as compared to the situation in its in situ location. Some epitopes may not be accessible in situ at all. This especially pertains to epitopes that are the cyclin segments involved in formation of complexes with the partner CDKs, CDK inhibitors, or other molecules such as proliferating cell nuclear antigen (PCNA). Since there is strong homology between different cyclin types, cross-reactivity may also be a problem. Because commercially available monoclonal antibodies may differ, e.g., in specificity and degree of cross-reactivity, it is important to use reagents that have been already tested and referenced in published papers. It is required that the authors provide information (the vendor and hybridoma clone number) on the reagent used in their study.

A very important control is examination of the stained cells by UV light microscopy, or preferably confocal microscopy. All cyclins, with the notable exception of cyclin B1, have nuclear localization. Cyclin B1 has cytoplasmic localization during late S and most of G_2, and is localized in the chromatin only at mitosis. Cyclin B2 is localized to Golgi (Jackman et al., 1995). Inappropriate localization of the fluorescence of the cells stained with the presumed anti-cyclin antibody may be an indication of its nonspecific reactivity with other cell constituents.

The relative cellular content of a particular cyclin plays a role in its detection. The signal-to-noise ratio (ratio of fluorescence intensity of the cyclin-positive cells to the control cells, stained with the isotype immunoglobin), for example, is higher in the case of cyclin B1 than in the case of cyclins E or A, most likely due to the fact that the absolute level of cyclin B1 is higher compared to cyclins E or A. The level of expression of D-type cyclins varies markedly depending on the cell type and the phase of cell growth. High sensitivity of the instrument and low level of cell autofluorescence, therefore, are of greater importance for the detection of cyclins E or A than of cyclin B1 or D-type cyclins.

While isotypic immunoglobin or irrelevant isotypic antibody are generally accepted as appropriate controls, they are not perfect for this purpose, as their fluorescence may also vary depending on the source (vendor) and may not be representative the actual background. Ideal controls represent the cells of the same type and of the same species, but with the gene that codes for the detected protein deleted. Such control cells should be subjected to identical immunocytochemical procedure as the studied cells. Unfortunately, few cell lines with deleted cyclin genes are currently available.

Anticipated Results

Univariate cellular DNA content analysis

Figure 8.4.3 presents DNA frequency histograms of HL-60 cells stained with DAPI according to Alternate Protocol 1 and Alternate Protocol 2, respectively. As is evident based on differences in DNA content, one can identify a population of $G_{0/1}$ cells with uniform low DNA content values, G_2/M cells with DNA content twice that of $G_{0/1}$ cells, and S phase cells with intermediate DNA content. To reveal the percentage of cells in $G_{0/1}$, S, and G_2/M, the DNA frequency histograms in the figure were deconvoluted using the Multicycle software (Phoenix Flow Systems). Similar results are expected when using Basic Protocols 1 and 2. Supravital cell staining with Hoechst 33342, however, yields less accurate DNA measurements, which

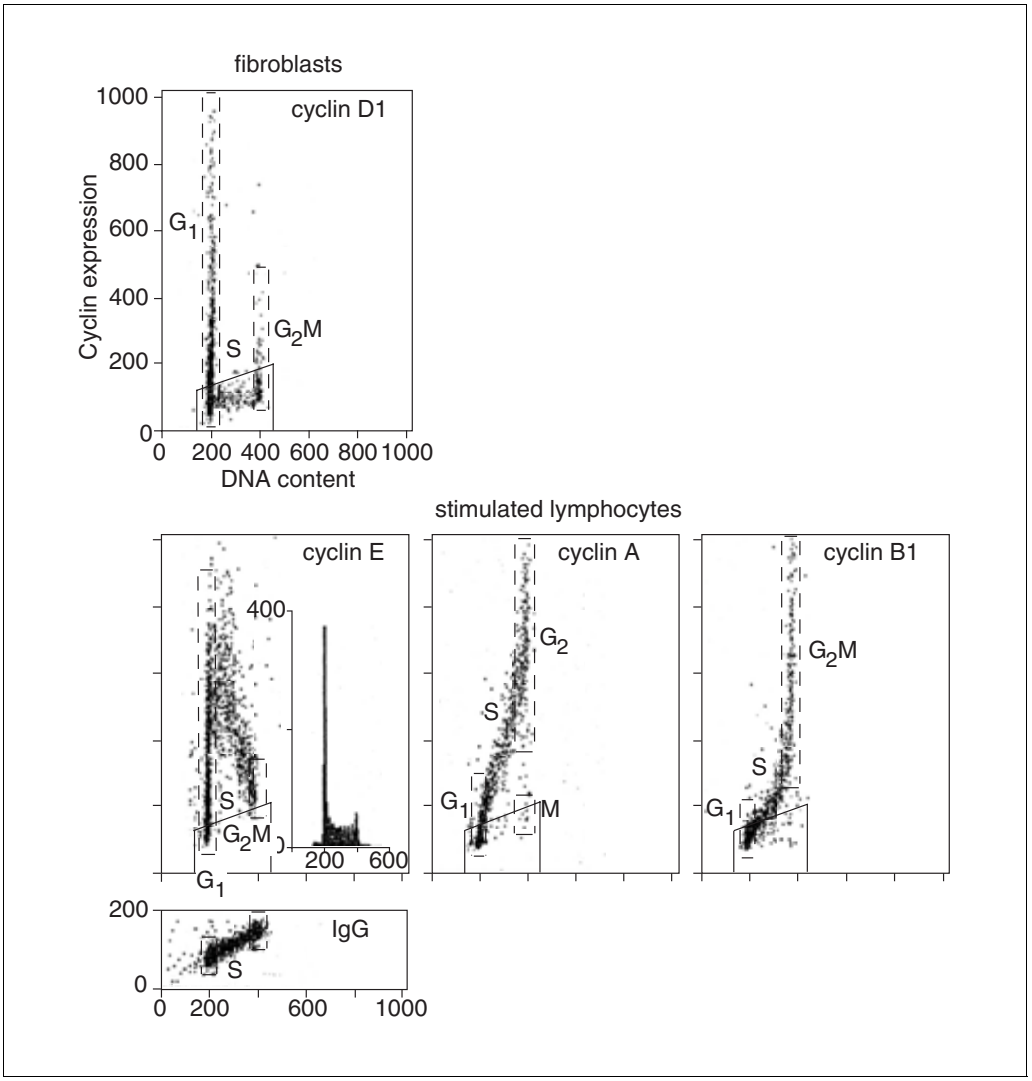

Figure 8.4.5 Bivariate cyclin versus DNA content distributions (scatter plots) showing expression of cyclin D1 in normal human fibroblasts and cyclins E, A, and B1 in mitogen-stimulated human lymphocytes. The trapezoidal windows represent level of fluorescence of the respective control cells stained with the isotype IgG, rather than the respective cyclin-anti-cyclin antibody. The $G_{0/1}$ and G_2/M populations gated based on differences in DNA content are marked by dashed lines.

are reflected by the increased width of the $G_{0/1}$ and G_2/M peaks (i.e., increased CV of the mean fluorescence of $G_{0/1}$ and G_2/M cell populations).

Bivariate analysis of DNA content and cyclin expression

The scheduled timing of expression of cyclins B1, A, E, and D1 in relation to the major phases of the cell cycle is reflected by a very characteristic pattern of the bivariate cyclin–versus–cellular DNA content distributions. These distributions are shown in Figure 8.4.5 for normal human proliferating lymphocytes (cyclins B1, A, and E) and fibroblasts (cyclin D1). As is evident from the cytograms, the expression of cyclin B1 is limited to late S phase cells and the cells with a G_2/M DNA content, while early- and mid–S phase cells show a very low level of this protein. Cells in G_1 phase are essentially cyclin B1–negative.

Similar to cyclin B1, expression of cyclin A is minimal in G_1 cells. It becomes pronounced, however, during S phase where its level progressively increases as the cells advance towards G_2. Maximal expression of cyclin A is seen in cells having a G_2/M DNA content (Fig. 8.4.5). It should be mentioned, however, that because cyclin A is abruptly degraded during prometaphase (Pines and Hunter, 1991), mitotic cells that have advanced past prometa-

phase are essentially cyclin A–negative (not shown).

Expression of cyclin E can be summarized as follows: (1) the maximal level of this protein is detected in the cells undergoing transition from G_1 to S; (2) its level continuously decreases during cell progression through S, with the result that most G_2/M cells are cyclin E–negative; and (3) a distinct threshold in cyclin E expression is apparent at the G_1/S transition. As it is evident from the continuity of the cell clusters on scatter plots (Fig. 8.4.5) the cells have to accumulate cyclin E above the threshold level to enter S phase.

The presence of cyclin D1 in exponentially growing normal fibroblasts is limited to cells in $G_{0/1}$ (Fig. 8.4.5). Most cells in S and G_2/M are cyclin D1–negative, with the exception of a few cells with a G_2/M DNA content. The latter may be G_1 cell doublets, since not all doublets can be identified by analysis of the shape (pulse width) of the electronic signal.

It should be stressed that, as mentioned before (see Background Information), the cyclin distributions as shown in Figure 8.4.5 characterize only those cells that are growing normally, exponentially, and asynchronously. The distributions are very different when the cell-cycle progression is perturbed, or in the case of some tumor cell lines that display unscheduled expression of these cyclins.

Time Considerations

For Basic Protocol 1 (PI staining), cell fixation takes ~10 min, but cells have to be kept in fixative 2 hr; the cell staining procedure takes ~45 min. Alternate Protocol 1 (DAPI staining) requires similar times for cell fixation. However, because there is no need to incubate cells with RNase, the time of staining is shorter. The detergent-based cell-staining procedure of Basic Protocol 2 takes ~60 min. For Alternate Protocol 2, which is simpler, cell staining takes ~15 min. Supravital staining of cells (Basic Protocol 3) requires ~20 min for staining, although extended staining times (up to 90 min) may be needed for some cell types.

For Basic Protocol 4 (DNA and cyclins) cell fixation takes ~10 min, but the cells have to be kept in fixative for ≥2 hr. The cell-staining procedure takes ~1 hr if the antibodies used are directly conjugated with a fluorochrome. The staining may take an additional 40 min if the primary antibody is not fluorochrome-tagged and therefore indirect labeling has to be used. It is sometimes convenient, however, to leave the cells for incubation with the primary antibody overnight, at 4°C.

Centrifugal Elutriation to Obtain Synchronous Populations of Cellsab

Counterflow centrifugal elutriation (CCE) is a generally noninvasive method for separating large numbers of mixed particles (bacteria, yeast, mammalian cells) into populations on the basis of their size and mass. For mammalian cells the method is particularly useful for separating mixed cell populations (e.g., T cells or monocytes from peripheral blood mononuclear cells or, as described here, for obtaining proliferating cell populations partitioned at progressive stages of the cell division cycle. CCE does not perturb cell metabolism, a fundamental problem encountered with metabolic synchronizing agents (see *UNIT 8.3*). Thus, the characteristics of populations separated by CCE more closely reflect normal cell cycle regulation. The standard protocol permits separation of ~2×10^8 cells into six to ten progressive populations using a Beckman JE-6B rotor (see Basic Protocol). For separation of a larger number of cells (~10-fold more), parameters are modified for use with a large JE-5.0 rotor (see Alternate Protocol). Because the task of harvesting cells from large volumes of culture medium by repetitive centrifugation is time consuming and can adversely effect cell viability, this protocol also presents a convenient method for concentrating cells from culture media by continuous flow using the large elutriation rotor. To accurately assess elutriated cell fractions for purity and to verify cell cycle position, short protocols are provided to quantify DNA content by flow cytometry with propidium iodide (see Support Protocol 1), to quantify nascent DNA synthesis by incorporation of [^{3}H]thymidine deoxyribose (see Support Protocol 2), and to quantify DNA synthesis and content by flow cytometry using PI and incorporated 5-bromo-2′-deoxyuridine (BrdU; see Support Protocol 3).

SEPARATION OF CELLS INTO PROGRESSIVE STAGES OF THE CELL DIVISION CYCLE BY COUNTERFLOW CENTRIFUGAL ELUTRIATION

BASIC PROTOCOL

This section describes the setup and equilibration of the Beckman J-6B elutriator system for sterile separation of mammalian cells into progressive populations through the cell division cycle based on cell size and mass.

NOTE: Methodical tissue culture technique (Chapter 1) is the single most important parameter to ensuring reproducible results and good yields at all cell cycle phases. Healthy cells are less prone to lysis and clumping from released DNA and eliminate the need for DNase treatment during the run. Large clumps in the elutriation chamber will adversely effect fluid flow and separation. Sustained log-phase growth is required for high viability, low debris, and sufficient levels of S- and G_2/M-phase cells.

Materials

70% (v/v) ethanol
Elutriation medium (see recipe) equilibrated ≥2 hr at ambient temperature
Nonadherent cells in log-phase growth: suspension cultures at 2–5 × 10^5 cells/ml with fresh medium added at each doubling

Beckman J-6B or J25I centrifuge with view port door and strobe assembly
Beckman JE-6B rotor with standard elutriation and bypass chambers
Elutriation liquid system assembly (Fig. 8.5.1), consisting of:
  Medium reservoir: 2-liter roller bottle and 2-ml pipet
  Loading syringe: 10-ml syringe barrel and three-way valve
  High-quality peristaltic pump with 10-turn potentiometer or digital control (e.g., Masterflex 7520 or 7550), capable of 100 rpm, 0 to 150 ml/min in 0.1 ml/min increments

continued

Current Protocols in Cell Biology (1999) 8.5.1-8.5.16

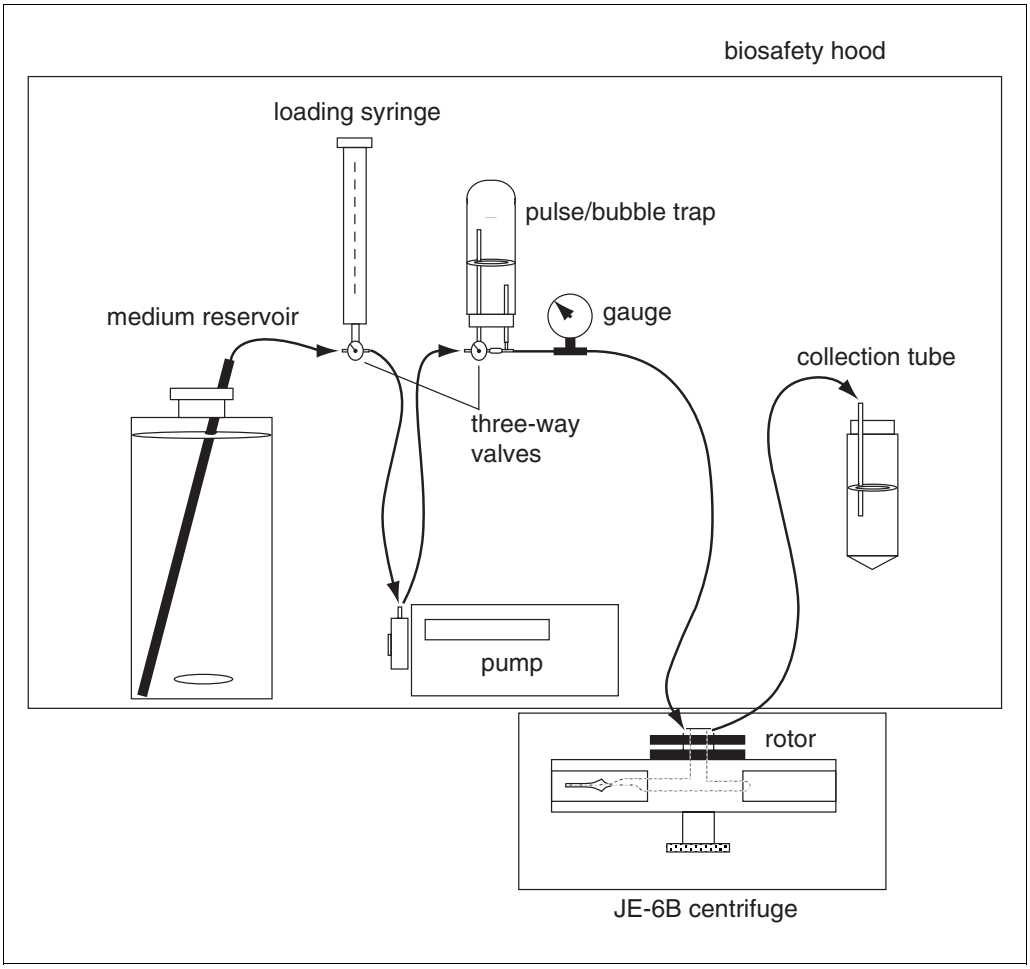

Figure 8.5.1 Schematic of the counterflow centrifugal elutriation system. Fluid is drawn from a reservoir past a valved loading syringe and through a peristaltic pump. It proceeds through a pulse/bubble trap compensator and pressure gauge to the rotor, and returns from the chamber to a 2-ml pipet into a collection vessel. The entire setup (with the exception of the centrifuge itself) is assembled in a hood.

Pulse/bubble trap and three-way valve (Beckman)
Pressure gauge (Beckman)
Collection tube: 250-ml conical centrifuge bottle (Corning)
¼-in.-o.d. (0.64-cm) Silastic tubing (Masterflex 6411-14)
Ring stand and clamps
18-G needle
10-ml syringe
250-ml conical centrifuge bottles
Beckman GPR centrifuge (or equivalent) with swinging bucket rotor
Additional reagents and equipment for counting cells with a hemacytometer (*UNIT 1.1*)

NOTE: Elutriation is performed with the centrifuge, media, and cells at ambient temperature. Cell fractions are processed immediately after collection or stored on ice in multiple runs.

Set up elutriation system

1. Set up a JE-6B elutriation rotor, strobe assembly, and J-6B or J25I centrifuge according to manufacturer's specifications (Beckman Instruments, 1981, 1989).

Ensure that the internal rotating seal is free from wear and is correctly seated against the head assembly.

Failure of the rotating seal will either result in leakage into the centrifuge chamber or allow input and output fluid to mix and bypass the elutriation chamber.

2. Ensure that the elutriation and bypass chambers are in the correct positions and that the fluid flowing into the rotor enters the bottom (outermost) region of the elutriation chamber.
3. Set up the elutriation liquid system assembly as shown in Figure 8.5.1. Secure the loading syringe, pulse/bubble trap, and pressure gauge using clamps and a ring stand. Use ¼-in.-o.d. Silastic tubing throughout the system. Bevel the input and output pipet ends to prevent flow obstruction during the run.

   This design differs from that described by the manufacturer.

   The pulse/bubble trap is held inverted (as shown) with a three-way valve connected to the first input tee. This allows the cells to bypass this chamber. After loading, the chamber is switched in-line to compensate for any flow pulsation caused by the pump.
4. To ensure sterile sorting, place the entire assembly (step 3) in a laminar flow hood and place the centrifuge directly adjacent to the hood (Fig. 8.5.1). Minimize the length of tubing used in the system.

Sterilize elutriation system

5. With the centrifuge off, sterilize the entire system by pumping 70% ethanol through at ~30 to 40 ml/min, being careful to fill the loading reservoir, bypass chamber, pressure gauge, bypass tubing, and all valves. Allow to sit for 10 min.
6. Remove ethanol, being careful to drain all components by starting at the loading chamber and finally drain the rotor by lifting and tilting.
7. Rinse any residual ethanol by pumping sterile water through the system as described for ethanol.

   Residual ethanol will cause precipitate in the elutriation medium.
8. Allow to recirculate 5 to 10 min by putting both input and output lines into a sterile water vessel, then remove lines and drain the system.

Equilibrate elutriation system

9. Equilibrate the system with elutriation medium that is well equilibrated at the operating (ambient) temperature. Circulate the medium as described in step 5, placing both input and output lines into a 2-liter vessel containing elutriation medium.

   Cold medium placed in a warm system will degas and create bubbles in the system.
10. Begin removing trapped air from the system by pinching off tubing to create ~20 lb back pressure and quickly releasing. Start at the loading chamber and progress toward the elutriation chamber, switching valves as necessary to ensure that all bubbles are removed. Remove air in the elutriation chamber by lifting the rotor and tilting 90 degrees to allow medium to fill the chamber.
11. Turn on the centrifuge, bring the rotor to running speed, and repeat step 10 to remove trapped air.
12. Stop rotor and lift to check for leakage.

    This step also helps to dislodge additional trapped air.
13. Restart rotor and recheck the entire system for trapped air bubbles.

    Air that becomes trapped in the elutriation input will impede flow into the chamber and ruin the run.

An air cushion of ~1 in. (2.5 cm) should remain in the pulse/bubble chamber to dampen any pump pulsation during the run.

Calibrate pump

14. Set rotor speed to 1800 rpm and loading flow rate at 12 ml/min.

    As an example, this protocol loads cells at 12 ml/min at a rotor speed of 1800 rpm, with ten samples taken at 3 ml/min increments up to 42 ml/min. Elutriation of most mammalian cells is done at rotor speeds between 1800 and 2500 rpm, with corresponding loading flow rates ranging between 12 and 20 ml/min. See Table 8.5.1 for examples of flow rates used to elutriate Jurkat cells using the JE-6B rotor. See Beckman Instruments (1981, 1989) for a detailed discussion of the selection of rotor speed and flow rate based on particle size and mass.

    Although separation of populations is achieved by varying either speed or flow rate, the authors have found that varying flow rate with a digitally controlled pump provides the most reproducible results.

15. Calibrate the pump to the loading flow rate with the complete system in place and the rotor running at the desired speed. To calibrate, collect medium from output line into a graduated cylinder for 1 min and measure volume. If necessary, readjust pump calibration setting and collect again for 1 min. Repeat until pump speed is accurate. Also check maximum flow rate to ensure that this is obtainable with minimum back pressure (~5 psi).

    Obstruction of input and output tubes or a change in their respective heights will affect pressure, flow rates, and separation. A high-quality digital pump will retain linearity through the range of flow rates. For pumps utilizing a 10-turn potentiometer, settings should be determined to deliver each incremental flow rate.

Harvest cells

16. Transfer 2×10^8 nonadherent log-phase cells (~0.5 to 1 liter) to 250-ml conical centrifuge bottles and centrifuge for 10 min at $200 \times g$ (e.g., in a Beckman GPR centrifuge). Gently resuspend pellet in 10 ml elutriation medium and verify cell density (final 2×10^7/ml).

Table 8.5.1 Jurkat Elutriation Parameters[a] and Cell Cycle Phase Content of the Separated Populations

Fraction	Flow rate (ml/min)	Cell number	% of load	% G_1[b]	% S[b]	% G_2[b]
Load	13	2.0×10^8	100[c]	55.6	27.3	17.1
1	18	3.3×10^6	1.6	96.2[d]	3.6	0.2
2	21	2.1×10^7	10.5	91.0	5.2	3.8
3	24	3.7×10^7	18.5	86.8	11.0	2.2
4	27	3.2×10^7	16.0	78.0	19.4	2.6
5	30	2.3×10^7	11.5	59.7	35.4	4.9
6	33	1.9×10^7	10.6	29.9	55.0	15.1
7	36	1.5×10^7	7.5	13.0	50.7	36.3
8	39	1.2×10^7	6.0	4.8	40.3	54.9
9	42	7.7×10^6	3.8	4.1	32.3	63.6
10	45	5.7×10^6	2.8	2.9	19.8	77.3
11	48	4.3×10^6	2.2	2.7	10.4	86.9

[a] JE-6B rotor maintained at constant speed of 1800 RPM.

[b] Percentage distribution calculated from histograms of total DNA content (Fig. 8.5.3).

[c] The percentages from fractions 1 to 11 add up to <100% because small amounts are lost to the system during loading (load fraction) or aggregate in the chamber and are unrecoverable (dump fraction).

[d] Approximately 3% of these cells contain apoptotic DNA with sub-G_1 content.

For most efficient use of time and to maintain cells in optimal condition, cells can be centrifuged during equilibration of the elutriator.

17. Load concentrated cells into a 10-ml syringe and pass three times *slowly* through an 18-G needle just prior to loading. Check cells under a microscope to ensure that the culture is monomeric with high viability.

Load elutriator and collect fractions

18. Check that the pump and rotor are at speed (12 ml/min, 1800 rpm). Transfer the 10-ml cell suspension directly from the syringe used for dispersion (step 17) into the loading syringe. Place elutriator output line into a 250-ml conical centrifuge bottle (collection vessel). Set the valve at the pulse/bubble trap to bypass the trap.

    Loading can be done through the pulse/bubble trap, but this dilutes the cells and increases the time needed for loading and equilibration.

19. Open the valve to the loading syringe to allow cells to be drawn into the medium stream, being careful to prevent air from being drawn into the system. Do not allow the loading syringe to empty completely (shut the valve once all but ~250 µl of the cell suspension has been drawn into the system).

20. Add ~2 to 4 ml elutriation medium to the loading syringe and load the additional volume to ensure complete loading of the cells. Again, leave ~250 µl remaining in the loading syringe.

    If air has entered the elutriator line during loading, the rotor must be stopped and purged of air and the cells must be reloaded.

21. Once cells have bypassed the pulse/bubble trap, open this valve to trap bubbles and to compensate for pump pulsation. Carefully monitor cells through the view port of the centrifuge door.

    Cells appear as a broad translucent band that should fill the chamber to just below the elutriation boundary (Fig. 8.5.2), below the top of the chamber.

22. Watch the cells carefully. Do not allow the cells to pack (increase flow rate if necessary) or to flow over the top of the elutriation boundary (decrease flow rate). Allow cells to equilibrate while collecting 125 ml medium (load fraction).

    For pilot runs, examine the load fraction to ensure that it contains only debris. If a significant number of viable cells are present, the load should be repeated at a lower-flow rate.

    Elutriation is a balance of g force and counterflow. If cells do not appear to be filling the chamber, gradually increase pump speed. If cells are reaching the elutriation boundary, reduce the pump speed to prevent loss of cells and then gradually increase until they are at the appropriate level. Do not change rotor speed.

23. Once cells have equilibrated, transfer the output line to a fresh 250-ml collection vessel to collect fraction 1. Gradually increase pump speed by 0.1 ml/min increments from 12 ml/min to 15 ml/min and collect another 125 ml medium. Place cells on ice.

    Cold shock will cause sustained growth arrest of some cell types. Placing these populations on ice is not recommended when kinetic cell growth studies are to follow elutriation.

24. Collect remaining fractions in 125 ml medium each at 3 ml/min increments in pump speed. Collect ten samples up to 42 ml/min and place on ice.

25. Once the last fraction has been collected, remove any remaining cells from the rotor by stopping the rotor and continuing to pump 125 ml medium through the system.

    For multiple elutriation runs of the same cell line, fractions may be overlaid into the same 250-ml bottle; however, all run conditions must be reproduced. The same number of cells must be loaded and rotor/pump speeds and fractions must be kept the same in order to

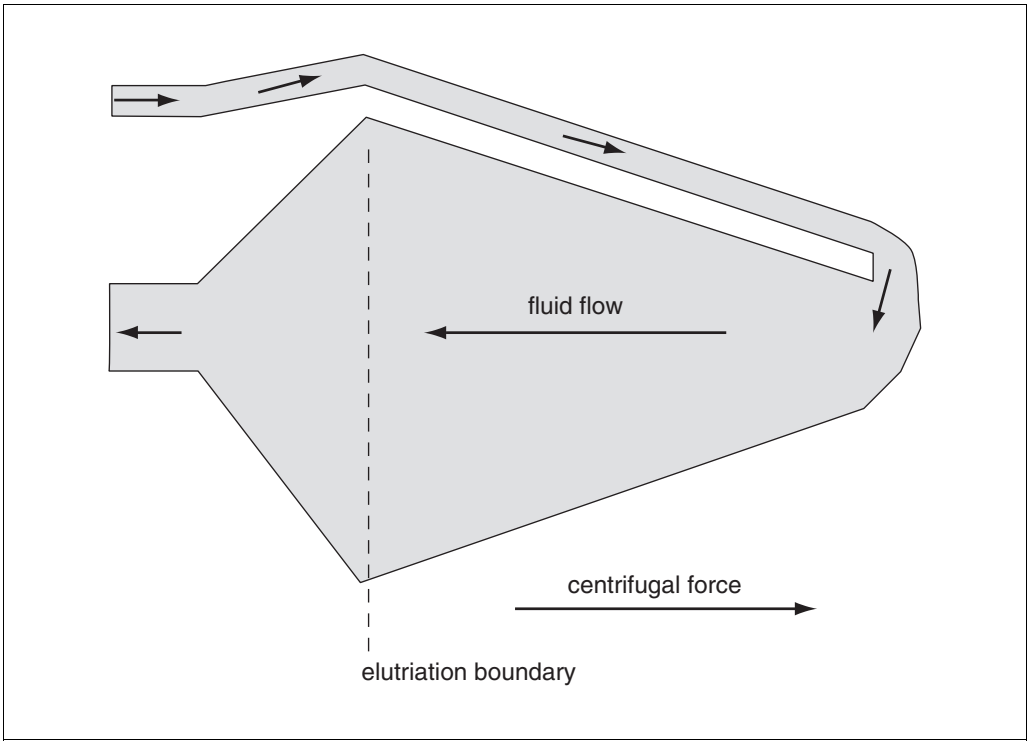

Figure 8.5.2 Schematic of the standard elutriation chamber.

duplicate each fraction. Store fractions on ice to slow cell cycle progression during subsequent runs.

26. Carefully and thoroughly resuspend cells in centrifuge bottles for each fraction. Count cells using a hemacytometer (*UNIT 1.1*) and concentrate the desired number of cells by centrifugation for use in experiments.

Very early and late fractions contain fewer cells. To obtain a more accurate cell count, cells from these fractions must first be concentrated by centrifugation.

ALTERNATE PROTOCOL

LARGE-SCALE ELUTRIATION WITH THE JE-5.0 ROTOR

Setup and equilibration of the larger JE-5.0 elutriator for concentration and large-scale elutriation is as described above (see Basic Protocol) with minor modifications (e.g., the size of the system tubing is increased to accommodate increased flow rate). If large and small rotors are used interchangeably, it is convenient to keep a separate, preassembled plumbing system (loading syringe, pulse/bubble trap chamber, gauges, and so on) for each rotor. The careful handling of healthy cells and the loading conditions are as described in the Basic Protocol.

To accommodate the volume of cells needed to fuel the large rotor, cells are concentrated from one large vessel (such as a 10-liter spinner flask) using the JE-5.0 rotor. With careful monitoring to prevent cells from pelleting or flowing through the chamber, a large volume of cells can be conveniently concentrated by gradually increasing rotor speed while maintaining a constant pump speed. The flowthrough medium is collected in a large waste flask and the concentrated cells are collected by transferring the output line to a 250-ml bottle and stopping the rotor. This concentration procedure is less time consuming and labor intensive than traditional centrifugation procedures and also preserves better viability. Thus, it is very useful on its own to concentrate cells for any purpose.

Additional Materials *(also see Basic Protocol)*

Beckman JE-5.0 rotor with 40-ml chamber
⅜-in.-o.d. (1.0-cm) Silastic tubing (Masterflex 6411-16)
30-ml syringes for loading chamber and for dispersing cells
4-liter vessel
Large sterile vessel
Large waste flask

Concentrate cells

1. Set up elutriator (see Basic Protocol, steps 1 to 4), but use a Beckman JE-5.0 rotor, ⅜-in.-o.d. Silastic tubing throughout the assembly, a 30-ml syringe for the loading chamber, and a 4-liter vessel for the medium reservoir.
2. Sterilize, equilibrate, and calibrate elutriator (see Basic Protocol, steps 5 to 15), calibrating at a pump speed of 70 ml/min and a rotor speed of 2000 rpm.
3. Pool nonadherent log-phase cultured cells into a large sterile vessel.

   At 2×10^5 cells per ml, this procedure will require ~10 liters of cells to load the chamber.
4. Place both input and output lines in the loading vessel and load cells into the chamber at a pump speed of 70 ml/min and rotor speed of 2000 rpm. Continue to recirculate for 8 to 10 min to ensure that cells are visible in the chamber.
5. Gradually increase rotor speed to 2400 rpm over a 5-min interval, and then transfer the output line into waste flask.
6. Continue to gradually increase the rotor speed to 2900 rpm, keeping cells well below the elutriation boundary near the top of the chamber (Fig. 8.5.2). Be careful not to allow cells to pack into a pellet (increase flow rate if necessary).
7. Once the desired number of cells are collected based on cells/ml medium, transfer the output line into a 250-ml centrifuge bottle. Stop the rotor and collect 250 ml medium in each of two centrifuge bottles (500 ml total).

Prepare cells and equipment for elutriation

8. Centrifuge cells for 10 min at $200 \times g$ (e.g., in a Beckman GPR centrifuge) and gently resuspend in 30 ml elutriation medium.
9. While the cells are centrifuging, reequilibrate the system with elutriation medium and recalibrate at a pump speed of 50 ml/min and a rotor speed of 1800 rpm.

   Preparing the system for elutriation while the cells are centrifuging provides for the most efficient use of time and helps maintain cells in optimal condition.

   See Table 8.5.2 for example of flow rates used for WEHI-231 cells elutriated using the JE-5.0 rotor.
10. Load concentrated cells into a 30-ml syringe and pass three times slowly through an 18-G needle just prior to loading. Check cells under a microscope to ensure mono-dispersion.

Load elutriator and collect fractions

11. Load elutriator (see Basic Protocol, steps 18 to 22), making sure pump and rotor speed are set at 50 ml/min and 1800 rpm. Follow cells with ~10 ml elutriation buffer to ensure complete cell loading (step 20), and leave 1 ml to prevent complete emptying of the syringe (steps 19 and 20). Collect 250 ml for the load fraction (step 22).

Table 8.5.2 WEHI-231 Elutriation Parameters[a] and Cell Cycle Phase Content of Separated Populations

Fraction	Flow rate (ml/min)	Cell number	% of load	% G_1[b]	% S[b]	% G_2[b]
Load	50	2.0×10^9	100[c]	24.3	58.8	16.9
1	60	7.8×10^6	0.4	98.7	1.2	0.1
2	70	2.6×10^8	13.0	67.7	32.2	0.1
3	80	3.5×10^8	17.5	39.0	60.4	0.6
4	90	3.3×10^8	16.5	18.4	79.2	2.4
5	100	2.0×10^8	10.0	7.5	82.2	10.3
6	110	2.1×10^8	10.5	4.0	69.4	26.6
7	120	2.1×10^8	10.5	3.8	50.5	45.7
8	130	1.5×10^8	7.5	5.2	36.3	58.5
9	140	4.2×10^7	2.1	6.2	29.5	64.3

[a]JE-5.0 rotor maintained at constant speed of 1800 RPM

[b]Percentage distribution calculated from dot plots of BrdU and total DNA (Fig. 8.5.5).

[c]The percentages from fractions 1 to 11 add up to <100% because small amounts are lost to the system during loading (load fraction) or aggregate in the chamber and are unrecoverable (dump fraction).

12. To collect first fraction, transfer output line to a fresh 250-ml collection vessel. Gradually increase pump speed by 1.0 ml/min increments to 60 ml/min and collect the next 250-ml fraction. Place cells on ice.

    Cold shock will cause sustained growth arrest of some cell types. Placing these populations on ice is not recommended when kinetic cell growth studies are to follow elutriation.

13. Collect remaining fractions in 250 ml medium each at 10 ml/min increments in pump speed. Collect ten samples up to 150 ml/min and place cells on ice.

14. Remove any remaining cells from the rotor using 250 ml medium, and count and concentrate cells as desired (see Basic Protocol, steps 25 and 26).

ANALYSIS OF CELL FRACTIONS TO DETERMINE CELL CYCLE POSITION

Three protocols are presented here for accurately assessing elutriated cell fractions for purity and for verifying cell cycle position. To determine DNA content, elutriated fractions may be examined by flow cytometry using the DNA-binding fluorophore propidium iodide (PI; see Support Protocol 1; also see *UNIT 8.4*). To determine cell cycle stage, nascent DNA synthesis can be assessed by [^{3}H]TdR incorporation into cells (see Support Protocol 2). This is one way of characterizing the proportion of cells that are in S phase. DNA content and active DNA synthesis can be assessed simultaneously by a dual staining method using both PI and 5-bromo-2′-deoxyuridine (BrdU) incorporation (see Support Protocol 3; also see *UNIT 8.2*). The PI staining procedures, both alone and in combination with BrdU incorporation, generally follow the protocols from Becton Dickinson Immunocytometry. Cell cycle stage can also be determined by characterizing the cyclin-dependent kinase (CDK) activity of the cells (see *UNIT 8.2*).

SUPPORT PROTOCOL 1

Standard PI Staining and Flow Cytometric Analysis

Materials

Elutriated cell populations (see Basic Protocol or Alternate Protocol)
PBS (*APPENDIX 2A*), ice cold
Methanol, ice cold

continued

Buffered PI solution (see recipe)
200 U/ml RNase in PBS

12×75–mm tubes
Nylon cloth, 41-μm mesh
Flow cytometer (Becton Dickinson Immunocytometry FACScan or equivalent)

Additional reagents and equipment for counting cells with a hemacytometer (*UNIT 1.1*)

1. Set up 12×75–mm tubes with 1×10^6 cells from each elutriated population in 1 ml ice-cold PBS.

   Maintain equal cell density and PI concentration for each sample for comparison of DNA in different populations (also see step 7).

2. While gently vortexing cells, gradually add 1 ml ice-cold methanol in a dropwise fashion. Incubate on ice for 30 min.

   The methanol must be ice cold. Be sure to begin vortexing cells before adding methanol to prevent clumping. Cells are now fixed and may be stored at 4°C for several days prior to analysis.

3. Centrifuge cells at $300 \times g$, room temperature, for 10 min. Carefully aspirate liquid from cell pellet and then loosen pellet by flicking tube or vortexing.

4. Combine equal volumes of buffered PI solution and 200 U/ml RNase solution, and add 500 μl to each tube.

5. Incubate for 30 min at room temperature, protected from light. Transfer tubes to ice and keep on ice until analysis.

6. Immediately before analysis, carefully vortex samples and then filter through a 41-μm nylon mesh to remove any cell clumps.

7. Analyze on a flow cytometer using an FL2 linear detector.

   A histogram of FL2 area versus number of events will show DNA content and cell cycle stage (see Fig. 8.5.3).

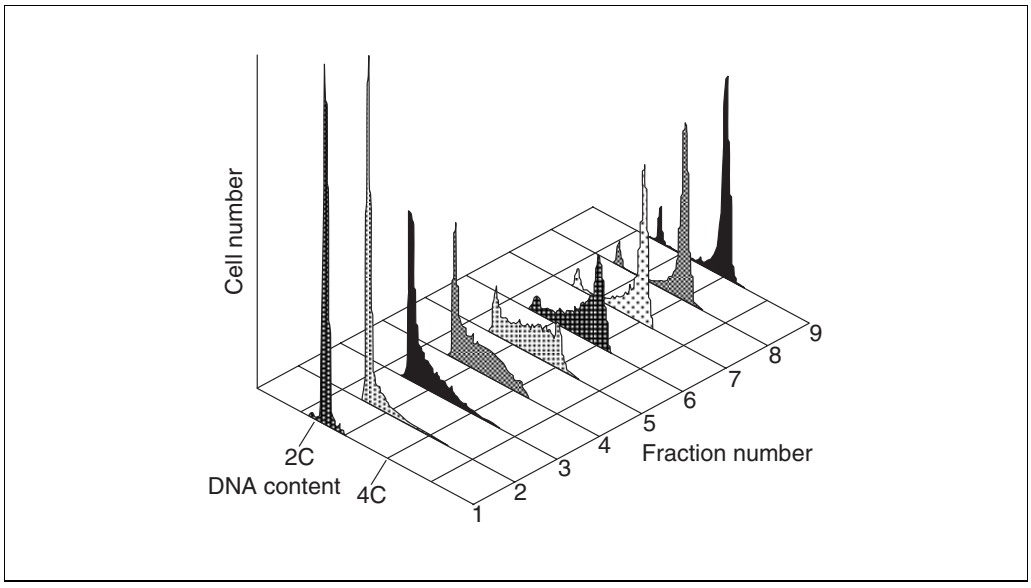

Figure 8.5.3 Three-dimensional histogram of DNA content by flow cytometry versus elutriation fractions of WEHI-231 cells, a murine lymphocytic B cell line. An aliquot of each fraction was fixed in methanol and stained with propidium iodide. The relative DNA content of each fraction was determined by flow cytometry, collecting 10,000 events (*x* axis, propidium iodide fluorescence intensity for DNA content; 2C, diploid; 4C, tetraploid; *y* axis, relative cell number).

Equal cell density between samples is important for equilibration of PI incorporation. Detection of fluorescence intensity will be decreased if greater than equal numbers are used (resulting in a leftward shift in the DNA histogram), or increased if using less than equal cell numbers (resulting in a rightward shift). If cell numbers between samples are fairly close, compensation for this shift may be made by setting a marker at 200 and adjusting FL2 detectors for each sample so that the G_1 peak appears at 200. This should only be done when the position of the G_1 peak is easily recognized.

SUPPORT PROTOCOL 2

[^{3}H]Thymidine Deoxyribose Incorporation

Materials

Elutriated cell populations (see Basic Protocol or Alternate Protocol)
Culture medium prewarmed to 37°C
[Methyl-^{3}H]thymidine deoxyribose ([^{3}H]TdR; 6.7 Ci/mmol)
Aqueous liquid scintillation fluid

96-well microtiter plate
Glass fiber filters
Cell harvester

1. Prepare an aliquot of each elutriated cell population at a density of 4×10^5 cells/ml in an appropriate culture medium. Plate 150 µl of each aliquot into triplicate wells of a 96-well microtiter plate and set up control wells with 150 µl culture medium. Warm the plate at 37°C for 10 min.

   Maintain equal cell numbers between samples for comparison of thymidine incorporation between cell populations.

2. Prepare an aliquot of 37°C culture medium containing [^{3}H]TdR at 10 µCi/ml. Add 50 µl to each well containing cells and each control well.

3. Incubate for 30 min at 37°C.

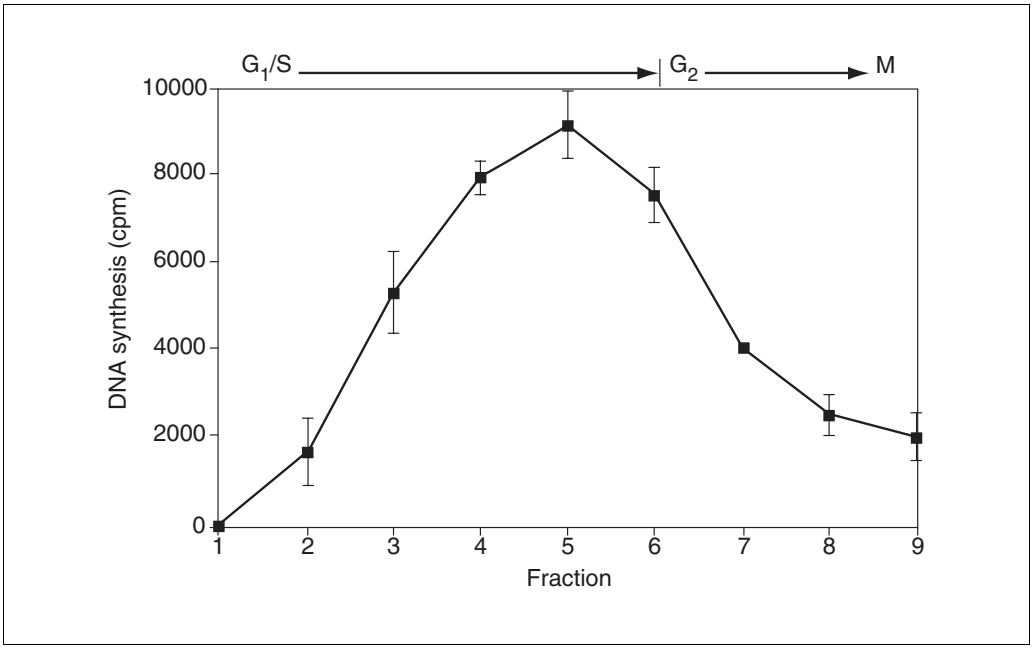

Figure 8.5.4 DNA synthesis profiles of elutriated WEHI-231 murine B cells by [^{3}H]TdR incorporation. The level of cellular DNA synthesis was determined by incubating equal numbers of cells from each elutriated fraction with [^{3}H]TdR for 30 min prior to cell harvest and scintillation counting (*x* axis, elutriation fraction number; *y* axis, DNA synthesis in cpm). On the basis of flow cytometry and DNA synthesis data, relative positions within the cell cycle are shown at the top of each plot. Each data point is the mean of triplicate determinations; bars are SD.

4. Transfer medium and cells onto glass fiber filters using a cell harvester and wash with water.
5. Air dry filters and seal each in a bag with aqueous liquid scintillation fluid.
6. Quantify radioactivity in a β scintillation counter.

A representative graph of DNA synthesis as a function of elutriation fraction number is shown in Figure 8.5.4.

Combined BrdU Incorporation and PI Staining

SUPPORT PROTOCOL 3

Materials

Elutriated cell populations (see Basic Protocol or Alternate Protocol)
Culture medium
1 mM BrdU solution (see recipe)
PTB buffer (see recipe)
PBS (*APPENDIX 2A*), ice cold
100% ethanol, ice cold
2 N HCl/0.5% (v/v) Triton X-100 (store at 4°C)
0.1 M sodium tetraborate ($Na_2B_4O_7$), pH 8.5 (store at 4°C)
Fluorescein isothiocyanate (FITC)–conjugated anti-BrdU antibody
5 µg/ml PI solution (see recipe)

12 × 75–mm tubes
Flow cytometer (Becton Dickinson Immunocytometry FACScan or equivalent)

Additional reagents and equipment for counting cells with a hemacytometer (*UNIT 1.1*)

1. Set up 12 × 75–mm tubes with 1×10^6 cells from each elutriated population in 1 ml culture medium.

Maintain equal cell density and PI and BrdU concentration for each sample for comparison of DNA in different populations (also see step 12).

2. Add 10 µl of 1 mM BrdU solution (final 10 µM) and incubate for 15 min at 37°C.

For cell lines with shorter cell division times, incubation time may be reduced to 2 min; slower cycling cells may require a 30-min incubation.

3. Wash cells twice in 3 ml PTB buffer and centrifuge at 300 × *g* for 10 min at room temperature. Aspirate medium, resuspend cell pellet in 500 µl ice-cold PBS, and place cells on ice.

Be certain that PBS is cold and cell pellets are placed on ice both before and after cold ethanol is added.

4. While gently vortexing cells, gradually add 1 ml ice-cold ethanol in a dropwise fashion. Incubate on ice for 30 min.

It is critical that ethanol be ice cold. Be sure to begin vortexing cells before adding ethanol and maintain vortexing to prevent clumping. Cells are now fixed and may be stored several days at 4°C.

5. Centrifuge cells at 300 × *g*, 10°C, for 10 min. Carefully aspirate liquid from cell pellet and then loosen pellet by flicking tube or vortexing.
6. Add 1 ml of 2 N HCl/0.5% Triton X-100 and incubate for 30 min at room temperature.

This step denatures the DNA, producing single-stranded molecules that allow the subsequent binding of anti-BrdU antibody.

7. Centrifuge at 300 × *g*, room temperature, for 10 min. Resuspend pellet in 1 ml of 0.1 M $Na_2B_4O_7$, pH 8.5, to neutralize. Incubate ~10 to 15 min at room temperature.
8. Centrifuge at 300 × *g*, room temperature, for 10 min. Resuspend pellet in 80 µl FITC-conjugated anti-BrdU antibody diluted 1:4 in PTB buffer. Incubate for 30 min at room temperature.
9. Add 3 ml PTB buffer to each tube, centrifuge cells, and resuspend pellet in 500 µl of 5 µg/ml PI solution.
10. Incubate for 15 min at room temperature, protected from light, and then place on ice.
11. Analyze on a flow cytometer using FL1 log (FITC) and FL2 linear (PI) detectors. Show dot plot as FL2 area versus FL1 height.

    A histogram of FL2 area will also show DNA content and cell cycle stage (see Fig. 8.5.5).

    Equal cell density between samples is important for equilibration of PI incorporation. Detection of fluorescence intensity will be decreased if greater than equal numbers are used (resulting in a leftward shift in the DNA histogram), or increased if using less than equal cell numbers (resulting in a rightward shift). If cell numbers are fairly close, compensation for this shift may be made by setting a marker at 200 and adjusting FL2 detectors for each sample so that the G_1 peak appears at 200. This should only be done when the position of the G_1 peak is easily recognized.
12. To calculate percentage of cells in each stage of the cell cycle, draw regions in dot plot and then calculate with Region Stats (standard with FACScan).

    Calculations can also be done using the PI histogram and CELLFIT (Becton Dickinson) formulas; however, the relatively pure cell cycle populations in transition between cell cycle phases obtained through elutriation cells cannot be analyzed, as the Becton Dickinson algorithm requires profiles with G_1, S, and G_2 content. Manually marking peak areas is also inaccurate as S phase overlaps into G_1 and G_2.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BrdU solution, 1 mM

30.7 mg 5-bromo-2′-deoxyuridine (BrdU)
100 ml PBS (*APPENDIX 2A*)
Divide into 1-ml aliquots
Store up to 6 months at −20°C (do not refreeze)

Buffered PI (propidium iodide) solution

10 mg propidium iodide
0.1 ml Triton X-100
3.7 mg EDTA
90 ml PBS (*APPENDIX 2A*)

Combine, stirring gently to dissolve completely (protect from light). Adjust volume to 100 ml with PBS. Store up to 1 month at 4°C protected from light.

CAUTION: *Use gloves. Propidium iodide is a mutagen and suspected carcinogen.*

Elutriation medium

1.9 liters RPMI culture medium
100 ml heat-inactivated FBS (*APPENDIX 2A*)
Make fresh and use at room temperature

The composition of elutriation medium can vary. Typically, it is either culture medium or PBS without Ca^{2+} or Mg^{2+}, and is supplemented with 5% (v/v) FBS or 5% (w/v) BSA.

PI (propidium iodide) solution, 5 μg/ml

Prepare a 100 μg/ml stock solution by mixing 10 ml propidium iodide in 100 ml PBS (*APPENDIX 2A*) and stirring gently to dissolve completely (protect from light). Store up to 6 months at 4°C protected from light. Immediately before use, dilute 1/20 in PBS (final 5 μg/ml).

CAUTION: *Use gloves. Propidium iodide is a mutagen and suspected carcinogen.*

PTB (PBS/Tween/BSA) buffer

2.5 ml Tween 20 (20% final)
5 g BSA (1%)
Adjust to 500 ml with PBS (*APPENDIX 2A*)
Mix slowly to dissolve
Pass through 0.2-μm filter
Store up to 6 months at 4°C

COMMENTARY

Background Information

A detailed characterization of the physical separation properties of the elutriation system can be found in Keng et al. (1981) and the respective JE-6B and JE-5.0 instruction manuals (Beckman Instruments, 1981, 1989). Additional information on cell cycle separation is found in Kaufman et al. (1990) and Donaldson et al. (1997). B cell separation is described in Thompson et al. (1983), separation of T cells in Marjanovic et al. (1991), and separation of mixed populations in Meistrich (1983). CCE is relatively simple to perform and has the advantage of providing large quantities of cells with minimal impact on cell metabolism.

The combined separation and analysis protocols presented here are generally applicable to a wide variety of human and mouse nonadherent cell lines. Specific parameters are given for Jurkat cells using the standard rotor chamber (Table 8.5.1) and for WEHI-231 cells with the large chamber (Table 8.5.2). Although published protocols and the rotor speed and flow rate Nomogram contained in the Beckman elutriator manual will provide approximate starting conditions, a pilot run is likely to be required for each cell line. Cycling cells will separate differently depending on a wide variety of parameters including culture and medium conditions and ploidy. Some primary cells such as stimulated human peripheral T cells are much smaller than their transformed (Jurkat) counterparts, allowing twice as many cells to be loaded (Donaldson et al., 1997). As the majority of stimulated proliferating cells are in the G_1 phase of the cell cycle, with few cells in G_2/M, it may be difficult even in the best logarithmic cultures to obtain highly enriched G_2 fractions. Although elutriation can be carried out with a refrigerated rotor and cold media, the authors have found little advantage to cell viability, and degassing becomes more problematic.

The JE-5.0 rotor with the 40-ml chamber can be used to elutriate ten times as many cells as the JE-6B rotor, and the JE-5.0 is useful for harvesting large volumes of cells from culture medium prior to elutriation. The general conversion from the low-volume rotor used for analysis and methods development to the high-volume rotor for preparative work requires an ~4-fold increase in flow rate. As concentrating cells from large volumes of culture media by repetitive centrifugation can be time consuming and diminish cell viability, harvesting by continuous flow using the JE-5.0 rotor is a convenient alternative. Although it is possible to proceed from harvest in the JE-5.0 directly to sorting the cells without emptying the chamber, in practice, most cells types must first be removed and passed through an 18-G needle to ensure monodispersion prior to sorting.

Cell cycle position and distribution of the elutriated cell populations can be confirmed by several methods, the simplest being pulse labeling of each population with [^{3}H]TdR (Fig. 8.5.4). DNA content can be determined by PI staining and flow cytometry. Fluorescence intensity is directly proportional to DNA content (Fig. 8.5.3). Three-dimensional histograms show total DNA content of each elutriated fraction of WEHI-231 cells determined by flow cytometry of PI-stained nuclear DNA. The method of combined labeling of cell populations with PI for total DNA content and pulse BrdU for nascent DNA synthesis allows for the simultaneous and accurate determination of total DNA and active synthesis (Fig. 8.5.5). Dot plots of DNA content detected by PI staining (*x*

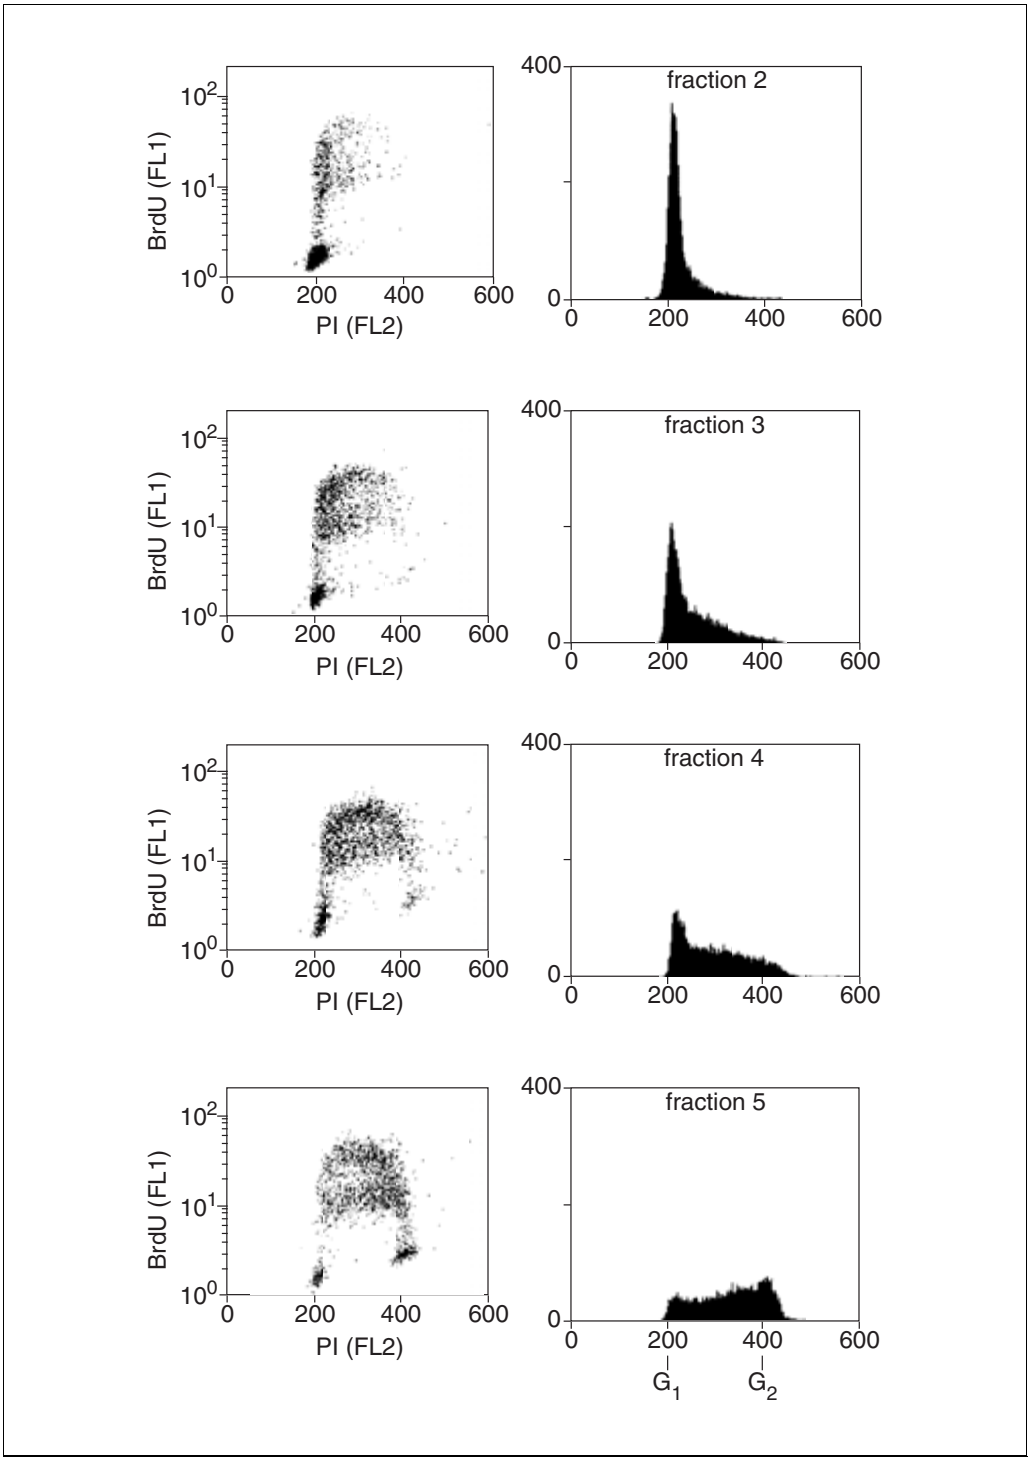

Figure 8.5.5 *(above and at right)* Simultaneous analysis of DNA synthesis and DNA content of elutriated WEHI-231 cells by BrdU incorporation, PI staining, and flow cytometry. Aliquots of cells from each elutriated fraction were pulsed with BrdU for 15 min, fixed in ethanol, and stained for DNA synthesis with FITC-conjugated anti-BrdU antibody and for DNA content with propidium iodide. Dot plots (left) were generated by analysis of 10,000 events and show DNA content by FL2 area (linear; *x* axis) and DNA synthesis by FL1 height (log; *y* axis). The corresponding histogram for DNA content is also shown immediately to the right (*x* axis, PI fluorescence intensity; *y* axis, relative cell number).

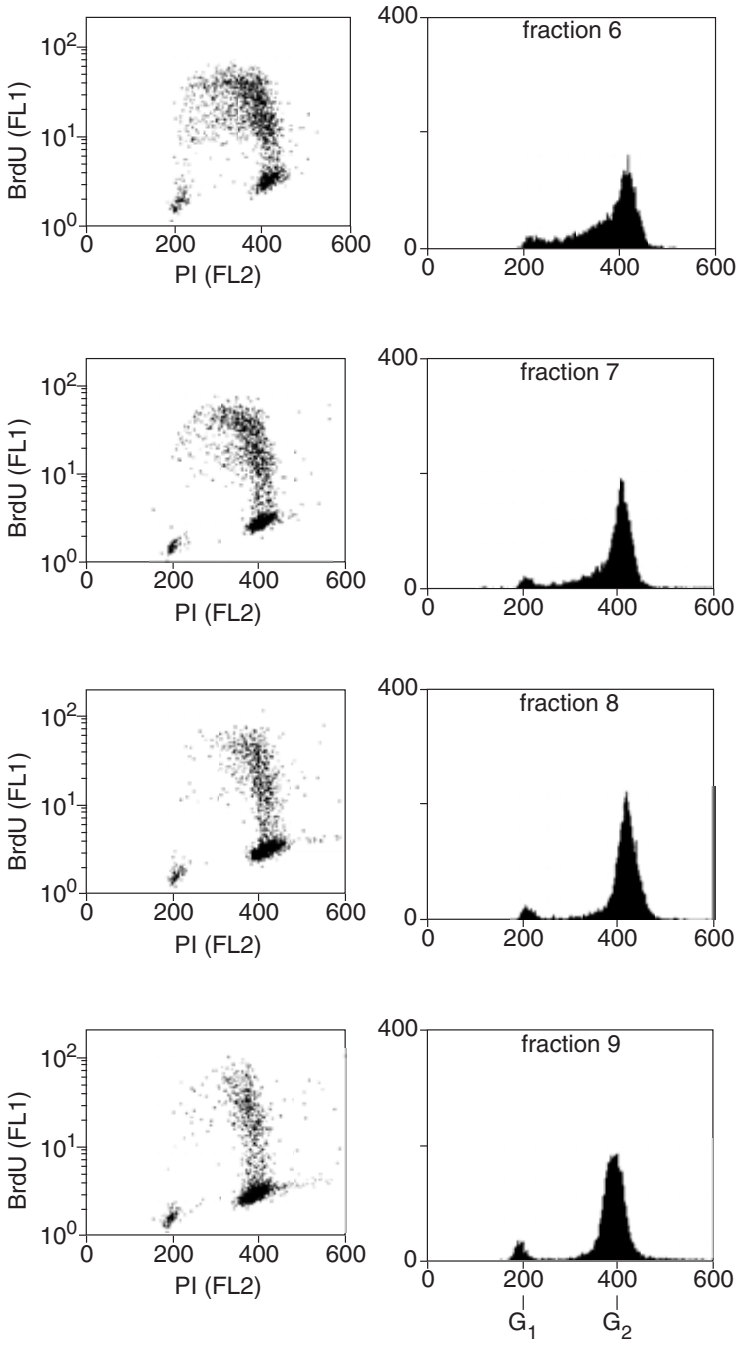

axis) with DNA synthesis by FITC-labeled anti-BrdU (*y* axis) are shown for each elutriated fraction. Cells synthesizing DNA shift upward on the *y* axis (FL1 height) and appear as an arc above G_1 and G_2 populations of cells. DNA content by PI staining on the *x* axis (FL2 area) is also shown as a histogram immediately to the right of each dot plot. Accurate percentages of cell cycle populations can be determined by gating separate regions around these G_1, S, and G_2 populations.

Critical Parameters

Experiments should be fully planned and all equipment, reagents, and tubes should be prepared and ready well in advance. Set up, sterilization, and equilibration are time consuming and it is helpful to coordinate these tasks with cell concentration. Even the best biophysical

predictions will not eliminate the need for a pilot elutriation run to verify speed and flow rates needed for optimal separation.

Cells in poor condition are not worth elutriating. Maintaining cells at $2–5 \times 10^5$ cells/ml with systematic 1:2 dilution with fresh medium for the week prior to elutriation will ensure healthy, log-phase cells. For cell cycle studies, this also ensures good yields of S- and G_2/M-phase populations. Cells must be monomeric. Doublets of G_1 cells can approximate the mass of a G_2 cell and contaminate later fractions. Similarly, highly aneuploid cells will not sort well due to overlaps in mass with near-diploid cells at different stages of their division cycle. Highly aneuploid cells can be eliminated from a mixed population by elutriating the mixed cells and harvesting the smallest population. Upon reculture, cells with high ploidy are greatly diminished.

Although the authors do not recommend it for these protocols, some protocols include EDTA or DNase treatment to reduce aggregation. The release of chromosomal DNA from damaged cells is the major cause of clumping within the chamber. Careful handling during concentration, resuspension, and syringe dispersion will greatly reduce lysis. Resuspend the cells in elutriation medium and load the same number of cells each time. Varying the medium or cell number can shift the buoyant density and eluting population.

Anticipated Results

A combination of CCE and analysis of elutriated fractions should provide ten fractions enriched for cells at specific stages of the cell cycle. The viability of the cells is maintained and the elutriated cells are suitable for culture and/or biochemical analysis.

Time Considerations

Effective CCE requires 90 min to set up, sterilize, equilibrate, and calibrate the equipment; 90 min to harvest the cells; and 30 min to elute the fractions. PI staining takes 2 hr, [^{3}H]TdR labeling takes 90 min, and PI staining plus detection of BrdU incorporation takes 4 hr.

Dynamic Proliferation Assessment in Flow Cytometry

Simone Diermeier-Daucher[1] and Gero Brockhoff[1]

[1]Department of Gynaecology and Obstetrics, University of Regensburg, Regensburg, Germany

ABSTRACT

Dynamic proliferation assessment via flow cytometry is legitimately supposed to be the most powerful tool for recording cell cycle kinetics in-vitro. The preeminent feature is a single cell–based multi-informative analysis by temporal high-resolution. Flow cytometric approaches are based on labeling of proliferating cells via thymidine substitution by a base analog (e.g., 5-bromo-2′-deoxyuridine, BrdU) that is added to cell cultures either for a short period of time (pulse labeling) or continuously until cell harvesting. This unit describes the alternative use of the thymidine analog 5-ethynyl-2′-deoxyuridine (EdU) in place of BrdU for three different applications: (1) dynamic proliferation assessment by EdU pulse cell labeling; (2) the same approach as (1) but in combination with live/dead cell discrimination; and (3) dynamic cell cycle analysis based on continuous cell labeling with EdU and Hoechst fluorochrome quenching. In contrast to the detection of BrdU incorporation, EdU-positive cells can be identified by taking advantage of click chemistry, which facilitates a simplified and fast cell preparation. Further analysis options but also limitations of the utilization of EdU are discussed. *Curr. Protoc. Cell Biol.* 48:8.6.1-8.6.23. © 2010 by John Wiley & Sons, Inc.

INTRODUCTION

Dynamic analysis of cell proliferation by flow cytometry enables high-resolution identification and quantification of effects and efficacies of growth factors and anti-cancer drugs (e.g., therapeutic antibodies, tyrosine kinase inhibitors) on tumor cells in-vitro (Brockhoff et al., 2001, 2007). In contrast to so-called static DNA analysis, dynamic techniques basically enable investigations into the regulation of cell proliferation under defined conditions: (1) calculation of the distribution of cells that actively contribute to cell multiplication according to their attribution to G1-, S-, and G2/M-phases of the cell cycle; (2) quantification of the percentage of resting cells, i.e., cells not actively contributing to cell multiplication (G0-phase cells); (3) determination of the absolute duration of the phases of cell cycle—up to three sequential cell cycles can be determined; (4) information about the probability with which resting cells are recruited into the "active cell cycle" and with which other cells cross from one phase into the next (transition of restriction points); and (5) retracing of the replication history of individual cells.

In the past, dynamic proliferation assays were usually based on the incorporation of the synthetic thymidine analog 5-bromo-2′-deoxyuridine (BrdU) into the DNA during its replication stage—cells are exposed to the base analog either continuously or during a brief pulse of ∼30 min. Currently, 5-ethynyl-2′-deoxyuridine (EdU, Fig. 8.6.1) can be used in place of BrdU, an alternative approach that features some advantages over the use of BrdU. The proof of thymidine substitution is determined either by immunological antibody staining (anti-BrdU) and/or "click chemistry" (EdU technique), or by using a fluorochrome whose fluorescence characteristics are dependent on the amount of BrdU/EdU incorporated.

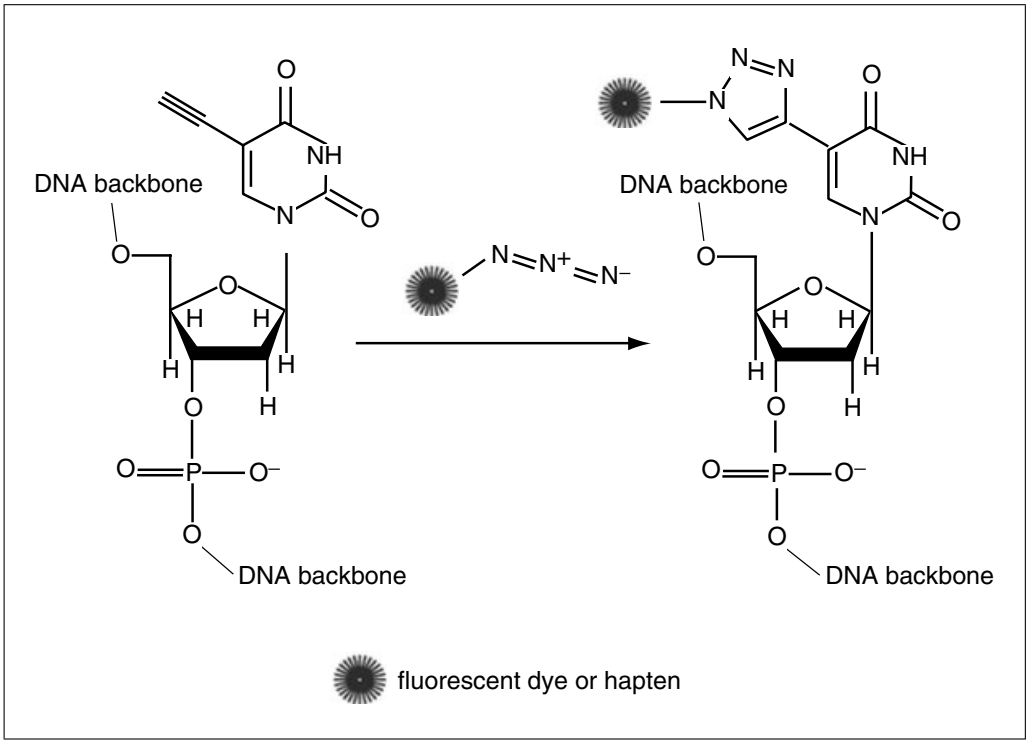

Figure 8.6.1 DNA labeling using the Click-iT EdU Cell Proliferation Assay (Molecular Probes/Invitrogen). The alkyne group of the EdU nucleoside analog reacts with an azide in a copper-catalyzed reaction (click chemistry) forming a very stable covalent bond. Prior denaturation of dsDNA with the antibody-based detection of BrdU-labeled DNA is not required.

S-phase labeling with thymidine analogs has expanded techniques and applications for detailed evaluation of cell cycle progression (Rabinovitch et al., 1988). However, cell line and cell type specific cytostatic effects of the widely used BrdU for cell cycle studies (Diermeier-Daucher et al., 2004) and a technically challenging antibody detection of BrdU demanded alternatives (Warren et al., 2009). 5-Ethynyl-2′-deoxyuridine (EdU, Fig. 8.6.1) is a nucleoside analog of thymidine that is incorporated into DNA during S-phase just like BrdU and is unreactive in biological systems (Buck et al., 2008). To prove substitution of thymidine by EdU, the protocols presented here use either click chemistry (see Basic Protocols 1 and 2; Salic and Mitchison, 2008) or the fluorochrome Hoechst 33258 whose fluorescence characteristics are dependent on EdU incorporation (EdU/Hoechst quenching technology, see Basic Protocol 3; Diermeier-Daucher et al., 2009).

The application of click chemistry to detect EdU incorporation into DNA is based on a copper-catalyzed covalent reaction between a dye-conjugated azide and the alkyne group of EdU (Fig. 8.6.1; Buck et al., 2008; Salic and Mitchison, 2008). Compared to antibody detection of BrdU-based techniques (Darzynkiewicz and Juan, 1997), click chemistry after EdU pulse-labeling allows a simple cell preparation and staining procedure based on aldehyde fixation and detergent permeabilization. This in turn enables penetration of the dye-conjugated azide into the cell, which facilitates coupling of the EdU-alkyne group. In combination with stoichiometric DNA counterstaining, EdU detection facilitates the detailed analysis of cell cycle kinetics and simple multiplexed cell analysis, as well as dead cell exclusion from subsequent analysis (Diermeier-Daucher et al., 2009). Dead cells can be labeled with a dye that permeates leaky cell membranes before DNA labeling takes place. Furthermore, the dead cell fraction can be quantified to evaluate drug-induced cell death in combination with cell cycle analysis of the surviving cell fraction (Diermeier-Daucher et al., 2009). A wide selection of available dyes for live/dead

discrimination (LIVE/DEAD Fixable Dead Cell Stain Kits, Molecular Probes/Invitrogen; see Internet Resources) and fluorescent EdU labeling with click chemistry (Click-iT EdU Cell Proliferation Assays, Molecular Probes/Invitrogen; see Internet Resources) offers an extensive variety of dye combinations that can be selected based on the available flow cytometer and excitation laser lines.

A high time resolution of flow cytometric proliferation assessment is a feature of the recently performed EdU/Hoechst quenching technique (Diermeier-Daucher et al., 2009), which requires a continuous incubation of cells with the nucleoside analog EdU. During the first cell cycle of DNA replication, complete thymidine substitution takes place in one DNA strand and during the second cell cycle in the second DNA strand. DNA of these cells is stained with two DNA dyes: Hoechst 33258 and a DNA intercalating dye, such as propidium iodide (PI). Hoechst 33258 fluorescence is quenched by the EdU/thymidine exchange while PI fluorescence is not affected by EdU incorporation (for excitation and emission wavelengths, see Table 8.6.3). Application of these dyes enables one to distinguish cells in different cell cycle phases (G0/G1, S, and G2/M) of successive cell cycles (Fig. 8.6.2; Diermeier-Daucher et al., 2009). Non-cycling cells (that are driven into the G0-phase by drug treatment) do not incorporate EdU into their DNA, which is a feature that distinguishes them from cycling cells and enables quantification.

This unit presents three protocols for dynamic analysis of cell proliferation. Basic Protocol 1 applies an EdU pulse to label cells in S-phase, click chemistry for EdU detection with Alexa Fluor 488 azide, and stoichiometric DNA labeling with Click-iT EdU cell cycle dye 633 (both Molecular Probes/Invitrogen). The Alternate Protocol extends the procedure described in Basic Protocol 1 to a three-parameter flow cytometric analysis for live/dead discrimination with LIVE/DEAD Fixable Violet dead cell stain (Molecular Probes/Invitrogen) and subsequent fixation prior to EdU and stoichiometric DNA labeling. Support Protocol 1 is suited for extended characterization and quantification of the dead cell fraction determined in Alternate Protocol by determination of the sub-G1 peak. Basic Protocol 2 outlines the procedure for the EdU/Hoechst quenching technique with continuous cell labeling with EdU, cell permeabilization, simultaneous nuclei

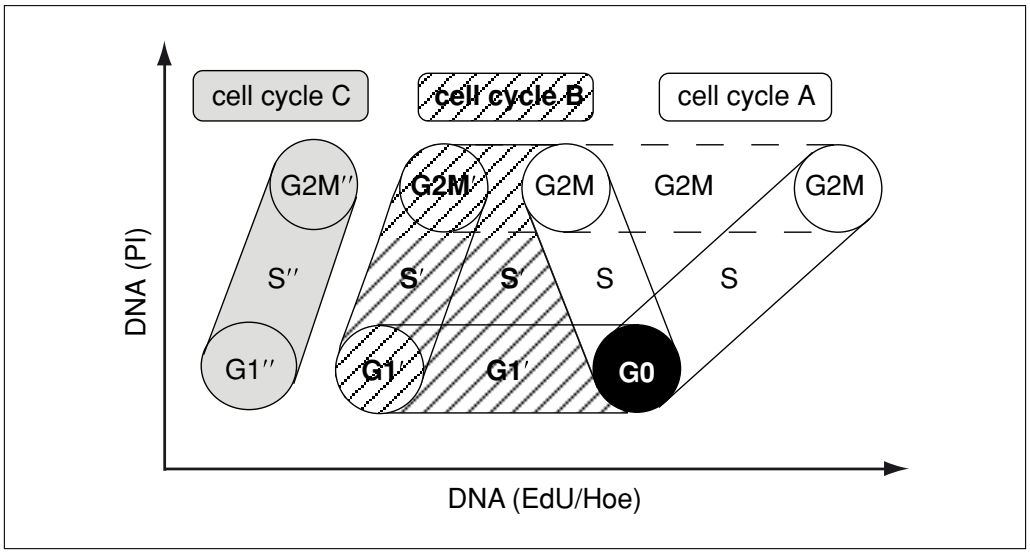

Figure 8.6.2 Schematic bivariate diagram of DNA/Hoechst 33258 versus PI fluorescence intensities. The figure shows the distribution of three successive cell cycles with cell cycle phases G0/G1, S, and G2/M of an asynchronous cell population continuously exposed to EdU. Superscript bars: first (none), second (′) and third (″) cell cycle. For quantitative calculation of the fraction of dormant cells, see instructions under Equation 8.6.1.

preparation, and subsequent staining with Hoechst 33258 and PI. Support Protocol 2 describes the calculation of the G0 cell fraction.

STRATEGIC PLANNING

Number of Samples for EdU Pulse–Labeling Experiments

Control samples

Two samples should be prepared for background staining control (see Table 8.6.1): (1) no EdU treatment, no staining (sample no. 1), (2) EdU treatment, no staining (sample no. 2). In addition, EdU negative cells are used for an unspecific Alexa Fluor 488 staining control (sample no. 3).

These protocols circumvent the need for compensation and compensation controls due to appropriate dye selection for the available flow cytometer. However, if the experimenter wants to check if the respective experiment requires compensation, prepare an unstained sample, single-stained control samples (see Table 8.6.1, samples no. 4 and 5; and Table 8.6.2, sample B), and one sample labeled with two (see Basic Protocols 1 and 2) or three (see Alternate Protocol) fluorescent dyes. Theoretical background on and the procedure of compensation in flow cytometry are described in detail in Roederer (2002).

Test samples

EdU cell proliferation assessment is highly suited for comparing the effects of different treatment modalities on cell cycle progression. Cells are labeled with EdU and treated with the agent of interest to slow down or accelerate proliferation of the respective cell type compared to untreated cells. Any treatment modality requires one additional (EdU-labeled) cell culture flask (Table 8.6.1: samples no. 7 to *x*) to be seeded. One drug-untreated (EdU-labeled) sample must be prepared to serve as a control (Table 8.6.1: sample no. 6).

The number of parallel cultures that is needed for dynamic cell proliferation assessment depends on the total period of time that the cell kinetic is to be analyzed. For pulse-labeling techniques, the observation period should span the time from the detection of initial EdU-positive, S-phase cells until they proceed into S-phase from the G1-phase of the second cell cycle. This procedure allows one to determine the duration of the entire cell cycle with single cell cycle phases in the order: G2/M-phase (1st cell cycle), S-phase (1st cell cycle), and G1-phase (2nd cell cycle). For most cell types, a period of 40 hr

Table 8.6.1 Untreated Control (1 to 6) and Drug-Treated Test Samples (7 to *x*) for Dynamic Cell Proliferation Assessment with EdU Cell Labeling and Click Chemistry for EdU Detection in Basic Protocol 1

No.	Drug treatment	EdU	Alexa Fluor 488	Click-iT EdU cell cycle dye 633	
1	–	–	–	–	Background staining control
2	–	+	–	–	Background staining control
3	–	–	+	–	Unspecific staining control
4	–	–	–	+	Positive single staining
5	–	+	+	–	Positive single staining
6	–	+	+	+	Double stained test sample
7 – *x*	+	+	+	+	Double stained test sample

Table 8.6.2 Samples Labeled Differently or Prepared in Addition to Basic Protocol 2 Compared to Samples Prepared for Basic Protocol 1

No.	Drug treatment	EdU	LIVE/DEAD Violet dead cell stain	Alexa Fluor 488	Click-iT EdU cell cycle dye 633	
6	–	+	+	+	+	Triple stained test sample
7 – *x*	+	+	+	+	+	Triple stained test sample
A	–	–	+	–	+	Unspecific staining control
B	NaN_3	–	+	–	+	Positive control for cell death/single staining

is sufficient for analysis (Brockhoff, 2009). For quenching analysis, the total period of continuous EdU labeling can span the total period of three successive cell cycles.

Additional control samples for live/dead discrimination

Live/dead discrimination as described in the Alternate Protocol requires additional control samples (Table 8.6.2) compared to Basic Protocol 1. While samples 1 through 5 remain the same, an additional sample A serves as a nonspecific staining control for the LIVE/DEAD Fixable dead cell stain. The NaN_3-treated (and LIVE/DEAD Fixable dead cell stained) sample B is used for BT474 cell death induction and consequently serves as a positive control. For analysis of other cell lines, select an appropriate treatment for the positive control sample. Samples no. 6 and 7 to *x* are triple stained (live/dead discrimination, EdU-labeled, and DNA content).

Time Schedule for Cell Culture

The protocols in this unit describe an equal growth period for all cell culture flasks of one experiment to ensure that the same growth density is obtained at time of harvesting. All cell culture flasks are seeded and harvested on the same day, but are incubated with EdU or drugs (e.g., growth factors, therapeutic antibodies, or cell cycle inhibitors) for different time intervals. The addition of these reagents must take place at different time points. For evaluation of cell cycle kinetics and of the time interval of interest (where differences in cell cycle progression become apparent, see Strategic Planning, Control samples), add EdU at 2-hr intervals (and wash out for pulse-labeling techniques) before harvesting to produce, e.g., 40, 38, 36, 34, 32, and 30 hr of cell culture before harvesting. Add drug of interest sufficiently before EdU addition takes place so that the effect of the drug will become apparent compared to untreated cells. Determination of cell number at harvest offers an additional parameter to check for an effect of the drug on cell multiplication.

Cell Culture for Optimal Growth

The total duration of the cell cycle depends on the specific cell line. To ensure subconfluent conditions at the time of harvest and to prevent cell-cell contact-induced inhibition of proliferation, the optimal plating density must be determined for each individual cell line.

Dye Combinations and Available Laser Lines

The choice of fluorescent dyes for EdU detection, DNA labeling, and live/dead discrimination depends on the number and wavelength of the available laser lines and must be adapted according to the available flow cytometer. Basic Protocol 1 applies Alexa Fluor 488 and Click-iT EdU cell cycle dye 633 and is suited for a two-laser flow cytometer

with two different laser lines (488 nm and 633 nm). The set of dyes used in the Alternate Protocol is expanded for the Live/Dead Fixable Violet dead cell stain, which represents an optimal dye combination for a three-laser flow cytometer (488 nm, 633 nm, 405 nm). For applying Basic Protocol 2, a 488-nm and UV (325 nm) excitation line is required for PI and Hoechst 33258 excitation, respectively. Dye characteristics of fluorochromes used in this unit are outlined in Table 8.6.3.

CAUTION: Dye solutions are potentially toxic and/or mutagenic. Handle with appropriate care. See manufacturer's safety datasheets.

For planning a three-color experiment, first assign one dye per available laser line before the two-fold assignment of two fluorochromes to the same laser line to minimize spectral overlap and to avoid the need for compensation (see Roederer, 2002, for background on compensation).

Alternative dyes for EdU detection (see Internet Resources) and live/dead labeling (see Internet Resources and Bradford and Buller, 2008) in Basic Protocol 1 and Alternate Protocol are available for custom-made multicolor experiments. For stoichiometric DNA labeling in EdU pulse-labeling experiments, alternative DNA dyes have been proven to be compatible with click chemistry for EdU detection (see Table 8.6.4; Bradford et al., 2008a,b).

PI is not recommended as a DNA dye in combination with EdU detection by click chemistry due to the increase of coefficients of variation (CV; for details about the importance of low CVs, see Brockhoff, 2009).

Table 8.6.3 Excitation/Emission Maxima, Excitation Wavelength, and Filter Characteristics for Flow Cytometric Detection of Dyes

Dye	Absorption maxima (nm)	Emission maxima (nm)	Excitation wavelength (nm)	Filter[a]
Hoechst 33258	345	478	325	450/50 BP
LIVE/DEAD Fixable Violet dead cell stain	416	451	405	450/50 BP
Alexa Fluor 488	495	519	488	530/30 BP
Propidium iodide (PI)	536	617	488	670 LP
Click-iT EdU cell cycle dye 633	640	658	633	660/20 BP

[a]BP, band-pass filter; LP, long-pass filter.

Table 8.6.4 Alternative DNA Dyes Compatible with Click Chemistry for EdU Detection Absorption and Emission Maxima, Excitation Wavelength, and Filter Characteristics for Flow Cytometric Detection[a]

Dye	Absorption maxima (nm)	Emission maxima (nm)	Excitation wavelength (nm)	Filter[b]
Hoechst 33258	343	483	325	450/50 BP
4′,6-Diamidino-2-phenylindol (DAPI)	358	461	325	450/50 BP
Vybrant DyeCycle Violet stain	369	437	325 or 405	450/50 BP
7-Aminoactinomycin (7-AAD)	546	647	488	695/40 BP
Sytox Red	640	658	633	660/20 BP

[a]Bradford et al., 2008a,b.
[b]band-pass filter.

Preparation of Nuclei

The detergent IGEPAL (see Basic Protocol 2) is used for nuclei preparation. Consequently, cytoplasmic or cell membrane–located antigens cannot be analyzed at the same time. However, the staining procedure may be simultaneously combined with an immunofluorescence staining to reveal detailed information on the expression of cell cycle–related nuclear antigen expression such as proliferation-associated antigens (Endl et al., 1997).

DYNAMIC CELL PROLIFERATION ASSESSMENT WITH EdU CELL LABELING AND DETECTION BY CLICK CHEMISTRY

BASIC PROTOCOL 1

In this protocol, parallel cultures of the cell line of interest are treated with the drug or growth factor of interest at different time points or are left untreated. After pulse-labeling of cell cultures with 5-ethynyl-2′-deoxyuridine (EdU) and removal of EdU by washing the cells thoroughly, the cells are cultured further until harvested in parallel. Detached cells are fixed and permeabilized for subsequent Alexa Fluor 488 azide coupling to EdU by click chemistry and DNA-labeling with Click-iT EdU cell cycle dye 633. This protocol is optimized for the human breast cancer cell line BT474.

Materials

Click-iT EdU Alexa Fluor 488 Cell Proliferation Assay Kit (store kit at 2°–6°C, do not freeze):
- 5-Ethynyl-2′-deoxyuridine (EdU)
- DMSO
- Click-iT fixative
- 10× saponin-based permeabilization and wash reagent
- Alexa Fluor 488 azide
- 10× Click-iT EdU reaction buffer
- 100 mM $CuSO_4$ stock solution
- Click-iT EdU buffer additive
- Click-iT EdU cell cycle dye 633
- 20 mg/ml RNase A

PBS/1% BSA: phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 1% bovine serum albumin (BSA); store up to 2 weeks at 4°C

BT474 breast cancer cells (ATCC #HTB-20; see *UNIT 1.1* for culture of mammalian cells)

Complete Dulbecco's modified Eagle medium (DMEM; *UNIT 1.1*)

Complete DMEM containing 5% fetal bovine serum (FBS; DMEM-5; *UNIT 1.1*)

Complete DMEM containing 2% FBS (DMEM-2)

Drug to be tested for its effect on cell proliferation (e.g., trastuzumab, also known as rhuMAb, 4D5, and herceptin, humanized monoclonal antibody acting on the ErbB2 (HER2/neu) receptor)

Trypsin/EDTA solution (*APPENDIX 2A*)

PBS/0.01% NaN_3/0.2% BSA: phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 0.01% NaN_3 and 0.2% BSA; store up to 2 weeks at 4°C

75-cm^2 cell culture flasks

15- and 50-ml centrifuge tubes (e.g., polypropylene tubes, Greiner Bio-one)

Refrigerated centrifuge, 4°C

Water jet vacuum pump (e.g., BRAND), optional

Hemacytometer (*APPENDIX 3B*)

5-ml sample tubes (e.g., 12 × 75–mm polystyrene round-bottomed tubes, BD)

Flow cytometer with 488-nm and 633-nm excitation lasers (see Table 8.6.3 for required/appropriate filters)

Acquisition software that stores data in list-mode flow cytometry standard (FCS) files (e.g., BD FACS Diva software v6.1.1, BD Biosciences)
Evaluation software (e.g., FlowJo 7.6.1, Tree star)

NOTE: Protect labeling solutions and labeled samples from light.

Prepare working solutions with components of Click-iT EdU Alexa Fluor 488 kit

1. Allow all solutions to warm to room temperature.
2. Dissolve 10 mg EdU in 4 ml DMSO (10 mM final EdU concentration), mix well.
3. Dilute 10× saponin-based permeabilization and wash reagent 1:10 with PBS/1%BSA.

   CAUTION: *This solution contains sodium azide. Acidic conditions liberate very toxic gas. Avoid contact with skin.*

4. Add 260 µl DMSO to Alexa Fluor 488 azide, mix well.
5. Dilute 10× Click-iT EdU reaction buffer 1:10 with distilled water to give a 1× Click-iT EdU reaction buffer working solution.
6. Reconstitute Click-iT EdU buffer additive with 4 ml of distilled water to give a 10× stock solution and mix well until powder has fully dissolved.
7. Add 270 µl DMSO to Click-iT EdU cell cycle dye 633 and mix well.

   CAUTION: *Click-iT EdU cell cycle dye is a nucleic acid–intercalating dye and is considered a potential mutagen that must be handled with care and stored according to the local regulations.*

   The 1× saponin-based permeabilization, wash solution, $CuSO_4$ stock solution, and 1× Click-iT EdU reaction buffer working solution can be stored for up to 6 months at 2° to 6°C. Reconstituted EdU solution, Alexa Fluor 488 azide working solution, 10× Click-iT EdU buffer additive solution, and Click-iT EdU cell cycle dye 633 can be stored for up to 1 year at ≤20°C.

   Saponin-based permeabilization and 1× wash solution supplied with the Click-iT EdU Alexa Fluor 488 Cell Proliferation Assay Kit may be substituted with PBS/1% BSA containing 0.05% (v/v) saponin.

   Commercially available formalin (e.g., SG Planung) or a freshly prepared 4% (w/v) paraformaldehyde (PFA; see recipe) may be used in place of Click-iT fixative.

Pulse label cells with EdU

8. Seed 1×10^6 exponentially growing cells in complete DMEM with 5% FBS (DMEM-5) in four 75-cm^2 cell culture flasks (day zero). Seed as many test samples that are to be treated both with EdU and the drug under investigation as required.

   Two flasks are labeled with EdU (cells from these flasks are used for samples no. 2, 5, and 6, Table 8.6.1). The remaining two flasks are used as EdU-negative control (cells from these flasks are used for samples no. 1, 3, and 4, Table 8.6.1).

   For running all control samples given in Table 8.6.1, 3×10^6 drug-untreated, EdU-positive cells and 3×10^6 drug-untreated, EdU-negative cells should be available after cell harvesting (steps 17 to 20). The cell culture protocol described here provides ~3×10^6 cells at time of harvesting per 75-cm^2 cell culture flask. Therefore, seeding four 75-cm^2 cell culture flasks (two for EdU treatment and two untreated) are sufficient to give this number of cells.

   As the total number of samples depends on the experimental setup (e.g., the number of control samples and drug-treated samples), the volumes for reagents in the protocols refer to 1×10^6 cells and therefore to one sample.

Larger cell culture flasks (e.g., 175-cm^2 cell culture flasks) and a higher number of cells (e.g., 2.3 × 10^6 cells per 175-cm^2 cell culture flasks) may be seeded to yield a sufficient number of control samples and to reduce work load and material consumption. However, for cell proliferation assessment and for comparing drug-untreated (Table 8.6.1, sample no. 6) versus drug-treated samples (Table 8.6.1, samples no. 7 to x), applying the same cell culture conditions (i.e., seeded cell number, size of cell culture flasks) is essential.

9. (Optional) Replace medium after 8 hr of growth with complete DMEM with 2% FBS (DMEM-2; day 0).

   For testing for the effect of different growth factors on cell cycle progression, reduction of FBS in the medium from 5% to 2% is recommended to reduce the amount of disturbing growth factors in the FBS.

10. Add drug to test samples (see Table 8.6.1, samples no. 7 to *x*), e.g., 10 μg/ml trastuzumab (day 1) and continue cell culturing.

11. Add 10 μM EdU for 3 hr to the two cell culture flasks for positive control samples (Table 8.6.1, samples no. 2, 5, and 6) and to all drug-treated test samples (Table 8.6.1, samples no. 7 to *x*) (day 2). Leave two cell culture flasks EdU-untreated as the negative control samples (Table 8.6.1, samples no. 1, 3, and 4). Provide standard cell culture conditions for cell culture flasks during the incubation time.

12. Add 10 μl DMSO (EdU solvent) to EdU-untreated cell culture flasks (Table 8.6.1, samples no. 1, 3, and 4).

    If preliminary experiments showed that addition of DMSO does not affect cell proliferation of the cell line under investigation, then this step can be omitted.

13. Remove the medium after 3 hr of EdU incubation.

14. Carefully wash cells with 10 ml PBS (37°C) to each culture flask and remove with vacuum. Repeat two times to completely remove the EdU from the cells.

15. Add fresh complete DMEM-5 (or DMEM-2, see above) and incubate under standard cell culture conditions until cells are harvested.

16. If cells have been treated with a drug in step 10, then replace the reagents in respective cell culture flasks and incubate under standard cell culture conditions until cells are harvested.

Harvest and fix cells

17. Harvest the cells using trypsin/EDTA solution (e.g., see *UNIT 1.1*) on day 4 for BT474. Collect cells into 50-ml centrifuge tubes, and transfer onto ice.

    If using trypsin/EDTA solution for cell harvesting, stopping the enzymatic reaction with medium containing FBS may stimulate the cells. However, each experimenter must decide, according to the applied drug treatment, if stopping the enzymatic reaction with FBS-containing medium is appropriate. Alternatively, trypsin enzyme activity may be stopped using ice-cold medium with FBS or accutase, or solely EDTA may be used for cell harvesting. Cells from the two EdU-labeled and EdU-unlabeled 75-cm^2 cell culture flasks may be merged.

18. Centrifuge cells 5 min at ~350 × *g*, 4°C.

19. Decant or remove the supernatant with a water jet vacuum pump.

20. Resuspend the cell pellet in 1 to 2 ml ice-cold PBS/0.01% NaN_3/0.2% BSA.

21. Repeat steps 18 to 20.

22. Determine cell number using a hemacytometer, as described in *UNIT 1.1*. Add 1×10^6 cells per sample (see Table 8.6.1) to 5-ml sample tubes.

    Samples no. 5 and 6 (Table 8.6.1) may be stained with Alexa Fluor 488 azide in one tube and divided before the DNA labeling steps.

23. Centrifuge cells 5 min at ~350 × *g*, 4°C.

24. Decant or remove the supernatant with a water jet vacuum pump.

25. Add 100 µl Click-iT fixative to each sample (containing 1×10^6 cells per sample) while vortexing to avoid cell clumping.

    CAUTION: *Click-iT fixative contains 4% PFA in PBS. PFA is harmful and should be handled with appropriate care.*

26. Incubate for 15 min at room temperature in the dark.

Wash and permeabilize cells

27. Add 3 ml of 1× saponin-based permeabilization buffer.

28. Centrifuge cells 5 min at ~350 × *g*, 4°C.

29. Decant or remove the supernatant with a water jet vacuum pump.

30. Repeat steps 27 to 29.

Couple EdU using click chemistry

31. Prepare 500 µl Click-iT reaction buffer per sample (1×10^6 cells) with the following components and use within 15 min:

    438 µl 1× Click-iT Edu reaction buffer (working solution)
    10 µl $CuSO_4$
    2.5 µl Alexa Fluor 488 azide
    50 µl reaction buffer additive

32. Add 500 µl Click-iT reaction buffer to samples no. 3, 5, 6, and to all test samples (Table 8.6.1, samples no. 7 to *x*), and mix well.

33. Add 500 µl Click-iT reaction buffer without adding the Alexa Fluor 488 dye to unstained samples (Table 8.6.1, samples no. 1, 2, and 4).

    Alternatively, 500 µl of 1× saponin-based permeabilization buffer is added to samples no. 1, 2, and 4. However, preliminary experiments to prove that incubation in 1× saponin-based permeabilization buffer does not give different results than the Click-iT reaction buffer without dye are required.

    Saponin temporarily permeabilizes the cell membrane to allow entry of reagents. Although saponin is not present in the Click-iT reaction buffer, it has been proved that permeability is sufficient for dye azide entry and the click reaction. However, for further wash steps and DNA labeling, saponin-containing buffer is used to allow dye entry into the cells.

34. Incubate 30 min at room temperature in the dark.

Label DNA content

35. Centrifuge cells 5 min at ~350 × *g*, 4°C.

36. Decant or remove the supernatant with a water jet vacuum pump.

37. Prepare 500 µl DNA labeling solution per sample (1×10^6 cells) with 493 µl of 1× saponin-based permeabilization buffer, 5 µl RNase A, and 2 µl Click-iT EdU cell cycle dye 633.

Usually, more than one sample is labeled with DNA dye in an experimental setup. To optimize the comparability of the measured fluorescence intensities and to reduce pipetting errors, all samples should be labeled with the same dye concentration. Therefore, preparing the necessary volume of the DNA labeling solution in one vial for all samples is recommended.

38. Add 500 µl of DNA labeling solution to each test sample (Table 8.6.1, samples no. 7 to *x*) and to control samples no. 4 and 6.

39. Add 500 µl of 1× saponin-based permeabilization buffer to the remaining control samples no 1, 2, 3, and 5.

40. Incubate 15 min at 37°C in the dark.

Measure fluorescence

41. Measure fluorescence without further washing using filter settings as described in Table 8.6.3.

42. If available, activate 633-nm excitation pulse processing option on Click-iT EdU cell cycle dye 633 detection channel (DNA content) for gating aggregates/doublets on the flow cytometer (for required filter settings, see Table 8.6.3)

43. Draw the following plots and histograms with the acquisition software:

    a. FC/SC dot blot,
    b. Histogram for Alexa Fluor 488 detection (optional),
    c. Histogram for Click-iT EdU cell cycle dye 633 detection (optional),
    d. Click-iT EdU cell cycle dye 633 area/Alexa Fluor 488 area dot plot.

    Use pulse-processing for gating of doublet cells (Brockhoff, 2009), if available, on the instrument. For example, using instruments from BD Biosciences draw a Click-iT EdU cell cycle dye 633 width/area dot plot.

44. Set the detector gains for Alexa Fluor 488 detection channel (EdU coupling) to logarithmic signal amplification and for Click-iT EdU cell cycle dye 633 detection channels (DNA content) to linear signal amplification in such a way as to enable discrimination of EdU-positive and EdU-negative cells in the Alexa Fluor 488 detection channel and to gain a cell cycle histogram in the Click-iT EdU cell cycle dye 633 detection channel.

    Alexa Fluor 488 and Click-iT EdU cell cycle dye 633 were selected for this assay as their excitation and emission maxima are largely separated from each other (see Table 8.6.3) and are suited for excitation with two different lasers. These dye characteristics allow avoiding the need for compensation and compensation controls. If the experimenter wants to check whether compensation is needed with his experimental system, see Strategic Planning, Dye Combinations and Available Laser Lines.

45. Acquire at least 1×10^4 cells per sample with appropriate software that stores data in list-mode flow cytometry standard (FCS) files (e.g., BD FACS Diva software v6.1.1).

Perform data analysis

46. Analyze data with appropriate software (e.g., FlowJo 7.6.1).

47. Gate live cells in FC/SC dot plot.

48. If the pulse-processing option is supported by the flow cytometer and was used during acquisition, gate single cells, e.g., in the Click-iT EdU cell cycle dye 633 width/area dot plot for BD instruments.

49. Visualize gated cells in the Click-iT EdU cell cycle dye 633 area/Alexa Fluor 488 area dot plot (see Anticipated Results; Fig. 8.6.3).

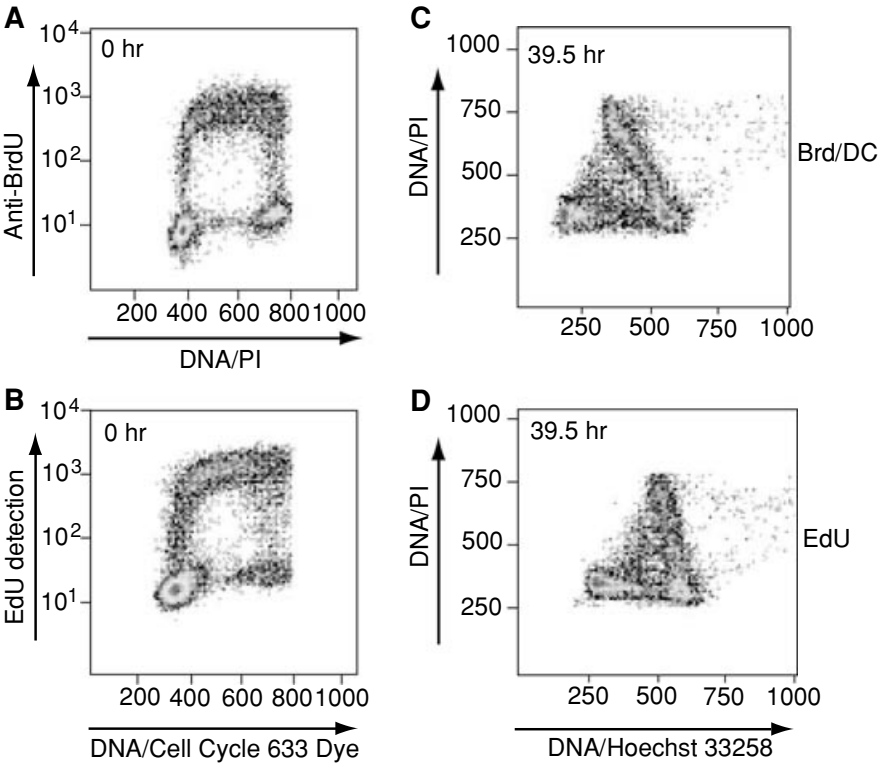

Figure 8.6.3 Comparison of BrdU/DC and EdU for dynamic cell proliferation assessment in BT474 human breast cancer cells. Anti-BrdU (**A**) versus click chemistry detection of EdU (**B**) measured on a FACSCanto II (BD Biosciences). Cells were pulse labeled with 20 μM BrdU/10 μM 2′-deoxycytidine (DC) for 30 min (A) or with 20 μM EdU for 3 hr (B). DNA labeling was performed with PI for BrdU-(A) and Click-iT EdU cell cycle dye 633 for EdU-labeled cells as described in Basic Protocol 1 (B). **C, D**: BrdU/Hoechst quenching versus EdU/Hoechst quenching measured on an LSRII (BD Biosciences). Cells were continuously labeled with 120 μM BrdU/60 μM DC (C) or 100 μM (D) EdU for 39.5 hr and stained with Hoechst 33258 and PI as described in Basic Protocol 3 (Diermeier-Daucher et al., 2009). The slope of BrdU/DC (C) and EdU (D) treated cells proliferating from G1- into S- and G2/M-phase in the first cell cycle depends on the ratio of the concentration of DNA dyes and the amount of nucleoside analog incorporated into the DNA and is therefore different for both nucleoside analogs (also see Critical Parameters and Troubleshooting: Hoechst/PI Concentrations).

ALTERNATE PROTOCOL

DYNAMIC CELL PROLIFERATION ASSESSMENT WITH EdU CELL LABELING AND DETECTION BY CLICK CHEMISTRY IN COMBINATION WITH LIVE/DEAD DISCRIMINATION

The LIVE/DEAD Fixable dead cell stains (Molecular Probes/Invitrogen) allow evaluation of the viability of mammalian cells by flow cytometry. This is accomplished by the reaction of a fluorescent reactive dye with cellular amines in combination with further antigen (which is beyond the scope of this unit) or DNA staining after cell fixation in a multicolor experiment. In necrotic cells, the reactive dye permeates the compromised membranes and reacts with free amines both in the interior of the cell and on the cell surface. Therefore, fluorescent staining is intense compared to staining of only cell-surface amines of viable cells showing a relatively dim staining (see Internet Resources; Diermeier-Daucher et al., 2009). Staining is completely preserved after fixation of the sample with formaldehyde.

The single-color LIVE/DEAD Fixable Dead Cell Stain Kits are available with different fluorescent colors of the included dye (blue, violet, aqua, yellow, green, red, far red,

or near IR; Internet Resources). This protocol describes the optimal dye selection for live/dead discrimination followed by cell cycle analysis with click chemistry with a three-laser flow cytometer: 405-nm (excitation of LIVE/DEAD Violet dead cell stain; live/dead discrimination), 488-nm (excitation of Alexa Fluor 488; EdU labeling), and 633-nm (excitation of Click-iT EdU cell cycle dye 633; DNA content) laser lines. For alternative dye selection, see Strategic Planning, Dye Combinations. This protocol is optimized for the human breast cancer cell line BT474.

***Additional Materials** (also see Basic Protocol 1)*

LIVE/DEAD Fixable Violet Dead Cell Stain Kit for 405-nm excitation (Molecular Probes/Invitrogen)
Drug for induction of cell death in the cell line of interest, e.g., sodium azide (NaN_3; Sigma) for BT474 (Diermeier-Daucher et al., 2004)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
4% (w/v) paraformaldehyde (PFA; see recipe)

NOTE: Protect labeling solutions and labeled samples from light.

Prepare working solution of LIVE/DEAD Fixable Violet dead cell stain

1. Allow one vial of LIVE/DEAD Fixable Violet dead cell stain and DMSO to warm to room temperature.
2. Dissolve LIVE/DEAD Fixable Violet dead cell stain in 50 µl DMSO and mix well until all dye has dissolved.
3. Use working solution as soon as possible (within a few hours after reconstitution).

   Once reconstituted, LIVE/DEAD Fixable Violet dead cell stain may be stored up to 2 weeks at ≤20°C.

Seed and pulse label cells with EdU

4. Seed cells as described in Basic Protocol 1. Provide for an additional 1×10^6 EdU-unlabeled and drug-untreated cells (unspecific staining control) and an additional 75-cm^2 cell culture flask to induce cell death (positive control, see Table 8.6.2).
5. Proceed with Basic Protocol 1, steps 9 through 16.
6. Add drug for induction of cell death to positive control cells (sample B) at an appropriate time point before harvesting.

   For the BT474 breast cancer cell line, incubation with 180 mM NaN_3 for 4 hr can be used as positive control (Diermeier-Daucher et al., 2004).

Harvest cells

7. Harvest the cells on day 4 for BT474 (the optimal time point for harvesting of other cell lines must be determined individually) using trypsin/EDTA solution (e.g., see *UNIT 1.1*), collect into 50-ml centrifuge tubes, and transfer onto ice.

   See annotation in Basic Protocol 1, step 17.

8. Centrifuge cells 5 min at ~350 × *g*, 4°C.
9. Remove the supernatant.

   If it is aimed to identify and to discriminate dead cells from the evaluation, the cell culture supernatant should be removed using a water jet vacuum pump. However, if the amount of cell death (e.g., in response to drug treatment) needs to be analyzed and quantified, collect the cell culture supernatant (including apoptotic and necrotic cells) and combine it with the cell suspension after trypsinization.

10. Resuspend the cell pellet in 1 to 2 ml ice-cold PBS.

    Do not use NaN_3- or BSA-containing buffers for cell washing and labeling with amino-reactive fluorescent dyes (e.g., LIVE/DEAD Fixable Violet dead cell stain).

11. Repeat steps 8 through 10.

12. Determine cell number using a hemacytometer, as described in *UNIT 1.1*. Add 1×10^6 cells per sample (see Table 8.6.1 and Table 8.6.2) to 5-ml sample tubes.

13. Centrifuge cells 5 min at ~350 × *g*, 4°C.

14. Decant or remove the supernatant with a water jet vacuum pump.

Label with LIVE/DEAD fixable dead cell stain

15. Prepare the same LIVE/DEAD Fixable Violet dead cell stain labeling solution for all samples by adding 1 µl LIVE/DEAD Fixable Violet dead cell stain to 1 ml PBS per sample.

16. Add 1 ml LIVE/DEAD Fixable Violet dead cell stain labeling solution to samples no. 6, 7 to *x*, A and B (see Table 8.6.2).

17. Incubate 30 min on ice in the dark.

Fix cells

18. Centrifuge cells 5 min at ~350 × *g*, 4°C.

19. Resuspend the cell pellet in 1 to 2 ml ice-cold PBS.

20. Centrifuge cells 5 min at ~350 × *g*, 4°C.

21. Decant or remove the supernatant with a water jet vacuum pump.

22. Dislodge cell pellet and add 1 ml of 4% PFA to each sample while vortexing.

    Commercially available formalin (e.g., SG Planung) may be used instead of PFA. If cell clumping is prevalent resuspend cells in PBS (e.g., 900 µl PBS), mix thoroughly by pipetting up and down and add concentrated PFA (100 µl of ~40% PFA) for fixation while vortexing.

23. Incubate for 15 min at room temperature in the dark.

Permeabilize cells and couple EdU with click chemistry

24. Add 2 ml of 1× saponin-based permeabilization buffer and proceed as described in Basic Protocol 1, steps 28 to 40.

Measure fluorescence

25. Measure fluorescence without further washing using filter settings as described in Table 8.6.3.

26. If available, activate the 633-nm excitation pulse processing option on Click-iT EdU cell cycle dye 633 detection channel (DNA content) for gating aggregates/doublets on the flow cytometer (for required filter settings see Table 8.6.3).

27. Draw the following plots and histograms with the acquisition software:

    a. FC/SC dot plot
    b. Histogram for LIVE/DEAD Fixable Violet dead cell stain detection
    c. Histogram for Alexa Fluor 488 detection (optional)
    d. Histogram for Click-iT EdU cell cycle dye 633 detection (optional)
    e. Click-iT EdU cell cycle dye 633 area/Alexa Fluor 488 area dot plot.

Use pulse-processing for gating of doublet cells (Brockhoff, 2009) if available for the instrument. For example, using instruments from BD Biosciences, draw a Click-iT EdU cell cycle dye 633 width/area dot plot.

28. Set the detector gains for LIVE/DEAD Fixable Violet dead cell stain and Alexa Fluor 488 detection channels (EdU coupling) to logarithmic signal amplification and for Click-iT EdU cell cycle dye 633 detection channels (DNA content) to linear signal amplification. Enable discrimination of live and dead cells in the LIVE/DEAD Fixable Violet dead cell stain detection channel and EdU-positive and EdU-negative cells in the Alexa Fluor 488 detection channel, respectively, and set detector gains to give a cell cycle histogram in the Click-iT EdU cell cycle dye 633 detection channel.

    LIVE/DEAD Fixable Violet dead cell stain, Alexa Fluor 488, and Click-iT EdU cell cycle dye 633 were selected for this assay as their excitation and emission maxima are largely separated from each other (see Table 8.6.3) and are suited for excitation with three different lasers. These dye characteristics allow one to avoid the need for compensation and compensation controls. If the experimenter wants to check whether compensation is needed with the specific experimental system, prepare unstained, single-stained, and one triple-stained sample and refer to Roederer (2002) for the procedure of compensation.

29. Acquire at least 1×10^4 cells per sample with appropriate software that stores data in list-mode flow cytometry standard (FCS) files (e.g., BD FACS Diva software v6.1.1).

Analyze data

30. Analyze data with appropriate software (e.g., FlowJo 7.6.1).

31. Gate live cells in FC/SC dot plot.

32. If the pulse-processing option is supported by the flow cytometer and was used during acquisition, gate single cells, e.g., in the Click-iT EdU cell cycle dye 633 width/area dot plot for BD instruments.

33. Gate LIVE/DEAD Fixable Violet dead cell stain–negative cells in the respective histogram (see step 27).

34. Visualize gated cells in the Click-iT EdU cell cycle dye 633 area/Alexa Fluor 488 area dot plot (see Anticipated Results, Fig. 8.6.3).

EVALUATION OF CELL DEATH BY DETERMINATION OF THE SUB-G1 FRACTION

SUPPORT PROTOCOL 1

Labeling with LIVE/DEAD Fixable Violet dead cell stain according to the Alternate Protocol allows one to exclude the dead cell fraction from evaluation of data in a multi-parametric assay. In addition, the dead cell fraction may also be quantified with LIVE/DEAD Fixable Violet dead cell stain by gating on the respective cell population. Furthermore, labeling according to the Alternate Protocol allows for a more detailed characterization of the dead cell fraction by visualization of the sub-G1 peak due to DNA labeling with Click-iT EdU cell cycle dye 633 and therefore provides the possibility to quantify the amount of cell death with a second marker for cell death in one assay. For a positive control, also label samples A and B (Table 8.6.2) with Click-iT EdU cell cycle dye 633 according to Basic Protocol 1, steps 37 to 40.

For flow cytometric measurements, reduce the threshold value so that data on cell fragments is also stored and not excluded from data storage. For visualization of the cells and cell fragments with lower than G1 DNA content, extend the gate in the FC/SC dot plot and the gate for single cells in the Click-iT EdU cell cycle dye 633 width/area dot plot to lower signal intensities.

BASIC PROTOCOL 2

DYNAMIC CELL PROLIFERATION ASSESSMENT BY EDU/HOECHST QUENCHING

Continuous exposure of proliferating cells to EdU results in substitution of thymidine in DNA during S-phase while quiescent/dormant cells remain EdU negative. Staining of cells with Hoechst 33258 and PI after detergent permeabilization leads to quenching of Hoechst 33258 fluorescence while PI fluorescence is stoichiometric to the DNA content. This allows distinguishing cells of different cell cycle phases (G0/G1, S, G2/M) of subsequent cell cycles. In addition, the EdU-negative G0 cell fraction is quantified. This technique is highly suited not only to determine drug-induced changes in cell cycle progression but also to quantify drug-caused cell cycle exit or re-entry. This protocol is optimized for the human breast cancer cell line BT474.

Materials

BT474 breast cancer cells (ATCC #HTB-20; see *UNIT 1.1* for culture of mammalian cells)
Complete DMEM containing 5% (v/v) fetal bovine serum (FBS; DMEM-5; *UNIT 1.1*)
Drug to be tested for its effect on cell proliferation (e.g., trastuzumab, also known as rhuMAb, 4D5, and herceptin, humanized monoclonal antibody acting on the ErbB2 (HER2/neu) receptor)
Complete DMEM containing 2% (v/v) FBS (DMEM-2), optional
10 mM 5-ethynyl-2′-deoxyuridine (EdU; e.g., Molecular Probes/Invitrogen) in DMSO
Trypsin/EDTA solution (*APPENDIX 2A*)
PBS/0.01% NaN_3/0.2% BSA: phosphate-buffered saline (PBS; *APPENDIX 2A*) containing 0.01% (w/v) NaN_3 and 0.2% (w/v) BSA; store up to 2 weeks at 4°C
Freezing medium without phenol red (e.g., RPMI, 10% FBS, 10% DMSO; Brockhoff, 2009; see *UNIT 1.1*), optional
DNA washing buffer (see recipe)
DNA staining buffer (see recipe)
250 μg/ml propidium iodide (PI; e.g., Sigma) solution in PBS

75-cm^2 culture flasks
50-ml centrifuge tubes (e.g., Polypropylene tubes, Greiner Bio-one)
Refrigerated centrifuge, 4°C
Hemacytometer (*UNIT 1.1*)
Water jet vacuum pump (e.g., BRAND), optional
37°C water bath (optional)
5-ml sample tubes (e.g., 12 × 75–mm polystyrene round-bottomed tubes, BD)
70-μm nylon mesh, optional
Flow cytometer with a 488-nm and UV laser excitation (see Table 8.6.3 for required filters)
Acquisition software that stores data in list-mode flow cytometry standard (FCS) files (e.g., BD FACS Diva software V6.1.1, BD Biosciences)
Evaluation software (e.g., FlowJo 7.6.1, Tree star)

NOTE: Protect labeling solutions and labeled samples from light.

Seed cells and incubate cells with EdU

1. Seed 2×10^5 exponentially growing cells (day 0) in complete DMEM with 5% FBS (DMEM-5) in 75-cm^2 culture flasks.

   The number of necessary cell culture flasks depends on the number of time points or different treatment modalities with drugs (see below). For studying cell cycle kinetics, seed a sufficient number of cell culture flasks that allows iterative EdU addition at 2-hr intervals before harvesting simultaneously.

Provide EdU-negative cultures to serve as a negative control for whether the continuous EdU incubation has an inhibitory effect on cell proliferation. Examine these controls in a single-parameter histogram. The distributions of the cell cycle phases with and without EdU labeling must be similar.

Subject to the cell type–specific doubling time of the cells under investigation, seed a cell number to guarantee a sub-confluent cell culture after 7 days of growth.

2. (Optional) Add drug to test samples, e.g., 10 μg/ml trastuzumab (day 1); use untreated samples as controls. Continue cell culture.

   For testing for the effect of different growth factors on cell cycle progression, reduction of FBS in the medium from 5% to 2% is recommended.

3. Add 100 μg/ml EdU to both drug-treated and untreated cell samples on days 2, 3, and/or 4 to give different incubation times with EdU for comparison of cell cycle progression of the differentially treated test samples. Continue cell culture.

   The time point of EdU addition and the time interval of EdU continuous labeling of cells highly depends on the cell cycle time of the cell line under investigation and on the information required. Therefore, the optimal time points of EdU addition and the duration of continuous EdU exposure must be determined for each cell line separately. In addition, the EdU concentration that results in optimal quenching of Hoechst 33258 must be determined for each cell line.

   EdU has not yet been demonstrated to be a photosensitizer as it has been verified for BrdU. Hence there is no need to incubate and handle EdU-treated samples under dim conditions. However, since EdU has been found to potentially cause dsDNA breaks (Diermeier-Daucher et al., 2009), it should be applied at the lowest concentration possible.

4. Change medium on day 4 and replace EdU and drugs where appropriate. Continue cell culture.

Harvest cells

5. Harvest cells on day 7 for BT474 using trypsin/EDTA solution (e.g., see *UNIT 1.1*), collect into 50-ml centrifuge tubes, and transfer to ice.

   The optimal time point for harvesting cell lines must be determined individually according to the time point where differences in cell cycle progression become apparent. In addition, cells should be subconfluent at harvesting; see Strategic Planning, cell culture for optimal growth.

6. Centrifuge cells 5 min at ~350 × *g*, 4°C.

7. Decant or remove the supernatant with a water jet vacuum pump.

8. Resuspend the cell pellet in ice-cold PBS/0.01% NaN_3/0.2% BSA.

9. Repeat steps 6 to 8.

10. Determine cell number using a hemacytometer as described in *UNIT 1.1*. Store cells frozen at −20°C for later measurement, proceed to step 11, or label and measure on the same day, proceed to step 13.

Store cells for sample collection (Optional)

11. Freeze cells in freezing medium without phenol red (Brockhoff, 2009; see *UNIT 1.1*) at a final cell concentration of 1×10^6 cells/ml.

    Cells can be stored up to 6 months at −20°C without detectable degradation.

12. For labeling frozen cells, thaw cells in a 37°C water bath and immediately proceed to step 13.

Prepare and stain nuclei

13. Add 5×10^5 cells per sample to 5-ml sample tubes containing 1 to 2 ml DNA-washing buffer.
14. Centrifuge cells 5 min at ~350 × *g*, 4°C.
15. Decant or remove the supernatant with a water jet vacuum pump.
16. Resuspend the cell pellet in 1 to 2 ml ice-cold DNA-washing buffer.
17. Repeat steps 14 and 15 and proceed with step 18.
18. Add 994 µl DNA-staining buffer (containing 1.2 µg/ml Hoechst 33258).
19. Incubate 15 min at room temperature.
20. Add 6 µl PI (250 µg/ml, 1.5 µg/ml final concentration) and incubate for at least 15 min at 4°C.

Measure fluorescence

21. (Optional) Pass nuclei through a 70-µm nylon mesh to remove aggregates prior to flow cytometric analysis.
22. Measure fluorescence without further washing, using filter settings as described in Table 8.6.3.
23. If available, activate 488-nm excitation pulse processing option on PI detection channel (DNA content) for gating aggregates/doublets on the flow cytometer (for required filter settings, see Table 8.6.3).
24. Draw the following plots and histograms with the acquisition software:
    a. FC/SC dot plot
    b. Hoechst 33258/PI area dot plot.

    Use pulse-processing for gating of doublet cells (Brockhoff, 2009) if this option is available for the instrument. For example, using a BD Biosciences instrument draw a PI width/area dot plot.
25. Set the detector gains for PI and Hoechst 33248 detection channels to linear signal amplification.

    PI and Hoechst 33248 excitation and emission maxima are largely separated from each other (see Table 8.6.3) and are suited for excitation with two spatially separated lasers for time-resolved sample excitation. These dye characteristics allow neglecting compensation and compensation controls. Data shown in Anticipated Results were gained without compensation.
26. Acquire at least 1×10^4 events per sample with appropriate software that stores data in list-mode flow cytometry standard (FCS) files (e.g., BD FACS Diva software v6.1.1).

Analyze data

27. Analyze data with appropriate software (e.g., FlowJo 7.6.1).
28. Gate intact nuclei in FC/SC dot plot.
29. If the pulse-processing option is supported by the flow cytometer and was used during acquisition, gate single nuclei, e.g., in the PI width/area dot plot for BD instruments.
30. Visualize gated events in the Hoechst 33248 area/PI area dot plot.

QUANTIFICATION OF THE G0 CELL FRACTION WITH THE EDU/HOECHST QUENCHING TECHNIQUE

The fraction of quiescent cells (G0 cells) and their potential to re-enter the cell cycle via G0- to G1-transition can be quantified. Cells progress through successive cell cycles at different rates depending on the individual treatment. Therefore, calculation of the dormant cell fraction has to account for cells that have divided once, twice, or three times within the observation period (Brockhoff et al., 2007).

1. Draw regions with appropriate software (e.g., FlowJo 7.6.1) around the cells/nuclei that are attributed to G0 cells and to cells of the first, second, and third cell cycle, respectively, according to Figure 8.6.2 (Anticipated Results). Use the statistics displayed by the software to gain the cell number in the respective gates.
2. Calculate dormant cell/nuclei number according to Equation 8.6.1.

   Calculate the fraction of dormant cells ($G0_{korr.}$) analyzed with the EdU/Hoechst quenching technique by determining the number of G0 cells (G0) and cell numbers in the first (A), second (B), and third (C) cell cycles (also see Fig. 8.6.2).

$$\frac{G0}{\frac{A}{1}+\frac{B}{2}+\frac{C}{4}+G0} = G0_{korr.}$$

Equation 8.6.1

Divide the number of G0 cells by the sum of:

(1) the number of cells that have incorporated EdU, but have not divided (A, cells of the first cell cycle that are in S or G2/M-phase),
(2) the number of cells that have divided once (B, cells that are assigned to the second cell cycle) divided by 2 (two cells in the second cycle have resulted from one cell in the first cycle),
(3) the number of cells that have divided twice (C, cells that belong to the third cell cycle) divided by 4 (four cells in the third cycle have resulted from one cell in the first cycle), and
(4) the number of G0 cells.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DNA buffer

100 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
154 mM NaCl
1 mM $CaCl_2$
0.5 mM $MgCl_2$
Store up to 1 year at room temperature

DNA staining buffer

DNA buffer (see recipe)
0.2 % (w/v) BSA
0.1 % (v/v) IGEPAL CA-630 (nonylphenylpolyethylenglycol, e.g., Sigma)
40 μg/ml RNase A

continued

1.2 μg/ml Hoechst 33258
Prepare fresh

Cut off ~0.3 cm of the pipet tip for facilitating pipetting of the viscous IGEPAL.

Allow the necessary volume to warm to room temperature before use.

A stock solution consisting of DNA buffer, 0.2% (w/v) BSA, and 0.1% (v/v) IGEPAL may be prepared and stored for up to 2 weeks at 4°C. Add RNase A and Hoechst 33258 immediately before use of DNA staining buffer.

DNA washing buffer

DNA buffer (see recipe)
0.2 % (w/v) BSA
Store up to 2 weeks at 4°C

Paraformaldehyde (PFA), 4% (w/v)

Add 40 ml of PBS (*APPENDIX 2A*) to 2 mg of solid paraformaldehyde. Add 3 to 4 ml of 1 M NaOH and mix until the solid dissolves. Adjust the pH to 7.4. Bring the volume to 50 ml with water and check the pH again. Store up to 1 week at 4°C. Discard after 1 week.

CAUTION *Wear gloves and do not inhale PFA powder.*

COMMENTARY

Background Information

Nucleoside analog-based flow cytometric techniques constitute powerful tools to determine cell cycle kinetics and to disclose potential mitogenic, cytostatic, and cytotoxic effects upon specific cell treatment (Brockhoff et al., 2001, 2007; Diermeier-Daucher et al., 2005; Cappella et al., 2008a; Brockhoff, 2009). The high information content of flow cytometric studies of cell cycle kinetics has led to alternative procedures in addition to the classical BrdU pulse-labeling techniques (Darzynkiewicz and Juan, 1997) with the aim to circumvent the requirement of DNA denaturation and to allow for multicolor experiments and multiplexing with antigen staining.

Click chemistry has proven to fulfill these requirements and was recently introduced for labeling and detection of newly synthesized DNA by coupling the thymidine analog EdU with a fluorescent azide probe. Since its publication in 2002 (Rostovtsev et al., 2002; Tornoe et al., 2002) click chemistry has proven extremely useful for cell culture studies with flow cytometry (Buck et al., 2008; Cappella et al., 2008a; Brockhoff, 2009; Diermeier-Daucher et al., 2009), automated fluorescence microscopy (high content screening; Bradford et al., 2008c), and high-speed ImageStream image cytometry (George et al., 2008). Recent reports highlight the application of EdU for in vivo studies applying intraperitoneal injection of EdU into mice followed by click chemistry on paraffin tissue sections (Salic and Mitchison, 2008) and the combination of EdU incubation of whole-mount embryos with click chemistry and immunofluorescent antigen staining of tissue sections (Warren et al., 2009).

A strategy to avoid the need for denaturation of dsDNA in combination with an antibody-based detection protocol was recently published by Cappella et al. (2008b). EdU incorporated into DNA is covalently linked to a BrdU azide by click chemistry, which in turn is labeled with fluorophore-conjugated anti-BrdU antibodies.

The antibody detection method of DNA-labeled BrdU was augmented by Clarke et al. (2008) with the non-antibody approach of EdU detection by click chemistry, which enables double labeling of proliferating cells. As simultaneous addition of both nucleosides only results in the incorporation of BrdU into DNA of S-phase cells, the sequential addition of EdU followed by BrdU allows one to distinguish three nucleoside-labeled populations (EdU-positive, EdU/BrdU-double positive, and BrdU-positive) and was suggested for detection of rapid changes in cell proliferation upon drug treatment.

Furthermore, the highly informative Hoechst quenching technique with (continuous) EdU incubation was developed as an option rather than the BrdU/Hoechst quenching technique (Poot et al., 2001) for

detailed analysis of cell cycle kinetics of cell lines that show BrdU-induced effects on cell proliferation (Diermeier-Daucher et al., 2009). Continuous BrdU exposure has been shown to result in cell-type specific changes in cell cycle progression (Diermeier-Daucher et al., 2004). The EdU/Hoechst quenching technique offers an alternative. As an informative technique for high-resolution assessment of cell cycle kinetics, it represents a powerful tool for analysis of cell cycle distribution and kinetics with a broad field of applications, including studying effects of growth factors and drugs on a specific cell cycle phase.

Critical Parameters and Troubleshooting

EdU-induced effects on cell cycle progression

Continuous treatment with EdU may have cytostatic or cytotoxic effects (Diermeier-Daucher et al., 2009). However, different cell types of different origins differentially and individually respond to nucleoside treatment, which is valid for both BrdU (Diermeier-Daucher et al., 2004) and EdU (Diermeier-Daucher et al., 2009). Therefore, it is recommended to test the cell line under investigation for a potential impact of EdU on cell viability, DNA synthesis, and cell cycle progression before applying both pulse-labeling and continuous treatment with nucleoside analogs. Nevertheless, determination of the G0 cell fraction applying the EdU/Hoechst quenching technique with continuous EdU exposure of cells is even possible with cell lines that are affected by EdU in cell cycle progression. The comparison of EdU-labeled drug-untreated control cells with EdU-labeled drug-treated cells allows one to compensate for the EdU-caused effect and to solely analyze cell cycle exit (or re-entry) mediated by the drug of interest. However, incorporation of BrdU into DNA has been suggested to increase the sensitivity of cells towards certain drugs (Poot et al., 1991). EdU as an alternative nucleoside analog may have similar effects.

Hoechst/PI dye concentrations

The fluorescence of DNA-bound dye and the quenching effect may vary among different cell lines. Therefore, in the Hoechst 33258 versus PI dot plot, the slope of cells that were proliferating from G0/G1 into S and G2/M in their first cell cycle during EdU incubation may not be left-facing, (Fig. 8.6.3). To optimize the slope, change the concentration ratio of Hoechst 33258 versus PI dyes by variation of, e.g., the PI concentration while the Hoechst 33258 concentration remains constant.

Reduce artifacts

Detergent is present in cell suspensions of EdU/Hoechst quenching measurements. This may disturb the current streaming through the flow cytometer and artifacts may develop during signal detection. A reduction of the flow velocity <300 events/sec may improve the quality of the measurement.

Deficient discrimination of EdU-positive versus EdU-negative cells

To increase the separation of EdU-positive versus EdU-negative cells in pulse-labeling experiments, the EdU concentration used may be increased. However, this procedure may increase the probability for cytostatic or even cytotoxic effects of the nucleoside analog. Therefore, to minimize the risk for nucleoside-induced effects, the shortest incubation time in combination with the lowest EdU concentration is recommended for these experiments.

Weakly stained cells in addition to EdU-positive and EdU-negative cells

For EdU-pulse labeling, the nucleoside analog must be removed completely after the 3-hr pulse. Otherwise, cells can insert the EdU remnants into the DNA, which becomes visible after cell staining and results in a weak, positive reaction. These cells appear as dimly positively-stained cells in the two-dimensional dot-plot and distort the accurate temporal resolution of cell cycle phases. Therefore, to ensure a complete removal of non-incorporated EdU, wash the cultures thoroughly (at least three times) with warm PBS.

Anticipated Results

Interpretation of data gained with the quenching technique

Consecutive cell cycles of synchronized or asynchronously growing cell populations in vitro can be investigated. The measured fluorescence of PI is directly proportional to the DNA content of cells, which is twice as high in G2/M cells compared with G0/G1 cells. Fluorescence intensity of Hoechst 33258 depends on the amount of EdU incorporated into DNA over time and increases with cell cycle phases (from G0/G1- and S- to G2/M-phase) and in successive cell cycles. Quenching of Hoechst 33258 fluorescence occurs over the first cell cycle (Diermeier-Daucher et al., 2009) and is

due to the unifiliary thymidine substitution by EdU during the first cell cycle of EdU exposure and results in a decrease of Hoechst 33258 fluorescence intensity with increasing DNA content. During the second cell cycle, EdU is incorporated into the second DNA strand and the EdU substitution level increases from 50% to 75%. Since the percentage increase in thymidine substitution by EdU in the DNA is lower than in the first cell cycle (increase in nucleoside substitution after one cell cycle: 50%; after two cell cycles: 25%; Brockhoff, 2009), Hoechst 33258 fluorescence intensity is no more efficiently quenched but increases with DNA content to generate a mirror image between the first and second cell cycles. Cells of the third cell cycle run in parallel to cells of the second cycle.

Figure 8.6.2 shows that after EdU incubation non-proliferating cells remain at the starting point of the first cell cycle. After an extended incubation with the nucleoside analog (e.g., after a 96-hr EdU incubation), these dormant cells separate from the EdU-positive fraction of proliferating cells. Hence EdU-negative, non-proliferating cells can be quantified with appropriate gating and calculation procedures described in Support Protocol 2 and in Diermeier-Daucher et al. (2009). For further details on dynamic analysis of cell cycle kinetics, see Brockhoff (2009) or the original literature can be consulted (Latt et al., 1977; Kubbies et al., 1985; Poot et al., 1988, 1994; Rabinovitch et al., 1988). For calculation of the dormant cell fraction, see Support Protocol 2. Original data derived from an EdU/Hoechst 33258 quenching measurement are shown in Figure 8.6.3.

Examples for dynamic cell proliferation assessment with EdU

EdU can be used in place of BrdU for dynamic cell proliferation assessment of BT474 breast cancer cell line both for the pulse-labeling anti-BrdU technique (Fig. 8.6.3A,B) and for the continuous labeling BrdU/Hoechst quenching technique (Fig. 8.6.3C,D). Nucleoside analog–labeled S-phase and nucleoside analog–negative G1- and G2/M-phase cells separate to a similar extent for BrdU detection with anti-BrdU antibodies (49-fold difference) and for EdU labeling with click chemistry (55-fold difference) at the 0-hr time point (Fig. 8.6.3A,B). Compared to BrdU, EdU is capable of quenching Hoechst 33258 to a similar extent. Figure 8.6.3C,D shows one representative time point (39.5 hr; Diermeier-Daucher et al., 2009).

Time Considerations

Coupling of EdU with fluorescent dye by click chemistry and staining with DNA dye takes ~2 hr, including cell harvesting, cell counting, and all incubation and washing steps (see Basic Protocol 1). Staining for live/dead discrimination as a three-step staining protocol in addition to the two-step staining in Basic Protocol 1 requires an additional 1 hr (see Alternate Protocol). Flow cytometric measurement requires 30 min for about ten samples. Staining and measurement for the EdU/Hoechst quenching technique takes ~1 hr each (see Basic Protocol 2).

CHAPTER 9
Cell Adhesion

INTRODUCTION

Cell-adhesive interactions determine the organization of tissues and mediate and guide precise cell migrations during embryonic development, inflammation, the immune response, and wound repair. They also help to regulate gene expression, growth, differentiation, and apoptosis. Research into cell adhesion has undergone dramatic evolution over the past two to three decades, from phenomenological studies of the biophysical and morphological mechanisms used by cells to adhere to other cells and the extracellular matrix, to the discovery and in-depth mechanistic analyses of a variety of specific cell adhesion systems, and then to the recent paradigm shift whereby adhesion molecules are now viewed as activators or regulators of a remarkably wide range of signal transduction pathways.

FUNCTIONS OF ADHESION MOLECULES

Cell adhesion molecules function by forming specific protein-protein or protein-carbohydrate bonds at the cell surface to mediate cell interactions. In addition, cell adhesion molecules or cell adhesion receptors often form direct links to multimolecular protein complexes on the cytoplasmic face of the plasma membrane. These cytoplasmic adhesion and signaling complexes interact with the cytoskeleton and signal transduction pathways. As a result, cell adhesion not only links cells with other cells and the extracellular matrix, but also helps to integrate extracellular physical information with the major signal transduction pathways within cells.

Cell adhesion is often categorized into cell-to-cell adhesion and cell-to-substrate adhesion. In each case, the physical structures that mediate cell adhesion can be either specialized adhesive structures or broad expanses of plasma membrane. For example, cells can initially adhere to other cells along large areas of plasma membrane using general-purpose adhesive molecules such as cadherins. But they can also form attachments to each other by using specialized adhesive structures, such as desmosomes, adherens junctions, and tight junctions. Each type of junctional complex involves specific adhesion-molecule components, such as cadherins and associated cytoplasmic components involved in linkage to the actin-containing cytoskeleton. Fibroblasts can also form adhesions to other fibroblasts, but they most characteristically form adhesive interactions with extracellular matrix molecules. Such cell-to-matrix adhesion sites can also be either broad zones or specialized structures. For example, rapidly migrating cells typically interact with tissue culture substrates through broad areas of contact termed “close contacts,” and the entire basal surface of epithelial cells adheres via integrins to their underlying basement membranes. Specialized adhesive structures include the hemidesmosomes of certain epithelial cells and the focal adhesions of fibroblastic and endothelial cells. The protein composition of the complexes involved in cell-to-matrix adhesions can sometimes involve a few of the same proteins as in cell-to-cell adhesions, such as vinculin and actin, but they mainly consist of distinct types of adhesive, cytoskeletal, and signal transduction molecules.

GENERAL CHARACTERISTICS OF CELL ADHESION PROTEINS

Cell adhesiveness generally involves specific binding of a cell adhesion protein or receptor to a target molecule. Adhesion mediated by the binding of an adhesion molecule to the same type of protein on a neighboring cell is termed a "homophilic" interaction. Members of the calcium-dependent cadherin family are major mediators of such interactions, and some calcium-independent adhesion proteins, such as N-CAM, can also provide homophilic interactions. Cadherin adhesion molecules characteristically form tightly packed dimeric and multimeric complexes that mediate adhesion with high avidity via cooperativity, even though the affinity of a single cadherin protein-protein interaction alone is not high.

A particularly common type of adhesive interaction involves the binding of a receptor to a specific ligand. In the process of cell-to-cell adhesion, the target protein of an adhesion receptor can be either a "counter-receptor" or a complex carbohydrate linked to a protein anchor in the plasma membrane. In cell-to-matrix interactions, a plasma membrane adhesion receptor such as an integrin binds to an adhesive extracellular matrix protein. For example, a number of types of integrin receptors can bind to fibronectin, laminin, or collagen. Integrin receptors directly mediate cell adhesion, migration, and anchorage to these structural components of the extracellular matrix.

Molecules that mediate cell-cell or cell-matrix adhesion fall into two broad structural classes. One type is anchored to the plasma membrane, often as a transmembrane protein. These membrane-anchored molecules are generally receptors, homophilic adhesion molecules, or counter-receptors. They often consist of an extracellular domain containing one or more specific cell interaction domains or sites, as well as a stalk region, a hydrophobic transmembrane domain, and a cytoplasmic domain or tail. This type of adhesion molecule is often likely to be involved in the transmembrane transmission of signals after binding to their target molecule.

The second broad class of adhesion molecules consists of cell surface or extracellular matrix proteins (see Chapter 10) that contain domains involved in cellular adhesion. Nearly all matrix proteins contain such sites. For example, this class includes fibronectin, laminins, vitronectin, collagens, and many other extracellular proteins. These proteins contain one or more cell-binding domains, which are comprised of a primary recognition motif consisting of a short peptide sequence (e.g., Arg-Gly-Asp or Leu-Asp-Val) and often a synergy site or other structural feature that substantially enhances receptor-binding specificity and affinity.

Adhesion molecules frequently have many of the following characteristics (for reviews, see Alberts et al., 1994; Chothia and Jones, 1997; Edelman and Thiery, 1985; Gumbiner, 1996; Hay, 1991; Richardson and Steiner, 1995).

1. The backbone structure of adhesion proteins is often based on multiple repeats of protein motifs, such as the immunoglobulin (Ig) motif, EGF repeat, or fibronectin motif. The basic immunoglobulin repeat is quite common, as is the structurally related fibronectin type III repeat.

2. They have specialized functional domains, including one or more domains for binding molecules on other cells or in extracellular matrix. Often a domain for forming dimers or higher polymers is also present, as well as another for binding to complex carbohydrates.

3. They often bind with only moderate affinity, e.g., in the range of $K_d = 10^{-6}$ to 10^{-7} M for fibronectin, and as low as 10^{-4} M for leukocyte adhesion molecules involved in rolling adhesion. This modest affinity appears to be important for allowing dynamic changes in cell adhesions and to permit cell migration involving cyclic attachment and detachment of cell adhesion sites to a substrate or other cells.

4. They often function by clustering to generate complexes of high avidity: adhesion molecules such as integrins and cadherins often organize into large local clusters or aggregates in the plane of the plasma membrane, which can produce strong total avidity as a result of the summation of the otherwise weak binding of many individual molecules.

5. Their binding functions can be regulated by activation, e.g., "inside-out" signaling that changes their ability to bind ligands effectively; examples are integrin activation during leukocyte adhesion and platelet activation, and the suppression of the cadherin system by tyrosine phosphorylation.

MAJOR FAMILIES OF CELL ADHESION MOLECULES

Adhesion molecules that are anchored in the plasma membrane include several large groups of proteins that share common structural motifs, such as the immunoglobulin repeat. **Cadherins** comprise a large family of proteins particularly centrally involved in cell-to-cell adhesive interactions (Takeichi, 1990; Yap et al., 1997; see *UNIT 9.3*). Cadherins on one cell bind in homophilic fashion to the same type of cadherin on other cells by means of specific cell interaction domains, which can include the short peptide recognition sequence His-Ala-Val. The cytoplasmic domain of cadherin molecules characteristically binds to catenins, which provide direct linkages to the actin cytoskeleton (e.g., via α- and β-catenins).

The "classical" cadherins such as E-cadherin and N-cadherin mediate adhesion over broad expanses of cell-cell contact, or they can become further organized into adherens-type junctions that are linked to cytoplasmic molecules such as vinculin and actin. A number of other types of cadherins have been discovered recently, whose functions are probably also adhesive, but which remain to be characterized. Finally, certain highly specialized cadherins found exclusively in desmosomes, termed desmocollins and desmogleins, link cells together at particularly strong attachment sites connected to intermediate filaments such as keratins or vimentin.

Cadherin activity is quite sensitive to calcium ion concentration, which accounts for the ability of calcium chelators such as EDTA to dissociate tissues into their individual component cells. Chelation of divalent cations appears to disrupt conformation, so that the cadherin molecules become quite sensitive to general proteolytic attack; this latter property has been used to classify cell-cell adhesion molecules (see *UNIT 9.3*). Although desmosomal and other cadherins can be found widely in epithelia of organisms at all ages, the cadherins are particularly important during embryonic development, when they appear to organize groups of cells and tissues by specific cell-cell adhesions. They help to define tissues by binding primarily to cadherins of the same type, rather than to other cadherins on unrelated cell types; this activity can lead to "sorting out" of different types of cells from others.

Integrins are nearly ubiquitous cell surface receptors for a wide variety of extracellular matrix proteins, as well as for "counter-receptor" ligands on other cells. There are more than 20 distinct integrin subunits, which are combined to form heterodimers that always consist of one α and one β subunit. Genetic loss of almost any integrin subunit leads to disease or death, often during embryonic development or near the time of birth. Integrin molecules have a head domain containing a ligand-binding site, two spindly legs, and usually rather short cytoplasmic domains. Integrin binding is often inhibited by depletion of divalent cations.

CAMs (cell adhesion molecules) and integrin counter-receptors are structurally related by their use of the immunoglobulin repeat, and they often have the term "-CAM" in their names, yet they differ functionally. Molecules such as NCAM are calcium-independent,

homophilic adhesive molecules that bind to the same type of molecule on an adjacent cell surface, often a cell of the same tissue type (Edelman and Crossin, 1991). In contrast, counter-receptors such as the ICAMs and VCAM have specialized peptide recognition sites that are bound specifically by integrins such as LFA-1 (CD11a/CD18 or $\alpha_L\beta_2$) or VLA-4 ($\alpha_4\beta_1$), which are often present on other types of cells (e.g., endothelial cells and lymphocytes). The functions and sites of expression of these molecules can consequently differ widely. For example, molecules such as NCAM are implicated in embryonic developmental events such as axonal guidance and bundling, whereas ICAM counter-receptors are present as targets for binding by cells circulating in blood. The levels of these counter-receptors on the cell surface can often also be regulated rapidly in response to cytokines, for example during inflammatory responses.

A family of transmembrane proteins termed **ADAMs** (membrane proteins with a disintegrin and metalloprotease domain; Wolfsberg and White, 1996) contain a protease-like domain plus an integrin recognition site in the disintegrin domain. They appear to play roles in cell adhesion; for example, one member of this family is present on sperm and has been implicated in sperm-egg adhesion. **Syndecans** are cell-surface heparan sulfate proteoglycans with a protein core that crosses the plasma membrane and terminates in a cytoplasmic tail. Syndecans appear to function as "co-receptors," mediating signaling in association with a primary adhesion molecule. For example, syndecans synergize with fibronectin during formation of focal adhesion sites and form linkages to protein kinase C (Woods and Couchman, 1998).

Adhesive extracellular matrix molecules are described in Chapter 10. One interesting aspect of their function involves the striking effects of adsorption or attachment to a substrate. Molecules such as fibronectin and vitronectin circulate in blood at relatively high concentrations (e.g., 100 to 300 μg/ml), yet binding to cell surface receptors is relatively limited. On the other hand, even very low concentrations of the same proteins (1 to 10 μg/ml) bind to substrates and then mediate strong cell adhesion. This functional enhancement of binding of cells to molecules attached to a substrate has been variously ascribed to activation of molecules such as fibronectin and vitronectin by conformational changes resulting from binding to a substrate, to enhanced ability to interact with cells due to multivalency, or to a physical chemical enhancement in free energy (overall avidity) due to immobilization of a ligand. Whatever the mechanisms, it is clear that the binding of extracellular adhesion molecules to substrates can enhance functional activity, which appears to be important biologically to generate strong adhesion only when a circulating ligand is immobilized. For example, in wounds, immobilized fibronectin forms a crucially important provisional matrix that permits adhesion and migration of cells to close the wound.

FUNCTIONS OF CELL ADHESION MOLECULES IN SIGNAL TRANSDUCTION AND CYTOSKELETON

The functions of cell adhesion molecules and their receptors can be understood intuitively as physical mechanisms by which cells attach to other cells, adhere to extracellular matrix molecules, and provide traction during cell migration. This concept can be extended to intracellular structural effects—i.e., the organizing of the cytoskeleton. For example, transmembrane adhesion proteins provide membrane anchors for a host of cytoskeletal proteins such as keratin or vimentin in desmosomes and hemidesmosomes, actin microfilaments and other proteins in epithelial adherens junctions, and a number of adhesion plaque proteins and actin in cell-substrate adhesion plaques (e.g., see Jockusch et al., 1995; Yamada and Geiger, 1997).

It is now clear, however, that adhesion molecules also play crucial roles in helping to trigger or modulate many major signal transduction pathways. In fact, their signaling

functions are probably at least as important in cell biology as their attachment and cytoskeletal activities. A notable characteristic of the intracellular complexes of proteins induced by binding of adhesion molecules is that their formation also induces accumulation of a variety of signal transduction molecules that can trigger downstream signaling pathways (Clark and Brugge, 1995; Schwartz et al., 1995; Lafrenie and Yamada, 1996). As a consequence, adhesion proteins are actually cell-interaction proteins that have multiple functions in the bidirectional transfer of information at the cell surface. They can mediate outside-in transfers of signaling information, such as cellular responses to binding of specific extracellular matrix proteins involving the activation of intracellular signaling, but they can also mediate inside-out information in which intracellular signals modulate the activity of integrins and assembly of extracellular matrix. Even classical adhesive proteins such as fibronectin can trigger a bewildering range of activities after binding by integrins; these can include activation or modulation of many well-known mammalian signal transduction pathways (such as tyrosine phosphorylation, MAP kinases, protein kinase C, Ca^{2+} and H^{+} fluxes, and phosphoinositide pathways) which can activate specific gene transcription, mediate anchorage-dependent growth stimulation, and prevent apoptosis.

Two structural regions in transmembrane adhesion molecules that allow them to function as signal transduction receptors are their extracellular ligand-binding domains and their cytoplasmic domains. The ligand-binding domains are obviously essential for binding to extracellular molecules, but in at least some cases, they have additional, intriguing roles. For integrin adhesion receptors, there appear to be separable functions for ligand occupancy (filling the binding site with a ligand), as opposed to receptor clustering (which can be induced by multivalent ligands such as fibrils of fibronectin or collagen). These two inputs can synergize to promote the accumulation of specific cytoskeletal proteins such as α-actinin and actin to form strong adhesions (Yamada and Miyamoto, 1995).

Even though they lack intrinsic enzymatic activities, integrins appear to function as signaling receptors and regulators of actin cytoskeletal organization by recruiting other molecules to bind to their cytoplasmic domains. Integrins appear to bind directly to certain cytoplasmic proteins, such as talin, α-actinin, and tensin, in a process that is sometimes regulated by ligand occupancy on the outside of the cell. Also important, however, are docking proteins such as focal adhesion kinase, which can bind to integrins as well as binding to at least eight cytoplasmic molecules to form molecular complexes. Other docking proteins such as $p130^{Cas}$ probably increase the repertoire of cross-linked and complexed proteins. Integrin clustering appears to play a central role in forming large complexes that can consist of over 30 different types of molecules. These integrin-induced multimolecular complexes can serve as signaling centers, e.g., for tyrosine phosphorylation and MAP kinase activation (reviewed by Yamada and Miyamoto, 1995; see *UNIT 14.2* and *UNIT 14.3* for protocols measuring these post-translational modifications).

Cell-to-cell adhesion molecules also appear to undergo a very similar process of local clustering, complex formation, binding of cytoskeletal proteins such as actin, and accumulation of signaling molecules (Kirkpatrick and Peifer, 1995; Yap et al., 1997; Yamada and Geiger, 1997). It will become increasingly important to understand how these processes are controlled. The cadherin system can be suppressed by tyrosine phosphorylation mediated by v-Src kinase, and certain integrin functions can be down-modulated by the phosphatase PTEN (Takeda et al., 1995; Tamura et al., 1998). There are likely to be large numbers of other regulatory pathways that affect the widespread intracellular effects of cell-cell and cell-substrate adhesion molecules on cytoplasmic processes. It is clear that adhesion molecules are crucial, integral components of the basic signaling and regulatory mechanisms of cells, providing dynamic links to the external environment.

CELL ADHESION ASSAYS

A crucial first step for effective analysis of a cell adhesive process is to characterize it in a quantitative in vitro assay. Cell-to-substrate adhesion assays are used to examine the ability of cells to attach to matrix molecules, such as fibronectin or laminin, and to determine which specific adhesion receptors are involved using antibodies or synthetic peptide inhibitors. Roles of cytoplasmic molecules such as cytoskeletal proteins and signaling molecules can also be evaluated with these assays using pharmacological inhibitors of intracellular processes—for instance inhibitors of kinases and other molecules.

There are several types of cell-substrate adhesion assays, which can quantitate (1) cell attachment, (2) cell spreading, or (3) detachment of previously adherent cells. Each assay measures different parameters of the adhesion process: cell attachment assays generally determine the numbers of cells that can attach to a substrate in a specific time period after washing off nonattached cells (*UNIT 9.1*); cell spreading assays determine the percentage of cells that show spread morphologies, or measure the surface area of spread cells, after certain times of incubation (*UNIT 9.1*); and cell detachment assays measure the ease with which cells can be detached after a particular period of time, for example by determining the numbers of cells detached from a dish using each of a series of increasing centrifugal force levels (*UNIT 9.2*). Although conceptually distinct, these three types of assays can in practice have features that overlap significantly.

In order to compare these assays, it is useful to consider the steps in cell-substrate adhesion and spreading. The first step in cellular adhesion to a substrate is the attachment of plasma membrane receptors or other cell interaction molecules to substrate molecules such as extracellular matrix (ECM) proteins (Chapter 10). For example, if cells are cultured on tissue culture dishes or glass in serum-containing medium, they often adhere to serum proteins such as vitronectin and fibronectin that are nonspecifically adsorbed to the substrate. Integrins frequently mediate such adhesions (e.g., attachment of cells to an extracellular matrix protein), although various other cell attachment proteins, such as the selectins, also exist.

The binding of integrins to ligands can occur even at 4°C, because it is a direct protein-protein interaction. However, this mechanism of cell adhesion is initially quite weak and can often require centrifugation of the cell against the substrate to produce close enough apposition of the plasma membrane to substrate proteins for effective binding. In contrast, normal adhesion appears to involve active cellular processes involving the plasma membrane and the cytoskeleton. The latter, poorly understood process of cytoskeletal strengthening of adhesions can produce enormous increases in attachment strength (see *UNIT 9.2* for a conceptual discussion). This strengthening phenomenon may be related to the formation of multimolecular complexes in adhesion structures containing a variety of cytoskeletal and signal transduction proteins (Burridge et al., 1997; Yamada and Geiger, 1997). Cell attachment assays are generally performed shortly after plating cells before much cell spreading can occur (e.g., within 10 to 20 min for fibroblasts).

Attachment is rapidly followed by spreading of the cell on the substrate in a dynamic adherence response involving cell movements; spreading can become maximal by 30 to 60 min. Even in simple attachment assays, it appears likely that there are some contributions from cell spreading, as the area of attachment of the cell to the substrate expands, accompanied by increasing organization of the cytoskeleton. As spreading and firmer adhesion ensue, cells often form strong focal adhesions to the substrate that are sites of termination of actin microfilament bundles (also known as stress fibers, since the bundles appear to follow lines of linear stress between focal adhesions). As cells attach and spread, they rapidly acquire resistance to detachment, for example by centrifugal force.

Although assays for cell attachment, spreading, or detachment each focus on one particu-

lar facet of cell-substrate adhesion, each assay has strengths, weaknesses, and partial overlaps with the others. Attachment assays are conceptually the simplest, but nonetheless usually unavoidably involve an element of measuring resistance to detachment of the cells by shear forces. In order to rinse unattached cells out of 96-well plates, medium must be poured in and then aspirated or flicked out, thereby generating substantial shear forces as the meniscus passes over attached cells. Cell spreading assays can provide rapid semiquantitative data and evaluate the cytoskeletal facet of cell-adhesive interactions. As a consequence, however, they do not measure only the simple interaction of an adhesion receptor with its ligand, but instead the more complete adhesion response. Spreading assays also involve an element of judgment in choosing to record whether a cell is spread or not spread, which can sometimes perturb a researcher unaccustomed to microscopy. The advantage of centrifugal detachment assays is that they can provide direct physical measurements of adhesive strength as measured in force units ($\times g$). However, this sort of assay is particularly sensitive to timing, and waiting slightly too long before an assay can permit rapid cytoskeletal organization and strengthening responses that anchor cells so tightly to the substrate that they cannot be detached without being destroyed. Nevertheless, centrifugal detachment assays arguably provide the most rigorous quantitative data.

Methods for quantification of cell-to-cell adhesion generally depend on determining the rates of reaggregation of dissociated cells (see *UNIT 9.3*). Although it is also possible to estimate strengths of adhesion by determining the force needed to separate two cells using microneedles, aggregation assays are the norm. These assays are conceptually related to the platelet aggregometer assays used routinely in clinical laboratories to measure platelet adhesion (aggregation). An added feature with nucleated cells, however, is that multiple types of adhesion molecules can often be involved in any particular cell-cell adhesive event. Three commonly observed types of adhesion molecule are the calcium-dependent cadherins, calcium-independent molecules such as N-CAM and other immunoglobulin-repeat molecules, and integrins, though other adhesion molecules may also be involved.

CHARACTERIZATION OF CELL ADHESION MECHANISMS

Once the adhesive characteristics of a cell toward a particular cellular or substrate adhesive system are established, a variety of inhibitors or modulators of adhesion can be tested in order to better define the adhesion system. Examples include function-blocking antibodies against the many dozens of known adhesion molecules to determine which are required for an adhesive event, competitive peptide inhibitors that target the active sites of adhesion receptors, and pharmacological and ionic activators and inhibitors. The latter categories include phorbol esters or Mn^{2+} to activate certain integrins, and chelators for depleting Ca^{2+} to inhibit cadherins and integrins. For routine analyses of integrins, the pertinent receptor(s) involved in a particular adhesive function can be identified by targeting a broad class of integrins first—for instance using an antibody that inhibits all β_1 or all α_v integrins—and then narrowing down the possible candidate receptors involved in a particular function by using more specific antibodies within that class (e.g., anti-α_5 within the β_1 integrin class). Monoclonal antibodies against integrins are widely available. For cadherins, specific antibodies against classical but not novel cadherins are also available, as are various cell biological approaches as described in this chapter. Reagents for analyzing other types of adhesion molecules should become increasingly available from commercial sources.

PROCEDURES DESCRIBED IN THIS CHAPTER

Two semiquantitative assays for measuring cell adhesion to a substrate are provided in *UNIT 9.1*. The first is a cell spreading assay in which adhesion is evaluated by determining

the percentage of cells that spread on a substrate, using microscopy to count spread cells. The second assay quantitates cell attachment after washing out nonattached cells, using a colorimetric protocol for quantification. The relative advantages of each of these widely used assays are compared.

The McClay centrifugation assay for directly quantitating the strength of adhesion of cells to a substrate is described in *UNIT 9.2*. This assay determines the proportion of cells detached by the graded application of centrifugal force. A new variation of the original method provides a simple method for quantitation by counting numbers of stained cells under a light microscope. This simplification of the assay should further enhance the applicability and popularity of this assay. *UNIT 9.2* also provides a helpful in-depth conceptual discussion of the issues involved in quantitating cell adhesiveness.

In *UNIT 9.3*, the original discoverer of the important cadherin cell-cell adhesion system provides an overview of cadherins, as well as detailed laboratory protocols for assaying cell-cell adhesion. Both quantitative and qualitative methods for identifying cadherin function are presented. Besides providing complete protocols for assaying cell-cell adhesion of a single cell type in short- and long-term cultures, this unit describes a method for assaying the sorting-out behavior of different types of cells in a mixed-cell aggregation culture. In addition, a variety of approaches for the detection and characterization of cadherin and associated catenin systems are discussed, along with dominant-negative inhibitor approaches to characterizing this centrally important cell-cell adhesion system.

UNIT 9.4 describes current experimental approaches used to analyze integrin functions in mediating adhesive and other interactions of cells with specific substrates. This unit also provides detailed procedures for in vitro analyses of binding interactions between purified integrins and their ligands.

UNIT 9.5 provides a variety of protocols for studying the major group of calcium-independent cell-cell adhesion proteins termed the immunoglobulin superfamily of cell adhesion molecules (IgSF-CAMs). This superfamily contains over 100 adhesion molecules. After describing how to purify IgSF-CAMs from tissues or culture supernatants, this unit describes a number of approaches to characterizing their biological functions in vitro and in living cells. Assays with fluorescent beads provide ways to mimic and to analyze IgSF-CAM adhesive functions in isolation or in interactions with cells. Complementary approaches using various transfection, adhesive-substrate, inter-molecular interaction, and functional disruption analyses provide a powerful collection or tools to understand the roles and mechanisms of this major class of adhesion proteins.

UNIT 9.6 turns to dynamic analyses of cell adhesion. Cell adhesion often consists of sequential steps in dynamic processes that can be difficult to visualize and experimentally analyze in terms of mechanisms using simple cell attachment protocols. For example, leukocytes in the blood stream do not simply settle by gravity onto surfaces such as endothelial cells or exposed matrix in vessel walls, but they instead interact dynamically in the presence of flow and shear stress. In addition, some adhesive events that occur rapidly are difficult to study in static assays but can be analyzed effectively using dynamic flow methods. *UNIT 9.6* describes methods for such analyses using commercially available flow chambers in which cells being carried in suspension attach in the presence of laminar flow. Flow assays can measure cell adhesion either to a monolayer of endothelial cells or to purified extracellular matrix proteins attached to a substrate. The resulting data obtained in the form of video microscopy recordings can then be analyzed using approaches described in the second basic protocol.

Further supplements will provide protocols for analyzing other types of cell adhesion systems.

Cell-Substrate Adhesion Assays

This unit describes two standard assays for quantitating the adhesion of cells to an immobilized substrate. The first is an assay employing phase-contrast microscopy to measure the spreading of adherent cells (see Basic Protocol 1); the second is a colorimetric assay measuring attachment of cells (see Basic Protocol 2). The relative usefulness of spreading versus attachment assays is discussed later in this unit (see Background Information). Both assays employ microtiter plates and are performed in a humidified 5% to 10% (v/v) CO_2 atmosphere at 37°C. These protocols can be used to determine whether there is adhesion between a given cell type and a given adhesion molecule. Additionally, they can be used to test the regulatory effects of exogenous agents on cell-substrate adhesion.

When the adhesive substrate is a peptide, it should be conjugated to an inert protein to improve immobilization. An additional protocol is provided for preparation of such peptide-protein conjugates (see Support Protocol).

CAUTION: Glutaraldehyde and crystal violet are hazardous chemicals; follow appropriate precautions for handling, storage, and disposal.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be performed in a humidified 37°C, 5% to 10% (v/v) CO_2 incubator unless otherwise specified. CO_2 levels should be adjusted to maintain pH 7.4.

SPREADING ASSAY

BASIC PROTOCOL 1

In this protocol, cells are added to a microtiter plate coated with an adhesive molecule and are incubated to allow spreading. After the incubation period, all cells are fixed with glutaraldehyde, and the wells are examined for the percent spread cells using morphological criteria and phase-contrast microscopy.

Materials

Adhesion molecule of interest
Dulbecco's PBS (DPBS; Life Technologies; *APPENDIX 2A*)
10 mg/ml heat-denatured BSA solution (see recipe)
Cells of interest
Dulbecco's modified Eagle medium with 25 mM HEPES (DMEM/HEPES; Life Technologies; *APPENDIX 2B*), prewarmed to 37°C and gassed with 5% to 10% (v/v) CO_2
2× exogenous agent (e.g., antibody, peptides) in DPBS
5% (w/v) glutaraldehyde (dilute 50% stock solution with water)
CMF-DPBS/NaN_3: divalent cation–free Dulbecco's PBS (CMF-DPBS; Life Technologies; *APPENDIX 2A*) containing 0.05% (w/v) sodium azide (NaN_3)

96-well tissue culture microtiter plates (Costar)
Aspirator
Multichannel pipettor
15-ml polypropylene tubes
Glass coverslips

Additional reagents and equipment for counting cells with a hemacytometer (*UNIT 1.1*)

Immobilize substrate

1. Dilute adhesion molecule with DPBS.

   For adhesion to extracellular matrices or purified extracellular matrix molecules (see Chapter 10), 1 to 20 μg/ml is usually adequate. Purified matrix proteins and other molecules can be purchased from a variety of commercial suppliers, including Sigma, Life Technologies, Becton Dickinson Labware, and Calbiochem. If a nonmatrix molecule or a complex mixture is to be tested, a higher concentration should be used (see Critical Parameters and Troubleshooting).

   The handling of adhesion molecules prior to dilution varies; some molecules (e.g., fibronectin) are best thawed quickly at 37°C, while others (e.g., laminin) are best thawed slowly on ice.

   Occasionally, it may be necessary to measure adhesion of cells to peptides rather than proteins. In this case, peptides should be conjugated to inert protein carriers as this permits efficient immobilization (see Support Protocol for details).

2. Add 100 μl diluted adhesion molecule to the appropriate wells of a 96-well, tissue culture microtiter plate. Leave a blank well or wells for measuring background spreading on blocked plastic.

   There is generally no need to carry out spreading assays with replicate wells, as quantification is performed by counting multiple fields from within the same well.

3. Incubate 60 min at room temperature or overnight at 4°C.

   Time-course studies have shown that there is substantial coating of proteins onto plastic within an hour at room temperature, which allows the assay to be performed quickly. However, if the adhesion molecule binds weakly to plastic, or if it is more convenient to carry out the experiment the next day, the wells can be coated overnight, usually without detrimental effects.

Block nonspecific adhesion

4. Aspirate fluid, add 200 μl of 10 mg/ml heat-denatured BSA solution to each well with a multichannel pipettor, and incubate 30 min at room temperature.

   Although simple BSA solutions, or other inert proteins, can be used for blocking plastic, heat-denatured BSA is the most effective agent in the author's hands. Nevertheless, its preparation is not straightforward and the procedure must be followed closely. To ensure blocking of the sides of the wells, 200 μl is used rather than 100 μl.

   The time can be varied at this step; 30 min is probably the minimum time for efficient blocking of plastic, but longer times are not detrimental. Even overnight blocking at 4°C produces good results.

Prepare cells

5. During blocking, prepare a suspension of the cells to be examined (e.g., *UNIT 1.1*) in a 15-ml polypropylene tube.

   Trypsin, EDTA, or trypsin/EDTA solutions are commonly used to detach adherent cells. The action of these reagents must be terminated—e.g., by resuspending the cells in DMEM with 10% (v/v) FBS—prior to using the cells in spreading assays. However, the use of these agents usually has no deleterious effect on adhesive activity provided that the cells are not overtrypsinized. It is important to guard against clumping or aggregation of cells; therefore, gentle conditions should be used when centrifuging and resuspending cells. All solutions used during the preparation of cell suspensions should be warmed to 37°C.

   Freshly isolated cells from tissue can also be used, but results are much more variable.

6. Count cells using a hemacytometer (*UNIT 1.1*), and resuspend the cells at 2×10^5/ml in warm DMEM/HEPES gassed with 5% to 10% (v/v) CO_2. Incubate 10 min at 37°C with the lid off in a CO_2 incubator.

   For most cells, this density prevents cells added to the microtiter plate from interfering with each other during the spreading process. If cells contact each other, substrate-dependent adhesive effects can be altered; on the other hand, if cells are too sparse, quantification becomes difficult.

   Cells are left in a polypropylene tube with the lid off to allow them to recover from the process of detachment. Alternatively, the tube can be capped and left on its side in an incubator to prevent the cells from settling and aggregating into a large clump at the bottom of the tube. However, they should not be left too long (to prevent nonspecific adhesion to the sides of the tube), and they should be pipetted gently prior to use (to ensure dispersion).

   Gassing the cell suspension with CO_2 can sometimes give enhanced spreading, although this is not always needed.

   Molecules that mediate spreading are not always resistant to trypsin treatment. However, this 10-minute recovery period is generally sufficient for reexpression.

Perform adhesion assay

7. Aspirate the BSA solution and wash the wells with 100 µl DPBS.

   The heat-denatured BSA is toxic for some cells.

8. To test spreading of specific cell types on given adhesion molecules, add 50 µl DPBS followed by 50 µl cells to the appropriate wells. To examine the effects of exogenous agents (e.g., antibodies, peptides) on spreading, add 50 µl of 2× exogenous agent followed by 50 µl cells. In this case, also add 50 µl DPBS followed by 50 µl cells to control wells.

   Spreading can sometimes be increased by incubating the plate containing exogenous agents several minutes at 37°C, allowing them to warm up prior to addition of cells.

   To ensure good spacing of cells, guard against swirling, tapping, or shaking the wells once cells have been added. In the author's experience, a single pipetting of cells down the side of the well and into the DPBS solution produces good dispersion.

   A number of adhesion studies have focused on divalent cation–dependence, particularly when integrins are involved. Calcium, magnesium, and manganese ions are the most frequently studied. It is worth noting that manganese ions will precipitate phosphate from PBS. Therefore, in the presence of manganese, HEPES-buffered saline should be used in place of DPBS.

9. Incubate 60 to 90 min at 37°C in a 5% to 10% (v/v) CO_2 incubator with the microtiter plate lid off.

   It is important that the DMEM/DPBS mixture has the opportunity to equilibrate as rapidly as possible with gaseous CO_2 in order to reestablish the buffer (see Critical Parameters and Troubleshooting).

   Ensure that the shelves holding the microtiter plates are level, as uneven shelves lead to uneven settling of cells.

Fix and analyze cells

10. Aspirate medium and fix cells by directly adding 100 µl of 5% (w/v) glutaraldehyde down the side of the well and incubating 30 min at room temperature.

11. Aspirate fixative and store cells in 200 µl CMF-DPBS/NaN_3.

    Fixed assay plates can be stored at 4°C for several weeks protected from evaporation.

12. Add sufficient CMF-DPBS/NaN_3 to form an inverted meniscus at the top of the well and carefully place an appropriately sized glass coverslip over the plate.

Understandably, the optical quality of the plastic that is used to make microtiter plates is not ideal for phase-contrast microscopy. However, adding a coverslip to an overly full well can greatly improve the observation of adherent cells in microtiter plates.

13. Using an inverted phase-contrast microscope, quantify percent spreading in each well by counting three separate, randomly selected fields of 100 cells each. Use an eyepiece graticle to aid the selection of cells and to minimize double counting. Use specific morphological criteria, such as a phase-dark cell body and cytoplasm that is visible around the entire circumference of the nucleus, to identify cells with spread morphology.

Alternatively, image analysis software can be used to measure average cell area (see Critical Parameters and Troubleshooting).

BASIC PROTOCOL 2

ATTACHMENT ASSAY

This protocol measures the attachment of cells to microtiter plates coated with an adhesion molecule. After incubation, nonattached cells are removed and the remaining attached cells are fixed with glutaraldehyde, washed, and stained with crystal violet. The plates are read by a microtiter plate reader, and the percent attached cells is calculated.

Materials

Adhesion molecule of interest
Dulbecco's PBS (DPBS; Life Technologies; *APPENDIX 2A*)
10 mg/ml heat-denatured BSA solution (see recipe)
Cells of interest
Dulbecco's modified Eagle medium with 25 mM HEPES (DMEM/HEPES; Life Technologies; *APPENDIX 2B*), prewarmed to 37°C and gassed with 5% to 10% (v/v) CO_2
2× exogenous agent (e.g., antibody, peptides) in DPBS
5% (w/v) glutaraldehyde (dilute 50% stock solution with water)
0.1% (w/v) crystal violet solution (see recipe)
10% (v/v) acetic acid

96-well tissue culture microtiter plates (Costar)
Aspirator
15-ml polypropylene tubes
Microtiter plate reader

Additional reagents and equipment for counting cells with a hemacytometer (*UNIT 1.1*)

Immobilize substrate

1. Dilute adhesion molecule with DPBS.

For adhesion to extracellular matrices or purified extracellular matrix molecules (see Chapter 10), 1 to 20 μg/ml is usually adequate. Purified matrix proteins and other molecules can be purchased from a variety of commerical suppliers, including Sigma, Life Technologies, Becton Dickinson Labware, and Calbiochem. If a nonmatrix molecule or a complex mixture is to be tested, a higher concentration should be used (see Critical Parameters and Troubleshooting).

The handling of adhesion molecules prior to dilution varies; some molecules (e.g., fibronectin) are best thawed quickly at 37°C, while others (e.g., laminin) are best thawed slowly on ice.

Occasionally, it may be necessary to measure adhesion of cells to peptides rather than proteins. In this case, peptides should be conjugated to inert protein carriers as this permits efficient immobilization (see Support Protocol for details).

2. Add 100 µl diluted adhesion molecule to the appropriate wells of a 96-well, tissue culture microtiter plate using a P200 pipettor. Prepare sufficient wells to perform assays in triplicate or quadruplicate. Leave sufficient blank wells to determine 100% attachment at three cell concentrations and to determine background binding of crystal violet to plastic.

   A standard pipettor should be used rather than a multichannel pipettor, as attachment assays rely much more heavily on the accuracy of pipetting than do spreading assays.

   The blank wells for 100% attachment are not blocked with BSA. The background wells are treated as shams, and therefore are blocked with BSA.

3. Incubate 60 min at room temperature or overnight at 4°C.

   Time-course studies have shown that there is substantial coating of proteins onto plastic within an hour at room temperature, which allows the assay to be performed quickly. However, if the adhesion molecule binds weakly to plastic, or if it is more convenient to carry out the experiment the next day, the wells can be coated overnight, usually without detrimental effects.

Block nonspecific adhesion

4. Aspirate fluid, add 200 µl of 10 mg/ml heat-denatured BSA solution to each sample well, and incubate 30 min at room temperature. Block wells for background crystal violet binding, but not those for 100% attachment.

   Although simple BSA solutions, or other inert proteins, can be used for blocking plastic, heat-denatured BSA is the most effective agent in the author's hands. Nevertheless, its preparation is not straightforward and the procedure must be followed closely. To ensure blocking of the sides of the wells, 200 µl is used rather than 100 µl.

   The time can be varied at this step; 30 min is probably the minimum time for efficient blocking of plastic, but longer times are not detrimental. Even overnight blocking at 4°C produces good results.

Prepare cells

5. During blocking, prepare a suspension of the cells to be examined in a 15-ml polypropylene tube. Prepare a sufficient number of cells to perform assays in triplicate or quadruplicate.

   Trypsin, EDTA, or trypsin/EDTA solutions are commonly used to detach adherent cells. The action of these reagents must be terminated—e.g., by resuspending the cells in DMEM with 10% (v/v) FBS—prior to using the cells in spreading assays. However, the use of these agents usually has no deleterious effect on adhesive activity provided that the cells are not overtrypsinized. It is important to guard against clumping or aggregation of cells; therefore, gentle conditions should be used when centrifuging and resuspending cells. All solutions used during the preparation of cell suspensions should be warmed to 37°C.

   Freshly isolated cells from tissue can also be used, but results are much more variable.

6. Count cell density on a hemacytometer (*UNIT 1.1*), and prepare working cell suspensions at 5×10^5/ml for fibroblasts and similarly sized cells, and at 1×10^7/ml for leukocytic cells in warm DMEM/HEPES gassed with 5% to 10% (v/v) CO_2. Incubate 10 min at 37°C with the lid off in a CO_2 incubator.

   It is advisable to use pipet tips that have their ends cut off for attachment assays. This is to prevent coated proteins and/or cells from being washed off directly by a fine stream of liquid.

These densities prevent cells from interfering with each other during the attachment process. If cells contact each other, substrate-dependent adhesive effects can be altered; on the other hand, if cells are too sparse, quantification becomes difficult.

Cells are left in a polypropylene tube with the lid off in a CO_2 incubator to allow them to recover from the process of detachment. Alternatively, the tube can be capped and left on its side in an incubator to prevent the cells from settling and aggregating into a large clump at the bottom of the tube. However, they should not be left too long (to prevent nonspecific adhesion to the sides of the tube), and they should be pipetted gently prior to use (to ensure dispersion).

It is more important to gas the medium for an attachment assay than it is for the spreading assay, particularly when the level of adhesion is predicted to be low. Gassing the cell suspension with CO_2 can sometimes give enhanced attachment, although this is not always needed.

Perform adhesion assay

7. Aspirate the BSA solution and wash the wells with 100 µl DPBS.

   The heat-denatured BSA is toxic for some cells.

8. To estimate 100% attachment, dilute cells to 20%, 50%, and 100% of the working cell suspension using warm DMEM/HEPES gassed with 5% to 10% (v/v) CO_2. Add 50 µl DPBS followed by 50 µl cells to uncoated wells.

   Cells can also be plated on poly-L-lysine-coated plastic (APPENDIX 2A) to determine 100% attachment.

   Using cell dilutions and extrapolating the resulting graph is the most accurate way of determining 100% attachment, as the absorbance value for 100% attachment with undiluted cells may be off the linear range of the plate reader.

   To ensure good spacing of cells, guard against swirling, tapping, or shaking the wells once cells have been added. In the author's experience, a single pipetting of cells down the side of the well and into the DPBS solution produces good dispersion.

9. To test attachment of specific cell types to given adhesion molecules, add 50 µl DPBS followed by 50 µl cells to the appropriate wells. To examine the effects of exogenous agents (e.g., antibodies, peptides) on attachment, add 50 µl of 2× exogenous agent followed by 50 µl cells. In this case, also add 50 µl DPBS followed by 50 µl cells to control wells.

   Attachment can sometimes be increased by incubating the plate containing exogenous agents several minutes at 37°C, allowing them to warm up prior to addition of cells.

   A number of adhesion studies have focused on divalent cation–dependence, particularly when integrins are involved. Calcium, magnesium, and manganese ions are the most frequently studied. It is worth noting that manganese ions will precipitate phosphate from PBS. Therefore, in the presence of manganese, HEPES-buffered saline should be used in place of DPBS.

10. Incubate 15 to 20 min at 37°C in a 5% to 10% (v/v) CO_2 incubator with the microtiter plate lid off.

    The incubation time for attachment assays may need to be adjusted depending on the cell type, as some cells adhere more quickly than others.

    It is important that the DMEM/DPBS mixture has the opportunity to equilibrate as rapidly as possible with gaseous CO_2 in order to reestablish the buffer (see Critical Parameters and Troubleshooting).

    Ensure that the shelves holding the microtiter plates are level, as uneven shelves lead to uneven settling of cells.

Remove loose cells and fix adherent cells

11. Fix cells only in the wells to be used for determining 100% attachment by adding 100 µl of 5% (w/v) glutaraldehyde.

12. Remove nonadherent and loosely attached cells from remaining wells by either tapping the plate or gently washing the wells 1 to 3 times with 100 µl DPBS and cut-off pipet tips.

    This is the most critical stage in an attachment assay, and needs to be optimized for each cell type used (see Critical Parameters and Troubleshooting).

13. Aspirate the final wash and fix attached cells by adding 100 µl of 5% (w/v) glutaraldehyde and incubating 20 min at room temperature (or at 4°C overnight, if necessary).

14. Wash wells three times with 100 µl water.

Stain and analyze adherent cells

15. Add 100 µl of 0.1% (w/v) crystal violet solution to each well and incubate 60 min at room temperature.

    Avoid getting crystal violet solution on the rims of the wells, as this dries during incubation and can be difficult to remove by washing.

    Staining can also be performed overnight without detriment to the final results.

16. Wash wells three times with 400 µl water.

    A larger wash volume is used to remove all traces of stain.

17. Solubilize dye in 100 µl of 10% (v/v) acetic acid and incubate 5 min on an orbital shaker at 150 rpm, room temperature.

18. Measure absorbance at 570 nm using a microtiter plate reader. Subtract background crystal violet staining from all experimental and 100% attachment results. Plot data from 20%, 50%, and 100% inocula (A_{570} versus cell density) and determine the value for 100% attachment by extrapolation. Use this value to express experimental data as percent attachment.

PREPARATION OF PEPTIDE-PROTEIN CONJUGATES

SUPPORT PROTOCOL

The discovery that many large adhesion proteins contain short peptide sequences that are recognized by cellular receptors has enabled these receptor sites to be probed with the use of synthetic peptide reagents. By definition, these peptides are small and usually bind poorly to plastic. In addition, immobilization of peptides may reduce their cellular adhesivity by masking key residues that endow adhesive activity. For these reasons, it is necessary to use an alternative method to simple coating from a peptide solution. The author prefers to prepare covalent conjugates of peptides to protein carriers that are inert in terms of adhesive activity. Many different cross-linkers and carriers are available for such syntheses, but consistent success can be obtained with *N*-succinimidyl 3-(2-pyridyl-dithio)propionate (SPDP), a heterobifunctional cysteine-lysine cross-linker, and rabbit IgG as carrier. *m*-Maleimidobenzoyl-*N*-hydroxysuccinimide (MBS) also works well as a cross-linker, and BSA and keyhole limpet hemocyanin are good carriers. A detailed description of the use of these agents can be found in Humphries et al. (1994). The first step in the conjugation reaction is the conjugation of the cross-linker to the carrier. The second step is the conjugation of the cross-linker/carrier to the peptide, which requires disulfide bond formation between the cross-linker and peptide, and is slow. Thus, peptides are usually designed with a terminal cysteine residue.

Materials

6 mg/ml normal rabbit IgG (Sigma) in CMF-DPBS
3 mg/ml *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP; Pierce) in ethanol
Divalent cation–free Dulbecco's PBS (CMF-DPBS; Life Technologies; *APPENDIX 2A*)
Cysteine-containing peptide, solid
Dulbecco's PBS (DPBS; Life Technologies; *APPENDIX 2A*)
10-ml Sephadex G25 columns (PD-10, Amersham Pharmacia Biotech)

Additional reagents and equipment for dialysis (*APPENDIX 3*)

1. Pipet 1 ml of 6 mg/ml normal rabbit IgG into a microcentrifuge tube. Add 0.2 ml of 3 mg/ml SPDP by rapid injection and mix thoroughly. Incubate 30 min at room temperature on a rotator.

   SPDP is not very soluble in aqueous solution. It should be added to and mixed with IgG rapidly to avoid precipitation.

2. Equilibrate a 10-ml Sephadex G25 column with 10 to 20 vol CMF-DPBS.
3. Add the rabbit IgG/SPDP mixture to the column followed by CMF-DPBS. Discard the first 2.5 ml eluate and collect the next 3.5 ml (containing cross-linker-derivitized IgG) in a single tube.
4. Aliquot the collected fraction as necessary (depending on the number of conjugates to be made) and add to 1 to 2 mg solid cysteine-containing peptide. Vortex briefly and incubate overnight at room temperature on a rotator.

   Radiolabeled peptide can be used to quantify coupling if necessary, although, in the author's experience, coupling is quite consistent from peptide to peptide.

5. Dialyze the mixture (*APPENDIX 3*) against several changes of DPBS (with divalent cations) to remove uncoupled peptide. Dialyze using standard dialysis tubing in ≥1000-fold DPBS at 4°C with gentle stirring. Dialyze >3 hr for each change of DPBS.
6. Divide into 100-µl aliquots and store indefinitely at −80°C.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Crystal violet solution, 0.1%

Dissolve 0.1% (w/v) crystal violet in 200 mM 2-(*N*-morpholino)ethanesulfonic acid (MES), pH 6. Filter through a 0.22-µm filter. Store at room temperature.

CAUTION: *Crystal violet is hazardous; handle with caution and dispose of properly.*

It is imperative to filter this crystal violet solution. It can be difficult to determine whether it has dissolved properly due its intense color. If the solution is not filtered, specks of solid crystal violet can sometimes be added to the experimental wells, resulting in spuriously high absorbance readings.

Heat-denatured BSA solution, 10 mg/ml

Dissolve BSA at 10 mg/ml in divalent cation–free Dulbecco's PBS (CMF-DPBS; Life Technologies; *APPENDIX 2A*) in a 15-ml polystyrene tube. Filter through a 0.22-µm filter to remove undissolved protein, and incubate 10 to 12 min in an 85°C water bath. Cool to room temperature and use the same day.

The major aim is to prepare a solution that contains microparticulate BSA, as this will coat plastic very efficiently. The solution should go slightly hazy. A clear solution indicates insufficiently aggregated BSA, while a white solution indicates that aggregates are too large. After cooling, the solution is ready for use.

COMMENTARY

Background Information

As the name suggests, adhesion assays measure cell adhesion. However, because adhesion is a complex process involving receptor-ligand binding, modulation of intracellular signaling, and cytoskeletal modulation, these assays can also be a source of information about other cellular events and a means of probing the contribution of these processes to adhesion. In general, adhesion assays are used to test whether a certain cell type can adhere to a certain adhesive substrate, and to test the sensitivity of a particular cell-substrate interaction to inhibitors. This unit describes two standard assays for quantifying the adhesion of cells to an immobilized substrate. The spreading assay is based on an original publication by Yamada and Kennedy (1984), and the attachment assay is based on Kueng et al. (1989). As presented here, the attachment assay employs colorimetric detection of bound cells. However, this is actually one of many different readouts that can be applied to the basic assay. Common alternatives include the use of radiolabeled or fluorescently labeled cells (Dustin and Springer, 1989; Chan et al., 1992), or the measurement of endogenous gene activity (e.g., phosphatase; Prater et al., 1991). In general these are more time-consuming to perform.

A number of considerations will affect the decision whether to use a cell spreading assay or a cell attachment assay. Spreading assays take longer to perform, but are less prone to nonspecificity. For example, many molecules can mediate attachment of cells that is not physiologically relevant, but very few of these molecules can mediate morphological spreading. Importantly, by observing cells in a spreading assay, a lot of information can be gained about the biological response of the cells to the substrate. The morphology of cells can differ even if the percent spreading is the same. Additionally, now that signaling mechanisms that control cell morphology are better understood, spreading assays can give indirect indications of the intracellular events that are triggered by certain substrates. Spreading assays are more sensitive when used to measure the inhibitory activity of an exogenous agent, because the readout from the assay is more reliant on multiple adhesive interactions, and partial disruption by an inhibitor is sufficient to see a biological effect. A greater degree of receptor blockade is probably needed to observe an inhibitory effect in an attachment assay. Finally, as spreading assays do not need replicate wells, it is easier to construct detailed dose-response curves.

Nonetheless, use of attachment assays is sometimes obligatory, because not all cells are able to spread and because some cells only spread on certain substrates. It is misleading to think that attachment assays measure single adhesive contacts: multiple contacts are needed for a cell to withstand the washing steps in an attachment assay. Nevertheless, fewer contacts are needed for attachment than for a cell to spread.

Critical Parameters and Troubleshooting

General considerations for adhesion

The major problem likely to be encountered in both assays is that cells fail to adhere. Many factors can lead to this, including coating plates with insufficient amounts of adhesive substrate, using bad batches of adhesive substrate, using poor protein-binding microtiter plates or badly constructed plates with uneven wells, squirting liquids too vigorously onto the bottom of the wells, using cultures that are growing poorly or have a mycoplasma infection, having variations in pH during adhesion, and (for attachment assays) overwashing. Several of these factors are discussed in further detail below.

Substrate concentration. The concentration of adhesion molecule required for coating depends on a number of factors, including the size of the molecule, the efficiency with which it coats plastic, and the apparent affinity with which it is bound by cellular receptors. In most cases, spreading assays are used to measure the adhesion of cells to extracellular matrices or purified extracellular matrix molecules (also see Chapter 10). The key components of such matrices are usually large macromolecules that coat plastic relatively well; they are also bound with at least moderate affinity by cells. For these reasons, a concentration range between 1 and 20 μg/ml is usually adequate, although it is advisable to carry out a range-finding dose-response experiment before focusing on a narrow range. If a nonmatrix molecule or a complex mixture is to be tested, a higher concentration should be used.

Plates. Most tissue culture microtiter plates are adequate for spreading and attachment experiments, although the author finds Costar to be excellent. Immulon 4HB plates from Dynex

Technologies (formerly Dynatech Labs) have higher protein-binding capacity and are particularly good for assays involving small proteins.

Cultures. For cell spreading assays, an important parameter is the health of the cells. Cultures should be actively growing, but should have been passaged >24 hr previously. Relatively poor spreading responses have been observed in cells that were passaged the day before a spreading assay.

pH. When cells and DPBS (with or without exogenous agents) are combined in the coated well, it is important that the DMEM/DPBS mixture has the opportunity to equilibrate as rapidly as possible with gaseous CO_2 in order to reestablish the buffer. This process can be aided by leaving the lid off the microtiter plate in the incubator. It is also the author's experience that the adhesion of some cell types is improved by raising the concentration of gaseous CO_2 from 5% to 10% (v/v). This can be particularly effective at increasing binding to poorly adhesive substrates. It may also be advisable to use a particular incubator and/or time of day when the door to the incubator will not be opened, as this helps prevent alkalinization of the medium.

Washing. For attachment assays, the key parameter is the washing protocol, as this is the major determinant of the signal-to-noise ratio. When washing unattached cells (see Basic Protocol 2, step 12), different cells respond differently to tapping and washing, and it is recommended to vary the number of tapping or washing cycles to obtain the best signal-to-noise ratio (i.e., attachment to an adhesive substrate compared to attachment to BSA-blocked plastic). Sometimes this can even be judged by eye in a pilot experiment. Cut-off pipet tips are particularly important at this stage to avoid removal of attached cells.

More specific problems include cell death in the assay (which can be caused by exposure of sensitive cells to heat-denatured BSA) and clumping of cells either in the center of a well or around the perimeter (which is caused by swirling the plate). In addition, large errors in attachment assays can result from inaccurate pipetting, which can come from use of multichannel pipettors, or suboptimal washing of wells (note that the volume of BSA blocking solution is higher than the volume of adhesive substrate, and that the wash step after crystal violet staining is larger still).

Assessing cell spreading

Different methods can be used to determine whether a cell is spread or not. Perhaps the most quantitatively accurate method is to use image analysis software to measure average cell area; however, this tends to produce small differences that may be hard to interpret without the application of other criteria relating to cell shape. Instead, the author prefers to assign specific criteria to a definition of spreading and apply these to each cell individually. The usual criteria are that the cell body should be phase-dark and that cytoplasm should be visible around the entire circumference of the nucleus. Different cells adopt different morphologies and therefore these criteria might need to be slightly modified on a case-by-case basis.

Anticipated Results

Both the spreading and attachment assays measure percent adhesion, and the level of adhesion obtained depends upon the cell type and adhesive substrate under study. In spreading assays, a level of 80% should be anticipated, and often higher levels can be obtained. It is critical that the background level of spreading on BSA-coated plastic be as low as possible. Frequently, this is actually zero, but certainly this should not rise above 2% to 3%. The level of attachment observed by the crystal violet staining method is usually not as high as for spreading, but 60% to 70% should be attainable. The background level of attachment (i.e., on BSA-coated plastic) should also be as low as possible; however, for attachment assays, this level is usually higher (5% to 10%).

Time Considerations

Both spreading and attachment are relatively quick to perform. Coating and blocking the wells requires <2 hr. The actual assays can be carried out easily in half a day, and the subsequent quantification of spreading assays can take a similar length of time. Quantification of attachment assays is much quicker (i.e., <2 hr).

Quantitative Measurement of Cell Adhesion Using Centrifugal Force

The following protocol was developed in order to study the biophysical sequence of events in cell-substrate adhesion, and it can also be adapted to study cell-cell adhesion. The method allows quantification of the weak association between cells and their substratum at 4°C, thereby giving a measure of the receptor-ligand affinity only. The approach also allows measurement of the ATP-dependent events that strengthen adhesion and that involve the cytoskeleton following initial binding. This is done by incubating cells in contact with substrate at 37°C for increasing periods of time. Centrifugal force is the only shear force involved in the assay; thus the strength of any adhesion that resists this applied force can be accurately measured. The original centrifugal adhesion assay developed by McClay et al. (1981) used radioactively labeled cells in a rather cumbersome procedure to quantify adhesion. The protocol given here is much easier than any previously published version. At the same time, the assay remains highly quantitative and has simple innovations that can accommodate many kinds of adhesion studies.

The procedure is as follows: 96-well polyvinyl chloride (PVC) plates with flat bottoms are coated with the substrate target for the cells. The wells are then treated with BSA or another nonadherent protein that blocks nonspecific binding sites. Cells are added to the PVC plates on ice, the wells are filled to the brim, and then sealed with clear packing tape. The idea is to enclose each well as a sealed, fluid-filled compartment without any air bubbles. The cells are then gently centrifuged into contact with the substrate. To measure cell-substrate affinity alone, the wells are kept at 4°C, flipped upside down, and centrifuged to provide a defined dislodgement force for the cells (Fig. 9.2.1). Using replicates challenged with different centrifugal forces one can determine the relative avidity of cells for a substrate. If cells are incubated at 37°C after being centrifuged onto the substrate, one can follow the progress of adhesive strengthening due to cytoskeletal engagement. This process generally occurs rapidly, and progress can be monitored by this assay.

There are many ways to quantify cells adhering to the substrate. Currently, the simplest is to image the well bottom and count cells bound relative to controls and to the total

number of cells originally added. Other approaches can easily be adapted; however, this method provides a simple visual measure of adhesion that is quite easy to learn, is easily adapted by any laboratory at low cost, and allows for a number of variations to be applied, including morphometrics (see Background Information).

BASIC PROTOCOL

CENTRIFUGATION CELL ADHESION ASSAY

Materials

96-well flat-bottom polyvinyl chloride (PVC) plates (Falcon)
Substrate molecule of interest in PBS
40 mg/ml BSA (fraction V; Sigma) in PBS
PBS (*APPENDIX 2A*)
Tissue culture medium without FBS
Dissociated cells of interest, suspended at $5–10 \times 10^5$/ml in calcium-free physiological solution (see Critical Parameters, discussion of suitable media)
Clear packing tape (3M Scotch 375, 4.8 cm wide, although any clear packing tape will probably work)
Microtiter plate support template
Low-speed refrigerated cell centrifuge with microtiter plate carrier

1. Cut away the sides of a 96-well flat-bottom PVC plate with scissors, and then cut the plate into a 3 × 8–well rectangle.

   Only the six wells in the middle are used. Since the assay involves filling the wells over the brim to eliminate air bubbles, some of the medium will spill into the surrounding empty wells. Plates can be cut into other configurations depending upon the centrifuge carrier, the microscope, or other variables that are particular to the lab.

2. Add 50 µl substrate per well, leaving blank wells for 100% attachment (no substrate or blocking) and for background binding (no substrate). Use at least three replicates for each parameter tested. Incubate ~30 min at room temperature.

   Polyvinyl chloride has a natural avidity for many proteins.

   As a control, determine how much of the substrate protein is attached to the plate. In the first set of experiments with a substrate protein or peptide, determine the threshold concentration for binding (relative to the BSA control wells and at a low g force), and then operate just above that threshold in subsequent experiments (see Critical Parameters).

3. Wash three times with 100 µl PBS. Then block substrate-coated and background binding wells (but not 100% attachment control wells) ~30 min with 50 µl of 40 mg/ml BSA at room temperature. Wash three times with 100 µl PBS, flicking the contents of the wells into the sink to eliminate the fluid after each wash.

   It is important that the background control well does not bind cells. BSA treatment should block all spaces not covered by the substrate molecule. Typically 100% of cells bind to the untreated wells, and <1% bind to the background wells. Although this varies according to the cell type used and the dislodgement force applied, in most cases the conditions can be adjusted so that <1% of cells bind to the BSA-blocked wells. This leaves the test substrate with a wide range in which to examine adhesion avidity.

   If desired, poly-L-lysine can be added to the 100% attachment control well (no substrate, no blocking) to bind cells even more tightly.

4. Place the plate on ice. Add 100 µl tissue culture medium to all wells, add 100 µl cell suspension ($5–10 \times 10^4$ cells), and then fill all wells with another 100 µl tissue culture medium.

   Fewer cells can be added, especially if fluorescent cells are used for later quantification. For fluorescent cells, good results can be obtained with as few as 1000 cells per well. Also,

it is possible to employ two different fluorescent colors and unstained cells in the same well, so that two experimental cell types can be compared to a control cell population under exactly the same conditions.

Medium and cells should be added on ice to prevent cells from attaching and adhering prematurely. There should be a positive meniscus bulging above the top of the well, as excess fluid is necessary to seal the well without any air bubbles.

5. Gently lay a piece of clear packing tape over the wells, and place the plate on a microtiter plate support. Apply the tape, starting from one end and squeegeeing the excess medium to spill over into the empty wells next to the test wells. Press down on the tape to make sure it adheres to the PVC surrounding each well.

   The microtiter plate support is a rubber or metal template that holds the PVC plate while it is being sealed. A firm backing is necessary to support the pressure applied when sealing the tape. A metal plate can be made by a machine shop. Its thermal conductance keeps the wells cold during the manipulation and sealing procedures. If metal supports are unavailable, a 96-well plate can be used as a mold to make a plastic support device.

   With a little practice, this maneuver can be done without introducing any bubbles into the sealed wells. If sealing is done correctly, each well should now be a completely filled, enclosed chamber, and should survive centrifugal forces up to ~500 × g without leaking. Some cells will be lost in the process of sealing, but that will not add an error factor to the analysis because of the way cells are counted against controls in the assay.

6. Centrifuge cells into contact with the substrate for ~3 min at 35 × *g*, 4°C, in a low-speed refrigerated centrifuge with a microtiter plate carrier.

   Some larger cells can be allowed to settle onto the substrate at 1 × g. If cells are centrifuged onto the substrate, ~3 min of centrifugation will place 100% of the cells into contact with the substrate.

   If this is done at 4°C, receptor-ligand combinations are brought into contact. As long as the plate is left at 4°C, this receptor-ligand affinity can be measured independent of cytoskeletal contributions.

   One can substitute a big centrifuge bucket as a swinging bucket carrier if a microtiter plate carrier is not available.

7. *Optional:* To measure strengthening events in adhesion, simply move the plate, with cells in contact with the substrate, to a 37°C water bath and float the plate for the desired period of time.

   For many cell types, incubations <5 min are sufficient to convert the weak receptor-ligand binding into a highly strengthened adhesion that is strongly resistant to centrifugal shear forces.

8. Invert the plate and centrifuge the cells in the inverted position using a microtiter plate carrier, 5 min at the desired speed. Return the plate to ice, keeping it in the inverted position.

   This should dislodge cells if enough centrifugation force is applied and if the cells are not strongly adhering. Obviously there are a number of parameters that can be controlled in this step: e.g., duration of contact at 37°C, rate of dislodgement, force of centrifugation, and rate of strengthening.

9. Place the wells on the stage of a compound microscope, and count cells using a 10× objective. Subtract background binding from substrate binding, and determine the percent binding compared to the 100% attachment control.

   Imaging software can be used to capture frames and automatically count the cells in each frame. To increase accuracy, set up the microscope so it will image a well prior to centrifugation, then return to the same field after centrifugation to assess adhesion.

COMMENTARY

Background Information

Early cell adhesion assays used cell aggregation as a semiquantitative measure. These assays were useful for studying some adhesive phenomena, but suffered from an inability to quantify the sequence of adhesion. Attempts to quantify adhesion have used viscometers, cell particle counters, spectrophotometers, radioactivity, and other approaches. In most cases, adhesion assays were limited in that they required cells to associate rather tightly with one another in order to survive unknown, or poorly defined, shear forces intrinsic to the assay.

This centrifuge assay was designed to use a single shear force of defined magnitude. The force operating on a cell can be easily calculated, providing an impression of the strength of an adhesion. This approach, though quantitative, is still not perfect. For example, one would really like to measure the "on rate" as an adhesion is formed, but this is an exceedingly difficult parameter to measure. Also, the assay described here measures the proportion of adherent cells within a population, rather than the behavior of individual cells. Single cell assays may offer advantages not offered by the assay given here.

The present assay is based on previously published versions (McClay et al., 1981; Lotz et al., 1989; Burdsal et al., 1991, 1994) in which centrifugal force is used as a dislodgement force (F_D) for the cells. This assay is highly modified and simplified compared to the original assays, but enjoys a better and more versatile capacity for quantification.

The following relationship is important for understanding where force fits into the adhesion process. As measured in the centrifugal adhesion assay, $F_D = (\rho_{cell} - \rho_{medium}) \times V_{cell} \times$ RCF, where F_D is the dislodgement force (dynes/cell) tending to pull the cell from the substrate, $(\rho_{cell} - \rho_{medium})$ is the specific density difference between the cell and the medium (usually 1.07 g/cm^3), V_{cell} is the volume of the cell, and RCF is the relative centrifugal force (McClay et al., 1981). Because of the small difference in specific density between the fluid and the cell, cells in culture are little affected by alterations at $1 \times g$, since in reality these cells are already experiencing microgravity.

The assay as presented above allows for very precise comparisons between cells that are only slightly different from one another. For example, if one cell population is transfected with a construct and the other population is a non-transfected control, the two can be tested in the same well (with one of the populations fluorescently tagged) to accurately compare adhesive performance.

Most other cell-substrate assays have a certain unknown shear force that can confound quantification, especially when one wants simply to measure receptor-ligand interactions. The simple "stick-and-wash" assay, in which one allows cells to bind to the substrate for a period of time and then washes the wells, may be simpler to use than the assay presented above, but suffers from several problems. It has an undefined shear force (washing) that is difficult to control accurately. Stick-and-wash assays also cannot measure the initial receptor-ligand interactions, because cells must adhere at least somewhat tightly to the substrate in order to survive washing. Thus, the adhesion measured in a stick-and-wash assay is actually both adhesion and engagement of the cytoskeleton. Often such assays are completed hours after cells were added to wells, so that any number of postadhesion events could occur before measuring "adhesion." In contrast, the present assay allows measurement of the progression of several adhesion events separately, and therefore has the capacity to examine several parameters in the sequence of forming an adhesion. It should be mentioned that for more than two decades the simpler "stick-and-wash" assay was successfully employed by a number of laboratories to find and characterize most of the known adhesion molecules. The present assay is useful for detailed structure-function analyses of those molecules.

An additional parameter that can be measured with the centrifugal adhesion assay is the relationship between adhesiveness and cell phenotype. Since the cells are counted by microscopy, one can also score cell phenotypic properties (e.g., spreading or motility). This adds to the versatility of the assay. The assay can be used, with minimal adaptation, for a wide variety of cell types, including cells from several phyla, tumor cells, and cells of all stages of embryonic development.

Initial binding

In practice there are many events in the establishment of an initial adhesion. There is an on rate by which the first receptor-ligand interactions occur. Then there is a rate of recruitment of additional cellular adhesion molecules to the site of adhesion. This parameter has

been measured, and is related to the rate of diffusion of the protein in the phospholipid bilayer. As long as no additional molecules are added to the bilayer, the total recruitment of receptor-ligand combinations is limited to the total population in the membrane at the time of the assay. Finally, since the interaction is not covalent, there is an off rate. Most cell types bind to substrates with a force that resists 10^{-6} to 10^{-5} dynes/cell of applied centrifugal dislodgement force. In reality, cells come off the substrate when the off rate (increased by centrifugal force) exceeds the on rate. Red blood cells fail to adhere to most substrates at around 10^{-8} dynes/cell. Some cells, such as macrophages, naturally adhere with a receptor-ligand avidity that is slightly higher than the 10^{-5} dynes/cell level. When measuring initial binding one must measure the adhesion at very low substrate concentrations. Once the well becomes supersaturated with multiple layers of substrate, the initial binding loses specificity for the receptor-ligand combination under investigation. This presumably results from nonspecific effects of charge and substrate heterogeneity.

Cytoskeletal contribution to strengthening

After obtaining a measurement of initial binding (receptor-ligand affinity), a measurement can be made of the strengthening of that adhesive process. This cellular process is remarkably fast. Using this assay, most strengthening is completed within 5 min at 37°C. The degree of strengthening is usually more than 2 orders of magnitude, and may be as much as 5 to 6 orders of magnitude.

The limitations of this assay come into play during the strengthening process. Although we recommend a range of 1 to $500 \times g$ for the assay, the centrifuge plate carriers have a maximum safe speed that cannot be exceeded. Using large buckets as plate carriers can increase the centrifugation speed to ~4000 rpm. This means that the assay can be extended to forces between 1 and $\sim 2500 \times g$ in most centrifuges. In measurements using the ultracentrifuge to achieve very high forces, it was found that adherent fibroblast cells are not released by $15{,}000 \times g$, and only 30% are released at $\sim 59{,}000 \times g$ (Rich, 1978). Thus, for practical measurements of strengthening, one can quantify the early events to monitor the rate of strengthening, and one can study cells with modified cytoskeletons to experimentally address this mechanism.

Again it should be noted that the "stick-and-wash" assays that are employed in many laboratories simply measure strengthened adhesion. In contrast, this is an accurate assay as long as the rate-limiting step in the adhesion sequence is the adhesive step of interest. The stick-and-wash assays can be misleading in such tests. For example, consider a laboratory with an interest in cytoskeleton contributions. Hopefully, if the stick-and-wash assay is used with cytoskeletally impaired cells, the data will indicate that no adhesion has occurred. This must assume that the initial binding occurs as normal, but that the cells then fail to strengthen due to the missing critical cytoskeletal component. However, if the initial cell-substrate binding step fails to occur properly, the investigator might be misled into thinking the cytoskeleton is at fault. With the centrifugal assay, it is possible both to separate initial adhesion from strengthening, and to determine the extent of strengthening. This application has been very useful in a variety of circumstances involving embryonic cells of different stages, or transfected cells with different adhesion deficiencies.

Biophysical analogy of initial binding versus strengthened adhesion

There are many biophysical models of adhesion that attempt to explain how the cytoskeleton works to accomplish an increase in adhesive strength by orders of magnitude. Based largely on the knowledge that cells are malleable, and knowing that cells adhere by noncovalent receptor-ligand interactions, Dembo and Bell (1987) showed that initial binding was relatively weak and was similar for most adhesion molecules. Strengthened adhesion, on the other hand is highly resistant to shear forces. In the Dembo and Bell model, cells adhering by receptor-ligand interactions alone simply peel away from the substrate breaking bond by bond. When adhesion is strengthened by recruitment of the cytoskeleton into the adhesion complex, there is a rapid and very large increase in adhesive strength. As a simple analogy of the initial binding versus strengthened adhesion, consider a piece of double-stick Scotch tape. The following test is a simple means of demonstrating this principle.

Stick a piece of double-stick Scotch tape onto a desk. The Mylar backing of the tape is malleable so that the force needed to initially start peeling one end of the tape away from the substrate will be fairly small, and will remain fairly constant until the entire strip of tape is peeled away from the substrate. This is because the peeling force is the force necessary to break

the adhesive bonds only at the immediate point of contact as the tape is progressively peeled away (Fig. 9.2.2A). The rate of peeling depends upon the applied force, the number of bonds, the strength of an individual bond, and the on and off rates of the bonds. As the peeling force is increased, a point is reached when the off rate exceeds the on rate causing the adhesion to fail at that peeled interface. In the centrifugal assay, the centrifugal force just below the threshold point of cell removal is a measure of the initial binding affinity of the cell.

To demonstrate how adhesive strengthening appears to work, place a microscope slide on top of the same piece of double-stick tape on the desk. The tape is the same, the adherence to the substrate is the same, but now instead of a malleable backing the glass provides a very stiff backing for the tape. An exposed end of the tape peels away rather easily until the edge of the slide is encountered. Then a force that is orders of magnitude larger must be used to remove the tape from the substrate. The massive additional force needed to lift the tape from the substrate is a consequence of the hard backing provided by the glass slide. Because of that rigid backing, the entire piece of tape must be removed all at once. Thus, the entire adhesive surface of the tape under the glass slide simultaneously resists the removal force (Fig. 9.2.2B).

By analogy, this rigidity is a biophysical property provided by the cytoskeleton that enables the adhesion to be strengthened. By cooperatively linking multiple adhesive molecules into more of a unit, a vast increase in apparent adhesive strength can be accomplished without an increase in number of adhesion molecules. Mechanically, the cytoskeleton causes a local stiffening of the adhesion complex so that many more adhesion molecules are acting together to cooperatively strengthen the adhesion.

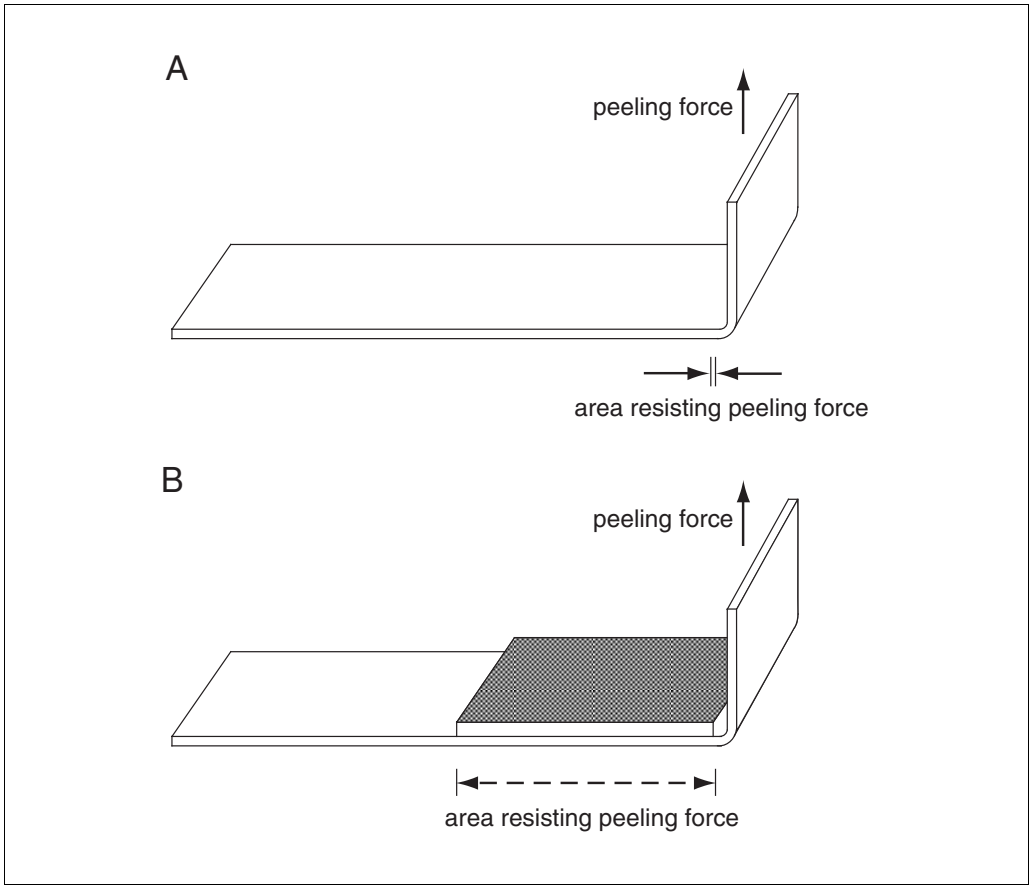

Figure 9.2.2 Tape analogy of two states of cell adhesion. (**A**) Double-stick tape applied to a surface is analogous to the adhesive behavior of cells that have only receptor-ligand association with the substrate. The adhesive area that resists the peeling force is small, limited to the area between the two arrows. (**B**) Adding a glass slide to the upper surface of the tape creates a situation analogous to the adhesive behavior of cells with cytoskeleton-supported cooperativity of cell-substrate association. The stiffened area of tape (membrane) increases the adhesive area that resists the peeling force.

Obviously, the cortex of the cell is not as rigid as the glass backing. Nevertheless, any coupling of the cytoskeleton to the group of adhesion molecules that allows these molecules to act as a unit rather than as freely diffusing molecules, provides an important cooperativity for strengthening. Conveniently, this allows the cell to control its own adhesiveness by controlling intracellular microcompartments (areas where adhesive molecules can couple with cytoskeleton and other areas where the cytoskeletal connections are released). An ability to measure many components of these dynamic associations is necessary to understand how adhesion molecules and cytoskeleton components work together to provide cells with a range of adhesive properties. The centrifugal adhesion assay can help with such analyses.

Critical Parameters

Concentration of substrate

As a rule, the substrate should be applied as a molecular monolayer on the plate. In the first set of experiments with a substrate protein or peptide, determine the threshold concentration for binding, and then operate just above that threshold in subsequent experiments. If one calculates the total surface area occupied by one substrate molecule, and calculates the total surface area of the well bottom, it is a simple calculation to figure out how much substrate would form a molecular monolayer. For example, ~1 μg of fibronectin per well is about the right amount. Some overlapping is assumed, since the protein is filamentous, but the point is that it takes very little protein to completely coat the plate. At a concentration of 10 μg/well, the assay loses specificity, presumably because many nonspecific factors can now contribute to the adhesion. Also, if the protein is layered on the plate, the effects of fibronectin peeling away from fibronectin may confound the assay.

Timing of adhesive strengthening

Significant strengthening is seen after even 1 min of incubation at 37°C. By 5 min at 37°C, the strengthening of most cells exceeds the ability of the cell centrifuge to provide enough force to dislodge them, because most bucket carriers or 96-well plates have a maximum RCF at which they can be centrifuged (usually on the order of 2500 × *g*). Note that this level of strengthening occurs well before any significant change can be seen in the cells, and before they establish visible focal contacts.

Increments in centrifugal force

For initial binding, cells can be centrifuged onto the substrate at ~35 × *g*. For dislodgement of cells kept at 4°C, the force can vary from 1 to ~2500 × *g*. Most cells will maintain adhesion to between 50 and 200 × *g*, but will be removed by higher *g* forces. For strengthened adhesions, a good guideline is to use a dislodgement force that is twice that necessary to remove the initially bound cells, and then ask how long it takes for the cells to strengthen at 37°C enough to remain adherent at that force. Usually that time is <2 min.

Suitable media

The selection of medium depends on the cell type used, and several kinds of media are used for each assay. Cells should be dissociated using established protocols and media for each cell type. The cells are then maintained in a calcium-free buffer for counting and handling during the short time prior to adding them to the wells (see discussion of cations below). Finally, tissue culture medium without any fetal bovine serum (or equivalent) should be used as the cell adhesion test medium. If necessary, fetal bovine serum can be included, provided that proper controls are done for the contribution of cell adhesive substrates in the serum.

Phosphate buffered saline (PBS) containing 40 mg/ml BSA is used as a blocking solution for all wells pretreated with the substrate in question, as well as for background binding wells. In the authors' experience, the BSA eliminates almost all background binding to the well bottom. PBS without BSA serves as the washing reagent and as the buffer into which the substrates are diluted when initially coating the wells.

Role of cations

Many cell-cell interactions require calcium for some aspect of association. The actual function of calcium in these interactions has a rich literature. For the present case, keeping cells in calcium-free solutions is a useful way to control the experiment and to prevent adhesion from occuring prematurely. Thus, cells are added in calcium-free saline to the medium in the wells. There is enough calcium in most tissue culture media to allow this dilution of calcium in the well. Note that the calcium-free medium does not contain EGTA or any other calcium chelator. If the dissociation protocol uses calcium chelators, resuspend the cells in calcium-free medium without the EGTA after they are dissociated.

Recovery period after dissociation

If cells are enzymatically dissociated, they will need a recovery period to regenerate surface adhesion molecules prior to using the centrifugation assay. It is preferable to use nonenzymatic methods for dissociation so that cells are ready to use without recovery. If a recovery period is necessary, cells can be resuspended in complete culture medium with serum, and incubated in flasks at a rotation speed >70 rpm. This provides a chronic fluid shear force that prevents cells from adhering, yet allows them to recover from enzymatic treatments. The length of recovery varies according to cell type, but 4 hr at 37°C is a good first approximation. The cells should then be washed into calcium-free, serum-free medium for the assay.

Fluorescent molecules for labeling

Many fluorescent tags are available, though some work better than others. Rhodamine isothiocyanate (RITC) is the authors' first choice simply because it works on all cells and is slow to fade. The method of labeling is simple. Take ~1 mg of RITC (a bit on the end of a spatula) and add it to 50 µl dimethylsulfoxide (DMSO). Add the RITC/DMSO to calcium-free medium (without phenol red as a pH indicator) until the color of the medium barely turns pink. If the medium turns red, too much RITC has been added and the medium is toxic. Allow the cells to accumulate the RITC from the slightly pink medium, and they will be healthy. Usually 30 min or less is all that is necessary for labeling.

Several markers can be used as a second label. Fluorescein isothiocyante (FITC) tends to be a bit difficult, as batches of FITC lose activity quickly. The fluorescein quenches easily as well. The easiest to use is Hoechst dye (33342 or 33258), which is easily loaded into cells, stains nuclei brightly, and is retained well. To label the cells, dissolve a small amount of Hoechst (or DAPI) dye in aqueous medium, add it to the cells at ~1:200, and incubate 30 min. Other dyes such as calcein AM or acridine orange can also be used to label other populations of cells. These dyes are easily loaded, and have good retention (i.e., do not bleed into unlabeled cells). To label cells, add 10 µl of a freshly prepared dye solution (up to 1 mg in 50 µl DMSO) to 100 ml cells in aqueous medium. Incubate 30 min, wash, and check labeling. Adjust as necessary, as labeling varies with cell type. High dye concentrations should be avoided because they may be toxic, and because most dyes are cumulative (i.e., they will gradually be accumulated from a weak solution).

Troubleshooting

There are three potential pitfalls to be avoided in the assay. All three can be managed with relative ease, but some tips are offered below if these problems confound the assay.

Bubbles from improper sealing

The biggest problem encountered by the novice is the introduction of bubbles of air into the chamber when the wells are sealed. The bubble will act like a bulldozer and sweep cells off the substrate when the wells are inverted. To avoid this, it may take some practice sealing the wells. The easiest way to put the tape on is to place the wells in a rubber support, which acts as a backstop when the tape is pressed down. The tape is then rolled onto the wells, and any remaining medium is squeegeed by rubbing the top either with fingers or a flat surface.

Bubbles generated during the warming incubation

If the sealed plate is incubated at 37°C for >5 min, air bubbles are often introduced. To avoid this, the plates can be sealed after the 37°C incubation. For long incubations, fill the wells with 100 µl of medium plus 100 µl of cell suspension (2/3 full). After the incubation, place the plates on ice and add 100 µl of medium to brim the wells. Add the tape and do the dislodgement step. In practice, this is really an easy step; however, it does introduce a potential error in that the late addition of medium adds a shear force other than centrifugal force to the system. One can easily control for this by examining the wells both prior to and after topping them off.

Quantifying cells

The cells will not be uniformly distributed on the bottom of the wells, which can potentially cause a sampling problem. This can be completely avoided by comparing an experimental population of cells, labeled with one dye, against a reference control population of cells, labeled with a different dye, in the same well. It is then possible to detect very small differences that might exist between the two cell populations. To count cells, it is simplest to capture images of the well bottoms, and either count the cells manually or use a computer-generated macro to automatically count the cells in the field.

Anticipated Results

With most cell types, two basic types of results will be obtained. Measuring adhesion as a function of *g* force will generate the two curves seen in Figure 9.2.3A. The cells adhering by a receptor-ligand interaction alone (4°C) will survive the dislodgement force until a certain force is reached and then there will be a rather sharp drop in their ability to resist the dislodgement force. On the other hand, if the cells are subjected to a brief incubation at 37°C with time held constant, they will tend to resist removal. Figure 9.2.3B shows an example of expected results when measuring adhesion as a function of time at 37°C, with the dislodgement force held constant.

Time Considerations

A typical assay requires 1 hr to complete. Extra time is required if the cells must recover afer dissociation or if strengthened adhesion is measured.

Cadherin-Dependent Cell-Cell Adhesion

Cell-cell adhesion mechanisms are subdivided into the Ca^{2+}-dependent system (CDS) and Ca^{2+}-independent system (CIDS), and cadherins are the major components of the former. In general, both systems are present in a single cell, and therefore these two adhesion systems must be discriminated for accurate assays of cell adhesion. This unit provides multiple protocols to assay cell-cell adhesion that is mediated by classic cadherins (see Background Information). Reaggregation of dissociated cells is described for measuring cadherin activity in a variety of cultures: short-term aggregation cultures (see Basic Protocol 1), long-term aggregation cultures (see Alternate Protocol), and mixed-cell aggregation cultures (see Basic Protocol 2). The methods for cell reaggregation should be modified depending on the purpose of the experiment. Two Support Protocols describe methods for dispersing cells while selectively preserving cadherins but removing CIDS. These protocols are optimized for using cultured fibroblastic cells (see Support Protocol 1) and embryonic tissue cells (see Support Protocol 2). Cells can also be dissociated by removing cadherins from the cell surface (see Support Protocol 3). The selection of a dissociation protocol is discussed in detail below (see Strategic Planning). Additional protocols describe how to detect and identify cadherins from cells (see Basic Protocol 3), how to inhibit cadherin-mediated cell adhesion (see Basic Protocol 4), and how to restore cadherin activity in cadherin- and catenin-deficient cell lines (see Basic Protocol 5).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

STRATEGIC PLANNING

Cells of multicellular solid tissues are connected to each other by various forms of cell-cell junctions—tight junctions, adherens junctions, desmosomes, and gap junctions—and by multiple classes of cell-surface molecules, each of which has distinctive functions. These structurally and molecularly complex adhesion systems can be subdivided operationally into CDS and CIDS (Takeichi, 1977, 1988). It is possible to selectively remove either of these two systems (or both) from cell surfaces by differential trypsin treatments (Takeichi et al., 1979; Urushihara et al., 1979). CDS is highly sensitive to trypsin even at low concentrations, but it can be protected from protease digestion by Ca^{2+}. On the other hand, CIDS can be removed only by treatment with relatively high concentrations of trypsin, and this proteolysis, in general, cannot be protected by Ca^{2+}. Accordingly, if cells are treated with a high concentration of trypsin in the presence of Ca^{2+} (TC treatment; see Support Protocols 1 and 2), CDS is left intact but CIDS is removed from the cell surface. If cells are treated with a low concentration of trypsin in the absence of Ca^{2+} (LTE treatment; see Support Protocol 3), CIDS is left intact, whereas CDS is digested and inactivated. Cells disaggregated by TC or LTE treatment can quickly reaggregate if placed in appropriate culture conditions, because adhesion molecules belonging to either CDS or CIDS are left intact on their surfaces.

As expected from the above properties of CDS and CIDS, treating cells with a high concentration of trypsin in the absence of Ca^{2+} (TE treatment; see Support Protocol 3) inactivates both adhesion systems. Thus, for most cell types, TE-treated cells temporarily lose all cell-cell adhesion activities, although they generally retain their cell-substrate adhesiveness. To have the TE-treated cells reaggregate, the adhesion molecules must be restored (see Basic Protocol 5).

Contributed by Masatoshi Takeichi and Shinichi Nakagawa

Current Protocols in Cell Biology (1998) 9.3.1-9.3.15

Most cell-cell adhesion molecules identified thus far can be grouped into either CDS or CIDS. Classic cadherins (Ca^{2+}-dependent cell-cell adhesion molecules) are the major components of CDS and, to the authors' knowledge, no other adhesion molecules are similar to the cadherins in their trypsin/Ca^{2+} sensitivity. Some of the other cell-cell adhesion molecules require Ca^{2+} for their activity, but are not preserved by Ca^{2+} during TC treatment. Therefore, CDS preserved from TC-treatment is represented virtually by a single family of adhesion molecules, the cadherins. CIDS includes multiple classes of adhesion molecules, especially members of the immunoglobulin superfamily; its entire biochemical profile remains to be clarified. Adhesion molecules left on LTE-treated cell surfaces may vary greatly according to cell type.

Cells retain a clustered state during and after TC treatment, because cadherins are active due to the presence of Ca^{2+}. To dissociate them into single cells, they must be washed with a Ca^{2+}-free medium. This strategy for cell disaggregation can be applied to many cell types, including fibroblasts (see Support Protocol 1), early embryonic cells (see Support Protocol 2), and neuroepithelial cells. However, it can be difficult to disaggregate certain cell types into single cells after TC treatment, especially differentiated epithelial cells. Some junctional structures seem to be resistant to the removal of Ca^{2+}. For these cells, it is not possible to obtain healthy, single cells after TC treatment, and only TE treatment (see Support Protocol 3) is an effective way to obtain single cells. In the latter case, cadherins must be sacrificed to allow cell dissociation. Their activity can be studied, however, by letting the cells recover by long-term culture of the cells (see Alternate Protocol).

Each cadherin type can confer specific adhesiveness on cells. This nature of cadherins can be assayed by mixing cells expressing different cadherin types (Nose et al., 1988; Murphy-Erdosh et al., 1995; Nakagawa and Takeichi, 1995; see Basic Protocol 2). Cadherins are associated with cytoplasmic proteins, collectively called catenins, and this association is essential for cadherin activity (Aberle et al., 1996; Barth et al., 1997). On this molecular basis, manipulation of either cadherin or catenins can alter cadherin activity (see Basic Protocols 4 and 5).

BASIC PROTOCOL 1

SHORT-TERM AGGREGATION CULTURE

This protocol describes a method for allowing dispersed cells to reaggregate within short incubation periods. Cells are cultured for up to two hours in a simple balanced salt solution. This method should be chosen when adhesion molecules are assumed to be left intact on cell surfaces after trypsin treatments, and their activity is to be assayed. Physiological recovery of the trypsinized molecules is not expected in this simple culture system.

Materials

1% (w/v) BSA (see recipe)
HCMF (see recipe)
Cells of interest (see Support Protocols 1 to 3), suspended in ice-cold HCMF at $0.5–1 \times 10^5$ cells/ml for cell lines, or at $2–5 \times 10^6$ cells/ml for early embryonic neurons
100 mM $CaCl_2$ (*APPENDIX 2A*)
8% (w/v) paraformaldehyde in HCMF

24-well tissue culture plate (Falcon)
Gyrating shaker (New Brunswick Scientific, Model G2)
BSA-coated Pasteur pipets (see recipe)

Additional reagents and equipment for counting cell aggregates with a hemacytometer (*UNIT 1.1*) or Coulter counter

1. Precoat the wells of a 24-well tissue culture plate with 0.5 ml of 1% (w/v) BSA overnight at 4°C. Rinse the wells a few times with HCMF just before use.
2. Place the plate on ice and add 0.5 ml cells of interest to each well. Add 56 µl of 100 mM $CaCl_2$ (1 mM final) to activate cadherins on TC-treated cells. Add an equal volume of water to controls wells to check the effect of Ca^{2+}.

   When desired, also add other substances, such as antibodies (Table 9.3.1) and inhibitors.

   Cell density varies between cell lines and embryonic cells, because the latter are often smaller than the former.

   Release of DNA from damaged cells tends to perturb cell aggregation processes (see Support Protocol 2). To avoid this, add DNase I (10 µg/ml final) and $MgCl_2$ (1 mM final)

[a]Inhibitory activity is indicated only for antibodies that have been tested directly by the authors. For other antibodies, refer to original descriptions.

[b]BIB, Boehringer Ingelheim Bioproducts; BLD, BioLine Diagnostics; ICN, ICN Biomedicals; DSHB, Developmental Studies Hybridoma Bank; PGN, Progen Biotechnik GmbH. See *SUPPLIERS APPENDIX* for addresses.

[c]Species name is omitted for catenins, as most antibodies can recognize a wide variety of species.

to the aggregation medium. The presence of DNase is often critical for accurate measurement of natural cell aggregation. Mg^{2+} might activate integrins, but this effect is generally negligible in cadherin assays. Cadherins themselves are insensitive to Mg^{2+}.

3. Place the plate on a gyrating shaker at ~80 rpm, and incubate 30 min to 2 hr at 37°C. Monitor the aggregation process every 30 min (or at shorter intervals during the initial 30-min period) with an inverted microscope, being careful not to disturb the central accumulation of cells.

   The cells soon become concentrated at the center of each well, and will aggregate at this position. Accumulation can be perturbed by contaminating fibrous materials (such as cotton fibers), affecting the pattern and rate of cell aggregation. Therefore, it is very important to avoid such contamination.

   TC-treated cells start to aggregate within 10 min in the presence of Ca^{2+}. Without Ca^{2+}, TC-treated cells should not aggregate. If they aggregate in the Ca^{2+}-free wells, it is possible that adhesion molecules other than cadherins are active in these cells. On the other hand, LTE-treated cells do aggregate in the absence of Ca^{2+}. TE-treated cells, in general, do not aggregate under any of these conditions. Sometimes, a low degree of aggregation may be observed for TE-treated embryonic cells, suggesting that some residual adhesion molecules are present.

   Maximum aggregation of the cells is generally attained within 2 hr under the above culture conditions, and 30 to 60 min incubation is often sufficient to assess their aggregation properties. Longer incubations may cause cell death, as well as nonspecific cell aggregation due to various factors.

4. Place the plate on ice.

   Cooling the cells stops cadherin-mediated aggregation. Ca^{2+}-independent aggregation may still proceed for LTE-treated cells.

5. Add an equal volume of 8% (w/v) paraformaldehyde to each well, mix, and incubate 15 min on ice.

   Light fixation with an aldehyde-based fixative helps prevent redissociation of the aggregates. Quick mixing of the fixative with the cell suspension is essential to ensure that there is no artificial (fixation-induced) cell aggregation.

6. Gently stir the wells, obtain an aliquot of the cell suspension (or the whole suspension) using a BSA-coated Pasteur pipet, and count the number of cell aggregates and single cells with a hemacytometer or automated cell counter. Determine N_t/N_0, where N_t is the total particle number (aggregates plus single cells) at incubation time t, and N_0 is the total cell number in the cell suspension (see Support Protocols 1 to 3, and the materials list above).

   Be certain that cells or aggregates are uniformly distributed in the well when an aliquot of the cell suspension is removed for counting. See Background Information for details on how to quantify cell aggregation.

ALTERNATE PROTOCOL

LONG-TERM AGGREGATION CULTURE

As mentioned above (see Strategic Planning), for some cell types including most epithelia, complete disaggregation of cells cannot be achieved by TC treatment, and TE treatment (see Support Protocol 3) must be used. The long-term aggregation culture involves incubating cells for several hours to days, by maintaining cells in nutritious culture medium in place of HCMF. Under these conditions, cells undergo de novo protein synthesis, and therefore TE-treated cells gradually recover adhesion molecules, allowing them to aggregate. Cadherin-mediated aggregation begins within a few hours of culture. This aggregation can be inhibited with specific blocking antibodies to cadherins, if they are available. Cadherin activities of TE-treated cells can be studied by this method. TC- and LTE-treated cells do not require long-term cultures.

Additional Materials *(also see Basic Protocol 1)*

1% (w/v) agar (e.g., Noble agar, Difco) in standard culture medium
Cells of interest (see Support Protocol 3), suspended at 0.5–1 × 10^5 cells/ml for cell lines, or at 2–5 × 10^6 cells/ml for early embryonic neurons, in standard cell culture medium (e.g., supplemented Dulbecco's modified Eagle medium, DMEM; *APPENDIX 2A*) with 10% FBS (*APPENDIX 2A*)

1. Pour a minimum amount of 1% agar into the wells of a 24-well tissue culture plate (or other dishes) to cover the entire bottom surface. Allow the gel to set.

   Agar is a powerful inhibitor of cell attachment to the substratum. For long-term cultures, BSA coating is not sufficient to prevent cells from attaching to the dishes.

2. Add cells of interest to agar-coated wells (see Basic Protocol 1, step 2). Incubate as in Basic Protocol 1 (step 3) for the desired period, placing the plate on a shaker in a 5% to 10% (v/v) CO_2 incubator if the medium is buffered with a $NaHCO_3/CO_2$ system.

   The cultures can be maintained for several days if the culture medium is properly refreshed (e.g., by changing half of the medium every day). Cell aggregation also can be induced without rotating the plates. CO_2 levels should be adjusted to maintain pH 7.4.

3. Fix the cells and determine the extent of aggregation (see Basic Protocol 1, steps 4 to 6).

MIXED-CELL AGGREGATION CULTURE

BASIC PROTOCOL 2

To evaluate whether two given populations of cells can adhere to each other, they are mixed and allowed to reaggregate in one of the above culture systems. The resultant cell aggregates are analyzed to determine whether or not the cells have segregated. To do this, the two cell populations must be distinguishable. This can be achieved by staining one population of cells with a fluorescent dye or by labeling two populations with optically distinct dyes. Suitable dyes include 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI), 3,3′-dioctadecyloxacarbocyanine perchlorate (DiO), Cell Tracker (Molecular Probes), PKH26 (ZYNAXIS), or Fluoro-gold (Fluorochrome).

Materials

Cell cultures
Standard cell culture medium (e.g., supplemented Dulbecco's modified Eagle medium, DMEM; *APPENDIX 2A*) with 10% FBS (*APPENDIX 2A*)
Fluorescent dye(s): e.g., 3 mg/ml 3,3′-dioctadecyloxacarbocyanine perchlorate (DiO) in dimethylsulfoxide
HEPES buffer (see recipe)
8% (w/v) paraformaldehyde in HCMF (see recipe for HCMF)
Glycerol-based mounting medium containing antifading reagents (e.g., 1 mg/ml *p*-phenylenediamine in 90% glycerol)
BSA-coated microcentrifuge tubes (see recipe)

Additional reagents and equipment for dispersing cultures (see Support Protocol 1 to 3), for counting cells (*UNIT 1.1*), and for short-term or long-term aggregation culture (see Basic Protocol 1 or Alternate Protocol)

1. Label one culture with a fluorescent dye, or label both cultures with optically distinct fluorescent dyes. For example, label a monolayer cell culture by incubating the cells overnight at 37°C with standard cell culture medium containing 15 µg/ml DiO, and wash 3 times with HEPES buffer. Disperse cultures into single cells (see Support Protocols 1 to 3) and resuspend.

   Cells can also be labeled after the dissociation step.

For other fluorescent dyes, follow the manufacturer's instructions. Make sure that all the cells have been equally labeled by examining with a fluorescence miscroscope.

2. Count the cells (*UNIT 1.1*) and adjust the density with medium to be used for the following aggregation culture. Mix the two disaggregated cell cultures in a 1:1 ratio and incubate for aggregation (see Basic Protocol 1, steps 1 to 3, or see Alternate Protocol, steps 1 and 2).
3. Add an equal volume of 8% paraformaldehyde to each well of the dish, and fix the cells 30 min at 4°C.
4. Transfer the contents of each well into a BSA-coated microcentrifuge tube, and centrifuge the sample 1 min at 700 × *g*, 4°C.

   The microcentrifuge tube should be coated with 1% BSA so that the cells will not stick to the wall of the tube.

5. Discard the supernatant, and gently wash the cells three times with HEPES buffer.
6. Mount the cells on a glass slide with a minimum amount of glycerol-based mounting medium containing antifading reagents.
7. Analyze the aggregation pattern of the aggregates using a fluorescence microscope.

   In mixed-cell aggregation assays, three kinds of pattern can be observed for the distribution of the two cell populations. (1) Cells of each population form separate aggregates, indicating that they can adhere only to like cells. (2) Two cell populations randomly intermix with each other, suggesting that they share common adhesion mechanisms. (3) Each cell aggregate contains the two cell types, but their distribution is not random, and they tend to segregate from each other within the aggregate, forming their own clusters. By analyzing these patterns, selectivity in the adhesiveness of two given cell populations can be evaluated.

SUPPORT PROTOCOL 1

DISSOCIATION OF FIBROBLASTS BY TC TREATMENT

This protocol describes cell dissociation employing a high concentration of trypsin in the presence of Ca^{2+} (TC treatment), which has been used successfully for cultured fibroblasts and similar cells. For other cell types, some modifications of the method may be necessary (see Support Protocol 2).

Materials

Semiconfluent monolayer of the cells of interest
HMF (see recipe)
TC solution (see recipe)
0.5% (w/v) soybean trypsin inhibitor solution (see recipe)
HCMF (see recipe), ice cold
BSA-coated 10-ml test tubes and Pasteur pipets (see recipe)

Additional reagents and equipment for disaggregation by TE treatment (see Support Protocol 3) and for counting (*UNIT 1.1*)

Prepare cultures

1. Prepare semiconfluent monolayer cultures of cells by seeding them 1 or 2 days before use. To confirm successful TC treatment, prepare parallel cultures treated with TE (see Support Protocol 3).

   Overcrowded or old cultures should not be used, as they are often difficult to dissociate into healthy single cells.

2. Rinse the cultures three times with HMF.

Perform TC treatment

3. Remove HMF and add TC solution to the rinsed cultures (e.g., ~4 ml for a 5-cm dish).

   The Ca^{2+} concentration can be modified, balancing protection against proteases and adequate cell disaggregation according to cell type (see Critical Parameters and Troubleshooting).

4. Incubate 15 to 30 min at 37°C on a rotary shaker, and then examine the cells with an inverted microscope.

   The suspended cells should exist as tight clumps if the TC treatment is successful. In sharp contrast, TE-treated cells should be virtually dispersed as single cells. If TC treatment results in a nearly complete dispersion of the cells, either the cells do not have any cadherins, or something was wrong with the treatment procedure, resulting in inactivation of cadherins. To test the latter possibility, the Ca^{2+} concentration in the TC solution can be increased to 5 mM.

Dissociate cells

5. Transfer cells into a BSA-coated 10-ml test tube. If necessary, collect attached cells by flushing the solution with a BSA-coated Pasteur pipet.

   In general, cells spontaneously detach from the dishes during trypsin treatment.

6. Centrifuge 3 to 4 min at 700 × *g*, 4°C, and remove the supernatant.

7. Add 100 µl of 0.5% soybean trypsin inhibitor solution to the cell pellet, followed by 5 ml ice-cold HCMF. Resuspend the cells by brief pipetting with a BSA-coated Pasteur pipet and centrifuge them again. Aspirate the supernatant.

8. Add 5 ml ice-cold HCMF to the cells and disperse the cell clumps by gentle pipetting. Centrifuge as in step 6 and aspirate the HCMF. Repeat.

   For complete dispersion of TC-treated cells, vigorous pipetting is generally required. After several repeats of pipetting, place a tiny aliquot of the cell suspension onto a glass slide and examine it under an inverted microscope. If cell clumps are still present, repeat the pipetting until essentially all cells become dissociated.

   Some cell types, such as epithelial cells, may resist being dissociated into single cells after TC treatment. For such samples, prolonged pipetting might eventually kill them. In this case, other methods for cell dispersion should be employed (e.g., TE treatment; see Support Protocol 3).

9. Resuspend the cells in 2 to 5 ml ice-cold HCMF, and pipet them using a BSA-coated Pasteur pipet in order to obtain completely dissociated cells.

10. Count cell density (*UNIT 1.1*), centrifuge the cells as in step 6, and finally suspend the cells at 0.5–1 × 10^5 cells/ml in ice-cold HCMF (see Basic Protocol 1). Store on ice, and use as soon as possible.

    Never leave the cell suspension at room temperature, as this causes cadherin degradation if Ca^{2+} is absent, and induces precocious cadherin-mediated aggregation if Ca^{2+} is present.

DISSOCIATION OF EMBRYONIC CELLS BY TC TREATMENT

SUPPORT PROTOCOL 2

This protocol describes how to modify TC treatment (see Support Protocol 1) for dissociating embryonic tissues. This protocol works nicely to dissociate early neural and fibroblastic tissues. For some tissues (e.g., early embryonic brains), Ca^{2+} concentration can be increased up to 10 mM to optimize preservation of cadherins without reducing the efficiency of cell disaggregation. On the other hand, it may be difficult to dissociate epithelial organs into single cells by the standard TC treatment (see Support Protocol 3 to resolve this problem).

Additional Materials (also see Support Protocol 1)

Embryo(s)
HEPES buffer (see recipe), ice cold
DNase I
1 M $MgCl_2$ (*APPENDIX 2A*)
BSA-coated 5-cm petri dish (see recipe)

1. Remove tissue from embryos and place in ice-cold HEPES buffer. Cut the tissue into small pieces in HEPES buffer.
2. Transfer the collected tissue with a minimum amount of HEPES buffer to the edge of a 5-cm BSA-coated petri dish, and mince with a pair of fine-tipped scissors.
3. Add 4 to 5 ml TC solution, and incubate 20 to 30 min at 37°C on a rotary shaker.

   Larger pieces of tissue may require longer incubation periods.
4. Lightly pipet the suspension with a BSA-coated Pasteur pipet to briefly disperse the tissue, and examine with an inverted microscope. If viscous DNA gels are present, digest them by adding an excess amount of soybean trypsin inhibitor (add 1/10th vol of a 0.5% solution) followed by 10 µg/ml DNase I and 10 mM $MgCl_2$ (final concentrations). Incubate without shaking at 37°C until the viscous material completely disappears (several minutes).

   DNA gels can cause nonspecific cell aggregation (see Critical Parameters and Troubleshooting).
5. Transfer the cell suspension to a BSA-coated 10-ml test tube, and wash (see Support Protocol 1, steps 6 to 9).

   If soybean trypsin inhibitor was added in step 4, it does not need to be added again here.

   The trypsinized cell suspensions may contain undigested, large cell clumps or tissue debris, mainly derived from extracellular matrices. These should be removed by low-speed centrifugation or with a filter (e.g., Cell Strainer, Falcon), at some step in the washing process.
6. Count and resuspend cells (see Support Protocol 1, step 10), bringing embryonic brain cells, for example, to $2–5 \times 10^6$ cells/ml.

SUPPORT PROTOCOL 3

DISSOCIATION OF CELLS BY LTE OR TE TREATMENT

Treatment of cells at a low concentration of trypsin (LTE treatment) or at a high concentration of trypsin (TE treatment), both in the presence of 1 mM EDTA, was designed to obtain cells lacking cadherins. In LTE-treated cells, CIDS remains active, whereas in TE-treated cells, both cadherins and CIDS are inactivated. Thus, TE treatment produces temporarily null-adhesive cells, and this treatment is useful for complete dissociation of most cell types. As mentioned above, cells of certain tissues (e.g., epithelial tissues) cannot be completely dissociated by TC treatment. In this case, TE treatment is the only choice for obtaining single-cell preparations. Many aspects of the LTE and TE treatments are identical to those for TC treatment; only those steps that must be modified are present here.

Additional Materials (also see Support Protocols 1 and 2)

TE solution (see recipe)
LTE solution (see recipe)

1a. *For cultured cells:* Wash cells three times with HCMF.

1b. *For embryonic tissue:* Rinse tissue with HCMF and transfer to a 5-cm BSA-coated petri dish for trypsin treatment.

2. Add 4 to 5 ml LTE or TE solution to the dish and incubate 15 to 30 min at 37°C on a rotary shaker.

   For LTE treatment, the best trypsin concentration should be determined for every tissue or cell line to ensure that a sufficient CIDS activity is preserved, that cadherins are fully inactivated, and that cells can be dissociated into single cells. For many cell lines, 0.0001% (w/v) trypsin gives satisfactory results; 0.0005% is suitable for embryonic brain.

3. Examine the cells with an inverted microscope. For cells from embryonic tissues, digest DNA gels as necessary (see Support Protocol 2, step 4).

   In contrast to TC-treated cells, which are tightly clumped, LTE-treated cells should be more loosely clustered, and TE-treated cells should be virtually dispersed as single cells.

4. Transfer cells to a BSA-coated 10-ml test tube and wash (see Support Protocol 1, steps 6 to 9).

5. Count and resuspend cells (see Support Protocol 1, step 10), bringing cell lines to $0.5–1 \times 10^5$ cells/ml, and embryonic cells to $2–5 \times 10^6$ cells/ml.

   For long-term culture, suspend cells in the appropriate culture medium (see Alternate Protocol).

DETECTION OF CADHERINS AND CATENINS

BASIC PROTOCOL 3

When working with cells for which no information is available concerning cadherin expression or activity, the following procedures should be helpful in determining their cadherin activity.

Examine morphology

Observe the morphology of cell colonies in relatively low-density cultures. If any cadherins are active, the cells should exhibit firm associations with each other at their margins. If the cells have no cadherin activity, individual cells should be independent (i.e., not forming any tight contacts with others). When these cells become confluent, they may temporarily form monolayer-like sheets, which are sometimes indistinguishable from cadherin-active cell sheets. However, upon further proliferation, overgrown cells tend to be excluded from the sheets if cadherins are inactive; many of the excluded cells may stay on the top of the sheets, exhibiting a round shape. This type of cell association pattern is generally not observed for cadherin-active confluent cell layers, as they maintain tight mutual associations even at high densities.

Examine catenin protein localization

Immunostain cell layers with fluorophore-conjugated antibodies to β-catenin, αE-catenin, or αN-catenin (*UNIT 4.3*; Table 9.3.1). If one of these molecules is concentrated at contact sites between the cells, it strongly suggests that a certain type of cadherin is present and colocalizes with the catenins.

Determine Ca^{2+}-dependent trypsin sensitivity

Treat the cells by the TC (see Support Protocols 1 or 2) and TE (see Support Protocol 3) methods. If cells are detached from the dish as tight clumps after TC treatment, but are dispersed into single cells by TE treatment, this is a strong indication that they have certain cadherins.

Examine cadherin expression

If anti-cadherin antibodies are available (Table 9.3.1), use them for immunoblotting (*UNIT 6.2*) or immunostaining (*UNIT 4.3*). If cadherins are active, immunostaining signals

should be concentrated at cell-cell contact sites. Note that most anti-cadherin antibodies can recognize only limited species.

If immunological strategies do not work, try reverse transcription PCR (RT-PCR) using primers that can amplify fragments of multiple cadherin types. Refer to Suzuki et al. (1991) and Sano et al. (1993) for appropriate PCR primers.

BASIC PROTOCOL 4

INHIBITION OF CADHERIN FUNCTION

There are at least three established ways for blocking cadherin activity: removal of Ca^{2+}, use of inhibitory antibodies, and expression of dominant negative cadherin constructs. Each is detailed below.

Inhibition by Ca^{2+} removal

Removal of Ca^{2+} is the most effective way for blocking cadherins. For most cell types, cadherins are inactivated at <0.1 mM Ca^{2+}. Incubation of cells with EGTA or EDTA (e.g., 1 mM) greatly facilitates Ca^{2+} removal and induces visible dissociation of the cells within several to 10 min at 37°C. Any cells treated with these chelators tend to round up, exhibiting formation of clear gaps between them. However, it should be stressed that many cells, especially epithelial cells, are not completely separated from each other by chelator treatment alone. They often maintain tight connections through fine processes. These chelator-resistant connections cannot be disrupted by a simple mechanical force. The molecular nature of these connections is not fully understood, and only TE treatment can disrupt them.

Inhibition with antibodies

Many antibodies raised against the extracellular domain of cadherins can inhibit their adhesion activities. In monolayer cultures, one can observe morphological changes in antibody-treated cells. These changes are not as drastic as those observed with Ca^{2+} removal, but careful investigators can detect clear differences between the antibody-treated and untreated cells. Most importantly, gaps often become visible between the antibody-treated cells. These changes can be recognized within a few hours after addition of the antibodies. High-density cultures should not be used for these observations, because it is difficult to detect morphological changes. When three-dimensional tissues are treated with anti-cadherin antibodies, their response is seen as a rounding-up of individual cells and a loss of the compact tissue appearance.

For anti-cadherin antibodies, the following points should be kept in mind. (1) Among available anti-cadherin antibodies, those with blocking activity are limited (Table 9.3.1). (2) Many antibodies show species-specific reactivity. (3) A single cell usually expresses multiple cadherin types. For complete inhibition of a cell's cadherin-mediated adhesion, all types must be blocked. Nevertheless, blocking the major cadherin expressed by the cell is often sufficient to induce a morphological response to the antibodies.

Inhibition with dominant negative cadherin constructs

The products of two groups of cadherin cDNA constructs are known to exhibit a dominant negative effect (Takeichi, 1995). One group (ΔN) encodes a molecule with a truncated extracellular domain and an intact cytoplasmic domain (Kintner, 1992; Fujimori and Takeichi, 1993). These molecules are not functional as adhesion molecules themselves, because they lack the extracellular domain. However, they can associate normally with the cytoskeletal system. Based on this nature, the ΔN molecules can compete with endogenous, intact cadherins for interactions with cytoplasmic components, thus interfering with the adhesion activity of the latter. ΔN can nonspecifically inhibit a wide variety of classic cadherins.

The other type of dominant negative cadherin construct (ΔC) was designed to encode a molecule consisting of the intact extracellular domain and a truncated cytoplasmic domain (Levine et al., 1994). Again, the products of these constructs are not functional as adhesion molecules, and they are assumed to interfere with the homophilic interactions at the extracellular domain of endogenous cadherins. In contrast with the use of ΔN, it is possible to specifically block the function of a particular cadherin type with these constructs, because each cadherin type has a unique sequence in its extracellular domain. ΔC has been used successfully when overexpressed in *Xenopus* embryos but not in cell lines. It may be that a large excess of the mutant molecule is required to fully compete with endogenous intact cadherins.

RESTORATION OF CADHERIN ACTIVITY IN CADHERIN- OR CATENIN-DEFICIENT CELL LINES

BASIC PROTOCOL 5

Cell lines with impaired cadherin function are useful materials for studying the mechanisms of cadherin-mediated adhesion. Cadherin dysfunction can be induced by various mechanisms, including loss or mutation of cadherin or catenin genes, or down-regulation of their expression. Cell lines that do not show any cadherin expression include L (Nagafuchi et al., 1987), Neuro 2a (Matsunaga et al., 1988), and S180 (Mege et al., 1988). α-Catenin-deficient lines include PC9 (Hirano et al., 1992) and HCT-8/R1 (van Hengel et al., 1997). HSC39 has a truncated β-catenin gene (Kawanishi et al., 1994; Oyama et al., 1995). In some lines, cadherin function is blocked despite the presence of all known components for the cadherin adhesion machinery. Such blocking is perhaps based on physiological mechanisms. Cadherin dysfunction is most frequently found in carcinoma cell lines. In many of them, not only cell-cell adhesion but also cell-substrate adhesion is often impaired, and they grow as suspended cells without forming tight clumps. If a cell line is found to grow as single cells, it is highly possible that the cells' cadherin activity is abnormal due to one of the above mechanisms.

In cadherin- or catenin-deficient cell lines, cadherin activity can be restored by transfecting with a cDNA encoding the affected protein products. Isolation of successfully transfected clones is relatively easy, because their morphology is dramatically changed from a dispersed to an adhesive type, allowing selection of positive colonies by microscopic observation. On the other hand, the physiologically blocked cadherin function cannot be rescued by a simple addition of cadherin or catenin cDNA.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BSA-coated glass- and plasticware

Place 1% (w/v) BSA solution (see recipe) into test tubes, dishes, and microcentrifuge tubes to be used for collection of cells. Submerge Pasteur pipets in the BSA solution. Let sit at room temperature for at least 1 hr before the experiment. Rinse with HCMF (see recipe) before use.

Cells suspended in protein-free solutions readily attach to plastic or glass surfaces, causing loss of and damage to the cells. To avoid this, all plastic or glass dishes, tubes, and pipets to be used for cell preparation must be precoated with BSA.

If necessary, BSA can be left in tubes/pipets overnight at 4°C.

BSA solution, 1% (w/v)

1 g bovine serum albumin (Fraction V; Sigma)
HCMF (see recipe) to 100 ml
Adjust pH to 7.4 with NaOH
Filter sterilize through a 0.45-µm filter
Store ≤1 week at 4°C

HEPES buffer

1 liter HCMF (see recipe)
1 ml 1 M $CaCl_2$ (*APPENDIX 2A*)
1 ml 1 M $MgCl_2$ (*APPENDIX 2A*)
Filter through a 0.45-µm pore-sized filter to remove any dusty materials
Store up to several months at 4°C

HEPES buffer, Ca^{2+}- and Mg^{2+}-free (HCMF), pH 7.4

8 g NaCl (0.137 M final)
0.4 g KCl (5.4 mM final)
0.12 g $Na_2HPO_4 \cdot 12H_2O$ (0.34 mM final)
1.0 g glucose
2.38 g *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES; 10 mM final)
H_2O to 1 liter
Adjust pH to 7.4 with 1 N NaOH
Filter through a 0.45-µm filter to remove any dusty materials
Store up to several months at 4°C

HEPES buffer, Mg^{2+}-free (HMF)

1 liter HCMF (see recipe)
1 ml 1 M $CaCl_2$ (*APPENDIX 2A*)
Filter through a 0.45-µm filter to remove any dusty materials
Store up to several months at 4°C

LTE solution

10 µl 0.1% (w/v) trypsin solution (see recipe; 0.0001% final)
100 µl 100 mM EDTA (*APPENDIX 2A*) or ethylene glycol bis(β-aminoethylether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) (1 mM final)
9.89 ml HCMF (see recipe)
Prepare fresh

EDTA or EGTA should give the same effect.

Soybean trypsin inhibitor solution, 0.5% (w/v)

50 mg soybean trypsin inhibitor (Sigma)
HCMF (see recipe) to 10 ml
Divide into 100-µl aliquots
Stored ≤1 month at −20°C

TC solution

1 ml 0.1% (w/v) trypsin solution (see recipe; 0.01% final)
100 µl 100 mM $CaCl_2$ (1 mM final)
8.9 ml HCMF (see recipe)
Prepare fresh

TE solution

1 ml 0.1% (w/v) trypsin solution (see recipe; 0.01% final)
100 µl 100 mM EDTA (*APPENDIX 2A*) or ethylene glycol bis(β-aminoethylether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA; 1 mM final)
8.9 ml HCMF (see recipe)
Prepare fresh

EDTA or EGTA should give the same effect.

Trypsin solution, 0.1% (w/v)

10 mg crystalline trypsin (Sigma)
HCMF (see recipe) to 10 ml
Divide into 1-ml aliquots
Store ≤1 month at −20°C

COMMENTARY

Background Information

The cadherins constitute a large superfamily of molecules with diverse primary structures (Takeichi, 1995). Among its members, those of the "classic cadherin" subfamily have most extensively been characterized as cell-cell adhesion molecules. More than 20 members of the classic cadherin subfamily are known, and they are subdivided into type I and II groups (Takeichi, 1995). All of them bind cells by homophilic interactions. Based upon specificity in their molecular interactions, cells tend to preferentially adhere to those expressing the same cadherin (Takeichi, 1995). Each cadherin is expressed in restricted tissues, and a single cell generally expresses multiple cadherin types. This expression profile should be kept in mind when identifying cadherins in a given cell. The protocols described in this unit should be applied only to the classic cadherins. Other cadherins such as desmosomal cadherins and protocadherins may show different biochemical and biological properties.

The cytoplasmic domain of classic cadherins is associated with catenins (Aberle et al., 1996; Barth et al., 1997). The catenins are subdivided into the β-catenin and α-catenin groups. The former includes β-catenin Armadillo in *Drosophila*), plakoglobin (γ-catenin), and $p120^{cas}$, and the latter consists of αE-catenin and αN-catenin. The β-catenin group directly associates with the carboxy terminal domain of cadherins. α-Catenins bind to β-catenin, and the cadherin/β-catenin/α-catenin complex formation is crucial for full activity of this adhesion machinery. Therefore, cadherin dysfunction can be brought about by loss of any of these three components. TE treatment cleaves only the cadherins.

The mechanism by which Ca^{2+} protects cadherins from proteolytic digestion is not fully understood, although the Ca^{2+}-binding sites have now been identified (Overduin et al., 1995; Shapiro et al., 1995). Although cadherins are generally resistant to TC treatment, this procedure can cleave the proximal portion of the cadherin extracellular domain if incubation is long (especially when isolated cell membranes are treated), resulting in the production of an extracellular fragment (Takeichi, 1988).

How the strength of cell-cell adhesion should be quantified is a classic controversial issue. The simplest way, which does not require sophisticated equipment, is to measure the decrease in the total particle number in cell suspensions. The degree of cell aggregation can be represented by the index N_t/N_0, where N_t is the total particle number (aggregates + single cells) at incubation time t, and N_0 is the total cell number in the cell suspension. Counting of particle number can be done using a hemacytometer (*UNIT 1.1*) but is greatly facilitated if a Coulter counter or its equivalent is available.

Critical Parameters and Troubleshooting

Calcium

When preparing cells for cadherin assays, the presence or absence of Ca^{2+} affects the preservation of cadherins on the cell surfaces, even when exogenous proteases are absent. With physiological concentrations of Ca^{2+}, cadherins are always protected from protease digestion. In contrast, in Ca^{2+}-free media, cadherins tend to be gradually degraded by proteases released from lysed cells in a temperature-dependent manner. Therefore, when the preservation of cadherins is desired, it is highly

recommended that 1 to 2 mM Ca^{2+} be added to all solutions used for cell preparation or tissue dissection. Higher concentrations of Ca^{2+} are more effective in preserving cadherins against tryptic digestion, but they can cause difficulty in cell disaggregation in subsequent steps. For cells that disaggregate with relative ease, the Ca^{2+} concentration should be increased to 5 to 10 mM. Conversely, the Ca^{2+} concentration can be reduced to 0.2 to 0.5 mM for other cell types; this enhances cell disaggregation but reduces cadherins left intact on the cell surface. Ca^{2+} at <0.1 mM fails to protect cadherins. It should also be remembered that more Ca^{2+} is required when higher concentrations of trypsin are used. Ca^{2+} can protect cadherins against many classes of proteases.

To dissociate cells, however, they must be exposed to Ca^{2+}-free conditions to inactivate cadherins. At this time, cadherins can be protected by low temperatures. Ca^{2+}-free cell suspensions should always be kept at an ice-cold temperature. If Ca^{2+} is added to a suspension of cells with cadherins, it induces immediate cell aggregation at physiological temperatures. Under ice-cold conditions, however, cadherin-mediated aggregation is inhibited. Thus, placing cells in an ice-cold, Ca^{2+}-containing medium is the best way to both preserve their cadherin activity and keep them dispersed.

Nonspecific aggregation or adhesion

In cell aggregation assays, the cell suspension should be as clean as possible, as any noncellular contaminant can disturb natural cell aggregation. For example, one piece of cotton fiber can act as a core to induce artificial clumping of the cells.

DNA gels most effectively clump cells. During the trypsin treatments, DNA may be released from lysed cells. The DNA forms viscous gels, which trap cells in loose aggregates. These artificial aggregates should be distinguished from those mediated by real cell-cell adhesion molecules. The presence of DNA gels can also block cell pelleting in the washes that follow trypsin treatment. Therefore, if a significant amount of viscous material is observed in the cell suspension, it should be removed by DNase treatment before the cell washes (see Support Protocol 2). This pretreatment with DNase is generally not required when cell lines are used, because DNA release is not as extensive.

BSA precoating of the dishes, tubes, and pipets to be used for the rotation culture or for cell preparation is an absolute requirement for the success of the experiments, as it prevents the attachment of cells to these surfaces. If cells attach to the dish during the cell aggregation assay, the aggregation process is severely affected, and such cultures should be discarded.

Anticipated Results

In suspension cultures, cadherin-mediated cell aggregation results in the formation of compacted cell masses, especially when the cells are cultured for a long period (e.g., overnight) in a nutritious medium. In the initial phase of the cadherin-mediated cell aggregation (e.g., during the first 2 hr after inoculation), cell aggregates often grow in a one-dimensional, branching pattern. Even in such aggregates, mutual cell-cell contacts are very tight. In principle, the cells in a pair, bound together by cadherins, tend to maximize their contact area by spreading onto one another. On the other hand, when only CIDS is active, cells are clustered maintaining their original round shape. This is the principal morphological difference between the cadherin-dependent and -independent cell-cell contacts.

Time Considerations

Short-term aggregation assays can be completed in <1 day; long-term assays require 1 to several days.

Analyzing Integrin-Dependent Adhesion

This unit describes methods for the analysis of integrin-ligand binding in both cell-based assays (see Basic Protocol 1) and solid-phase assays (see Basic Protocol 2). A major application of cell adhesion assays is in investigating whether a certain cell type can adhere to a specific adhesive substrate, and, if so, which receptors are involved. Particularly if the substrate is a matrix component (e.g., fibronectin), members of the integrin family are likely to play a dominant role in adhesion. Procedures are described here for assessing which integrins are involved in this process. A detailed analysis of ligand recognition by individual integrins can be performed using a solid-phase receptor-ligand binding assay. The unit also contains support protocols for integrin purification (see Support Protocol 1) and coupling of antibodies to Sepharose for use in this purification (see Support Protocol 2), as well as for biotinylation of integrin ligands to be used in the solid-phase assay (see Support Protocol 3).

ANALYZING INTEGRIN-DEPENDENT ADHESION IN CELL-BASED ASSAYS

BASIC PROTOCOL 1

Cell-based assays for integrin-dependent adhesion are conducted in the same manner as the spreading and attachment assays described in *UNIT 9.1*, except that antibodies to integrins (see Table 9.4.1), peptides, or other reagents are included to identify the integrin(s) and characterize the molecular events associated with adhesion. Function-blocking monoclonal antibodies are the most useful reagents for these analyses because of their high degree of specificity. If only a single integrin is involved in mediating adhesion, antibodies to either the α or β subunit should abrogate cell adhesion. For example, antibodies to either α5 or β1 should completely block HT-1080 fibrosarcoma cell attachment and spreading on fibronectin, showing that this interaction is mediated solely by α5β1 (Akiyama et al., 1989). If multiple integrins are involved, a combination of monoclonal antibodies will be required to block adhesion (Mould et al., 1990, 1994). Although peptides and other inhibitors have, in general, less specificity than monoclonal antibodies, they can be useful for determining what amino acid sequence in the ligand is recognized by the integrin. For example, CS1 peptide inhibits A375-SM melanoma cell attachment to fibronectin, demonstrating that the CS1 sequence is involved in adhesion to this substrate.

Materials

Adhesion molecule of interest
Dulbecco's phosphate-buffered saline (DPBS, Life Technologies; also see *APPENDIX 2A*)
10 mg/ml heat-denatured BSA solution (*UNIT 9.1*)
Cells of interest
DMEM/HEPES: Dulbecco's modified Eagle medium (Life Technologies; *APPENDIX 2B*) with 25 mM HEPES, gassed with 5% to 10% CO_2
Inhibitor: integrin-specific monoclonal antibody (see Table 9.4.1) or peptide, dissolved in DPBS at appropriate concentration
96-well tissue culture microtiter plate

Additional reagents and equipment for counting cells with a hemacytometer (*UNIT 1.1*) and spreading or attachment cell-substrate adhesion assays (*UNIT 9.1*)

1. Prepare the 96-well plate by coating the wells with the adhesion molecule of interest diluted to the appropriate concentration in DPBS and blocking with 10 mg/ml heat-denatured BSA solution (see *UNIT 9.1*, Basic Protocol 1, steps 1 to 4).

Contributed by A. Paul Mould
Current Protocols in Cell Biology (2002) 9.4.1-9.4.16

Unless the level of adhesion is low, use a concentration of adhesion molecule that promotes 50% to 70% maximal adhesion for coating the wells.

2. Prepare a suspension of the cells of interest at a density of 2×10^5 cells/ml in warm DMEM/HEPES gassed with 5% to 10% CO_2. Incubate cells in an open tube 10 min at 37°C in a CO_2 incubator.

3a. *For cell spreading assay:* Remove BSA solution from the 96-well plate, wash the wells with 100 µl DPBS, and add 50 µl DPBS containing the inhibitor at twice the desired final concentration to each well. Add 50 µl cell suspension to each well.

Table 9.4.1 Monoclonal Antibodies Suitable for Use in Cell Adhesion Assays

Integrin subunit[a]	Ligand[b]	mAb[c]	Function-blocking	Supplier
α1	COL/LN	5E8D9	Yes	Upstate Biotechnology
		TS2/7	No	Serotec
α2	COL/LN	Gi9	Yes	Beckman Coulter

αM	FG, ICAM-1	ICRF 44	Yes	Serotec
		LM11	No	Chemicon
β2		MHM 23	Yes	Dako
αV	VN/FN/FG/TSP	69-6-5	Yes	Beckman Coulter
		P3G8	No	Chemicon
β3		SZ21	Yes	Beckman Coulter
		PM6/13	No	Serotec
β4		ASC-3	Yes	Chemicon
		450-90	No	Serotec
β5		P1F6	Yes	Life Technologies

[a]Note that β1 associates with α1-α9, β2 associates with αL and αM, β1, β3, and β5 associate with αV, and β4 associates with α6; β2 integrins are expressed only on leukocytes, but most other integrins are widely expressed.

[b]Abbreviations: COL, collagen; FG, fibrinogen; FN, fibronectin; ICAM, intercellular adhesion molecule; LN, laminin; TN, tenascin, TSP, thrombospondin; VCAM, vascular cell adhesion molecule; VN, vitronectin.

[c]All mAbs, with the exception of GoH3, mAb 16, 69-6-5, and mAb 13, are mouse anti-human. GoH3, mAb 16, 69-6-5 and mAb 13 are rat anti-human. See above list of suppliers for antibodies to other species. Antibodies should be stored in small aliquots at −70°C.

[d]Available by Materials Transfer Agreement from K.M. Yamada, National Institutes of Health.

3b. *For cell attachment assay:* Mix an aliquot of the cell suspension with an equal volume of DPBS containing the inhibitor at twice the final concentration. Incubate 15 to 30 min at 37°C. Remove BSA solution from the 96-well plate, wash the wells with 100 µl DPBS, and add 100 µl of the cell/inhibitor mixture to each well.

In the authors' experience, a final mAb concentration of 10 µg/ml, or 1:500 dilution of ascites, gives a maximal inhibitory effect. However, the concentration of mAb to achieve a maximal level of inhibition should be tested using a range of mAb concentrations. An important consideration is that the mAbs should be azide-free. Many commercially available mAbs contain sodium azide as a preservative. This is toxic to all cells and will inhibit attachment and spreading. Therefore it is essential that the sodium azide be removed by dialysis into an appropriate buffer such as DPBS.

Peptides can be used in place of mAbs to analyze the contribution of integrins to cell adhesion. However, these are generally less useful than mAbs because only for a small number of integrins have specific inhibitor peptides been described. Examples are CS1 (DELPQLVTLPHPNLHGPEILDVPST) for α4β1 and α4β7, GACRRETAWACGA for α5β1, and KQGADV for αIIbβ3. RGD peptides (e.g., GRGDS) are of broad specificity and inhibit α5β1, αIIbβ3, and all αV integrins. However, RGD peptides may be useful as a "first screen" to determine if receptors of this class are important for adhesion, or alternatively to confirm their involvement if cell adhesion is inhibited by, for example, mAbs to α5 or αV. Concentrations of peptides required to inhibit cell adhesion are generally higher than for mAbs: typically 0.1 to 1 mg/ml. Higher concentrations are normally required for inhibiting cell attachment than for inhibiting cell spreading. GRGDS, KQGADV, and CS1 peptides are available from Bachem.

4. Incubate, fix, and analyze for spreading assay (see *UNIT 9.1*, Basic Protocol 1, step 8 to 13) or for attachment assay (see *UNIT 9.1*, Basic Protocol 2, steps 8 to 18).

It is essential that the effect of each mAb on cell attachment or spreading be compared with appropriate controls. The best controls to use are mAbs that are noninhibitory against the integrins under test—e.g., K20 for β1 (see Table 9.4.1). However, if these are not available, the following controls can be used: (1) wells to which no mAbs are added (DPBS only); (2) nonimmune mouse or rat IgG or ascites; (3) irrelevant isotype-matched mAb controls. Control peptides (e.g., GRGES) should be used in parallel with the authentic peptides to exclude any toxic or nonspecific effects.

If a partial inhibitory effect is observed with several different anti-integrin mAbs, the assay can be repeated using two or more mAbs in combination to analyze the relative contribution of each integrin to cell adhesion.

ANALYZING INTEGRIN-LIGAND INTERACTIONS IN SOLID-PHASE ASSAYS

BASIC PROTOCOL 2

This protocol describes a simple integrin-ligand binding assay in which the integrin is adsorbed to the wells of an ELISA plate. The plate is blocked using BSA (to reduce nonspecific binding of the ligand) and then biotin-labeled ligand is added. After washing to remove unbound ligand, bound ligand is detected by addition of an avidin-peroxidase conjugate followed by a colorimetric detection step. An example of an application of this procedure would be use of biotinylated fibronectin or fibronectin fragments as ligands for the integrin α5β1.

Materials

Purified integrin (see Support Protocol 1)
Dulbecco's phosphate-buffered saline (DPBS, Life Technologies; also see *APPENDIX 2A*)
Blocking solution (see recipe)
Biotin-labeled ligand (see Support Protocol 3)
Binding buffer (see recipe)

ExtrAvidin peroxidase reagent (Sigma)
ABTS reagent (see recipe)
2% (w/v) SDS in water (*APPENDIX 2A*)

ELISA plate (e.g., Immulon 1B or 4HBX; Dynex Technologies)
Plastic film (e.g., Nescofilm, Parafilm, Saran wrap)
Multichannel pipettor
21-G hypodermic needle
Side-arm flask
Microtiter plate reader

Coat ELISA plate with integrin

1. Dilute purified integrin to ~1 μg/ml with DPBS.

   At least a 50-fold dilution is required, otherwise the detergent present in the purified integrin interferes with adsorption to the plate.

2. Add the diluted integrin to the wells of an ELISA plate (100 μl/well). Leave a set of wells empty for measuring binding of the ligand to BSA.

   The authors normally perform the assay using 4 to 6 replicates for each sample.

   Immulon 1B and 4 HBX ELISA plates (Dynex) are suitable. More recently, the authors have found that one-half area EIA/RIA plates (Costar) also work well, and have the advantage that similar results can be obtained with half as much integrin (i.e., 50 μl/well)

3. Wrap the plate in plastic film and store overnight at room temperature.

   Alternatively, the plate can be stored for up to 1 week at 4°C.

Block the ELISA plate

4. Add 25 μl blocking solution to each integrin-containing well using a multichannel pipettor, then remove the solution by aspiration using a 21-G hypodermic needle attached by tubing to a side-arm flask connected to a vacuum source, or by inverting the plate over a sink and flicking out the liquid.

   A small amount of blocking solution is added to the wells before aspirating the integrin solution because the authors have found that this renders the wells hydrophilic and prevents them from drying out when they are aspirated. Drying out of the wells destroys the activity of some of the integrin.

5. Add 200 μl blocking solution to each well (including those used for testing binding to BSA alone) using a multichannel pipettor. Leave the plate at room temperature for 1 to 3 hr, then aspirate or flick out the blocking solution.

6. Add 200 μl of binding buffer to each well using a multichannel pipettor. Remove the buffer by aspirating or flicking it out. Repeat two times.

7. Remove residual liquid by inverting the plate and striking it hard several times onto adsorbent paper towels.

Add biotin-labeled ligand

8. Dilute the biotin-labeled ligand in binding buffer to the appropriate concentration. Add 100 μl of this solution to each experimental well.

   The appropriate concentration must be determined by pilot experiments. A concentration of 0.1 μg/ml works well for biotinylated 80-kD fragment of fibronectin (Mould et al., 1995a).

   Other reagents (e.g., mAbs, peptides, or synthetic compounds) can be added simultaneously with the ligand at this stage to test for their effects on ligand binding.

9. Cover the plate with plastic film and incubate 3 hr at 37°C.

   A cell culture incubator is suitable for this incubation.

10. Aspirate solutions from the wells to remove unbound ligand.

11. Wash wells three times with 200 µl binding buffer (see step 6). Remove the residual buffer (see step 7).

Detect bound biotin-labeled ligand

12. Dilute ExtrAvidin-peroxidase reagent 1:500 in binding buffer. Add 100 µl of the diluted ExtrAvidin-peroxidase reagent to each well using a repeating pipettor. Incubate the plate 10 to 15 min at room temperature. During this time prepare the ABTS reagent.

13. Aspirate solutions from wells to remove unbound ExtrAvidin peroxidase reagent.

14. Wash wells two times with 200 µl of binding buffer and then two times with 400 µl of binding buffer. Remove the residual buffer (see step 7).

15. Add 100 µl of ABTS reagent to each well using a repeating pipettor. Allow the reaction to proceed until a strong (but not dark) green color is obtained (typically 10 to 30 min).

16. Stop the reaction by adding 100 µl of 2% SDS solution to each well using a repeating pipettor.

17. Read the plate using an automatic microtiter plate reader at 405 nm.

18. Calculate the mean and standard deviation of the absorbance readings for ligand binding to integrin, and for ligand binding to BSA alone, using the following equations.

$$\text{net binding to integrin} = (\text{mean of absorbance readings for ligand binding to integrin}) - (\text{mean of absorbance readings for ligand binding to BSA alone})$$

$$\text{standard deviation of net binding} = \sqrt{(\text{standard deviation of absorbance readings for ligand binding to integrin})^2 + (\text{standard deviation of absorbance readings for ligand binding to BSA alone})^2}$$

INTEGRIN PURIFICATION

SUPPORT PROTOCOL 1

This protocol describes the affinity purification of the integrin α5β1 from human placenta using anti-β1 and anti-α5 mAbs. The procedure can be adapted to purify other integrins from different tissue sources or from pellets of cultured cells. If one is starting from cultured cells, typically enough cells should be used to give at least 10 ml of packed cells, and the volumes of reagents and resins should be scaled down 2- to 4-fold.

Materials

Human placenta (from maternity unit of local hospital; process within a few hours of delivery)
Homogenization buffer (see recipe)
1% (w/v) Virkon (Merck) in water

Extraction buffer (see recipe), 4°C
Sepharose 4B resin (Sigma)
Rat IgG–Sepharose resin (see Support Protocol 2)
mAb 13 (anti-β1)–Sepharose and mAb 16 (anti-α5)–Sepharose (see Support Protocol 2)
Wash buffer (see recipe), 4°C
Elution buffer (see recipe), 4°C
1 M Tris·Cl, pH 8.2 (*APPENDIX 2A*; store up to 6 months at 4°C), 4°C
0.1 M Tris·Cl, pH 8.3 (*APPENDIX 2A*)/0.1% (w/v) Triton X-100 (Ultra grade, Sigma), 4°C (store up to 3 months at 4°C)
Phosphate-buffered saline (PBS; prepare using 10× stock solution from Life Technologies) containing 0.05% (w/v) sodium azide (add from 20% w/v sodium azide stock in H_2O)
PBS (Life Technologies)
5× SDS-PAGE sample buffer (see recipe)
6% SDS-PAGE gel (*UNIT 6.1*)

Large scissors
Blender
Beckman J6-B centrifuge with JA-10 and JA-20 rotors (or equivalent refrigerated centrifuge)
500-ml polycarbonate centrifuge bottles (Nalgene)
50-ml polyallomer centrifuge tubes (Nalgene)
Econo-Pac 20-ml disposable polypropylene columns (Bio-Rad)
50-ml screw-top polypropylene tubes (Becton Dickinson Labware)
Rotating platform (Cole-Parmer)
1.6 × 20–cm C16 column (Amersham Pharmacia Biotech)
Peristaltic pump
Fraction collector
0.8-cm diameter Poly-Prep 2-ml disposable polypropylene column (Bio-Rad)

Additional reagents and equipment for SDS-PAGE and staining of gels (*UNIT 6.1*)

CAUTION: Human placenta should be treated as potentially biohazardous; take suitable precautions such as wearing latex gloves, eye protection, and a lab coat. The homogenization should be performed in a primary cell culture cabinet and any spillage of homogenate or extract should be treated with 1% Virkon. Centrifuge bottles and tubes should be soaked in 1% Virkon after use.

Homogenize placenta

1. Cut the placenta (minus umbilical cord and amniotic membranes) into small chunks using large scissors, and place the pieces in a blender with ~500 ml of cold homogenization buffer. Homogenize the placenta using a moderate speed for ~1 min. Pour the homogenate into 500-ml polycarbonate centrifuge bottles and store at −70°C until required (up to 2 years).

   One placenta yields ~1 liter of homogenate. Commercially available laboratory homogenizers may be used, but a robust domestic blender is adequate for this purpose.

Extract the homogenate

2. Thaw the homogenate in a cold room (preferable) or at room temperature overnight.

   Perform all subsequent operations at 4°C where possible.

3. Centrifuge the homogenate 10 min at 4400 × *g* (5000 rpm in a JA-10 rotor), 4°C. Discard the supernatant into a bucket containing 5 liters of 1% Virkon, and resuspend

the pellets in 600 ml of homogenization buffer. Centrifuge again under the same conditions and discard the supernatant as described.

Most of the soluble proteins have been removed at this stage. The next step uses detergent (Triton X-100) to solubilize proteins (including integrins) from cell membranes. The extraction buffer contains protease inhibitors and BSA to minimize proteolytic degradation of the integrins.

4. Extract pellet by adding 400 ml extraction buffer to the centrifuge bottle and keeping on ice for ~1 hr, shaking vigorously every few minutes to ensure that the pellets are fully resuspended.

   The extract obtained will be red in color because not all of the hemoglobin has been removed in step 3.

5. Centrifuge the extract 10 min at 6400 × *g* (6000 rpm in a JA-10 rotor), 4°C. Pipet the supernatant into 50-ml centrifuge tubes, then centrifuge 30 min at 48,000 × *g* (20,000 rpm in a JA-20 rotor), 4°C.

Purify the β1 integrins

6. Pack a 20-ml disposable column with 4 ml of Sepharose 4B by pouring 8 ml of a 50% suspension of Sepharose 4B into the column. Preclear and filter the supernatant from step 5 by passing it through the column and collecting the flowthrough.

   Several columns can be used simultaneously to speed up this step.

7. Mix the flowthrough with 8 ml of a 50% suspension of rat IgG–Sepharose in screw-top 50-ml polypropylene centrifuge tubes and agitate for 2 hr on a rotating platform. Remove the rat IgG–Sepharose by pouring through 20-ml disposable columns (filtration is accomplished by the fritted disc at the bottom of the column).

   This step removes proteins that bind to rat IgG. If a murine mAb is being used in the subsequent purification steps mouse IgG–Sepharose should be used in place of rat IgG–Sepharose. The authors normally discard the rat IgG–Sepharose at this stage.

8. Mix the flowthrough from step 7 with 8 ml of mAb 13–Sepharose in 50-ml polypropylene tubes and agitate for 2 hr on a rotating platform. Recover the mAb 13–Sepharose by pouring through a 20-ml disposable column. Retain the flowthrough and store at 4°C.

9. Resuspend the mAb 13-Sepharose in wash buffer, pack the suspension into a 1.6 × 20–cm C16 column, and wash the column overnight at ~10 ml per hr with wash buffer, delivered via a peristaltic pump.

10. Elute integrin by passing elution buffer through the column at 45 ml/hr for 30 min. During this time collect 2-min (1.5-ml) fractions (using a fraction collector) into tubes to which 0.5 ml of 1 M Tris·Cl, pH 8.2, has been added. Mix the fractions with this buffer as they elute from the column to ensure prompt neutralization. Store fractions at 4°C.

11. Neutralize the column immediately with 20 ml of 0.1 M Tris·Cl (pH 8.3)/0.1% Triton X-100 at a flow rate of 45 ml/hr. Reequilibrate the column with PBS/0.05% sodium azide and store the mAb 13–Sepharose (removed from the column) at 4°C.

    Because of the low pH used to elute the integrin, the mAb 13–Sepharose gradually deteriorates in its capacity for integrin purification. However, in our experience the column can be reused about ten times before replacement is necessary.

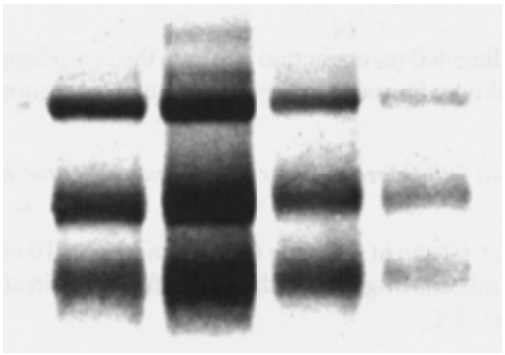

Figure 9.4.1 SDS-polyacrylamide gel of sequential fractions from low-pH elution of mAb 13 column. The major bands observed are (from top) α1 subunit, other α subunits, and β1 subunit. The migration positions of molecular weight standards are indicated (in kDa).

Analyze the purified β1 integrins

12. To 25-µl aliquots of the fractions, add 25 µl 1× PBS and 12.5 µl of 5× SDS-PAGE sample buffer to each aliquot. Heat the samples in a boiling water bath for 3 min and run on a 6% SDS-polyacrylamide gel (*UNIT 6.1*).

13. Stain the gel with Coomassie blue for 1 hr (*UNIT 6.1*). Destain the gel and check for elution of integrin. A typical elution profile is shown in Figure 9.4.1.

The flowthrough from step 8 can be reapplied to the mAb 13–Sepharose, after any precipitate has been removed by centrifuging for 10 min at 4400 × g (5000 rpm in a JA-10 rotor), 4°C (follow step 8 onwards; elute and neutralize the column before chromatographing the flowthrough a second time, then pool the β1 integrin fractions; repeat until the yield of β1 integrins is markedly lower than from the first purification). In the authors' experience, the mAb 13 purification step needs to be repeated several times before all the β1 integrins have been depleted from the extract.

Purify the integrin α5β1

14. Pool the fractions from step 10 that contain the purified β1 integrin. Centrifuge the pooled fractions 10 min at 48,000 × *g* (20,000 rpm in a JA-20 rotor), 4°C. Mix the supernatant with 2 ml of mAb 16–Sepharose for 2 hr on a rotating platform. Pack the suspension into a 0.8-cm diameter 0.8-cm diameter Poly-Prep 2-ml disposable column and wash with 12 ml of wash buffer.

15. Elute α5β1 with 5 ml of elution buffer, added in 0.4-ml aliquots. Collect 0.4-ml fractions in 1.5-ml microcentrifuge tubes containing 0.1 ml of 1 M Tris·Cl, pH 8.2. Mix the fractions with this buffer as they elute from column to ensure prompt neutralization. Store fractions up to 2 years at −70°C.

16. Neutralize the column with 5 ml of 0.1 M Tris·Cl (pH 8.3)/0.1% (w/v) Triton X-100. Re-equilibrate the column with PBS/0.05% sodium azide and store the mAb 16–Sepharose at 4°C.

Analyze the purified α5β1

17. Analyze 25-µl aliquots of the fractions by SDS-PAGE as described in steps 12 and 13.

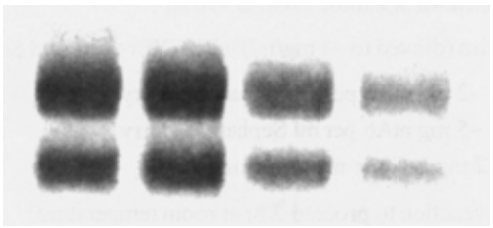

Figure 9.4.2 SDS-polyacrylamide gel of sequential fractions from low-pH elution of mAb 16 column. The major bands observed are (from top) α5 subunit and β1 subunit. The migration positions of molecular weight standards are indicated (in kDa).

The major bands detected by Coomassie blue staining should be those corresponding to expected positions of the α5 and β1 subunits (Fig. 9.4.2). The molecular weights are ~150 kDa for α5 and ~130 kDa for β1.

COUPLING OF ANTIBODIES TO SEPHAROSE

SUPPORT PROTOCOL 2

Suitable mAbs for purification may be available in-house or can be generated using published protocols (e.g., Akiyama et al., 1989). Some anti-integrin hybridomas are available from cell culture collections (e.g., ATCC). The authors have found that the anti-β1 mAb 13 and the anti-α5 mAb 16 are particularly suitable for affinity purification of α5β1. Both mAbs are available from K.M. Yamada, National Institutes of Health.

Materials

Antibodies/IgG to be coupled: anti-β1 and anti-α5 mAbs (e.g., mAb 13 and mAb 16) and rat IgG (Sigma)
Coupling buffer: 0.5 M NaCl/0.1 M $NaHCO_3$ (store up to 6 months at room temperature)
CNBr-activated Sepharose (Sigma)
1 mM HCl
1 M ethanolamine in H_2O (store up to 6 months at room temperature)
Acetate wash buffer: 0.1 M sodium acetate, pH 4 (adjust with glacial acetic acid)/0.5 M NaCl (store up to 6 months at room temperature)
Tris wash buffer: 0.1 M Tris·Cl, pH 8 (*APPENDIX 2A*)/0.5 M NaCl (store up to 6 months at room temperature)
Phosphate-buffered saline (PBS; prepare using 10× stock solution from Life Technologies) containing 0.05% (w/v) sodium azide (add from 20% sodium azide stock solution in H_2O)
PBS (Life Technologies)

Buchner funnel with medium-porosity fritted-glass disc
Conical flask with side arm
50-ml screw-top polypropylene centrifuge tubes
Rotating platform (Cole-Parmer)

Additional reagents and equipment for dialysis (*APPENDIX 3*)

1. Dialyze the antibodies (if necessary) into an amine-free buffer (e.g., PBS or coupling buffer). Measure the absorbance of an aliquot of the dialyzed mAb at 280 nm. Dilute or concentrate antibodies to ~1 mg/ml

   Dialysis is only necessary where the mAb is supplied in amine-containing buffer (e.g., Tris).

2. Pre-swell the CNBr-activated Sepharose in ~50 ml of 1 mM HCl. Wash with ~200 ml of 1 mM HCl per ml of resin in a Buchner funnel. Prepare a 50% resin slurry in PBS.

   3 g of CNBr-activated Sepharose swells to ~10 ml.

3. Mix the antibodies (diluted to ~1 mg/ml) with CNBr-activated Sepharose as follows.

   a. *For mAb 13:* ~2 mg mAb per ml Sepharose slurry
   b. *For mAb 16:* ~5 mg mAb per ml Sepharose slurry
   c. *For rat IgG:* 2 mg IgG per ml Sepharose slurry.

   Allow coupling reaction to proceed 2 hr at room temperature.

4. Following the coupling reaction, add the mixture to a Buchner funnel attached to a conical flask with side arm and remove the supernatant by vacuum filtration. Determine the absorbance at 280 nm for an aliquot of the recovered supernatant and compare to the starting value according to the following equation, where D is the dilution factor (total volume divided by volume of starting solution).

$$\text{coupling efficiency} = \left(1 - \frac{A_{280} \text{ of filtrate} \times D}{A_{280} \text{ of starting solution}}\right) \times 100\%$$

   Typical coupling efficiencies are 95% to 99%.

5. Wash the Sepharose in the Buchner funnel with 20 ml of coupling buffer and remove all buffer under suction. Remove the Sepharose from the funnel using a spatula, place it in a 50-ml conical polypropylene centrifuge tube with 20 ml of 1 M ethanolamine, and incubate 1 hr at room temperature on a rotating platform

   The buffer for washing may be added in several aliquots if the capacity of the funnel is low.

6. Return the Sepharose to the Buchner funnel and wash with three alternating applications, 50 ml each, of acetate wash buffer and Tris wash buffer.

7. Wash the Sepharose with 20 ml of PBS and store in PBS/0.05% sodium azide at 4°C.

   The buffer for washing may be added in several aliquots if the capacity of the funnel is low.

SUPPORT PROTOCOL 3

BIOTINYLATION OF INTEGRIN LIGANDS

This protocol describes labeling of ligands for in vitro integrin-binding assays (see Basic Protocol 2). Biotin is covalently conjugated to amino groups on the ligand to permit quantification of bound ligand.

Materials

Ligand of interest
Coupling buffer 0.5 M NaCl/0.1 M $NaHCO_3$ (store up to 6 months at room temperature)
Sulfo-NHS Biotin (Pierce)
Tris/saline: 25 mM Tris·Cl (pH 7.4)/150 mM NaCl

Tris/saline containing 0.05% sodium azide
Rotating platform (Cole-Parmer)

Additional reagents and equipment for dialysis (*APPENDIX 3*) and protein assay (*APPENDIX 3*)

1. Dialyze ligand into 1 liter of coupling buffer (*APPENDIX 3*) for at least 2 hr at room temperature.

   About 0.5 ml of ligand at a concentration of ~0.5 mg/ml gives sufficient material for a large number of assays.

2. Add an equal mass of sulfo-NHS-biotin (~0.25 mg) to the dialysate in a 1.5-ml microcentrifuge tube and mix on a rotating platform 30 min at room temperature.

   For some proteins, sulfo-NHS-LC-biotin (Pierce) gives higher signals than sulfo-NHS-biotin in the solid phase assay.

3. Dialyze the solution against two changes of 1 liter Tris/saline, and once against 1 liter of Tris/saline, 0.05% azide (at least 2 hr per dialysis) at room temperature.

4. Microcentrifuge the dialysate for 15 min in a 1.5-ml microcentrifuge tube at maximum speed, room temperature.

   This removes any large aggregates or precipitate from the solution.

5. Measure the concentration of biotinylated protein in the supernatant using, for example, the BCA assay (*APPENDIX 3*). Store up to 6 months at 4°C.

   Alternatively, many biotinylated proteins can be stored in aliquots at −70°C. This procedure will typically provide sufficient material for >100 α5β1 fibronectin assays. How much material will be required for any assay will depend upon the affinity of the integrin-ligand interaction.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ABTS reagent

ABTS buffer:
0.05 M Na_2HPO_4
0.1 M sodium acetate
Adjust pH to 5.0 using concentrated HCl
Store up to 3 months at room temperature

ABTS reagent: Immediately before assay, dissolve 11 mg of 2,2′-azinobis(3-ethylbenzthiazoline)sulfonic acid (ABTS; Sigma) in 0.5 ml water. Mix 67 µl of 30% H_2O_2 with 7 ml water. Add 0.5 ml of this ABTS solution to 10 ml ABTS buffer (see above) and 100 µl H_2O_2 solution. Mix thoroughly.

This amount of reagent is sufficient for one full 96-well plate assay.

Binding buffer

Mix the following components in the order indicated:
150 mM NaCl
25 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
1 mM $MnCl_2$
0.1% (w/v) BSA (fraction V; Sigma, 99% pure)
Prepare fresh

This is conveniently prepared from Tris/saline [25 mM Tris·Cl (pH 7.4)/150 mM NaCl] and a stock solution of 1 M $MnCl_2$. BSA is then added.

Blocking solution

Prepare a solution of 25 mM Tris·Cl containing 150 mM NaCl. Add sufficient 20% sodium azide stock for a final concentration of 0.05% (w/v). Add BSA (fraction V; Sigma, 98% pure) for a final concentration of 5% (w/v) and dissolve by vigorous stirring. Centrifuge the solution in 50-ml centrifuge tubes for 5 min at 2800 × *g* (4000 rpm in a JA-10 rotor), and filter the supernatant through a 20-ml disposable column. Store up to 3 months at 4°C.

This is conveniently prepared from Tris-saline [25 mM Tris·Cl (pH 7.4)/150 mM NaCl] to which sodium azide is added from a 20% stock solution. BSA is then added and dissolved by vigorous stirring. The solution is then centrifuged and filtered as above. Final concentrations are 150 mM NaCl; 25 mM Tris·Cl, pH 7.4, 5% (w/v) BSA, and 0.05% (w/v) sodium azide.

Elution buffer

10 mM sodium acetate, pH 3.25
1 mM $CaCl_2$
1 mM $MgCl_2$
0.1% (w/v) Triton X-100 (Sigma, Ultra grade)
Store up to 1 month at 4°C

Extraction buffer

150 mM NaCl
25 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
2% (w/v) Triton X-100 (Sigma, Ultra grade)
1 mM PMSF (100 mM stock solution prepared in isopropanol; also see *APPENDIX 1B*)
10 µg/ml leupeptin (1 mg/ml stock solution prepared in water; also see *APPENDIX 1B*)
2 mg/ml BSA (fraction V; Sigma, 98% pure)
Prepare fresh, then cool on ice

Homogenization buffer

150 mM NaCl
25 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.005% (w/v) digitonin
Store for up to 3 months at 4°C

SDS-PAGE sample buffer, 5×

25% (v/v) glycerol
125 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
10% (w/v) SDS
0.1% (w/v) bromophenol blue
Store indefinitely at 4°C. Warm in a hot water bath and mix well before use.

Wash buffer

150 mM NaCl
25 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
1 mM $CaCl_2$ (add from 1 M stock)
1 mM $MgCl_2$ (add from 1 M stock)
0.1% (w/v) Triton X-100 (Sigma, Ultra grade)
Store up to 1 month at 4°C

This is conveniently prepared from Tris-saline [25 mM Tris·Cl (pH 7.4)/150 mM NaCl] and stock solutions of 1 M $CaCl_2$ and 1 M $MgCl_2$.

COMMENTARY

Background Information

Monoclonal antibodies were of crucial importance in the initial identification of cell surface receptors that mediated adhesion of cells to extracellular matrix components (e.g., Wayner and Carter, 1987). A wide range of well characterized anti-integrin mAbs are now commercially available for use in cell attachment and spreading assays. The choice of which anti-integrin mAbs to use is determined in part by the substrate. For example, if collagen type I is the substrate, anti-α1 and anti-α2 mAbs should be tested, as these are the likely integrins involved. The complement of integrins expressed by the cell also helps to determine which mAbs should be tested. If the profile of integrin expression is unknown, it can be determined by flow cytometry or by immunoprecipitation of surface-labeled cells. Conversely, if a mAb blocks cell adhesion, it is important to demonstrate that the corresponding integrin subunit is expressed by the cells.

Historically, the first purification of an integrin receptor was a major advance in understanding the molecular basis of cell-matrix interactions (Pytela et al., 1985). This and later methods employed a ligand affinity column as the major purification procedure. In particular, fibronectin fragments have been used to purify α5β1, and RGD peptides have been used to purify αVβ3 and αIIbβ3 (Pytela et al., 1987; Smith and Cheresh, 1988; Yamada and Yamada, 1990). Ligand affinity columns remain the method of choice where mAbs are unavailable. However, the use of mAbs has the advantage that the purification is more specific (e.g., several different integrins bind to fibronectin affinity columns) and higher yields of integrins can be obtained. Multiple β1 integrins can also be obtained from the same source. For example, other β1 integrins from human placenta that are present in the flowthrough from the mAb 16 column can be purified using other specific anti-α mAbs. For some assays, and particularly where one β1 integrin predominates in the tissue or cell extract, it may be sufficient to purify the total β1 integrins and use this partially purified preparation in the solid-phase assay. For example, β1 integrins purified from MOLT-4 cells (Newham et al., 1998) contain ~75% α4β1, the remainder being α5β1. The protocol described here can be adapted to purify other integrins from other tissues or from pellets of cultured cells.

The major advantage of assays using purified integrins, as compared to cell-based assays, is that integrin-ligand binding can be studied in isolation. Integrin clustering, signaling, and cytoskeletal interactions are all known to affect the strength of adhesion in cell-based assays. Furthermore, adhesion may be modulated by indirect effects (e.g., by signaling from other cell-surface receptors). Although doubts are often expressed as to whether plastic-adsorbed integrin is representative of integrin in its native environment, a number of careful studies have shown no significant differences between the behavior of integrins in solid-phase assays and on cell surfaces. Hence, this approach has been broadly validated. The first solid-phase integrin-ligand binding assay was described by Charo et al. (1991) for studying fibrinogen binding to αIIbβ3. The α5β1-fibronectin assay developed by the author of this unit is both extremely sensitive and highly versatile. For example, the author has described how the assay can be used to investigate the effects on ligand binding of divalent cations, activating and inhibitory mAbs, peptide inhibitors, and mutations (Mould et al., 1995a,b, 1996, 1997). Another important area in which this type of assay is finding use is in the pharmacological screening of inhibitors of integrin-ligand interactions. This assay can give information about the inhibitory potency of a compound and whether it is a direct competitive or allosteric inhibitor of ligand binding. The attenuation of mAb epitopes can also provide data on the location of the binding site of an inhibitor on the integrin (Mould et al., 1997).

The author's preferred method for labeling of integrin ligands is biotinylation, because of its safety and simplicity. One potential drawback is that if one or more lysyl residues in the ligand are crucial for integrin binding, their modification may render the ligand inactive. In this case, a possible solution may be to reduce the amount of biotinylation reagent so that some of the lysyl residues remain unmodified. Other labeling methods such as radioiodination can also be used. Alternatively, if the ligand is a recombinant protein, a "tag" such as an epitope sequence or the Fc region of IgG can be incorporated for use in the detection of bound ligand.

Table 9.4.2 Troubleshooting Guide for Problems Encountered in Solid-Phase Assays

Problem	Possible cause	Solution
High background binding to BSA-coated wells	Insufficient blocking of wells Ligand concentration too high	Block for longer time (e.g., overnight) Test range of ligand concentrations for optimal signal/background
Spuriously high signal in some wells	Insufficient washing Tops of wells contaminated	Follow washing protocol carefully Add reagents to the center of wells
Wide variation in signal in experimental wells	Integrin added to plate insufficiently mixed Wells aspirated before adding blocking reagent Plate contaminated, e.g., by dust	Mix diluted integrin thoroughly before coating the plate Add blocking reagent before removing coating solution Use fresh, clean plates
Low signal above background binding to BSA	Insufficient integrin Ligand concentration too low Inactive ligand	Use lower dilution of integrin Use higher concentration of ligand Check activity of ligand in cell-based assay

Critical Parameters and Troubleshooting

For cell-based assays, as described in *UNIT 9.1*, the health of the cells and careful preparation are important for achieving optimal spreading or attachment. In order to optimize the sensitivity of cell attachment or spreading to inhibition, the author recommends that a concentration of substrate be chosen that gives 50% to 70% of maximal adhesion (unless this value is low, in which case a concentration of substrate that gives near maximal adhesion should be used). If the level of adhesion is near maximal, inhibitors are less effective at blocking adhesion.

Failure of a mAb to inhibit spreading or attachment can normally be taken to mean that the integrin it recognizes is not involved in adhesion. However, it is important to check that the antibody is effective in a system where inhibition should be observed (e.g., an anti-α5 mAb should block spreading of HT-1080 fibrosarcoma cells on fibronectin). Conversely, if an antibody does inhibit, it is important to test that it does not inhibit adhesion to an inappropriate ligand (e.g., an anti-α5 mAb should not perturb HT-1080 cell spreading on collagen). Most of the antibodies described in Table 9.4.1 are well characterized and should not show any non-specific effects. However, as described earlier, it is essential that the antibodies not contain sodium azide.

It is also important to bear in mind that inhibition of adhesion can be caused by "cross-talk"—i.e., where ligation of one integrin (e.g., by peptide) indirectly affects the activity of a second integrin via intracellular signaling (Diaz-Gonzalez et al., 1996). While it is often difficult to rule out such effects, they normally only cause a partial reduction in adhesion, whereas adhesion is frequently totally ablated by specific antibody or peptide inhibition. Finally, if anti-integrin mAbs or peptides do not completely block cell adhesion, it is possible that non-integrin receptors may play some role. This may be observed particularly in cell attachment assays. For example, cell-surface proteoglycans contribute to melanoma cell attachment to the heparin-binding domain of fibronectin (Mould et al., 1994).

For solid-phase assays, the specificity of the assay must be tested carefully. The most important test for specificity is the ability of unlabeled ligand to compete with labeled ligand for binding to the integrin. Hence, in the presence of a large excess of unlabeled ligand, very little binding of labeled ligand should be observed. Nearly all integrin-ligand interactions are divalent-cation dependent. Hence, replacing the Mn^{2+} in the binding buffer with EDTA should reduce binding to levels similar to that observed for BSA-coated wells. Further tests for specificity can be carried out. For example: (1) mAbs that are inhibitory in cell-based assays should also inhibit ligand binding in solid-phase assays, (2) mutations known to affect integrin binding sites should perturb ligand recognition, and (3) known ligand mimetics (e.g., RGD peptides for α5β1 or CS1 peptide for α4β1) should block ligand binding. All of these tests have been performed for the α5β1-fibronectin

Table 9.4.3 Troubleshooting Guide for Problems Encountered in Integrin Purification

Problem	Possible cause	Solution
Large number of proteins copurify with integrins	Inadequate preclearing or filtration of extract, or precipitate forms during purification procedures	Recentrifuge after preclearing and filtering extract on Sepharose 4B, or when any precipitate is visible
Small amounts of integrins purified	Insufficient mAb coupled to Sepharose Affinity of mAb too low Column has been used many times	Couple more mAb to Sepharose Use mAb with higher affinity Replace with fresh mAb-Sepharose
Integrin degraded	Insufficient levels of protease inhibitors in extraction buffer Extraction or other manipulations performed at too high a temperature	Increase levels of protease inhibitors and BSA in extraction buffer Perform all manipulations at 4°C or on ice

assay. Table 9.4.2 is a troubleshooting guide for solid-phase ligand-binding assays.

For integrin purification, it is essential to have sufficient tissue or cell pellets for the extraction and enough mAb-Sepharose to perform a successful purification. Table 9.4.3 is a troubleshooting guide for integrin purification.

Anticipated Results

For cell-based assays, in most cases, it is possible to obtain levels of spreading or attachment of >50%. It should be feasible using anti-integrin mAbs, either alone or in combination, to reduce the level of spreading or attachment to close to that seen on BSA.

For integrin purification, yields of α5β1 are ~2 mg per placenta (estimated by Coomassie blue staining). Each full 96-well-plate solid-phase assay uses <10 µg of integrin. Hence, this is enough to perform a large number (~200) of solid-phase assays. In these assays, a strong positive signal (OD_{405} ~1) is normally achieved in ≤30 min, whereas background binding to BSA is generally very low (OD_{405} ~0.1).

Time Considerations

Cell attachment and spreading assays are quick to perform. The actual assays can be carried out in about half a day or less; however, particularly if many different mAbs or peptides are being tested, quantification of spreading assays can take several hours.

Purification of α5β1 from placenta takes ~3 days in total. Allow an additional day for preparation of buffers and mAb-Sepharose. The solid-phase assay can be performed in 5 to 8 hr but only requires 1 to 2 hr of hands-on time. However, the assay needs to be planned in advance so that the appropriate number of wells can be coated with integrin overnight. Plates can be coated with integrin several days in advance.

Analysis of Cell-Cell Contact Mediated by Ig Superfamily Cell Adhesion Molecules

The calcium-independent cell adhesion molecules (CAMs) constitute a large family of cell surface molecules. A major group among these are the immunoglobulin superfamily (IgSF) molecules. IgSF-CAMs may be composed of immunoglobulin (Ig) folds only, Ig folds linked to fibronectin type III (FnIII) folds, or Ig folds linked to protein modules other than FnIII folds. The IgSF is a large protein superfamily comprising >100 proteins involved in cell-cell adhesion. Its members are found in vertebrates, invertebrates, and also in yeast. Most of the molecules of the IgSF are cell surface molecules that are membrane-anchored either by a single transmembrane segment or by a glycosylphosphatidylinositol (GPI) anchor that is posttranslationally attached to the C-terminus. Some of the IgSF-CAMs also occur in soluble form, e.g., in the cerebrospinal fluid or the vitreous fluid of the eye, due to a cleavage of the GPI-anchor or the membrane-proximal peptide segment. In some cases, such as NCAM, various forms may be generated by alternative splicing.

This unit provides protocols for the purification of IgSF-CAMs from tissue extracts and tissue culture supernatants and for the analysis of the adhesive functions of IgSF-CAMs with isolated molecules and in the cellular context. Following personal expertise, the authors have added a few frequently used functional assays demonstrating the role of IgSF-CAMs in neural development, such as neurite outgrowth from cultured neurons, and the use of antibodies for the inhibition of IgSF-CAM functions in vitro. The first group of protocols describe affinity purification of IgSF-CAMs (see Basic Protocol 1), preparation of the affinity column (see Support Protocol 1), solubilization of membrane proteins (see Support Protocol 2), transient transfection of HEK 293 cells to express IgSF-CAMs (see Support Protocol 3), and detection of IgSF-CAMs by dot blot analysis (see Support Protocol 4). Assays using fluorescent microspheres with coupled proteins are used for one type of functional analysis based either on interactions between microspheres (see Basic Protocol 2) or on interactions between microspheres and cultured cells (see Basic Protocol 3). There are two protocols for coupling proteins to microspheres: coupling proteins to fluorescent microspheres (see Support Protocol 5) and coupling proteins to glutaraldehyde-activated amino beads (see Support Protocol 6). A second group of protocols analyze the functions in cell-based assays. *Trans*-interactions are studied using IgSF-CAM-transfected myeloma cells (see Basic Protocol 4). This protocol requires stable transfection of myeloma cells (see Support Protocol 7). *Cis*-interactions are detected by chemical cross-linking (see Basic Protocol 5) and antibody co-capping (see Basic Protocol 6). IgSF-CAMs and other substrates have the ability to promote neurite outgrowth (see Basic Protocol 7), which requires coating of the growth surface with IgSF-CAM (see Support Protocol 8), nitrocellulose as a binder for the substrate of interest (see Support Protocol 9), poly-D-lysine (see Support Protocol 10), collagen (see Support Protocol 11), or laminin (see Support Protocol 12). Differential fixation protocols are used for fluorescent immunohistochemistry samples (see Support Protocol 13) or for morphological analyses (see Support Protocol 14). Finally, there is a protocol for assessing the effect of inhibiting CAM-CAM interactions in vitro (see Basic Protocol 8).

BASIC PROTOCOL 1

Purification of IgSF-CAMs by Immunoaffinity Chromatography

The best method for the purification of native, functionally intact proteins is certainly the use of standard chromatography, such as ion exchange, hydrophobic interaction, and gel permeation columns. However, the establishment of such a standard purification protocol can be time-consuming and requires expensive equipment. As the specific characteristics exploited for chromatography differ from protein to protein, purification protocols cannot be generalized. A faster and less expensive way to purify IgSF-CAMs is to use affinity chromatography. Tissue homogenates, body fluids in the case of secreted proteins, or cell lines engineered to express a particular protein of interest, either transiently or stably, can be used as a source for IgSF-CAM purification. Affinity chromatography makes use of the specific binding properties of the proteins, e.g., receptors for their ligands, enzymes for their substrates, or antibodies for their antigens. For IgSF-CAMs, the purification by immunoaffinity is most commonly used. A disadvantage of affinity purification is the possibility of the loss of activity, as the protein is sometimes eluted from the column by rather harsh conditions. The protocol described below has been successfully used for the purification of functionally intact IgSF-CAMs (Stoeckli et al., 1991, 1996; Rader et al., 1993).

The general principle of immunoaffinity chromatography is the use of a resin-coupled monoclonal antibody directed against the protein to be purified. Generally, activated Sepharose resins are used. The resin is packed into a column connected to a peristaltic pump and to a UV-detector to monitor the elution profile of the column. The purity of the eluted protein is analyzed by SDS-PAGE (*UNIT 6.1*). Here, we describe a purification protocol for a membrane-bound IgSF from brain membranes (see Support Protocol 2 for membrane preparation and protein solubilization).

Materials

CNBr-activated Sepharose 4B column (see Support Protocol 1)
Loading buffer: 0.5% CHAPS in PBS with Ca^{2+}/Mg^{2+}
Elution buffer: 0.5% CHAPS in 50 mM diethylamine
Protein solution (see Support Protocol 2)
1 M Tris·Cl, pH 7.0 (*APPENDIX 2A*)
PBS with Ca^{2+}/Mg^{2+} (see recipe)
0.02% (v/v) merthiolate or equivalent bacteriostatic agent

Prepare column

1. Rinse the column extensively with loading buffer, especially for a column that was prepared earlier and has been stored for a while. Add 2 to 3 vol (i.e., 3 times the volume of the column) of elution buffer to the column to test the stability of the column under the elution conditions and to make sure that the column does not contain any contaminations, such as unspecifically bound proteins from previous use of the column.

2. Properly reequilibrate the column to loading conditions before loading the protein solution (see Support Protocol 2 for protein solution preparation).

   As the binding affinity of antibodies is usually not temperature-sensitive, the authors recommend running the affinity column at 4°C rather than at room temperature. Keeping the column and the protein solution to be loaded at 4°C helps to prevent contamination and slows down degradation of the proteins.

Load the column

3. During loading of the protein solution onto the column, adjust the flow rate to a sufficiently slow rate (usually 0.1 ml/min is chosen for good yields) to allow good interaction between antigen and antibodies coupled to the sepharose beads.

   The capacity of the column can be tested by collecting fractions of the flow-through and subsequent immunoblot analysis (see Support Protocol 4). For best yield, the capacity of the column should not be exhausted. Typically, column volumes of 1 ml are used.

Elute column

4. Incubate the column in 0.9 vol elution buffer for 10 min.

   This will increase the elution efficiency (a higher concentration of the eluted protein in eluate, rather than a broad elution peak with a long tail). Do not expose the column to elution conditions for longer times than necessary, because the high pH of the buffer could be detrimental for the affinity column.

5. Elute the column at a rate of 1 ml/min. Collect the eluate in vials containing enough 1 M Tris·Cl, pH 7.0, to buffer the eluate at a neutral pH value.

   For a 1-ml column, 1-ml fractions are collected in 1.5-ml microcentrifuge tubes.

   The volume of 1 M Tris·Cl, pH 7.0, required for restoring the pH should be determined at 4°C, as the pH value of Tris is extremely temperature sensitive.

   The flow rate for elution can be much higher than that for loading. However, check the maximal flow rate acceptable for a specific resin. For Sepharose resins a maximal flow rate of 30 ml $hr^{-1}cm^{-2}$ is recommended.

   The eluate can be stored a few days at 4°C; for longer storage below −20°C is recommended. However, keep in mind that repeated thawing and freezing is detrimental to the protein. Furthermore, freezing of dilute protein solutions is not recommended.

6. Re-equilibrate the column to loading conditions for a second run, or prepare the column for storage.

Regenerate and store the affinity column

7. Immediately after elution re-equilibrate the column to neutral pH values with PBS with Ca^{2+}/Mg^{2+}. For storage, add 0.02% merthiolate or an equivalent bacteriostatic agent to the PBS to prevent bacterial growth. Store the column at 4°C.

   Prevent drying of the column during storage. The column can be stored for several months at 4°C.

Preparation of the Affinity Column

SUPPORT PROTOCOL 1

This protocol only describes the preparation of an immunoaffinity column. Generally, because IgSF-CAMs have low binding affinities for their binding partners and have no enzymatic activity that could be used for substrate-based purification, the use of immunoaffinity columns is the method of choice.

However, a prerequisite is the availability of a monoclonal antibody against the protein to be purified. This antibody is covalently coupled to a Sepharose resin. Affinity columns are versatile, they can be used for tissue homogenates, solubilized membrane proteins, or culture supernatants from cell lines that are engineered to produce and release IgSF-CAMs. If stored appropriately, affinity columns can be reused many times over several months.

Materials

CNBr-activated Sepharose 4B gel
1 mM HCl
Buffer I: 0.5 M NaCl in 0.1 M $NaHCO_3$, pH 8.3
Monoclonal antibody against the protein to be purified
0.2 M glycine, pH 8.0
Buffer II: 0.5 M NaCl in 0.1 M sodium acetate, pH 4.0
Loading buffer (see Basic Protocol 1)

Sintered glass filter connected to a vacuum pump
Column (e.g., Poly-Prep column, Bio-Rad)
U-bottomed polypropylene vial that can be closed tightly

1. Soak 1:2 (w/v) CNBr-activated sepharose 4B in 1 mM HCl for 15 min at room temperature.

   For a 1-ml column, start with 350 to 400 mg Sepharose.

2. Transfer beads to a sintered glass filter connected to a vacuum pump, and wash with ≥25 vol of 1 mM HCl, followed by buffer I.

   It is very important to prevent the beads from drying between the additions of buffer (one gram dry resin yields ~3.5 ml swollen gel).

3. Transfer the slurry to a U-bottomed polypropylene vial containing the antibody solution in buffer I. Carry out the reaction for 2 hr at room temperature. Close the vial tightly.

   The final concentrations should be: 100 mg Sepharose (dry weight) and 5 mg antibody per ml coupling reaction mix.

   Ideally, rotating the vial end-over-head is used to maximize the coupling efficiency.

   Do not use a magnetic stirrer, which will damage the agarose beads.

4. Stop the reaction by gently centrifuging the Sepharose beads for 5 min at 2000 × *g*, room temperature.

5. Add 3 vol 0.2 M glycine, pH 8.0, to the pellet and continue to rotate the vial end-over-head for an additional 2 hr.

   Collect the supernatant of the coupling reaction to check the coupling efficiency.

6. Pack the slurry into a column.

   Typically, column volumes are ~1 ml with a column diameter of 0.5 cm.

7. Wash the column with 5 vol buffer I followed by 5 vol buffer II. Repeat wash procedure four times to remove excess uncoupled ligand.

8. Before loading the protein solution (see Support Protocol 2), wash the column thoroughly with 25 to 30 vol loading buffer.

   An affinity column can be used repeatedly, if stored appropriately with an antibacterial agent (e.g., 0.02% merthiolate) at 4°C. Before using the column after storage, rinse the column extensively with loading buffer. Use 2 to 3 vol elution buffer to clean the column, restore loading conditions by rinsing thoroughly with loading buffer (≥10 vol).

Solubilization of Membrane Proteins

Most IgSF-CAMs are either glycosyl-phosphatidylinositol-anchored or transmembrane proteins, therefore, they have to be solubilized from cell membranes with detergents. In the authors' experience, the use of CHAPS has given the best results with respect to yield and functional integrity of the purified proteins. Keep in mind that for many functional assays, detergent removal from the protein solution is necessary after purification; the presence of detergents can also interfere with binding assays. Especially sensitive assays are those that involve neurons, such as neurite outgrowth assays (see Basic Protocol 7). For removal of detergents from protein solutions, the authors have used SM-2 beads from BioRad or Calbiosorb from Calbiochem. The use of high concentrations of detergents can interfere with the purification by immunoaffinity columns, therefore, dilution of the protein solution after the solubilization step, i.e., before the solution is loaded onto the affinity column, is recommended. The protocol given below has been successfully used for the purification of functionally intact L1/NgCAM from E14 chicken brain membranes (e.g., Stoeckli et al., 1991, 1996). It is adapted from the purification protocol described by Grumet and Edelman (1984). However, the authors have used the same protocol for the solubilization and purification of other IgSF-CAMs (Rader et al., 1993; Fitzli et al., 2000). For storage, membranes and proteins can be frozen at the indicated steps. However, repeated freez-thaw cycles are detrimental for proteins and for high yields of intact proteins and should be minimized.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

14-day-old chicken embryo brains, freshly frozen in liquid nitrogen
Liquid nitrogen
Ca^{2+}/Mg^{2+}-free buffer (CMF buffer; see recipe)
0.8 M and 2.25 M sucrose in PBS
1 M and 2 M NaCl in PBS
50 mM triethylamine
0.5% and 1% CHAPS in PBS

Mortar and pestle
Dounce homogenizer
Centrifuge tubes for Sorval SS-34 or equivalent rotor
38-ml polycarbonate tubes for ultra high-speed centrifuge

Prepare membranes

1. Remove brains of 14-day-old chicken embryos and immediately freeze in liquid nitrogen.

   If necessary, brains can be stored at −70°C for extended periods of time.

2. Cool a mortar and pestle of sufficient size with liquid nitrogen and grind frozen brains in batches to a fine powder. Add small volumes of liquid nitrogen to keep brains/brain powder frozen during grinding.

   Carefully avoid thawing of the tissue at any time.

3. Add ~3 vol CMF buffer to 1 vol brain powder. Homogenize the brain powder in a Dounce homogenizer.

4. Centrifuge homogenate for 20 min at 45,000 × *g* (10,000 rpm in a SS-34 rotor), 4°C.

5. Resuspend the pellets in 1.5 to 2 vol of 2.25 M sucrose, use Dounce homogenizer to get homogenous suspension.
6. Transfer ~24 ml suspension to each polycarbonate ultracentrifuge tube, overlay with ¼ vol of 0.8 M sucrose.
7. Centrifuge for 60 min at 150,000 × *g*, 4°C.
8. Transfer the membranes that are accumulated in the interphase to the Dounce homogenizer, resuspend them in 25 vol PBS.
9. Centrifuge for 60 min at 150,000 × *g*, 4°C.
10. Decant supernatant and resuspend in PBS, centrifuge as in step 9, and resuspend pellets in smallest possible volume of PBS for storage at −20°C, or use directly for stripping.

Samples can be stored up to 1 month at −20°C, or at −70°C for longer storage.

Strip packed membranes

11. Add 1 vol of 2 M NaCl in PBS to packed membrane suspension (from step 10), homogenize suspension.
12. Add 1 M NaCl in PBS to a final volume of 4 to 5 times the volume of the packed membranes.
13. Stir suspension 1 hr on a magnetic stirrer at low speed, 4°C, to strip membranes from peripheral membrane proteins.
14. Centrifuge for 60 min at 150,000 × *g*, 4°C.
15. Resuspend pellets in 20 vol of 50 mM triethylamine, stir for 60 min at 4°C.
16. Repeat centrifugation step 14. Carefully remove the supernatant with a pipet, as the membranes do not form a stable pellet after the high pH extraction step.
17. Resuspend the pellets in PBS.
18. Centrifuge for 60 min at 150,000 × *g*, 4°C.
19. Repeat washing the membranes with PBS at least one time to restore a pH value between 7.2 and 7.6. Keep an aliquot for measuring the protein concentration.
20. Freeze the stripped membranes at −20°C or use directly for solubilization step.

For storage longer than 1 month, store at −70°C.

Solubilize integral membrane proteins

21. If frozen membranes are used, they should be washed once again with PBS (steps 17 and 18).
22. Transfer pellets into a Dounce homogenizer and resuspend in 1 vol of 1% CHAPS buffer. Add 4 vol of 0.5% CHAPS buffer.

For good solubilization the protein concentration should be adjusted to ~1 mg/ml.

23. Extract the membrane proteins by stirring the suspension for 60 min at 4°C.
24. Centrifuge for 60 min at 150,000 × *g* , 4°C.
25. Combine supernatants, measure the volume, and remove aliquot to determine the protein concentration.

Do not freeze the solubilized proteins, but use directly for affinity purification step.

Production of Recombinant CAM by Transient Transfection of HEK293 Cells with Calcium Phosphate

SUPPORT PROTOCOL 3

Transient transfection of HEK 293 cells with expression vectors containing cDNAs of IgSF-CAMs represents a fast and convenient method for the production of intermediate amounts (100 μg to 1 mg) of recombinant protein. The human embryonic kidney cell line 293 (HEK 293) is a well established, easily transfectable cell line that is widely used for the expression of recombinant proteins. The transfection method of choice with HEK 293 cells is always calcium phosphate transfection, an inexpensive, convenient technique that results in high efficiencies of transfection.

DNA can be introduced into a wide variety of cultured cell lines as a calcium phosphate complex (Graham and van der Eb, 1973; Wigler et al., 1977). The transfected DNA can either integrate into the genome of the recipient cell, resulting in stable transgene expression accompanied by a stably altered phenotype of the cell (stable transfection) or remain episomal resulting in only transient expression of the transgene (transient transfection). The following protocol can be used likewise for the generation of stable cell lines by subsequent selection for stable transfectants or for transient expression only.

Efficient transfection requires the formation of a fine precipitate of calcium phosphate in the presence of DNA. The formation of the DNA-containing calcium phosphate particles is initiated under defined chemical conditions, in the absence of cells or serum. The particle size is the most critical parameter regarding efficiency of transfection, that is uptake of DNA-containing calcium phosphate particles by the cells. The main determinants of particle size are calcium and phosphate concentrations, the concentration of DNA, size of DNA fragments involved, pH, temperature, and time of incubation. After initial formation of the DNA-containing calcium phosphate particles, the precipitate is added to the cells. During the incubation of the precipitate with the cells, the formation of DNA-containing calcium phosphate particles continues and preexisting particles grow in size. The particles adhere to the cells and are taken up by endocytosis. After a few hours of exposure, the medium is changed and the cells start to express the recombinant protein. The period of efficient transgene expression varies between different expression vectors but lasts generally for a few days.

Materials

HEK 293 cells
Cell culture medium for HEK 293 cells (see recipe)
Purified DNA of interest
$CaCl_2$ solution (see recipe)
HBS solution (see recipe)
175-cm^2 tissue culture flasks
Additional reagents and equipment for trypsinizing cells (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

1. For transient transfection, grow HEK 293 cells of low passage number (passage <40) and split cells every 2 to 3 days before 80% confluency is reached.

   By frequent splitting and growth in subconfluent density, the cells remain in their exponential growth phase and are highly susceptible for transfection up to about passage number 40.

2. One day prior to the experiment, trypsinize cells briefly (*UNIT 1.1*) and prepare a single cell suspension. Plate 5×10^6 cells in 30 ml of medium per 175-cm^2 flask and incubate for 16 to 20 hr at 37°C, 5% CO_2 incubator.

   For optimal transfection efficiency, 60% to 70% confluency of cells is required. This allows two additional cell divisions after transfection. Some 293 lines adhere only poor to tissue culture plastic, especially after transfection. To achieve more stable adherence, tissue culture flasks can be coated with poly-D-lysine (see Support Protocol 10).

   HEK 293 cells do not need a medium change prior to addition of the calcium phosphate precipitate.

3. Mix purified DNA (40 to 80 µg in a maximum volume of 100 µl) with 1.5 ml $CaCl_2$ solution and incubate for a few minutes at room temperature.

   For efficient formation of the DNA-containing calcium phosphate particles, temperature is critical. The solutions should be kept at room temperature for a couple of hours before use. The optimal amount of DNA depends on the particular expression construct used for transient transfection and has to be determined individually for each system.

4. Add 1.5 ml of HBS solution and mix well. Incubate for 1 to 15 min at room temperature and then add the reaction mixture to the cells (from step 2).

   The formation of the DNA-containing calcium phosphate particles starts immediately after mixing the two solutions and can be observed by a slightly opaque appearance of the solution. Longer incubation periods generally result in the formation of a precipitate with larger particles. The optimum time of incubation critically depends on the size of the plasmids used.

   The growth rate of the calcium phosphate particles frequently correlates inversely with the size of the plasmids. For very large plasmids(>30 kb), preincubation of no longer than 1 min is recommended.

5. Incubate the DNA-containing calcium phosphate particles with the cells for 4 to 6 hr at 37°C in an incubator.

   The formation of the calcium phosphate precipitate can be monitored under an inverted light microscope with a 63× objective. The precipitate should become visible as tiny particles (~300 nm in diameter) especially on the surface between the cells. However, long exposure to the atmosphere outside of the incubator should be avoided.

6. Change medium after the incubation period and continue incubation. Begin testing for expression of the recombinant protein 1 day after transfection.

   The cells should now express the recombinant protein for a few days.

   Uptake of the DNA-containing calcium phosphate particles by cells can be checked by examination of free surfaces between cells. The margins surrounding the cells should be cleared of particles, due to their uptake by the cells.

SUPPORT PROTOCOL 4

Detection of IgSF-CAMs by the Dot Immunoblot Method

A rapid and convenient method for the detection of IgSF-CAMs in eluates from chromatography or affinity columns are dot immunoblots. Similar to immunoblots, dot blots are a semi-quantitative method to detect proteins transferred onto a nitrocellulose membrane via a chromogenic reaction. For this purpose, secondary antibodies coupled to peroxidase or alkaline phosphatase are used to detect binding of the first antibodies directed against the protein of interest. However, in contrast to immunoblots, proteins are not separated on a polyacrylamide gel, therefore dot blots are a much faster way to demonstrate the presence of a specific protein in a given sample. Furthermore, as the proteins are directly applied to the nitrocellulose membrane for dot blots, there is no loss due to difficulties in

transfer from the gel to the membrane. The fact that only small volumes can be applied onto the membrane for dot blots may, however, limit its use for detection of proteins in dilute solutions.

The procedure described here can also be used to stain IgSF-CAMs after immunoblotting. Use manufacturer's manuals and protocols for sample preparation, SDS-PAGE, and blotting of proteins onto nitrocellulose (also see *UNITS 6.1* and *6.2*).

Materials

Protein solution of interest
TBS: 0.2 M NaCl in 50 mM Tris, pH 7.4
Blocking solution: 2% (w/v) milk powder in TBS with or without 0.1% (w/v) Tween 20
Antibody against the protein of interest diluted in blocking solution
Secondary antibody coupled with horseradish peroxidase (HRP) diluted in blocking solution
4-chloro-1-naphthalene solution (see recipe)

0.2-µm nitrocellulose membrane (e.g., Schleicher and Schuell)
96-well plates
Rotary shaker

1. Place matching round disks of 0.2-µm nitrocellulose membrane into wells of a 96-well plate.

   When large numbers of samples have to be analyzed, the use of a commercially available protein-dispersing device is advised (e.g., Dot Punch IM-96, Inotech AG). These devices allow the application of protein solutions to the membrane before they are put into the wells. This is more convenient and less time-consuming compared to the procedure described below.

2. Apply small volumes (<10 µl) of the protein solution onto the membrane.

   The solution should not cover the entire membrane but remain confined to a segment of the membrane (dot). This is important in order to ensure the attachment of sufficient amounts of proteins per area to reach detection limits. If the protein solution is very dilute, the dotting procedure can be repeated after drying the nitrocellulose after the first application. The repeated application of protein to the membrane increases the amount of the protein of interest.

3. Dry the membranes to optimize protein adherence to the nitrocellulose.

4. Wash membranes three times with 100 µl TBS per well.

5. Block protein adsorbance of the membrane by incubating ≥30 min with blocking solution, room temperature.

   Generally, 2% to 5% milk powder in TBS with or without 0.1% Tween 20 works well as a blocking solution. In some cases, addition of 2% to 10% (v/v) serum in TBS improves the signal-to-background ratio.

6. Apply 1 to 10 µg/ml first antibody diluted in blocking solution and shake for ≥1 to 2 hr, room temperature, on a rotary shaker.

   If necessary, incubate overnight.

   Shaking the 96-well plate improves antibody/antigen interaction.

7. Wash thoroughly with TBS (≥3 times).

8. Incubate with blocking solution for ≥30 min before applying the secondary antibody.

9. Apply 1 to 10 µg/ml of secondary antibody coupled with horseradish peroxidase diluted in blocking solution to the membrane and incubate 1 hr at room temperature.

   As a secondary antibody, the use of a peroxidase-coupled antibody is described, but good results can also be obtained with phosphatase-coupled antibodies. Generally, an antibody concentration of 1 to 10 µg/ml is used to get good signal-to-noise ratios but batches or products from different suppliers vary.

10. Remove antibody solution and wash membrane thoroughly with at least three changes of TBS.

11. Visualize the antibody by adding 0.1 ml of 4-chloro-1-naphthalene solution.

    Generally, the dark blue color develops immediately.

12. Stop the reaction by rinsing the membranes with water.

FUNCTIONAL ASSAYS WITH PURIFIED PROTEINS

BASIC PROTOCOL 2

Analysis of Protein Interactions with Fluorescent Microspheres

There are essentially two ways to analyze the binding properties of cell adhesion molecules, (1) binding assays based on purified proteins, and (2) binding assays based on heterologously expressed proteins in their physiological environment (cell aggregation assays). This protocol describes a method that utilizes biochemically purified proteins coupled to fluorescent microspheres, whereas Basic Protocol 4 is based on cell aggregation assays. If pure cell adhesion molecules are available, proteins can be coupled to polystyrene beads of different fluorescent colors. Coupling can be either by covalent linkage or by hydrophobic adsorption of the protein to the microsphere surface. After dispersion of the beads by ultrasonication, pairwise combinations of differently coupled beads aggregate during a particular incubation period. Binding activities are analyzed by the evaluation of aggregate formation both qualitatively, by inspection on a fluorescent microscope, and quantitatively, using a fluorescence-activated flow cytometer. Although this protocol is a reliable method to detect binding activities of IgSF-CAMs and has been used by several laboratories, one has to consider false negative results as well as discrepancies between results of bead and cell aggregation assays. Some discrepancies have been explained by differences in the orientation of proteins coupled to beads in comparison to proteins on the surface of cells.

Materials

Protein-conjugated fluorescent microspheres; stock solutions contain 10^{11} beads/ml in 0.5% (w/v) BSA (see Support Protocol 5; Duke Scientific; Bangs Laboratories; Polysciences)
0.5% (w/v) BSA solution (see recipe)
0.5 mg/ml Fab fragments of antibodies against proteins of interest in PBS (optional)
0.5% (w/v) trypsin (optional)
PBS (see recipe)

Water bath sonicator (Branson Ultrasonics)
Fluorescence microscope equipped with FITC and TRITC filters
0.5-ml microcentrifuge tube
Rotator
Glass microscope slides
Refrigerated microcentrifuge
Fluorescence-activated flow cytometer

Prepare mixtures of fluorescent microsphere

1. Sonicate test tubes containing stock solutions of protein-conjugated microspheres in a water bath sonicator for 2 min at room temperature. Use lowest sonicator output setting needed to achieve monodisperse bead solution to prevent protein structure damage.

   Make relatively small aliquots of protein-conjugated bead stocks because repetitive ultrasonication may damage protein structure.

   For the applications described here, fluorescent microspheres with a nominal diameter of 0.5 μm work best. Both covalent coupling of proteins via surface-exposed functional groups or hydrophobic adsorption may be used. The best mode of coupling may depend on the particular nature of the protein to be studied.

   The authors have consistently used Covaspheres fluorescent microspheres from Duke Scientific (Kuhn et al., 1991; Suter et al., 1995; Rader et al., 1996; Kunz et al., 1998; Fitzli et al., 2000). Fluorescent Covaspheres with a nominal diameter of 0.5 μm were easy to handle, allowed covalent coupling of the proteins, and were readily detectable in the light microscope and cell sorter. However, Duke Scientific has discontinued the distribution of Covaspheres, but a new line of beads with well characterized fluorescence and charge density is available. Different functional groups for covalent coupling of proteins will be offered, including carboxylate and aldehyde groups.

   Support Protocol 5 describes covalent coupling of proteins to Covaspheres as well as the hydrophobic adsorption of proteins to polystyrene beads. With some modifications, it may also be suited for other types of beads.

   The authors have added a support protocol that can be used for coupling proteins to microspheres exhibiting amino groups on their surfaces (see Support Protocol 6).

2. Check monodispersity of bead stock solution by quick inspection of a 1:100 dilution in 0.5% BSA under a fluorescence microscope.

3. Immediately after ultrasonication, prepare different test mixtures by combining protein-coupled beads of different fluorescent colors. Add 2 μl of green-fluorescent beads conjugated with protein 1 and 2 μl of red-fluorescent beads conjugated with protein 2 into a 0.5-ml microcentrifuge tube and bring to a final volume of 20 μl with 0.5% BSA solution (the concentration of each species of beads in the test mixture is 10^{10}/ml). Vortex beads.

   Use as many controls as possible. Typical control incubations are:

   a. Each type of beads alone.

   b. Beads conjugated with control proteins that should not bind to protein of interest (e.g., BSA, non-immune IgG).

   c. Protein-conjugated beads that were either incubated in boiling water for 10 min or treated with 0.5% trypsin overnight.

   These treatments should abolish specific protein interactions.

   d. Pretreat beads with Fab fragments that are specific to the conjugated protein of interest. For this purpose, incubate an appropriate volume of the bead stock solution with Fab from polyclonal IgG at a concentration of 0.5 mg/ml in PBS for 2 hr at room temperature. Remove unbound antibodies by three consecutive washes with PBS. For solution changes, centrifuge beads in a microcentrifuge tube for 10 min at 16,000 × *g*, 4°C. Dissolve possible aggregates of beads by ultrasonication as in step 1.

4. Incubate by slowly rotating test mixtures protected from light for 1 hr at room temperature on a rotator.

   If such a rotator is not available, invert tubes a few times every 15 min. Tubes can be light protected with aluminum foil.

Analyze by fluorescence microscopy

5. Analyze the test mixtures for aggregate formation by fluorescence microscopy. Prepare a 1:10 dilution of the different incubations in 0.5% BSA solution and place 20 µl of this dilution on a glass slide for inspection.

   Most fluorescent microspheres emit a relatively intense signal. Therefore, antifading agents are not necessary for inspection. After a while, aggregates will settle and pictures can be taken for documentation or quantification of aggregate sizes. Adhesive interactions between two different proteins coupled to beads labeled with FITC and TRITC, respectively, should result in aggregates consisting of up to 100 beads of both colors that are equally distributed throughout the clusters. Carefully check for bleed-through between the different fluorescence channels.

Analyze by fluorescence-activated flow cytometry

6. Use flow cytometric analysis for quantification of aggregate formation. Calibrate the flow cytometer correctly for nonaggregated beads of each color.

7. Dilute test mixtures 1:1000 in 0.5% BSA solution and inject into a fluorescence-activated flow cytometer equipped with appropriate FITC and TRITC filter sets (Kuhn et al., 1991).

   Always use fluorescence microscopy in parallel to flow cytometer analysis to obtain information on the distribution of the beads in aggregates (see Critical Parameters and Troubleshooting).

8. Use uncoated, nonaggregating beads to determine relative fluorescence intensity (RFI) of individual beads of each color. Compensate for the spectral overlap of the FITC and TRITC emission electronically.

9. Record the data output for number, size, and composition of mixed aggregates.

   Data can be presented as two-dimensional contour or dot plots with the RFIs in the FITC and TRITC channel as x- and y-coordinates indicating size and composition of aggregates (Kuhn et al., 1991; Suter et al., 1995). The signal intensity represents the number of aggregates of a certain size and composition. The RFI values of single beads will allow the investigator to set the boundaries between mixed aggregates and aggregates that consist only of one species of beads. Determination of these boundaries is necessary to calculate the percentage of beads found in mixed aggregates as an indicator for protein binding.

SUPPORT PROTOCOL 5

Coupling Proteins to Fluorescent Microspheres

This support protocol describes a method for the preparation of protein-conjugated fluorescent microspheres required for the protein interaction studies described in Basic Protocols 2 and 3. It is based on the procedure that the authors have used for the coupling of proteins to Covaspheres (Duke Scientific). However, the same procedure has successfully been used for the adsorption of proteins to polystyrene beads, which bind proteins by hydrophobic interactions.

Additional Materials *(also see Basic Protocol 2)*

10^{11} unconjugated beads/ml fluorescent polystyrene microspheres, 0.5-µm diameter (Duke Scientific; Bangs Laboratories; Polysciences)

Biochemically purified IgSF-CAMs (see Basic Protocol 1) in a phosphate-based buffer system (either PBS or 20 mM sodium phosphate, pH 7.0)

1. Sonicate tubes containing stock solutions of 10^{11} unconjugated beads/ml fluorescent polystyrene microspheres in a water bath sonicator for 2 min at room temperature.

2. If bead solution is monodisperse, transfer 100 µl of beads to a new tube and add 50 µg of biochemically purified IgSF-CAMs in PBS to a total volume of 1 ml (10^{10} beads/ml during coupling). Vortex tubes.

   Before coupling, test protein preparations carefully for purity with SDS-PAGE to avoid false positive, as well as false negative, results.

   Store proteins under sterile conditions in PBS or 20 mM sodium phosphate, pH 7.0, 4°C. For highly stable proteins, storage for up to 1 year at 4°C under sterile conditions is possible.

   Cell adhesion molecules with transmembrane and cytoplasmic domains (e.g., NgCAM and NrCAM) require the presence of detergents such as CHAPS and deoxycholate during purification. The authors found that biological activity, such as binding, is better preserved when these detergents are maintained during protein storage at 4°C and during coupling to beads.

3. Incubate the mixture for 1 hr in a 37°C water bath. Mix periodically by inverting tube.

4. Centrifuge for 10 min at 16,000 × *g*, 4°C. Remove supernatant containing unbound protein and save for coupling analysis. Resuspend beads in 1 ml of 0.5% BSA solution.

   This step is necessary to block residual binding sites that could result in unspecific bead-bead interactions.

5. Sonicate beads as in step 1 and incubate 30 min at room temperature.

6. Centrifuge beads as in step 4 and resuspend pellet in 100 µl of 0.5% BSA solution. Store beads at 4°C.

   Protein-conjugated microspheres should never be frozen and can be kept up to 1 year at 4°C (depending on protein stability).

7. (*Optional*) Determine coupling yield by SDS-PAGE of serial dilutions of protein samples taken before and after coupling.

   Densitometric analysis of bands after silver staining or immunoblot detection allows the determination of both coupling efficiency and the number of protein molecules bound per microsphere.

   Typically, a coupling yield of >50% is obtained under the conditions described. In the case of the IgSF-CAMs axonin-1 and NgCAM, ~16,000 molecules were found to bind per Covasphere bead (Kuhn et al., 1991).

Covalent Coupling of Proteins to Glutaraldehyde-Activated Amino Beads

SUPPORT PROTOCOL 6

As an alternative method for coupling proteins to beads, this protocol describes the glutaraldehyde-activated coupling of proteins to microspheres with amino-functional groups. Purified IgSF-CAMs can be coupled directly (not oriented) to amino beads. Alternatively, Fc-containing recombinant proteins can be bound to protein A–conjugated microspheres in an oriented manner.

Additional Materials *(also see Basic Protocol 2)*

Amino-functional microspheres (e.g., silica aminopropyl beads from Bangs Laboratories)
0.1 M NaOH or HCl (optional)
8% (v/v) EM-grade glutaraldehyde, newly opened bottle
400 µg/ml biochemically purified IgSF-CAMs (see Basic Protocol 1) in a phosphate-based buffer system (either PBS or 20 mM sodium phosphate, pH 7.0)
Blocking solution (see recipe)

1. Prepare an appropriate volume (e.g., 0.5 ml) of 1% amino-functional microsphere stock solution in ultra pure water. Wash beads two times with 1 ml water. Centrifuge for 4 min at 16,000 × *g*, room temperature, to separate microspheres from wash solution. Remove supernatant and resuspend microspheres in 0.5 ml water.

   The amino-functional microspheres are available as powder or 10% (w/v) solution. Keep microsphere stock solutions at 4°C and never freeze.

2. Before adding the glutaraldehyde solution, check under the microscope whether the bead solution is monodisperse. If the bead solution contains significant clumps, sonicate in the water bath sonicator for 5 min at room temperature. If clumps persist, use a Branson microtip sonicator at the lowest output power needed to disrupt the clumps. Check pH of bead solution with cut pH strips and, if necessary, adjust pH to 6.5 or 7.0 with 0.1 M NaOH or HCl, respectively.

   Glutaraldehyde activation works best at pH 6 to 7.

3. If the bead solution is monodisperse and has a pH of 6.5 to 7.0, add an equal volume of a newly opened bottle of 8% EM-grade glutaraldehyde and mix. Incubate beads on rotator for ≥6 hr or overnight at room temperature.

4. Centrifuge beads as in step 1, remove supernatant, and wash activated beads at least three times with 1 ml water, and once with the buffer in which the protein is dissolved (PBS or 20 mM sodium phosphate).

5. Add 0.5 ml of 400 µg/ml purified IgSF protein in PBS, pH 7.3, or in 20 mM sodium phosphate, pH 7.0, to bead pellet and resuspend beads in protein solution (1% beads during coupling reaction). Incubate on rotator for 4 hr at room temperature or overnight at 4°C.

   If less protein is available, scale down amounts of protein and beads proportionally.

6. Centrifuge beads 4 min at 16,000 × *g*, room temperature, save supernatant for coupling analysis on SDS-PAGE, and resuspend beads in 0.5 ml blocking solution. Incubate beads in blocking solution for 30 min at room temperature on rotator.

7. Centrifuge beads again. Resuspend beads in 0.5 ml blocking solution (1% bead stock) and store at 4°C for months.

BASIC PROTOCOL 3

Binding of Protein-Conjugated Microspheres to Cultured Cells

This protocol determines binding specificity of a cell adhesion molecule to a receptor on a particular cell type. Both primary cell cultures (Kuhn et al., 1991; Suter et al., 1995) and cell lines (Buchstaller et al., 1996; Rader et al., 1996) can be incubated with protein-conjugated microspheres under live conditions to determine interactions between specific proteins and cells. Antibody preincubations can be used as a control but also for receptor identification. Furthermore, cells transiently transfected with mutated receptor forms can be used for the identification of extracellular protein domains necessary for binding of the cell adhesion protein (Rader et al., 1996; Kunz et al., 1998; Fitzli et al., 2000).

Materials

Primary cultures of neuronal and/or glial cells or other cells
Complete medium used for cell cultures
Serum-free BSA-containing cell culture medium
10^{11} beads/ml protein-conjugated fluorescent polystyrene microspheres; stock solutions in 0.5% BSA (see Support Protocol 5)

0.5 mg/ml Fab against protein of interest in serum-free medium (optional)
Fixation solution (see recipe)
PBS (see recipe)
Mounting medium (see recipe)

Waterbath sonicator
37°C, 10% CO_2 humidified incubator
Glass microscope slides
Fluorescence microscope

Prepare and bind microspheres to cells

1. Cultivate primary neurons and/or glial cells in conditions that allow live cell incubations in relatively small volumes.

   For example, grow cells on substrate-coated coverslips using a removable donut-shaped Teflon ring to limit the incubation volume to 200 to 250 µl (Suter et al., 1995).

   If culture conditions include the use of serum, prepare also a corresponding serum-free, BSA-containing medium as in Stoeckli et al., 1991; see recipe.

2. Wash cultured cells one time with complete culture medium and one time with serum-free, BSA-containing cell culture medium.

   Medium exchanges are carried out carefully with a pipet.

3. Prepare 1:1000 dilutions of 10^{11} beads/ml protein-conjugated fluorescent polystyrene microspheres in serum-free cell culture medium, sonicate dilutions for 2 min, room temperature and immediately add to cultured cells.

4. (*Optional*) To test whether a specific CAM binds to a particular cell type via a characterized receptor (to which antibodies are available), preincubate cells with 0.5 mg/ml Fab fragments in serum-free medium, before adding the beads, for 2 hr in a 37°C, 10% CO_2 humidified incubator. Remove unbound antibodies by washing two times with serum-free medium before proceeding to step 5. To test for the specificity of bead binding to cells, use control protein–conjugated beads as well as beads that were preincubated with the corresponding Fab fragments.

5. Incubate the cells with the bead solution (step 3) for 1 hr in a 37°C, 10% CO_2 humidified cell culture incubator.

6. Use a Pasteur pipet to carefully aspirate medium with unbound beads. Immediately add serum-free medium. Repeat this step three times.

   Do not allow the cells to dry.

   Beads bound to live cells can now be inspected. However, if more time is needed for analysis, the authors recommend fixing the cells. Fixation also allows processing of the cells for immunostaining of marker proteins or CAMs and, therefore, correlative analysis of CAM binding and CAM expression.

Fix cells

7. Fix the cells by adding 80 µl of 4× fixation solution to the cultures, which are in 240 µl of serum free medium. Gently mix and incubate 1 hr at 37°C.

8. Wash fixed cells three times with PBS.

9. For immunofluorescence staining of the cells, proceed as described in *UNIT 4.3*. Otherwise mount cells on a glass microscope slide in mounting medium for inspection under a fluorescence microscope.

   Beads are generally intensely fluorescent. Therefore, relatively short exposure times are sufficient when taking pictures.

BASIC PROTOCOL 4

Trans-Interaction Assay with Myeloma Cells

Interactions between IgSF-CAMs that have been determined either by a fluorescent microsphere assay or by binding of fluorescent microspheres to cells do not provide any information on whether the interaction occurs between molecules located on different cells (*trans*-interaction) or between molecules residing on the membrane of the same cell (*cis*-interaction). In order to distinguish between a *trans*- and a *cis*-interaction, the IgSF-CAMs need to be studied in a natural environment, i.e., as membrane-bound molecules residing in their proper orientation in a biological membrane. Expression in nonadherent myeloma cells (see Support Protocol 7) provides a means of assessing IgSF-CAMs for *trans*-interactions. Two populations of stably transfected myeloma cell clones are stained with optically distinct intracellular fluorescent dyes. The cells are dissociated, incubated, and examined under a microscope in order to determine whether re-aggregation has occurred.

To evaluate whether two populations of myeloma cell clones expressing the IgSF-CAMs of interest on their surface can adhere to each other, they are labeled, mixed, dissociated, and allowed to re-aggregate. Labeling with optically distinct fluorescent dyes is necessary to distinguish the two populations.

Materials

Two populations of myeloma cell clones expressing the CAMs of interest
Selection medium, e.g., 5 mM L-histidinol in DMEM supplemented with 10% (v/v) FCS
PBS with Ca^{2+}/Mg^{2+} (see recipe)
Stock solution of green fluorogenic dye, e.g., 1 mM 2′,7′-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein acetoxymethyl ester (Molecular Probes) in DMSO
Stock solution of red fluorogenic dye, e.g., 7.5 mM 5-(and-6)-carboxynaphtofluorescein diacetate (Molecular Probes) in DMSO
1% (v/v) FCS in PBS with Ca^{2+}/Mg^{2+}
5 mg/ml *p*-phenylenediamine in 1% FCS in PBS with Ca^{2+}/Mg^{2+}

15-ml conical polypropylene centrifuge tubes
Hemacytometer
V-shaped 96-well microtiter plate (e.g., Costar, Corning)
Centrifuge and rotor for microtiter plates
22-G needle attached to 1-ml syringe
Glass microscope slide
Fluorescence microscope with appropriate filters for green and red fluorescence, e.g., FITC and Texas Red
Additional reagents and equipment for counting cells (*UNIT 1.1*)

Prepare cells

1. Grow transfected myeloma cell clones that express the CAM(s) of interest on their surface in selection medium to a cell density of ~5×10^5 cells/ml. Use a hemacytometer to monitor the cell density (the aggregation assay requires 5×10^5 cells per population per sample; see *UNIT 1.1*).

   Transfected myeloma cell clones that express high concentrations of a homophilically trans-interacting cell adhesion molecule can grow in very large cell aggregates consisting of thousands of cells that are easily visible by eye. The authors found that cultures of aggregating myeloma cell clones contain more dead cells than nonaggregating myeloma cell clones. This might, at least in part, be due to a limited oxygen and nutrition supply to

the center of the aggregate. In order to limit the number of dead cells, aggregating myeloma cell clones should be split more frequently avoiding large cell aggregates. The cell density can be determined with a hemacytometer after dissociating the cells by repeated pipetting through a 22-G needle.

2. Transfer 5 to 10 ml of cell culture into 15-ml conical polypropylene tubes and centrifuge for 3 min at 500 × *g*, room temperature. Aspirate the supernatant and resuspend the cells in 1 to 2 ml PBS with Ca^{2+}/Mg^{2+}. Determine the cell density with a hemacytometer (*UNIT 1.1*). Add PBS with Ca^{2+}/Mg^{2+} to give a cell density of 5×10^5 cells/150 µl. Pipet 150 µl/well to a V-shaped 96-well plate.

   The aggregation assay requires two populations in distinct wells per sample. Use wells A1 and A2 for the first sample, B1 and B2 for the next sample, etc.

   When desired, the cells can be pre-incubated with antibodies at this step by incubating the cells with Fab monoclonal or polyclonal antibodies in a concentration range of 10 to 500 µg/ml in 1% FCS in PBS with Ca^{2+}/Mg^{2+} for 1 hr at room temperature.

3. Centrifuge the microtiter plate for 2 min at 500 × *g*, room temperature, remove the supernatant by flicking plate into a sink (cells will remain in wells). Resuspend cells in 90 µl PBS with Ca^{2+}/Mg^{2+}.

Label cells

4. Prepare fresh working solutions of both, green and red, fluorogenic dyes by diluting 10 µl of the stock solution in 990 µl PBS with Ca^{2+}/Mg^{2+}. Add 10 µl of the appropriate working solution to the well with the appropriate 90-µl cell suspension. Use one column for one fluorogenic dye (e.g., stain A1, B1, etc. with green and A2, B2, etc. with red). Incubate 30 min at 37°C.

   The end concentration of the fluorogenic dyes is 1 µM of 2′,7′-bis-(2-carboxyethyl)-5-(and-6)-carboxyfluorescein acetoxymethyl ester and 7.5 µM of 5-(and-6)-carboxynaphtofluorescein diacetate. The electrically neutral ester substrates freely diffuse through the cell membrane into the cell, where they are cleaved into fluorescent products by nonspecific intracellular esterases. The charged fluorescent products are retained by cells with intact plasma membranes. Serum of the cell culture medium contains esterases and has to be washed away prior to the incubation and avoided during the incubation.

5. Centrifuge microtiter plate and remove the supernatant as in step 3. Resuspend the cells in 150 µl PBS with Ca^{2+}/Mg^{2+}. Repeat step.

6. Centrifuge microtiter plate 2 min at 500 × *g*, room temperature and remove the supernatant by flicking plate into sink. Resuspend cells in 75 µl of 1% FCS in PBS with Ca^{2+}/Mg^{2+}.

Dissociate cells and allow re-aggregation

7. Combine complementarily stained cells of one sample in one well (e.g., add A2 to A1, B2 to B1, etc.). Dissociate cells by slowly pipetting up and down ten times through a 22-G needle attached to a 1-ml syringe. Avoid foaming. Incubate 45 min at 4°C.

   During re-association the plate should not be moved.

8. Centrifuge microtiter plate for 2 min at 500 × *g*, room temperature, and remove the supernatant by flicking plate into sink. Resuspend the cells in 150 µl of 1% FCS in PBS with Ca^{2+}/Mg^{2+}. Repeat step.

9. Centrifuge microtiter plate and remove the supernatant as in step 8. Resuspend the cells in 40 µl of 1% FCS in PBS with Ca^{2+}/Mg^{2+}.

Analyze cells

10. Immediately prior to microscopic analysis of an individual sample, add 10 µl of 5 mg/ml *p*-phenylenediamine in 1% FCS in PBS with Ca^{2+}/Mg^{2+}. Pipet the sample several times up and down using a 200-µl pipet tip. Mount 10 µl of the sample on a glass slide.

    The use of the antifading reagent p-phenylenediamine in an end concentration of 1 mg/ml markedly preserves the fluorescence intensity.

11. Analyze the aggregates with a fluorescence microscope using FITC and Texas Red filters.

    Filters that allow the simultaneous detection of green and red fluorescence facilitate the analysis.

SUPPORT PROTOCOL 7

Stable Transfection of Myeloma Cells by Protoplast Fusion

This protocol describes the stable transfection of myeloma cells with a vector that allows the surface expression of IgSF-CAMs. A vector particularly suited for myeloma cell expression was described by Traunecker et al. (1991). Expression by this vector is driven by an Ig κ promoter and enhancer. The 3′ end of the transcript of interest is spliced onto an exon encoding the Ig κ constant domain in order to mimic stable Ig transcripts. The vector contains a histidinol dehydrogenase gene that allows the selection of stable transfectants in the presence of L-histidinol. L-histidinol is a precursor of L-histamine and an inhibitor of protein synthesis. The vector has been stably transfected into the mouse myeloma cell line J558L for the production of soluble lymphocyte-derived cell-surface receptor proteins (Traunecker et al., 1991). The system has also been used for the surface expression of IgSF-CAMs (Rader et al., 1993; Buchstaller et al., 1996; Fitzli et al., 2000). Alternatively, other mammalian expression vectors and myeloma cells can be used.

Myeloma cell clones that stably express large amounts of IgSF-CAMs on their surface were generated by a transfection method known as protoplast fusion. Transfection by protoplast fusion is a highly efficient method for the direct transfer of mammalian expression vectors from bacteria to mammalian cells (Schaffner, 1980; Sandri-Goldin et al., 1981; Rassoulzadegan et al., 1982; Gillies et al., 1983). It involves digesting bacterial cell walls with lysozyme to produce protoplasts and then fusing the protoplasts to mammalian cells in the presence of polyethylene glycol. The following protocol is based on the myeloma expression system described by Traunecker et al. (1991) and can easily be adapted to other systems.

Materials

Glycerol stock of an *E. coli* strain 803 clone (ATCC #35581) transformed with a mammalian expression vector containing the cDNA of the IgSF-CAM of interest (store at −80°C)
LB agar/ampicillin plates (see recipe; store at 4°C)
DMEM supplemented with 10% (v/v) FCS
LB medium (see recipe), prewarmed to 37°C
50 mg/ml ampicillin (store at −20°C)
60 mg/ml chloramphenicol in ethanol (store at −20°C)
DMEM supplemented with 10% (w/v) sucrose and 10 mM $MgCl_2$, prewarm
20% (w/v) sucrose in 50 mM Tris·Cl, pH 8.0, ice cold
1 mg/ml lysozyme (Roche Molecular Systems), freshly dissolved 10 mg in 10 ml of 250 mM Tris·Cl, pH 8.0, and filtered through 0.22-µm filter
250 mM EDTA, pH 8.0, ice cold
50 mM Tris·Cl, pH 8.0, ice cold

10 mg/ml DNase I (Roche Molecular Systems; store at −20°C)
DMEM
PEG 1500 in DMEM supplemented with DMSO (see recipe)
Mouse BALB/c myeloma cell line J558L (ECACC #88032902) or another myeloma cell line
50 mg/ml kanamycin
50 mM L-histidinol (see recipe)
Polyclonal anti-IgSF-CAM antibody
Fluorescein-conjugated secondary antibody

25-ml cell culture flasks
12-ml and 50-ml polypropylene tubes
15- and 50-ml conical polypropylene centrifuge tubes
37°C bacterial shaker
500-ml Erlenmeyer flask
Refrigerated tabletop centrifuge
37°C water bath
Glass microscope slides
Microscope with 1000× magnification
Multipipet trays
24- and 96-well tissue culture plates
Multipipettor and tips
Plastic wrap (e.g., Saran)
96-well plates with V-shaped wells

Additional reagents and equipment for indirect immunofluorescence (*UNIT 4.3*) and freezing cells (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

NOTE: The following protocol is written for one sample. It is not recommended to handle more than four samples in parallel.

Day 1: grow transformed bacterial strain

1. Streak a glycerol stock of an *E. coli* strain 803 clone containing the mammalian expression vector onto an LB agar/ampicillin plate. Grow overnight at 37°C.

   E. coli strain 803 (also termed 1106) might be more efficient than other E. coli strains in producing stable protoplasts (Rassoulzadegan et al., 1982).

   The antibiotic has to be adapted to the prokaryotic selection marker of the mammalian expression vector.

2. Grow myeloma cells in DMEM supplemented with 10% (v/v) FCS in 25-ml cell culture flasks. Aim at a high cell density of ~1×10^6 cells/ml that is reached on day 3 (protoplast fusion requires 5×10^6 cells per sample).

Day 2: grow transformed bacterial cultures

3. Inoculate 2 ml LB medium prewarmed at 37°C in a 12-ml polypropylene tube with a single *E. coli* colony from the freshly streaked LB agar/ampicillin plate. Add 2 µl of 50 mg/ml ampicillin. Grow for 4 hr at 250 rpm in a 37°C bacterial shaker.

4. Dilute 100 µl of cell culture into a 500-ml Erlenmeyer flask with 100 ml of LB medium and 100 µl of 50 mg/ml ampicillin. Grow to an OD_{600} of ~0.6. Start checking the optical density after 3 hr.

5. After OD_{600} ~0.6 is reached, add 200 µl of 60 mg/ml chloramphenicol to a final concentration of 120 µg/ml. Grow overnight at 250 rpm in a 37°C bacterial shaker.

   Plasmids carrying the colE1 origin of replication can be amplified in the presence of chloramphenicol (Hershfield et al., 1974).

Day 3: harvest bacterial cells and form protoplasts

6. Transfer the overnight culture into two 50-ml conical polypropylene centrifuge tubes and centrifuge 10 min at 2500 × *g*, 4°C.

7. In the meantime, prewarm 20 ml DMEM supplemented with 10% sucrose and 10 mM $MgCl_2$ in a 50-ml polypropylene tube in a 37°C water bath.

8. Pour off the supernatants of the spun culture.

Prepare protoplasts

9. From here on proceed in a sterile laminar flow bench. Vortex and combine the two bacterial pellets in 2.5 ml ice-cold 20% sucrose in 50 mM Tris·Cl, pH 8.0.

10. Add 500 µl ice-cold 1 mg/ml lysozyme in 250 mM Tris·Cl, pH 8.0, mix gently (swirl), and incubate 5 min on ice.

11. Add 1 ml ice-cold 250 mM EDTA, pH 8.0, gently swirl, and store on ice 5 min.

12. Add 1 ml ice-cold 50 mM Tris·Cl, pH 8.0, gently swirl, and incubate 10 min at room temperature. During this incubation period, mount 10 µl of the sample on a glass microscope slide and analyze protoplast formation under a microscope.

    A microscope with 1000× magnification is required to distinguish between spherical protoplasts and rod-shaped bacteria. At the end of incubation, ~90% protoplasts should be formed.

13. Add 20 ml DMEM supplemented with 10% sucrose and 10 mM $MgCl_2$ very slowly to the protoplast preparation. To do this, swirl protoplasts gently, start adding drops of DMEM supplemented with 10% sucrose and 10 mM $MgCl_2$, and slowly increase the added volume.

    The prepared protoplasts are fragile and need to be handled with care. Protoplast lysis is indicated by an increasing viscosity of the preparation due to the release of genomic DNA. The preparation can be analyzed using a microscope as above.

14. Add 40 µl of 10 mg/ml DNase I and incubate 15 min at room temperature.

    Addition of DNase I reduces the viscosity of the protoplast preparation.

Prepare for fusions

15. In the meantime, prewarm the following in separate 50-ml propylene tubes in a 37°C water bath:

    15 ml DMEM
    10 ml DMEM supplemented with 10% (v/v) FCS
    50 ml DMEM supplemented with 10% (v/v) FCS.

    Thaw at room temperature:

    2 ml PEG 1500 in DMEM supplemented with DMSO.

16. Centrifuge protoplast preparation in the 50-ml polypropylene tube 30 min at 2500 × *g*, room temperature.
17. In the meantime, transfer 5×10^6 mouse BALB/c myeloma cells into 15-ml conical polypropylene centrifuge tubes and centrifuge 10 min at 500 × *g*, room temperature. Aspirate the supernatant and resuspend the cells in 5 ml prewarmed DMEM.

    The myeloma cell preparation should be serum-free.

    Other myeloma cell lines that have been transfected by protoplast fusion or electroporation include mouse P3-X63Ag8.653, mouse Sp2/0-Ag14, mouse NSO, and rat YB2/0 (Gillies et al., 1989; Nakatani et al., 1989; Bebbington et al., 1992; Shitara et al., 1994).

18. Pour off the supernatant of the centrifuged protoplast pellet.

    The protoplast pellet should have a smooth surface.

Carry out fusions

19. Slowly layer the myeloma cell preparation on top of the protoplast pellet in the 50-ml conical polypropylene centrifuge tube. Centrifuge 10 min at 500 × *g*, room temperature.
20. Aspirate the supernatant. Mix cell and protoplast pellet by hand-flicking the tube and tapping it on the benchtop.
21. Add 2 ml PEG 1500 in DMEM supplemented with DMSO. Resuspend the pellet by pipetting up and down several times.
22. After addition of the PEG solution (~1 to 2 min), very slowly add 10 ml prewarmed DMEM. To do this, swirl protoplasts gently, start adding drops of DMEM, and slowly increase the added volume.
23. Add 10 ml prewarmed DMEM supplemented with 10% FCS, swirl gently, and centrifuge 10 min at 500 × *g*, room temperature.
24. Aspirate the supernatant, resuspend the pellet in 50 ml prewarmed DMEM supplemented with 10% FCS, and add 100 µl of 50 mg/ml kanamycin.
25. Pour into a multipipet tray and distribute among five 96-well tissue culture plates by adding 100 µl/well using a multipipettor. Wrap tissue culture plates in plastic wrap and incubate for 48 hr in a 37°C, 10% CO_2 humidified incubator.

Day 5: select transfected cells

26. After 48 hr, prepare selection medium by adding 10 ml prewarmed 50 mM L-histidinol to 40 ml prewarmed DMEM supplemented with 10% FCS. Add 100 µl of 50 mg/ml kanamycin. Pour into a multipipet tray and add 100 µl/well using a multipipet. Rewrap tissue culture plates in plastic wrap and continue incubation in a 37°C, 10% CO_2 humidified incubator.

    The antibiotic, here L-histidinol, has to be adapted to the eukaryotic selection marker of the mammalian expression vector. Only transfected myeloma cells will survive the treatment with L-histidinol.

27. Examine plates visually for clones ~10 days after selection medium is added.

    No medium change or any other treatment is necessary during this time

Identify IgSF-CAM expressing clones

28. Once a clone becomes clearly visible by eye, analyze it for the expression of IgSF-CAM by indirect immunofluorescence staining (*UNIT 4.3*). Transfer ≤50% of the cloned cells to a well of a 96-well plate with V-shaped wells and perform indirect

immunofluorescence analysis with a polyclonal anti-IgSF-CAM and a fluorescein-conjugated secondary antibody. Identify clones that are expressing IgSF-CAM.

29. Expand positive clones into 24-well tissue culture plates.
30. Subclone positive clones by limiting dilution in 96-well tissue culture plates.
31. Maintain positive subclones in selection medium, e.g., 5 mM L-histidinol in DMEM supplemented with 10% FCS. Store backup cells frozen in liquid nitrogen using standard procedures (*UNIT 1.1*).

Cells from positive subclones are used in myeloma cell aggregation assays.

BASIC PROTOCOL 5

Detecting *Cis*-Interactions between IgSF-CAMs by Chemical Cross-Linking

The following basic protocols describe methods for the detection of *cis*-interactions, i.e., interactions between proteins that reside in the same membrane. In the chemical cross-linking methods described in this protocol, bifunctional reagents are used to establish covalent cross-bridges between associated proteins. The covalently linked protein complexes are then analyzed by SDS-PAGE (*UNIT 6.1*) and immunoblots (*UNIT 6.2*), using specific antibodies. In the antibody-induced co-capping methods (see Basic Protocol 6), a hypothesized *cis*-interaction between two cell surface proteins is evaluated by inducing a redistribution of one molecule and testing whether the putative binding protein follows. For both methods, the cells analyzed should be cultured at low density, in order to prevent contact between cells. Under these conditions, close associations of proteins are only possible between proteins residing in the membrane of the same cell.

Chemical cross-linking joins two molecules by means of a cross-linking reagent. The method critically depends on the cultivation of the cells of interest as single cells at low density to avoid the formation of cell-cell contacts. Moreover, the structural integrity of the cells should be maintained throughout the procedure. The use of hydrophilic, membrane-impermeable bifunctional cross-linking reagents restricts the cross-linking to extracellular domains of membrane proteins. Considering the close spatial association between proteins interacting within the same membrane, a high degree of specificity of chemical cross-linking is mandatory.

The specificity of chemical cross-linking is mainly determined by the chemical reactivity of the functional groups of the cross-linking reagent and the length of the spacer separating the reactive groups. The *N*-succinimidyl group combines efficient reactivity with a high selectivity for primary amino groups, thereby limiting the cross-linking to lysine side chains at the surface of proteins engaged in interactions. Since most IgSF-CAMs contain multiple lysine residues in their extracellular domains, the amino-group-specific homobifunctional *N*-succinimide-derivatives are suitable reagents for the detection of *cis*-complexes formed between such molecules. The following protocol will primarily focus on the application of hydrophilic homobifunctional di-*N*-succinimidyl derivatives with relatively short (0.6 to 1.2 nm) spacer sequences separating the reactive groups. In order to enhance the specificity of the chemical cross-linking reaction to stably associated proteins, lateral movement in the cell membrane is reduced by performing the cross-linking reaction on ice. Ideal spacer length of the cross-linking reagent, optimal concentrations of cross-linkers, and reaction times strongly depend on the specific system that is analyzed and must be evaluated empirically. The parameters described below turned out to be optimal in many experimental situations and represent a good starting point for further optimizations. After quenching the cross-linking reaction, cells are lysed and the cross-linked complexes ideally isolated by immunoprecipitation (*UNIT 7.2*) using specific antibodies against the molecule of interest. Immunoprecipitates are separated by SDS-PAGE and cross-linked complexes can be detected by immunoblot analysis. The presence of

known binding partners within the cross-linked complexes can be addressed by immunochemical techniques, which require only low amounts of proteins. However, immunochemical analysis clearly restricts the detection of cross-linked binding partners to known molecules against which antibodies are available. Scaling-up of the procedure may result in the isolation of sufficient amounts of cross-linked material for subsequent microsequencing allowing the detection of novel binding partners.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Materials

Cells of interest growing in tissue culture at low density
PBS with Ca^{2+}/Mg^{2+} (see recipe)
100 mM cross-linking reagent (see recipe):
Bis(sulfosuccinimidyl)suberate (BS^3) in water
Disuccinimidyl tartrate (DST) in water-free DMSO
Disulfo disuccinimidyl tartrate (Sulfo-DST) in water
3, 3′-Dithiobis(sulfosuccinimidyl propionate) (DTSSP) in water
5 mM EDTA in Ca^{2+}/Mg^{2+}-free PBS
1 M glycine solution in water, pH 8.0
Lysis buffer (see recipe)
Primary antibody: serum, purified immunoglobulin, or purified immunoglobulin immobilized on agarose or Sepharose matrix
Protein A or protein G coupled to agarose or Sepharose matrix (optional)
Wash buffer (see recipe)
Sample buffer for SDS-PAGE (*APPENDIX 2A*)
10-cm tissue culture dishes precoated with poly-D-lysine combined with additional substrates, such as laminin (see Support Protocols 10 and 12)
Horizontal shaker
Cell scraper
2-ml microcentrifuge tubes
End-over-end rotator (model 750)
100- or 200-µl and 500-µl Hamilton syringe and 22-G needle
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblot analysis (*UNIT 6.2*), and immunoprecipitation (*UNIT 7.2*)

Prepare cells

1. Prior to the experiment, seed cells onto 10-cm tissue culture dishes at a low density. Plate slowly dividing (division rate of <1 division in 48 hr) or nondividing cells, e.g., primary neurons, 12 to 16 hr prior to the experiment at a density of 10^4 cells per cm^2 on cell culture dishes precoated with poly-D-lysine (Support Protocol 10) combined with additional substrates, such as laminin (see Support Protocol 12).

   Fast dividing cells, especially fast-growing cell lines, are problematic in this experiment as extensive contacts are formed between the progeny of cell divisions. With COS or HEK 293 cells, cultures of mainly single cells can be obtained by plating the cells 4 to 6 hr prior to the experiment on poly-D-lysine coated cell culture dishes in a density of 1-2 × 10^4 cells per cm^2. For the final passage of cells, do not trypsinize cells. Most cell lines can easily be detached when cultured on untreated cell culture plastic by incubation for a few minutes in 5 mM EDTA in Ca^{2+}/Mg^{2+}-free PBS at room temperature. Care must be taken to generate single-cell suspensions without any cell aggregates by careful trituration using a large-bore

pipet tip. Glass pipets (Pasteur pipets) are not recommended, since the sharp glass edges and the strong shearing forces damage the cells resulting in the formation of clumps and aggregates.

2. Use one 10-cm tissue culture dish (containing ~10^6 cells) for each reaction. In the first set of experiments, include three different concentrations of cross-linking reagent and three to four different reaction times, resulting in a total of nine to twelve individual samples.

3. Prior to the experiment, check cells for homogenous distribution under an inverted microscope that allows the examination of living cells. Do not use cultures containing aggregates or clumps of cells.

4. Remove culture medium and wash the cells three times with PBS containing Ca^{2+}/Mg^{2+}. Add 10 ml PBS with Ca^{2+}/Mg^{2+} and incubate 5 to 10 min on ice.

   Incubation on ice not only reduces lateral movements of proteins within the cell membrane but also decreases endocytosis of membrane proteins.

   The cells are living and therefore, during this and subsequent steps, 5 through 8, are very fragile, especially primary neurons that have the tendency to detach spontaneously during the procedure. All steps must be carried out with the utmost care to protect the cultures from mechanical stress.

Cross-link cells

5. During the incubation period of step 4, freshly prepare 10 ml each of 0.1 mM, 1 mM, and 10 mM cross-linker solution per dish in PBS with Ca^{2+}/Mg^{2+}, using the 100 mM DST stock solution in water-free DMSO.

   The concentration of the cross-linking reagent is a very critical parameter. Most published protocols use concentrations of ~1 mM for efficient cross-linking. For a first set of experiments, the authors recommend 0.1 mM, 1 mM, and 10 mM for the reagents DST and DSSP.

   The cross-linker solution in PBS with Ca^{2+}/Mg^{2+} is unstable at room temperature and should be kept on ice for ≤5 to 10 min prior to adding to cells.

6. Remove PBS from cells and add the prechilled cross-linker solution carefully to the cells. Carry out the cross-linking reaction on ice with gentle shaking (20 to 30 rpm) on a horizontal shaker.

   Tilt cell culture dish slight and add cross-linker solution at the edge of the dish with a pipet. Distribute the cross-linker solution carefully over the entire surface of the dish.

Quench reaction and lyse cells

7. Quench the reaction after 0, 5, 15, and 45 min by adding 0.5 ml of 1 M glycine solution, pH 8.0 (final glycine concentration is 50 mM). Perform the quenching reaction for 15 min.

   The reaction time is a critical parameter regarding specificity and yields of chemical cross-linking. Quenching of the reaction in an initial experiment after 0, 5, 15, and 45 min results in a "kinetic profile" of the cross-linking reaction. This "kinetic profile" is often valuable, not only for the optimization of the reaction time as a parameter but also in the interpretation of the results.

8. Completely remove the reaction mixture from the cells without detaching them and add 2 ml of lysis buffer per dish. Remove cells from the culture dish with a cell-scraper and lyse them for 30 min on ice on a horizontal shaker.

9. Transfer cell lysate to 2-ml microcentrifuge tubes and microcentrifuge 15 min at 12,000 to 14,000 rpm, 4°C.

This centrifugation step clears the cell lysates from nuclei and cell debris. Still, the cleared lysates frequently have an opaque appearance. The lysates can be frozen and kept for several weeks at −20°C.

Immunoprecipitate cross-linked proteins

10. In 2-ml microcentrifuge tubes, prepare the primary antibody for immunoprecipitation.

    Primary antibodies for immunoprecipitation can be used in the form of whole serum, purified immunoglobulins, or coupled to an agarose or Sepharose matrix (for coupling of purified immunoglobulins to cyanogen bromide agarose or Sepharose see Support Protocol 1).

    Prior to the addition of the cell lysate, preincubate whole serum with Sepharose-coupled protein A (ideal for rabbit antisera) or protein G (for goat or sheep antisera) in a ratio serum/protein A/G Sepharose of 2:1 and purified immunoglobulins with protein A/G matrix in a ratio of 5 μg immunoglobulin/μl matrix for 30 min at room temperature. For an efficient immunoprecipitation ~10 to 20 μg of specific immunoglobulin are required. A total matrix volume between 10 and 20 μl is recommended.

11. Add the cleared cell lysate to the primary antibody and rotate for 4 to 16 hr end-over-head at 4°C.

12. Microcentrifuge samples for 1 min at 14,000 rpm, 4°C and carefully remove the supernatant; keep supernatant and store at −20°C.

13. Resuspend matrix in 1 ml wash buffer, vortex for 20 sec, and microcentrifuge 30 sec at 14,000 rpm, 4°C. Repeat the wash step three times and carefully remove the supernatant after final wash step. Remove the residual fluid from the matrix pellet with a 100- or 200-μl Hamilton syringe without aspirating matrix material.

14. Elute material bound to the matrix in 50 to 100 μl sample buffer for SDS-PAGE by boiling 5 min. Microcentrifuge samples for 1 min at 14,000 rpm, room temperature.

    After boiling, the protein sample in SDS-PAGE sample buffer can be stored several months at −20°C or years at −70°C.

15. Analyze protein samples by SDS-PAGE (*UNIT 6.1*) and detect the cross-linked complexes by immunoblot analysis (*UNIT 6.2*).

Detecting *Cis*-Interactions between IgSF-CAMs by Antibody-Induced Co-Capping

BASIC PROTOCOL 6

The lateral mobility of integral membrane proteins within the plane of the cell membrane allows the induction of large clusters of molecules by cross-linking their extracellular moieties with antibodies. This phenomenon is termed "antibody-induced capping". Interactions between two cell surface proteins in the plane of the same membrane (*cis*-interactions) can be addressed by examining the effects of antibody-induced capping of one molecule on the distribution of the other molecule. Reciprocal co-capping or co-distribution of two molecules after induction of capping with antibodies against one of them strongly indicates a (direct or indirect) *cis*-interaction. The following protocol describes a basic method for the induction of capping by antibodies and the detection of co-capping by fluorescence microscopy.

Cells of interest are cultivated at low density to avoid the formation of extensive cell-cell contacts. Incubation with the primary antibody against the first molecule (A) is performed on intact, live cells in the cold to reduce lateral movement of membrane proteins. Following the incubation with primary antibody against molecule A, unbound antibody is removed. Bound primary antibody is detected by a fluorochrome-conjugated secondary

antibody against the animal species in which the anti-A primary antibody was raised. Subsequently raising the temperature to 37°C restores the lateral mobility of proteins in the cell membrane and results in the formation of clusters of molecule A due to antibody-mediated cross-linking. The cells are washed, fixed, and counter-stained with a primary antibody against the putative binding partner of molecule A (molecule B). To this end, the primary antibody against molecule B must be raised in a different species than the anti-A antibody. The anti-B antibody is detected by a secondary antibody conjugated to a different chromophore than the secondary antibody against molecule A. Care should be taken that the two antibody combinations do not cross-react. Further, the emission wavelengths of the chromophores coupled to the secondary antibodies must be distinct to allow a complete separation of the signals by the use of narrow band-pass filters in the subsequent examination by immunofluorescence microscopy. Once the conditions for antibody-induced capping and for observing specific immunolocalization have been established, co-localization of the fluorescence signals elicited by the secondary antibodies allows the detection of co-clustering of molecules A and B on the cell surface. Quantitative analysis of the localization of the fluorescent signals requires a spatial resolution not normally achieved by standard light microscopes. To this end, due to its superior resolution power, confocal laser scanning microscopy represents a powerful technique for the quantitative assessment of co-distribution induced by antibody-induced capping.

Materials

Cells of interest growing in tissue culture (e.g., nondividing cells or primary neurons)
Cell culture medium (used for the cells of interest) without serum
PBS (see recipe)
Hank's Balanced Salt Solution (HBSS; *APPENDIX 2A*)
HBSS/1% FCS: HBSS containing 1% (v/v) fetal calf serum (FCS)
Primary antibodies (serum or purified immunoglobulin) for molecules A and B
Secondary antibodies of the appropriate sources coupled to different fluorescent dyes
4× Fixative solution (see recipe)
Vectashield mounting medium for fluorescence (H-1000, Vector Laboratories)
10-cm tissue culture dishes
12-mm no. 1 round glass coverslips, sterilized by autoclaving or soaking in 70% ethanol for 1 hr and precoated with poly-D-lysine (see Support Protocol 10)
Watchmaker's forceps
24-well tissue culture plates
Microscope slides
Nail polish
Fluorescence microscope with 63× and/or 100× oil immersion objectives

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All cell culture incubations should be carried out in a 37°C, 5% CO_2 humidified incubator.

Prepare cells

1. One day prior to the experiment, seed cells at low density onto 10-cm cell culture dishes, each containing 15 to 20 sterilized poly-D-lysine coated 12-mm round glass coverslips. Plate nondividing cells or primary neurons 12 to 16 hr prior to the

experiment at a density of 2×10^4 cells per cm^2 and fast-growing cell-lines 8 to 12 hr prior to the experiment at a density of 10^4 cells per cm^2.

These cell densities should result in ~10% confluency at the time of the experiment.

Coating of glass coverslips with poly-D-lysine is always recommended, in order to prevent cell detachment during the procedure.

2. Two to 4 hr prior to the experiment, transfer the glass coverslips with watchmaker's forceps from the 10-cm cell culture dish to wells 24-well tissue culture plates containing 1 ml cell culture medium per well. Incubate at 37°C

Aseptic technique is recommended, but not mandatory.

3. After 2 to 4 hr of incubation, remove the culture medium and wash the cells three times with 1 ml HBSS at room temperature, each time by adding 1 ml of HBSS, incubating 1 min, and aspirating wash solution. Add 200 µl HBSS/1% FCS per well and incubate the 24-well plate for 10 min on ice.

Do not let the cells dry throughout the procedure. The incubation with HBSS/1% FCS on ice will block potential unspecific sites for antibody adsorption. Incubation on ice not only reduces lateral movements of proteins within the cell membrane but also decreases endocytosis of membrane proteins.

The cells are living and therefore, during this and subsequent steps are very fragile, especially primary neurons that have the tendency to detach spontaneously during the procedure. Carry out all steps with the utmost care to protect the cultures from mechanical stress.

Prepare and bind primary antibody for molecule A

4. Prepare the appropriate dilutions of primary antibody and control antibody to molecule A in HBSS/1% FCS in microcentrifuge tubes and centrifuge for 1 min at maximum speed. Transfer supernatants to new tubes and put primary antibody solutions on ice ≥5 min prior to use.

For co-capping experiments the primary antibodies are generally applied at higher concentrations than for standard immunofluorescence protocols. Titrate optimal antibody concentrations for each experimental system individually. As a rule, dilute affinity-purified antibodies to a range of 5 to 20 µg/ml and antisera between 1:20 and 1:200. If using a commercially available antibody, multiply the concentration recommended for immunofluorescence staining by a factor of five. For a first set of experiments, try a range of dilutions and test for potential cross-reactivity of the primary antibodies in advance. Add negative controls to ensure specificity of antibody-induced capping. To this end, preimmune serum or purified antibodies from preimmune serum are required.

Antibody dilution is a critical parameter regarding cross-reactivity: this phenomenon may occur at the high concentrations that are used for co-capping experiments even if absent at concentrations based on own experience or recommended by manufacturers for standard immunofluorescence protocols.

5. Remove HBSS/1% FCS from cells and add 200 µl of cold anti-A antibody in HBSS/1% FCS to each well. Incubate with the primary anti-A antibody for 30 min on ice.

Prepare and bind secondary antibody for molecule A

6. Dilute fluorochrome-conjugated secondary antibody in HBSS/1% FCS in microcentrifuge tubes and centrifuge for 1 min at maximum speed. Transfer supernatants to new tubes and place secondary antibody solutions on ice ≥5 min prior to use.

Commercially available preparations of secondary antibodies must be tested for cross-reactivity with the primary and secondary antibodies against molecule B in advance. Even

if manufacturers assure that no such cross-reactivity occurs, consider that the concentrations of secondary antibodies used in co-capping experiments are well above those normally applied for immunofluorescence staining. Typical dilutions of commercial preparation are between 1:20 and 1:200 (~5 to 10 times higher than for standard immunofluorescence applications).

7. Aspirate primary antibody solution and wash cells two times with ice-cold HBSS. Add 250 µl/well of secondary antibody and incubate for 30 min on ice. Protect from light.

8. Remove the solution containing the secondary antibody and wash the cells two times with ice-cold HBSS. Add 200 µl of ice-cold cell culture medium without serum and put the 24-well cell culture plate for 30 min in a 37°C, 5% CO_2 humidified incubator.

   Never use HBSS or PBS for this incubation step. The phosphate buffer system present in HBSS and PBS is insufficient to buffer the pH efficiently in a 5% CO_2 atmosphere. The pH would drop too much and lead to false results. Always use the cell culture medium normally applied for the cell cultures of interest without serum. When stored on ice, keep the cell culture medium in air-tight tubes.

Fix cells

9. Add 66.7 µl of 4× fixative solution to each well and allow cells to fix for 15 µin at 37°C in the dark.

   A frequent source of experimental artifacts in co-capping experiments is fixation. It is necessary to block any further lateral movement of the capped proteins after fixation. The fixation in culture medium with 2% formaldehyde/0.1% glutaraldehyde results in total immobilization of membrane proteins without permeabilization of the cell membrane (for a detailed discussion, see Dubreuil et al., 1996).

10. Aspirate fixative and wash cells two times with PBS. Remove the PBS after the second wash step and add 500 µl PBS/1% FCS. Incubate for 15 min at room temperature.

Prepare and bind primary antibody for molecule B

11. Prepare dilutions of the primary antibody for molecule B in PBS/1% FCS as described in step 4.

    For the counter-staining (here of molecule B), the primary antibodies are generally applied in concentrations comparable to standard immunofluorescence protocols. Titrate optimal antibody concentrations for the counter-staining in a way that similar intensities of fluorescence signals result for both molecules. As a rule, dilute affinity-purified antibodies in a range of 1 to 10 µg/ml, purified Fab fragments 5 to 20 µg/ml, and antisera between 1:100 and 1:1000.

    If using a commercially available antibody, the concentration recommended for immunofluorescence staining is a good starting point for the optimization of the counter-staining. For a first set of experiments, try a range of dilutions and test again for potential cross-reactivity of the antibodies in advance. Add negative controls to ensure specificity of the counter-staining. In addition to preimmune serum or purified antibodies from preimmune serum, include further primary antibodies against molecules for which no co-capping with molecule A is expected in the experiment. The specificity of co-capping is the most critical issue in the whole experiment.

12. Remove the PBS/1% FCS and add 200 µl/well of diluted primary anti-B antibody in PBS/1% FCS. Incubate 1 hr at room temperature. Protect from light with aluminum foil or place 24-well plate in a drawer.

Prepare and bind secondary antibody for molecule B

13. Dilute the secondary antibody against anti-B antibody in PBS/1% FCS as described in step 6.

    If commercially available preparations of secondary antibodies are used for the counter-staining, dilutions between 1:100 and 1:500 are recommended in most cases. These concentrations are similar to those used for standard immunofluorescence applications. The issue of cross-reactivity with the primary and secondary antibodies against molecule B is much less critical than in case of the antibody used for capping but have to be tested anyway to use the system in reverse order to detect reciprocal co-capping (see below).

14. Remove primary anti-B antibody solution and wash cells two times with PBS/1% FCS. Add 200 µl/well secondary anti-B antibody in PBS/1% FCS and incubate 45 min at room temperature. Protect from light.

Fix cells

15. Wash cells two times with PBS/1% FCS and one time in PBS only. Add 250 µl of 1× fixative solution (2% formaldehyde/0.1% glutaraldehyde in PBS) and let cells fix for 5 min at room temperature in the dark.

16. Remove fixative and wash cells two times with PBS.

    The samples can be stored protected from light for up to 1 day at 4°C.

Mount and examine cells

17. Label microscope slides and place 1 drop of Vectashield mounting medium onto slide. Carefully remove each coverslip from the 24-well plate with watchmaker's forceps and blot excess fluid by touching edge with a paper towel. Invert coverslip, cell-side down onto mounting medium. Do not apply pressure. Blot excess mounting medium with a paper towel and allow slides to dry 5 min at room temperature in the dark. Seal around the rim of the coverslip with nail polish.

18. Examine specimen on a standard fluorescence microscope using a 63× or 100× oil immersion objective.

    Due to its superior resolution power, confocal laser scanning microscopy represents the preferred technique for the quantitative assessment of capping and co-capping.

Neurite Outgrowth Assay

BASIC PROTOCOL 7

This protocol describes a method to quantify the growth of neurites from cultured neurons. Neurite outgrowth assays are used to determine a potential role of an IgSF-CAM as a substratum for neurite outgrowth. The authors describe here the use of embryonic chicken sensory neurons (Stoeckli et al., 1991), however depending on the substratum to be tested and the responsiveness of the cells, other neurons such as tectal, cerebellar, and spinal cord neurons, may be used as well. It is important that for these assays the neurons are plated at a very low density in order to prevent contact between neurons and their axons, as well as contact between neurons and non-neuronal cells. Only then does the measured neurite length reflect the neurite outgrowth-promoting activity of the substratum used.

Many IgSF-CAMs were found to be potent neurite outgrowth-promoting substrates for various types of neurites. This protocol is an example of the one used for low-density cultures of dorsal root ganglia neurons on an IgSF-CAM substrate. Low-density cultures (Stoeckli et al., 1991, 1996), rather than explants or high-density cultures, are used to minimize effects derived from cell-cell contacts. To achieve reproducible results for growth assays use serum-free, chemically defined media wherever possible.

Many commercially available software packages (e.g., NIH Image, Metamorph) provide convenient methods for neurite length measurements. The goal of this protocol, therefore, is not the explication of a particular method of neurite length measurement, but rather the discussion of basic requirements and principles that need to be fulfilled to obtain reproducible values.

Materials

Chicken embryos (E8 to E10)
0.5% (v/v) glucose in PBS
0.25% (w/v) trypsin in PBS without Ca^{2+}/Mg^{2+} (Life Technologies)
Serum-free culture medium (see recipe)

Tissue culture dishes coated with substrate of choice (see Support Protocol 8)
Sterile dissecting tools
15-ml centrifuge tubes
Fire-polished Pasteur pipet, ~0.3-mm diameter bore
Neubauer chamber for cell counting (Fig. 1.1.1)
35-mm cell culture dishes
Image analysis software and required equipment
Additional reagents and equipment for counting cells (*UNIT 1.1*)

Dissect dorsal root ganglia and process cells

1. Coat 35-mm tissue culture dishes with appropriate substrate according to Support Protocol 8, 9, 10, 11, or 12.
2. Dissect dorsal root ganglia (DRG) from 10-day-old chicken embryos (Sonderegger et al., 1985) with sterile dissecting tools and collect DRGs in a noncoated 35-mm tissue culture dish on ice in 1 ml of 0.5% glucose in PBS.

   Younger embryos can also be used, but the dissection before E8 requires more skills and practice.
3. Transfer DRG to a 15-ml centrifuge tube and centrifuge 3 to 5 min at 300 to 500 × *g*, room temperature.
4. Carefully remove supernatant and add 2 ml of 0.25% trypsin solution to pellet. Resuspend ganglia and incubate 25 min in 37°C water bath.
5. Centrifuge DRG for 3 to 5 min at 300 to 500 × *g*, room temperature, decant trypsin solution supernatant, and add 1 ml serum-free culture medium.
6. Use a fire-polished Pasteur pipet with an opening of ~0.3-mm diameter to mechanically dissociate (triturate) the ganglia. Continue until no cell clumps are visible by eye.

   Less than ten passages should be sufficient to get a single cell suspension.

Count and plate cells

7. Count an aliquot of the cell suspension in a Neubauer chamber (*UNIT 1.1*).
8. Obtain a cell suspension dilution of 150,000 cells/ml. Plate 1 ml of cell suspension per 35-mm cell culture dish.
9. Incubate cultures for 24 to 30 hr in a 37°C, 5% CO_2 humidified incubator.

   Axons reach their maximal length after 24 to 30 hr. However, growth rate and onset of axon growth are substratum-dependent.

Measure and count neurites

10. At the appropriate time, measure neurite length for neurites extending from single cell bodies without contact to other neurites (see Fig.9.5.1 and legend).

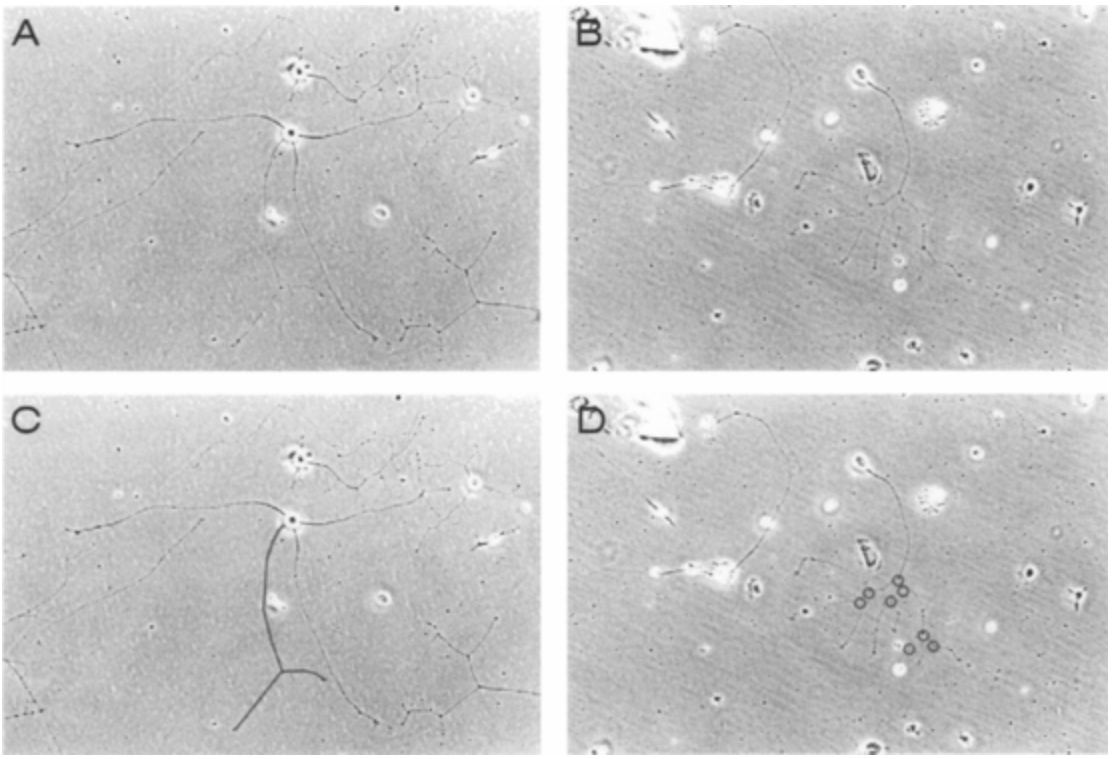

Figure 9.5.1 In order to be a valid assessment of the neurite outgrowth-promoting qualities of a test substrate, the evaluation of neurite outgrowth has to be carried out according to strict standards. Culture conditions have to be reproducible and identical. Therefore, chemically defined media should be used rather than serum containing media. Even minor changes in the composition of media can dramatically alter growth characteristics and the morphology of neurons (e.g., Savoca et al., 1995). The main criteria in the evaluation of neurite growth-promoting qualities of a test substratum is neurite length. However, keep in mind that only neurite lengths of single axons and not bundles of axons should be measured, as the latter would reflect a combination of neurite outgrowth promoted by the substratum and neurite growth along axons. Neurite length can be assessed either as length of the longest neurite (**C**) or as total neurite length of a neuron, in which case the lengths of all neurites of a neuron are added up and represented as one value. Different means can be used to measure the length of a neurite. The most convenient way is the use of a computerized system where one can trace the neurite with the joy stick and the computer will automatically determine its length. Make sure that the software allows the inclusion of the length of the side branches, as they have to be included into the measurements. The comparison between the neurons shown in (**A**) and (**B**) clearly demonstrates that the branching of a neurite is an important trait characteristic for a given substratum. The clear morphological differences between the neurons shown in (**A**) and (**B**) are reflected in the length plots (see Fig. 9.5.2). While the curves for the length of the longest neurite and the total length of all neurites of a neuron would greatly differ for neurons such as the one shown in (**A**), they would be superimposed for neurons like the one shown in (**B**). In other words, a strong deviation of the two curves indicates that neurons have, on average, multiple neurites, whereas a small deviation indicates that the majority of the neurons have only one neurite. Another way to quantify the morphological differences between neurons is the counting of branch points per neurite as shown in (**D**). While the neuron shown in (**A**) has 0 to 2 branch points per neurite, the neuron shown in (**B**) has 8 branch points (**D**).

A prerequisite for reliable neurite length measurements are low-density cultures of sufficient and reproducible quality. Care has to be taken to avoid the measurement of neurite fascicles rather than single neurites, as this confuses the results.

Fasciculation as well as cell-cell contact positively influences neurite length. Thus, for accurate determination of the neurite outgrowth-promoting capacity of a particular substrate or experimental condition, only single neurites extending from single cell bodies without contact to other neurites and especially without contact to non-neuronal cells should be included in the experiment. Cell numbers and culture conditions have to be chosen accordingly.

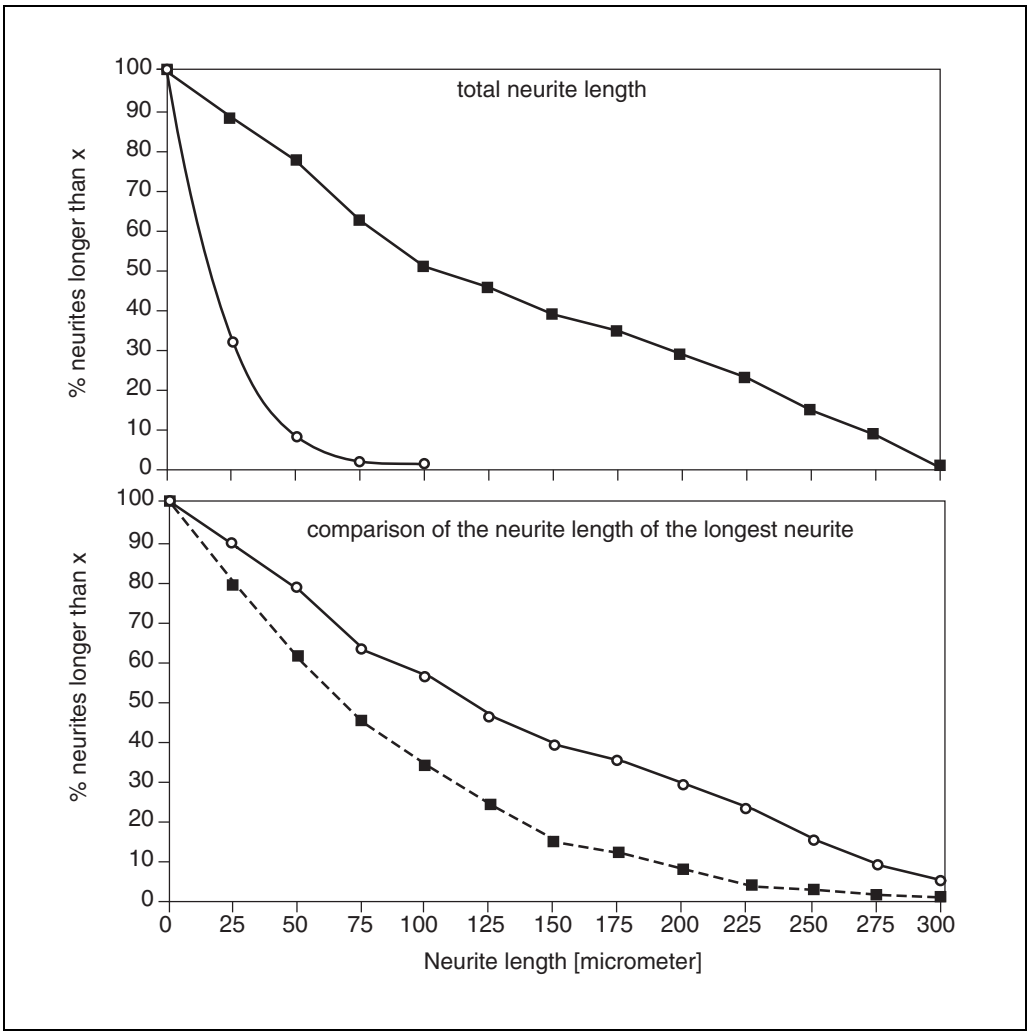

Figure 9.5.2 Graphic representation of neurite length. The neurite outgrowth-promoting activity of different IgSF-CAMs compared to each other or compared to a control protein can be represented in the type of plot that was introduced by S. Chang and colleagues (1987). In these plots the total length of all neurites extending from a neuron can be shown. The two curves in (**A**) represent a good (solid line) versus a poor substrate (dashed line). The same type of plot can also be used to represent a difference in neurite morphology (**B**). When the two curves representing the length of the longest neurite of a cell (dashed line with squares) and the total length of all neurites of a given cell (solid line with dots) differ a lot from each other, the neuron has most likely several long neurites, whereas cells with only one long neurite have plots where the two curves are almost the same.

11. Count the number of neurites per neuron, number of branches, and branching order.

    Very often the morphology of neurites is substratum-specific. Therefore, the total neurite length per neuron may only give you a partial account of the differences between distinct substrates. Therefore, additional information should be collected, such as number of neurites per neuron, number of branches per neurite, and branching order (i.e., appearance of secondary or even tertiary branches).

12. Analyze the growth cone. Measure the area, number of filopodia, and length of filopodia.

    Sometimes the analysis of the growth cone morphology is crucial. Characteristics, such as growth cone area, number of filopodia, or length of filopodia, can change dramatically depending on the substrate used. However, the culture conditions must be controlled carefully, because many of these characteristics can vary depending on the culture medium

as well as on the substratum used. Also, carefully control the origin of the neurons: only neurons from the same embryonic age can be compared. Neurites taken from adult animals can show completely different growth characteristics compared to embryonic neurons. This is especially true with respect to the dependence of neurons for trophic factors. Ideally, serum-free, chemically defined media are used in comparative studies of neurite length and morphology, as the content and concentration of serum components is subject to considerable batch-to-batch variability.

13. Represent the quantitative results.

A very common graphic representation of neurite length is the plot introduced by Chang et al. (1987). In these graphs the percentage of neurons with a total neurite length longer than x is easily visible (Fig. 9.5.2). Similarly, the length of the longest neurite per cell or the number of branches can be represented. The comparison between the curves for total neurite length per neuron and the length of the longest neurite can be used as a graphical representation of the difference between neurons with predominantly one neurite that is very long and neurons with many neurites per neuron that amount to the same total length when added together (Fig. 9.5.2B).

Inhibiting CAM-CAM Interactions In Vitro

BASIC PROTOCOL 8

One way to investigate the function of a particular protein is the analysis of changes resulting from blockage of function. This can be done with several methods both in vivo and in vitro. Whereas in vivo experiments are far more difficult and complex to perform, they more likely reflect the true function of the particular CAM because all parameters are the same, all binding partners are present, all interactions are possible, and even the most difficult parameter to test experimentally, the factor time, can be taken into account. However, there are also disadvantages; in vivo assays are far more complicated and time-consuming than in vitro studies. Most in vivo studies in vertebrates are done in "knock-out" mice, whereby homologous recombination in embryonic stem cells, a gene of interest is replaced by a construct that selects for the cells that have lost the expression of this gene. These "knock-out" mice can be analyzed for phenotypes resulting from the lack of expression of the gene of interest. While this is certainly a very potent method to analyze the function of CAMs, there are several major drawbacks; it is time-consuming, expensive, labor-intensive, and requires appropriate facilities with specially trained experimenters.

Furthermore, as the analysis of several knock-out lines has shown in the past, some mutations result in early embryonic lethality, in which case the organ of particular interest may not have developed by the time of death. This is especially true, when the function of a particular gene is to be analyzed in the nervous system. Alternatively, the lack of one gene may be compensated for, in which case, phenotypes are not detectable or only minor changes occur that are detectable only by very detailed analyses that often exceed the potential of one lab.

An alternative to these genetic loss-of-function analyses is an in vivo study where the blockage of function is done at the protein level (e.g., Stoeckli and Landmesser, 1995; Perrin and Stoeckli, 2000). Due to the relatively easy accessibility of the chicken embryo, it is the model of choice for this type of study. Obviously in contrast to the in vivo experiments described above, this is only possible for functional studies during embryonic development. Although less expensive and less dependent on an appropriate animal facility, in vivo studies using chicken embryos as a model system are time-consuming and require a considerable level of technical skills and training.

A description of in vivo loss-of-function studies would exceed the scope of this unit. For that reason, only in vitro methods for inhibition of IgSF-CAM function will be discussed.

The blockage of IgSF-CAM function in cultures of dissociated cells or tissue explants is much less complex than the inhibition of IgSF-CAM function in vivo; however, the results obtained in vitro may not reflect or only partially reflect the function of a particular IgSF-CAM in vivo. The advantages of in vitro experiments are: they are easier to perform, less time-consuming, and more suitable to study a particular question, due to lower degree of complexity. Assays as the one described in this protocol were used to study the role of NgCAM (Chang et al., 1987) and axonin-1 (Stoeckli et al., 1991) in the fasciculation of dorsal root ganglia axons.

Explants of intact dorsal root ganglia (DRG) are grown on a collagen substrate. Under these culture conditions axons extend from the explants in a radial fashion in the form of fascicles. The role of NgCAM as a candidate molecule mediating the axon/axon interaction under these conditions has been tested by the addition of Fab from anti-NgCAM antibodies to the culture medium.

Materials

10-day-old chicken embryos (E10)
0.5% (w/v) glucose in PBS
Chemically defined, serum-free cell culture medium (see recipe)
Control Fab
Fab against CAM of interest

15-ml centrifuge tubes
8-well-slide cell culture dishes (e.g., LabTek, Life Technologies) coated with IgSF-CAM (see Support Protocol 8)
Pasteur pipet or automatic pipettor with 200-µl tips

1. Dissect DRG from E10 embryos, collect in 0.5% glucose in PBS on ice.
2. Transfer DRG to a 15-ml centrifuge tube, and centrifuge for 3 to 5 min at 300-500 × *g*, 4°C or room temperature.
3. Decant supernatant and resuspend pellet in 1 ml serum-free cell culture medium by tapping the vial on the bench and swirling the tube.
4. Prepare 8-well-slide cell culture dishes coated with IgSF-CAM according to Support Protocol 8 by filling the wells with 300 µl medium containing no Fab, control Fab, or Fab against CAM of interest in different concentrations.

   Antibody concentrations ranging from 100 to 500 µg/ml for polyclonal and 10 to 500 µg/ml for monoclonal IgGs have been found useful for in vitro studies.

5. Plate DRG in the smallest possible volume either by using a Pasteur pipet or an automatic pipettor with a 200-µl tip.

   The DRG should be carefully placed on the surface of the dish rather than just put in the medium to facilitate attachment to the substratum. Take care not to scratch the coated surface of the cell culture dish.

   Carefully avoid shear forces that can destroy the ganglia. For inexperienced investigators, it is best to use an automatic pipettor set at 20 µl.

6. Grow DRG for 40 hr in a 37°C, 5% CO_2 humidified incubator.
7. Fix DRG as described in Support Protocol 13 by adding fixative directly to the culture medium to avoid detachment of the ganglia.

COATING OF CULTURE DISHES

To provide a suitable substratum for neurite growth, tissue culture dishes are coated with components of the extracellular matrix, such as laminin (see Support Protocol 12) or collagen (see Support Protocol 11). Alternatively, IgSF-CAMs can be used as substratum by either coating them directly onto tissue culture plastic (see Support Protocl 8) or on top of a nitrocellulose layer (see Support Protocol 9). The application of a nitrocellulose layer prior to coating of the protein substrate (Lagenaur and Lemmon, 1987; see Support Protocol 9) is useful to increase the coating efficiency. When glass has to be used instead of tissue culture plastic, precoating with nitrocellulose can be necessary. For coating with ECM components such as collagen (see Support Protocol 11) or laminin (see Support Protocol 12), glass is an acceptable surface even without precoating.

NOTE: All solutions and equipment must be sterile, and proper sterile technique should be used accordingly. Use filtration to sterilize solutions.

Coating with IgSF-CAM

SUPPORT PROTOCOL 8

Purified IgSF-CAMs can be used to coat culture surfaces for neurite growth assays. As purified IgSF-CAMs are usually available in limited amounts, draw a ~0.5-cm^2 circular area near the center of a 35-mm dish with a lab marker on the bottom outside surface of the dish. Then apply the protein to be tested to the marked area of the dish only. Coat the rest of the dish with bovine albumin (Albumax). This configuration provides better optical access to the cells than a 24 well plate. It also allows comparison of the growth-promoting effect of the protein of interest with that of bovine serum albumin in the same dish.

Materials

Protein to be coated
PBS (see recipe)
10 mg/ml bovine serum albumin (e.g., Albumax, Life Technologies) in PBS

1. Dissolve the proteins in PBS at concentrations of 10 to 100 µg/ml.

   Dilute protein solutions should not be stored for extended periods of time, no more than a few days at 4°C and never frozen. If freezing is required, add 100 µg/ml BSA as a carrier protein. Check for possible interference with the assay.

2. Pipet 20 µl protein solution per 0.5-cm^2 area of the culture dish and spread over marked area or use sufficient solution to cover entire surface.

   If glass is used, the volume per area should be doubled to reach sufficient dissipation of liquid.

3. Incubate for 2 hr in a 37°C humidified incubator.
4. Aspirate protein solution and rinse the entire surface of the dishes three times with PBS.
5. To saturate the protein adsorbance capacity of the tissue culture plastic or glass coverslip, incubate dishes for 30 min with a 10 mg/ml BSA solution. Cover the entire surface of the dish (1 ml per 35-mm culture dish).

   The use of BSA purified as fraction V from bovine serum is not advised, as most batches contain contaminations of endotoxins that are detrimental for cell survival, especially for neurons. The bovine serum albumin sold as Albumax from Life Technologies has given very satisfactory results.

6. Rinse dishes three times with PBS. Remove PBS immediately before plating cells. For reproducible results, do not allow the coated proteins to dry.

   Dishes should be coated immediately before use; storage is not recommended.

SUPPORT PROTOCOL 9

Pre-Coating Glass Surfaces with Nitrocellulose

IgSF-CAMs do not adhere well to glass surfaces unless those surfaces have previously been coated with nitrocellulose.

Materials

Methanol
Nitrocellulose (e.g., BA-83, Schleicher and Schuell), 0.2-µm pore size
Coverslips, 22-mm diameter (preclean glass with acetone before coating, dry, and autoclave)

1. Dissolve a 5-cm^2 piece of 0.2-µm pore size nitrocellulose membrane in 17 ml methanol.

   Make sure membrane is completely dissolved. The membrane becomes translucent and is difficult to see. The solution has to be prepared immediately before use. Do not store.

2. Dilute 300 µl of nitrocellulose membrane/methanol solution with 3.7 ml sterile water to obtain a coating solution.
3. Coat 22-mm glass coverslips by incubating with 200 µl coating solution for 2 hr in a laminar flow hood. Remove excess coating solution and let coverslips dry before use. Do not store. Proceed with coating with IgSF-CAM (Support Protocol 8).

   The same procedure has been used to precoat Thermanox coverslips for electron microscopic use.

   Tissue culture plastic can be coated with undiluted nitrocellulose solution, using 450 µl of the stock solution per 35-mm culture dish.

SUPPORT PROTOCOL 10

Pre-Coating with Poly-D-Lysine

The neurite outgrowth-promoting capacity of laminin is enhanced by precoating culture surfaces with poly-D-lysine. Alternatively, poly-D-lysine coating alone provides a good substrate for attachment of neurons and nonneuronal cells (also see Basic Protocol 5).

Materials

0.5 mg/ml poly-D-lysine (see recipe)

1. Make a stock solution of 0.5 mg/ml poly-D-lysine in sterile 150 mM sodium borate, pH 8.4. For coating tissue culture plastic, prepare a working solution immediately prior to use.

   Stock solution may be stored for a few weeks at 4°C. The sodium borate buffer can be autoclaved or filtered before poly-D-lysine is added.

   Depending on the type of culture, the coating concentrations range between 10 and 500 µg/ml. Dilute the appropriate volume of the poly-D-lysine stock solution with sodium borate.

2. Incubate dishes with 1 ml coating solution per 35-mm cell culture dish overnight in a 37°C humidified incubator.
3. Aspirate coating solution and rinse dishes at least three times with sterile water. Incubate the dishes overnight with sterile water in a 37°C humidified incubator.

   The dishes can be used immediately or dried and stored for several weeks.

Coating with Collagen

SUPPORT PROTOCOL 11

Collagen is a good substrate for many non-neuronal cells, but can also be used for axon growth assays e.g., for motor neurons. For most neuronal populations, laminin is the better neurite outgrowth promoting substrate than collagen.

Materials

2 mg/ml collagen in 0.1% (v/v) acetic acid, sterile
35-mm cell culture dishes

1. Dilute a 2 mg/ml stock solution of collagen in 0.1% acetic acid to get a final concentration of 0.25 to 0.5 mg/ml.
2. Coat 35-mm cell culture dishes with 750 µl of 0.25 to 0.5 mg/ml collagen solution. Evaporate the solution by incubating the dishes at 60°C overnight or until dry.

The dishes can be kept for a few weeks in a dry place at room temperature.

Coating with Laminin

SUPPORT PROTOCOL 12

Laminin is a very potent substrate for most neuronal and non-neuronal cells. It can be coated directly to tissue culture plastic and glass surfaces. However, laminin reveals best neurite outgrowth-promoting capacities when coated on dishes precoated with poly-D-lysine (see Support Protocol 10).

Laminin should not be stored in diluted solutions. For best results, keep small aliquots at −20°C, thaw slowly at 4°C, and prepare coating solution immediately before use. Use 750 to 1000 µl of 10 to 20 µg/ml solutions of stock per 35-mm cell culture dish. Coating is done as described in Support Protocol 8 for IgSF-CAMs. Dishes coated with laminin can be stored.

FIXATION OF CELLS FOR IMMUNOHISTOCHEMICAL STAINING PROCEDURES USING FLUORESCENT ANTIBODIES

SUPPORT PROTOCOL 13

In order to avoid the detachment of axons or the collapse of growth cones, the fixative should be added directly to the culture medium. For staining procedures involving fluorescent antibodies, glutaraldehyde can only be used in a very limited concentration, as it is autofluorescent. A concentration of 0.1% (v/v) is compatible with the use of fluorescent secondary antibodies. However, some antigens do not tolerate fixation by glutaraldehyde.

Materials

Paraformaldehyde solution (see recipe)
Cell culture medium

Add 350 µl of concentrated paraformaldehyde solution to 1 ml cell culture medium to get a final concentration of 2% paraformaldehyde and 0.1% glutaraldehyde. Fix cells for 30 min to 1 hr at 37°C or 2 hr to overnight at 4°C.

FIXATION FOR MORPHOLOGICAL ANALYSIS, NEURITE LENGTH MEASUREMENTS, AND FOR IMMUNOHISTOCHEMISTRY WITH NON-FLUORESCENT SECONDARY ANTIBODIES

If the autofluorescence of glutaraldehyde does not matter, higher concentrations than 0.1% (v/v) can be used. Glutaraldehyde has a higher crosslinking activity than formaldehyde and therefore, is the fixative of choice for good preservation of morphology. Final concentrations of up to 1% can be used. Add ⅓ vol 4× fixative solution (see recipe) to culture medium. Fix cells 30 min to 1 hr at 37°C or 2 hr to overnight at 4°C. For non-neuronal cells that are more strongly attached to the culture dish than neurons with axons, aspirate the culture medium and add 1× fixative solution.

NOTE: The preservation of antigens may restrict the use of high concentrations of glutaraldehyde, even if not used in combination with fluorescent secondary antibodies.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking solution (for amino bead coupling)

0.5 g bovine serum albumin (Fraction V; Sigma)
0.02% (w/v) NaN_3
50 mM Tris, pH 8.0, to 100 ml
Sterilize by filtering through a 0.45-µm filter
Store up to 1 month at 4°C

BSA solution, 0.5% (w/v)

0.5 g bovine serum albumin (Fraction V; Sigma)
0.02% (w/v) NaN_3
PBS (see recipe) to 100 ml
Sterilize by filtering through a 0.45-µm filter
Store up to 1 month at 4°C

Ca^{2+}/Mg^{2+}-free buffer (CMF buffer)

137 mM NaCl
4 mM KCl
0.4 mM $Na_2HPO_4 \cdot 2\ H_2O$
0.18 mM KH_2PO_4
12 mM $NaHCO_3$
11 mM glucose, pH 7.2
Filter sterilize through 0.22-µm filter
Store <2 weeks at 4°C

$CaCl_2$ solution

250 mM $CaCl_2$
Dissolve in ultrapure water
Sterilize by filtering through a 0.22-µm filter
Store at room temperature

Cell culture medium for HEK 293 cells

DMEM containing:
2 mM glutamine
2.4 g/liter sodium bicarbonate
10 mM HEPES, pH 7.5
10% (v/v) FCS
Filter sterilize through 0.45-µm filter
Store no more than a few days
Warm to 37°C before adding to cells

Chemically defined, serum-free medium

MEM containing
5 mg/ml lipid-rich bovine serum albumin with 0.1% IgG (e.g., AlbuMAX I, Life Technologies)
2 mM L-alynyl-L-glutamine or dipeptide glycyl-L-glutamine (e.g., GlutaMAX I, Life Technologies)
100 µg/ml transferrin
10 µg/ml insulin
20 ng/ml triiodothyronine
40 nM progesterone
200 ng/ml corticosterone
200 µM putrescine
60 nM sodium selenite
20 ng/ml nerve growth factor (NGF)
Prepare fresh

4-chloro-1-naphthalene solution

Stock solution: Dissolve 4-chloro-1-naphthalene in ethanol to give a 3 mg/ml solution. Store several weeks at −20°C.

Working solution: Immediately before use, dilute stock solution in TBS (*APPENDIX 2A*) and add 30% H_2O_2 to give final concentrations of 0.5 mg/ml chloronaphthalene and 0.01% H_2O_2 in TBS.

Cross-linking reagents

100 mM stock solution of cross-linker in water (BS^3, Sulfo-DST, and DTSSP) or water-free DMSO (DST). Stocks in DMSO can be stored at −20°C under dry nitrogen or argon for 1 to 2 months.
Bis(sulfosuccinimidyl)suberate (BS^3, Pierce)
Disuccinimidyl tartrate (DST, Pierce)
Disulfo disuccinimidyl tartrate (Sulfo-DST, Pierce)
3, 3′-Dithiobis(sulfosuccinimidyl propionate) (DTSSP, Pierce)

These reagents can be stored under water-free nitrogen or argon for up to 1 year at–20°C.

Working solution: Dilute stock solution of cross-linker in PBS with 0.9 mM Ca^{2+} and 0.5 mM Mg^{2+} to a concentration of 1 mM. Prepare fresh and do not keep for >1 hr on ice.

Fixation solution, 4×

40 ml concentrated paraformaldehyde solution (see recipe)
5 ml 20× PBS
0.4 ml 50% (v/v) glutaraldehyde (reagent grade) in water
H_2O to 50 ml

For best results, prepare fresh. If necessary, the fixative can be stored 2 to 3 days at 4°C.

HBS solution

50 mM HEPES
1.5 mM Na_2HPO_4
140 mM NaCl
Dissolve in ultrapure water
Adjust pH to 7.05 with 1 M NaOH or 1 M HCl
Sterilize by filtering through a 0.22-µm filter
Store for months at 4°C

L-histidinol, 50 mM

Dissolve 535 mg L-histidinol dihydrochloride (Sigma) in 50 ml of 100 mM HEPES, pH 7.4, pass through a 0.22-µm filter, and store in aliquots for up to 1 year at −20°C.

LB medium

Dissolve 10 g NaCl, 10 g bacto-tryptone (Difco), and 5 g yeast extract (Difco) in 1 liter water, autoclave, and store at 4°C.

LB/ampicillin agar plates

Dissolve 15 g bacto-agar in 1 liter LB medium (see recipe) by autoclaving, cool down to 50°C, add 1 ml of 50 mg/ml ampicillin, mix, and pour into 10-cm polystyrene plates. Let sit at room temperature overnight and store protected from light at 4°C.

Lysis buffer

1% (w/v) CHAPS
0.1% (w/v) SDS
50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
150 mM NaCl
5 mM EDTA
10 µg/ml leupeptin
10 µg/ml aprotinin
10 µg/ml pepstatin A
1 mM PMSF

Protease inhibitors except PMSF are stable in lysis buffer at −20°C for several months. However, PMSF has to be added fresh. Prepare a 100 mM PMSF stock solution in isopropanol and <5 min before use add to lysis buffer to a final concentration of 1 mM. PMSF stock solution can be stored several weeks at −20°C.

Mounting medium

10 ml 1M Tris·Cl, pH 9.0 (*APPENDIX 2A*)
70 ml glycerol (70% v/v final)
5.09 g *n*-propyl-gallate (0.24 M final)
H_2O to 100 ml
Adjust pH to 9.0
Make 1-ml aliquots and store at −20°C

Paraformaldehyde solution, 10% (w/v)

Add 5 g paraformaldehyde to 45 ml water, add 75 µl of 1 M NaOH and dissolve by heating to 60°C in a water bath. Let solution cool to room temperature, add water to a final volume of 50 ml, check that pH does not exceed 7.4. For best results prepare fixative immediately before use. Do not store >2 to 3 days at 4°C.

PBS

8.00 g NaCl (137 mM final)
0.20 g KCl (2.7 mM final)
2.16 g $Na_2HPO_4 \times 7\ H_2O$ (8 mM final)
0.20 g KH_2PO_4 (1.5mM final)
990 ml H_2O
Adjust pH to 7.4 with 1 N HCl or 1 N NaOH
Adjust volume to 1 liter with water
Filter sterilize through a 22-mm filter
Store at 4°C

PBS with Ca^{2+}/Mg^{2+}

8.00 g NaCl (137 mM)
0.20 g KCl (2.7 mM)
2.16 g $Na_2HPO_4 \times 7\ H_2O$ (8 mM)
0.20 g KH_2PO_4 (1.5 mM)
0.10 g $CaCl_2$ (0.9 mM)
0.10 g $MgCl_2 \times 6\ H_2O$ (0.5 mM)
990 ml H_2O
Adjust pH to 7.4 with 1 N HCl or 1 N NaOH
Adjust volume to 1 liter with water
Filter sterilize through a 0.22-mm filter
Store at 4°C

PEG 1500 in DMEM supplemented with DMSO

Melt 42.5 g polyethylene glycol 1500 (PEG 1500) in a microwave oven, add 50 ml DMEM and 10 ml DMSO, pass through a 0.22-μm filter, and store in aliquots up to 1 year at –20°C.

Poly-D-lysine solution

Dissolve 0.5 mg/ml poly-D-lysine (Sigma) in sterile 150 mM sodium borate, pH 8.4. Store a few weeks at 4°C.

Wash buffer

0.1% (w/v) CHAPS
0.1% (w/v) SDS
50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
150 mM NaCl
5 mM EDTA
1 mM PMSF
Add <5 min before use

COMMENTARY

Background Information

IgSF-CAMs have been characterized as crucial molecules for both the development and the normal function of multicellular organisms. They exert their function by mediating the interactions between cells under various circumstances. Interactions mediated by IgSF-CAMs may determine whether a cell remains where it is or whether it moves somewhere else; they may be involved in determining the path of cell migration and the time and the location of the end of the migratory path. Other IgSF-CAMs have been implicated in processes such as the extravasation of white blood cells, inflammation, wound healing, as well as tumor invasion and metastasis. In the developing nervous system, IgSF-CAMs play important roles in cellular migration, in the regulation of axonal outgrowth and pathfinding, and in synaptogenesis. In the adult nervous system, IgSF-CAMs play a role in the regulation of neural plasticity and in nerve regeneration after injury. Defective

genes of IgSF-CAMs have been found to result in severe cerebral malformations and mental retardation.

Recent advances in the characterization of IgSF-CAMs have revealed that in several cases IgSF-CAMs not only mediate cell-cell adhesion by binding to each other, but that they are often capable of eliciting intracellular signals upon binding an extracellular ligand. Intracellular signals elicited by extracellular ligand contact of IgSF-CAMs comprise many signal pathways, including the production of second messengers and the activation of transmembrane or intracellular kinases and phosphatases.

The enormous complexity of binding partners is the most striking difference between the calcium-dependent cell adhesion molecules and the calcium-independent cell adhesion molecules of the IgSF. Many IgSF-CAMs have been found not only to bind to their own kind in so-called homophilic interactions, but also to engage in several heterophilic interactions. Therefore, the determination of ligands plays a very important role in the characterization of IgSF-CAMs. Only by identifying the macromolecular binding partners of IgSF-CAMs can their functional roles in living organisms be elucidated. Some of these very basic studies demonstrating interactions between IgSF-CAMs and other binding partners may be applicable to the study of cell surface molecules in general, including molecules specifically expressed in the immune system, virus receptors, tumor growth markers, or growth factor receptors. However, the analyses of the specific functional roles of these proteins is beyond the scope of this unit. For these, the reader is referred to more specialized applications.

Trans-interactions

IgSF-CAMs are composed of at least one Ig fold, which is also the molecular building block of antibodies (Rader and Sonderegger, 1998). It is therefore conceivable to express IgSF-CAMs in myeloma cells that are specialized in the production of antibodies. An expression system based on myeloma cells was established for the production of soluble lymphocyte-derived cell-surface receptor proteins by Traunecker et al. (1991). This system has also been used for the expression of IgSF-CAMs on the surface of myeloma cells (Rader et al., 1993). By studying the IgSF-CAMs in a natural environment, i.e., as membrane-bound molecules residing in their proper orientation in a biological membrane, *trans*-interactions between molecules residing in different membranes can be readily detected through cell aggregation. Nonadherent myeloma cells provide an established natural environment for these studies. The myeloma cell aggregation assay described here has contributed significantly to the elucidation of the complex interaction pattern of two IgSF-CAMs, axonin-1 and NgCAM, which were found to *trans*-interact homophilically and *cis*-interact heterophilically (Rader et al., 1993; Buchstaller et al., 1996; Rader and Sonderegger, 1998; Sonderegger et al., 1998). In addition, the myeloma cell aggregation assay can be used for the structure-to-function analysis of a *trans*-interaction. Monoclonal antibodies that have been mapped to particular epitopes on the IgSF-CAMs can be analyzed for interference with myeloma cell aggregation. Defined mutants of IgSF-CAMs, e.g., engineered domain deletion mutants or pathological point mutations, can be expressed in myeloma cells and assessed for their effect on *trans*-interactions (Freigang et al., 2000). Furthermore, the influence of soluble molecules, e.g., ligands or toxins, on *trans*-interactions of IgSF-CAMs can be studied using myeloma cell aggregation. The expression in myeloma cells has also facilitated the production of soluble variants of IgSF-CAMs and fragments thereof (Rader et al., 1993, 1996).

Chemical cross-linking

Chemical cross-linking is a special form of chemical modification that results in the covalent coupling of molecules by a cross-linking reagent. In contrast to the simple conjugation of two molecules, cross-linking refers to the covalent coupling of two molecules that undergo an interaction with each other. The interacting molecules involved can be proteins, peptides, nucleic acids, or carbohydrates. Cross-linkers for proteins are bifunctional molecules containing two reactive groups that undergo reactions with side chains of amino acids. Cross-linkers can be generally classified into two main families, the homobifunctional cross-linkers, which contain two identical functional groups, and the heterobifunctional cross-linkers, which contain different types of reactive moieties. Simple homobifunctional cross-linkers, such as dialkyl halides and bis-imidoesters, were introduced in the 1950's. Since then >300 different cross-linking reagents have been synthesized and a large number of these are commercially available (Ji, 1983; Staros and Anjaneyulu, 1989). Recent developments led to the design and synthesis of cleavable bifunctional compounds that allow the recovery of the

individual compounds present within a cross-linked complex after its isolation.

Using bifunctional reagents for cross-linking of macromolecules, such as proteins, two different reaction products are generated resulting from either intramolecular or intermolecular cross-linking. For the study of protein-protein interactions as described in the protocol, intermolecular cross-linking is of interest. In the past, intermolecular cross-linking was instrumental in the investigation of antigen-antibody complexes, membrane protein structures, and protein-protein interactions at the quarternary structural level, e.g., in receptor-ligand or multienzyme complexes. The application of chemical cross-linking to identify membrane receptors for macromolecular ligands has become an established technique that can be successfully applied to the analysis of interactions between IgSF-CAMs (Staros, 1988).

The choice of reagents for cross-linking membrane proteins must take into consideration the particular physicochemical properties of biological membranes. A major problem is represented by the unspecific, random-collision dependent cross-linking, due to the lateral mobility of membrane proteins. Chemical cross-linking of membrane proteins should, therefore, generally be carried out in the cold to reduce lateral movements of proteins. A second major factor to be considered is the hydrophobicity of the membrane core. Hydrophobic and hydrophilic reagents have the potential to probe different regions of integral membrane proteins for interactions with binding partners. To study interactions between extracellular domains of IgSF-CAMs, hydrophilic, membrane-impermeable cross-linkers that bear hydrophilic or charged groups can be used (Buchstaller et al., 1996; Kunz et al., 1998). The limitation of cross-linking to closely associated binding partners within complexes of membrane proteins requires reagents with short spacers between their reactive groups. However, cross-linkers with spacer lengths of <0.5 nm result in poor yields of intermolecular coupling, whereas extensive cross-linking with decreasing specificity is generally observed with reagents with spacer lengths of >1.1 nm (Middaugh et al., 1983). The use of a homologous series of cross-linking compounds is recommended for the evaluation of the system.

For efficient cross-linking between extracellular domains of membrane proteins, two functional groups that differ in reactivity and chemical selectivity are predominantly used, (1) the *N*-succinimidyl group and (2) the photoactivatable aryl azide group. The *N*-succinimidyl group combines efficient reactivity with a high selectivity for primary amino groups, thereby limiting the cross-linking to lysine side chains and free N-termini of proteins. Disuccinimidyl derivatives of variable spacer length and hydrophilicity are currently commercially available. Popular hydrophilic disuccinimidyl reagents are the disuccinimidyl suberate (DSS) derivative bis(sulfosuccinimidyl)suberate (BS^3) with a spacer length of 1.14 nm, disuccinimidyl tartrate (DST) and its disulfo-variant disulfo disuccinimidyl tartrate (Sulfo-DST) with a spacer length of 0.64 nm. A water-soluble, membrane-impermeable, thiol-cleavable disuccinimidyl reagent with a spacer length of 1.2 nm is represented by 3, 3′-dithiobis(sulfosuccinimidyl propionate) (DTSSP).

The aryl azide group undergoes a UV light–induced chemical reaction resulting in the generation of a nitrene, a highly reactive, short-lived intermediate containing a nitrogen electron sextet (aza-analogon to a carbene). Analogous to carbenes, the nitrenes react immediately with their direct environment. The major reaction of interest is the insertion into C-H and N-H bonds resulting in the formation of a new covalent bond. This broad specificity allows the nitrenes to react with virtually all chemical groups present on a protein surface, making this type of cross-linking extremely efficient. Common nitrene precursors are arylazides with absorbance maxima in the long UV region. Nitro-substitution of the aromatic ring results in a further shift of absorbance towards longer wave lengths, away from the absorbance maxima of proteins. Photosensitive heterobifunctional cross-linkers containing one amine-reactive *N*-succinimidyl group with the photoactivatable aryl azide group are widely used reagents for the cross-linking of membrane proteins with their receptors (Hermanson, 1996). Commercially available products of this group are *N*-hydroxysulfosuccinimidyl-4-azidobenzoate (Sulfo-HSAB, spacer length of 0.9 nm) and the highly versatile thiol-cleavable reagent sulfosuccinimidyl 4-(*p*-azidophenyldithio) propionate (Sulfo-SADP, with a spacer length of 1.39 nm). For protocols regarding the use of these photoreactive cross-linkers see Jung and Moroi (1983) and Wood and O'Dorisio (1985).

Co-capping

The detection of *cis*-interactions by antibody-induced co-capping is based on the lateral mobility of integral membrane proteins within

the plane of the cell membrane. The freedom of lateral movement allows the induction of large clusters of these molecules at the cell surface by cross-linking their extracellular moieties with antibodies, so-called capping. Molecules that undergo (direct or indirect) interactions with the capped molecules in the plane of the cell membrane are co-clustered and exhibit co-capping when examined by immunofluorescence microscopy.

Antibody-induced co-capping has been an established technique, in particular in the field of immunology, for the last decades and was instrumental for the detection of many interactions of leukocyte surface molecules that are involved in antigen presentation and recognition (Rojo et al., 1989; Zhou et al., 1993). The co-capping approach allows detection of interactions between membrane proteins at the level of individual intact cells. The availability of novel fluorescent dyes allows the detection of three or four different fluorochromes simultaneously. This allows the examination of the cellular distribution of, for example, effector molecules of signal transduction or cytoskeleton components as a function of co-clustering of cell surface proteins by a combination of classical co-capping protocols with intracellular immunofluorescence staining.

Classical biochemical techniques, for example co-immunoprecipitation or chemical cross-linking (see Basic Protocol 5), require a homogeneous sample. In contrast, co-capping studies examine interactions between proteins at the level of individual cells and can, therefore, be performed on heterogeneous samples, like mixed primary cell cultures derived from animal tissue, if appropriate markers are available that allow one to distinguish between different cell types. A further major advantage is the requirement for only a limited number of cells for co-capping studies. This opens the possibility to study specific, rare cell types, which can be isolated only in small quantities. A powerful combination is represented by the prior isolation of a specific cell type, e.g., by fluorescence-activated cell sorting (FACS), using appropriate combinations of cell surface markers with subsequent co-capping studies.

The crucial prerequisite of the co-capping approach is the availability of suitable antibodies. This limits application of the technique to already described molecules against which antibodies are available. In addition, the antibodies used must meet the following criteria, (1) absence of any cross-reaction with other cell surface proteins on the cells of interest; and (2) no interference of antibody binding with the interaction that is studied (this point often represents an unknown factor that may influence the result). In addition, the two primary antibodies used must be raised in two different species.

Critical Parameters and Troubleshooting

Preparation of IgSF-CAMs

For the functional analysis of an IgSF-CAM, it is extremely important to have a highly purified protein sample. Due to the high complexity of their interaction pattern, a contamination of the protein sample to be analyzed by another IgSF-CAM could confound the results of binding assays (see Basic Protocols 2 and 3) or neurite outgrowth assays (see Basic Protocol 7). For this reason, protein samples purified with affinity columns should always be analyzed by SDS-PAGE followed by silver staining to confirm the absence of contaminating proteins. When possible contaminants are known, for instance based on their high expression level in the tissue used as a source for the purification, or when the absence of a particular IgSF-CAM is important for the experimental procedure, their absence can best be documented by immunoblot analysis of the purified fractions. As a quick alternative, dot blots described in Support Protocol 4 can be used. If contaminants are found, the following possibilities should be considered.

Affinity column was not rinsed properly after loading or has run dry. Make sure absorbance is back to baseline before starting elution. Take an aliquot from the wash fraction to confirm the absence of protein. It is extremely important that the column never runs dry.

Antibody used to make column is not specific or antibody is denatured because column is too old or was not stored properly. When the quality of the purified protein samples decreases, it is time to prepare a new affinity column. It is possible that the antibody is very sensitive to high pH conditions used for elution. Try an elution buffer with low pH (0.1 M glycine/HCl, pH 2.7) as an alternative. Change concentration and/or type of detergent used.

Because of the large number of IgSF-CAMs expressed in the nervous system and based on the enormous complexity of their interactions, the specificity of the antibodies used for function-blocking assays and the purity of IgSF-CAM preparations have to be tested carefully. It is important to include appropriate controls,

such as the use of preimmune IgG purified according to the same protocols as the specific IgGs to rule out toxicity of the antibody preparations. Assess the dose-dependence of the effect. A very convincing control for the specificity of the assay is the absence of an effect in the presence of a specific antibody against another IgSF-CAM that is expressed by the same cell.

Transfection

The most critical parameter determining the efficiency of the calcium phosphate protocol described is the 293 cells that are used. Cells of low passage numbers (not more than 40 passages) exhibit a much higher transfection efficiency than later passages.

The formation of the precipitate prior to the addition to cells is mainly influenced by the following parameters: concentrations of calcium, phosphate, and DNA, the nature of the DNA construct, pH, temperature, and time of incubation. The calcium and phosphate concentrations given in this protocol are optimized for this system. Optimal DNA concentration depends on the construct and must be determined for each system individually. A good starting point for optimizations when dealing with medium-sized plasmids of 5 to 10 kb is 40 to 80 μg DNA. Plasmids of different sizes vary considerably in behavior in calcium phosphate transfection. The protocol described works best for average sized expression plasmids (5 to 10 kb). Very large plasmids (>30 kb) frequently result in the formation of much larger precipitates, reducing the efficiency of transfection considerably. A reaction at pH 7.0, room temperature (20° to 25°C), and 1 min reaction time are good starting conditions for optimizations. The formation of precipitate after mixing $CaCl_2$ solution with HBS solution can be monitored by measuring the absorbance at 320 nm (e.g., for the testing of new batches of solutions).

After addition to the cells, the stability of the DNA-containing calcium phosphate particles is the most critical factor for the efficiency of transfection. One source of instability is a reduction in medium pH due to the metabolic activity of cells. It is therefore important to include 10 mM HEPES (final concentration) in the 293 cell culture medium. The reduction of the CO_2 partial pressure to 3% is another option to raise the pH value, if necessary. Increased time of exposure to the precipitate can further enhance the efficiency of transfection. An incubation time of 4 to 6 hr given in the protocol is a good starting point and can be extended up to 24 hr in cases where no cytotoxicity is observed. However, the combination of exposure to the precipitate with an osmotic shock, e.g., by adding 10% (w/v) glycerol to the cell culture medium, as suggested by some authors for the calcium phosphate transfection of Chinese hamster ovary (CHO) cells, is not recommended for 293 cells.

Immunoblotting

No positive dots. The concentration of the protein of interest may be below the detection limit. Use repeated applications of protein solution to the nitrocellulose membrane. Apply the purified protein onto the membrane as a positive control. If the total protein concentration of the solution applied to the membrane is high, even repeated applications of protein solution to the membrane may not give a satisfactory result.

High background. Make sure that the volumes of protein solution applied to the membrane are small. Let the dot dry before the next step. Wash membranes more thoroughly. Change the blocking solution and/or blocking time. For instance, try blocking with serum from the same species that was used to raise the secondary antibody.

Microsphere assays

False negative results in the bead aggregation assay. Coupling reaction results in protein orientation on the bead surface in a way that binding sites are not accessible. Alternatively, proteins could not be physiologically active after purification (e.g., elution after immunoaffinity column).

False positive results in the bead aggregation assay. Protein preparations that are not pure and contain another CAM could result in false positive binding results. Furthermore, if each of the two test proteins has homophilic binding properties, weak unspecific aggregation of preformed homophilic aggregates could result in false positive results with respect to heterophilic interactions. Therefore, check for unevenly distributed beads in mixed aggregates under the microscope (bead distribution in aggregates is not detectable in a flow cytometer).

Discrepancies between results of bead and cell aggregation assays. The orientation of proteins on the beads is likely to be random and not uniform as in a biological membrane. This has to be considered when interpreting and comparing the results with the ones of the cell aggregation assay. Furthermore, the orientation problem has to be taken into account when

analyzing *cis*- and *trans*-interactions (Kuhn et al., 1991; Buchstaller et al., 1996; Rader et al., 1996; Sonderegger et al., 1998).

Orientation of proteins on beads can be better controlled when using proteins with domains or tags that tightly bind to a linker protein that is coupled first to the microsphere. For example, recombinant Fc-fusion proteins can be coated on protein A-conjugated beads in an oriented manner. One has to consider that this linkage includes a noncovalent protein interaction.

Trans-interactions

The stably transfected myeloma cell clones may differ from the parental myeloma cell line in more than only the expression of the IgSF-CAM. The upregulation of endogenous cell adhesion molecules, such as integrins and IgSF-CAMs, can result in myeloma cell aggregation (Kawano et al., 1991). It is therefore essential to run a series of control experiments that address the question whether any cell aggregation is caused by a *trans*-interaction of the expressed IgSF-CAMs or by other factors. For this, follow these guidelines:

1. Confirm the functional surface expression of the IgSF-CAM using, for example, monoclonal antibodies directed against conformational epitopes.
2. Each aggregation assay should be performed in duplicate with cross-wise exchange of the fluorescent dyes.
3. Myeloma cell clones that express an IgSF-CAM should not form mixed aggregates with the parental myeloma cell line.
4. Independent myeloma cell clones that express the same IgSF-CAM should give the same aggregation pattern.
5. Independent myeloma cell clones that express different quantities of the same IgSF-CAM should be analyzed for a correlation between expression and aggregation.
6. Pre-incubation with polyclonal Fab directed to the IgSF-CAM should prevent aggregation.
7. Pre-incubation with an enzyme that removes the IgSF-CAM selectively from the surface should prevent aggregation. A very useful enzyme for this is phosphatidylinositol-specific phospholipase C, which selectively cleaves glycosyl-phosphatidylinositol-anchored proteins.

Chemical cross-linking

The application of cross-linking reagents on intact, live cells may result in possible artifacts due to the perturbation of the architecture of the cell membrane by the chemicals. Very often, the reagents are used at millimolar or higher concentrations (0.1 to 10 mM) and must be dissolved in organic solvents prior to use. It is therefore very important to assure that the reagents by themselves and especially organic solvents, if used, do not affect the structural integrity and viability of the cells tested. Water-soluble reagents like BS^3, Sulfo-DST, and DTSSP that carry sulfonyl groups can be used to circumvent the solvent problem.

Successful detection of *cis*-interactions between IgSF-CAMs requires a high specificity of chemical cross-linking on the one hand, and sufficient yields of cross-linked materials on the other hand, for subsequent biochemical characterization of cross-linked partners. As described above, the specificity and efficiency of the cross-linking reaction is determined by the following parameters: length of the spacer separating the reactive groups; chemical reactivity of the functional groups of the cross-linking reagent; concentration of cross-linking reagent; and reaction time.

Cross-linking reagents with short spacers between the reactive groups such as DST and Sulfo-DST restrict chemical coupling to closely associated molecules and are therefore preferable for the detection of *cis*-complexes between membrane proteins. However, due to the spatial proximity of their functional groups, these reagents exhibit an enhanced tendency for intramolecular cross-linking, i.e., coupling lysine side chains of the same molecule with each other, which may result in very low yields of cross-linked material. The application of reagents with longer spacers between the reactive groups such as BS^3 and DTSSP generally results in higher yields, but bears the risk of unspecific reactions. As previously discussed, the chemical reactivity of the functional groups present in commercially available cross-linking reagents range from highly selective, like the *N*-succinimidyl group, to rather unselective photoactivated groups, like aryl azides, which generate highly reactive, unstable intermediates that undergo reactions with a wide variety of chemical structures within a protein. Although the *N*-succinimidyl group is most frequently used for modifications and cross-linking of cell surface proteins, its selective reactivity with primary amino groups (mainly lysine side chains) excludes this class of cross-linkers from extended hydrophobic interfaces through which IgSF-CAMs may interact. Upon photoactivation, reagents containing aryl azide groups exhibit a high reactivity towards ali-

phatic hydrocarbon groups, like RCH_2R and R_2CHR, that allows cross-linking within a strongly hydrophobic environment. However, the high reactivity and low selectivity of photoactivated aryl azides frequently results in a high degree of unspecific cross-linking, not only among proteins, but also extensive protein-lipid cross-linking. For the detection of specific interactions among the closely associated proteins on the surface of intact cells, these reagents are, therefore, not recommended as first choice, but represent an option in cases where no cross-linking products are obtained using more specific reagents.

Optimal concentrations of cross-linking reagents must be evaluated empirically for every experimental system. A more detailed discussion of the chemical background can be found in Lomant and Fairbanks (1976), Lewis et al. (1977), and Smith et al. (1978). For homobifunctional *N*-succinimidyl derivatives, like DST and DSSP, optimal concentrations for cross-linking on intact cells are consistently in the range of 0.1 to 10 mM in published protocols. This range of concentrations represents a good starting point for optimizations. Cross-linking reagents with higher reactivity, like e.g., aryl azides, are generally applied in much lower concentrations, usually between 10 μM and 1 mM, for cross-linking on intact cells.

A further critical parameter is reaction time. Longer reaction times generally result in better yields of cross-linked products, but also in more unspecific reactions. Using homobifunctional *N*-succinimidyl reagents, quenching of the cross-linking reaction after 0, 5, 15, and 45 min results frequently in a "kinetic profile" of the process. Specifically, a different pattern of cross-linked products is observed during the time course of the cross-linking reaction. This reflects the tendency of many membrane molecules, such as IgSF-CAMs, to form oligomeric or even multimeric aggregates in the membranes of living cells. The appearance of initial cross-linked molecules, after a few minutes, is often followed by the appearance of further cross-linked complexes with higher molecular masses, generated from the coupling of the initial complexes with additional molecules. Initial cross-linked products that are generated within the first minutes of the reaction may correspond to the first assembly units from which larger oligomeric or multimeric complexes are formed. The "kinetic profile" of the cross-linking reaction may, therefore, give some information about the nature of the complexes or aggregates formed by molecules like IgSF-CAMs.

Co-capping

The demonstration of a *cis*-interaction by antibody-induced co-capping of cell surface molecules critically depends on many factors. To allow the induction of caps by antibody cross-linking and co-capping mediated by a *cis*-interaction, the molecules of interest must have a minimal lateral mobility within the plane of the cell membrane. In addition to mobility, the relative stoichiometry of the molecules of interest is critical for the detection of co-capping after antibody-induced capping. Ideally, comparable levels of expression at the cell surface allow reciprocal co-capping of two molecules that interact with each other in *cis* with sufficient affinity. However, large stoichiometric excess of one molecule due to different expression levels results in asymmetric results in reciprocal co-capping experiments; capping of the more abundant component is followed by clearly detectable co-capping of the less abundant molecule. In contrast, capping of the molecule expressed at lower level results in only partial co-capping of the more abundant component. For the detection of partial co-capping, confocal laser scanning microscopy is a powerful technique that allows the reliable detection of locally enhanced fluorescence signals (co-capping) versus a relatively high homogeneous background signal (uncapped monomers of the molecule present in stoichiometric excess).

In addition to the factors described above, the availability of specific primary antibodies against the molecules of interest, raised in different species, is an essential prerequisite for co-capping experiments. For antibody-induced capping, polyclonal or monoclonal antibodies can be used. Polyclonal antibodies are able to cross-link the cell surface antigen to some extent in the absence of secondary antibody, whereas in the case of monoclonal primary antibodies, cross-linking of bound primary antibody with the secondary antibody is required for the induction of caps. The most critical factors of every co-capping experiment is the specificity of the primary antibodies used. A major source of experimental artifacts is the potential of cross-reactivity of primary antibodies, either between the molecules of interest or with other, unidentified molecules expressed on the cell. It is therefore of pivotal importance to exclude any cross-reactivity under the conditions (antibody concentrations, temperature,

incubation times, etc.) used for co-capping and counter-staining. It is not recommended to test for cross-reactivity with other immunochemical techniques like immuno-blot or ELISA, because the antigens are presented in a different form on nitrocellulose and on plastic surfaces than on live cells. The absence of cross-reactivity of the partially or totally denatured proteins present in such immunochemical assays does, therefore, not necessarily exclude cross-reactivity of the native proteins present on the live cells under the conditions used for co-capping experiments. In situations where the proteins of interest are co-expressed in recombinant form in a cell type that does not normally express them, the test for cross-reactivity is straightforward. Specificity of detection can be checked by immunostaining of single transfectants and mock-transfected cells (as a negative control) with both antibodies (see, e.g., Buchstaller et al., 1996; Kunz et al., 1998). It should be noted that cross-reactivity of antibodies is a phenomenon that depends on the antibody concentrations used. Even in cases where no cross-reactivity is reported in the literature (e.g., based on experience with standard protocols for immunofluorescence), cross-reactivity may occur at the higher antibody concentrations that are normally applied in co-capping experiments. Cross-reactivity of the secondary antibodies represents only a minor problem, since highly specific preparations of fluorochrome-labeled secondary antibodies against a wide variety of species are commercially available. The use of phylogenetically more distant species is desirable since the potential of cross-reactivity between the secondary antibodies is lower. Combinations that are frequently documented in the literature are mouse/rabbit, mouse/goat (or sheep), rabbit/goat (or sheep). A considerable risk of cross-reactivity exists especially for the combination mouse/rat. In this case the choice of secondary antibodies has to be made with care.

Several controls must be included to ensure specificity of antibody-induced capping. The use of preimmune serum, or purified IgG from preimmune serum, is an essential negative control in cases where complete sera or total IgG fractions, respectively, are used as a source of primary antibodies. Additional controls should include the detection of unrelated molecules expressed by the cell of interest that are not expected to co-distribute with one of the molecules tested for *cis*-interaction.

Apart from false-positive results due to cross-reactivity of antibodies, false-negative results can be due to potential interference of antibody binding with the interaction between the molecules of interest. Polyclonal antibodies directed against a variety of epitopes can perturb molecular interactions. It is therefore worthwhile to test several different antibodies, polyclonal as well as monoclonal, if available. The potential interference of antibody binding with the interaction between the molecules of interest can be prevented by using heterologously expressed recombinant proteins. Specifically, different *N*-terminal peptide tags, like the myc-tag or the influenza hemagglutinin-tag can be introduced by molecular cloning into the polypeptide sequences of the studied proteins. Subsequent capping with antibodies specific for the N-terminally localized tag sequences will reduce the risk of interference with a binding site on the surface of the molecule.

It should always be kept in mind, that the detection of antibody-induced co-capping between two molecules is no proof of a direct molecular interaction between the two components. In order to demonstrate such a direct binding, additional experimental techniques, like chemical cross-linking (see Basic Protocol 5) or biochemical binding assays using isolated, purified proteins (see Basic Protocol 2) are required.

Neurite outgrowth

Many IgSF-CAMs have a neurite outgrowth-promoting activity, therefore, neurite growth assays are widely used for functional analysis. The preparation of neuronal cultures takes some practice and should best be learned in a laboratory where culture techniques are established. The reproducibility of the cultures is very important to get results. Keep in mind that the growth and the morphology of neurites depend on the substrate and the medium. As the quality and the components of serum differ considerably from batch to batch, the lot of serum used should not be changed during analysis. For best reproducibility, the use of a chemically defined, serum-free medium is recommended. All the solutions and the purified proteins to be tested for their neurite outgrowth-promoting activity have to be of high quality. Especially, the absence of endotoxins is extremely important for the survival of neurons. Make sure that detergents are removed carefully from protein solutions before using them in tissue culture.

The growth characteristics of neurites are age-dependent. In particular, the dependence on specific growth factors may change dramati-

cally. Therefore, it is essential not to mix different ages of tissue. Similarly, the response of neurons to different substrates may be species-specific. Remember that neurite length is not the only criterion that can be assessed in neurite growth assays. Closely monitor neurite and growth cone morphologies and branching patterns.

Anticipated Results

Transfection

For transient transfections with the protocol described, reporter constructs can be used to assess the efficiency of transfection and calculate the percentage of transfected cells. Using reporter constructs that express green fluorescent protein (GFP) as a reporter under the control of the human cytomegalovirus (CMV) immediate early promoter (plasmid size of 5 to 10 kb, DNA amounts for transfection between 40 and 80 μg), the authors repeatedly observed transfection efficiencies of 30% to 40% based on the detection of GFP expression 24 to 48 hr after transfection. Expression of recombinant protein under the control of strong viral promoters lasts, generally, for 48 to 96 hr after transfection.

Microsphere assays

With the appropriate controls, all the protocols described here that involve microsphere and cell aggregation techniques are powerful methods to study binding properties of IgSF-CAMs. Furthermore, these assays are not very time-consuming and enable processing of several tests in parallel.

Trans-interactions

Myeloma cell clones that were stably transfected to express IgSF-CAMs form aggregates when the IgSF-CAMs interact in *trans*. Homophilic *trans*-interactions are indicated by aggregates of cells that express the same IgSF-CAM. Heterophilic *trans*-interactions are indicated when two populations of cells that express distinct IgSF-CAMs form mixed aggregates.

Transfection-protoplast fusion

On average, 100 clones are obtained per 96-well tissue culture plate, i.e., 500 clones per 5×10^6 transfected myeloma cells. Thus, the transfection efficiency is in the range of 1×10^{-4}. Even with an optimized electroporation procedure, the transfection efficiency was ~20 times lower (Rader et al., 1993). While the majority of myeloma cell clones expresses moderate amounts of the IgSF-CAM, a small percentage typically reveals very high expression. Thus, the higher the transfection efficiency, the higher becomes the likelihood to obtain a myeloma cell clone with very high expression. This makes protoplast fusion the method of choice for the transfection of myeloma cells.

Chemical cross-linking

During optimization of the cross-linking protocol, the emphasis should be placed on the specificity of the reaction. As described, there is generally an inverse relationship between specificity of a cross-linking reaction and its efficiency. A protocol that ensures a high degree of specificity often has the drawback of low yields of cross-linked material. Based on published results and experience in the authors' laboratory, yields of cross-linking protocols, like the one described, range from 0.1% to 1%, corresponding to a few hundred nanograms of cross-linked material from a reaction performed on 10^6 cells. This amount of protein is normally sufficient for immunochemical characterization of the cross-linked molecules, e.g., by immunoblot analysis or re-immunoprecipitation (Buchstaller et al., 1996; Kunz et al., 1998).

The appearance of only one or a few complexes of a molecule of interest indicates some degree of specificity of the reaction. The cross-linked complexes isolated by immunoprecipitation can be separated by SDS-PAGE (ideally two-dimensional; *UNIT 6.4*). The detection of presumed binding partners in the cross-linked complexes by immunoblot analysis should always include controls, that is the detection of a membrane protein present in the cell used for cross-linking that is not expected to associate with the molecule of interest.

Co-capping

Antibody-induced co-capping can be observed between molecules that undergo direct or indirect *cis*-interactions. Very clear results can be obtained in cases where the two components are expressed at comparable levels and directly interact with each other with relative high affinity, as demonstrated in the example shown in Figure 9.5.3. Co-capping of molecule A (NgCAM) with molecule B (axonin-1) was studied on stably double-transfected CV-1 cells. Capping of molecule A (NgCAM), induced by the subsequent incubation with a mouse monoclonal primary and a rabbit-anti mouse secondary antibody (Fig. 9.5.3A), re-

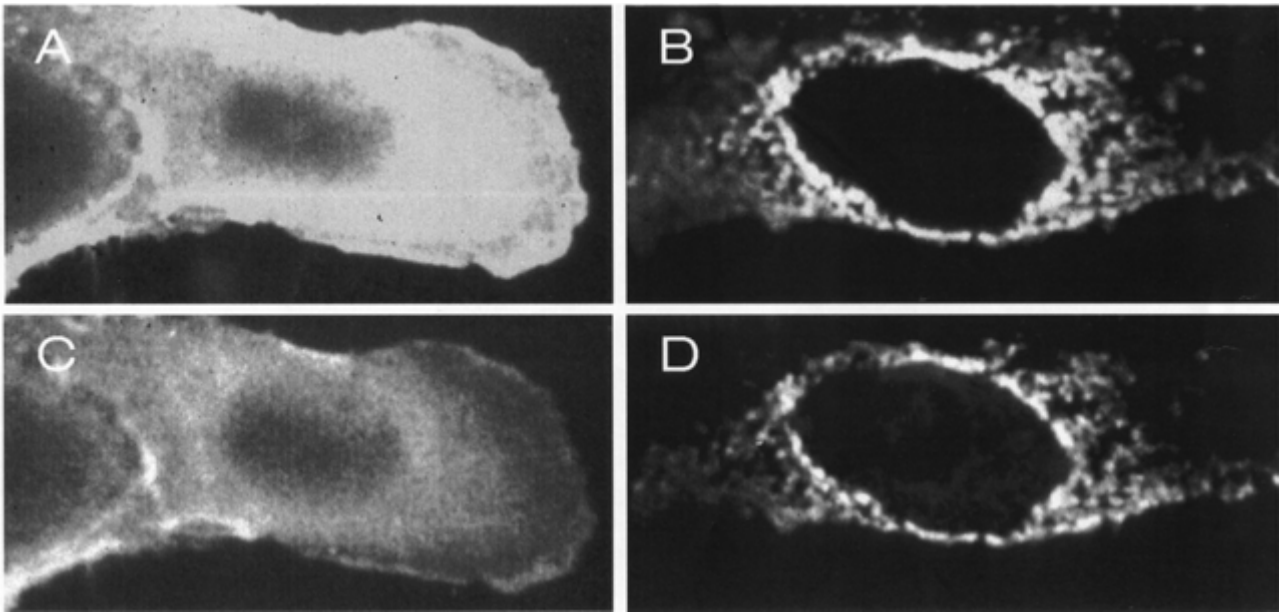

Figure 9.5.3 Antibody-induced co-capping of axonin-1 with NgCAM on stably double-transfected CV-1 cells. In double-transfected CV-1 cells, NgCAM (**A**) and axonin-1 (**C**) were randomly distributed. Capping of NgCAM was induced by a mouse monoclonal antibody and a rabbit anti-mouse IgG. NgCAM caps were detected by a Texas Red–labeled donkey-anti-rabbit IgG (**B**). The distribution of axonin-1 was detected by counter-staining with goat anti-axonin-1 Fab fragments and a FITC-labeled donkey anti-goat IgG (**D**). For examination of the cells, a confocal laser-scanning microscope equipped with an argon/krypton laser was used. Texas Red was detected using the 568-nm band-pass excitation filter (**A,B**) and FITC with the 488-nm band-pass excitation filter (**C,D**), minimizing cross-talk between the two fluorochromes.

sults in extensive co-capping of molecule B (axonin-1), as shown by counter-staining with goat anti-B (axonin-1) Fab fragments on the same cell (Fig. 9.5.3C). As expected, no capping or co-capping is detected in the absence of primary antibody against molecule A (NgCAM).

Time Considerations

Preparation of affinity column

The preparation of an affinity column takes 1 working day. Because affinity columns have to be loaded slowly, it is convenient to load large volumes of protein solution overnight to have the column ready for elution the following day. However, ensure that the column never runs dry.

Transfection

The entire transfection procedure can be performed in <1 hr for up to 12 samples.

Trans-interactions

Stable transfections of myeloma cells including selection, subcloning, and analysis require 4 to 6 weeks. Myeloma cell aggregation assays can be completed in <1 day.

Chemical cross-linking

The entire procedure can be performed within 2 days. The cross-linking reaction, including the making of the cell lysates, can be carried out within 3 to 4 hr. The lysates can be stored for several weeks at −20°C. Immunoprecipitation can be performed either with an incubation of 4 hr with the first antibody or with an incubation overnight.

Co-capping

The entire procedure can be performed in 4 to 5 hr. Incubation periods given here for antibody-induced capping are based on the authors' own optimized and published protocols. The time periods given for counter-staining can be extended for the primary antibody from 1 hr at room temperature to overnight at 4°C, if desired or necessary for higher sensitivity. The protocol can be interrupted after step 11 and 16 and the fixed coverslips stored at 4°C under light protection for up to 1 day before the subsequent steps are carried out.

Neurite outgrowth

The time required for neurite growth assays depends on the type of neurons used. Dissociated dorsal root ganglia neurons, for instance, will extend long neurites on many IgSF-CAMs

in <24 hr. DRG explants may take an additional day to reach their full length. Coating of IgSF-CAMs as a substrate is best done immediately before neurons or explants are plated, whereas dishes coated with poly-D-lysine or collagen can be stored. Dishes coated with laminin or IgSF-CAMs should not be stored and must not be dry.

Measurement of Adhesion Under Flow Conditions

This unit describes the analysis of dynamic cell adhesion using a flow chamber assay. The flow chamber enables the researcher to reconstruct cell systems in the presence of shear stress to assay adhesion under well-defined forces. These assays are most commonly used to study leukocyte adhesion, either to cultured endothelial cell monolayers or to purified substrates, simulating physiological interactions of leukocytes with endothelial cells. The assay described (Basic Protocol 1) utilizes commercially available parallel-plate flow chambers, in which cells are introduced under conditions of laminar flow between two flat surfaces, allowing for visualization of dynamic adhesion on a microscope (Lawrence and Springer, 1991). Flow cell assays are particularly useful to investigate adhesive events that occur very rapidly, on a time scale shorter than those assayed by static assays (Alon et al., 1995; Smith et al., 1999). Some adhesive events occur only in the presence of shear and, thus, cannot be characterized under static conditions (Finger et al., 1996; Lawrence et al., 1997). In addition, the flow cell assay allows visualization of the subprocesses of adhesion, including rolling, firm arrest, adhesion strengthening, spreading, and migration (Cinamon et al., 2001). Methods of data analysis are also discussed (Basic Protocol 2).

This assay can be also be used to characterize transient adhesive events or adhesion strengthening even for cells that do not normally experience shear stress, because contact time between cells and substrates and anti-adhesive forces can be closely regulated by stopping and starting the flow (Kassner et al., 1995). Flow chamber assays are also useful for measuring bacterial adhesion under flow (Mohamed et al., 2000; Poelstra et al., 2000).

FLOW ASSAY FOR CELL ADHESION

BASIC PROTOCOL 1

Commercial flow chambers incorporate the surface of either a culture dish or a coverslip as one of the two parallel plates between which laminar flow occurs. This surface should be coated with either endothelial cells or purified extracellular matrix proteins as an adhesive substrate.

Although several flow chambers are available, the same basic methods are used to conduct flow cell adhesion experiments regardless of the particular flow chamber apparatus used. Until recently, investigators often constructed their own laminar flow chambers, but with the advent of relatively inexpensive commercial models, this is not worthwhile unless special characteristics are required. The following method usually assumes that a GlycoTech flow chamber is used, but this protocol can easily be adapted for use with other chambers. Simply modify the assembly procedure according to the manufacturer's instructions and use cell- or ligand-coated glass coverslips instead of coated dishes if required.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Materials

Substrate coating solutions:
- Fibronectin, gelatin, or other extracellular matrix proteins, either alone or in combination, for cell monolayers only
- 10 μg/ml matrix protein, such as fibronectin or collagen, in PBS (*APPENDIX 2A*), pH 7.4, for dishes and coverslips coated with purified ligand only

Contributed by Dennis F. Kucik
Current Protocols in Cell Biology (2009) 9.6.1-9.6.10

Cultured endothelial cells (*UNIT 1.1*) growing as a confluent monolayer culture in tissue culture dish or on a coverslip of a size appropriate for the chamber used

1% (w/v) BSA in PBS (*APPENDIX 2A*), pH 7.4, for dishes and coverslips coated with purified ligand only

PBS (*APPENDIX 2A*), pH 7.4, for dishes and coverslips coated with purified ligand only

100 μg/ml poly-L-lysine (PLL; e.g., Sigma), for coverslips coated with purified ligand only

1% (v/v) glutaraldehyde, for coverslips coated with purified ligand only

Leukocytes or other cells of interest

HBSS (*APPENDIX 2A*), room temperature and 37°C

2 mM 2′,7′-bis(2-carboxyethyl)-5(6)-carboxyfluorescein, acetoxymethyl ester (BCECF-AM; Molecular Probes) in DMSO

35-mm plastic tissue culture dishes for GlycoTech chamber or glass coverslips of a size appropriate for the flow chambers that require them, sterilized by autoclaving, UV light, or flaming with ethanol

35-mm tissue culture dishes or 6-well tissue culture plates, for glass coverslips only

Permanent marker or diamond stylus, for dishes coated with purified ligand only

25-ml syringes

Programmable syringe pump

Flow chamber (e.g., GlycoTech) and appropriate tubing

Inverted phase-contrast microscope with low-power (~10 to 20×) objective, fluorescence optics (recommended but not required), and stage incubator set to 37°C

Video camera (e.g., CCD-300T-RC; Dage-MTI) and other recording equipment (e.g., VCR, television monitor, video cables)

Prepare substrates

For cell monolayer preparation

1a. Incubate a 35-mm sterile plastic tissue culture dish or glass coverslip with 1 ml substrate coating solution of fibronectin, gelatin, or other extracellular matrix proteins, either alone or in combination (Table 9.6.1) for 30 min at 37°C.

There are a number of commercially available flow chambers that require glass coverslips of different sizes. In general, only a small portion of the surface area of the coverslip is used for the assay. The size of the coverslip required has more to do with the geometry of the chamber than the actual surface area used.

2a. Remove excess coating solution and, if using coverslip, place the coverslip in a 35-mm dish or in the well of a 6-well tissue culture plate.

Table 9.6.1 Endothelial Cells and Culture Conditions

Cell type[a]	Dish coating[b]	Plating density (cells/cm^2)	Days to confluence
HUVEC	0.05% (w/v) gelatin		
	10 μg/ml fibronectin	5000	3-4
HAEC	0.05% (w/v) gelatin		
	10 μg/ml fibronectin	5000	3-4
MAEC	1% (w/v) gelatin	6000	8-10

[a]Abbreviations: HAEC, human aortic endothelial cells; HUVEC, human umbilical vein endothelial cells; MAEC, mouse aortic endothelial cells.

[b]The buffer used for the coating solution is HBSS (Hanks' balanced salt solution).

3a. Add 2 ml endothelial cell suspension (see Table 9.6.1 for cell density). Culture at 37°C.

4a. Feed cells every 2 to 3 days with an appropriate medium until confluent. Continue with step 9.

Coating density and the time to reach confluency depend on the cell type (Table 9.6.1). Optimal conditions for endothelial cell types other than those listed in Table 9.6.1 should be worked out empirically. Higher seeding densities result in less time to confluency, but lower densities and more time generally result in a more uniform monolayer. Depending on the cell type, cells are usually suitable for assays for 2 to 3 days after they reach confluency.

Endothelial cell adhesion to tissue culture plastic is generally superior to adhesion to glass coverslips, even if both are coated with extracellular matrix materials. Optical properties of plastic, however, are inferior to glass, because of a relatively high fluorescent background. Birefringence of plastic can also be a problem if Nomarski imaging is used. The optical properties of plastic are, however, adequate for the level of resolution needed for visualization and analysis of adhesion under flow, and they can provide better visualization of rolling cells than, for example, ex vivo preparations of blood vessels.

Leukocytes interact more with endothelial cells that have been stimulated. Interleukin 1 (IL-1), tumor necrosis factor α (TNF-α), and lipopolysaccharide (LPS) have been considered good paradigms for pro-inflammatory mediators and are often used experimentally on cultured endothelial cells to simulate inflammation (Cines et al., 1998). Stimulation results in expression of a number of adhesion molecules, in addition to other effects. Whether and how the endothelial cells should be stimulated will depend on the physiologic conditions that are being mimicked.

For plastic dishes coated with purified ligand

1b. Use a permanent marker or diamond stylus to outline a 5-mm diameter area of a sterile plastic tissue culture dish for coating.

If a diamond stylus is used, the scratches should be shallow enough that they do not prevent the flow chamber gaskets from sealing.

The size of the area covered depends less on the size of the dish or coverslip than on the area of obseervation required. The authors find that a 5-mm diamerer circular area is sufficient to provide several fields of view for independent measurements of cell-substrate adhesion.

2b. Add 25 µl of 10 µg/ml matrix protein in PBS to the marked area and incubate 1 hr at room temperature.

3b. Remove coating solution and add 1 ml of 1% BSA in PBS. Incubate 1 hr at room temperature.

4b. Remove BSA solution. Wash twice with 5 ml PBS each. Continue with step 9.

The coated dish can be stored for 1 day at 4°C.

For glass coverslips coated with purified ligand

1c. Place sterile glass coverslip in a 35-mm tissue culture dish or in the well of a 6-well tissue culture plate.

2c. Add 0.2 ml of 100 µg/ml poly-L-lysine (PLL) to the dish. Incubate 10 min at room temperature.

The amount of PLL used should be scaled up as needed depending on the coverslip size (e.g., 0.5 ml should be used for a 22 × 22–mm coverslip). The authors routinely use PLL with a molecular weight of 70 to 150 kDa.

3c. Wash coverslips three times with 5 ml PBS each.

4c. Add 1% glutaraldehyde and incubate 30 min at room temperature.

5c. Wash coverslips three times with 5 ml PBS each.

6c. Add 25 μl of 10 μg/ml matrix protein and incubate 1 hr at room temperature.

For a 22 × 22–mm coverslip, 100 μl coating solution should be used.

7c. Add enough 1% BSA in PBS to completely cover the coverslip to block. Incubate 30 min at room temperature.

8c. Wash coverslip with 5 ml PBS. Add fresh PBS to keep moist until used for flow assay. Use within 1 day.

This protocol, in which matrix molecules are covalently linked to adsorbed PLL, results in tighter, more uniform binding of matrix materials to coverslips than direct adsorption of matrix molecules to the glass. If, however, PLL needs to be avoided, direct adsorption of matrix materials, as in the plastic dish protocol, may provide an adequate substrate.

Coverslips precoated with PLL are also commercially available, but the authors have not tried them.

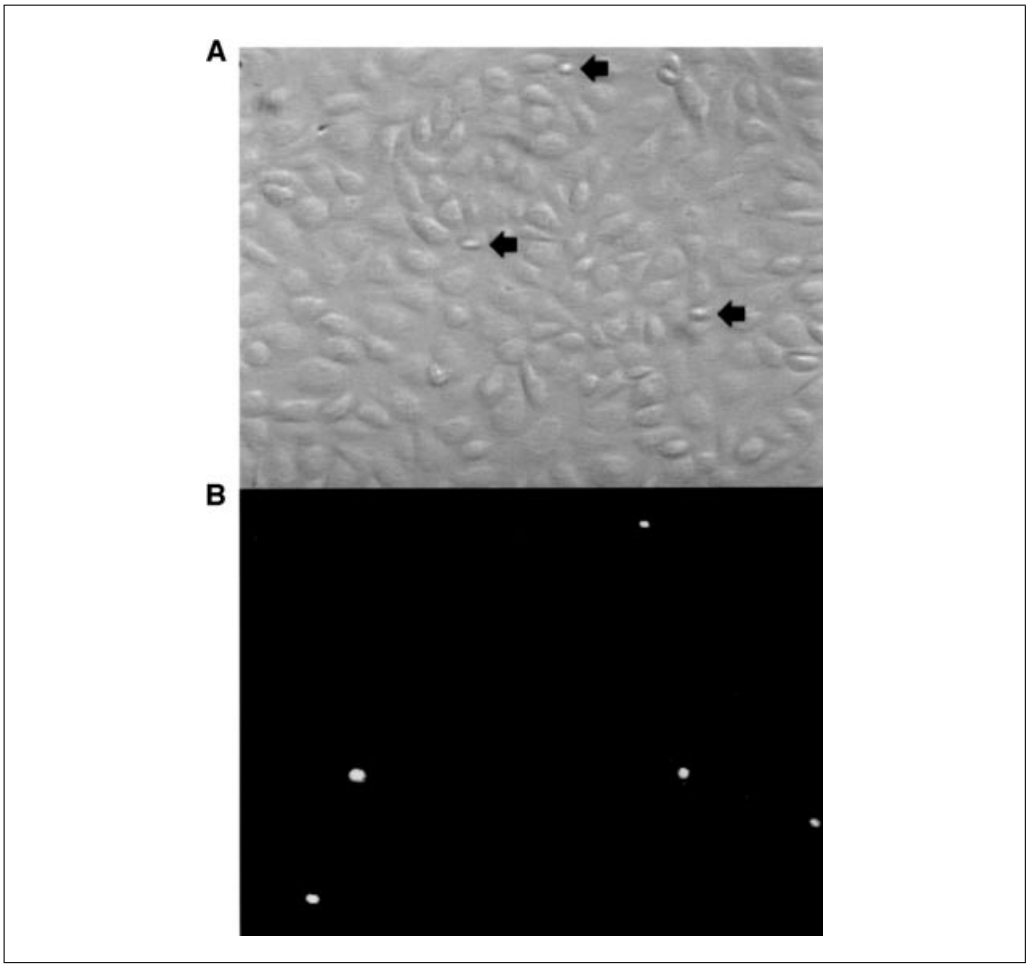

Figure 9.6.1 Visualization of endothelial cells and leukocytes using (**A**) phase contrast and (**B**) fluorescent optics. Arrows in (A) indicate leukocytes. Fluorescent optics provide high-contrast images that facilitate manual counting and are especially useful for computer tracking. When using endothelial cells as the substrate, however, it is important to observe the system with phase contrast or similar optics to assess the integrity of the monolayer before switching to fluorescence.

Load cells with flourescent dye(optional)

9. Wash leukocytes or other cells of interest in HBSS and then resuspend them at 1–2 $\times$ 10^6/ml in 25 ml HBSS.

   Although rolling and adherent cells can be visualized without fluorescence, the increase in contrast afforded by labeling the perfused cells greatly facilitates observation and counting (Figure 9.6.1) and is sometimes a requirement for object-tracking software.

10. Add 12.5 µl of 2 mM BCECF-AM and incubate 30 min at room temperature in the dark.

11. Wash cells three times with 35 ml HBSS each.

Carry out flow assay

12. Resuspend leukocytes in prewarmed HBSS to a concentration of 0.5 $\times$ 10^6 cells/ml

    Cell concentration should be high enough that sufficient events are observed in the few minutes of recording, but not so high that cell behavior is dominated by collisions with other rolling or adherent cells. The authors find that 0.5 $\times$ 10^6 cells/ml works well. The number of cells required will depend on the rate of flow and the length of observation needed to gather sufficient data to answer the particular experimental question. The authors usually use 3–5 $\times$ 10^7 cells/experiment (including controls).

    In general, it is a good idea to perform experiments at 37°C (this necessitates a stage warmer), although useful data can sometimes be obtained at room temperature, depending on the experimental question.

13. Load leukocytes into a 25-ml syringe, if using the pushing method, or into a centrifuge tube or other reservoir, if using the pulling method.

    There are two ways to use a syringe pump to perfuse cells through a flow chamber. The syringe can be filled with cells and the pump can be used to push them through the chamber. Alternatively, some investigators prefer to attach the syringe to the outlet side of the system to pull fluid and cells through the chamber.

14. Attach the tubing of a flow chamber to the syringe and remove any air bubbles from the system.

15. Assemble a flow chamber according to the manufacturer's instructions, using a tissue culture dish containing the monolayer of cultured endothelial cells (step 4a) or coated with purified ligand (step 4b or 8c). Again, work out any bubbles in the system.

    Flow chambers come in a wide variety of sizes. Generally, the smaller the chamber, the more economical the experiment is in terms of cells used per experiment. The dimensions of the GlycoTech flow chamber are determined by the size of the gasket used because the gasket forms the side walls of the chamber and also determines its height. GlycoTech supplies four gaskets with its basic kit; these range in width from 0.25 to 1.0 cm in width and in thicknesses ranging from 0.005 to 0.010 in. The length is fixed at 2 cm.

    Increasing the dimensions of the flow chamber will decrease the wall shear stress for a given flow rate. This has the disadvantage of requiring more volume (and thus more cells) to be perfused per unit time for a given shear. It can be advantageous, however, to use a larger chamber when low shears are desired because the syringe pump flow rates are less accurate and more pulsatile as flow is decreased. A wider chamber has the further advantage of providing more observation area if many fields of view are desired.

    Significant shear stresses can be created during assembly, which can sometimes tear endothelial cell layers loose from the dish. Therefore, care must be taken to assemble the system slowly and gently.

16. Program the syringe pump to give the desired flow according to the manufacturer's instructions.

    To determine the desired flow, flow rates must be converted to shear stresses. The manufacturer of the flow chamber will usually provide a handy conversion chart or table. Alternatively, shear stress can be calculated from the dimensions of the flow chamber and the rate of fluid flow (Lawrence et al., 1987). The shear stress desired will depend on the physiological condition to be mimicked. For example, simulation of arterial flow will require higher shear rates than simulation of venous or postcapillary venule conditions. The authors usually do a range of shears to determine the shear dependence of any phenomena observed. As a rule of thumb, physiologic shear stresses are typically thought to be in the range of 0.5 to 5.0 dynes/cm^2.

17. Mount the flow chamber on an inverted phase-contrast microscope with a prewarmed stage incubator. Focus the system and adjust the optics, video camera, and any other recording equipment as needed.

    If using endothelial cells, it is important to visualize the area of observation adequately to assess the integrity of the monolayer. Rips or other defects in the monolayer will confound interpretation of the results, because the data will reflect interactions of flowing cells not only with endothelial cells but also with bare plastic or glass.

    It is advisable to do a sample recording of a minute or so at this point and to play it back to be sure that all of the equipment is working properly.

18. Choose an area to observe, start the recording equipment, and begin the flow.

    The authors record on sVHS videotape for later digitization. Images can also be captured directly to computer. This may be necessary if the camera used does not have a video output.

19. Record a few minutes of data at each shear rate.

    The authors generally record ~3 to 6 min of data at each shear rate from each area of observation. For preliminary experiments they use at least three or four shear rates. Once the optimal shear and the shear dependence are determined, one or two shear rates may be sufficient. Considerations include the number of cells available (e.g., primary mouse cells are more precious than cell lines) and any time dependence of treatment regimens. It is important to record diligently the points on the videotape where shear rates are changed so that data can be interpreted when it is time to do the analysis.

20. Move to a new field of view and repeat steps 18 to 19. If using the pushing method, with the cells in the syringe, rotate the syringe 180° to compensate for any settling. If using the pulling method, with the cells drawn from a tube or other reservoir, make certain that the cells are still suspended.

    Most flow systems are large enough to allow a number of areas of observation for each preparation. It is important to observe multiple areas to control for any peculiarities in density of substrate coating or properties of endothelial cells. The number of fields to observe for each preparation will again depend on the number of cells available, any time dependence of treatment regimens, and the statistical power required.

21. Perform data analysis (see Basic Protocol 2).

BASIC PROTOCOL 2

DATA ANALYSIS

Quantifying Adherent Cells

The raw data from flow cell adhesion experiments will be videos of rolling and firmly adhering cells. The method of analysis will depend on the scientific questions to be answered. A simple count of adherent cells per minute can be obtained by visual review of videotapes. Just choose an appropriate time period (e.g., 1 min) and roll the tape to count the number of cells that become immobilized in the field of view during that time.

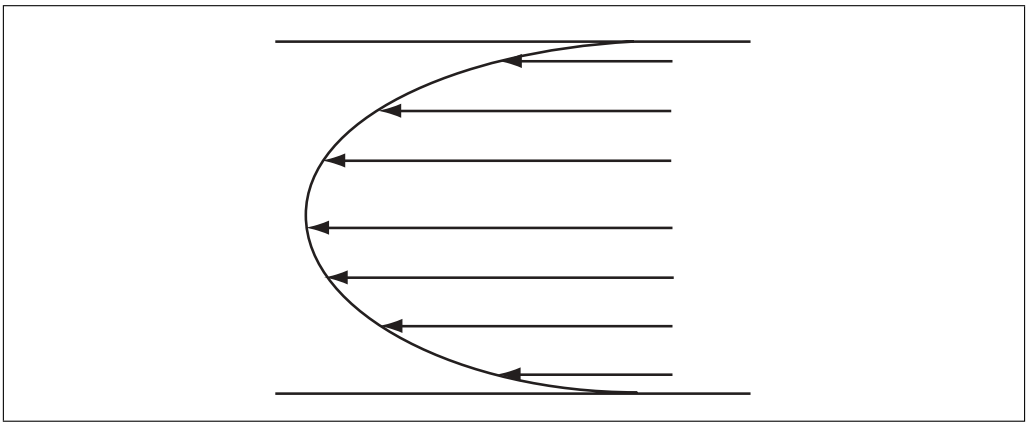

Figure 9.6.2 Velocity profile for fluid flow in a parallel-plate laminar flow apparatus. Longer arrows correspond to higher velocities. The velocity profile is parabolic, with a maximum velocity midway between the two plates and a slowest fluid flow near the plates.

It may be helpful to use two people to do this, one who counts and one who watches the time. Because the number of cells recorded will depend on the size of the field observed, it should be normalized for the area of observation. Area can be calculated using a stage micrometer, available from many scientific supply companies (e.g., Fisher), as a known length standard. A stage micrometer (also called a calibration plate) is a glass slide with accurate distance scales etched into the surface. By imaging this size standard, the size (in microns) of the video image or monitor screen can be determined.

An important consideration for meaningful comparisons of experimental conditions is that the number of cells perfused per minute must be the same under all experimental conditions. This requires that cells are loaded into the syringe or reservoir at a consistent density and that cells are not allowed to settle out of suspension.

Quantifying Rolling Cells

The number of rolling cells per minute can also be determined by visual review, but care must be taken in identification of rolling cells. By definition, under laminar flow there will be a parabolic hydrodynamic velocity profile, with the lowest velocity of the fluid occurring nearest the flow chamber wall (Figure 9.6.2). Thus, it may not be obvious which cells are moving slowly because of their position in the flow field and which are retarded by adhesive interactions (Goldman et al., 1967). Whereas under some optical conditions rolling cells can be distinguished by plane of focus, it is a good idea to calculate a critical velocity to verify that cells counted as rolling do indeed have adhesive interactions with ligand. The critical velocity is an objective measure that has been developed to identify rolling cells (Ley and Gaehtgens, 1991). A simple calculation for critical velocity is $V_c = \beta r \gamma$, where V_c is the critical velocity, β is a drag factor, r is the radius of the cell, and γ is the shear rate. A reasonable estimate of β that can be used for cells in a flow chamber is 0.5. Cells moving more slowly than the critical velocity can be confirmed as being rolling cells. Thus, even if the experimental question deals only with the number of rolling cells, and not their velocity, a few velocities should be measured to ensure that what appears to be rolling cells are moving more slowly than the critical velocity and, thus, are indeed rolling. With some practice, though, rolling cells can often be identified visually.

Rolling Velocities

The calculation of cell position in each digitized image can be done by comparison with a known size standard, again using a stage micrometer. A known length (in microns) can then be marked on the monitor screen with a laboratory marker. With a known distance

established, velocities can be determined by simply counting the number of video frames required for a cell to travel this known distance. Alternatively, more accurate velocity determinations can be made using more sophisticated image processing software that can accurately localize objects in each image and convert pixels to distances. A variety of commercial software packages are available. NIH Image, which is available online at no cost, will also track object motion (see Internet Resources).

COMMENTARY

Background Information

Leukocyte rolling and adhesion in vivo has been observed microscopically for more than 100 years (Cohnheim, 1889). More recently, investigators have used parallel-plate flow chambers to mimic the environment of the blood vessel under more controlled conditions. Much of what we know today about inflammation and leukocyte homing has been learned by examining leukocyte interactions with either endothelial cell monolayers or purified ligands in flow chambers (Butcher, 1991; Rossiter et al., 1997; Smith, 2000; Orsello et al., 2001). In addition, adhesion assays using flow chambers have provided important information about bacterial adhesion to surfaces. Today, adhesion under flow can readily be assayed economically using a variety of commercially available flow chambers. When mounted on a microscope and coupled to a video camera and a VCR, simple analysis of adhesion under shear is possible. More detailed analysis of rolling cell motion can be achieved by digitization of images coupled with motion analysis software.

Commercially available flow chambers, in general, work very well and make it easy to produce conditions that mimic physiological cell interactions with well-defined and tightly controlled shear stresses. Increased use of these assays will provide a fuller understanding of physiologic cell adhesion than could ever be achieved with static adhesion assays.

Critical Parameters and Troubleshooting

Flow experiments require some diligence to ensure that the system is working properly. The experimenter should watch the monitor carefully during the experiment to be sure that the flow is smooth and that perfused cell concentrations are uniform. Although a programmable syringe pump is capable of providing very steady perfusion, flow can become pulsatile when the syringe is almost empty or if the syringe is not mounted securely. Other sources of variability in flow are leaks or bubbles anywhere in the system. It is also a good idea to isolate the system from vibration.

If fluorescent dyes are used to label perfused leukocytes, it is a good idea to develop a protocol that labels a high percentage of the cells (>97%), because unlabeled cells will likely be missed during analysis, confounding quantification of the number of cells interacting with the endothelium or substrate. Care should be taken, however, not to overload the cells, because fluorescent dyes can be somewhat toxic. Too much label interferes with cell motility and may affect regulation of adhesion in general. The optimal dye-loading protocol can be determined by varying both dye concentration and incubation times and should be worked out for each new cell type.

When using object tracking software, the experimenter should observe the tracking closely. Although most available programs do a very good job and provide temporal resolution not obtainable by cruder methods, they also make occasional errors, briefly locking onto an object other than the cell of interest. The operator should confirm visually for each cell track that the software has faithfully tracked the object of interest and has not misidentified the cell at any point.

Uniformity and integrity of the substrate are also of vital importance. This is especially true of endothelial cell monolayers. High shear forces associated with assembly of the chamber or with manual flushing of bubbles can dislodge portions of the monolayer. Thus, to avoid mistaking leukocyte interactions with the chamber itself for interactions with the endothelium, the importance of a visual inspection of each recorded field of view cannot be overemphasized. Purified protein substrates present less of a problem, but care should be taken to ensure uniform distribution and density of adsorbed matrix materials through use of good experimental technique.

Cameras

The authors recommend cameras with a video (rather than digital) output, because storage of images is more economical on videotape than on digital media. This allows the experimenter to record continuously throughout the experiment. This can be an important

consideration if one is working with valuable perfused cells (e.g., leukocytes purified from gene-targeted mice). An economical recording system also encourages collection of the maximum amount of data from each experiment, avoiding the need to repeat experiments simply to increase statistical power. In addition, higher time resolution (30 frames/sec) is possible with video than with most digital systems. Images can be digitized later for computer analysis using a variety of commercially available systems.

If fluorescent cells are to be visualized, a highly light-sensitive camera must be used. This is because when rolling cells are visualized, the time to acquire the image is limited. Extended exposures cannot be used, as the cells will appear blurry from their movement. Several camera companies offer cameras that are sensitive enough for this application, but the authors know of few with both adequate sensitivity and video output. The authors have found the CCD-300T-RC (Dage-MTI) to work well. Equivalent cameras may be available from other manufacturers as well.

It is also possible to do flow cell experiments without fluorescently labeling the cells. Although this results in less contrast between rolling cells and underlying endothelial cells or substrate, the images can be perfectly acceptable (Fig. 9.6.1). Imaging without fluorescence also avoids possible deleterious effects of dye loading on the cells. In addition, the time required for each experiment is shortened by the amount of time needed to load the cells with fluorescent dye, which may be useful if short-acting treatments are used. A major determinant of whether fluorescence can be omitted is the quality of the microscope optics. Another factor to consider, however, is whether any tracking software to be used depends on cell intensity for tracking motion. Although some programs can track objects based on their size and shape, other packages require the tracked object to be brighter than its surroundings.

When imaging without fluorescence, it is especially important to avoid fingerprints and other smudges on the culture dish or coverslip and other optical elements of the flow chamber, to avoid degrading the image.

Video recording

It is recommended that video be recorded using an sVHS, rather than a VHS (the typical home-recording format), VCR. Not only will the sVHS spatial resolution be better, but the recordings are more resistant to degradation with repeated playback. Alternatively, images can be recorded directly to computer memory or hard drive. With some cameras, this may be the only option.

Image digitization and compression technologies are progressing so rapidly that any hardware recommendations are likely to be out of date within months. Therefore, it is recommended that the investigator research available products when setting up a system. An important factor to consider is the amount of compression necessary with each system, because increased compression can lead to decreased image quality and, consequently, a decrease in accuracy of cell position determination.

Anticipated Results

In general. leukocytes perfused over stimulated endothelial cells at physiological flow rates will be expected to interact with both rolling and firm adhesion. The amount and type of interaction will depend on the leukocyte type and its state of activation as well as the endothlial cell type (venous versus arteerial, mouse versus human). Endothelial cells can be stimulated by TNF-α (e.g., 10 to 100 ng/ml for 8 hr). This induces expression of a number of adhesion molecules and should dramatically increase adheive interactions with almost any leukocyte type. Human umbilical vein endothelial cells (HUVEC; *UNIT 2.3*) have been used in a number of flow chamber adhesion studies (Munn et al., 1994; Macconi et al., 1995; Thelilmeier et al., 1999; Patel, 1999; Kaur et al., 2001), are widely available, and make a good test system to validate experimental technique.

Time Considerations

The time required to prepare a culture monolayer is 1 to 2 hr with several days required for cells to reach confluency (Table 9.6.1). Preparing a pure ligand substrate requires 5 to 6 hr for either culture dishes or coverslips. The flow assay requires about 3 hr to do two cell types and three conditions, and at least 1 day, depending on the analysis performed is needed to analyze the data.

CHAPTER 10
Extracellular Matrix

INTRODUCTION

Most cells of multicellular organisms interact routinely with extracellular matrix (ECM) molecules. The ECM provides structural support, as well as important regulatory signals governing cellular growth, metabolism, and differentiation. Epithelial cells of all types generally require various ECM components in the basement membranes to which they adhere for maintaining their characteristic polarized organization, differentiated state, and specific gene expression. Connective tissue cells nestle within matrices of collagens, proteoglycans, and other ECM components. Even circulating blood cells such as lymphocytes can interact extensively with ECM as they extravasate from blood vessels and localize in tissues during recirculation and inflammation. Two particularly dynamic tissue-remodeling processes in which ECM becomes critically important are cell movements during embryonic development and wound repair. In addition, tumor cells often must invade through basement membranes and connective tissue in order to metastasize (see *UNIT 19.1*).

Throughout these various cell-biological processes, ECM can act both as a structural scaffolding for cell adhesion and migration and as a trigger for signaling through ECM receptors. Binding of specific ECM molecules to their plasma-membrane receptors activates signal-transduction responses that can include activation of various tyrosine and serine-threonine kinase families, MAP kinase systems, ion fluxes, or phosphoinositide and arachidonic acid pathways. The study of these complex processes has blossomed recently due to the availability of individual purified ECM molecules, along with the realization that ECM modulates many crucial cell-biological functions.

UNIT 10.1 reviews key ECM functions, as well as the biochemistry of the major classes of ECM molecules. This comprehensive review provides a solid framework for understanding the initially somewhat bewildering complexity of ECMs, which range from basement membranes to loose connective tissue, cartilage, and ligaments.

Basement membranes are crucial for normal epithelial cell biology. *UNIT 10.2* describes the preparation of the basement-membrane extract termed Matrigel and the isolation of two important components, laminin and type IV collagen. Although these proteins are also available commercially, preparing them within the laboratory is much more economical for larger-scale studies. These purified proteins can be used in cell adhesion assays (*UNITS 9.1 & 9.2*) and for studying other cell-biological responses such as migration and differentiation.

Because extracellular matrices are generally three-dimensional, and their effects can be greater than the sum of their isolated components, cell biologists also use ECM gels. *UNIT 10.3* details the preparation and use of gels of purified collagen and of Matrigel basement-membrane extracts. Collagen gels and Matrigel can be used to study the three-dimensional behavior of epithelial, fibroblastic, and other cells. Matrigel can also be used in animals for angiogenesis assays (*UNIT 10.3*) and in tumor cell invasion assays (*UNIT 12.2*), as well as to promote the survival and growth of primary tumor cells that would not otherwise grow in vivo (*UNIT 10.3*).

Current Protocols in Cell Biology 10.0.1-10.0.4, September 2010
Published online September 2010 in Wiley Online Library (wileyonlinelibrary.com).
DOI: 10.1002/0471143030.cb1000s48

An alternative approach is to use intact extracellular matrices assembled by living cells in culture; the cell monolayers are extracted away to leave just the three-dimensional extracellular matrix. *UNIT 10.4* describes the preparation of two forms of such complex matrices, which can be used as substrates for cell biological studies in vitro.

A particularly widely used approach involves purified extracellular matrix molecules as substrates. Both fibronectin and vitronectin can be purified by affinity chromatography from human plasma, providing large quantities of an individual adhesive protein useful for cell culture studies using many types of cells. *UNIT 10.5* presents simple, reliable methods for purifying substantial quantities of fibronectin from plasma. Also included are two different protocols for purifying the cellular form of fibronectin, by extraction from cell surfaces or from fibronectin secreted by cells into serum-free medium; this form of fibronectin contains additional peptide sequences and has moderately enhanced adhesive activity. *UNIT 10.6* describes a simple protocol for the isolation of vitronectin, which is a cell adhesion protein used by many cells—e.g., by most adherent cells cultured in medium that contains 10% serum.

Even though proteoglycans are a major class of diverse extracellular and cell-surface molecules with important roles in a myriad of regulatory and structural functions, many researchers have hesitated to study them because they are technically difficult to analyze. These large, highly charged, readily aggregated molecules are now known to be present not only in extracellular matrices, but also linked to membranes by phospholipid, in transmembrane locations (e.g., the syndecans), or even in intracellular locations in some cells. *UNIT 10.7* provides numerous protocols and valuable tips for isolating and analyzing these widely distributed molecules implicated in signal transduction, adhesion, and ECM structure.

The glycoproteins and proteoglycans of the extracellular matrix are not static, but are instead in a state of dynamic balance between synthesis and degradation. The continuous turnover and active remodeling of the extracellular matrix in embryonic development, growth, and tissue repair depend critically on carefully regulated degradation by proteolytic enzymes, particularly by the matrix metalloproteinases (MMPs). The MMPs are regulated by activation and by their inhibitors (the TIMPs, as well as α2-macroglobulin). *UNIT 10.8* provides a series of methods for studying MMPs and their inhibitors, including a live-cell collagen degradation assay, analysis by either direct or reverse zymography, and enzyme-capture techniques.

The ECM of living organisms is often organized into a fibrillar, three-dimensional matrix. Although collagen gels and Matrigel provide valuable three-dimensional cell culture model systems, recent findings suggest that some cells require a matrix that more closely mimics their natural microenvironment in vivo in order to form normal cell adhesions; such matrices also enhance cell attachment, migration, and proliferation. *UNIT 10.9* provides methods for generating a fibroblast-derived three-dimensional ECM that closely resembles in vivo matrices. It also describes protocols for assessing cell adhesive signaling and morphological responses to such matrices, as well as methods for generating two-dimensional substrate controls.

ECM proteins in a group termed ‘matricellular’ proteins play complex and interesting roles in regulating the interaction of cells with other ECM molecules. These proteins include SPARC (also known as osteonectin; *UNIT 10.11*), thrombospondin (*UNIT 10.10*), tenascin, and other molecules that function to modulate a wide range of biological responses to the ECM. *UNIT 10.11* provides comprehensive protocols for isolating and purifying SPARC, a matricellular protein that can regulate cell adhesion, proliferation, and other processes. This unit presents methods for its purification from a cell line or

platelets, as well as for purifying recombinant SPARC from *E. coli* or insect cells. Finally, it also describes assays for its inhibitory effects on cell proliferation and adhesion.

Assembly of the extracellular matrix is currently thought to be a cell-directed process. For example, even though collagens can self-polymerize, their patterns of deposition are controlled by cells. The cell-mediated formation of a fibronectin fibrillar matrix is a particularly dramatic example, since cells have to convert soluble fibronectin dimers into an insoluble fibrillar matrix. *UNIT 10.12* provides detailed methods for analyzing this process of fibronectin matrix assembly based on measuring conversion of this protein to a detergent-insoluble form after polymerization. It describes the isolation and analysis of the resultant insoluble fibronectin matrix from cultured cells, as well as assays using exogenously added fibronectin or endogenous labeling. Because some laboratories may prefer to avoid using radioactivity, *UNIT 10.13* provides an alternative method of quantifying fibronectin matrix assembly using biotin-labeled fibronectin. This protocol includes an internal control to ensure equal recovery of detergent-insoluble material, as well as methods for parallel analyses of signal transduction processes that are involved in matrix assembly or result from this important process.

Cell interactions with three-dimensional matrices help to regulate cell growth, migration, and differentiation in vivo. Researchers now have increasing numbers of options for natural and synthetic extracellular matrices that can mimic various types of three-dimensional microenvironments. A new type of synthetic matrix termed Extracel is described in *UNIT 10.14* that consists of hyaluronan cross-linked to gelatin. It forms a hydrogel that is an effective culture system for both normal and malignant cells. This biodegradable scaffold can be designed to deliver growth factors to cells, and it provides an excellent environment for growth of tumor xenografts.

In order to study the roles of patterns and topology of matrix molecules, the newly developed process termed micro photopatterning provides a simple and highly flexible methodology to generate any protein pattern on a substrate. As described in detail in *UNIT 10.15*, this new technique uses a standard two-photon confocal microscope controlled by its built-in software to ablate any desired pattern in a polyvinyl alcohol thin film. Any protein can then be coated onto the exposed pattern, and the process can be repeated multiple times to generate complex patterns of multiple proteins positioned as close as a few micrometers from each other. Another advantage of this method compared to others is that it readily permits fluorescence and total internal reflection fluorescence (TIRF) microscopy.

Recent research on the mechanisms by which the extracellular matrix regulates processes as diverse as stem cell differentiation and tumor cell invasion has focused increasingly on physical properties of the local matrix microenvironment. Physical characteristics such as stiffness and surface topology are now known to provide important regulatory information that complements the microenvironmental effects of biochemical composition. *UNIT 10.16* provides a rigorously established protocol for experimentally controlling the stiffness or elasticity of extracellular matrices by using polyacrylamide hydrogels. This now-standard approach controls matrix stiffness by altering the concentrations of acrylamide and a molecular cross-linker to which a specific extracellular matrix molecule is attached to provide a substrate of known stiffness. Another physical property important for cell migration and invasion is the topology of matrix molecules, which is readily sensed by cells. *UNIT 10.17* provides two detailed protocols for generating aligned matrices comprised of collagen fibers. Cells align and migrate along these oriented fibers. This unit also provides methods for visualizing the aligned matrix containing cells by using second harmonics and for quantifying matrix alignment.

Studies of cells cultured in three-dimensional collagen gels have provided many valuable insights into cell behavior, but immunofluorescence staining of subcellular structures in these cells, such as cell-matrix adhesions, can be technically difficult—especially in thick collagen gels. *UNIT 10.18* provides detailed protocols and technical tips for obtaining high-quality confocal microscopy images of molecules in cells within three-dimensional collagen gels. It also provides methods for imaging the collagen fibrils in these gels by confocal reflection microscopy, as well as a method for sandwiching cells between very thin collagen gels to ensure that they are located in a three-dimensional microenvironment.

The units in this chapter span topics from individual purified ECM proteins to complex three-dimensional matrices consisting of many molecules interacting to form gels. They provide the opportunity to study the functions and mechanisms of the whole range of types of cell-ECM interactions, which are now recognized to play crucial roles in cell biology and pathology.

Kenneth M. Yamada

Overview of Extracellular Matrix

In all multicellular organisms, development is influenced by the interactions between cells and their extracellular matrix (ECM). Information contained in the ECM provides the cell with temporal and positional clues, such as where it is, where it should be going, how old it is (in terms of cellular differentiation), and in some instances, when it is time for it to die (through apoptosis). It is not surprising, then, that there has been a great deal of interest in defining the extracellular signals as well as the cell surface receptors that interact with these molecules and interpret the information. Now more than ever, understanding cell biology requires understanding the ECM.

Studying the ECM, however, is not for the faint of heart! In most instances, the functional form of matrix macromolecules is a large, sparingly soluble aggregate that cannot easily be solubilized or dissociated into component units. Even when dissociated matrix components are obtained, the biological properties of the constituent chains often differ from the intact form. To complicate matters, most ECM macromolecules participate in supramolecular assemblies where their biological properties are modified by the molecules with which they interact.

These unusual physical properties create serious problems for matrix characterization using a standard "wet chemistry" approach. They also create some, though not many, unique advantages. For example, the multimeric, cross-linked nature of ECM imparts an element of stability that is not found in other proteins. This is most obvious if one takes a historical look at techniques used for matrix purification (Partridge, 1962; Piez, 1997). In the early days of matrix biology, "connective tissue" was purified using extraction protocols that relied on the ability of the target matrix component to withstand relatively harsh conditions: acid solutions were used for purifying collagen, chaotropic agents for mucopolysaccharides (now called proteoglycans), and, the harshest of them all, boiling sodium hydroxide for purifying elastin. It is quite remarkable that so much of what we know about these three matrix classes resulted from experiments using products purified in this way. Although purification strategies are now a bit more sophisticated, modifications of these basic protocols are still used today. The use of molecular biology and mouse genetics has quickened the pace of matrix characterization and opened the door to functional studies of complex matrices that were unthinkable several years ago.

One of the most important properties of ECM is its functional diversity (Kleinman, 1993). Some components are designed to be rigid, others elastic; some wet, others sticky. All have modular designs that impart diverse roles, yet allow for highly specialized functions. The formation of a basement membrane, for example, requires the assembly of ECM molecules that have significant tensile strength (collagen), can act as charged molecular sieves (proteoglycans), and facilitate cell attachment (laminin). These molecules are woven together through processes that involve self-assembly and interactions with molecules that are specifically designed to serve as molecular bridges or linkers (nidogen/entactin; Yurchenco, 1994).

It is not possible to ascertain the functional properties of a complex matrix such as basement membrane without studying its individual components. At the same time, however, it is also clear that the functional complexity of the assembled basement membrane is greater than the sum of its component parts. To comprehend this greater sum requires shifting one's view away from a reductionist biochemical approach to one focused on cell and developmental biology. Here the cell becomes the reagent, interpreting informational signals contained in the ECM and adjusting its physiology accordingly. The researcher's task is to understand the readout.

The sections below contain an overview of the major classes of ECM. Molecules have been selected to illustrate specific functional or structural properties that are common to a matrix class or to ECM macromolecules generally. Where possible, recent reviews with references to more detailed literature are cited. Although somewhat dated, the text *Cell Biology of Extracellular Matrix* (Hay, 1991) provides an excellent overview of ECM biology. More detailed reviews can be found in various volumes of the *Biology of Extracellular Matrix* series, published by Academic Press.

COLLAGENS

Structure of Collagens

Collagen is the most ubiquitous ECM protein and is designed to provide structure and resiliency to tissues. It is defined by the pres-

Contributed by Robert P. Mecham
Current Protocols in Cell Biology (1998) 10.1.1-10.1.14

ence of a triple-helical domain containing peptide chains with repeating Gly-Xaa-Yaa triplets, and by the presence of hydroxyproline and hydroxylysine (Kühn, 1987; Prockop and Kivirikko, 1995). To date, nineteen distinct genetic collagen types have been identified. The characteristic molecular form of collagen is a triple helix made up of three polypeptides, called α chains, that coil into a right-handed triple helix. Collagens exist either as homotrimers composed of three identical α chains $(\alpha 1)_3$ or as heterotrimers consisting of two $([\alpha 1]_2\alpha 2)$ or three (α1α2α3) α chains.

The nomenclature for the collagen superfamily consists of an indication of their genetic type (a Roman numeral that generally denotes the chronological order in which the collagens were characterized) together with the α-chain composition. Type I collagen, for example, is a heterotrimer of two α1 chains and one α2 chain, and is indicated as $(\alpha 1[I])_2\alpha 2(I)$. Type II collagen is a homotrimer of three α1 chains and is written $(\alpha 1[II])_3$. Other collagens consist of three different α chains and (using type IX as an example) are written in the form α1(IX)α2(IX)α3(IX). It is important to note that each α chain within a collagen type is a distinct gene product; that is, an α1 chain in one collagen type is not the same protein as the α1 chain in any other collagen type. It is critical, therefore, to indicate the collagen type when referring to a particular α chain (e.g., the α1 chain of type I collagen).

Synthesis of Collagens

Collagen α chains are synthesized on membrane-bound ribosomes (ER) as large precursors, called pre-pro-α chains. In addition to the signal peptide (the "pre" part of the name) required for transport into the ER, each collagen precursor has extension peptides (the "pro" part) on both its N- and C-terminal ends (Fig. 10.1.1). Each pro-α chain combines with two others in the lumen of the ER to form the triple-helical molecule. The extension peptides are required for correct triple helix formation and remain with the triple-helical unit throughout the secretory pathway.

In the triple helix, the side chain of every third α-chain residue is directed towards the center of the helix, shifted by 30° from the preceding central residue of the same chain (Brodsky and Ramshaw, 1997). Steric constraints dictate that the center of the helix be occupied only by glycine residues; side chains of any other amino acid would perturb the triple-helical conformation.

Hydroxylation of proline residues in the Yaa position occurs as a post-translational modification in the lumen of the ER. The side-chain hydroxyl group of hydroxyproline stabilizes the helix through the formation of intermolecular hydrogen bonds. In fact, hydroxylation of ~100 prolyl residues is essential for the three pro-α chains of fibrillar collagens to form a triple helix that is stable at body temperatures. Hydroxylation of α chains is catalyzed by prolyl4-hydroxylase, a tetrameric enzyme consisting of two α and two β subunits (α2β2; Kivirikko and Myllyharju, 1998). Interestingly, the β subunit is protein disulfide isomerase, an ER protein that catalyzes thiol-disulfide interchange during protein folding (Koivu et al., 1987). The hydroxylation reaction catalyzed by

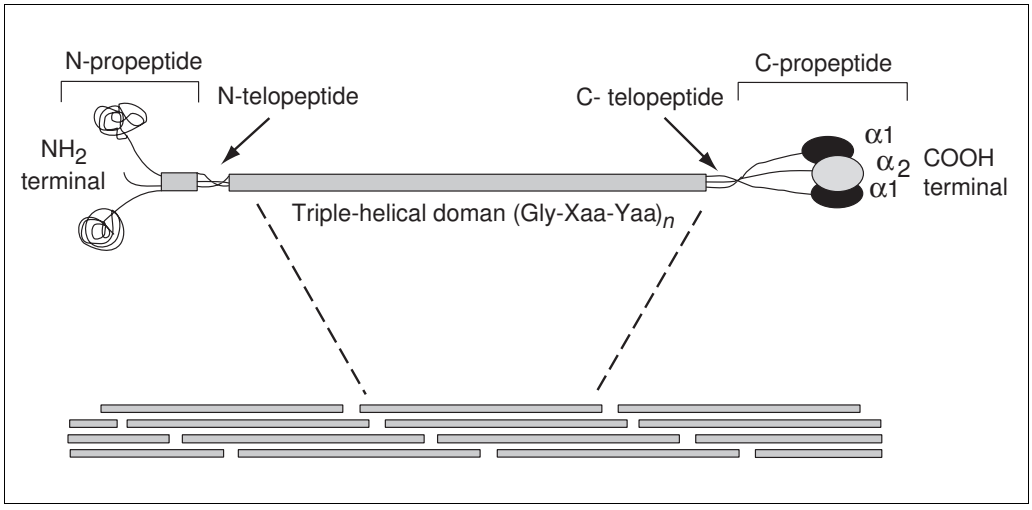

Figure 10.1.1 Functional domains of the type I procollagen molecule. Following cleavage of the propeptide domains in the extracellular space, collagen units assemble in a quarter-stagger arrangement to form a fibril.

prolyl 4-hydroxylase requires Fe^{2+}, 2-oxoglutarate, O_2, and ascorbate. Conditions that prevent proline hydroxylation (such as nutritional deficiency of iron or of vitamin C) affect helix formation or stability. In scurvy, a human disease caused by a dietary deficiency of vitamin C, the nonhydroxylated pro-α chains are unstable and the skin and blood vessels become extremely fragile.

A second post-translational modification of procollagen that is crucial to its function is the hydroxylation of lysine residues. This reaction, which also occurs in the ER, is catalyzed by the enzyme lysyl hydroxylase. The active enzyme is a homodimer and, like prolyl hydroxylase, requires Fe^{2+}, 2-oxoglutarate, O_2, and ascorbate. Hydroxylysine residues have two important functions: their hydroxy groups act as attachment sites for carbohydrate units, and they are essential for the stability of the intermolecular collagen cross-links that occur in the extracellular space after secretion. The glycosylation of hydroxylysine is unusual, consisting of a single galactose residue or a glucosylgalactosyl disaccharide attached to the hydroxyl group. The amount of carbohydrate added to procollagen varies greatly among different types of collagen, and its function is unknown.

Assembly of Collagens

After secretion into the extracellular space, the extension peptides of procollagen are removed by specific proteolytic enzymes. Both the N and C proteinases are members of the zinc metallopeptidase family and contain domains that suggest the ability to interact with cells and other matrix components (Kessler et al., 1996; Colige et al., 1997). Removal of the extension peptides converts the procollagen molecules to collagen (once called tropocollagen). Triple-helical collagen units then come together in the extracellular space to form the much larger collagen fibrils. The process of fibril formation is driven, in part, by the tendency of the collagen molecules to self-assemble. The fibrils form close to the cell surface, however, and it seems likely that the cell regulates the sites and rates of fibril assembly. The nonfibrillar collagens (see below) undergo only limited proteolytic processing prior to assembly. Here it is important to distinguish between collagen and gelatin. As stated above, collagen is the triple-helical form of the protein and can exist as single triple-helical units or triple-helical units polymerized into fibrils. Gelatin is denatured collagen. The individual α chains are no longer in a triple helix but can nevertheless polymerize into a random gel under appropriate conditions of temperature and ionic strength.

Collagen fibrils are greatly strengthened by covalent cross-links within and between the constituent collagen molecules. The types of covalent bonds involved are unique to connective tissue and are formed through deamination of certain lysine and hydroxylysine residues to yield highly reactive aldehyde groups. The aldehydes then undergo classical condensation reactions to form covalent bonds with each other or with other lysine or hydroxylysine residues. The extent and type of cross-linking varies from tissue to tissue, depending on tissue requirements. For example, collagen is highly cross-linked in tendons, where tensile strength is crucial. Lysyl oxidase, the enzyme that catalyzes cross-link formation, requires copper and molecular oxygen. If cross-linking is inhibited, collagenous tissues become fragile, and structures such as skin, tendons, and blood vessels tend to tear.

Collagen Classification

The polymeric structures formed by members of the collagen family vary depending on collagen type (Prockop and Kivirikko, 1995). The structures formed result, in large part, from the nontriple-helical "modules" found within many of the nonfibrillar collagens (Brown and Timpl, 1995). Based on structural similarities, the collagen superfamily can be divided into the following classes.

Fibril-forming collagens: types I, II, III, V, and XI. These collagens (Kühn, 1987; Kadler, 1994) all share a long triple-helical segment with a continuous Gly-Xaa-Yaa repeat over its entire length. They assemble into cross-striated fibers upon cleavage of N and C propeptides, with the individual units adopting a one-quarter stagger relative to their neighbors in the fibril. Types II and XI collagen undergo alternative splicing, and hybrid molecules containing both types V and XI collagen have been identified in some tissues.

Network-forming collagens: types IV, VIII, and X. α chains in the type IV collagen family (Hulmes, 1992; Kühn, 1994; Yurchenco, 1994) contain a large collagenous domain that is frequently interrupted by short noncollagenous sequences (i.e., something other than Gly-Xaa-Yaa). Noncollagenous domains are also found at the N and C termini of the chain, with the C-terminal domain being the larger of the two. Monomers associate at the C termini to form dimers and at the N termini to form tetramers.

The triple-helical domains intertwine to form supercoiled structures, resulting in a net-like structure. Type VIII collagen is found in Descemet's membrane in the eye and forms a stack of hexagonal lattices. A similar structure is formed by type X collagen synthesized by hypertrophic chondrocytes in the deep-calcifying zone of cartilage.

Fibril-associated collagens with interrupted triple helices (FACIT): types IX, XII, XIV, XVI, and XIX. These collagens (Mayne and Brewton, 1993; Olsen et al., 1995) are characterized by short triple-helical segments interrupted by short noncollagenous domains. They attach to the surface of fibril-forming collagens and do not form fibrils themselves. Type IX collagen is found on the surface of type II collagen, to which it is covalently bound. An unusual property of this collagen is the presence of a glycosaminoglycan (GAG) chain attached to a noncollagenous domain of the α2(IX) chain. Types XII and XIV collagen show structural similarities to type IX, including an attached GAG side chain. Types XVI and XIX have not been fully characterized but show similarities in structure to other members of the family.

Beaded filaments and anchoring fibrils: types VI and VII. Among the collagens of this family (Burgeson, 1993; Timpl and Chu, 1994), type VI collagen is characterized by α chains containing large N- and C-terminal globular domains separated by a small triple-helical segment. Alternative splicing produces variants of the α2(VI) and α3(VI) chains. Type VI collagen forms small beaded filaments in the ECM. Type VII collagen forms anchoring fibrils that link basement membranes to anchoring plaques of type IV collagen and laminin in the underlying ECM. Type VII collagen contains the longest triple helix of any known collagen, with only small interruptions throughout. The NC1 domain of type VII collagen binds to collagen types I and IV, fibronectin, and laminin 5.

Collagens with a transmembrane domain: types XIII and XVII. Types XIII and XVII collagen (Li et al., 1996) are unique in having a transmembrane domain with its N terminus predicted to be in the cytoplasm. Type XIII collagen undergoes extensive alternative splicing. Type XVII collagen is found primarily in the hemidesmosomes of the skin and is one of the antigens that produces the autoimmune disease bullous pemphigoid.

Other nonfibrillar collagens: types XV and XVIII. Types XV and XVIII collagen (Rehn and Pihlajaniemi, 1994) have large N- and C-terminal globular domains and a highly interrupted triple helix. Their large number of potential *N*- and *O*-linked glycosylation sites suggests that both types have the potential to be highly glycosylated.

ELASTIN AND MICROFIBRILLAR PROTEINS

Elastin

During evolution, with the advent of the closed circulatory system, came the requirement for blood vessels to accommodate the pulsatile blood flow of the heart. Vessels made mostly of collagen were too stiff, so in its place, we see the emergence of a matrix protein that has the properties of elastic recoil. This protein, elastin, is the predominant protein component of the elastic fiber that is of particular importance to the structural integrity and function of tissues in which reversible extensibility or deformability are crucial, such as the major arterial vessels, lungs, and skin.

In contrast to the genetic diversity evident in the collagen gene family, elastin is encoded by only one gene. Like collagen, elastin maturation in the ECM involves the assembly of a soluble precursor molecule (tropoelastin) into a highly cross-linked polymer. This assembly process is more complex than that for collagen, however, because the ability to self-assemble does not appear to be an intrinsic property of tropoelastin. Instead, elastin assembly requires helper proteins to align the multiple cross-linking sites on elastin monomers (Mecham and Davis, 1994).

Two functional domains repeat along the tropoelastin molecule (Fig. 10.1.2). One domain, related to cross-link formation, is an α helix containing alanine and lysine. The other, related to extensibility, is enriched in glycine, valine, and proline. The hydrophobic amino acids in this domain are arranged in repeating sequences that form a succession of β turns. The stacked β turns form a β spiral with a hydrophobic core. Stretching the elastin polymer exposes the hydrophobic core to water. Recoil occurs when the leaves of the β spiral contract to shield the hydrophobic amino acids from the aqueous microenvironment. Mature, cross-linked elastin is extremely hydrophobic and insoluble under most conditions (including when boiled in sodium hydroxide; Partridge, 1962). Its unusual physical properties make insoluble elastin one of the most stable proteins in the body—lasting the lifetime of the organism. Two polyfunctional cross-links, desmos-

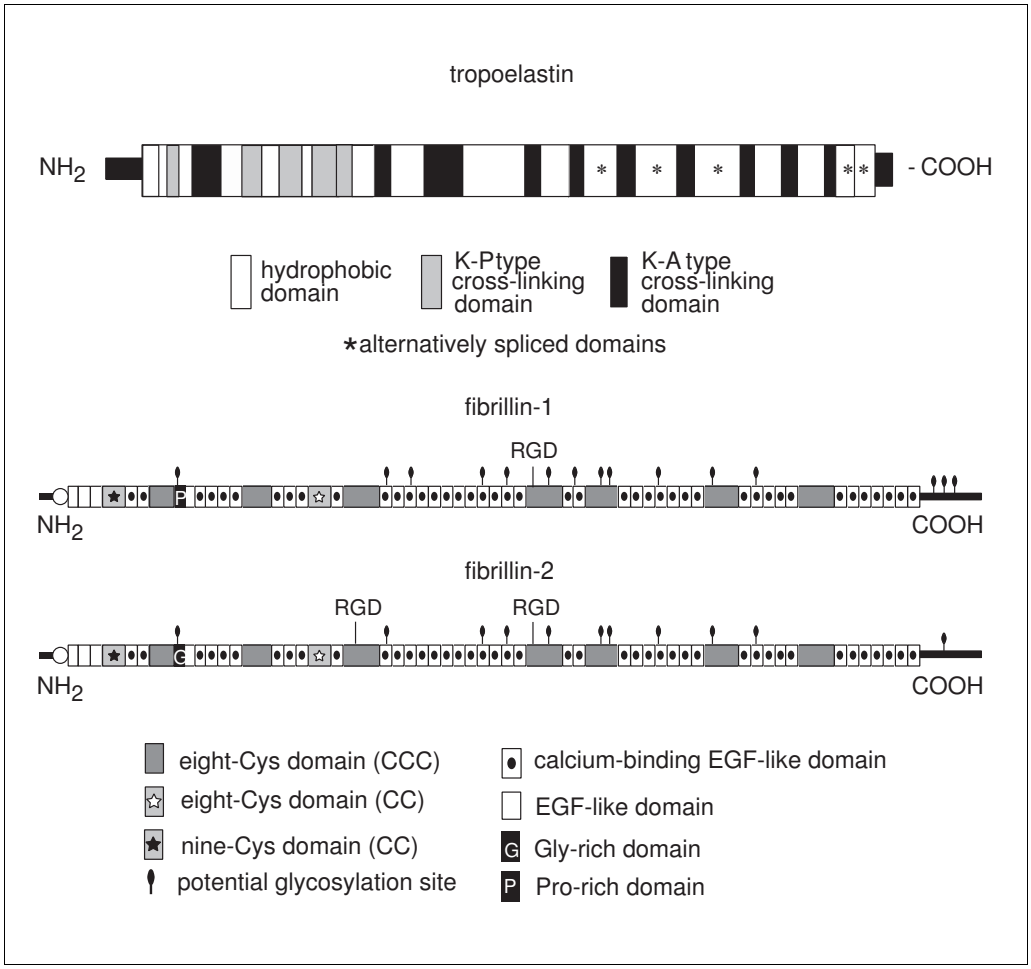

Figure 10.1.2 Domain map of tropoelastin and the fibrillins. Tropoelastin is secreted as a peptide of ~70 kDa and undergoes extensive covalent cross-linking during incorporation into the elastic fiber. Fibrillin-1 and fibrillin-2 each have a molecular weight of ~350 kDa and are the major structural elements of 10- to 12-nm-diameter microfibrils. Abbreviations: K-A, alanine-rich cross-linking domain; K-P, proline-rich cross-linking domain; RGD, Arg-Gly-Asp; CC, Cys-Cys sequences; CCC, Cys-Cys-Cys sequences; EGF, epidermal growth factor.

ine and isodesmosine, are unique to elastin and can be used as specific markers for this protein.

Fibrillin

Microfibrils were first identified as components of elastic fibers. They are found in greatest abundance in elastic tissues or in the ciliary zonules of the eye, although their distribution is widespread. Fibrillin-1 and -2 play key roles in microfibrillar architecture. These 350-kDa glycoproteins are highly homologous (Fig. 10.1.2), with modular structures consisting of repeating calcium-binding epidermal growth factor (EGF)–like domains interspersed between 8-cysteine domains similar to those found in the latent transforming growth factor-β (TGF-β)–binding protein family (Lee et al., 1991). Tandemly arranged EGF domains form a structural motif found frequently in ECM macromolecules (e.g., laminin, fibulin, latent TGF-β-binding protein, nidogen). When stacked together, these tightly folded, disulfide-bonded loop structures form a rigid, rod-like arrangement stabilized by interdomain calcium binding and hydrophobic interactions (Downing et al., 1996). The precise function of microfibrils is unclear, although their association with developing elastic fibers suggests a role in elastin assembly. Both fibrillin-1 and fibrillin-2 interact with the αvβ3 integrin through an Arg-Gly-Asp (RGD) sequence (see Adhesive Glycoproteins).

ADHESIVE GLYCOPROTEINS

Most, if not all, ECM macromolecules interact with binding proteins on the surface of cells. In many instances, this is through a unique sequence motif that is accessible as part

of the protein's folded functional structure, or cryptic and exposed only when the protein undergoes a conformational change induced by binding to another protein or as the result of degradation or denaturation. One such "recognition motif" is the well-known RGD sequence that is recognized by several members of the integrin family.

Fibronectin

A great deal of biochemical work has led to a model of the fibronectin molecule in which the protein's binding functions and its structure are clearly correlated (Hynes, 1990). The molecule is secreted as a dimer consisting of two similar subunits joined together at the C terminus by disulfide bonds (Fig. 10.1.3). Each chain has a molecular weight of ~220 to 250 kDa and is subdivided into a series of tightly folded domains. Each domain is responsible for one of fibronectin's binding functions. In plasma, fibronectin exists as a soluble dimer, but in the ECM it is found as an insoluble multimer.

Amino acid sequence analysis of fibronectin shows that the molecule is made up mostly of three repeating motifs, referred to as types I, II, and III repeats. These repeats are organized into functional domains that contain binding sites for ECM proteins and cell surface receptors (see Fig. 10.1.3). For example, there are two fibrin-binding domains consisting of multiple type I repeats on each subunit of the protein. Type I repeats are also found in the collagen-binding domain, and the first five type I repeats play an important role in matrix assembly. The N-terminal domain of fibronectin also mediates fibronectin's binding to gram-positive bacteria through type I modules. The type I module contains ~45 amino acids with four cysteines forming two disulfide bonds (Potts and Campbell, 1994). This module has also been found in a number of other proteins. In addition to type I repeats, the collagen-binding domain contains the only type II repeats found in fibronectin. Like type I repeats, these motifs contain two disulfide bonds, but they are larger than type I motifs.

The predominant structural feature of fibronectin consists of type III repeats, accounting for more than 60% of the sequence. No disulfide bonds are present in this structure, although two of the repeats contain a free cysteine. The cell-binding RGD sequence is located in the tenth type III repeat. This sequence is recognized by many members of the integrin family, including $\alpha5\beta1$, $\alpha v\beta1$, $\alpha v\beta3$, $\alpha v\beta5$, $\alpha v\beta6$, $\alpha IIb\beta3$, and $\alpha8\beta1$. Other cell-binding regions include the C-terminal heparin-binding domain and the type III–connecting segment (IIICS), including the CS1 region. The type III consensus sequence is frequently found in other proteins.

Only one gene for fibronectin has been identified, but mRNAs for fibronectin have been shown to give rise to multiple versions of the protein through variable patterns of RNA splicing during gene transcription. Alternative splicing occurs predominately at three sites, termed extra type III domain A (EDA or EIIIA), extra type III domain B (EDB or EIIIB), and the

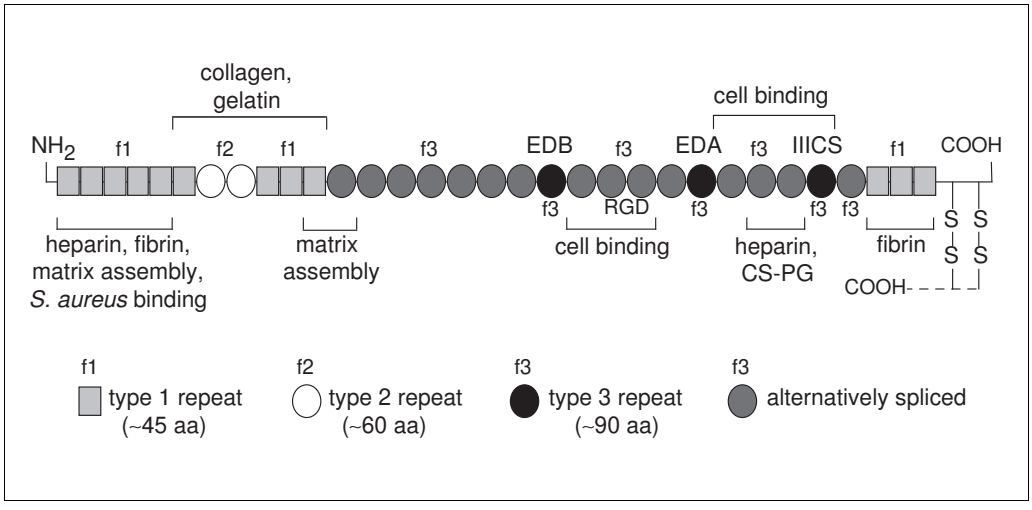

Figure 10.1.3 Domain map of fibronectin. The subunits of fibronectin vary in size between ~235 and 270 kDa. Alternative splicing occurs at three positions: EDA, EDB, and IIICS. Binding sites for other molecules and cells are indicated. Abbreviations: EDA, extra type III domain A; EDB, extra type III domain B; IIICS, connecting segment between the fourteenth and fifteenth type III repeats; RGD, Arg-Gly-Asp; CS-PG, chondroitin sulfate proteoglycan; aa, amino acids.

connecting segment between the fourteenth and fifteenth type III repeats (IIICS or V). Splicing within the IIICS segment produces five variants, such that twenty different fibronectin subunits can result from splicing within the three segments.

Subunits of plasma fibronectin produced by adult hepatocytes contain neither EDA nor EDB segments, and one subunit lacks the entire IIICS domain. Cultured fibroblasts, however, typically produce a form of fibronectin, referred to as cellular fibronectin, that contains the EDA and/or EDB segments. Fibronectins expressed in fetal and tumor tissues contain a greater percentage of EDA and EDB segments than those expressed in normal adult tissues. The biological functions of fibronectin isoforms are only poorly understood, despite having been studied extensively. Differences in solubility have been demonstrated, but it has been difficult to detect functional differences between plasma and cellular fibronectin in their ability to promote cell adhesion and spreading.

Vitronectin

Vitronectin (also called serum spreading factor, S-protein, and epibolin) is a multifunctional protein found in plasma and ECM. It is synthesized as a single chain that undergoes N glycosylation, tyrosine sulfation, and phosphorylation prior to secretion. In plasma, vitronectin circulates in two forms: a single chain of ~75 kDa and a proteolytically cleaved, two-chain form that dissociates into 65- and 10-kDa fragments upon reduction. It is present in fibrillar form in the ECM of a variety of tissues, where it sometimes colocalizes with fibronectin and elastic fibers. While little vitronectin immunoreactivity is detectable in most normal tissues, increased deposition has been observed in areas of tissue injury and necrosis. Tissue vitronectin was believed to be plasma derived, but recent studies indicate that extrahepatic cells have the biosynthetic potential to produce vitronectin and that its synthesis can be regulated under inflammatory conditions (Seiffert, 1997).

The cell attachment activity of vitronectin results from an RGD sequence that is recognized by a wide variety of integrins. Most of the cell adhesive activity of serum used for tissue culture can be attributed to vitronectin.

Laminin and Basement Membranes

Like fibronectin, the laminins are modular proteins with domains that interact with both cells and ECM (Ekblom and Timpl, 1996). They constitute a family of basement membrane glycoproteins that affect cell proliferation, migration, and differentiation. Eleven different laminins have been identified, each containing an α, β, and γ chain (Fig. 10.1.4). Electron microscopy has revealed that all laminins have a cross-like shape with three short arms and one rod-like long arm, a shape well suited for mediating interactions between sites on cells and components of the ECM (Beck et al., 1990; Maurer and Engel, 1996). The rod-like regions separating the globular units of the short arms are made up of repeating EGF-like domains. The long arm is formed by all three component chains folding into an α-helical coiled-coil structure, and is the only domain composed of multiple chains. It is terminated by a large globular domain composed of five homologous subdomains formed by the C-terminal region of the α chain.

Along with type IV collagen, laminins are a major structural element of the basal lamina (Timpl, 1996). The molecular architecture of these matrices results from specific binding interactions among the various components. The structural skeleton is formed by type IV collagen chains that assemble into a covalently stabilized polygonal network. Laminin self-assembles through terminal domain interactions to form a second polymer network. Nidogen (Mayer and Timpl, 1994) binds laminin near its center and interacts with type IV collagen, bridging the two. A large heparan sulfate proteoglycan (HS-PG), perlecan, binds laminin and type IV collagen through its GAG chains and forms dimers and oligomers through a core-protein interaction. Perlecan is important for charge-dependent molecular sieving, one of the critical functions of basement membrane. Other components that are sometimes found associated with basement membranes but may not be intrinsic components include fibronectin, type V collagen, fibulin, osteonectin (also known as BM-40 or SPARC), and chondroitin sulfate proteoglycans.

Cells attach to laminin through specific interaction sites created by its multidomain structure. For example, sites for receptor-mediated cell attachment and promotion of neurite outgrowth reside in the terminal region of the long arm. A second cell-attachment site and a cell-signaling site with mitogenic action are localized in the short arms. Cell binding to laminin occurs via a variety of receptors, including non-integrins (Mecham and Hinek, 1996) and integrins (Aumailley et al., 1996). The β1 family includes most of the laminin-binding integrins (α1β1, α2β1, α3β1, α7β1, α9β1). Other

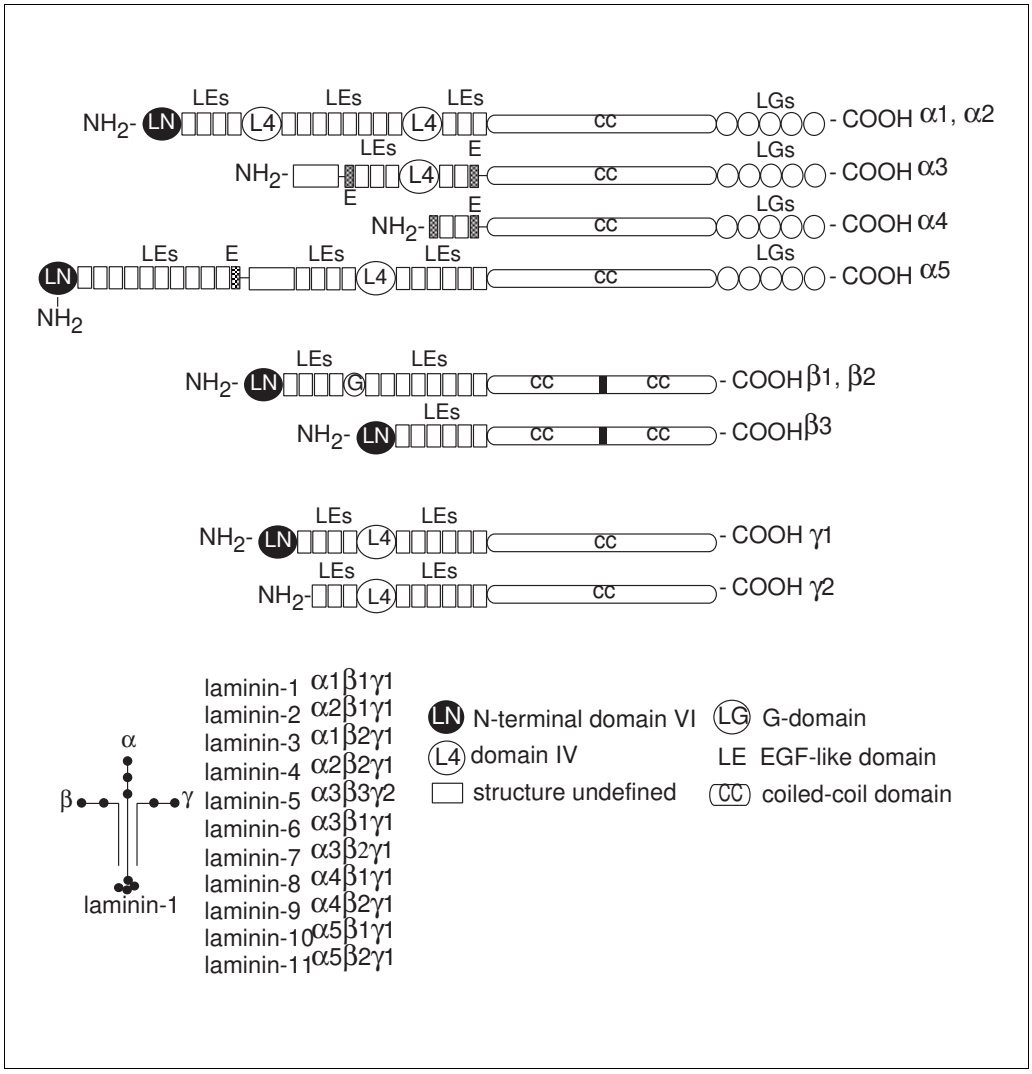

Figure 10.1.4 Domain map of laminin chains. Three polypeptide chains (α, β, and γ) form the laminin cross. The chain composition of known laminin types is shown in the insert. Abbreviation: EGF, epidermal growth factor.

integrins that bind laminin include αvβ3 and α6β4. Basement membrane can also have an indirect effect on cells by binding and sequestering growth and differentiation factors, such as fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), and TGF-β.

The importance of laminin to cell differentiation and migration has been demonstrated in developmental studies. Isoforms of laminin assembled from different chains are focally and transiently expressed and may serve distinct functions at early stages of development even before being deposited as components of basement membranes. Laminin is present at the two-cell stage in the mouse embryo, making it one of the first ECM proteins detected during embryogenesis.

MATRICELLULAR PROTEINS

The term "matricellular" has been applied to a group of extracellular proteins that function by binding to matrix proteins and to cell surface receptors, but do not contribute to the structural integrity of the ECM (Bornstein, 1995). Proposed members of this group include the thrombospondins, members of the tenascin protein family, SPARC/osteonectin (Lane and Sage, 1994), and osteopontin. These proteins are frequently called "antiadhesive proteins" because of their ability to induce rounding and partial detachment of some cells in vitro (Sage and Bornstein, 1991). Their ability to interact with many different matrix proteins and cell surface receptors may explain their complex range of biological functions.

Thrombospondin

The thrombospondin (TSP) family consists of five secreted glycoproteins (Adams et al., 1995). TSP-1 and TSP-2 have identical domain structures and are secreted as disulfide-bonded homotrimers (Fig. 10.1.5). TSP-3, TSP-4, and TSP-5/COMP (cartilage oligomeric matrix protein) are pentamers whose expression is more limited than that of TSP-1 and TSP-2. TSP-1 binds HS-PGs, various integrins, the integrin-associated protein, and CD36. It also binds plasminogen, fibrinogen, fibronectin, urokinase, and TGF-β (which it can also activate). TSP-1 exhibits variable effects on cell adhesion and cell proliferation (Bornstein, 1995). For example, TSP-1 promotes proliferation of vascular smooth muscle cells, yet inhibits proliferation of endothelial cells. It supports attachment and spreading of skeletal myoblasts but expresses antiadhesive activity toward endothelial cells. Thrombospondin is the most abundant protein of platelet alpha granules and is released when platelets are activated.

Tenascin

The tenascins constitute a gene family consisting of four members: tenascins-C, -R, -X, and -Y (Erickson, 1993; Chiquet-Ehrismann, 1995). Tenascin-C (early names include GMEM, cytotactin, J1, hexabrachion, and neuronectin) was the first form discovered and exists as a hexamer of disulfide-bonded subunits. Each subunit consists of a cysteine-rich N-terminal domain involved in oligomerization, EGF-like repeats, fibronectin type III–like repeats, and a fibrinogen-like globular domain (Fig. 10.1.5). The number of fibronectin type III–like repeats varies as a result of alternative splicing. Like TSP, tenascin-C has diverse biological effects when applied to cells. Both stimulation and inhibition of cellular proliferation have been observed in response to tenascin-C. In terms of cell adhesion, some cells do attach to tenascin, but weakly. In most instances, tenascin does not allow cell adhesion and can even inhibit cell attachment to other matrix proteins such as fibronectin and laminin. The finding that tenascin-C contains defined cell attach-

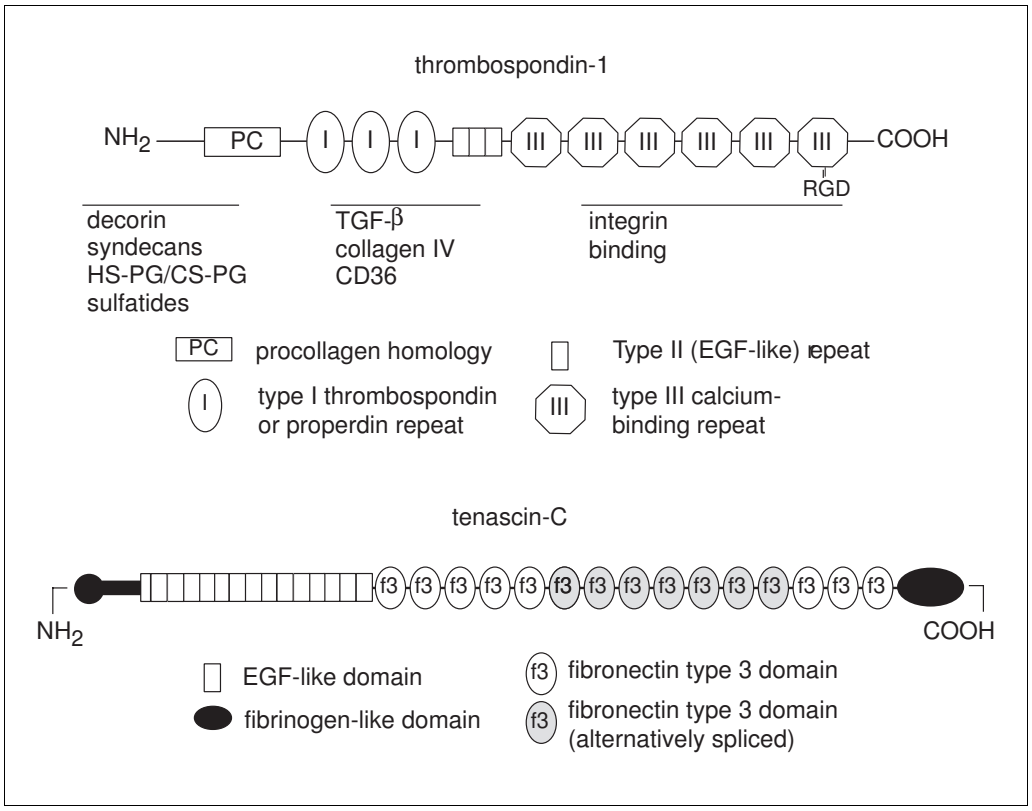

Figure 10.1.5 Domain map of thrombospondin-1 and tenascin-C. The functional form of thrombospondin is a homotrimer of ~420 kDa. It interacts with numerous matrix proteins and modulates cell attachment by interacting with various cell-surface receptors. Tenascin-C monomers form a hexameric structure joined at their N termini by disulfide bonds. Alternative splicing leads to subunits of differing molecular weights. Abbreviations: HS-PG, heparan sulfate proteoglycan; CS-PG, chondroitin sulfate proteoglycan; TGF-β, transforming growth factor-β; RGD, Arg-Gly-Asp; EGF, epidermal growth factor.

ment sites suggests that the overall antiadhesive properties of the glycoprotein are effected by separate domains that override the attachment domains.

PROTEOGLYCANS

The proteoglycans (once called acid mucopolysaccharides) constitute a number of genetically unrelated families of multidomain proteins that have covalently attached GAG chains. To date, more than 25 distinct gene products have been identified that carry at least one GAG chain (Iozzo and Murdoch, 1996). Like other matrix components discussed in this review, proteoglycans exist as structural variants, further increasing their functional and structural diversity.

For historical reasons, proteoglycans are named based on the type of attached GAG chain(s): (1) chondroitin sulfate and dermatan sulfate, consisting of a repeating disaccharide of galactosamine and either glucuronic acid or iduronic acid; (2) heparin and heparan sulfate, consisting of a repeating disaccharide of glucosamine and either glucuronic acid or iduronic acid; and (3) keratan sulfate, consisting of a repeating disaccharide of glucosamine and galactose. Hyaluronate is also a repeating disaccharide but is not sulfated and not bound to a core protein. GAG chains are usually attached through *O*-glycosidic linkages to serine residues in the proteoglycan core protein. A characteristic feature of GAG chains is that at physiological pH they contain one to three negative charges per disaccharide due to carboxylate and sulfate groups.

Knowledge of the structure and function of proteoglycans increased dramatically when molecular biology was used to study the core proteins (Hassell et al., 1993). The heterogeneity of this family of matrix proteins also became evident with the finding that there are no structural domains common to all proteoglycans. There are, however, distinguishing characteristics that allow them to be grouped into four broad categories.

Large Proteoglycans that Form Aggregates by Interaction with Hyaluronan

These proteoglycans interact with strands of hyaluronate to form a very-high-molecular-weight aggregate. A structural trait shared by these proteoglycans is the presence of three functional domains: a globular hyaluronan-binding domain at the N terminus, a central extended region that carries most of the GAG chains, and a modular C-terminal domain containing two EGF repeats, a C-type lectin domain, and a complement-regulatory-protein-like motif (Iozzo and Murdoch, 1996).

The largest member of this family is versican (Zimmermann and Ruoslahti, 1989), a major proteoglycan in blood vessels that is also expressed in nonvascular tissues. Aggrecan, the large aggregating proteoglycan of cartilage, has a smaller core protein than versican but contains nearly 3-fold more GAG chains (Fig. 10.1.6). The high charge density of aggrecan results in each monomer occupying a large hydrodynamic volume. Aggrecan's GAG chains result in a high density of fixed charge in cartilage, producing an osmotic swelling pressure that is balanced by tension in the collagenous network. The reversible redistribution of proteoglycan-bound water under loading gives cartilage the ability to absorb compressive loads (Wight et al., 1991). Two other members of this family include neurocan (Rauch et al., 1992) and brevican (Yamada et al., 1994), both found in brain tissues.

Basement Membrane Proteoglycans

HS-PGs appear to be ubiquitous components of all basement membranes. Perlecan is the largest basement membrane proteoglycan, with a modular core protein of 467 kDa (Fig. 10.1.6; Iozzo et al., 1994). It provides the basement membrane with a negative charge that is important to its sieving properties. The heparan sulfate chains of perlecan also bind growth factors and cytokines and sequester them into the basement membrane, where they may function as a reserve to be released during tissue repair. The interaction of heparan sulfate with the FGFs has been extensively studied (Aviezer et al., 1994). Perlecan interacts with other components of the basement membrane, particularly laminin and nidogen. The multidomain structure of perlecan core protein is reminiscent of other ECM proteins, and includes EGF repeats and repeats of structures found in the low-density lipoprotein receptor, laminin chains, and neural cell adhesion molecule.

Agrin was originally isolated from torpedo ray electric organ and was found to induce acetylcholine receptor aggregation. It is secreted by motor neurons and deposited in the synaptic cleft basement membrane. Agrin may also play a role in the sequestration of growth factors in the basement membrane. Like perlecan, agrin is a multidomain protein with regions of EGF and laminin G-domain homology. Agrin is found predominantly in the brain, but

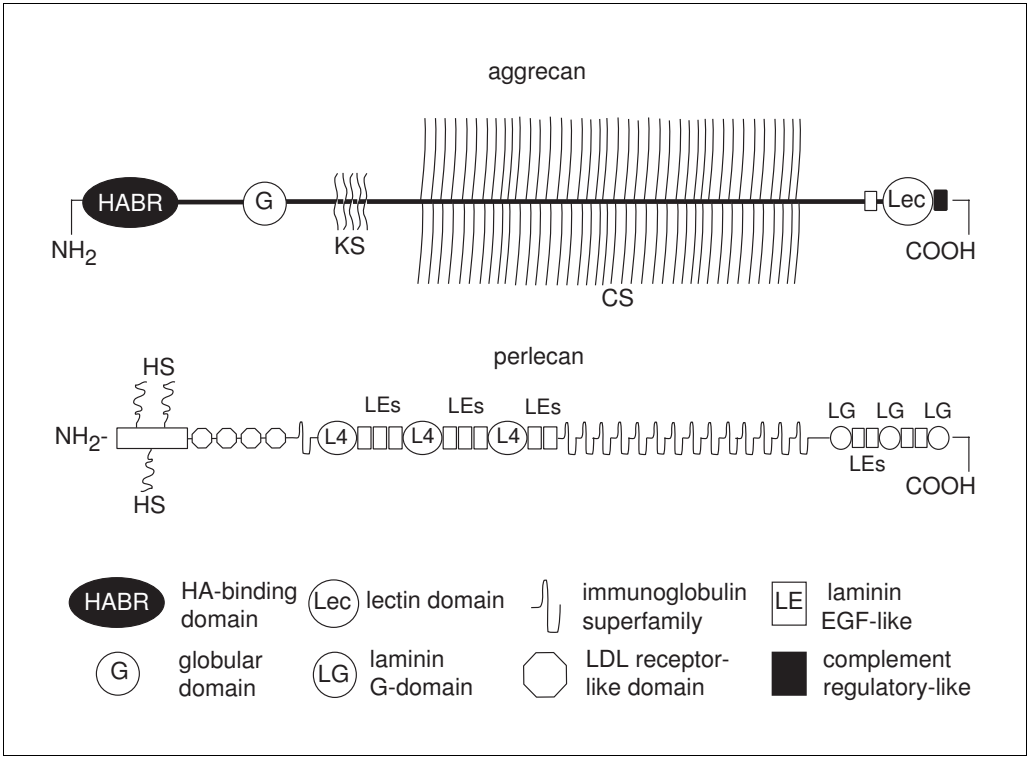

Figure 10.1.6 Domain map of two representative large proteoglycans. Aggrecan is the core protein of the aggregating proteoglycan found in cartilaginous tissues. The molecular weight of the aggrecan core protein is 210 to 250 kDa. There are 100 to 150 keratan sulfate chains and many more chondroitin sulfate chains that contribute to the 2500-kDa molecular weight of the mature proteoglycan. The glycosaminoglycans are attached to repetitive sequences in the middle two-thirds of the molecule, including several types of repeats containing Ser-Gly, the linkage site for chondroitin sulfate. Perlecan is the largest of the basement membrane proteoglycans and has two or three attached heparan sulfate side chains. Removal of heparan sulfate side chains by heparatinase produces a core protein of 400 to 450 kDa on SDS-PAGE. Abbreviations: HA, hyaluronate; KS, keratan sulfate; CS, chondroitin sulfate; HS, heparan sulfate; LDL, low-density lipoprotein; EGF, epidermal growth factor.

has also been localized to smooth and cardiac muscle.

Cell Surface Heparan Sulfate Proteoglycans

HS-PGs on the cell surface influence several important biological functions, including cell adhesion; the sequestration of heparin-binding ligands on the plasma membrane; and the promotion of dimerization/oligomerization of bound ligands, which enhances activation of primary signaling receptors.

Cell-associated HS-PGs have been divided into two major families, syndecan-like integral membrane HS-PGs (SLIPs) and glypican-related integral membrane HS-PGs (GRIPs; David, 1993; Carey, 1997). The SLIPs are transmembrane HS-PGs with a conserved intracellular domain that likely interacts with cytoskeletal and regulatory proteins. The GRIPs are linked to the cell surface by glycosyl phosphatidyl inositol in the outer leaflet of the lipid bilayer.

The syndecans, the principal form of cell-surface HS-PG, are synthesized by many cells. Syndecans bind a variety of extracellular ligands via their covalently attached heparan sulfate chains and are thought to play important roles in cell-matrix and cell-cell adhesion, migration, and proliferation. To date, four homologous syndecan core proteins have been cloned from vertebrate cells. All syndecans are type I transmembrane proteins, with an N-terminal signal peptide, an ectodomain that contains several consensus sequences for GAG attachment, a single hydrophobic transmembrane domain, and a short C-terminal cytoplasmic domain. The majority of GAG chains added to syndecan core proteins are of the heparan sulfate type, although syndecan-1 and syndecan-4 have chondroitin sulfate chains attached as well. Syndecans act as cell surface

receptors for a number of matrix molecules, thereby mediating cell attachment and tissue organization. They influence the interactions of basic FGF and other growth factors with their receptors on cells and are responsible for the maintenance of a nonthrombogenic surface on endothelial cells.

Small Leucine-Rich Proteoglycans

Small leucine-rich proteoglycans (SLRPs) comprise a class of secreted proteoglycans that include five structurally related members: decorin, biglycan, fibromodulin, lumican, and epiphycan (see Fig.10.1.7). Each has a leucine-rich core protein that assumes an arch-shaped structure with a concave surface capable of interacting with various other proteins. The N-terminal region contains one (decorin) or two (biglycan and epiphycan) GAG chains that can be either dermatan or chondroitin sulfate. Instead of GAG chains, fibromodulin and lumican have tyrosine sulfate in the N terminus, which provides an analogous negatively charged domain. These two SLRPs also contain N-linked keratan sulfate chains in their central domain.

SLRPs interact with numerous ECM proteins (e.g., fibronectin, TSP, fibrillin, microfibril-associated glycoprotein) and act to orient and order collagen fibers during development

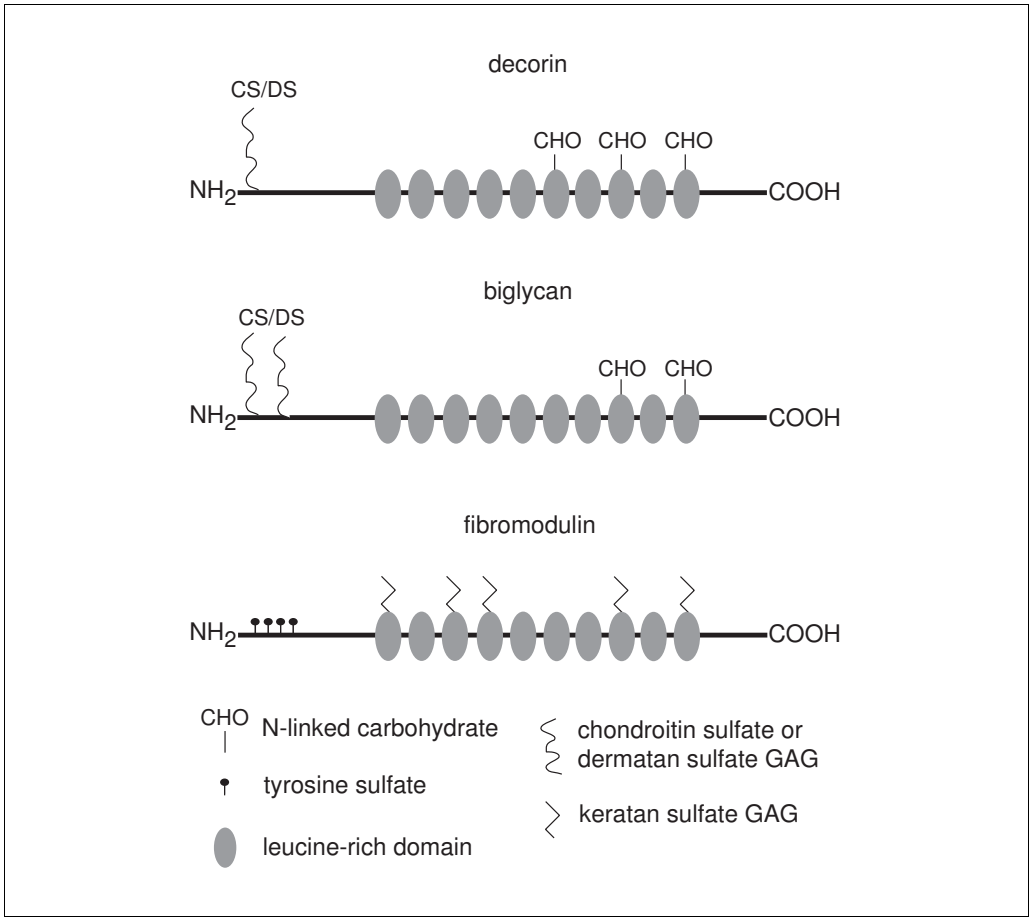

Figure 10.1.7 Domain map of representative members of the small leucine-rich proteoglycans. Decorin contains a single chondroitin or dermatan sulfate chain attached near the N terminus. The core protein is ~38 kDa. Decorin is heterogeneous with respect to glycosaminoglycan (GAG) chain size, such that the secreted proteoglycan shows a range of molecular weights centered between 100 and 250 kDa. The core protein of biglycan is similar in size to that of decorin, except biglycan contains two chondroitin or dermatan sulfate chains. The GAG chains are also heterogeneous in size, resulting in a broad band on SDS-PAGE centered anywhere from 200 to 350 kDa. Removal of GAG chains with chondroitin ABC-lyase results in a 45-kDa band. Fibromodulin has a core protein size of 42 kDa. Four of the five potential N-glycosylation sites in the leucine-rich region of the molecule are substituted with keratan sulfate chains. Five to seven closely spaced tyrosine sulfate residues are found in the N-terminal domain. Abbreviations: CS, chondroitin sulfate; DS, dermatan sulfate.

and tissue remodeling. Interactions with matrix proteins occur through the leucine-rich core which, in the case of type I collagen, influences collagen fibrillogenesis by binding to the surface of the collagen fibril at the d-band with the highly charged GAG chain extending out to regulate interfibrillar distances. Like other proteoglycans, SLRPs bind to growth factors (e.g., TGF-β) and thereby likely influence cellular differentiation and matrix synthesis. Decorin has recently been shown to directly regulate cell growth by activating the EGF receptor (Moscatello et al., 1998).

CONCLUSIONS

The furious pace of advances in the molecular biology of ECM has greatly expanded the knowledge of individual matrix components. The structure of many matrix macromolecules, for example, was determined from cloned cDNAs or genes long before complete protein information was available. With this increased knowledge as background, there is a growing realization that the information contained in the ECM is not a monosyllabic message encoded by individual molecules, but a complex and intricate arrangement dictated by the combinatorial organization of the supramolecular structure. As the focus of biological research changes from the letters to the message, understanding how cells read and interpret this information will undoubtedly reveal more about the letters in the code.

Preparation of Basement Membrane Components from EHS Tumors

This unit describes methods for passaging and harvesting the basement membrane matrix–producing EHS tumor and for the subsequent isolation of a crude mixture of basement membrane components termed Matrigel (see Basic Protocol 1), which promotes the differentiation of a variety of epithelial, endothelial, and neuronal cells. Procedures for the isolation of the adhesive glycoprotein laminin-1 (see Basic Protocol 2) and of type IV collagen (see Basic Protocol 3) are also included.

All epithelial and endothelial cells produce a basement membrane matrix, but in most tissues they do so only in small amounts. The approach described here, using tumor cells, enables one to obtain basement membrane material of high purity in significant quantities. The material isolated from EHS tumors is structurally and antigenically identical to material from normal tissue basement membranes. The isolated material is native, intact, and homogeneous. It can be used in biological assays and for studying extracellular matrix assembly. The isolation methods for Matrigel and laminin-1 can also be applied to nontumor tissues, but yields are generally low and additional purification may be needed.

Type IV collagen is normally highly cross-linked; therefore it is difficult to extract it intact from tissues in quantity unless the animals are placed for several weeks on a lathrogenic diet, which makes collagens soluble by blocking cross-link formation. Support protocols cover the maintenance and harvesting of EHS tumors in mice (see Support Protocol 1) and maintenance of mice on a lathrogenic diet (see Support Protocol 2).

Procedures for preparing laminin-1 and type IV collagen are similar to that for Matrigel but require additional steps and different extraction buffers. Both laminin-1 and type IV collagen can be prepared from the same batch of tumor if the mice are lathyritic, but only laminin-1 can be prepared from nonlathyritic tissue. Once Matrigel is prepared from the tumor, the residue cannot be used for large-scale preparations of laminin-1 or type IV collagen because most of the material has been extracted.

PREPARATION OF MATRIGEL

BASIC PROTOCOL 1

Matrigel significantly promotes the differentiation of a variety of cell types, including endothelial, smooth muscle, fat, and neuronal cells. Untransformed cells generally do not proliferate on Matrigel, whereas transformed cells continue to proliferate. This preparative procedure requires 100 g of tumor tissue and the volumes used are important.

Materials

EHS tumor (see Support Protocol 1)
3.4 M NaCl buffer (see recipe), 4°C
2 M urea buffer (see recipe), 4°C
Tris-buffered saline (TBS; *APPENDIX 2A*), 4°C
Chloroform
Tissue culture medium (e.g., DMEM, RPMI)
70% ethanol

Electric homogenizer (e.g., Polytron)
Centrifuge and rotor, 4°C
Sterile hemostat

Additional materials and equipment for dialysis and protein assays (see *APPENDIX 3*)

Contributed by Hynda K. Kleinman
Current Protocols in Cell Biology (1998) 10.2.1-10.2.10

NOTE: All reagents and equipment should be prechilled to 4°C, and all procedures must be performed at 4°C.

1. If frozen, thaw the EHS tumor (100 g) at room temperature in 200 ml of 3.4 M NaCl buffer for ~1 hr. Homogenize the tumor until dispersed with an electric homogenizer.

   A Polytron homogenizer works well. Do not homogenize for too long, as it is important not to warm the tissue.

2. Centrifuge the homogenate 15 min at 8000 × *g*, 4°C, to pellet the tumor tissue. Discard the pink supernatant and repeat homogenization (step 1).

   The centrifuge and rotor must be cold before and during use for all manipulations.

3. Add 100 ml of 2 M urea buffer to the tumor pellets and homogenize to disperse the tumor. Stir overnight at 4°C.

4. Centrifuge the urea homogenate 20 min at 23,000 × *g*, 4°C, and decant the supernatant gently. Save the supernatant on ice.

   Pour off the thick supernatant gently, as the pellet may detach from the bottom of the tube.

5. Homogenize the pellets in 50 ml of 2 M urea buffer and centrifuge as in step 4. Combine the supernatants and discard the pellets.

6. Dialyze the supernatant against 2 liters TBS containing 10 ml chloroform/liter for ≥4 hr (see *APPENDIX 3*). Manually rotate the bags after 2 hr to assure dispersion of the contents.

   This step sterilizes the inside of the bag; chloroform will kill bacteria and spores. Subsequent steps remove the urea and chloroform. When discarding the chloroform-containing dialysis buffer, it is best to decant the buffer and discard the remaining chloroform, which settles to the bottom of the vessel, in a chemical waste container.

7. Dialyze twice more, for ≥2 hr each time, against 2 liters TBS and then once more against 2 liters tissue culture medium.

   Manually rotate the bags between changes to facilitate the exchange of solutions.

8. Working in a sterile hood and holding the dialysis bag with a sterile hemostat, spray it with 70% ethanol, cut it with sterile scissors, and empty the contents into a sterile container on ice.

9. Determine the protein concentration using a conventional protein assay (e.g., Lowry assay; see *APPENDIX 3*). Divide the preparation (Matrigel) into aliquots and store up to 12 months at −20°C.

   Matrigel concentration should be 10 to 15 mg/ml.

   It is not desirable to freeze and thaw Matrigel too many times, so generally 1- and 10-ml aliquots are most useful. The size of the aliquots should be based on need.

PREPARATION OF LAMININ-1

Laminin-1 promotes the adhesion, differentiation, migration, and growth of many cells in culture. In addition, most neuronal cells tested extend long neuritic processes when grown on laminin-1. Laminin-1 cannot be prepared from the same batch of EHS tissue as Matrigel, but it can be prepared from the same batch of tissue as type IV collagen (see Basic Protocol 3).

Materials

EHS tumor (see Support Protocol 1)
3.4 M NaCl buffer (see recipe), 4°C
0.5 M NaCl buffer (see recipe), 4°C
Ammonium sulfate
TBS (*APPENDIX 2A*), 4°C
NaCl
Chloroform

Electric homogenizer (e.g., Polytron)
Centrifuge and rotor, 4°C
Sterile hemostat

Additional materials and equipment for dialysis and protein assays (see *APPENDIX 3*)

NOTE: All reagents and equipment should be prechilled to 4°C, and all procedures must be performed at 4°C.

1. Thaw 100 g of EHS tumor in 200 ml of 3.4 M NaCl buffer for ~1 hr at room temperature. Homogenize tumor with an electric homogenizer until dispersed.

   The volumes given in all the protocols are based on 100 g of tissue. Larger or smaller amounts of tumor can be used with proportional volumes of buffers.

   A Polytron homogenizer works well. Do not homogenize for too long, as it is important not to warm the tissue.

2. Centrifuge the homogenate 15 min at 8000 × *g*, 4°C, to pellet the tumor tissue. Discard the pink supernatant and repeat homogenization (step 1).

3. Add 200 ml of 0.5 M NaCl buffer to the tumor pellets and homogenize. Stir overnight at 4°C.

4. Centrifuge the homogenate 15 min at 8000 × *g*, 4°C. Save the supernatant in a container on ice. Repeat step 3 and repeat centrifugation.

   The tumor homogenate pellet can be used to prepare type IV collagen (see Basic Protocol 3) if the tumor tissue was taken from lathyritic animals. Otherwise, the pellet should be discarded.

5. To the combined 0.5 M NaCl supernatants, slowly add ammonium sulfate to 30% saturation (16.4 g/100 ml) with vigorous stirring. Stir 1 hr after all of the salt has dissolved.

6. Centrifuge 15 min at 8000 × *g*, 4°C.

   The pellets should be large and white, with a reasonably clear supernatant. The supernatant should be saved unless it is certain that all the laminin-1 precipitated.

7. Dissolve the laminin-1 pellets in 300 ml TBS and dialyze for ≥2 hr against 2 liters TBS (see *APPENDIX 3*). Repeat dialysis twice against 2 liters TBS each time.

8. Empty the dialysis bags, measure the volume of the sample, and slowly add NaCl, with stirring, to a final concentration of 1.7 M. Centrifuge 15 min at 8000 × *g*, 4°C.

   The solution is already 0.15 M NaCl, so 1.55 M NaCl or 90.6 g should be added per liter.

   The pellet should be very small. This step removes the contaminating type IV collagen. If the pellet is large, repeat step 7 and omit step 8.

9. Dialyze the supernatant against TBS for three changes (as in step 7). Optionally, include 5 ml/liter chloroform to TBS in the first dialysis step to sterilize the laminin-1. If chloroform is added, then perform an additional dialysis with TBS.

10. Working in a sterile hood and holding the dialysis bag with a sterile hemostat, spray it with 70% ethanol, cut it with sterile scissors, and empty the contents into a sterile container on ice.

11. Determine the amount of protein with a standard protein assay (e.g., Lowry assay; see *APPENDIX 3*). Divide the preparation (laminin-1) into 1-ml aliquots and store at −70°C for 24 months.

    The protein concentration should be 3 to 6 mg/ml.

BASIC PROTOCOL 3

PREPARATION OF TYPE IV COLLAGEN

Type IV collagen is used for cell adhesion and migration studies. Type IV collagen can be prepared from the same tumor tissue as laminin as long as the animals have been on a lathrogenic diet for ≥2 weeks prior to tumor harvest (see Support Protocol 2).

Materials

Tumor homogenate (see Basic Protocol 2, step 4), prepared from animals fed a lathrogenic diet (see Support Protocol 2)
0.5 M NaCl buffer (see recipe), 4°C
2.0 M guanidine·HCl buffer (see recipe), 4°C
2.0 M guanidine·HCl buffer containing 32 mg/liter dithiothreitol (DTT), 4°C
0.5 M acetic acid (28.5 ml acetic acid/liter water), 4°C

Centrifuge and rotor, 4°C

Additional materials and equipment for dialysis and protein assays (see *APPENDIX 3*)

NOTE: All reagents and equipment should be prechilled to 4°C, and all procedures must be performed at 4°C.

1. Prepare tumor homogenate in 300 ml of 0.5 M NaCl buffer. Centrifuge 15 min at 8000 × *g*, 4°C. Discard the supernatant and repeat centrifugation.

   These steps and the subsequent ones remove contaminating laminin-1.

2. Homogenize pellets in 2.0 M guanidine·HCl buffer and centrifuge 15 min at 8000 × *g*, 4°C. Discard the supernatant and repeat the wash.

3. Homogenize pellets in 250 ml of 2.0 M guanidine·HCl buffer/DTT solution and stir overnight at 4°C.

4. Centrifuge tumor homogenate 15 min at 8000 × *g*, 4°C. Save the supernatant in a container on ice.

5. Homogenize pellets in 250 ml of 2.0 M guanidine·HCl buffer/DTT. Centrifuge immediately for 15 min at 8000 × *g*, 4°C. Discard pellet and combine supernatant with that from step 4.

6. Dialyze supernatants against four changes of 0.5 M acetic acid for ≥2 hr each (see *APPENDIX 3*).

   If the collagen concentration is >0.8 mg/ml, it will precipitate, and it is difficult to recover the precipitated material. To ensure that the entire batch does not precipitate, dialyze one-tenth of the sample through three changes before processing the remainder. If the collagen does precipitate, the remaining supernatant should be diluted by half with cold distilled water and then dialyzed. The material that has precipitated can be collected by centrifugation, redissolved in twice the original volume of 2.0 M guanidine·HCl buffer/DTT solution, and then dialyzed against 0.5 M acetic acid.

7. Determine the amount of protein by amino acid analysis or by lyophilizing 10 ml and weighing the sample. Divide the preparation (type IV collagen) into 1-ml aliquots and store at −20°C for 24 months.

   The solution should be clear. The presence of a precipitate indicates that collagen has come out of solution. The precipitate can be removed by centrifugation, leaving considerable type IV collagen in the supernatant.

MAINTENANCE AND HARVEST OF EHS TUMORS

SUPPORT PROTOCOL 1

This protocol describes a method for maintaining and harvesting the EHS tumor. In addition, information is provided on the lathrogenic diet that is necessary when the tissue is used for isolating type IV collagen (see Support Protocol 2). The tumor passage protocol requires live dispersed EHS tumor tissue or single cells, which can be obtained from American Type Culture Collection (see *SUPPLIERS APPENDIX*). A cell line can also be obtained from the developers of the line (R.V. Iozzo and J.R. Hassell). One 4-g tumor can be passaged into ten mice by subcutaneous or intramuscular injection. The tumor is ready for harvest in 3 to 4 weeks.

Materials

Fresh EHS tumor
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
PBS containing 100 U/ml penicillin and 100 μg/ml streptomycin
C57BL/6 mice
Anesthetic (e.g., 3.2% Avertin)
Dimethylsulfoxide (DMSO)
70% ethanol

50-ml plastic tubes
20- to 30-ml and 3-ml syringes
16-G needles
Centrifuge and rotor, 4°C

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

1. Mince fresh EHS tumor (~4 g) from each animal as much as possible with scissors. Add 7 ml PBS and transfer tissue chunks into a 20- to 30-ml syringe without a needle. Force tissue chunks through the syringe several times until the suspension goes through easily. Place a 16-G needle on the syringe and repeat the process.

   Have several ice buckets handy to keep the tumor cold. Handle each tumor separately, using clean tubes and syringes, in case there is too much bacterial contamination with blood or pus in one of the tumors. Number the tubes and respective syringes when working with large numbers of tumors. This step can be messy; gloves, lab coats, and masks are recommended.

2. Add 40 ml PBS and gently shake the tube to disperse the tissue. Allow tumor tissue to settle for a few minutes, or centrifuge for 5 to 10 sec to speed up the process. Discard supernatant and dislodge and disperse pellet by tapping the tube.
3. Repeat step 2. Add PBS containing penicillin and streptomycin to a final volume of 10 ml.

   At this stage the preparation should be a thick slurry.
4. Lightly anesthetize mice by intraperitoneal injection of 200 µl Avertin. Inject 1 ml cell slurry into each mouse, either subcutaneously or intramuscularly, using a 16-G needle with a 3-ml syringe.

   It is possible to use two injection sites per animal to increase the yield. Watch the animals carefully as the tumors grow to be sure that the animals can obtain food, etc.

   Female mice are more docile and easier to handle than males, and may be preferred as tumor recipients. The cages should be marked with the tumor number to allow tracking in case of contamination in the tumor.

   Dispersed tumor can also be frozen and stored for future use: add PBS containing 5% DMSO to dispersed tumor, transfer 1-ml aliquots to freezing vials, place in a −70°C freezer for 2 hr, and then store in liquid nitrogen. It generally takes >3 weeks for the initial tumor to become fully grown when frozen material is injected, probably because some cells die during the freezing and thawing process. Where possible, it is best to work with fresh tumor tissue.
5. Harvest the tumors after 3 weeks. Euthanize mice by CO_2 asphyxiation and dip each one in 70% ethanol. Carefully excise the tumor to remove any capsule-like material. Place each tumor in a separate 50-ml tube if the tumor is to be passaged, or in a freezer bag if it is to be stored for preparation of basement membrane components.

   Tumor size should not exceed 3 cm in length, height, or width as larger tumors will become necrotic. Tumors that are very bloody or full of yellow pus should be discarded. For convenience, freeze tumors at 100 g/bag and label the bags with tumor weight and date.

   If not used immediately, fresh tumor can be frozen in powdered dry ice or immersed directly in liquid nitrogen and then stored for ≤1 year at −70°C in freezer bags.

SUPPORT PROTOCOL 2

MAINTENANCE OF MICE ON A LATHROGENIC DIET

The lathrogenic diet prevents collagen from cross-linking; hence type IV collagen derived from lathyritic mice is more soluble and easily extractable, which increases the yield of material obtained. If mice are maintained too long on the diet (>3 weeks), they develop spontaneous bone fractures. It is important to begin monitoring the health of the mice after 2 weeks, and it may be necessary to euthanize mice at slightly different times to maximize the yield of tumor.

Materials

Lathrogenic chow (see recipe)

CAUTION: Lathrogenic chow contains toxic materials; gloves, mask, and lab coat should be worn when handling it.

1. Feed mice regular chow until 6 days after injection of tumor cells. Replace regular chow with lathrogenic chow (placed in containers inside the cage) after 6 days.

   There is no need to feed mice lathrogenic diet until the tumor starts to grow. Animals may spread the food around the cage, so the levels of food should be checked daily.
2. Keep mice on the diet for ≤3 weeks, at which time the tumor should be harvested.

   After 2 weeks on the diet, mice should be monitored for bone fractures, which are observed with this diet. Mice in distress should be sacrificed and the tumors harvested.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Guanidine·HCl buffer, 2.0 M

191.0 g guanidine·HCl (2 M final)
12.1 g Tris base (0.05 M final)
H_2O to 1800 ml
Adjust pH to 7.4 with 2 M HCl
Add H_2O to 2 liters
Prepare fresh as needed

Lathrogenic chow

100 g β-aminopropionitrile (Sigma)
2 g iproniazid (Sigma)
0.2 g pargyline (Sigma)
5 kg standard ground chow

Dissolve the first three ingredients in 300 ml distilled water and mix with the ground chow for 20 min in a commercial mixer. Store 6 months at 4°C.

When adding the solution, sprinkle it on different areas of the chow to help the mixing process.

CAUTION: *Gloves, mask, and lab coat should be worn when handling these toxic materials.*

NaCl buffer, 0.5 M

7.5 g NaCl (0.5 M final)
6.05 g Tris base (0.05 M final)
H_2O to 900 ml
Adjust pH to 7.4 with 2 N HCl
Add H_2O to 1 liter
Store 6 months at room temperature

NaCl buffer, 3.4 M

397 g NaCl (3.4 M final)
3 g EDTA (0.005 M final)
5 g *N*-ethylmaleimide (NEM; 0.02 M final)
12.1 g Tris base (0.05 M final)
H_2O to 1800 ml
Adjust pH to 7.4 with 2 N HCl
Add H_2O to 2 liters
Prepare fresh as needed

Urea buffer, 2 M

240 g urea (2 M final)
12.1 g Tris base (0.05 M final)
H_2O to 1800 ml
Adjust pH to 7.4 with 2 N HCl
Add H_2O to 2 liters
Store 6 months at 4°C

COMMENTARY

Background Information

The EHS tumor produces an abundant basement membrane matrix (Orkin et al., 1977). Basement membranes are thin extracellular matrices that underlie epithelial and endothelial cells and surround muscle, fat, and nerve cells (Martin and Timpl, 1987; Kleinman et al., 1993). Preparation of basement membrane and its major components, laminin-1 and type IV collagen, from tissues is difficult because they are present in normal tissues only in small amounts and are poorly soluble. These components have many uses in cell biology research and are generally needed in large quantities. Preparation of these components from EHS tumors is advantageous because the components are highly soluble and type IV collagen cross-linking can be prevented by passaging the tumor in mice fed a lathrogenic diet. In the past, type IV collagen could be isolated only in degraded forms.

The EHS tumor is a spontaneous tumor that was propagated from a wild mouse in the 1940s. Its tissue of origin is not known. It was initially characterized as a chondrosarcoma because of the large amount of extracellular material observed by histology. In 1977, the EHS tumor was defined as a basement membrane tumor when type IV collagen was discovered to be a major component (Orkin et al., 1977). The availability of basement membrane components from this tumor has greatly accelerated research on the structure and function of the basement membrane. All of the components isolated from this tumor are chemically, structurally, and antigenically identical to authentic tissue basement membrane components (Beck et al., 1990; Yurchenco and Schittny, 1990; Timpl and Brown, 1994).

The laminin isolated from the EHS tumor is composed of three chains, designated α1, β1, and γ1, and is termed laminin-1 (Timpl et al., 1979; Burgeson et al., 1994). Five α, three β, and two γ chains of laminin have been described to date in various tissues. Eleven variant forms of laminin, composed of different combinations of these chains, have been described. Good tissue or tumor sources of these latter laminins have not yet been described. A fragment of laminin-2 (merosin composed of α2β1γ1) is commercially available. Many of these laminins have tissue-specific locations and are expressed at specific times in these tissues.

Type IV collagen isolated from the EHS tumor is composed of two different chains, present in a 2:1 ratio, with the formula $\alpha1(IV)_2\alpha2(IV)$ (Orkin et al., 1977; Kleinman et al., 1982). Additional chains of type IV collagen have also been identified, including α3, α4, α5, and α6. Like laminin, these molecules are tissue specific in their localization, and good sources for their isolation have not yet been found.

The components of the EHS tumor are important because of their biological activities. Matrigel, a mixture of basement membrane components, promotes the differentiation of various cells and is also active with tissue explants (Carey et al., 1986; Kleinman et al., 1986). The response to Matrigel depends on the cell type. Endothelial cells form capillary-like structures when cultured on Matrigel, while mammary cells form cyst-like structures that show an 80-fold induction of casein (Li et al., 1986; Kubota et al., 1988). Explants of dorsal root ganglia extend long neuritic processes that are surrounded by Schwann cells producing myelin (Carey et al., 1986).

Matrigel can be used to coat culture dishes, with cells plated directly onto the gelled material. Cells can also be mixed with the Matrigel to form a suspension when warmed (Hadley et al., 1985; *UNIT 10.3*). In vivo, Matrigel has been used to assess angiogenesis (Passaniti et al., 1992) and to increase the incidence of tumor take and the rate of growth (Fridman et al., 1991). Matrigel has also been used to coat filters in migration assay chambers to assess tumor cell invasion (Albini et al., 1987; *UNIT 12.2*). Laminin-1 has been used mainly as a culture substratum. It promotes cell adhesion, growth, migration, and neurite outgrowth (Evercooren et al., 1982; Kleinman et al., 1993). It also reduces fibroblast growth. Type IV collagen promotes the adhesion and growth of many cells and is also used to coat filters in migration assays.

Critical Parameters and Troubleshooting

EHS tumor. A major problem with propagating EHS tumors is bacterial infection. Infection is easy to recognize as the tumors become watery, yellow in areas, and full of pus. Infected tumors should be discarded and not used for passage. Infection can be minimized by using antibiotics and by keeping all of the tumors separate when passaging. It is also important not to let the tumors become too large, as necrosis will reduce the yield of usable mate-

rial. Generally tumors >4 g are necrotic. For preparation of matrix components, tumors can be stored frozen at −70°C for ≤1 year and then thawed as described in the protocols.

Matrigel. Matrigel should be prepared as quickly as possible, as activity is lost if the preparation is left too long at any of the steps. The entire isolation and dialysis can be completed in ≤4 days. It is also critical that Matrigel be kept cold at all stages of the preparation. Once isolated, it is important to keep Matrigel at 4°C, because the material cannot be recovered in the liquid form after it has gelled. Using cold pipets and syringes helps to keep Matrigel liquid. The Matrigel protein concentration should not be <9 mg/ml; at lower protein concentrations, Matrigel will not form solid gels. Diluted Matrigel can be recovered by 40% ammonium sulfate precipitation, followed by suspension in a smaller volume and dialysis.

Laminin-1. It is safest not to throw anything away until the laminin-1 preparation is complete. It is also very important to keep all solutions cold during the preparation of laminin-1.

Type IV collagen. A major problem with the collagen preparation is having too much type IV collagen in the extraction buffer. The collagen will precipitate out of solution at concentrations >0.8 mg/ml when dialyzed against acetic acid in the final step, and the precipitated material is difficult to recover. The yield of collagen can vary, depending on how lathyritic the animals are; therefore the final dialysis step should be performed first on a small batch to be sure that the collagen will stay in solution. Type IV collagen is best stored in acetic acid. For culture, type IV collagen is used as a dried substratum. This generally requires overnight drying in a sterile hood.

Anticipated Results

In general, 1 g of tumor tissue yields ~1.5 ml of Matrigel or 10 mg of laminin-1 and 5 mg of type IV collagen.

Time Considerations

EHS tumors generally reach ~4 g and can be harvested 3 weeks after injection of the cells into mice. It is important to begin monitoring the health of the animals at 2 weeks. It may be necessary to sacrifice the animals at slightly different times to maximize the yield. The preparations of Matrigel, laminin-1, and type IV collagen should all be performed in ≤1 week. Arresting the preparation at intermediate stages can result in some degradation.

Preparation of Gelled Substrates

This unit describes the use of type I collagen as a gelled substrate for cell culture, as well as various ways to handle and manipulate the basement membrane matrix preparation Matrigel for use in cell culture and in vivo. Both matrix components form gels at high concentrations under physiological conditions. Type I collagen gels have been used mainly to promote cell growth and differentiation. Most cells in culture proliferate at a high rate and lose their differentiated phenotype, but do not proliferate when cultured on Matrigel. Matrigel is advantageous as a culture substratum because it promotes the differentiation of a variety of epithelial and endothelial cells; the response of the cells depends on the cell type (see Table 10.3.1). Differentiated cells in vitro have a variety of uses, including determining how genes are regulated and which factors control differentiation. Matrigel has been used in vivo to assess angiogenesis, increase tumor growth, and promote the survival of explanted cells and tissues.

The basic protocols outline the most common uses of type I collagen (see Basic Protocol 1) and Matrigel (see Basic Protocol 2) as gelled substrates. Gelled type I collagen can also be used as a floating substrate. Dried type I collagen substrates have been used in cell culture. Additional protocols describe how to grow cells inside Matrigel (see Alternate Protocol 1) and how Matrigel can be used in vivo to assess angiogenesis and to initiate and increase tumor growth (see Alternate Protocol 2).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

PREPARATION OF TYPE I COLLAGEN SUBSTRATES

BASIC PROTOCOL 1

Gelled collagen substrates should be prepared on the same day that they will be used for cell culture. Gelled type I collagen substrates are used for a variety of cell types, including hepatocytes and endothelial cells. Dried collagen substrates can be prepared the day before use and are often used to culture skeletal muscle cells. Type I collagen substrates allow for better growth, survival, and differentiation of various cell types, including skeletal muscle and hepatocytes, than does plastic or glass alone.

Materials

3 to 5 mg/ml type I collagen in dilute acid (e.g., Vitrogen 100, Collagen), ice cold
10× phosphate-buffered saline, pH 7.4 (10× PBS; *APPENDIX 2A*) or 10× medium salts (e.g., Medium 199, Life Technologies), ice cold
0.1 M NaOH, ice cold
0.1 M HCl, ice cold
Dilute acetic acid: 28.5 ml glacial acetic acid/liter
Sterile deionized H_2O
Cells
Tissue culture medium, 37°C

Wet ice in a bucket
Culture dishes

Preparing gelled type I collagen substrates

1a. Using prechilled solutions and keeping solutions on ice, mix 8 ml type I collagen with 1 ml of 10× PBS, pH 7.4, and 1 ml of 0.1 M NaOH (all solutions should be prechilled). Adjust pH to 7.4 with additional drops of 0.1 M NaOH or 0.1 M HCl as needed, using pH test paper or a pH meter to assess pH, and using aseptic technique.

Contributed by Hynda K. Kleinman
Current Protocols in Cell Biology (1998) 10.3.1-10.3.9

Type I collagen commercially obtained at 3 to 5 mg/ml in dilute acid should not be further diluted more than necessary or the final gel will be too weak. Below 3 mg/ml, the gel will be very weak and will not withstand the usual manipulations of plating and feeding the cells. Type I collagen obtained as a powder can be solubilized at 3 to 5 mg/ml by stirring overnight at 4°C in dilute acetic acid.

Alternatively, 10× medium salts can be used in place of the PBS.

When a dried film of fibrillar collagen is desired, coat the dish with a small amount of collagen and air dry the material, usually overnight, in a sterile culture hood. Skeletal muscle cells are cultured on dried collagen to encourage cell differentiation (i.e., fusion to myotubes).

2a. Pipet the desired amount of collagen onto the culture dish and warm the dish at least 1 hr in a 37°C incubator.

The collagen should completely cover the surface of the dish; 1 ml is generally sufficient for a 35-mm dish. The matrix usually turns white when it gels.

CO_2 is not important for gelling of the collagen, but subsequent incubations with cells should be performed in a humidified 37°C, 5% CO_2 incubator.

3a. Before use, rinse dried gels and collagen films with sterile distilled water to remove the salts. Add cells and medium as usual and culture.

Warm all solutions and gently pipet onto the culture dish.

In some cases, one may want to grow cells inside a type I collagen gel. This can be done by overlaying the collagen after the cells have attached, or by mixing the cells in the liquid type I collagen prior to gelation (see Alternate Protocol 1).

Floating collagen gels can be obtained by gently agitating around the edge of the collagen gel with a spatula after the cells have attached. When type I collagen gels are used as floating gels with fibroblasts attached, some contraction of the gel will occur. Hepatocytes have also been successfully cultured on floating collagen gels.

Preparing nongelled type I collagen substrates

1b. Dilute 3 to 5 mg/ml collagen solution to 0.1 mg/ml with either dilute acetic acid or 0.1 M HCl.

When directly drying collagen on tissue culture dishes without gelation, usually much less material is needed than for gelled substrates. Generally 10 to 20 µg collagen provides good activity on 16-mm-diameter-well (24-well) dishes.

The collagen can be diluted with 0.1 M HCl as an alternative to acetic acid.

2b. Plate the desired amount of 0.1 mg/ml collagen in acetic acid onto the culture dish. Allow to air dry overnight.

For example, 200 µl of a 0.1 mg/ml collagen solution can be used for each 16-mm-diameter well of a 24-well dish; the solution should completely cover the bottom of the well.

3b. Before use, rinse collagen films with sterile distilled water (to remove salts). Add cells and medium as usual and culture.

Warm all solutions and pipet gently onto the culture dish.

PREPARATION OF GELLED MATRIGEL SUBSTRATES

Matrigel is a crude basement membrane preparation that provides an excellent substrate for the differentiation of a variety of cells (see *UNIT 10.2*). Epithelial, endothelial, smooth muscle, fat, and Schwann cells are in contact with a basement membrane in vivo. These cells do not differentiate well on tissue culture plastic, but show high degrees of differentiation on Matrigel in vitro.

Materials

Matrigel (*UNIT 10.2*; Matrigel can also be obtained commercially from Sigma or Becton Dickinson Labware)
Medium salts, 4°C (optional, for making weak gels)
Cells
Tissue culture medium, 37°C

Wet ice in a bucket
Culture dishes

1. Thaw Matrigel at 4°C.

   Thawing can be accomplished by leaving the Matrigel in the refrigerator on ice overnight or by rolling the bottle in the hands until it is thawed. Do not allow the solution to become warm, as it will gel and cannot be recovered. It is not desirable to thaw and refreeze Matrigel too many times, so it should be stored in appropriate-sized aliquots based on the quantities generally needed.

   It is best to always have fresh wet ice in a bucket when working with Matrigel to keep it cold.

2. In a sterile hood, pipet desired amount of Matrigel onto culture dish.

   The Matrigel should be at ≥9 mg/ml for maximum gelling. Concentrations below that will form weak gels that may fall apart. Matrigel can be diluted to 4 mg/ml and will still gel, but the gel will be weak. In some cases, however, a weak gel is needed. Dilute the stock Matrigel with cold medium salts and mix well.

   If there are bubbles in the Matrigel, which can cause problems once it gels, let stand for a few minutes on ice to allow them to dissipate. Keeping the dish level, quickly pipet the Matrigel into the dishes; when performing multiple pipetting steps, do these quickly, and change the pipets if the Matrigel starts to gel inside them. For 16-mm-diameter wells, use 320 µl per well (this volume is necessary because a large meniscus forms at the edge of the well and distorts the surface). For larger dishes, a thinner coating works well, but one must be aware of the curve in the gel at the edges of the dish. For ≥100-mm-diameter dishes, pipet the Matrigel so that the bottom of the dish is covered, then pour off the excess and use it for another dish.

3. Cover the culture dish and incubate 30 to 60 min at 37°C to allow gelling of the Matrigel.

   Since Matrigel will gel at room temperature, place dishes in incubator immediately.

4. Gently add warm medium and cells to the culture dish as for normal culture. Return the plate to the incubator as usual and check the culture often for changes in cell behavior. Change the medium as usual, taking care not to disturb the gel layer.

   For example, for in vitro assays of angiogenesis (tube formation), incubate 40,000 endothelial cells in 100 µl complete medium in 16-mm-diameter wells containing 320 µl gelled Matrigel. Fix the culture and stain with Diff-Quik (Baxter) using only the fix and solution II (use of solution I will stain the Matrigel and make it difficult to distinguish the cells). The assay can be quantified with an image processor (e.g., NIH Image).

ALTERNATE PROTOCOL 1

GROWTH OF CELLS INSIDE MATRIGEL

Various cells may differentiate to different extents depending on whether the cells are plated on top of a Matrigel substrate or inside of Matrigel. For example, Sertoli cells are highly columnar on a Matrigel substrate but form cord-like structures when grown inside of Matrigel.

Materials

Matrigel (*UNIT 10.2*; Matrigel can also be obtained commercially from Sigma or Becton Dickinson Labware)
Cells
Tissue culture medium, 37°C

Wet ice in a bucket
Culture dishes

1. Thaw Matrigel at 4°C.

   Thawing can be accomplished by leaving the Matrigel in the refrigerator on ice overnight or by rolling the bottle in the hands until it is thawed. Do not allow the solution to become warm, as it will gel and cannot be recovered. It is not desirable to thaw and refreeze Matrigel too many times, so it should be stored in appropriate-sized aliquots based on the quantities generally needed.

   It is best to always have fresh wet ice in a bucket when working with Matrigel to keep it cold.

2. Prepare the cells as usual for cell culture. Centrifuge 5 min at 170 × *g*, room temperature, to collect cells. Decant supernatant, tap pellet to disperse cells, and put tube of cells in wet ice. Add desired amount of thawed Matrigel, mix well, and pipet onto culture dish.

   Take care to fully mix the cells into the Matrigel without causing bubbles. This can be accomplished by gently tipping the tube 180° several times. Approximately 320 µl of Matrigel in a 16-mm-diameter well works well with endothelial cells.

   The number of cells and volume of Matrigel needed for cell differentiation vary among cell types. It may be necessary to test various numbers of cells in a constant volume of Matrigel. A good range to test initially is 10,000 to 100,000 cells per 320 µl.

   The cells will be trapped inside the Matrigel when it gels. Previous studies have found that some cells will migrate towards each other and form differentiated structures. Histological sectioning and/or electron microscopy is necessary to fully observe these structures.

3. Cover the dish and incubate 30 to 60 min at 37°C to allow gelling of the Matrigel.

   Since Matrigel will gel at room temperature, place dishes in incubator immediately.

4. Gently add warm medium to the culture dish as for normal culture. Return the plate to the incubator as usual and check the culture often for changes in cell behavior. Change the medium as usual, taking care not to disturb the gel.

ALTERNATE PROTOCOL 2

USE OF MATRIGEL IN VIVO FOR ANGIOGENIC ASSAYS AND TUMOR GROWTH

Matrigel implanted subcutaneously in an animal remains as a plug with very few cells invading for several months. If certain angiogenic factors are mixed with the Matrigel before injection, however, considerable endothelial cell invasion into the plugs is observed within 1 week. This migration of endothelial cells and subsequent formation of vessels can be quantified and used as an assay for measuring the activity of angiogenic and antiangiogenic compounds.

If tumor cells or minced pieces of biopsy material are premixed in the cold with liquid Matrigel and injected, an increase in the incidence of tumor take and growth can be observed. This technique is highly useful for tumors that are hard to grow and for human biopsy specimens.

Materials

Matrigel (*UNIT 10.2*; Matrigel can also be obtained commercially from Sigma or Becton Dickinson Labware)
C57BL6 mice for angiogenesis assay *or* athymic nude mice for human tumor growth
Test compound for angiogenesis assay *or* tumor sample
Proteases (e.g., trypsin or collagenase) for dissociating tumor pieces, if necessary
Hemoglobin assay kit (e.g., Drabkin Reagent Kit, Sigma) or additional materials and equipment for histology, including image processor (e.g., NIH Image)

Wet ice in a bucket
Culture dishes
1- to 3-ml syringes
23- or 25-G needles

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Care and Use Committee (IACUL) and must follow officially approved procedures for the care and use of laboratory animals.

1. Thaw Matrigel at 4°C.

   Thawing can be accomplished by leaving the Matrigel on ice in the refrigerator overnight or by rolling the bottle in the hands until it is thawed. Do not allow the solution to become warm, as it will gel and cannot be recovered. It is not desirable to thaw and refreeze Matrigel too many times, so it should be stored in appropriate-sized aliquots based on the quantities generally needed.

   It is best to always have fresh wet ice in a bucket when working with Matrigel to keep it cold.

2. Mix Matrigel on ice with the test substance for an angiogenesis assay or with cells or dispersed tumor pieces for the subcutaneous growth of tumors.

   See Alternate Protocol 1, step 2, for details of mixing cells and Matrigel. The final injected volume should not exceed 1 ml. It is best not to reduce the concentration of Matrigel below 9 mg/ml.

   Angiogenic factors for testing and tumor cells/pieces should be suspended in as small a volume as possible. Basic fibroblast growth factor at 1 to 5 ng/ml should be included with Matrigel in some plugs as a positive control.

   If using tumor biopsy pieces, the material must be finely minced or dissociated with proteases, including trypsin or collagenase, so that it will pass through the syringe.

3. Cool a 1- to 3-ml syringe fitted with a 23- or 25-G needle by placing it in a beaker on ice. Load the syringe with 1 ml of the Matrigel/test compound or Matrigel/tumor cell mixture. For the angiogenesis assay, hold each mouse firmly in one hand and inject the material subcutaneously on the lower ventral side near one or both of the lower legs. For tumor-growth studies, restrain mice in a box and inject material subcutaneously in the upper dorsal area. After injecting, hold the needle in place for ~30 sec until the Matrigel starts to gel. Pull the needle out slowly and turn it to minimize leakage of Matrigel out of the injection site (some leakage may occur anyway).

   Female mice are easier to handle than male mice. Mice do not need to be anesthetized.

   If doing multiple animals, it may be necessary to change needles often, as the Matrigel will clog the needle.

4a. *Subcutaneous angiogenesis assay:* Sacrifice mice after 1 week. Gently cut the skin away and excise the Matrigel pellet, which will be clearly visible attached either to the undersurface of the skin or to the underlying muscle layer. Measure angiogenesis either using a hemoglobin assay kit (if there is an obvious abundance of vessels) or by histology.

For histology, fix the plugs, stain them with Masson trichrome, and quantify angiogenesis using an image processor by counting the number of vessels and/or measuring the area occupied.

4b. *Tumor growth:* Tumors are usually observable by 2 weeks but some cells, such as NIH 3T3, require >2 months.

COMMENTARY

Background Information

Most cells in tissues are in contact with an extracellular matrix. The use of collagen substrates in vitro enhances the growth and differentiation of many cell types over that observed with glass or plastic substrates (Elsdale and Bard, 1972; Emerman et al., 1979; Kleinman et al., 1981). Cells adhere directly to collagen through integrin receptors or via adhesion proteins such as fibronectin, which bind to both the cells (via integrin receptors) and the collagen. Collagen substrates are particularly useful for the differentiation of hepatocytes and breast epithelial cells. Dried collagen substrates have been used successfully for the culture of muscle cells (Hauschka and Konigsberg, 1966).

The important role of the basement membrane in cell differentiation was not realized until the crude basement membrane preparation known as Matrigel was developed and became widely used as a cell growth substrate (Kleinman et al., 1986, 1987). Most untransformed cells in culture form a monolayer and proliferate until confluence is reached. Cells cultured on Matrigel differentiate and their proliferation is arrested (Table 10.3.1). The cellular response depends on the cell type. For example, endothelial cells form capillary-like structures with a lumen, and melanoma cells produce melanin (Kleinman et al., 1986; Kubota et al., 1988). Salivary gland cells form acini (Hoffman et al., 1996) and bone cells form canaliculi (Vukicevic et al., 1990). Explanted neural tissue, such as dorsal root ganglion, shows extensive neurite outgrowth and myelin production (Carey et al., 1986). Another advantage of using Matrigel in culture is that fibroblasts (which can overgrow many primary cultures) do not grow well in its presence.

Attempts have been made to use whole natural basement membranes, such as the lens capsule or amnion, for cell culture and differentiation studies, with limited success. Lack of reproducibility and difficulty in handling the natural materials have restricted their use. Type I collagen (the most abundant collagen, comprising some 30% of the dry weight of vertebrates) at 3 to 5 mg/ml gels when it is brought to neutral pH and warmed. Type I collagen gels have been used as culture substrata, but most cells do not differentiate as well on collagen as they do on Matrigel.

Matrigel can be used with the cells either plated on top of the gel or entrapped inside it (Hadley et al., 1985). Although limited data are available, there is evidence that cells behave differently under the two culture conditions. For example, Sertoli cells remain as a monolayer on plastic, but become 15-fold more columnar with polarized nuclei when plated on Matrigel. When cultured inside Matrigel, Sertoli cells migrate into cord-like structures that resemble an immature testis with polarized nuclei. In some cases, the amount and type of growth factors in the Matrigel have been altered either by their removal, antibody binding, or exogenous addition (Taub et al., 1990; Vukicevic et al., 1992). Manipulation of growth factor levels greatly affects differentiation for both kidney cells and bone cells. Other cell types have not been fully evaluated for the effects of growth factors and Matrigel.

The differentiation of cells in culture has provided some useful assay models. For example, although tube formation by endothelial cells on Matrigel does not mimic all of the steps in angiogenesis, tube formation has been used as an assay to define angiogenic and antiangiogenic agents. For example, the sera of vasculitis patients contain angiogenic activity as determined by the tube assay (Cid et al., 1993). Purification of the causative factor, haptoglobin, was monitored using the tube assay, and

Table 10.3.1 Effect of Matrigel on Cell and Explant Differentiation

Cell/explant	Biological effect	Reference
Bone cells	Formation of canaliculi	Vukicevic et al., 1990
Dorsal root ganglion	Outgrowth and myelination	Carey et al., 1986

Hepatocytes	Maintenance of albumin synthesis and cytochrome P_{450}	Ben-Ze'ev et al., 1988
Mammary cells	Formation of ducts and lumina, increased casein production	Li et al., 1986
Melanoma cells	Rapid pigmentation	Kleinman et al., 1986
Notochord	Outgrowth	Bilozur and Hay, 1988
Olfactory neuroblast	Odorant responsiveness	Coon et al., 1989
Oviduct cells	Formation of tubes with a lumen with polarized secretion	Joshi, 1991
Pancreatic acinar cells	Acinar formation with secretory vesicles near lumen	Bendayan et al., 1986
Salivary gland cells	Acinar formation	Hoffman et al., 1996
Sertoli cells	15-fold columnar form, germ cell survival and differentiation	Hadley et al., 1985
Thyroid cells	Thyroglobulin production	Greenberg and Hay, 1986
Type II pneumocytes	Cuboidal cells, phosphatidylcholine synthesis	Blau et al., 1988

the activity was subsequently confirmed in several in vivo assays.

Critical Parameters and Troubleshooting

Matrigel and type I collagen must be maintained at 4°C when being manipulated. For long-term culture of >1 week, denser substrates may be needed, as the gels may begin to break apart over time in culture with certain types of cells. It is usually not desirable to significantly reduce the protein concentration of Matrigel. When testing new cell types, it may be necessary to try the cells on all the possible substrates (collagen gels, dried collagen films, on Matrigel, inside Matrigel) to determine the best configuration. Do not become discouraged if cells do not have a defined appearance before histological sectioning. Histology often reveals polarity and other indications of differentiation.

Anticipated Results

Histological analysis is recommended to assess the morphological differentiation of most cells, because the three-dimensional nature of the response is difficult to observe using a standard microscope. In some cases, however, the appearance of the cells in vitro may be obvious. Defined structures are observed for some cell type/substrate combinations, such as hepatocytes on type I collagen and endothelial cells on Matrigel; the latter form capillary-like structures with a lumen (Kubota et al., 1988). Normal cells will not continue to grow when cultured on Matrigel but rather will differentiate. The growth rate of tumors, on the other hand, generally increases 3- to 6-fold on Matrigel (Fridman et al., 1991). For tumor cells, the incidence of tumor take is increased several-fold: ~5% of most tumors grow in the absence of Matrigel and >50% grow in the presence of Matrigel.

Time Considerations

Type I collagen and Matrigel form gels within 30 min in the culture dish, but it is recommended that the dishes be kept at 37°C for a full hour before warm medium is added. The time required for differentiation to occur in vitro on Matrigel varies depending on the cell type. Endothelial cells require 18 hr to form capillary-like structures and should not be left more than 24 hr (Kubota et al., 1988). In contrast, salivary gland cells require several days to form acinar-like structures (Hoffman et al., 1996). The in vivo angiogenesis assay also shows some time variation depending on the factors being tested. Fibroblast growth factor is generally fully active by 5 days; other factors require more time (Passaniti et al., 1992). Generally the assay is quantified 7 days after injection.

Preparation of Extracellular Matrices Produced by Cultured Corneal Endothelial and PF-HR9 Endodermal Cells

Cell behavior is regulated by the substratum upon which cells attach, migrate, and proliferate. Tissue culture surfaces are therefore coated with extracellular matrix (ECM) extracts or with single ECM components in order to better resemble the microenvironment of cells in vivo and promote cell adhesion, proliferation, and expression of differentiated functions. This unit outlines the coating of tissue culture surfaces with a natural ECM produced and deposited by cultured bovine corneal endothelial (BCE) cells or PF-HR9 mouse endodermal cells. BCE-ECM closely resembles the ECM of subendothelium in vivo, whereas ECM from PF-HR9 cells more closely resembles the composition of basement membranes of other epithelia in vivo (see Commentary).

The basic approach is to allow the cells to produce their own ECM, while avoiding extraction procedures and purification of single components that may alter the relative proportions of native ECM constituents, alter the ECM's supramolecular organization, and/or denature its active molecules. For this purpose, the ECM-producing cells are maintained in culture at a confluent cell density. Five to twelve days after seeding, cellular elements are removed by solubilization of the cell layer with Triton X-100 and NH_4OH, leaving the underlying ECM intact, free of cellular debris, and firmly attached to the entire area of the culture surface. The ECM is then washed and covered with PBS and stored at 4°C. Under these conditions there is no loss of biological activity (i.e., induction of cell attachment, proliferation, and differentiation) for up to 6 months.

The Basic Protocol describes the preparation of BCE-ECM-coated dishes. Alternate Protocols describe modifications for preparation of metabolically radiolabeled ECM (which can be used to study matrix degradation associated with cell invasion and metastasis) and ECM derived from PF-HR9 cells (HR9-ECM). To evaluate the quality of the ECM, Support Protocols present straightforward procedures for assessing the induction of cell attachment, cell proliferation, and cell differentiation by the ECM.

NOTE: All culture incubations should be performed in a humidified 37°C, 10% CO_2 incubator unless otherwise specified.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

PREPARATION OF BOVINE CORNEAL ENDOTHELIAL CELL ECM (BCE-ECM)

BASIC PROTOCOL

This protocol describes the initiation, establishment, and maintenance of stock primary and early-passage bovine corneal endothelial cell (BCE) cultures, as well as the preparation and storage of tissue culture surfaces coated with ECM produced by these cells. This ECM closely resembles that of the subendothelium in vivo, and is used to initiate primary cultures; to study the effects of local environment on cell adhesion, proliferation, differentiation, and survival; and to study various aspects of cell motility. Major constituents include collagens, proteoglycans, laminin, fibronectin, entactin, and elastin (see Background Information).

Although this procedure can be modified to coat any type of tissue culture dish, the best ECM-coated dishes (i.e., those with a homogeneous matrix that coats the entire surface of the dish) are obtained by plating the cells at a high density in 35-mm dishes. Thus, the strategy is to have the main extent of cell growth in 10-cm dishes (the primary stock

Contributed by Israel Vlodavsky
Current Protocols in Cell Biology (1999) 10.4.1-10.4.14

cultures), followed by two to three population doublings in 35-mm dishes (the early-passage cultures, yielding ECM-coated dishes).

Materials

10 to 20 eyes of freshly slaughtered cows
95% (v/v) ethanol
PBS (*APPENDIX 2A*)
Supplemented low-glucose DMEM-10 (see recipe)
Recombinant human basic fibroblast growth factor (bFGF; Sigma)
Trypsin/EDTA solution (see recipe)
Dextran T40 (Sigma)
Triton/NH_4OH cell lysis solution (see recipe)
Gentamicin (Life Technologies)
Fungizone (amphotericin B; Life Technologies)

18-G needles
10-cm, 6-cm, and 35-mm tissue culture dishes
Groove director (curette or spoon-headed spatula), sterile
37°C, 10% (v/v) CO_2 incubator with 100% humidity
10-cm gelatin-coated tissue culture dishes (see recipe)

Establish and maintain stock BCE cell cultures

1. Obtain 10 to 20 eyes of freshly sacrificed cows from a local slaughter house. Transport at 4°C or room temperature and process within 24 hr.

   The eyes can be stored at 4°C.

2. Ensure that eyes have unscratched, thin, crystal-clear corneas. Wash eyes with 95% ethanol to sterilize the outside of the corneas and destroy the outer epithelial cell layer.

3. Puncture the edge of each cornea at the junction of the cornea and the sclera with an 18-G needle. Insert dissecting scissors into the hole, dissect out the cornea, and place it endothelial side up in a 10-cm tissue culture dish.

4. Wash one cornea gently with PBS to remove traces of iris, which appear as small black fragments and may have adhered to the endothelium during its dissection.

5. Gently scrape the endothelium with a sterile groove director, being careful not to apply pressure.

   Applying pressure while scraping the endothelium may cause one to penetrate the Descemet's membrane and pick up stromal cells.

6. Transfer tissue fragments by dipping the groove director into a 6-cm tissue culture dish containing 5 ml supplemented low-glucose DMEM-10. Repeat steps 5 and 6 two to three times.

   Visual examination of the plate should reveal small whitish tissue fragments floating in the medium. When examined under a phase-contrast microscope, the tissue fragments appear to be composed of closely apposed hexagonal cells organized into a honeycomb pattern.

7. Repeat steps 4 to 6 for all remaining corneas, preparing a separate primary culture for each one.

8. Incubate plates at 37°C in a 10% CO_2 incubator with 100% humidity. Leave them untouched for 5 days, except for occasional examination under a phase-contrast microscope.

   After 3 to 5 days, several tissue fragments attach to the plastic, and cells can be seen migrating out of the explants.

9. On day 5 to 6, replace medium with fresh medium and start adding recombinant bFGF every other day at a final concentration of 1 ng/ml.

10. On day 8 to 12, aspirate medium from 6-cm primary culture dish, add 2 ml trypsin/EDTA solution, and incubate at 37°C for 5 min or until the cells have rounded up but are not detached.

    By day 8 to 12, well-developed colonies are clearly visible and each 6-cm dish contains ~1 × 10^6 cells.

    One primary culture is selected for preparation of stock culture dishes. Other primary culture dishes can be processed in parallel or maintained in the incubator for up to 3 weeks.

11. Aspirate trypsin/EDTA solution and resuspend cells in 5 ml supplemented low-glucose DMEM-10.

12. Transfer the entire 5-ml cell suspension (~1 × 10^6 cells) into one regular or gelatin-coated 10-cm tissue culture dish containing 5 ml supplemented low-glucose DMEM-10. Add bFGF at 1 ng/ml every other day until the plate is nearly confluent (5–7 × 10^6 cells/dish).

    Gelatin-coated dishes are used, if necessary, to improve the plating efficiency of BCE cells.

13. On day 4 to 6 of the first subculture (at near confluency), aspirate medium, add 5 ml trypsin/EDTA solution, and incubate at 37°C for 5 min or until the cells have rounded up but are not detached.

    It is best to passage the cells when subconfluent, because after reaching confluence the cells produce a large amount of ECM and hence become less susceptible to trypsinization and prone to damage in the process. This will be reflected in poor plating efficiency and cell growth, as well as in aberrant cell morphology.

14. Aspirate trypsin/EDTA solution and resuspend cells in 11 ml supplemented low-glucose DMEM-10.

15. Add 1 ml cell suspension to each of eleven 10-cm regular or gelatin-coated culture dishes, each containing 10 ml supplemented low-glucose DMEM-10 with 1 ng/ml bFGF. Add bFGF at 1 ng/ml every other day until the plates are nearly confluent (5–7 × 10^6 cells/dish).

    The surface area of a 10-cm stock dish is approximately equal to that of eight 35-mm dishes. Therefore, to prepare a batch of two hundred 35-mm dishes for production of ECM (see step 19), it is advisable to use the cells from stock dishes. A group of eleven 10-cm stock dishes can be used so that one dish is kept as a stock dish, and cells of the remaining ten 10-cm dishes are used to produce two hundred 35-mm ECM-coated dishes.

    If ECM is produced on a routine basis, try to prepare primary cultures once a month. Maintain confluent BCE cultures for up to 3 weeks in the CO_2 incubator with no medium change. The cells remain viable and can be readily subcultured at any time. The cells can also be frozen in liquid nitrogen using 10% (v/v) dimethyl sulfoxide (DMSO) in supplemented low-glucose DMEM-10, but the results are often not as good as those obtained with freshly isolated cells.

Prepare ECM-coated 35-mm dishes

16. Prepare 500 ml supplemented low-glucose DMEM-10 with 4% (w/v) dextran T40 and 1 ng/ml bFGF.

    Dextran T40 is added to the growth medium to increase its viscosity and hence the phagocytosis/exocytosis activity of the BCE. As a result, the amount (thickness) of ECM deposited is at least two-fold higher with dextran T40.

17. Trypsinize cells from ten 10-cm stock culture dishes by aspirating the medium, adding 5 ml trypsin/EDTA solution to each dish, and incubating at 37°C for 5 min or until the cells have rounded up but are not detached.

    Best production of ECM in terms of thickness and homogeneity is obtained with secondary or early passage BCE. Do not use cells beyond their sixth passage in culture.

18. Aspirate trypsin/EDTA solution and resuspend the cells of each dish in 5 ml supplemented low-glucose DMEM-10. Pool the cell suspensions and add to 500 ml supplemented low-glucose DMEM-10 with 4% dextran and 1 ng/ml bFGF.

19. Distribute 2-ml aliquots (~2×10^5 cells) into each of two hundred 35-mm plastic tissue culture dishes. Add 1 ng/ml recombinant bFGF every other day until the cultures are confluent (ordinarily within 4 to 6 days).

20. Incubate cultures for an additional 5 to 8 days without medium change.

Remove cells

21. Warm Triton/NH_4OH cell lysis solution 10 to 20 min at 37°C. Aspirate the culture medium from each 35-mm culture dish and add 1 ml cell lysis solution.

    In certain experiments, Triton X-100 and NH_4OH should be avoided (see Critical Parameters). In this case, cells are removed with 2 M urea in supplemented low-glucose DMEM-10, for 10 to 20 min at 37°C (Gospodarowicz et al., 1983).

22. Incubate dishes for 3 to 5 min with gentle shaking at room temperature and examine one of the dishes under a phase-contrast microscope.

    Generally, complete cell lysis occurs within 2 to 3 min and the ECM remains firmly attached to the tissue culture plastic. If cell nuclei remain bound to the bottom of the dish, incubate for an additional 5 to 10 min at 37°C to obtain complete solubilization of the cell layer.

    ECM produced by BCE cells appears as a delicate uniform network of amorphous material closely associated with the plastic. The homogeneous nature and thickness of the ECM lattice can be appreciated by scratching the plate with a needle, which may detach and lift the ECM membrane along the edge of the scratch. A more fibrillar, nonhomogenous type of ECM is less active and is often produced by late-passage cells.

    Detached ECM can be used for purification or biochemical analysis; however, purification of a single component from bound or detached ECM is not straightforward.

23. Wash each plate four times with 2 ml PBS.

24. Cover ECM-coated plates with 2 ml PBS supplemented with 50 µg/ml gentamicin and 0.25 µg/ml Fungizone. Store up to 4 months at 4°C.

ALTERNATE PROTOCOL 1

PREPARATION OF METABOLICALLY LABELED ECM

The procedure described in the Basic Protocol can also be applied to prepare radioactive, metabolically labeled ECM. Metabolically labeled ECM can be prepared by adding labeled sulfate ($Na_2{}^{35}SO_4$), amino acids ([^{3}H]proline or [^{14}C]glycine), or sugars (i.e., [^{14}C]glucosamine) to the tissue culture medium. The labeled ECM synthesized in this manner can be utilized as a substrate to study degradation of specific ECM constituents by certain purified enzymes or invasive cells, such as metastatic tumor cells or activated cells of the immune system. For example, sulfate-labeled ECM-coated dishes are useful as a natural basement membrane-like substrate for measurement of heparanase activity expressed by highly metastatic tumor cells and activated cells of the immune system (Vlodavsky et al., 1983, 1992, 1995; Naparstek et al., 1984).

To prepare sulfate-labeled BCE-ECM, add 40 µCi $Na_2{}^{35}SO_4$ (540 to 590 mCi/mmol; Amersham) per 35-mm dish on days 2 and 5 after seeding the early-passage cultures (see

Basic Protocol, step 19), and incubate without medium change. Ten to twelve days after seeding, prepare ECM as described (see Basic Protocol, steps 21 to 24). To increase the specific activity of the labeled ECM, use Fischer's medium (which does not contain sulfate) rather than DMEM for the 35-mm ECM-producing cultures. Supplement Fischer's medium (Life Technologies) as for supplemented low-glucose DMEM-10 and add 4% (w/v) dextran and 1 ng/ml bFGF. Maintain stock cultures as described above (see Basic Protocol). About 80% of the ECM-associated sulfate radioactivity is incorporated into sulfated proteoglycans, primarily heparan sulfate proteoglycans.

PREPARATION OF HR9-ECM

ALTERNATE PROTOCOL 2

Initiation of BCE cultures requires certain skills and is time consuming. It may, therefore, be more convenient to work with a permanent cell line capable of producing ECM. Such a cell line (PF-HR9) was derived from a differentiated mouse endodermal carcinoma (Chung et al., 1977) and can be obtained from ATCC or any of the many laboratories that are working with it (Kramer and Vogel, 1984; Rogelj et al., 1989). Unlike BCE cells, PF-HR9 cells are epithelial in nature and, as such, they produce ECM that better resembles epithelial basement membranes (rather than the subendothelial ECM produced by BCE). While the BCE-ECM provides an excellent model for basement membranes of blood vessels, the HR9-ECM provides a model for basement membranes underlying epithelial cells in a variety of organs and tissues. Major constituents of this ECM are laminin, entactin, collagen type IV, and heparan sulfate proteoglycans. Unlike the BCE-ECM, HR9-ECM contains little or no fibronectin, collagen type III, or dermatan sulfate proteoglycans, and no detectable bFGF (Gospodarowicz et al., 1984; Rogelj et al., 1989). It induces cell attachment and flattening, and promotes growth and differentiation of kidney tubule epithelial cells (Gospodarowicz et al., 1984), but fails to induce endothelial cell proliferation and neurite outgrowth in PC12 cells (Rogelj et al., 1989).

This procedure is described for 35-mm tissue culture dishes, but can easily be modified to coat other tissue culture plates and flasks. In fact, all available culture dishes and multiwell plates have been successfully coated with BCE-ECM and HR9-ECM.

Additional Materials *(also see Basic Protocol)*

PF-HR9 cells (ATCC; Chung et al., 1977; Kramer and Vogel, 1984)
Supplemented high-glucose DMEM-10 (see recipe)
Ascorbic acid (Sigma)
Penicillin
Streptomycin
Fibronectin-coated tissue culture dishes (see recipe)

1. Maintain stock cultures of PF-HR9 cells in supplemented high-glucose DMEM-10 in 10-cm tissue culture dishes at 37°C in a humidified, 10% CO_2 incubator. Dissociate stock cultures with trypsin/EDTA solution (5 min at 37°C) and subculture weekly at a 1:10 split ratio.

   PF-HR9 cells can be frozen in liquid nitrogen in high-glucose DMEM containing 10% (v/v) FBS and 10% (v/v) DMSO.

2. Dissociate one 10-cm stock culture of PF-HR9 cells with trypsin/EDTA solution (5 min at 37°C), rinse cells, and resuspend in 100 ml supplemented high-glucose DMEM-10.

   One stock culture provides enough cells for fifty 35-mm dishes.

3. Seed 2×10^5 cells per 35-mm fibronectin-coated tissue culture dish in supplemented high-glucose DMEM-10 with 4% (w/v) dextran T40.

These dishes will be coated with HR9-ECM. Precoating with fibronectin enforces a firm adhesion of the HR9-ECM to the plastic substratum.

4. Incubate for 5 or 6 days, adding ascorbic acid at 50 µg/ml to the culture medium on days 2 and 4.

5. Warm Triton/NH_4OH cell lysis solution 10 to 20 min at 37°C. Aspirate the culture medium from each 35-mm culture dish and add 1 ml cell lysis solution.

   In certain experiments, denudation with Triton X-100 and NH_4OH should be avoided (see Critical Parameters).

6. Incubate the dishes for 3 to 5 min with gentle shaking at room temperature and examine one of the dishes under a phase-contrast microscope.

   Generally, complete cell lysis occurs within 2 to 3 min and the ECM remains firmly attached to the tissue culture plastic. If cell nuclei remain bound to the bottom of the dish, incubate for an additional 5 to 10 min at 37°C to obtain complete solubilization of the cell layer.

   The appearance of the HR9-ECM is similar to that of BCE-ECM (see Basic Protocol, step 22) except that it often contains cellular debris and is slightly more fibrillar.

7. Aspirate the solubilized material and wash each plate four times with 2 ml PBS.

   If needed, remove cellular debris by pipetting. If plates have not been precoated with fibronectin, the HR9-ECM may come off the plates during washing.

8. Add 1 ml PBS containing 50 µg/ml gentamicin and 0.25 µg/ml Fungizone to each 35-mm HR9-ECM plate. Store at 4°C for up to 4 months.

SUPPORT PROTOCOL 1

CELL ATTACHMENT ASSAY

A human colon carcinoma cell line, isolated from the liver and designated HS703T, is used to evaluate the cell adhesion–promoting activity of the ECM. The cells can be obtained from the Cell Culture Laboratory (Oakland, CA), under the auspices of the Office of Naval Research and the Regents of the University of California. HS703T cells have previously been shown to utilize laminin but not fibronectin in order to attach and spread (Vlodavsky and Gospodarowicz, 1981). On uncoated or fibronectin-coated tissue culture plastic, the cells grow as loosely attached aggregates of spheroid cells. In contrast, as early as 5 min after plating on ECM, the cells migrate out of the cell aggregates and become firmly attached and flattened (Vlodavsky et al., 1980; Vlodavsky and Gospodarowicz, 1981; Fig. 10.4.1). Attachment and spreading of HS703T human colon carcinoma cells therefore provide a rapid, convenient, and sensitive assay for the presence of a uniform ECM coating on plastic surfaces. This protocol can be used to assess BCE-ECM as well as HR9-ECM.

Materials

HS703T cells (Vlodavsky et al., 1980; Vlodavsky and Gospodarowicz, 1981)
Supplemented high-glucose DMEM-10 (see recipe)
Trypsin/EDTA solution (see recipe)
35-mm ECM-coated tissue culture dishes (see Basic Protocol; see Alternate Protocol 2)
PBS (*APPENDIX 2A*)

35-mm tissue culture dishes
Coulter counter

1. Maintain stock cultures of HS703T cells in supplemented high-glucose DMEM-10 in a humidified 37°C, 10% CO_2 incubator.

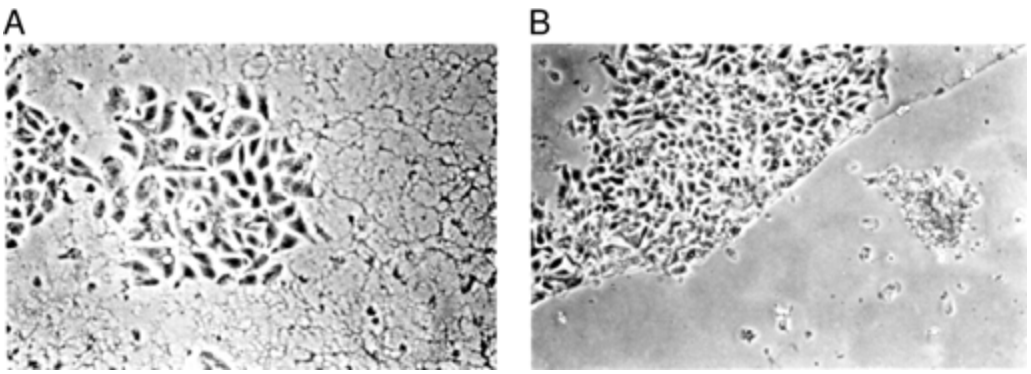

Figure 10.4.1 Adhesion and flattening of human colon carcinoma cells (HS703T) on BCE-ECM. (**A**) Intact ECM; (**B**) "wounded" ECM, where the ECM coating was scraped from part of the dish. Loosely attached aggregates of spheroid cells are seen on plastic (wounded ECM) as compared to firmly attached and flattened cells on ECM. Phase-contrast micrographs (180×) were taken 6 hr after seeding.

2. Dissociate cells with trypsin/EDTA solution (incubate 5 min at 37°C, then rinse with medium) or by repeated pipetting.
3. Seed 1×10^5 cells each onto duplicate 35-mm regular tissue culture dishes and duplicate ECM-coated tissue culture dishes.
4. At various times ranging from 5 to 60 min after seeding, remove unattached cells by gentle trituration and rinse the dishes twice with 2 ml PBS.
5. Dissociate remaining firmly attached cells with 1 ml trypsin/EDTA solution as above. Count the cells of duplicate dishes with a Coulter counter according to manufacturer's instructions.

   Alternatively, prelabel stock cultures with [^{3}H]thymidine (1 μCi/ml, 20 hr) and proceed as described above. Instead of counting cells, solubilize the firmly attached cells with 0.1 N NaOH (20 min, 37°C) and measure the radioactivity by liquid scintillation spectroscopy (Fridman et al., 1985).

CELL PROLIFERATION ASSAY

SUPPORT PROTOCOL 2

Bovine aortic vascular endothelial cells (BAEC; prepared according to Gospodarowicz, 1976) are applied to evaluate the growth-promoting activity of the BCE-ECM. When seeded in complete medium at a clonal cell density (300 cells/35-mm dish), the cells proliferate and form colonies on ECM (Fig. 10.4.2B), but not on regular tissue culture plastic (Fig. 10.4.2A; Gospodarowicz et al., 1980a,b; Rogelj et al., 1989). This protocol is not suitable for HR9-ECM.

Materials

Aortic tissue from freshly sacrificed cows
DMEM/BCS: supplemented low-glucose DMEM-10 (see recipe) in which FBS and newborn calf serum are replaced with 10% (v/v) bovine calf serum
Trypsin/EDTA solution (see recipe)
35-mm regular and BCE-ECM-coated tissue culture dishes (see Basic Protocol)
3.7% formaldehyde (prepared from commercial 37% formalin)
0.125% (w/v) crystal violet solution (see recipe)

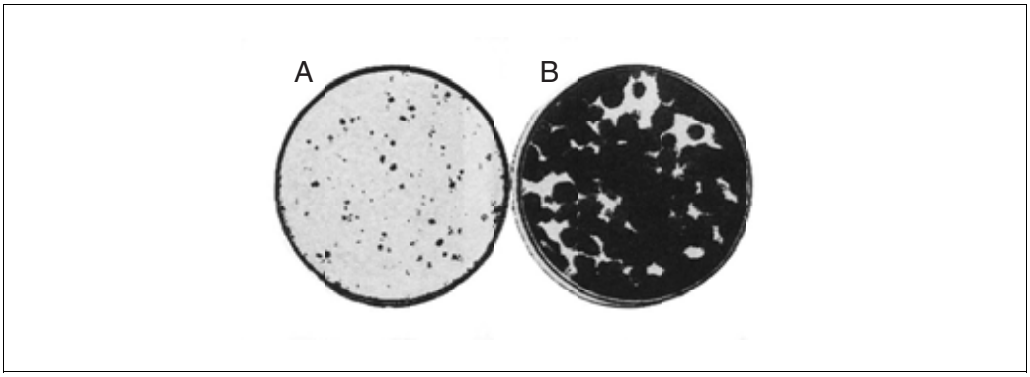

Figure 10.4.2 Clonal growth of bovine aortic endothelial cells on (**A**) plastic or (**B**) ECM. Cell colonies were fixed and stained with 0.125% crystal violet ten days after seeding (300 cells/35-mm dish).

1. Initiate clonal populations of bovine aortic endothelial cells (BAEC) from freshly obtained aortic tissue as described (Gospodarowicz et al., 1976), and maintain cells in DMEM/BCS in a humidified 37°C, 10% CO_2 incubator.
2. Dissociate a confluent stock culture into a single-cell suspension by incubating 5 min at 37°C with trypsin/EDTA solution. Rinse with medium.
3. Add 2 ml DMEM/BCS to duplicate 35-mm tissue culture dishes and duplicate BCE-ECM-coated tissue culture dishes, seed each with 300 cells, and incubate in CO_2 incubator.
4. At 10 to 12 days after seeding, aspirate medium and fix cells 1 hr at room temperature with 1 ml of 3.7% formaldehyde.
5. Stain cultures for 5 min with 1 ml of 0.125% crystal violet solution and rinse with tap water.

   At least 100 cell colonies, each containing >70 closely apposed, polygonal cells, should be seen on ECM. In contrast, uncoated dishes should have no cell colonies or very small and lightly stained colonies composed of senescent cells.

SUPPORT PROTOCOL 3

CELL DIFFERENTIATION ASSAY

The ability of PC12 cells, originally established from a transplantable rat pheochromocytoma, to extend neurites is used to evaluate the differentiation-promoting activity of BCE-ECM (Vlodavsky et al., 1982; Rogelj et al., 1989). This protocol is not suitable for HR9-ECM.

Materials

PC12 cells (ATCC)
Supplemented high-glucose DMEM-10 (see recipe)
Trypsin/EDTA solution (see recipe)
35-mm regular and BCE-ECM-coated tissue culture dishes (see Basic Protocol)

1. Maintain PC12 cells in supplemented high-glucose DMEM-10 in a humidified 37°C, 10% CO_2incubator.

   For PC12 cells, FBS in the medium should be heat inactivated (APPENDIX 2A).

2. Dissociate cells into a single-cell suspension by incubating 5 min at 37°C with trypsin/EDTA solution and rinse with medium.

3. Add 2 ml supplemented high-glucose DMEM-10 to each of the triplicate 35-mm tissue culture dishes triplicate ECM-coated tissue culture dishes, seed each with 1×10^5 cells, and incubate in a CO_2 incubator.

4. Examine cultures daily for neurite outgrowth.

   Extension of neurites to at least five-fold the length of the cell body is seen within 2 to 4 days on ECM. In contrast, there is almost no outgrowth on regular tissue culture plastic.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Crystal violet solution, 0.125% (w/v)

Dissolve 2.5 g crystal violet in 100 ml methanol. Stir overnight and filter through Whatman no. 3 paper. Store up to 4 months at room temperature. Dilute 1/20 in H_2O immediately before use.

Fibronectin-coated tissue culture dishes

Prepare a 25 µg/ml solution of human plasma fibronectin (Sigma) in PBS (*APPENDIX 2A*). Add 1 ml per dish to 35-mm tissue culture dishes and incubate 1 hr at room temperature. Remove fibronectin solution and rinse once with PBS. Store covered with PBS up to 1 month at 4°C. Rinse again after storage.

Gelatin-coated tissue culture dishes

Prepare a 0.2% (w/v) gelatin solution in PBS (*APPENDIX 2A*). Autoclave the solution, cool, and filter through a 0.2-µm filter. Add 5 ml solution per dish to 10-cm tissue culture dishes, and incubate ≥3 hr at 4°C. Remove the gelatin solution and wash the dishes once with 10 ml PBS. Store covered with PBS up to 1 month at 4°C. Rinse again after storage.

Supplemented low-glucose DMEM-10

Dulbecco's modified Eagle medium (DMEM) containing 1 g/liter glucose, supplemented with:
10% (v/v) FBS (*APPENDIX 2A*)
5% (v/v) newborn calf serum
50 µg/ml gentamicin
0.25 µg/ml Fungizone (amphotericin B; Life Technologies)
Store up to 1 month at 4°C

Supplemented high-glucose DMEM-10

Dulbecco's modified Eagle medium (DMEM) containing 4.5 g/liter glucose, supplemented with:
10% (v/v) FBS (*APPENDIX 2A*)
50 U/ml penicillin
50 µg/ml streptomycin
Store up to 1 month at 4°C

Heat inactivation of FBS is only required for PC12 cells (see Support Protocol 3).

Triton/NH_4OH cell lysis solution

PBS (APPENDIX 2A) containing:
0.5% (v/v) Triton X-100
20 mM NH_4OH
Store up to 3 months at 4°C

Trypsin/EDTA solution

2.5 g trypsin
0.2 g EDTA
8 g NaCl
0.4 g KCl
1 g glucose
0.35 g $NaHCO_3$
0.01 g phenol red
H_2O to 1 liter
Store up to 3 months at –20°C

COMMENTARY

Background Information

The ECM is an organized complex of collagens, proteoglycans, and glycoproteins, all interacting to produce a highly stable structure upon which cells migrate, proliferate, and differentiate in vivo (Kleinman et al., 1981). Historically, ECM was regarded as a relatively inert scaffolding that stabilizes the physical structure of tissues. Subsequent studies indicated that the ability of cells to respond to various growth and differentiation factors is determined to a large extent by their shape and orientation, and that these are modulated by components of the ECM through interaction with specific transmembrane cell-surface integrin receptors (Gospodarowicz et al., 1978; Ingber, 1990; Hynes, 1992; Damsky and Werb, 1992). Studies with mammary gland epithelial cells led not only to the identification of genes that are dependent upon the ECM for their transcription, but also to the discovery of ECM response elements (Boudrean et al., 1995). It was also proposed that mechanical forces generated through cell-ECM interactions produce an altered cytoskeleton, altered nuclear morphology, and ultimately changes in the pattern of gene expression (Chen et al., 1997). Based on these and other observations, it is recognized that the ECM plays an active and complex role in regulating the morphogenesis of cells that contact it, influencing their development, migration, proliferation, survival, and metabolic functions (Meredith et al., 1993; Vlodavsky et al., 1993; Aharoni et al., 1997).

It appears that cellular responses to ECM are mediated by the combined action of basement membrane (BM) macromolecules (i.e., collagen IV, laminin, nidogen/entactin, proteoglycans) and active molecules (i.e., growth factors, enzymes) that are immobilized and stored in the ECM by means of binding to its macromolecular constituents, primarily to heparan sulfate proteoglycans (HSPG; Ruoslahti and Yamaguchi, 1991; Vlodavsky et al., 1993). Heparan sulfate also contributes to the assembly and integrity of the ECM through binding to various ECM molecules, including the fibrillar interstitial collagens (types I, III, and V), fibronectin, laminin, thrombospondin, and tenascin.

Elucidating specific components of the ECM involved in controlling cell proliferation and differentiation either in vivo or in vitro is a difficult task, mostly due to its intricate nature. Because the correct in vitro reconstruction of the ECM from its isolated native components into the highly ordered structure that it represents in vivo would be a formidable task, advantage is taken of the fact that cultured bovine corneal endothelial cells (BCE) and PF-HR9 endodermal cells have the ability to produce, underneath their basal surface, a thick ECM that adheres strongly to plastic (Vlodavsky et al., 1980; Gospodarowicz et al., 1984). The ECM produced by cultured BCE cells closely resembles the subendothelium in vivo in its morphology and molecular composition. It contains primarily collagens (mostly types III and IV, with smaller amounts of types I and V), proteoglycans (mostly heparan sulfate and dermatan sulfate proteoglycans, with smaller amounts of chondroitin sulfate proteoglycans), laminin, fibronectin, entactin, and elastin. Vascular endothelial cells and other cell types plated in contact with the subendothelial ECM no longer require the addition of soluble basic fibroblast growth factor (bFGF) and/or other growth-promoting factors in order to proliferate and express their differentiated functions (Gospodarowicz et al., 1980a,b; Vlodavsky et al., 1982). Unlike cells maintained on plastic (e.g., vascular smooth muscle cells), cells cultured in contact with BCE-ECM resemble their in vivo counterparts and proliferate in response to plasma factors (Gospodarowicz and Ill, 1980).

PF-HR9 cells are epithelial in nature. As such, they produce ECM composed primarily of characteristic epithelial basement membrane components such as collagen type IV, heparan sulfate proteoglycans, laminin, and entactin (Timpl et al., 1979; Leivo et al., 1982). This ECM resembles epithelial basement membranes better than the subendothelial ECM produced by BCE. While the BCE-ECM provides an excellent model for basement membranes of blood vessels, the HR9-ECM provides a model for basement membranes underlying epithelial cells in a variety of organs and tissues. Unlike the BCE-ECM, HR9-ECM contains little or no fibronectin, collagen type III, dermatan sulfate proteoglycans, and no detectable bFGF (Rogelj et al., 1989).

Although many cell types are capable of producing ECM in vitro, the ECM is most often removed together with the cells when the cell layer is solubilized with Triton/NH_4OH. This is due primarily to secretion of ECM components by the cultured cells (i.e., fibroblasts, smooth muscle cells) both in between the cells and toward the bottom and top of the cell layer. In contrast, the corneal endothelial cells and, to a lesser degree, the PF-HR9 cells deposit their ECM in a polar fashion, almost exclusively underneath the cell layer. This enables a preferential removal of the cell layer while leaving the ECM bound to the tissue culture plastic. In particular, this property and mode of polar deposition is characteristic of BCE cells whose ECM is more firmly bound to the tissue culture dish than that produced by PF-HR9 cells. Thus, BCE-ECM can be washed extensively to efficiently remove cellular debris.

The polar secretion of ECM by BCE and the firm interaction of this ECM with the tissue culture plastic provide an appropriate system to obtain a naturally produced substrate, free of cellular elements (Vlodavsky et al., 1980; Gospodarowicz et al., 1980a,b). The presence of nuclei or cytoskeletal elements could not be detected on the denuded ECM when coated plates were examined by phase-contrast microscopy, scanning electron microscopy, or indirect immunofluorescence, using anti-actin and anti-vimentin antibodies, or the benzimidole derivative Hoechst 33258 for nuclear staining (Gospodarowicz et al., 1983). Moreover, ECM prepared after a 24-hr exposure of subconfluent BCE cultures to [^{3}H]thymidine was devoid of labeled material. Likewise, no labeled cell surface components remained associated with the ECM after solubilization (Triton/NH_4OH) of lactoperoxidase-iodinated BCE that were plated on ECM for 24 hr. No serum proteins could be identified in the ECM (Gospodarowicz and Ill, 1980).

Unlike the BCE-ECM, cellular debris is always left adhering to the HR9-ECM. This is mostly due to the fact that part of the PF-HR9 cell population dies while proliferating. Cellular debris is therefore trapped in the ECM that is continuously produced by the living cells. Cellular debris adhering to the apical surface of the HR9-ECM are probably derived from dead cells that are present within the monolayer and that are not fully lysed when exposed to the Triton/NH_4OH solution.

The presence of heparan sulfate as a major glycosaminoglycan (GAG) in the ECM raised the possibility that ECM serves as a reservoir for heparin-binding growth factors that are tightly bound and stabilized by heparan sulfate in the ECM. Among these factors is bFGF, extracted from the subendothelial BCE-ECM produced in vitro (Vlodavsky et al., 1987) and from BM of the cornea in vivo (Folkman et al., 1988). bFGF was identified in a variety of endothelial and epithelial basement membranes in vivo (Cordon-Cardo et al., 1990; Vlodavsky et al., 1993). These and other results indicate that bFGF is an ECM component required for supporting cell proliferation, differentiation, and survival (Vlodavsky et al., 1991, 1993).

ECM-coated dishes are widely used for initiating primary cultures; for studying the control of cell adhesion, proliferation, differentiation, and survival by the local microenvironment (Vlodavsky et al., 1993); and for investigating cell migration, invasion, and metastatic behavior (Vlodavsky et al., 1983, 1992, 1995). ECM-coated dishes have been useful in restoring the normal phenotypic expression of a number of normal cell types that would otherwise have lost normal phenotypes when maintained on plastic (Gospodarowicz and Tauber, 1980; Gospodarowicz et al., 1980a,b). In the field of aging, cells maintained on ECM and exposed to serum-supplemented medium have a much longer life span in culture than cells maintained on plastic. This effect is attributed to cell survival signals that inhibit programmed cell death (Aharoni et al., 1997). ECM-coated dishes have also been useful in allowing the maintenance of a number of normal diploid cells and tumor cells under serum-free conditions, so that plasma factors involved in the control of their proliferation could be studied (Gospodarowicz and Ill, 1980; Gospodarowicz et al., 1980a,b, 1984). This property also facili-

tates the initiation of biopsy-derived epithelial cell cultures, while suppressing overgrowth by stromal fibroblasts (Biran et al., 1983). The BCE-ECM has been used in studies of nerve and glial cell differentiation (Vlodavsky et al., 1982; Lubetzki-Korn et al., 1983). The nerve cells can be either tumoral, such as the pheochromocytoma PC12 cell line, or normal sensory ganglion cells (Fujii et al., 1982; Vlodavsky et al., 1982). In either case, when cells are maintained on ECM, neurite outgrowth is initiated.

The HR9-ECM preferentially supports the proliferation and differentiation of epithelial cells. In the case of kidney tubule epithelial cells, it not only supports their growth but also promotes their differentiation into tubules that are indistinguishable from those seen in vivo (Gospodarowicz et al., 1984). HR9-ECM also allows the maintenance of kidney tubule epithelial cells under serum-free culture conditions; such cultures led to the identification of the two main plasma factors (transferrin and high-density lipoprotein) involved in supporting their growth (Gospodarowicz et al., 1984).

Critical Parameters

The goal of the described procedure is to obtain culture dishes entirely coated with a homogeneous, naturally produced, basement membrane–like matrix. The strategy is to have the main extent of cell growth in stock dishes and then seed the ECM-producing cells at a high density, allowing the ECM to be deposited over the course of two to three population doublings. The best production of ECM, in terms of thickness and homogeneity, is obtained with secondary or early-passage BCE. Cells beyond their sixth passage in culture should not be used. Also, 4% dextran T40 should be included in the growth medium in order to increase its viscosity and hence the phagocytotic/exocytotic activity of the BCE, which in turn increases the amount of ECM deposited. Unlike BCE-ECM, PF-HR9 cells produce little or no fibronectin. To enforce a firm adhesion of the HR9-ECM to the plastic substratum it is necessary to precoat the culture dishes with fibronectin. Even then, extensive washing of the HR9-ECM should be avoided, and cellular debris is often left adhering to this ECM. In contrast, no cellular debris remains associated with the BCE-ECM.

In certain experiments, denudation with Triton X-100 and NH_4OH should be avoided. For example, cell lysis should be avoided in experiments aimed to prove that bFGF is deposited into the ECM prior to the actual denudation of the ECM, and that it is not sequestered by heparan sulfate in the ECM when the cells are lysed with Triton and NH_4OH. For this purpose, the ECM-producing cells are removed by a procedure involving little or no cell lysis. This can be best achieved by exposing the cell monolayer to 2 M urea in DMEM for 10 to 20 min at 37°C (Gospodarowicz et al., 1983). Under these conditions, the cells detach from each other, round up, and can be removed by pipetting as intact and viable cells, leaving the underlying ECM firmly bound to the tissue culture plastic (Vlodavsky et al., 1987, Gospodarowicz et al., 1983).

Anticipated Results

The described procedures enable the coating of any available tissue culture surface with intact, naturally produced ECM, similar in its molecular organization to subendothelial (BCE-ECM) and subepithelial (HR9-ECM) basement membranes in vivo. The basic approach is to allow cells to deposit their own ECM and avoid using extraction/enzymatic procedures that may alter or denature the native ECM constituent proportion and supramolecular organization.

One primary BCE culture maintained in a 6-cm dish can be subcultured into eleven 10-cm stock dishes, yielding enough cells to coat two hundred 35-mm tissue culture dishes. For PF-HR9 cells, one 10-cm stock culture provides enough cells to coat fifty 35-mm dishes.

Time Considerations

For BCE-ECM, it takes 8 to 12 days to obtain primary cultures, 8 to 10 days to get the appropriate stock cultures, and ~10 additional days for the actual deposition of ECM. A shorter time is needed for preparation of ECM deposited by the PF-HR9 teratocarcinoma-derived cell line. The HR9-ECM is obtained 5 to 6 days after seeding the cells, but unlike the BCE-ECM, it contains some cellular debris and lacks bFGF.

Purification of Fibronectin

The adhesive glycoprotein fibronectin can be purified from body fluids, cultured cells, or tissues. Because of its relatively high fibronectin content, plasma is the most convenient source of this protein, which can be used to promote the adhesion, migration, and growth of virtually all cultured cells. The protocol presented in this unit for the purification of human plasma fibronectin (see Basic Protocol 1) uses immobilized gelatin (denatured collagen) to bind the protein. A pH 5.5 buffer is used to specifically elute the bound fibronectin without resorting to denaturing conditions. Because there are structural and functional differences between plasma and cell-derived fibronectins, purification protocols for the latter form are also given. Cellular fibronectin can be easily extracted from the surface of cultured cells (see Basic Protocol 2) and further purified if necessary (see Alternate Protocol 1) or harvested from cell-conditioned serum-free culture medium (see Alternate Protocol 2).

CAUTION: When working with human blood, cells, or infectious agents, appropriate biosafety practices must be followed. Even screened human plasma should be treated as potentially contaminated with infectious agents such as HIV or hepatitis viruses. Two layers of gloves, safety glasses or goggles, and suitable protective clothing should be worn at all times. Plasma should be always be centrifuged in capped tubes or bottles. During thawing or warming, the plasma should be "double contained" (e.g., plastic bags of plasma should be contained in beakers before being placed in a water bath) in case of leakage. Any surfaces or skin on which plasma has been spilled or splashed should be disinfected with 10% sodium hypochlorite bleach or iodine-based disinfectant such as Wescodyne or Providone.

PURIFICATION OF PLASMA FIBRONECTIN

BASIC PROTOCOL 1

This protocol describes the purification of fibronectin from surplus or outdated human plasma. It can also been used to purify fibronectin from a variety of other species, including bovine, chicken, rat, and mouse from either plasma or sera. The yield of fibronectin will be much lower from sera because the process of precipitating the fibrin clot out of plasma to produce serum can also remove as much as 60% of the fibronectin. Surplus or outdated human plasma can be most easily obtained from local blood banks, or it may be purchased commercially. This protocol as described assumes 1 liter of human plasma as the starting material and can be easily scaled up proportionally.

Materials

1000 ml (3 to 4 units) surplus or outdated human plasma
Sepharose CL-4B (Amersham Pharmacia Biotech)
Gelatin-Sepharose (Amersham Pharmacia Biotech)
6 M urea
Tris-buffered saline (TBS): 0.9% (w/v) NaCl/10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.2 M EDTA, pH 7.0
0.2 M PMSF (see recipe)
ε-Amino-*n*-caproic acid
Column buffers A and B (see recipes)
Citrate elution buffer (see recipe)
0.5 M sodium phosphate, dibasic
Ammonium sulfate, ultrapure (Life Technologies or Sigma)
Dulbecco's PBS (*APPENDIX 2A*)
CAPS/saline (optional; see recipe)

5-cm-diameter column, ≥5 cm tall, siliconized with Aquasil (Pierce)
5-cm-diameter column, ≥10 cm tall, siliconized with Aquasil

continued

Contributed by Steven K. Akiyama
Current Protocols in Cell Biology (1999) 10.5.1-10.5.13

50-ml polycarbonate high-speed centrifuge tubes
250- or 500-ml centrifuge bottles
Dialysis tubing (12,000 to 14,000 MWCO; Spectrapor or equivalent)
High-speed refrigerated centrifuge with GS-3 and GSA rotors (Sorvall) or equivalent

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*)

Prepare columns

1. Pack a column (5 cm in diameter and ≥5 cm high) with 100 ml Sepharose CL-4B. Wash with at least 300 ml column buffer A as fast as possible by gravity flow.

   This will be used as a precolumn to remove plasma components that bind nonspecifically to gelatin or Sepharose. The flow rate can be increased by using tubing connected to the bottom of the column to siphon down the column eluate more rapidly.

2. Pack a column (5 cm in diameter, 10 cm high) with 200 ml gelatin-Sepharose. Wash the gelatin-Sepharose with at least 800 ml of 6 M urea in TBS, then at least 800 ml of column buffer A.

   Both of the preceding steps can be completed up to several days before the following steps.

Prepare plasma

3. Warm plasma to 37°C.

   All subsequent steps are performed at room temperature, except where noted.

4. Add protease inhibitors to plasma with stirring:

   25 ml 0.2 M EDTA (5 mM final)
   5 ml 0.2 M PMSF (1 mM final)
   6.6 g ε-amino-*n*-caproic acid (50 mM final).

5. Centrifuge 15 min at 10,000 × *g*, room temperature, and save the supernatant.

   Use 250- to 500-ml bottles appropriate for a Sorvall GSA or GS-3 rotor or equivalent. The rotor and the centrifuge should be at room temperature prior to and during centrifugation.

Affinity purify plasma fibronectin

6. Apply the plasma to the precolumn as fast as possible, then immediately apply the flowthrough to the gelatin-Sepharose column at a flow rate of no more than ~500 ml/hr.

   Treat the flowthrough fractions of the gelatin-Sepharose column as biohazardous waste and discard in a manner consistent with local and institutional regulations.

   The precolumn removes plasma components that bind nonspecifically to the gelatin or Sepharose beads.

7. Wash the column as rapidly as possible with 800 ml column buffer B, then with 400 ml column buffer A.

8. Elute the fibronectin from the column with citrate elution buffer and collect 40-ml fractions. Check fractions for the presence of eluted fibronectin by spectrophotometry (measuring A_{280}). Pool the fibronectin-containing fractions, and immediately add 4 ml of 0.5 M dibasic sodium phosphate per fraction to neutralize the solution.

   This is a possible stopping point. Neutralized fibronectin solutions can be stored up to several days at 4°C.

   The yield of fibronectin can be increased by following the citrate buffer elution by a second elution with 4 M urea in TBS. The urea-eluted fibronectin will be of lower purity and usually comprises less than half the yield of the citrate-eluted fibronectin; however, it is still potentially useful, especially as starting material for the preparation of fibronectin frag-

ments. The urea should be removed immediately by dialysis before the fibronectin is concentrated by ammonium sulfate precipitation as described in step 9.

To save the gelatin-Sepharose column for reuse, wash thoroughly with TBS containing 0.1% sodium azide immediately after the urea elution and store it at 4°C. The column can be used repeatedly for many years if it is kept hydrated. Reused gelatin-Sepharose can actually provide higher yields of fibronectin than "new" gelatin-Sepharose because of irreversible occupancy of nonspecific binding sites on the beads

Concentrate fibronectin by precipitation (optional)

9. If higher concentrations of fibronectin than those eluted from the column are necessary, precipitate the fibronectin by slowly adding 0.291 g ammonium sulfate per milliliter (50% saturation) while stirring on ice until the ammonium sulfate is completely dissolved. Let the ammonium sulfate-treated fibronectin incubate on ice without stirring at least 2 hr.
10. Centrifuge 15 min at 10,000 × *g*, 4°C. Resuspend the pellet and dialyze for several days at 4°C with stirring in 3.5 liters of a suitable buffer to remove any residual ammonium sulfate. Replace the buffer each day with 3.5 liters fresh buffer.

    A wide range of common buffers can be used to solubilize and dialyze the final plasma fibronectin product. It is generally easiest to use TBS or Dulbecco's PBS. It is possible to achieve fibronectin concentrations greater than ~10 mg/ml in most physiological buffers. If higher concentrations are needed, fibronectin is soluble at over 20 mg/ml in CAPS/saline.

    If necessary, fibronectin can be sterilized by filtration, although yields will be low due to binding of fibronectin to the filter.

11. Determine the concentration of fibronectin.

    This is most easily determined by measuring the A_{280} and using an extinction coefficient of 1.28 ml·mg^{-1}·cm^{-1}.

12. Analyze by SDS-PAGE (*UNIT 6.1*).

    In the presence of reducing agent, plasma fibronectin appears as a doublet of 230 and 220 kDa.

13. Freeze small aliquots on dry ice and store at −80°C.

    Stored at this temperature, fibronectin can remain active for 10 years or more.

    If storage at −80°C is not available, the second-best option is to store fibronectin as a liquid solution on wet ice. Storage of fibronectin at −20°C should be avoided—at this temperature, fibronectin tends to form a clot that cannot be redissolved. Thaw frozen fibronectin at 37°C with minimal shaking or agitation. Avoid repeated freezing and thawing.

PURIFICATION OF FIBRONECTIN FROM CULTURED CELLS

BASIC PROTOCOL 2

There are two major approaches for the purification of cellular fibronectin from monolayers of cultured fibroblastic cells: (1) extracting cell surface-bound fibronectin from the cell layer and (2) purifying fibronectin that is spontaneously released from the cell monolayer and secreted into the medium (see Alternate Protocol 2). The protocols have been used to produce cellular fibronectin from fibroblasts from several species including human, chicken, rat, and mouse. Although many cell types can be used, cultured fibroblasts are usually the cells of choice. These cells are easy to culture and produce relatively large amounts of fibronectin. Fibroblasts can either be prepared from embryonic or neonatal tissue from the appropriate animal species or be purchased from commercial sources, such as the American Type Culture Collection. Yields of fibronectin can vary widely depending on cell type and culture conditions, but can be surprisingly high. For example, fibronectin can comprise up to 3% of the total protein produced by chick embryo

fibroblasts. In general, earlier-passage cells provide higher yields of fibronectin than later-passage cells.

This protocol assumes that human fibroblasts have been cultured to confluency in ten 850-cm^2 tissue culture roller bottles. Alternatively, 150-cm^2 dishes or 175-cm^2 flasks can be used, with volumes adjusted accordingly. Since fibronectin yields depend on cell numbers, allow the cells to grow as dense as possible yet not so dense that they detach. Many fibroblastic cells (e.g., chick embryo fibroblasts) are not truly contact inhibited and can eventually form several cell layers in culture, although they will detach from the substrate if cultured too long without passaging.

Cellular fibronectin in substantially pure form can be extracted from fibroblast monolayers with 1 to 2 M urea. If 1 M urea is used, the yield will be lower but further purification is often not necessary. Extraction with 2 M urea is often necessary to get a good yield of fibronectin, especially when human fibroblasts are used as the starting material. Users are encouraged to do small pilot extraction of 35-mm or 60-mm dishes of cells to determine the yield and purity of extracted fibronectin at different urea concentrations. Although 2 M urea extracts cell surface fibronectin from fibroblasts better than 1 M urea, the higher concentration is also more efficient at extracting other cell surface proteins. Thus, further purification of cellular fibronectin extracted with 2 M urea is usually required.

Materials

Fibroblasts grown to dense confluence in roller bottles using serum-containing medium
Hank's balanced salt solution (HBBS; *APPENDIX 2A*)
Dulbecco's modified Eagle's medium (DMEM)
100 mM glutamine
0.2 M PMSF (see recipe)
Urea, ultrapure (Life Technologies or ICN)
Ammonium sulfate, ultrapure (Life Technologies or Sigma)
0.2 M CAPS buffer, pH 11.0 (see recipe)
CAPS/saline (see recipe)

Roller bottle apparatus
Refrigerated high-speed centrifuge
50-ml polycarbonate high-speed centrifuge tubes
Dialysis tubing (12,000 to 14,000 MWCO; Spectrapor or equivalent)
1.5-cm polypropylene column, 5 cm high
12 × 75–mm polypropylene tubes

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*).

Extract cells

1. Warm 2000 ml HBSS and 1500 ml DMEM supplemented with 60 ml of 100 mM glutamine (4 mM final) and 15 ml 0.2 M PMSF (2 mM final) to 37°C.

   Approximately 200 ml HBSS and 150 ml supplemented DMEM will be needed per bottle.

2. Gently rinse roller bottles four times with 50 ml warmed HBSS each time. Discard rinses.
3. Add 25 ml/bottle DMEM with 4 mM glutamine and 2 mM PMSF and incubate 1 hr at 37°C while rotating at 1 rpm to deplete the monolayer of adsorbed serum proteins.

4. Prepare 2 M urea in DMEM by dissolving 30 g ultrapure urea in DMEM supplemented with 4 mM glutamine in a total volume of 250 ml. Warm to 37°C. Just before use, add 2.5 ml of 0.2 M PMSF (2 mM final).
5. Discard the serum-free medium, then add 20 ml/bottle fresh 2 M urea in DMEM with 4 mM glutamine and 2 mM PMSF (prepared in step 4) and incubate 2 hr at 37°C while rotating at 1 rpm.

   This step extracts the fibronectin from the cell surface. Usually 2 M urea is needed to extract human fibronectin, but 1 M urea can be used with some cells, for example chick embryo fibroblasts. Alternatively, 1 M urea will extract human fibronectin, albeit at low yields. However, fibronectin extracted with 1 M urea is often sufficiently pure that affinity purification is not necessary.
6. Centrifuge the extracted fibronectin in eight 50-ml polycarbonate centrifuge tubes for 15 min at 15,000 × *g*, 4°C. Save the supernatant, which contains the fibronectin, and discard the pellets.

Precipitate fibronectin

7. Measure the volume and slowly add 0.472 g ultrapure ammonium sulfate per milliliter of supernatant (70% saturation) with stirring on ice. After all of the ammonium sulfate is dissolved, let the solution incubate ~1 hr on ice without stirring.
8. Centrifuge the precipitated fibronectin in 50-ml polycarbonate centrifuge tubes for 15 min at 15,000 × *g*, 4°C. Discard the supernatant and gently but rapidly resuspend all the pellets in a total of ~10 ml of 0.2 M CAPS buffer, pH 11.0. Readjust pH to 11.0 with NaOH as needed while resuspending.

Dialyze precipitate

9. Dialyze the resuspended cellular fibronectin against 3.5 liters CAPS/saline buffer at 4°C with stirring. Replace buffer twice.

   Care must be taken to seal the dialysis buffer from exposure to air as well as possible using Saran wrap or equivalent. To minimize the airspace in the beaker above the dialysis buffer, make sure the Saran wrap is touching the top of the buffer. Otherwise, carbon dioxide from the air can dissolve in the buffer, lowering its pH and precipitating the cellular fibronectin.
10. Centrifuge 20 min at 15,000 × *g*, 4°C, to clarify the purified fibronectin.
11. Determine the concentration of cellular fibronectin by measuring the A_{280} using an extinction coefficient of 1.28 ml·mg^{-1}·cm^{-1} and analyze by SDS-PAGE (*UNIT 6.1*).

    Cellular fibronectin should produce a band at ~250 kDa.
12. Rapidly freeze cellular fibronectin in small aliquots with liquid nitrogen.

    To avoid partial neutralization of the CAPS buffer, do not use dry ice. Cellular fibronectin should be stored in liquid nitrogen or at −80°C. In liquid nitrogen, cellular fibronectin will remain active for several years if it is not repeatedly frozen and thawed. Cellular fibronectin should be thawed at 37°C with a minimum of shaking or agitation.

AFFINITY PURIFICATION OF EXTRACTED CELLULAR FIBRONECTIN

ALTERNATE PROTOCOL 1

Cellular fibronectin extracted from cells can often be used without further treatment. However, this material can be contaminated with other cellular proteins, especially if 2 M urea is required to extract the fibronectin; in such cases further purification is necessary.

Additional Materials *(also see Basic Protocol 2)*

Tris-buffered saline (TBS; *APPENDIX 2A*)
Gelatin-Sepharose (Amersham Pharmacia Biotech)
5-ml siliconized glass or polypropylene column

1. Extract cellular fibronectin from monolayer cells (see Basic Protocol 2, steps 1 to 6).
2. Pack 5 ml of gelatin-Sepharose into a siliconized glass or polypropylene column.

   Do not use an excessively large affinity column. Recoveries of cellular fibronectin tend to be greater at higher ratios of fibronectin to gelatin-Sepharose, due a relative decrease in nonspecific binding to the beads. A 5-ml bed volume is sufficient.
3. Wash the gelatin-Sepharose with 2.5 ml of 8 M urea in TBS, then with 25 ml TBS.
4. Dilute the cellular fibronectin 1:3 with TBS to a final urea concentration of 0.5 M.
5. Apply the fibronectin to the affinity column and collect 3-ml fractions.
6. Wash the column-bound material extensively with TBS, checking the A_{280} of the effluent, until the A_{280} is <0.05.
7. Elute with 8 M urea in TBS and collect 3-ml fractions. Save and pool the fractions containing eluted fibronectin as determined by a peak in the A_{280}.
8. Proceed with dialysis of the fractions (see Basic Protocol 2, steps 9 to 12).

ALTERNATE PROTOCOL 2

PURIFICATION OF HUMAN CELLULAR FIBRONECTIN FROM CONDITIONED MEDIUM

Densely cultured fibroblastic cells can release substantial amounts of cellular fibronectin into culture medium. The approach described here is to culture roller bottles of human fibroblastic cells to dense confluence in serum-containing growth medium, and then culture the cells in serum-free medium. The use of serum-free medium is required in order to avoid contamination of the cellular fibronectin with plasma fibronectin. Fibroblasts usually cannot be expected to proliferate much under serum-free culture conditions, so they must be cultured in 850-cm^2 roller bottles in the presence of serum until they are heavily confluent. This procedure assumes that ten such roller bottles are used as the source of fibronectin.

This protocol was initially developed as described using a serum-free medium formulation called CRCM-30 that was commercially available from Life Technologies. Unfortunately, this medium is no longer available and neither is its formulation, so the protocol is described using an alternative serum-free medium consisting of a mixture of Ham's F-12 nutrient mixture and DMEM supplemented with antibiotics, pyruvate, amino acids, insulin, selenium, transferrin, and BSA. In trial experiments, this medium did not provide as high yields as CRCM-30, but it works adequately. A wide range of serum-free media is commercially available and any formulation without serum additives should be suitable.

Additional Materials *(also see Basic Protocol 2)*

Serum-free medium: e.g., 1:1 DMEM/Ham's F12; supplemented (see above)
Gelatin-Sepharose (Amersham Pharmacia Biotech)
BSA, crystalline (3× recrystallized; CalBiochem)
Tris-buffered saline (TBS; *APPENDIX 2A*)
Urea, ultrapure (Life Technologies or Sigma)
CAPS/saline (see recipe)
Ammonium sulfate

2.5-cm polypropylene or siliconized glass column, 5 cm high (siliconized with Aquasil, Pierce)
1-liter cylindrical polypropylene bottles
3-ml polypropylene tubes

Prepare cells and collect conditioned medium

1. Warm 2000 ml serum-free medium to 37°C.
2. Gently rinse roller-bottle fibroblast cultures four times each with 50 ml warmed serum-free medium.
3. Add 50 ml/bottle of serum-free medium and incubate at least 1 hr at 37°C while rotating at 1 rpm to deplete the monolayer of adsorbed serum proteins.

   The incubation period in this step can be as long as overnight with no deleterious effects.
4. Discard the serum-free medium. Add 100 ml of fresh serum-free medium to each roller bottle and incubate 24 to 48 hr at 37°C while rotating at 1 rpm.
5. Collect the serum-free, conditioned medium from the bottles and add 10 ml of 0.2 M PMSF per 1000 ml conditioned medium (2 mM final).
6. Centrifuge the extracted fibronectin in polypropylene centrifuge tubes for 15 min at 25,000 × *g*, 4°C. Save the supernatant, which contains the fibronectin, and discard the pellets.

   The conditioned serum-free medium from several bottles can be pooled and stored at –80°C, or used immediately in the next section.

   Secreted cellular fibronectin can often be repeatedly harvested from the same roller bottles by adding more serum-free medium. Usually the cells will eventually start to detach from the roller bottles. When this happens, they can be regrown to confluence by adding serum-containing medium before repeating steps 1 to 5. As the fibroblasts age, the amount of fibronectin they secrete will decrease, so this process cannot be repeated indefinitely. When the yield of fibronectin begins to decline, the cells should be discarded.

Affinity purify secreted cellular fibronectin

7. Prepare the gelatin-Sepharose affinity column. Pack 10 ml gelatin-Sepharose per liter of conditioned medium in a 2.5-cm polypropylene or siliconized glass column.
8. Wash the gelatin-Sepharose with 30 ml of 5 mg/ml BSA in TBS. Then wash the column with 50 ml of 8 M urea in TBS followed by 50 ml TBS.

   The column is prewashed with BSA in order to block nonspecific, irreversible protein binding to the gelatin-Sepharose.
9. Mix 1 ml of BSA-treated gelatin-Sepharose with 1 liter of conditioned medium and incubate for 24 hr at 4°C.

   This is most easily done by mixing the beads and medium together in 1-liter cylindrical polypropylene bottles placed on a roller bottle apparatus with rotation at 3 rpm at 4°C. During this time, the fibronectin in the conditioned medium should bind to the immobilized gelatin.

   Avoid mechanical stirring or excessive agitation of the gelatin-Sepharose, both of which can break up the Sepharose beads, decreasing subsequent column flow rates and the yield of fibronectin.

Recover fibronectin

10. Allow the beads to settle, decant off most of the medium, and pour the gelatin-Sepharose into a 2.5-cm diameter siliconized glass or polypropylene column.
11. Wash the column-bound material with 50 ml TBS at room temperature.
12. Elute with 8 M urea in TBS, collecting 3-ml fractions. Save and pool the fractions containing eluted fibronectin as determined by a peak in the A_{280}, until $A_{280} < 0.05$.

Concentrate fibronectin (optional)

13. If the concentration of cellular fibronectin obtained from the gelatin-Sepharose affinity column is >1 mg/ml, proceed to step 16. If a higher concentration of cellular fibronectin is needed, dialyze the eluted fibronectin against 3.5 liters CAPS/saline with stirring for at least 3 hr to remove most of the urea. Replace buffer at least twice.
14. Transfer the fibronectin to a polypropylene beaker, measure the volume, and slowly add 0.472 g ultrapure ammonium sulfate per ml (70% saturation) with stirring on ice. After all of the ammonium sulfate is dissolved, let the solution incubate at least 1 hr on ice without stirring.
15. Centrifuge the precipitated fibronectin in polypropylene centrifuge tubes for 15 min at 15,000 × *g*, 4°C. Discard the supernatant and gently but rapidly resuspend the cellular fibronectin pellets in 0.2 M CAPS buffer, pH 11.0. Readjust pH to 11.0 with NaOH if needed while resuspending.

Dialyze fibronectin

16. Dialyze the cellular fibronectin against 3.5 liters CAPS/saline buffer at 4°C with stirring. Replace buffer at least twice.

    Care must be taken to seal the dialysis buffer from exposure to air as well as possible using plastic (Saran) wrap. To minimize the airspace in the beaker above the dialysis buffer, make sure the Saran wrap is touching the top of the buffer. Otherwise, carbon dioxide from the air can dissolve in the buffer and lower its pH.

17. Clarify the purified fibronectin by centrifuging 20 min at 15,000 × *g*, 4°C.
18. Determine the concentration of cellular fibronectin by measuring the A_{280} using an extinction coefficient of 1.28 ml·mg^{-1}·cm^{-1} and analyze by SDS-PAGE (*UNIT 6.1*).
19. Freeze cellular fibronectin in small aliquots with liquid nitrogen.

    To avoid partial neutralization of the CAPS buffer, do not use dry ice. Cellular fibronectin should be stored in liquid nitrogen or at −80°C. In liquid nitrogen, cellular fibronectin will remain active for 10 years or more if it has not been repeatedly frozen and thawed. Cellular fibronectin should be thawed at 37°C with a minimum of shaking or agitation.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CAPS buffer, pH 11.0, 0.2 M

22.1 g CAPS (cyclohexylaminopropane sulfonic acid)
~450 ml H_2O
Adjust pH to 11.0 with 6 N NaOH
Add H_2O to 500 ml
Store protected from air up to several weeks at room temperature

After 1 to 2 months, check the pH and readjust with NaOH if necessary.

CAPS/saline

8.8 g sodium chloride
~900 ml H_2O
50 ml 0.2 M CAPS buffer, pH 11.0 (see recipe)
1 ml 1 M calcium chloride
H_2O to 1000 ml
Store protected from air up to 1 month at room temperature

After 1 month, check the pH and readjust with NaOH if necessary.

Citrate elution buffer

11.6 g NaCl
29.4 g sodium citrate (trisodium citrate, dihydrate)
~1800 ml H_2O
2 ml 20% (w/v) sodium azide stock (see recipe)
Adjust pH to 5.5 with 6 N HCl
Add H_2O to 2000 ml
Store up to 1 month at room temperature

Composition: 0.1 M NaCl and 50 mM sodium citrate, pH 5.5.

Column buffer A

12.1 g Tris·Cl
13.1 g ε-amino-*n*-caproic acid
11.8 g sodium citrate (trisodium citrate, dihydrate)
2 ml 20% (w/v) sodium azide stock (see recipe)
H_2O to ~1900 ml
Adjust pH to 7.6 with 6 N HCl
H_2O to 2000 ml
Prepare fresh on day of experiment and use within 2 days

Composition: 50 mM Tris·Cl, 50 mM ε-amino-n-caproic acid, and 20 mM sodium citrate, pH 7.6.

Column buffer B

58.4 g sodium chloride
6.0 g Tris·Cl
6.5 g ε-amino-*n*-caproic acid
5.9 g sodium citrate (trisodium citrate, dihydrate)
~800 ml H_2O
1 ml 20% (w/v) sodium azide stock (see recipe)
Adjust pH to 7.6 with 6 N HCl
Add H_2O to 1000 ml
Prepare fresh on day of experiment and use within 2 days

Composition: 1 M NaCl, 50 mM Tris·Cl, 50 mM 6-aminohexanoic acid, and 20 mM sodium citrate, pH 7.6.

PMSF stock solution, 0.2 M

Dissolve 69.6 mg PMSF (phenylmethylsulfonyl fluoride) in 2 ml isopropyl alcohol (Sigma). Store up to several days at room temperature, or divide into aliquots and store up to several years at −20°C.

Sodium azide, 20%

Dissolve 20 g sodium azide (Sigma) in water to 100 ml. Store for several months at room temperature.

COMMENTARY

Background Information

The fibronectins have been important as substrates to promote the adhesion and culture of cells in vitro and also as model systems for investigating mechanisms of cell adhesive interactions (Hynes, 1990; Mosher, 1989; Aota and Yamada, 1995; Potts and Campbell, 1994; Akiyama et al., 1995). Fibronectin contains two distinct regions that independently promote cell adhesion by binding integrin cell surface receptors. For most cells, adhesion is mediated by the central cell-binding domain of fibronectin through an Arg-Gly-Asp (RGD) sequence and a Pro-His-Ser-Arg-Asn (PHSRN) sequence that can interact synergistically with the RGD sequence to bind the α5β1 integrin (Pierschbacher and Ruoslahti, 1984; Yamada and Kennedy, 1984; Aota et al., 1994). A sec-

ond, independent cell-adhesive region of fibronectin that is located in the alternatively spliced IIICS (or V) module (Kornblihtt et al., 1985) binds the α4β1 integrin. At least two nonadjacent peptide sequences within the IIICS module contain cell adhesive activity—a Leu-Asp-Val (LDV) sequence and an Arg-Glu-Asp-Val (REDV) sequence (Humphries et al., 1987; Kormoriya et al., 1991). Unlike the central RGD and PHSRN sequences, the LDV and REDV sequences do not act in synergy but appear to have an additive effect on cell adhesion, although the REDV is much less active (~1% that of the LDV sequence).

Fibronectin is commonly found in most tissues and body fluids, but it is most easily purified from plasma and from cultured cells. The presence of cell adhesive factors in plasma or serum has been known for a long time and the existence of plasma fibronectin, in particular, has been known for about 50 years, although it has gone by a number of names, most commonly "cold insoluble globulin" or CIg (Morrison et al., 1948). Due to its relatively high content of fibronectin in soluble form, plasma is the most convenient source. Plasma-derived fibronectin is dimeric, consisting of two similar, but nonidentical, subunits, and is highly soluble under physiological conditions and over a wide range of pH values and salt concentrations.

Fibronectin has a number of ligands including heparin, collagen, and fibrin, as well as cell surface receptors. It actually binds denatured collagen (gelatin) better than it does native collagen; therefore, virtually all protocols for purifying fibronectin rely on its affinity for gelatin as described by Engvall and Ruoslahti (1977). The method in Basic Protocol 1 was first described by Miekka et al. (1982). It uses a pH 5.5 buffer to specifically elute the bound fibronectin without causing its denaturation and without eluting other gelatin-binding plasma proteins. The elution of fibronectin using a citric acid buffer provides a number of advantages over earlier procedures that use urea elution, including eliminating a second affinity purification column, preventing the denaturation the fibronectin, and avoiding exposure of the fibronectin to urea, which can chemically modify the fibronectin or irreversibly change its conformation.

Cellular and plasma fibronectins are derived from alternatively spliced variants of the same gene (Kornblihtt et al., 1985). Cellular fibronectin contains up to three inserted sequences not present in all chains of plasma fibronectin. The functional differences between plasma and cellular fibronectins are most striking in assays that measure morphological effects on cells, with the latter being more effective in certain adhesion and cell morphology assays (Yamada and Olden, 1978, Hashimoto-Uoshima et al., 1997; Manabe et al., 1997).

A number of cultured cell types synthesize fibronectin, including fibroblasts, endothelial cells, epithelial cells, myoblasts, and chondrocytes (Hynes, 1973; Jaffe and Mosher, 1978; Yamada and Weston, 1974; Chen et al., 1977; Dessau et al., 1978; Furcht et al., 1978; Ruoslahti et al., 1973). Cell-derived fibronectin is usually retained on the cell surface as insoluble fibers, but it can also be released into the culture medium. Virtually all cultured cells that synthesize fibronectin can be used a source of this protein, either by direct extraction with urea or by harvesting the fibronectin released into culture medium. The abundance of cellular fibronectin on fibroblasts and the ease with which these cells are isolated and cultured made these the most convenient choice.

Critical Parameters and Troubleshooting

The preparation procedures for plasma and cellular fibronectin are relatively simple and require a minimum of equipment, all readily available. The most common problem with these procedures is low yield, which is most often caused by improper handling of the purified fibronectin. Other potential causes are poor starting material and failure of fibronectin to either bind to or elute efficiently from the affinity column.

Except where noted, all of the steps in the purification protocols for fibronectin are performed at room temperature (~22°C); it is therefore necessary to include sodium azide in all column buffers to inhibit microbial growth. The protein content of all fractions is determined by the absorbance at 280 nm (A_{280}) and should be confirmed by SDS-PAGE (*UNIT 6.1*) with either Coomassie blue R-250 or silver staining.

In most cases, the final products of these protocols are obtained at relatively low concentrations—usually ≤1 mg/ml. Ammonium sulfate precipitation followed by resolubilization of fibronectin in a small volume and dialysis is usually the best method for increasing its concentration. Because all forms of fibronectin tend to adsorb readily onto surfaces, the use of membrane-type centrifugal concentrators

(such as Centricons or Centri-preps) is not recommended. Fibronectins of all forms are also quite susceptible to proteolytic cleavage. Therefore, these protocols usually require the addition of the serine protease inhibitor phenylmethylsulfonyl fluoride (PMSF; see *APPENDIX 1B*). Solid PMSF is only slightly soluble and highly unstable when added to aqueous buffers, so it must be prepared as a 200 mM stock solution in isopropanol, which is then diluted into the aqueous buffer. PMSF dissolved in isopropanol is stable for several weeks at room temperature. However, PMSF is quite unstable in aqueous solution and, therefore, must be added to buffers immediately before use. All buffers containing PMSF that are not used within 20 min should be discarded.

Improper handling of fibronectin can arise from a number of sources, many of which are unintentional. Most low yields are the result of irreversible adsorption of the fibronectin onto the surfaces of tubes and beakers, and/or precipitation or clotting of the purified fibronectin. To insure maximal recovery of fibronectin, only polypropylene or siliconized glass beakers and tubes should be used. Agitation and other physical disturbances of the fibronectin should be avoided because such rough handling can cause denaturation of fibronectin at the air-liquid interface, aggregation, and precipitation. Fibronectin can also be lost due to improper handling during freezing and storage. In fact, small amounts of fibronectin are unavoidably lost during freezing and thawing. Fibronectin is best snap-frozen in powdered dry ice (for plasma-derived protein) or liquid nitrogen and stored at −80°C. Freezing at −20°C usually results in irreversible precipitation of the fibronectin, probably because slow freezing gives the protein a chance to aggregate in the liquid phase and form a clot during the time the solution is partially liquid as it cools. Fibronectin should be thawed rapidly at 37°C with no agitation. Storing fibronectin in liquid form at or near 0°C for a week or more is preferable to repeated freezing and thawing or freezing at −20°C.

Variations in starting material are almost unavoidable. Plasma and sera, whether from human or animal sources, will show individual variations in fibronectin content, even if collected in exactly the same manner. Cultured cells can vary in their fibronectin production and secretion, and yields usually decrease substantially as cells "age." Since the preparation of fibronectin requires only 1 to 2 days, it is usually not worth the time it takes to assay a fibronectin source prior to trying the purification protocol.

Fibronectin binds with high affinity to gelatin. Thus, low yields are rarely due to the fibronectin not binding to the affinity columns. When this does happen, it is usually because the affinity column is very old or has been stored improperly before use. The gelatin-Sepharose should always be stored near pH 7 in the presence of 0.05% sodium azide to retard microbial growth. Furthermore, although the gelatin is covalently bound to the beads, it can "bleed" off with time and repeated use, and it is susceptible to proteolysis by gelatinases in plasma. Thus, the urea prewash of the gelatin-Sepharose is a crucial step to remove gelatin fragments that can competitively inhibit fibronectin binding to the immobilized gelatin. It is also recommended that careful records be kept documenting the yield of a gelatin-Sepharose affinity column, and if a substantial drop in yields of consecutive preparations is noticed, the column should be discarded.

The most common cause of low yield is failure to elute the purified fibronectin efficiently off the gelatin-Sepharose affinity column. This is most likely due to small errors in the pH of the elution buffer. Citrate elution of fibronectin occurs because fibronectin binds poorly to gelatin at its isoelectric point. Thus, elution will not occur if the pH is either too high or too low. One way to avoid a total loss is always to elute the gelatin-Sepharose with 4 M urea following the citrate elution and collect these fractions as well. The urea-eluted fibronectin will be less pure than citrate-eluted material, but it will be useful for most cell culture purposes.

Cellular fibronectin is not very soluble at neutral pH and is best stored at pH 11. The solution can then be diluted into neutral buffers with no problems. Precautions should be taken to avoid exposing cellular fibronectin to air, and especially dry ice, for long periods of time, as carbon dioxide will eventually dissolve in the buffer, lowering its pH and precipitating the fibronectin.

Occasionally, the flow rate of the affinity column can become very slow. The most common cause is that the fibronectin has formed a "clot" at the top the affinity column, especially if the flow rate is too slow. If this happens, use a polypropylene rod to break up the top centimeter or so of the column bed, which should increase the flow rate.

The most commonly used alternative protocol for the purification of plasma fibronectin

involves the use of two affinity columns—one of gelatin and one of heparin—as described by Hayashi and Yamada (1983). In this protocol, plasma fibronectin is first bound to a gelatin-Sepharose column and eluted with 4 M urea. This material is immediately bound to a heparin-Sepharose column and washed with 4 M urea. The urea is then washed away and the purified fibronectin is eluted with 0.3 M sodium chloride. Although this protocol takes more than 50% longer, it yields fibronectin of higher purity at the expense of having exposed the fibronectin to denaturing conditions. The extra affinity column is worth the extra effort if extremely high-purity fibronectin is required. The specific cell adhesive activities of urea-eluted and citrate-eluted fibronectins are similar.

Anticipated Results

Basic Protocol 1 should yield 100 to 300 mg of fibronectin, which is usually a more-than-adequate amount for most uses. This material is usually of very high purity, and there should be no detectable impurities when it is analyzed by gel electrophoresis. This protocol has been optimized to promote efficient use of gelatin-Sepharose, and therefore specifies a relatively high plasma to affinity support ratio. If the fibronectin is to be purified from a particularly valuable plasma or serum sample, the column, wash and elution volumes can be doubled to increase (though not double) the yield.

It is much more difficult to predict yields of cellular fibronectin since these can depend on culture conditions, passage number of the cells, and cell type as well as the efficiency of the protocol. Low-passage-number human fibroblasts in ten 850-cm^2 tissue culture roller bottles should typically provide between 10 and 20 mg of cellular fibronectin.

The major impurity in preparations of cellular fibronectin is the extracellular protein tenascin-C. The level of contamination can be quite high, despite the use of great care. An early paper described the separation of tenascin from preparations of chicken cell surface fibronectin (Erickson and Iglesias, 1984). The gelatin-Sepharose affinity column chromotography step should separate the cellular fibronectin from tenascin because the latter protein does not bind to gelatin (Erickson, 1989; Lightner et al., 1988).

Time Considerations

All of these protocols take ≤1 day of actual hands-on time. Basic Protocol 1 will yield purified protein 2 to 3 days after starting. Usually the first ½ day is spent preparing buffers and packing and washing columns. The affinity purification steps are usually performed in one more day. Possible stopping points are noted in each protocol and, of course, the protocol can be stopped overnight or even over weekends at dialysis steps.

Purification of Vitronectin

BASIC PROTOCOL

The protocol described here has been successfully used to purify vitronectin from plasma or sera of a number of species. This method takes advantage of the observation that vitronectin must be activated or "opened" by denaturation before it can bind to heparin. Plasma or serum is first passed through a heparin-Sepharose column to remove fibronectin and other heparin-binding serum components. Then urea is added to the heparin-cleared plasma (or serum) to activate the heparin-binding activity of vitronectin. The activated vitronectin then binds to heparin-Sepharose and is eluted at very high purity.

As described here, this protocol assumes the starting material consists of 400 ml of citrate-anticoagulated human plasma, which should yield 10 to 20 mg of vitronectin of high (usually >98%) purity. A similar volume of human serum, or plasma or sera from other mammals, can also be used. This protocol can be easily scaled up by using correspondingly larger columns and buffer volumes.

NOTE: Only citrate-anticoagulated, not heparin-anticoagulated, plasma or serum should be used with this protocol. Because vitronectin binds to glass, any glassware to be used in this protocol should first be siliconized (see *APPENDIX 3*). Alternatively, use plastic—polypropylene, polycarbonate, or polyethylene—equipment (polypropylene is suggested throughout but the others may be used). Polystyrene is also acceptable and is better than glass.

CAUTION: When working with human blood cells or infection agents, appropriate biosafety practices must be followed. Even screened human plasma should be treated as if it is contaminated with HIV and hepatitis viruses. Always wear two layers of gloves, safety glasses or goggles, and suitable protective clothing. Keep a 10% bleach solution, Wescodyne, or Providone on hand at all times to use as an emergency disinfection agent in case of plasma spills or splashes.

Materials

Sepharose CL-4B (Amersham, Pharmacia Biotech)
Heparin-Sepharose (Amersham, Pharmacia Biotech)
Phosphate/saline/EDTA (see recipe)
2 M NaCl in phosphate/saline/EDTA (see recipe)
~400 ml (1 to 2 units) citrate-anticoagulated human plasma or serum
0.2 M EDTA, pH 7.0 (*APPENDIX 2A*)
0.2 M phenylmethanesulfonyl fluoride (PMSF; *UNIT 10.5*)
95% ethanol, ice cold
Ultrapure urea
8 M urea in phosphate/saline/EDTA (see recipe)
8 M urea/2 M NaCl in phosphate/saline/EDTA (see recipe)
2-Mercaptoethanol
8 M urea/0.3 M NaCl in phosphate/saline/EDTA (see recipe)
Dulbecco's phosphate-buffered saline (DPBS; *APPENDIX 2A*)

20- and 50-ml (minimum) 2.5-cm-diameter polypropylene or siliconized glass columns
600- and 1000-ml polypropylene beakers
Polypropylene centrifuge tubes
Whatman no. 2 filter paper
10-ml polypropylene tubes
Quartz spectrophotomer cuvettes siliconized with Aquasil (Pierce)
Dialysis tubing (12,000 to 14,000 MWCO)

Contributed by Steven K. Akiyama
Current Protocols in Cell Biology (1999) 10.6.1-10.6.5

Prepare columns

1. Prepare a 2.5-cm-diameter, 8-ml Sepharose CL-4B precolumn. Wash with 24 ml phosphate/saline/EDTA.

   Follow manufacturer's instructions to prepare Sepharose CL-48 and heparin-Sepharose. All column chromatography steps in this protocol are at room temperature.

2. Prepare a 2.5-cm-diameter, 20-ml heparin-Sepharose column at room temperature. Wash with 80 ml of 2 M NaCl in phosphate/saline/EDTA, then with 80 ml phosphate/saline/EDTA.

   The columns can be washed up to several days in advance and kept at room temperature if 0.02% sodium azide is added to the phosphate/saline/EDTA.

3. To 400 ml citrate-anticoagulated plasma or serum, add 2.5 ml of 0.2 M EDTA and 0.5 ml of 0.2 M PMSF with rapid stirring at 4°C.

4. If serum is being used as the starting material, proceed to step 5. If plasma is used, place it in a 600-ml polypropylene beaker packed in ice and gradually add 48 ml ice-cold 95% ethanol with stirring. Continue to stir for 10 min.

   This step precipitates fibrinogen in plasma.

5. Centrifuge the plasma or serum 10 min at 12,000 × *g*, 4°C. Discard the pellet.

6. Save the supernatant and filter through Whatman no. 2 filter paper at 4°C.

   This is a possible overnight stopping point. The filtrate should be stored at 4°C.

Remove heparin-binding proteins

7. Apply the filtered plasma, preequilibrated at room temperature, to the Sepharose CL-4B precolumn to remove any plasma components that nonspecifically bind to the beads. After all the plasma has passed through the column, wash the column with 20 ml phosphate/saline/EDTA and add the wash to the plasma.

8. Apply the pooled flowthrough and wash from step 7 to the heparin-Sepharose column. After all the plasma has passed through the heparin-Sepharose column, wash the column with 50 ml phosphate/saline/EDTA and add the wash to the plasma.

   At this point, the procedure can be stopped until the next day or the vitronectin can be purified immediately. If the vitronectin is not to be purified immediately, wash the heparin-Sepharose with 80 ml of 2 M NaCl in phosphate/saline/EDTA to remove heparinases or glycosidases that could degrade the beads, and store the column-treated plasma containing the vitronectin at 4°C overnight. The column can be stored at room temperature if 0.02% sodium azide is added to the 2 M NaCl.

   This step removes plasma components (such as fibronectin) that bind to heparin in their native form.

Activate the vitronectin

9. Place the plasma in a 1000-ml polypropylene beaker at room temperature and add 384 g ultrapure urea to the plasma with gentle stirring. Then dilute the plasma to a final volume of 800 ml with phosphate/saline/EDTA. Let stand 1 to 2 hr at room temperature.

   This step activates the vitronectin so that it can bind to heparin. The final urea concentration is 8 M.

10. While the urea-treated plasma is left to stand, wash the heparin-Sepharose column used in step 8 above with 120 ml of 8 M urea/2 M NaCl in phosphate/saline/EDTA, then with 120 ml of 8 M urea in phosphate/saline/EDTA.

Urea is unstable in aqueous solution at room temperature. Therefore, all urea-containing solutions must be prepared fresh each day and subsequently discarded if not used the same day they are prepared.

Affinity purify vitronectin

11. Apply urea-treated plasma from step 11 to the heparin-Sepharose column at a flow rate of ≤100 ml/hr.

    This step can proceed overnight as long as precautions are taken to ensure that the column will not dry out.

    If step 11 proceeds overnight, prepare fresh solutions of 8 M urea in phosphate/saline/EDTA (see recipe) and 8 M urea/0.3 M NaCl in phosphate/saline/EDTA (see recipe).

12. Wash the column with 400 ml of 8 M urea in phosphate/saline/EDTA.

13. Add 140 µl 2-mercaptoethanol to 200 ml of 8 M urea in phosphate/saline/EDTA.

14. Wash the column with 100 ml of 8 M urea in phosphate/saline/EDTA supplemented with 2-mercaptoethanol.

    If this washing step takes ≤1 hr, stop the column so that the total exposure of the column to 2-mercaptoethanol is at least 1 hr to ensure removal of contaminants sensitive to reduction. Longer times, up to overnight, can also be used.

    If step 14 proceeds overnight, prepare fresh solutions of 8 M urea in phosphate/saline/EDTA (see recipe) and 8 M urea/0.3 M NaCl in phosphate/saline/EDTA (see recipe).

15. Wash the column with another 100 ml of 8 M urea in phosphate/saline/EDTA supplemented with 2-mercaptoethanol.

    The minimal exposure time of the column to 2-mercaptoethanol should be 1 hr.

16. Wash the column with 100 ml of 8 M urea in phosphate/saline/EDTA without 2-mercaptoethanol.

17. Elute the vitronectin with 8 M urea/0.3 M NaCl in phosphate/saline/EDTA. Collect 10-ml fractions. Pool and save the fractions containing eluted vitronectin as judged by A_{280} measured in siliconized quartz cuvettes. Save fractions with $A_{280} > 0.05$.

    It is recommended that the fractions containing higher concentrations ($A_{280} > 0.5$) be kept separate from those containing lower concentrations.

Dialyze fractions

18. Dialyze the fractions with higher concentrations ($A_{280} > 0.5$) at 4°C for 3 days against 3.5 liters DPBS, changing the buffer each day. Dialyze the lower-concentration fractions at 4°C for 3 days against 3.5 liters 10% DPBS (1 vol DPBS diluted with 9 vol H_2O), changing the buffer each day.

19. Centrifuge 20 min at 12,000 × *g*, 4°C, to clarify the purified vitronectin. Collect the supernatant.

20. Measure the concentration of vitronectin.

    The fastest way to estimate the protein concentration is to measure the A_{280} and calculate the concentration assuming an extinction coefficient of 1.36 ml/mgcm.

21. Aliquot 50 or 100 µl vitronectin into separate polypropylene tubes and lyophilize. Label the tubes to indicate which buffer was used, the original volume, and the amount of vitronectin in each tube.

    When the tubes are reconstituted with deionized water, the tubes that contained vitronectin in 10% DPBS should be reconstituted to one-tenth the original volume to yield higher concentrations of vitronectin in full-strength DPBS. Reconstituted vitronectin can be sterilized by autoclaving, if necessary.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

2 M NaCl in phosphate/saline/EDTA

29.4 g NaCl
5 ml 0.5 M sodium phosphate, pH 7.7 (see recipe)
6.3 ml 0.2 M EDTA, pH 7.0 (*APPENDIX 2A*)
0.25 ml 20% (w/v) sodium azide (*UNIT 10.5*)
Deionized H_2O to 250 ml
Store several weeks at room temperature

Phosphate/saline/EDTA

7.6 g sodium chloride (130 mM final)
20 ml 0.5 M sodium phosphate, pH 7.7 (see recipe; 10 mM final)
25 ml 0.2 M EDTA, pH 7.0 (*APPENDIX 2A*; 5 mM final)
1 ml 20% (w/v) sodium azide (0.02% final; *UNIT 10.5*)
Deionized H_2O to 1000 ml
Store several weeks at room temperature.

Sodium phosphate, pH 7.7, 0.5 M

79.7 g $Na_2HPO_4 \cdot 12H_2O$
4.29 g $NaH_2PO_4 \cdot 2H_2O$
Deionized H_2O to 1000 ml

8 M urea in phosphate/saline/EDTA

480 g ultrapure urea
7.6 g sodium chloride
20 ml 0.5 M sodium phosphate, pH 7.7 (see recipe)
25 ml 0.2 M EDTA, pH 7.0 (*APPENDIX 2A*)
Deionized H_2O to 1000 ml

The shelf life of this solution is <1 day.
Deionized H_2O to 500 ml

8 M urea/2 M NaCl in phosphate/saline/EDTA

60 g ultrapure urea
14.7 g NaCl
2.5 ml 0.5 M sodium phosphate, pH 7.7 (see recipe)
3.2 ml 0.2 M EDTA, pH 7.0 (*APPENDIX 2A*)
Deionized H_2O to 125 ml

The shelf life of this solution is <1 day.

8 M urea/0.3 M NaCl in phosphate/saline/EDTA

96 g ultrapure urea
3.5 g NaCl
4 ml 0.5 M sodium phosphate, pH 7.7 (see recipe)
5 ml 0.2 M EDTA, pH 7.0 (*APPENDIX 2A*)
Deionized H_2O to 200 ml

The shelf life of this solution is <1 day.

COMMENTARY

Background Information

Vitronectin, also known as serum spreading factor, S-protein, and epibolin, is found primarily in blood at concentrations ranging from 100 to 400 μg/ml and in other biological fluids as well as tissues (Preissner, 1991). Vitronectin can appear as two species of similar size. Human vitronectin appears as distinct bands of 65 and 75 kDa under reducing conditions. The ratio of the two species can vary. Vitronectin contains an Arg-Gly-Asp sequence which, as is the case for fibronectin, functions as a cell-adhesive recognition signal for integrins. However, cellular vitronectin and fibronectin receptors are usually distinct. Cells usually adhere to fibronectin primarily through β1 integrins while adhering to vitronectin primarily through β3 integrins.

The protocol described here was first developed by Yatohgo et al. (1988) and has been successfully used to purify vitronectin from plasma or sera of a number of species. This protocol can generally be used across species lines. It represents a major improvement over earlier methods, which relied on the propensity of vitronectin to bind to glass and used up to four different affinity columns and required several days (Barnes and Silnutzer, 1983). The protocol described here takes advantage of the observation that vitronectin, unlike the fibronectin present in plasma, must be activated or opened with 8 M urea before it can bind to heparin. Thus, plasma components that bind specifically or nonspecifically to heparin or the Sepharose beads can be removed prior to vitronectin activation, enabling this protocol to yield vitronectin of extremely high purity.

Critical Parameters and Troubleshooting

Low yields of vitronectin can be due to analogous causes as low yields in affinity-purification of plasma fibronectin. For example, heparin-Sepharose columns tend to bleed ligand. Therefore, extensive prewashing of the affinity columns is very important. Also, care must be taken to use only citrate-anticoagulated plasma. If heparin-anticoagulated plasma is used, the heparin can competitively inhibit vitronectin binding to the affinity column, greatly reducing the yields. A recurring problem in this protocol is the slowing of column flows to distressingly low rates. Thus, if it is necessary to scale up this protocol, it is recommended that column volumes be increased by changing the column diameters, rather than heights. Columns often run well initially but eventually slow down. A faster flow rate can sometimes be reestablished by breaking up the "crust" of aggregated proteins that can form on the top of the affinity column. It may be necessary to disturb the top of the gel to a depth of 1 to 2 mm. Vitronectin was so named from its propensity to bind to glass. Therefore, only polypropylene or siliconized glass columns, beakers, and tubes should be allowed to contact the vitronectin in all steps. Using untreated glass materials in this protocol can result in much lower yields. Finally, vitronectin can be stored at −80°C without lyophilization, but it slowly loses activity over the course of a year or two.

Anticipated Results

The protocol described here should yield 10 to 20 mg of vitronectin of relatively high purity (usually >98%). Purity can be checked by SDS-PAGE (*UNIT 6.1*). Human vitronectin usually appears as a doublet of bands at 65 and 75 kDa.

Time Considerations

This protocol requires a total of 2 to 3 days. Hands on time is between 1 and 2 days. Convenient stopping points are indicated in the protocol.

Proteoglycan Isolation and Analysis

This unit describes specific methods for isolation and analysis of proteoglycans and glycosaminoglycans. These molecules can be difficult to work with due to their large size, high negative charge, and tendency to aggregate and form complexes with other molecules. This requires modification of standard protocols and protocols unique to proteoglycans. Proteoglycans vary in size from small (e.g., decorin ≈ 100 kDa) to very large (e.g., aggrecan ≈ 1×10^6 kDa). Proteoglycans are present in extracellular matrices (e.g., perlecan), linked to cell surfaces by phospholipid (e.g., glypicans), as transmembrane components (e.g., syndecans), and in intracellular granules in some cells (also see *UNIT 10.1*). As a class of molecules, they can be isolated and purified utilizing their glycosaminoglycan chains (e.g., by ion-exchange chromatography) or their core proteins (antibody-affinity chromatography). Their glycosaminoglycan content can be further analyzed by treatment with degradative enzymes followed by size-exclusion chromatography or SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*).

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following guidelines provided by the local radiation safety office (also see *APPENDIX 1D*).

NOTE: Even where chemical amounts of proteoglycan may be harvested, the addition of a trace of radiolabeled material aids in monitoring the purification process. In the absence of radiolabel, commercial assays based on the binding of 1,9-dimethylmethylene blue (a cationic dye) to sulfated glycosaminoglycans may be used to monitor isolation (e.g., Blyscan Glycosaminoglycan Assay, Biocolor; Accurate Chemical and Scientific).

ISOLATION AND PURIFICATION OF PROTEOGLYCANS

This group of protocols contains methods for isolating proteoglycans from cultured cells and for chromatographic purification.

Isolation of Proteoglycans from Cultured Cells

BASIC PROTOCOL 1

The following protocol is used to isolate proteoglycans from conditioned medium (soluble), as well as cell-associated proteoglycans (cell surface and intracellular) and proteoglycans in the extracellular matrix (insoluble). This is a general method applicable to all proteoglycans, as compared to Alternate Protocol 1, which is specifically designed to isolate different subcellular pools, especially those membrane-intercalated proteoglycans that act as links between the cytoskeleton and extracellular matrix. If only soluble proteoglycans are required, medium may be removed and new medium incubated with cells to increase yield.

Proteoglycans can be isolated from radiolabeled cultured cells. Since low yields are expected, particularly for some proteoglycans, the equivalent of five 10-cm-diameter culture dishes should be used for each experiment (8 ml medium/dish).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified, 37°C, 5% to 10% CO_2 incubator (depending upon medium) unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Materials

Radiolabeled cultured cells in 10-cm tissue culture dishes (see Support Protocol)
PBS (*APPENDIX 2A*)
Urea, ultrapure
Solubilization buffer (see recipe) with and without Triton X-100

1. Collect supernatant from radiolabeled cultured cells by decanting into a 50-ml conical centrifuge tube. Rinse cell layer twice with 4 ml PBS each time, and add washes to the tube.
2. Centrifuge supernatant 10 min at 800 × *g*, room temperature, to remove any cellular material.
3. Add solid urea to the supernatant to a final concentration of 4 M. Store supernatant at 4°C; do not freeze. Use for analysis as soon as possible.

   All further stages with supernatant proteoglycans may be performed without detergent present in the buffers. The authors' experience, however, is that losses are decreased by the presence of 0.1% (v/v) Triton X-100.
4. Wash cell layers twice with 20 ml PBS to remove excess free radiolabel.
5. Add 2 ml solubilization buffer to the dish and scrape cells loose. Transfer suspension to a 15-ml conical tube.

   Do not substitute Tween 20 for Triton, as this detergent is not as effective in solubilizing syndecans.
6. Rinse cell layer and scraper sequentially twice with 2 ml solubilization buffer and add these washes to the tube. Incubate 30 min on ice with occasional vigorous shaking.
7. Centrifuge 10 min at 800 × *g*, room temperature.

   The supernatant should appear clear. If it is not, continue shaking and incubating until particulates are no longer seen. Proteoglycans (especially syndecans) aggregate readily, and may form large complexes that can be pelleted at higher g force if not solubilized.
8. Decant supernatant into a 100-ml graduated cylinder and dilute 1:5 with solubilization buffer without Triton to reduce detergent to 0.2%.
9. Store at 4°C; do not freeze. Use for analysis as soon as possible.

ALTERNATE PROTOCOL 1

Isolation of Proteoglycan Pools

Proteoglycans can be found soluble in culture supernatant, incorporated into insoluble matrix, attached to the cell surface, or as transmembrane components, some of which may link between the cytoskeleton and extracellular matrix. Methods presented here are adapted from Woods et al. (1985).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified, 37°C, 5% to 10% CO_2 incubator (depending upon medium) unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Additional Materials *(also see Basic Protocol 1)*

Serum-free culture medium
Phosphatidylinositol-specific phospholipase C (PI-PLC; Boehringer Mannheim, Molecular Probes)
Lysis buffer (see recipe) with and without detergent

Isolate conditioned medium pool

1. Wash radiolabeled cultured cell monolayers twice with 20 ml PBS and incubate 1 hour at 37°C with serum-free culture medium containing 0.1 mU PI-PLC.

   This releases glycosylphosphotidylinositol (GPI)–linked proteoglycans (Schmidtchen et al., 1990).

2. Decant into a 15-ml conical centrifuge tube. Rinse cell layer twice with 2.5 ml serum-free medium without enzyme and add to tube.

3. Add solid urea to 4 M final, agitate to dissolve, and incubate on ice until used. Concentrate and purify (step 11) as soon as possible (within 24 hr).

Isolate lysate pool

4. Add 2 ml lysis buffer to the dish and incubate 15 min at 37°C.

5. Transfer lysate to a 15-ml conical tube, rinse cell layer twice with 1 ml lysis buffer, and add washes to the tube.

   If desired, lysates from up to three dishes can be pooled in a single 15-ml tube, and up to twelve can be combined in a 50-ml tube.

6. Add solid urea to 4 M and stir to dissolve.

7. Dilute 1:1 with lysis buffer without detergent to dilute detergent to 0.1%. Incubate on ice until used. Concentrate and purify (step 11) as soon as possible (within 24 hr).

   This is the "lysate" material, which will contain hydrophobic proteoglycans not retained due to linkage to cytoskeleton/matrix, and proteoglycans undergoing degradation or synthesis. Cell layers will lose phase density, but nuclei and stress fibers should remain.

Isolate cytoskeletal/matrix pool

8. Rinse dish three times with 20 ml PBS, 4°C.

9. Add 1 ml solubilization buffer and scrape cell remnants into the solution.

10. Dilute 1:10 with solubilization buffer without detergent to dilute detergent to 0.1%. Incubate on ice until used. Concentrate and purify (step 11) as soon as possible (within 24 hr).

    This is the cytoskeletal/matrix fraction, which will contain hydrophobic proteoglycans linked to the cytoskeleton/matrix, as well as matrix proteoglycans.

Concentrate and purify pools

11. Concentrate and purify all three samples by DEAE-Sephacel chromatography (see Basic Protocol 2).

    The steps above all contain protease inhibitors in the buffers because cell lysis is occurring. However, it is essential to perform anionic-exchange chromatography directly after isolation of the three pools, or proteolysis will still occur.

Radiolabeling of Proteoglycans with $^{35}SO_4$ or [^{3}H]Glucosamine

SUPPORT PROTOCOL

Because glycosaminoglycan chains (except hyaluronan) are usually highly sulfated, they can be metabolically labeled with $^{35}SO_4$. This is done by adding 40 µCi/ml $H_2{}^{35}SO_4$ (1050 to 1600 Ci/mmol; NEN Life Sciences) to the medium when seeding the cells, and allowing the cells to grow until just subconfluent (e.g., 95%). Sulfate-free medium should not be used, as it does not appear to increase incorporation of radiolabel, perhaps because sulfate becomes limiting. Streptomycin sulfate should not be used as an antibiotic in the medium, as this increases the level of unlabeled sulfate. If supernatant is not needed for analysis, it can be decanted at cell harvest and reused for labeling additional cells.

Glucosamine derivatives are readily incorporated into glycosaminoglycans, so [^{3}H]glucosamine (40 to 60 Ci/mmol; Amersham) can be used to radiolabel proteoglycans and hyaluronan. This is done by adding 10 μCi/ml [^{3}H]glucosamine at seeding and then growing cells to confluency.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified, 37°C, 5% to 10% CO_2 (depending upon medium) incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

BASIC PROTOCOL 2

Anion-Exchange Chromatography Purification of Proteoglycans with DEAE-Sephacel

Anion-exchange chromatography is used to purify proteoglycans from conditioned medium or cells (Basic Protocol 1) or the isolated subcellular fractions (Alternate Protocol 1). Due to the high negative charge of the glycosaminoglycan chains, proteoglycans bind with higher affinity to DEAE than do most other cellular components.

Materials

Proteoglycan samples (see Basic Protocol 1 or Alternate Protocol 1)
Diethylaminoethyl (DEAE)–Sephacel: 50:50 (v/v) slurry in PBS
PBS (*APPENDIX 2A*)
DEAE-Sephacel equilibration buffer (see recipe)
Conditioned medium from cell line of interest, incubated with cells 24 to 48 hr
DEAE low-pH buffer (see recipe)
DEAE elution buffer (see recipe)
2 × 0.5–cm minicolumns

1. Prepare DEAE-Sephacel in 2 × 0.5–cm minicolumns with ~2 to 3 ml gel bed by adding a 50:50 slurry of DEAE-Sephacel in PBS.

   This is sufficient for isolation of proteoglycans from the equivalent of five 75-cm^2 tissue culture flasks. For larger amounts of material—e.g., from 0.5 to 10 liters of culture supernatants—use 5 to 10 ml gel volume per liter.

2. Attach inlet tubing to the top of the column. Place tubing in a PBS container and wash column with 10 column vol PBS using gravity or a pump at 16 ml/hr.

   An economic system for minicolumns is to place two syringe needles (18-G) through a rubber bung. Break one needle at the metal/plastic junction and attach tubing. Place a syringe on the other needle and use this to remove air and pull liquid down the tubing into the column. For smaller volumes, a reservoir can be inserted at the column mouth.

3. Equilibrate the column with 2 column vol DEAE-Sephacel equilibration buffer.

4. Condition the column by loading 20 ml conditioned medium from the cell line being used onto the column as in step 2, using a reservoir or tubing from a suitable container.

5. Wash the column twice with 5 ml each DEAE-Sephacel equilibration buffer.

6. Wash the column twice with 5 ml each DEAE low-pH buffer.

   Since this step removes most material other than proteoglycans, a less stringent protease inhibitor cocktail (i.e., lacking ε-aminocaproic acid and benzamidine·Cl) can be used in the low-pH and elution buffers.

7. Wash the column twice with 5 ml each DEAE elution buffer.

8. Reequilibrate as in step 3.
9. Load the proteoglycan sample onto the column. If a large volume is to be used, perform at 4°C.
10. Repeat washes in steps 5 and 6.
11. Elute the column with ten 1-ml aliquots of DEAE elution buffer.

    Typically the proteoglycans begin to elute after 0.5 ml and are fully eluted by 10 ml. A solution of 4 M guanididium·Cl can be used instead of high salt if the proteoglycan is to be concentrated by ethanol precipitation. If so, urea, salts, EDTA, NEM, and PMSF should be removed by washing with DEAE low-pH buffer without these ingredients.

12. Monitor elution by radiolabel if metabolically labeled, or by dye-binding assay (see unit introduction) if not. Combine fractions containing proteoglycans and store at 4°C. Do not freeze.

    DEAE-Sephacel columns can be reused indefinitely. The top 1 to 2 mm of gel can be discarded before reuse if it becomes heavily contaminated (grey in color). Columns should be stored upright at 4°C in equilibration buffer containing 0.02% (w/v) sodium azide. Rinse columns with two volumes equilibration buffer prior to use. If stored long-term (6 months), recondition as in steps 4 to 8 prior to use.

    Isolated proteoglycans can be dialyzed into new buffers or concentrated by precipitation and resuspended in the buffer of choice. For details, see Basic Protocol 4, steps 1a and 1b.

Isolation of Hydrophobic Proteoglycans

ALTERNATE PROTOCOL 2

This protocol is used to specifically isolate membrane-intercalated proteoglycans by virtue of their hydrophobic properties. It is used after Basic Protocol 2, which isolated all proteoglycans irrespective of hydrophobicity/hydrophilicity. Hydrophobic proteoglycans from Basic Protocol 2 have Triton associated with their core proteins. In the first part of this procedure, a cholate-containing buffer is used on the DEAE-Sephacel column (from Basic Protocol 2) to exchange Triton for cholate. This weaker detergent then allows binding of the hydrophobic proteoglycans to a purifying column of octyl-Sepharose.

Additional Materials *(also see Basic Protocol 2)*

DEAE-Sephacel eluate and column, *or* column loaded for elution (see Basic Protocol 2)
DEAE low-pH buffer (see recipe) without NaCl
Hydrophobic chromatography equilibration buffer (see recipe)
Hydrophobic chromatography exchange buffer (see recipe)
Hydrophobic chromatography washing buffer (see recipe)
Hydrophobic chromatography elution buffer (see recipe)
Octyl-Sepharose (Pharmacia): 50:50 (v/v) slurry in PBS containing 0.1% Triton X-100
0.1% (v/v) Triton X-100
Octyl-Sepharose equilibration buffer (see recipe) with and without NaCl
Octyl-Sepharose washing buffer (see recipe)
Octyl-Sepharose elution buffer I (see recipe)
Octyl-Sepharose elution buffer II (see recipe)
Minicolumn

Exchange detergent

1. Dilute DEAE-Sephacel eluate 1:10 (v/v) with DEAE low-pH buffer without NaCl to give a final NaCl concentration of 0.2 M.

2. Reequilibrate the DEAE-Sephacel column with 2 column vol hydrophobic chromatography equilibration buffer.

   The column is reequilibrated to increase the pH, and thus prevent precipitation of cholate.

3. Apply diluted eluate to the reequilibrated column.

   Alternately, start exchange while proteoglycans remain on DEAE-Sephacel (following step 10 of Basic Protocol 2). Rinse the column with hydrophobic chromatography equilibration buffer to increase pH, and then proceed with step 4 below.

4. Exchange proteoglycan-bound Triton with cholate by slowly passing 100 ml hydrophobic chromatography exchange buffer over the column.

   This is a slow process of exchange and is best achieved using gravity rather than a pump. The column will turn a brown color due to bound detergent.

5. Wash column with 10 ml hydrophobic chromatography washing buffer.

6. Elute with 20 ml hydrophobic chromatography elution buffer, collecting 1-ml fractions.

7. Monitor fractions by counts or dye binding (see unit introduction), and combine fractions that contain proteoglycans.

   The most concentrated fractions will be brown. These are typically fractions 1 to 5.

Purify hydrophobic proteoglycans

8. Prepare a minicolumn of octyl-Sepharose with a bed volume of 3 to 4 ml by adding 6 to 8 ml of 50:50 slurry in PBS containing 0.1% Triton X-100.

9. Wash with 20 ml of 0.1% Triton X-100 to remove ethanol, and then with 100 ml octyl-Sepharose equilibration buffer to remove Triton.

   This column is sufficient for analysis or isolation of 10,000 to 100,000 cpm hydrophobic proteoglycans from lysate or cytoskeletal/matrix pool (Alternate Protocol 1) purified by DEAE-Sephacel (Basic Protocol 2). Individual eluate fractions or pooled fractions may be used.

10. Dilute combined fractions (step 7) to 0.6 M NaCl with octyl-Sepharose equilibration buffer without NaCl, and add to octyl-Sepharose column. Incubate overnight at 4°C.

    The most efficient binding is achieved by allowing liquid above the column to drain, then adding 0.5 to 1.0 ml sample and allowing this to drain into the column before closing the column.

11. Wash column with twenty 1-ml aliquots of octyl-Sepharose washing buffer to remove cholate.

12. Wash column with twenty 1-ml aliquots of octyl-Sepharose elution buffer I to remove any material bound by ionic interactions.

13. Elute hydrophobic proteoglycans with twenty 1-ml aliquots of octyl-Sepharose elution buffer II, collecting 1-ml fractions.

    During this procedure the octyl-Sepharose will swell and shrink. This is normal.

    Following concentration by hydrophobic chromatography, proteoglycans may be highly aggregated. This is not reversed by boiling.

14. Use as soon as possible.

    If necessary, samples can be stored at 4°C, but not for more than 2 to 3 days. Samples should not be frozen.

ANALYSIS OF PROTEOGLYCANS

Analysis of proteoglycans can be very complex. This group of protocols contains methods for analyzing the size and composition of protoglycans isolated from cultured cells.

Analysis of Proteoglycans by Size-Exclusion Chromatography

BASIC PROTOCOL 3

Since proteoglycans are large and bear highly charged glycosaminoglycan chains, they often do not enter SDS-PAGE gels. One method of analysis is size-exclusion chromatography on Sepharose 4B (also see *UNIT 5.5*; Table 5.5.2). This procedure can be used for samples from Basic Protocol 2 or Alternate Protocol 2, or following immunoprecipitation (Basic Protocol 10). It is not suitable for unpurified samples (Basic Protocol 1 or Alternate Protocol 1), as high levels of unincorporated radiolabel may present a containment problem, and radiolabeled components other than proteoglycans will complicate the results obtained.

Materials

Sepharose 4B (Pharmacia)
SEC running buffer (see recipe)
Proteoglycan sample (see above)
Stock dye solution: 1 mg/ml each blue dextran (Sigma) and *N*-2,4-dinitrophenyl (DNP)–alanine (Sigma)

90 × 1–cm column
Column pump

1. Prepare a 90 × 1–cm column containing a 70-ml bed volume of Sepharose 4B according to the manufacturer's instructions. Pack the column at 9 ml/hr with SEC running buffer.
2. Decrease the rate to 6 ml/hr.

   This rate should be used for analysis to prevent collapse of the column.
3. Remove cap from the column and allow liquid to flow until the top of the gel is just dry. Add a maximum of 1 ml proteoglycan sample to be analyzed.

   For analytical purposes 8,000 to 10,000 cpm should be used.
4. Allow sample to enter gel, then rinse the top of the gel by adding 2 ml SEC running buffer and directly removing it.

   Failure to rinse will result in smearing of sample through the gel.
5. Replace cap and run column pump at 6 ml/hr. Collect 80 1-ml fractions and monitor content by radiolabel or dye-binding assay (see unit introduction).
6. Determine void volume (V_0; excluded volume) and total volume (V_t; total included volume) either by coelution (200 µl mixed dye in 800 µl sample) of a mixture of blue dextran (high molecular weight; totally excluded) and DNP-alanine (low molecular weight; totally included), or based on comparison with a previous run containing these dyes.

   V_0 is the volume at which blue dextran elutes (peak of blue color), and V_t is the volume at which DNP-alanine elutes (last fraction containing yellow color).

   See UNIT 5.5 for details on calibration with markers from a separate run.
7. Determine relative elution (K_{av}) using the equation $K_{av} = (V_s - V_0)/(V_t - V_0)$, where V_s is the elution volume of fractions where proteoglycans have peaks.

If HPLC equipment is available, a TSK 4000 column (TosoHaas) can be used to monitor proteoglycans. However, losses can be large if a prefilter is used, since many proteoglycans will tend to bind nonspecifically to the prefilter.

BASIC PROTOCOL 4

Analysis of Glycosaminoglycan Size Following Alkaline Elimination

Free glycosaminoglycan (GAG) chains can be obtained by alkaline elimination (here) or treatment with papain (see Basic Protocol 5) to destroy the core protein. Alkaline elimination removes all protein, leaving free intact glycosaminoglycans.

Materials

Proteoglycan sample (see Alternate Protocol 2 or obtain by immunoprecipitation)
Ethanol (optional)
1 M NaOH/2 M $NaBH_4$
10 M acetic acid
Dialysis tubing, MWCO 12-12,000 (optional)

1a. *For dialysis:* Transfer proteoglycan sample to distilled water by dialyzing against three changes of 100 vol water over 24 hr at 4°C. Use dialysis tubing with a MWCO of 12-12,000.

1b. *For precipitation:* Precipitate proteoglycan sample with 4 vol of 80% ethanol at −20°C, wash with 80% ethanol, and air dry. Resuspend in 0 to 5 ml distilled water.

2. Add an equal volume of 1 M NaOH/2 M $NaBH_4$. Incubate 16 hr at 4°C.

3. Neutralize with 10 M acetic acid, checking with pH paper until pH ≈ 7.

4. Reprecipitate with ethanol, if required to reconcentrate. Solubilize in water.

5. Analyze GAG size directly by size-exclusion chromatography (see Basic Protocol 3; *UNIT 5.5*) or HPLC.

NOTE: *If samples are not neutralized (step 3), analytical columns will be ruined.*

BASIC PROTOCOL 5

Analysis of Glycosaminoglycan Size Following Papain Digestion

Papain digestion degrades protein cores, leaving intact glycosaminoglycans. It requires no neutralization step.

Materials

Proteoglycan sample (see Alternate Protocol 2 or obtain by immunoprecipitation)
Papain digestion buffer (see recipe)
20 mg/ml papain (Sigma)
65°C water bath

Additional reagents and equipment for dialysis or ethanol precipitation (see Basic Protocol 4)

1. Transfer proteoglycan sample to papain digestion buffer (see Basic Protocol 4, step 1a or 1b).

2. Incubate with 2 mg/ml papain for 16 hr at 65°C.

3. Analyze GAG size directly by size-exclusion chromatography (see Basic Protocol 3; *UNIT 5.5*) or HPLC.

No enzyme inactivation is required.

Analysis of Glycosaminoglycan Content and Protein Core by GAG Degradation with Lyases

This analysis relies on the use of enzymes to selectively degrade glycosaminoglycans. Heparinase III will degrade heparan sulfate glycosaminoglycans. Chondroitinase ABC lyase will degrade all forms of chondroitin and dermatan sulfate glycosaminoglycans. Chondroitinase ACII lyase will degrade chondroitin but not dermatan sulfate glycosaminoglycans. Chondroitin B lyase will degrade dermatan sulfate. Each enzyme has different requirements and may not have maximum activity in the same buffer, but the heparinase III buffer listed below appears to work sufficiently well for most analyses if only core proteins are to be analyzed. Ovomucoid (Sigma) may be added at 100 µg/ml to prevent proteolysis of the protein core. These core treatments leave an intact case protein (unlike Basic Protocols 4 and 5), which can then be analyzed.

Materials

Proteoglycan sample (see Alternate Protocol 2 or obtain by immunoprecipitation)
Chondroitinase buffer (see recipe)
Heparinase III buffer (see recipe)
Chondroitin sulfate type C or B (chondroitin 6-sulfate or dermatan sulfate; Sigma)
Chondroitinase ABC (EC 4.2.2.4), ACII (EC 4.2.2.5), or B (no EC number) (Seikagaku America)
Heparinase III (a.k.a. heparitinase or heparitinase I; EC 4.2.2.8; Seikagaku America)
Additional reagents and equipment for dialysis or ethanol precipitation (see Basic Protocol 4)

For treatment with chondroitinases:

1a. Transfer proteoglycan sample to chondroitinase buffer (see Basic Protocol 4, step 1a or 1b).

Sample volumes depend on the proteoglycan concentration in the sample and the future method of analysis. For immunoblotting, a minimum volume is needed (i.e., resuspend precipitated sample from Basic Protocol 4, step 1b, in 50 to 200 µl of appropriate buffer). For SEC or HPLC, use 0.1 to 0.5 ml (≥2000 cpm if radiolabeled).

Since chemical amounts of isolated proteoglycans are usually small (µg levels), the amounts of carrier and enzyme do not need to be varied.

If performing dual digests with chondroitinases and heparinase, use heparinase III buffer. Chondroitinase B is inhibited by phosphate.

2a. Add ~2 µg chondroitin sulfate type C as carrier for chondroitinase ABC or ACII, or type B for chondroitinase B.

This increases the efficiency of digestion and recovery if low amounts of material (e.g., radiolabeled preparations) are used.

3a. Add 0.5 to 1 mU chondroitinase ABC, ACII, or B and incubate at 37°C.

Incubation times depend on the amount of proteoglycan present. For up to ~10 µg proteoglycan, an incubation of 2 to 3 hr should suffice; where amounts are higher, adding a second aliquot of enzyme for a further 2 hr may be needed.

4a. Monitor glycosaminoglycan digestion by size-exclusion chromatography (see Basic Protocol 3) or HPLC (degraded material will now elute in the V_t), or by immunoblotting (see Basic Protocol 8).

For treatment with heparinase III:

1b. Transfer proteoglycan sample to heparinase III buffer (see Basic Protocol 4, step 1a or 1b).

Sample volumes depend on the proteoglycan concentration in the sample and the future method of analysis. For immunoblotting, a minimum volume is needed (i.e., resuspend precipitated sample from Basic Protocol 4, step 1b, in 50 to 200 µl of appropriate buffer). For SEC or HPLC, use 0.1 to 0.5 ml (≥2000 cpm if radiolabeled).

Since chemical amounts of isolated proteoglycans are usually small (µg levels), the amounts of carrier and enzyme do not need to be varied.

2b. Add 2 to 5 µg heparan sulfate as carrier if low amounts of proteoglycan are present.

Do not add heparan sulfate if also digesting with chondroitinases. The products of heparan sulfate lyases are slightly inhibitory to chondroitinases. Dual digestions may, therefore, not be as efficient as separate incubations.

3b. Add 1 to 2 mU heparinase III and incubate at 37°C.

Time of incubation varies as indicated for chondroitinase treatment.

4b. Monitor glycosaminoglycan digestion by size-exclusion chromatography (see Basic Protocol 3) or HPLC (degraded material will now elute in the V_t), or by immunoblotting (see Basic Protocol 8).

BASIC PROTOCOL 7

Treatment with Nitrous Acid to Degrade Heparan Sulfate

Nitrous acid will degrade heparan sulfate glycosaminoglycans.

CAUTION: This procedure must be performed in a chemical fume hood, since nitrosamines are released.

Materials

1 N H_2SO_4
0.114 g/ml $Ba(NO_2)_2$
Proteoglycan sample (see Alternate Protocol 2 or obtain by immunoprecipitation)
10 N NaOH

1. Mix 1 ml of 1 N H_2SO_4 (0.5 mmol) with 1 ml of 0.114 g/ml $Ba(NO_2)_2$ on ice for 10 min, shaking occasionally.
2. Remove $BaSO_4$ precipitate by centrifuging 2 min at 500 × *g*, 4°C. Save the supernatant.

   The supernatant is nitrous acid at pH 1.5. This is stable for a few hours on ice.
3. Mix sample and nitrous acid at a 1:4 (v/v) ratio and leave 2 hr on ice.

   The proteoglycan sample should be unbuffered, preferably in water.
4. Neutralize with 10 N NaOH to a pH of ≈7, checking with pH paper.
5. Monitor heparan sulfate digestion by size-exclusion chromatography (see Basic Protocol 3) or HPLC (degraded material will now elute in the V_t), or by immunoblotting (see Basic Protocol 8).

   NOTE: *If samples are not neutralized (step 4), analytical columns will be ruined.*

Analysis of GAG Type and Core Protein

BASIC PROTOCOL 8

SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*) using standard procedures can be used to analyze GAG type and identify the core protein. These procedures can be used for analysis of whole cells or conditioned medium without proteoglycan isolation and purification, or they can be used on purified proteoglycans. Commercial antibodies are available for detection of carbohydrate "stubs" created on protein cores by lyase treatment. Monoclonal antibodies are available (Seikagaku America) against digested heparan sulfate (Δ heparan sulfate) and digested GAGs that had contained chondroitin sulfate that was nonsulfated (Δ di-0S) or was sulfated at the 4 or 6 position on galactosamine residues (Δ di-4S or Δ di-6S). These will detect all protein cores that had these specific saccharides. Specific proteoglycans can also be detected by core protein–specific antibodies. The appearance of a discrete polypeptide by SDS-PAGE analysis, representing the core protein, with a concomitant reduction in a high-molecular-weight smear characteristic of intact proteoglycans following treatment with specific lyases, determines which type of GAG was present on the protein core.

Nitrocellulose membranes may be used for immunoblotting, but intact proteoglycans will transfer poorly. Since this method relies on resolution of deglycanated core proteins following enzyme digestions, poor transfer of intact proteoglycan may not be important. Cationic membranes can, however, be used to capture intact proteoglycans more efficiently.

Size-exclusion chromatography of radiolabeled proteoglycans can also be used to analyze the composition of proteoglycans. Intact GAGs will elute in the V_0 of a Sephadex G-50 column, whereas disaccharides released by enzyme treatment will elute at or close to the V_t. Differential treatment susceptibility indicates the type (and relative amounts) of GAG in the sample. If HPLC is available, a TSK 4000 HPLC column (TosoHaas) column may be used.

Analysis of GAG Size

BASIC PROTOCOL 9

This is most easily performed using HPLC, but Sephadex G-200, Sepharose CL-6B, or equivalent resins may be used if HPLC is not available.

Materials

HPLC running buffer (see recipe)
Proteoglycan sample, enzymatically or chemically treated (see Basic Protocols 4 and 5)
DEAE-Sephacel column (see Basic Protocol 2)
PD-10 gel-filtration column (Amersham Pharmacia Biotech)
High-performance liquid chromatograph (HPLC) with TSK 4000 column (TosoHaas)

1. Isolate intact GAG chains from intact proteoglycans following treatments as above (see Basic Protocols 4 and 5), using anion-exchange chromatography on DEAE-Sephacel columns (see Basic Protocol 2).
2. Desalt samples on a PD-10 gel-filtration column according to manufacturer's instructions, using distilled water as buffer, and lyophilize.
3. Equilibrate a TSK 4000 HPLC column with HPLC running buffer.
4. Solubilize sample in HPLC running buffer. Load 100 to 500 µl sample and elute at a flow rate of 0.5 ml/min. Collect 0.5-ml fractions.

Isolated glycosaminoglycans do not bind the prefilter.

5. Assay fractions for radioactivity or dye binding (see unit introduction).

An alternate HPLC running buffer (see recipe) containing 4 M guanidium·Cl may be used to prevent self-association of GAGs.

GAG standards of known size should be used, since globular proteins are inappropriate for calibration.

BASIC PROTOCOL 10

Immunoprecipitation of Proteoglycans

Although some matrix proteoglycans can be immunoprecipitated by standard methods (*UNIT 7.2*), there are some specific problems. First, hydrophobic proteoglycans can be a problem, especially if analysis of associated components is required (Oh et al., 1997). The type of detergent used may result in differences in co-immunoprecipitation, as seen in studies with other membrane receptors (Serru et al., 1999). Second, GAG chains may limit accessibility of antibodies against core proteins. Use of a primary and secondary antibody, followed by immobilized protein A, may improve yield. Alternatively, GAG chains may be removed enzymatically prior to immunoprecipitation. Some proteoglycans may aggregate after GAG removal, resulting in precipitation.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Alternate HPLC running buffer

382.12 g guanidine·Cl (4 M final)
6.05 g Tris base (50 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 6.0 with 1 M HCl
Add 5 ml Triton X-100 (0.5% v/v final)
Add H_2O to 1 liter
Store up to 1 month at 4°C

Chondroitinase buffer

6.05 g Tris acetate (50 mM final)
4.08 g sodium acetate (30 mM final)
0.1 g bovine serum albumin (BSA; 0.1 mg/ml final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 8.0 with 1 M acetic acid
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add 1 ml Triton X-100 (for hydrophobic proteoglycans; 0.1% v/v final)
Stir slowly until Triton is dissolved
Add H_2O to 1 liter
Store up to 1 week at 4°C

DEAE elution buffer

87.66 NaCl (1.5 M final)
4.102 g sodium acetate (50 mM final)
240 g urea (4 M final)

continued

1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 4.0 with 1 M acetic acid
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add 1 ml Triton X-100 (0.1% v/v final)
Stir slowly until Triton is dissolved
Add H_2O to 1 liter
Store up to 1 week at 4°C

DEAE low-pH buffer

11.69 g NaCl (0.2 M final)
4.102 g sodium acetate (50 mM final)
240 g urea (4 M final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 4.0 with 1 M acetic acid
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add 1 ml Triton X-100 (0.1% v/v final)
Stir slowly until Triton is dissolved
Add H_2O to 1 liter
Store up to 1 week at 4°C

DEAE-Sephacel equilibration buffer

11.69 g NaCl (0.2 M final)
50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
240 g urea (4 M final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
0.783 g benzamidine·Cl (5 mM final)
13.12 g ε-aminocaproic acid (0.1 M final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 8.0 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add 1 ml Triton X-100 (0.1% v/v final)
Stir slowly until Triton is dissolved
Add H_2O to 1 liter
Store up to 1 week at 4°C

Heparinase III buffer

1.36 g sodium acetate (0.1 M final)
0.000158 g calcium acetate (0.01 mM final)
1 g ovalbumin (1% w/v final)
0.005 g leupeptin (50 µg/ml final)
0.0157 g benzamidine·Cl (1 mM final)
H_2O to 90 ml

continued

Adjust pH to 7.0 with 1 M acetic acid
Add 100 µl 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add 100 µl Triton X-100 (for hydrophobic proteoglycans; 0.1% v/v final)
Stir slowly until Triton is dissolved
Add H_2O to 100 ml
Store up to 2 days at 4°C

HPLC running buffer

13.6 g KH_2PO_4 buffer, pH 6.0 (0.1 M final)
29.2 g NaCl (0.5 M final)
2 g Zwittergent (Aldrich; 0.2% w/v final)
H_2O to 1 liter
Store up to 1 month at 4°C

Hydrophobic chromatography elution buffer

4 g sodium cholate (0.4% w/v final)
175.2 g NaCl (3 M final)
2.422 g Tris base (20 mM final)
1.25 *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.3 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add H_2O to 1 liter
Store up to 1 week at 4°C

Hydrophobic chromatography equilibration buffer

5.84 g NaCl (0.1 M final)
2.422 g Tris base (20 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.3 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add H_2O to 1 liter
Store up to 1 week at 4°C

Hydrophobic chromatography exchange buffer

20 g sodium cholate (2% w/v final)
2.422 g Tris base (20 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.3 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add H_2O to 1 liter
Store up to 1 week at 4°C

Hydrophobic chromatography washing buffer

4 g sodium cholate (0.4% w/v final)
2.422 g Tris base (20 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.3 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add H_2O to 1 liter
Store up to 1 week at 4°C

Lysis buffer

3.03 g Tris base (25 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
0.783 g benzamidine·Cl (5 mM final)
13.12 g ε-aminocaproic acid (0.1 M final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.5 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add 2 ml Triton X-100 (0.2% v/v final)
Stir slowly to dissolve Triton
Add H_2O to 1 liter
Prepare fresh just prior to use

Octyl-Sepharose elution buffer I

Prepare as for octyl-Sepharose washing buffer (see recipe), but adjust NaCl to 3 M final.

Octyl-Sepharose elution buffer II

175.2 g NaCl (3 M final)
2.422 g Tris base (20 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.3 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add 10 ml Triton X-100 (1% v/v final)
Stir slowly to dissolve Triton
Add H_2O to 1 liter
Store up to 1 week at 4°C

Octyl-Sepharose equilibration buffer

4 g sodium cholate (0.4% w/v final)
35.04 NaCl (0.6 M final)
2.422 g Tris base (20 mM final)
1.25 g *N*-ethylmaleimide (10 mM final)

continued

7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.3 with 1 M HCl
Add 1 ml 20 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add H_2O to 1 liter
Store up to 1 week at 4°C

Octyl-Sepharose washing buffer

5.84 g NaCl (0.1 M final)
2.422 g Tris base (20 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.3 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add H_2O to 1 liter
Store up to 1 week at 4°C

Papain digestion buffer

11.69 g NaCl (2 M final)
0.744 g EDTA (10 mM final)
0.4102 g sodium acetate (50 mM final)
0.0175 g cysteine·Cl (0.01 M final)
H_2O to 90 ml
Adjust pH to 5.5 with 1 M acetic acid
H_2O to 100 ml
Prepare fresh just prior to use

Size-exclusion chromatography (SEC) running buffer

1 g SDS (0.1% w/v final)
20.47 g NaCl (0.35 M final)
6.06 g Tris base (50 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 8.0 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
Add H_2O to 1 liter
Store up to 2 weeks at room temperature

Solubilization buffer

10 ml Triton X-100 (1% v/v final)
240 g urea (4 M final)
3.03 g Tris base (25 mM final)
1.25 g *N*-ethylmaleimide (NEM; 10 mM final)
7.44 g EDTA (20 mM final)
0.783 g benzamidine·Cl (5 mM final)

continued

13.12 g ε-aminocaproic acid (0.1 M final)
H_2O to 900 ml
Heat to dissolve
Adjust to pH 7.5 with 1 M HCl
Add 1 ml 0.2 M phenylmethylsulfonyl fluoride (PMSF) in ethanol while rapidly vortexing to prevent precipitation (0.2 mM final)
H_2O to 1 liter
Store up to 1 day at 4°C

COMMENTARY

Background Information

The analysis of proteoglycans has always been a specialized field due to the complexity of these molecules and their interactions with other molecules. Until relatively recently, it was only possible to isolate proteoglycans via the binding of their glycosaminoglycan chains to cationic matrices. Now, as core proteins are identified and characterized, antibody affinity chromatography can be used to purify individual proteoglycan species for analysis. However, analysis of glycosaminoglycans attached to the individual core proteins is still a tedious task, because the biological activity may depend on the fine structure of the glycosaminoglycan chains as well as the distinct core proteins. The glycosaminoglycan chain type can be readily identified by the use of selective enzyme degradation as detailed here. However, determining the fine structure of glycosaminoglycan chains—particularly the patterns of epimerization and sulfation of, for example, heparan sulfate chains—relies on techniques that are beyond the scope of this unit. For information on this, the reader should consult Vives et al. (1999).

Interest in proteoglycans, particularly cell-surface proteoglycans, has grown recently. This is due in part to the discoveries of the roles of cell-surface proteoglycans in signaling as co-receptors with integrins in adhesion, and with growth factors in cell cycle regulation (reviewed in Woods and Couchman, 1998; Bernfield et al., 1999; also see *UNIT 10.1*). It is often daunting for new researchers to enter the proteoglycan field, and it is hoped that these techniques will help.

Critical Parameters

The core proteins of proteoglycans are susceptible to proteolysis, but freezing often results in insoluble complexes. It is therefore important to design experiments so that isolation, purification, and analysis proceed as rapidly as possible. In addition, once the glycosaminoglycans are removed from the core protein, the core proteins aggregate, especially at high concentration or if hydrophobic. Again, speed is of the essence.

Troubleshooting

Core protein aggregation, particularly of the syndecans, results in SDS-resistant multimers, which are noncovalent. This results in several bands migrating more slowly on SDS-polyacrylamide gels than expected based on molecular weight. This has now been documented in several studies but often needs to be explained in manuscripts. It is not due to disulfide bonding; it appears to be an inherent capacity of the core proteins.

The enzymes used to degrade glycosaminoglycans are susceptible to inactivation and have a limited shelf life once they are hydrated. Where they are used infrequently, enzymes can be hydrated, divided into aliquots, and freeze dried. If a negative result is seen, the particular enzyme preparation should be checked for activity under the experimental conditions used. Manufacturer's data sheets explain this procedure.

Anticipated Results

Basic Protocol 1. Yield cannot be quantified since nonincorporated radiolabel is present. After Basic Protocol 2, the supernatant fraction will yield the highest amount of labeled materials (~4×10^6 cpm), with the cell-associated materials yielding 1×10^6 cpm. These results are typical of those obtained using rat embryonic fibroblasts (confluent monolayers from five 10-cm dishes).

Alternate Protocol 1. Yield cannot be quantified since nonincorporated radiolabel is present. After Basic Protocol 2, the supernatant fraction will yield the highest amount of labeled materials (~4×10^6 cpm), with the lysate yielding somewhat less (~950,000 cpm), and the cytoskeleton/matrix yielding the least (~150,000 cpm). These results are typical of

those obtained using rat embryonic fibroblasts (confluent monolayers from five 10-cm dishes).

Support Protocols 1 and 2. Each cell type synthesizes its own spectrum of proteoglycans in varying amounts. For fibroblasts, total incorporation into proteoglycans can be expected to be 5–6 × 10^6 cpm/5 dishes.

Basic Protocol 2. Anticipated yields from this procedure are listed under Basic Protocol 1 and Alternate Protocol 1 above.

Alternate Protocol 2. Little material should be lost on reapplication of isolated proteoglycans to DEAE-Sephacel and elution. If losses do occur, the column should be reconditioned with medium before use. Yields of the different fractions will differ with cell type. Typically, using rat embryonic fibroblasts, 40% to 60% of lysate proteoglycans and 20% to 40% of cytoskeleton/matrix proteoglycan pools, respectively, elute from octyl-Sepharose with detergent buffer.

Basic Protocol 3. It is possible to resolve a 1-ml sample of proteoglycan into three to six species by size-exclusion chromatography, depending upon the cell type.

Basic Protocol 4. Alkaline elimination quantitatively separates glycosaminoglycans from the core protein.

Basic Protocol 5. Treatment of proteoglycans with papain degrades the core protein and releases free glycosaminoglycans.

Basic Protocol 6. Treatment of proteoglycans with lyases followed by immunoblotting allows identification of three to six core proteins, depending on the species produced by the cell line.

Basic Protocol 7. Treatment of proteoglycans with nitrous acid degrades heparan sulfate to low-molecular-weight products.

Basic Protocol 8. Immunoblotting allows detection of which glycosaminoglycans are bound to specific proteoglycan protein cores.

Basic Protocol 9. HPLC analysis allows determination of GAG size.

Basic Protocol 10. Specific proteoglycans and protein cores can be immunoprecipitated from cell preparations, but yield is often low.

Time Considerations

Basic Protocol 1 and Alternate Protocol 1. The whole procedure should be completed in <30 min to keep proteolysis at a minimum. Once the samples have been applied to DEAE-Sephacel and the column is washed with low-pH buffer, proteolytic risk is reduced.

Support Protocol 1. Addition of radiolabel requires 15 min, but 3 to 4 days may be needed for growth to confluency.

Basic Protocol 2. The time needed to apply the extract to the DEAE column will depend on the volume of extract. Samples should not be loaded at speeds >16 ml/hr. Washing and elution each take ~30 min. A convenient stopping point, if needed, is after the second wash (step 6).

Alternate Protocol 2. The time taken to (re)load proteoglycans onto DEAE-Sephacel will depend on the volume to be loaded. Rates >16 ml/hr should not be used. Exchange to cholate detergent is most conveniently performed overnight. Loading onto octyl-Sepharose requires overnight incubation, and washing and elution of the column requires ~3 hr.

Basic Protocol 3. Each size-exclusion chromatography run takes ~16 hr. Several columns can be run simultaneously if multichannel pumps are used.

Basic Protocol 4. Alkaline elimination requires 16 hr, with 5 to 10 min for neutralization.

Basic Protocol 5. Papain digestion requires 16 hr.

Basic Protocol 6. Incubation times depend on the amount of proteoglycan present. For up to 10 µg proteoglycan, 2 to 3 hr should suffice. Where larger amounts are present, addition of enzymes for a further 2 hr may be needed.

Basic Protocol 7. Treatment with nitrous acid requires 2.5 hr.

Basic Protocol 8. Enzyme treatment requires 2.5 hr. SDS-PAGE, transfer, and immunoblotting require 24 hr.

Basic Protocol 9. HPLC analysis requires ~4 hr, while SEC requires 16 to 18 hr.

Basic Protocol 10. Immunoprecipitation requires ~4 hr.

ABSTRACT

Matrix metalloproteinases are a class of enzymes that play an important role in the remodeling of the extracellular matrix in development and cancer metastasis. This unit describes a set of methods—cell-mediated dissolution of type-1 collagen fibrils, direct and reverse zymography, enzyme capture based on α2-macroglobulin and TIMP-1 and -2, and demonstration of cryptic thiol groups in metalloproteinase precursors—that are used to characterize the functions of matrix metalloproteinases and their inhibitors. *Curr. Protoc. Cell Biol.* 40:10.8.1-10.8.23. © 2008 by John Wiley & Sons, Inc.

Keywords: matrix metalloproteinases • type-1 collagen • zymography • α2-macroglobulin • TIMP-1 and -2

This unit describes a set of methods that are relatively unique to studies of matrix metalloproteinases (MMPs) and their inhibitors (TIMPs, α2M), including cell-mediated dissolution of type I collagen fibrils (see Basic Protocol 1), direct and reverse zymography (see Basic Protocols 2 and 3), enzyme capture techniques based on α2-macroglobulin (α2M) and TIMP-1, and -2 (see Basic Protocol 4 and Alternate Protocol), and detection and demonstration of cryptic thiol groups in MMP precursors (see Basic Protocol 5). Support Protocols are included for preparation (see Support Protocol 1) and labeling of collagen with a fluorophore (see Support Protocol 2).

DISSOLUTION AND DEGRADATION OF COLLAGEN FIBRILS BY LIVE CELLS

BASIC PROTOCOL 1

Comparatively few methods allow detailed analysis of how live cells orchestrate MMP and inhibitor functions in the degradation and remodeling of extracellular matrices. The methods described in this protocol were developed to study the function of matrix metalloproteinases (MMPs) in the degradation of type I collagen fibrils by live cells under controlled but readily variable conditions. In its simplest form, cells are seeded on a few-micron-thick film of reconstituted collagen fibrils, then incubated for a period of 1 to 7 days. The progressive dissolution of the film under the cell layer—in response, e.g., to changing environmental conditions, inducing agents, or inhibitors—may be monitored directly and related to the level of expression of key components of the requisite proteolytic machinery. The system is readily manipulated in a number of ways: by induction/repression of transcription of components of the signaling and effector systems; by transfection of new genes of potential importance to the process; or by selective or specific blocking strategies using antisense-, MMP-specific inhibitor–, or antibody-based approaches. The limited susceptibility of type I collagen fibrils to cleavage and dissolution by MMPs permits one to narrow the scope of the investigation to a small number

Current Protocols in Cell Biology 10.8.1-10.8.23, September 2008

DOI: 10.1002/0471143030.cb1008s40

of ("collagenolytic") enzymes. This characteristic also makes it a realistic objective to dissect the entire sequence or set of reactions involved in cell-mediated dissolution of collagen fibrils, starting from the initial engagement of cell surface receptors by cytokines, growth factors, and other catabolic reagents, through the final enzymatic cleavage, dissolution, and disposal of the substrate. Important questions that may be addressed using this approach include the following:

a. What enzymes are actually involved in the cleavage reaction itself and in the precursor activation steps?
b. How do cells regulate the activity of the enzymes?
c. What role is played by TIMPs in modulating, containing, and blocking the response?
d. What is the ultimate fate of the collagen chains and peptides generated as a result of proteolysis?

Recent studies have shown that type I collagen (in solution or in reconstituted fibrillar form) may be cleaved by a larger number of enzymes than previously anticipated, including the three classical "collagenases," MMP-1, MMP-8, and MMP-13 (Birkedal-Hansen et al., 1993; Knäuper et al., 1996). In addition, reports suggest that MMP-14 (Ohuchi et al., 1997) and TIMP-free MMP-2 may also dissolve collagen fibrils at meaningful rates under physiologic conditions (Aimes and Quigley, 1995). It is of note that although the three classical collagenases (MMP-1, MMP-8, and MMP-13) were discovered because of their ability to dissolve reconstituted fibrils of type I collagen, no definitive proof has yet been rendered that cleavage of collagen fibrils is indeed the exclusive or even prevailing biologic function of any of these enzymes. Admittedly, the evidence seems compelling based on a large number of in vitro studies.

Earlier versions of this method have been published (Birkedal-Hansen, 1987; Birkedal-Hansen et al., 1989, 1993; Lin et al., 1987). The isolation and purification techniques of type I collagen and the methods for formation of reconstituted hydrated gels of type I collagen have been described elsewhere in detail (Birkedal-Hansen, 1987). The method relies on the ability of neutral solutions of type I collagen in an appropriate concentration range (0.1 to 5 mg/ml) to form hydrated gels of reconstituted fibrils by heating to 37°C. The method also takes advantage of the observation that such loose hydrated gels may be collapsed by gentle air-drying into a thin film of uniform, densely packed, randomly oriented fibrils which remain as highly resistant to proteolysis by enzymes such as trypsin, chymotrypsin, and plasmin as hydrated gels or natural fibrils (Fig. 10.8.1). Trypsin, which is often used as a standard for testing the resistance of collagen fibrils to "unspecific" proteolytic cleavage, is unable to dissolve the collagen fibril films prepared as described. The same is true for a large number of proteinases of all four classes, and it is this unique resistance to proteolysis which renders this assay system particularly valuable, as it greatly reduces the number of proteinases that are involved in the cleavage/dissolution reaction.

Several variants of the method may be used. While the authors often prefer (for ease of presentation and interpretation) to seed the cells in a small button in the middle of a much larger dish (35 mm; Fig. 10.8.1A, middle) in order to maintain medium excess, it is also possible to seed the cells over the entire collagen-coated surface, although a confluent monolayer rapidly exhausts the medium. The collagen may be used in its natural state or labeled either with radioactive or fluorescent tags to facilitate monitoring (see Support Protocol 2), retrieval, and quantification of dissolved collagen chains and fragments.

Depending on the casting conditions, collagen films may be generated with a thickness down to 1 to 2 μm, which is approximately the thickness of a single layer of well-spread cells. Most cell types seeded on this film spread within minutes to hours, although often

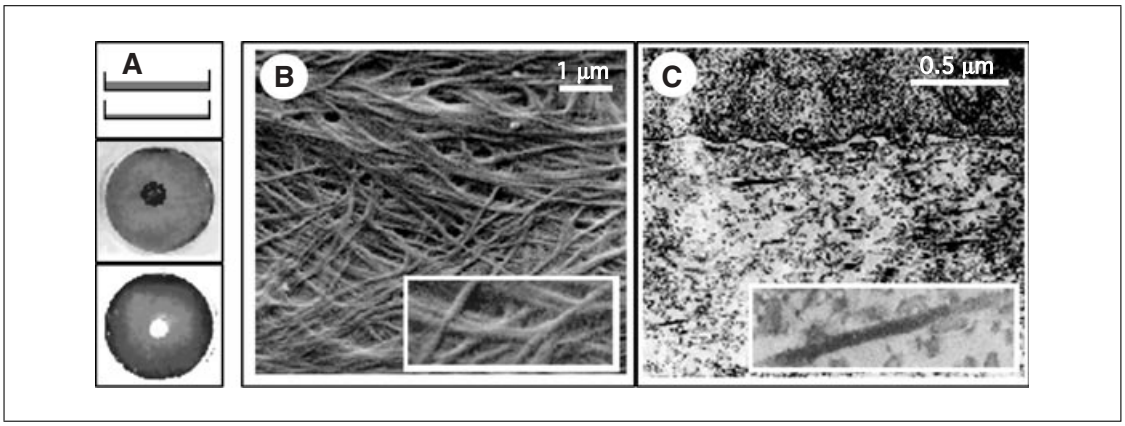

Figure 10.8.1 Reconstituted collagen fibril film. (**A**) Rat tail tendon type I collagen is polymerized by heat gelation. The gel is air dried and reduced in thickness to a few microns. Cells are seeded in the middle of the plate and incubated with culture medium. After incubation, the cells are removed and a clearing beneath the cell layer is exposed by staining with Coomassie blue. (**B**) The air-dried collagen fibril film consists of uniform, randomly oriented reconstituted fibrils. (**C**) Detail of cell attached to the collagen fibril film.

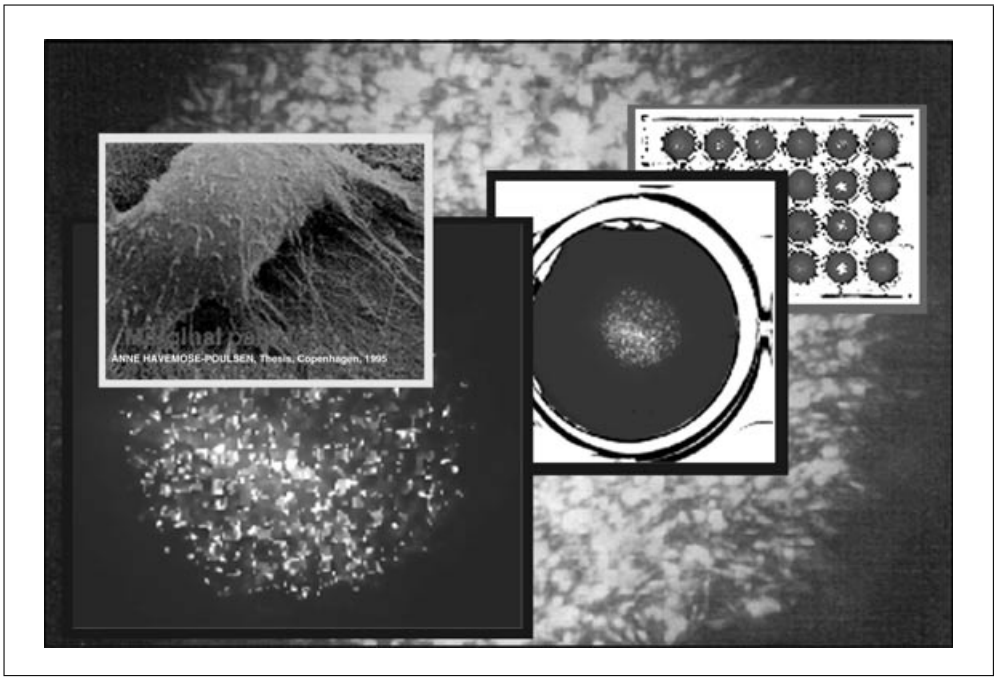

Figure 10.8.2 Dissolution of collagen fibrils by live adherent cells. Fibroblasts seeded in the center of the well dissolve the underlying collagen fibril film. Upper left panel shows scanning electron micrograph of fibroblast attached on collagen fibril film. Recreated from Havemose-Poulsen et al. (1998).

more slowly than on plastic. Cells that express an appropriate complement of MMPs either constitutively or after exposure to cytokines and growth factors (or phorbol ester) progressively dissolve the underlying fibril coating, and, within 24 to 96 hr, clear a path to the plastic surface (Fig. 10.8.1A, lower; Fig. 10.8.2). Coomassie blue staining of the residual collagen fibril film after removal of the cells is usually sufficient to visualize the dissolution of the underlying film (Fig. 10.8.2).

Materials

3 mg/ml rat tail tendon type I collagen in 13 mM HCl (see Support Protocol 1)
13 mM HCl, 4°C
Neutralizing buffer (see recipe), 4°C

Phosphate-buffered saline (PBS) without Ca^{2+} and Mg^{2+} (CMF-PBS; *APPENDIX 2A*) supplemented with 100 U/ml penicillin G and 100 μg/ml streptomycin sulfate
Cells of interest (e.g., fibroblasts, keratinocytes, or tumor cells)
DMEM (*APPENDIX 2A*) supplemented with 100 U/ml penicillin G and 100 μg/ml streptomycin sulfate with and without 10% (v/v) FBS (or other medium appropriate for cell type)
Growth factors/cytokines: e.g., IL-1β, TNF-α, TGF-α, or TPA; or phorbol ester (12-O-tetradecanoylphorbol-13-acetate, TPA, or phorbol myristate acetate, PMA)
1% (v/v) Triton X-100
0.05% (w/v) trypsin/0.53 mM EDTA (Invitrogen)
Coomassie blue stain (see recipe)
6-well cell culture plates

Additional reagents and equipment for trypsinizing and counting cells (*UNIT 1.1*)

Prepare collagen-coated plates

1. To cast one 6-well plate, dilute 1 ml of 3 mg/ml type I collagen stock solution with 7 ml of 13 mM HCl at 4°C. Mix the collagen solution with 2 ml of cold neutralizing buffer in a precooled test tube either by gently pipetting up and down while avoiding formation of air bubbles (which will form defects in the gel) or by gently inverting the tube several times.

   The neutralizing buffer is designed to bring the pH of the solution to 7.4 (check with pH paper). The concentration of this buffer is 0.2 M inorganic phosphate (as Na_2HPO_4/NaH_2PO_4) and 0.47 M NaCl. The final collagen concentration is 300 μg/ml in 40 mM P_i/~0.10 M NaCl. Since pH dramatically influences the gelling properties of the collagen solution it is often advantageous to first test the efficacy of the neutralizing buffer by mixing 4 volumes of 13 mM HCl with one volume of neutralizing buffer and checking the final pH (7.4).

   The final thickness of the collagen film depends on the concentration of the collagen solution. A 300 μg/ml solution dispensed at a volume of 1.5 ml per (35-mm) dish yields a film of 1.5 to 2.0 μm in thickness after drying. Higher concentrations yield thicker films. The lower concentration limit for proper gelling is around 100 μg/ml using rat tail tendon collagen prepared as described (see Support Protocol 1) but somewhat higher (500 μg/ml) with commercial type I collagen preparations.

2. Immediately after mixing, add a 1.5-ml aliquot of neutralized collagen solution to each well of the 6-well culture plate. Rotate the plate to permit the collagen to cover the entire well bottom evenly. Incubate in humidified incubator for 2 hr at 37°C. Avoid movement of gel and plate during gelling.

3. Remove plate from incubator, remove lid, and place at room temperature in an air stream (laminar flow hood) overnight (during this process the gel dries down to a thin film). Wash three times with distilled water, each time for 30 min at room temperature or 37°C, to remove salt crystals formed during the drying (check efficacy of washing step using a phase-contrast microscope). Dry again overnight in laminar flow hood and check for absence of residual salt crystals.

   It is important that all salt crystals be removed by washing before the plates are used.

4. Add 2 ml CMF-PBS or DMEM supplemented with penicillin/streptomycin. Store in this solution in incubator at 37°C or in refrigerator at 4°C in closed plastic bag to prevent evaporation.

   The plate can be stored in this manner for up to 2 weeks as long as evaporation is avoided.

5. Immediately before seeding cells, remove medium from wells by aspiration and wash with 2 ml distilled water for 30 min. Remove water and leave plate to air dry in hood.

Plate cells

6. Trypsinize and count cells (see *UNIT 1.1*), then dilute cell suspension to the appropriate concentration in DMEM/10% FBS, or in medium appropriate for the cell type being used.

   Best results are obtained with 10,000 to 50,000 cells in a 25-μl aliquot, using a cell suspension of 4×10^5 to 2×10^6 cells/ml, somewhat depending on cell size. The intent is to form a coherent monolayer in a small central button (Fig. 10.8.1A, middle).

7. Deliver a 25-μl aliquot to the center of the well without touching the fragile collagen film. Fill plate volume between wells with distilled water to avoid evaporation during seeding and attachment. Place plate in plastic box on wet paper towels to avoid evaporation, and then place in incubator for 5 hr or overnight at 37°C to allow cells to attach.

8. Add to each well 2 ml DMEM/10% FBS or appropriate medium and incubate overnight at 37°C to allow cell spreading.

   Some cell types can be transferred immediately to serum-free medium while others require overnight incubation in serum-supplemented medium.

   Once the cells are spread, incubation may be performed either with or without serum. The result depends somewhat on cell type. Some cells tend to detach in the absence of serum while others can be maintained for 2 to 3 days in complete absence of serum while degrading the collagen fibril matrix.

9. If the experiment is to be performed in the absence of serum, thoroughly and repeatedly wash with CMF-PBS or serum-free DMEM for 10 min at 37°C, to remove remnants of serum.

   Some cells may require special media formulations, i.e., keratinocytes. Most fibroblast strains do well under serum-free conditions either in DMEM or DMEM/F12 (1:1).

*Induce expression of MMP*s

10. Induce cells for expression of MMPs at this stage by including in the medium cytokines such as IL-1β (10^{-9}M), TNF-α (10^{-8}M), TGF-α (10^{-8}M), or TPA (1 to 2×10^{-7} M).

    Alternatively, cytokine or TPA induction may be achieved during the last 24 hr before trypsinization and seeding. If incubated under serum-free conditions, plasminogen may be added to the medium. Some cells respond to exposure to plasminogen by greatly accelerating the rate of dissolution, while others do not. If desired, plasminogen is added from a stock solution in CMF-PBS to give a final concentration of 4 μg/ml. Human plasminogen is either purchased from one of several commercial sources (i.e., Pharmacia Hepar or Sigma-Aldrich) or prepared as described (Deutsch and Mertz, 1970) from outdated human plasma by lysine-Sepharose chromatography.

11. Incubate the plates at 37°C for 1 to 4 days (or up to 7 days) depending on the experimental design. Follow the progress of the process with a phase-contrast microscope.

    To avoid evaporation it may be advantageous to fill the volume between the wells with sterile distilled water.

Stain plate and quantitate results

12. In order to visualize the dissolution of the film beneath the cell layer, remove the cells either by dissolution in 1% (v/v) Triton X-100, by 0.5% trypsin/0.53 mM EDTA (10 min, 37°C), or by a combination thereof.

    Avoid use of SDS, which dissolves the collagen fibril film as well as the cells.

13. Rinse the wells with distilled water.

14. Stain with Coomassie blue stain for 5 to 15 min to visualize residual collagen film, then wash three times with distilled water.

15. Destain in distilled water for 30 min (or perform three quick washes with water) and finally allow plates to air dry.

    After drying the plates, they can be stored indefinitely (Fig. 10.8.2).

    In order to follow the progressive dissolution of the collagen fibril film it is advantageous to terminate sample wells on consecutive days and to contrast the dissolution after 1, 2, 3 ... days.

    If desired the plates can be scanned directly into Adobe Photoshop using a scanner capable of scanning transparent originals.

16. Determine the extent or rate of dissolution of the substrate

    The degree of dissolution at the conclusion of the experiment may be measured photometrically in Coomassie blue–stained plates by measuring the absorption of light in a conventional light microscope equipped with a exposure (photo)meter as described in Havemose-Poulsen et al. (1998). The relationship between amount of collagen present on the plate and exposure time is strictly linear at least up to three times the collagen layer thickness used in this protocol.

    Alternatively, if the cells are seeded evenly as a confluent monolayer over the entire collagen-coated well bottom (see below), progression may be monitored daily by removal of aliquots of medium and measuring the release of collagen chains and peptides. To this end the collagen may be labeled either with ^3H (Birkedal-Hansen, 1987; Birkedal-Hansen and Danø, 1981) or with fluorescent tags (Ghersi et al., 2002). This approach is less useful if the cells are seeded in a small 2- to 4-mm button at the center of the well, because the background release of radioactivity and fluorescent label from the entire film compromises the sensitivity of the analysis (typically only 10% to 20% of the collagen fibril film is covered by cells in this variation).

SUPPORT PROTOCOL 1

PREPARING RAT TAIL TENDON COLLAGEN TYPE I

Methods for isolation and preparation of rat tail tendon type I collagen have been described in detail elsewhere (Birkedal-Hansen, 1987; Birkedal-Hansen and Danø, 1981). Alternatively, rat, bovine or human type I collagen may be purchased from Becton Dickinson Biosciences Discovery Labware. Briefly, tendons teased from rat tails are washed with distilled water and with 0.5 M NaCl. The acid-soluble collagen fraction is then extracted in 0.5 M acetic acid, and type I collagen is purified by sequential salt precipitation at neutral to slightly alkaline pH, first with 5% NaCl, then (after redissolution in acetic acid) with 0.02 M Na_2HPO_4.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Tails of ~400 g rats (freshly removed or stored frozen at −80°C)
0.5 M NaCl in 50 mM Tris·Cl, pH 7.4 (see *APPENDIX 2A* for Tris·Cl)
5 mM, 50 mM, and 0.5 M acetic acid
NaCl (solid)
0.02 M Na_2HPO_4
13 mM HCl
Neutralizing buffer (0.2 M NaP_i)

Glass wool or cheesecloth
500-ml centrifuge bottles
High-speed centrifuge (Sorvall with SS-34 and GSA rotors, or equivalent centrifuge and rotors)

10,000 to 14,000 MWCO dialysis membrane
One large (25-liter) or several smaller (4-liter) dialysis tanks
Sterile scissors
125-ml glass Wheaton bottles

Additional reagents and equipment for dialysis (*APPENDIX 3C*)

Extract collagen

1. Skin 10 to 20 rat tails and place tails on ice. Break tails at joints and tease out individual collagen fibers. Wash in large volume distilled water (2 to 3 liter) for 1 hr with agitation. Change wash water three to four times.

   The yield is 200 to 400 mg collagen per rat.

2. Extract overnight at 4°C with agitation in 2 liters of 0.5 M NaCl/50 mM Tris·Cl, pH 7.4. Discard extract and repeat step.

3. Discard second salt extract and wash collagen fibers extensively (over a 3-hr period with change two to three times per hr) in distilled water to remove salt.

4. Extract overnight at 4°C with slow agitation in 2 liters of 0.5 M acetic acid.

5. Remove insoluble remnants by filtration through glass wool or cheesecloth, then centrifuge in 500-ml bottles for 30 min at 11,000 × *g*, 4°C. Add solid NaCl little by little to a final concentration of 5% w/v (50 g/liter) under constant vigorous stirring. When the salt is completely dissolved, turn off stirrer, cover beaker, leave in cold room overnight, and let precipitate gather at bottom of vessel.

   The collagen immediately starts to precipitate upon addition of the salt.

6. Collect precipitate by centrifugation for 30 min at 11,000 × *g*, 4°C. Discard supernatant.

7. Redissolve collagen by adding 450 ml of 0.5 M acetic acid to first centrifuge bottle, transfer liquid to the second bottle, and so on, until collagen is redissolved/redispersed into ~900 to 1000 ml in 0.5 M acetic acid.

8. Stir vigorously overnight at 4°C until collagen is completely dissolved.

   If not dissolved overnight, add more acetic acid and bring volume up to 1600 to 1800 ml.

Dialyze collagen solution

9. Place collagen solution, 300 to 400 ml at a time, in dialysis bags. Dialyze in tank against 25 liters of 0.5 M acetic acid, then for 3 to 4 days against 50 mM acetic acid. Change daily and mix content of bags.

   See APPENDIX 3C for additional details on dialysis.

10. Dialyze against several changes of 0.02 M Na_2HPO_4 in the 25-liter tank over the next 72 hr.

    Precipitation should happen as fast as possible, so change solution frequently in the beginning and massage bags frequently to facilitate even distribution of reagents. The collagen precipitates as a thick white gel.

11. Harvest precipitate by centrifugation in 500-ml bottles for 30 min at 11,000 × *g*, 4°C. Redissolve collagen in 0.5 M acetic acid by vigorous stirring overnight at 4°C.

12. Dialyze 3 to 4 hr against 0.5 M acetic acid, then overnight against 50 mM acetic acid, and, finally, overnight against several changes of 5 mM acetic acid.

13. Centrifuge 1 hr at 11,000 × *g*, 4°C. Lyophilize supernatant and store in dessicator at −80°C.

14. Redissolve as follows.
    a. Weigh out no more than 150 mg collagen.
    b. Cut into 1-cm pieces with sterile scissors.
    c. Place collagen pieces into a 125-ml glass Wheaton bottle that has been autoclaved with a stir bar inside.
    d. Add cold 13 mM HCl to make a 3 mg/ml solution and stir briskly at 4°C with occasional shaking for ~24 hr.

    The collagen solution should be slightly opalescent.

15. Centrifuge solution for 20 min at 50,000 × *g*, 4°C, to remove any insoluble material, if necessary.

    Note that the solution remains somewhat opalescent even after centrifugation. This solution may be stored for months at 4°C. Freezing should be avoided.

SUPPORT PROTOCOL 2

LABELING OF COLLAGEN

Rat tail tendon type I collagen may be labeled using [^{3}H]acetic anhydride as described in detail in Birkedal-Hansen and Danø (1981) and Birkedal-Hansen (1987), or with fluorescent reagents. The following fluorescent labeling method was adapted from a technique devised by the Chen laboratory (G. Ghersi and W.T. Chen, unpub. observ.).

Materials

3 mg/ml rat tail tendon type I collagen originally dissolved in or dialyzed into 13 mM hydrochloric acid (see Support Protocol 1)
Neutralizing buffer (see recipe)
Borate buffer: 0.05 M $NaB_4O_7 \cdot 10H_2O$, pH 9.3, containing 0.04 M NaCl, filter sterilized
20 to 30 mg tetramethylrhodamine-5-(and 6)-isothiocyanate (TRITC) *or* fluorescein isothiocyanate (FITC) stock solutions, dissolved in DMSO
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
20 mM and 1 M hydrochloric acid, sterile

125-ml glass Wheaton bottle, autoclaved
Platform shaker

1. Mix 8 ml of 3 mg/ml rat tail tendon type 1 collagen with 2 ml neutralizing buffer in a sterile 125-ml bottle and incubate at 37°C overnight to form a gel.

   Rat tail tendon type I collagen may be prepared as described in Support Protocol 1, or purchased from BD Biosciences; bovine skin and human placental type I collagen are also available from the same supplier.

2. Wash for 1 hr with sterile borate buffer at room temperature by rotating at low speed on a platform shaker.

3. Remove buffer and replace with 10 ml borate buffer containing 2 to 3 mg/ml TRITC or FITC (prepared from 20 to 30 mg FITC or TRITC predissolved in a small volume of DMSO). Incubate at room temperature with gentle shaking for 20 to 30 min or until the dye diffuses through the gel. Protect from light from this point onward.

4. Wash with multiple changes of PBS at room temperature with rotation on a platform shaker for several days to remove free dye. Wash out salts with several changes of water.

   At some point, the collagen gel may become detached from the bottle. If so, pipet off solutions carefully in order to avoid breaking up the collagen.

   If unbound dye is not throughly washed from the collagen gel, subsequent experiments may be marred by high background fluorescence.

5. Add a sterile magnetic stir bar and stir to dissolve the gel in 8 ml pre-chilled 20 mM hydrochloric acid at 4°C. If the collagen is reluctant to dissolve, make sure the pH is around 2. If necessary adjust the pH by the addition of 1 M hydrochloric acid.

   Collagen can also be labeled with Alexa Fluor dyes using protein-labeling kits containing amine-reactive dyes from Molecular Probes/Invitrogen. Neutralize and gel 2.5 mg collagen as described in step 1, above, and equilibrate with several 10-min washes in PBS. Add 1 M bicarbonate buffer, pH 8.3 to 0.2 M. Resuspend a vial of Alexa Fluor dye (premeasured to label 1 mg protein) in a small amount of PBS and add immediately to the collagen. Incubate for 2 hr at room temperature and then wash extensively and redissolve as above.

   Collagen is labeled in the fibrillar state so that sites important for subsequent alignment and gelling are not being blocked by the labeling procedure. Consequently, collagen labeled in this fashion readily dissolves in dilute acid and gels again upon neutralization and mild heating. Depending on the need, the fluorescently labeled collagen may be diluted up to 10-fold with unlabeled rat tail tendon collagen and still yield a strong enough signal for quantification.

GELATIN/CASEIN ZYMOGRAPHY

BASIC PROTOCOL 2

Zymographic methods are designed to analyze the proteolytic capacity of latent and active MMPs (Heussen and Dowdle, 1980; Birkedal-Hansen and Taylor, 1982; Birkedal-Hansen, 1987). This set of techniques is based on a number of unique properties of MMPs: (1) MMPs retain (or refold to display) catalytic activity after electrophoresis in SDS-containing buffers as long as heating and reduction are avoided (Birkedal-Hansen and Taylor, 1982); (2) brief exposure to SDS opens the "cysteine switch" (Springman et al., 1990; Van Wart and Birkedal-Hansen, 1990) so that both precursor and proteolytically truncated ("activated") forms of the enzyme display catalytic activity; and (3) MMP catalytic activity is reversibly inhibited by SDS and readily restored when SDS is removed by washing with Triton X-100 (Birkedal-Hansen and Taylor, 1982). It is therefore possible to resolve a heterogenous group of MMPs and non-MMPs in SDS-containing gels copolymerized with a suitable substrate (gelatin, casein), remove the SDS, and develop (without distinction) the spontaneous or latent catalytic activity associated with each electrophoretic band. After appropriate incubation (to allow for proteolysis), the discrete bands of substrate lysis are made visible by Coomassie blue staining of the gel (Fig. 10.8.3). SDS opens the "cysteine switch" but instantly inhibits the switch-open enzyme and blocks autolytic truncation normally associated with activation. The proenzyme bands therefore migrate at their expected high-molecular weight, but display proteolytic activity because the switch is unable to again "close" after removal of the SDS with Triton X-100.

Zymography using gels containing 0.1 to 1.0 mg/ml gelatin are by far the most sensitive. Gels may either be purchased (Invitrogen) or prepared as described below. Gelatin works particularly well for MMP-2 and MMP-9, whereas MMP-1, MMP-3, MMP-7, MMP-8, and MMP-10 are better identified in casein-containing gels.

Materials

Gelatin (bovine skin, Sigma-Aldrich type B6-6269) or casein (Sigma-Aldrich, technical, C-0376)
2.0 M Tris·Cl, pH 8.8 (*APPENDIX 2A*)
30/0.8 acrylamide/bisacrylamide (*UNIT 6.1*)
Glycerol
10% (w/v) SDS (*APPENDIX 2A*)
TEMED
10% (w/v) ammonium persulfate

MMP preparation of interest (for standards, use 1 to 5 ng purified MMP)
5× electrophoretic sample buffer (see recipe)
Electrophoretic running buffer (see recipe)
Gel washing buffers 1 to 4 (see recipe)
Coomassie blue stain (see recipe)
Gel destaining solution (see recipe)

50-ml centrifuge tubes
57°C water bath
Whatman no. 1 filter paper *or* 0.5-μm syringe filter
Gel washing tray of appropriate size

Additional reagents and equipment for preparing SDS-PAGE gels according to Laemmli (*UNIT 6.1*)

NOTE: The following procedure is based on a standard 10% SDS-PAGE according to Laemmli (Laemmli, 1970; *UNIT 6.1*) using a 4% stacking gel and a pH 8.3 running buffer. It is important to avoid heating and/or reduction during sample preparation and running of the gel.

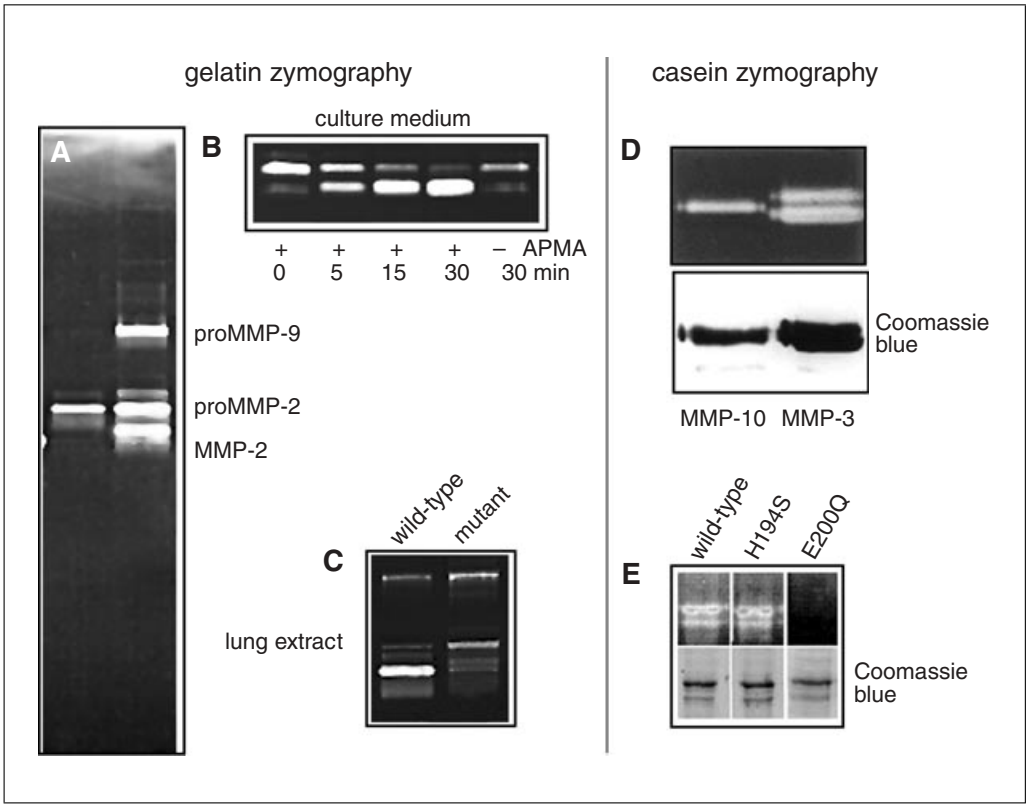

Figure 10.8.3 Zymography. (**A**) Zymography using gelatin-containing polyacrylamide gel. Culture medium containing proMMP-2 (left) or MMP-2/proMMP-2 and proMMP-9 (right). The proenzymes display catalytic activity because exposure to SDS during sample preparation opens the cysteine switch. (**B**) Detail showing conversion of proMMP-2 to MMP-2 by exposure to aminophenylmercuric acetate. From Caterina et al. (2000). (**C**) MMP-2 and MMP-9 activity in extracts of lungs of wild-type mice (left) or mice in which the TIMP-2 gene has been mutated to inactive form (modified from Caterina et al., 2000). (**D**) Zymography using casein-containing polyacrylamide gel. (pro)MMP-3 and MMP-10 cleave casein embedded in the gel (modified from Windsor et al., 1993). (**E**) Casein zymogram of mutant and wild-ype MMP-1. Inactivation of catalytic activity by mutation of catalytic site glutamic acid (E) to glutamine (Q) that abolishes casein cleavage. A histidine to serine replacement outside the active site does not. Modified from Windsor et al. (1994).

1. Weigh out appropriate amount of gelatin (for 0.1 to 1.0 mg/ml final concentration) or casein (for 1.0 mg/ml final concentration) and place in a 50-ml centrifuge tube.
2. For every 10 ml of solution to be prepared, add 4 ml of 2.0 M Tris·Cl, pH 8.8, and 6 ml water. Dissolve by heating in a 57°C water bath. Filter through Whatman no. 1 filter paper or syringe filter.
3. Prepare the 10% resolving gel (also see *UNIT 6.1*) by adding the following to 10 ml filtered gelatin or casein solution (0.2 to 13 mg/ml in 0.8 M Tris·Cl, pH 8.8; see step 2):

   6.6 ml 30/0.8 acrylamide/bisacrylamide
   2 g glycerol
   0.2 ml 10% (w/v) SDS
   13.3 μl TEMED
   67 μl 10% (w/v) ammonium persulfate

   Pour resolving gel as described in *UNIT 6.1*.
4. Prepare 4% stacking gel by combining the following (also see *UNIT 6.1*):

   1 ml 30/0.8 acrylamide/bis acrylamide
   0.36 ml 2 M Tris·Cl, pH 6.8
   75 μl 10% (w/v) SDS
   6 ml H_2O
   8 μl TEMED
   60 μl ammonium persulfate

   Pour stacking gel as described in *UNIT 6.1*.
5. Mix 1 part MMP solution (partially or fully purified MMP, culture medium, concentrated culture medium, or other preparation containing MMP) with 4 parts of 5× sample buffer (final concentration, 1% w/v SDS). Incubate at room temperature for 10 min, then load 20 to 30 μl into each well of the 15-ml gel prepared in steps 3 and 4.

   Alternatively, load 20 to 30 μl per well of an Invitrogen minigel.
6. Run gel at 200 V for 35 to 45 min or until dye front reaches bottom of gel using electrophoretic running buffer, pH 8.3.
7. Remove gel from electrophoretic apparatus and place in an appropriately sized container. Wash four times, 20 min each, successively, in washing buffers 1, 2, 3, and 4 at room temperature. Shake gently throughout.
8. Replace the last wash buffer with fresh washing buffer 4 and incubate 1 to 24 hr at 37°C.

   A few hours of incubation is usually sufficient to reveal MMP-2 and MMP-9 by gelatin zymography. Overnight incubation is required to visualize MMP-1, MMP-3, MMP-13, MMP-7, and MMP-10 by casein zymography.
9. Stain gel with Coomassie blue stain for 30 min and destain with gel destaining solution for several hours until bands are clear.

   Typical results are shown in Figure 10.8.3.

REVERSE ZYMOGRAPHY

BASIC PROTOCOL 3

Reverse zymography is specifically designed to identify electrophoretic bands which display MMP-inhibitory activity. The method is based on incorporation of both MMP activity and gelatin into the running gel. During the ensuing incubation, the SDS-activated MMP-2 (gelatinase A) cleaves the substrate everywhere in the gel except in and immediately around bands with inhibitory activity such as TIMPs. This method yields well

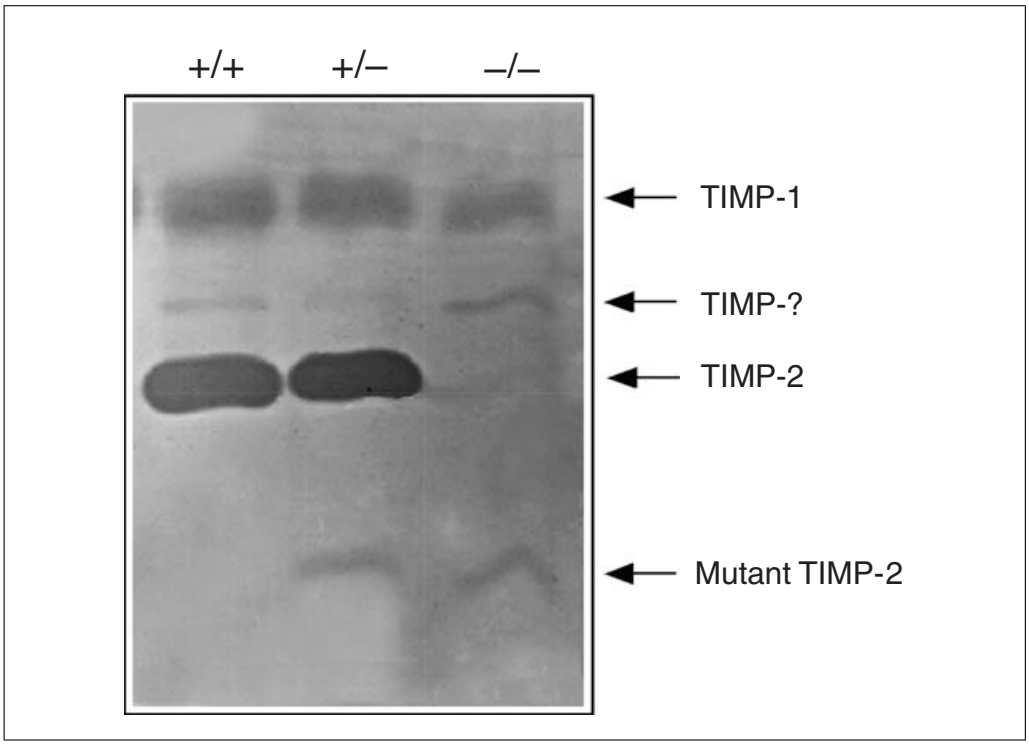

Figure 10.8.4 Reverse zymography. Inhibition of MMP-2 by TIMPs. Skin fibroblast culture medium obtained from wild-type, hemizygous, or homozygous TIMP-2-deficient mice was resolved by SDS-PAGE in a gel also containing MMP-2 and gelatin. During incubation, MMP-2 cleaves gelatin unless inhibited by electrophoretic bands of TIMPs. The TIMP-2-deficient cells still express TIMP-1 and unidentified component below TIMP-1, possibly TIMP-3 and a weakly inhibitory truncated mutant of TIMP-2. Modified from Caterina et al. (2000).

resolved bands of TIMP-1, TIMP-2, TIMP-3, and TIMP-4, as well as mutant forms of these inhibitors (Fig. 10.8.4). The following protocol is developed by the Stetler-Stevenson laboratory and used in the authors' laboratory as well. Quantities are for a 15-ml gel, but can be scaled down as necessary.

Materials

8.7 mg/ml gelatin solution (see recipe)
MMP-2 (Gelatinase A)
5× electrophoretic sample buffer (see recipe)
2.5% (w/v) Triton X-100
Incubation solution (see recipe)

Additional reagents and equipment for "forward" zymography (see Basic Protocol 2)

1. Prepare separating gel (17%), copolymerizing gel with gelatin (2.5 mg/ml) and purified gelatinase A (MMP-2), by mixing the following components (also see *UNIT 6.1*):

   4.2 ml 8.7 mg/ml gelatin solution
   0.16 μg/ml (final concentration) gelatinase A (MMP-2)
   8.25 ml 30/0.8 acrylamide/bisacrylamide
   2.1 ml H_2O
   0.29 ml 10% (w/v) SDS
   7.3 μl TEMED
   73 μl 10% (w/v) ammonium persulfate

Pour separating gel as described in *UNIT 6.1*.

Purified MMP-2 may be replaced with culture medium of cells that secrete this enzyme. The appropriate amount should be determined by trial and error.

2. Prepare 5% stacking gel by combining the following (also see *UNIT 6.1*):

   1.66 ml 30/0.8 acrylamide/bis acrylamide
   1.55 ml 2 M Tris·Cl, pH 6.8
   125 µl 10% (w/v) SDS
   8.2 ml H_2O
   10 µl TEMED
   200 µl ammonium persulfate

   Pour stacking gel as described in *UNIT 6.1*.

3. Mix samples with 5× sample buffer for reverse zymography. Incubate at room temperature for ≥10 min, then load 20 to 30 µl into each well of the gel.
4. Run gel at 150 V until buffer front reaches bottom of gel.
5. Remove gel and wash in three changes of 2.5% Triton X-100, each for 2 hr with gentle shaking.
6. Incubate overnight at 37°C in incubation solution.
7. Stain gel with Coomassie blue stain for 20 min and destain in gel destaining solution for several hours until background is clear.

   Typical results are shown in Figure 10.8.4.

α2-MACROGLOBULIN (α2M) CAPTURE

BASIC PROTOCOL 4

α2M capture is particularly valuable because it permits assessment of the proteolytic competence and activity of single bands of MMPs in a mixture of many partially or fully processed forms. The method was originally devised (Birkedal-Hansen et al., 1976) for separation of complexes from unreacted forms by molecular sieve chromatography (Fig. 10.8.5), but it is even more valuable when combined with electrophoretic analysis. The protocol is based on the observation that α2M forms complexes only with catalytically competent forms of MMPs. Unactivated MMP precursors or forms devoid of catalytic activity are not captured. The ensuing separation by SDS-PAGE permits easy identification of bands which have been captured and moved to the top of the gel because of the large molecular mass of the α2M (Fig. 10.8.5). Bands that escape capture continue to migrate at their usual position. Complexes formed with α2M are covalent and therefore not easily dissociated. The ability of α2M to discriminate between latent and overtly active forms of the enzyme is a result of the α2M inhibition mechanism. α2M is inert until the attacking proteinase cleaves a peptide bond in the bait region. This cleavage results in rapid conformational change and liberates a thiol ester which covalently bonds to and immobilizes the attacking proteinase.

Materials

MMP solution to be tested
2 to 3 mg/ml purified α2M in 50 mM Tris·Cl standard buffer (see recipe for buffer)
100 µg/ml TPCK-treated trypsin (e.g., Sigma) in 50 mM Tris·Cl standard buffer (see recipe), pH 7.4
1.0 mg/ml soybean trypsin inhibitor in 50 mM Tris·Cl standard buffer (see recipe), pH 7.4
5× electrophoretic sample buffer (see recipe)

Antibodies to MMPs of interest
Nitrocellulose paper

Additional reagents and equipment for SDS-PAGE according to Laemmli (*UNIT 6.1*) and for immunoblotting (*UNIT 6.2*)

1. Mix one half of the test solution with a sufficient volume of 1.5 mg/ml α2M to achieve a ≥10× molar ratio of inhibitor to MMP. Incubate 15 min at room temperature.

2. To compare "activated" and "unactivated" samples, preincubate the other half of the test sample with 10 μg/ml trypsin (added from 100 μg/ml stock) for 10 min at room

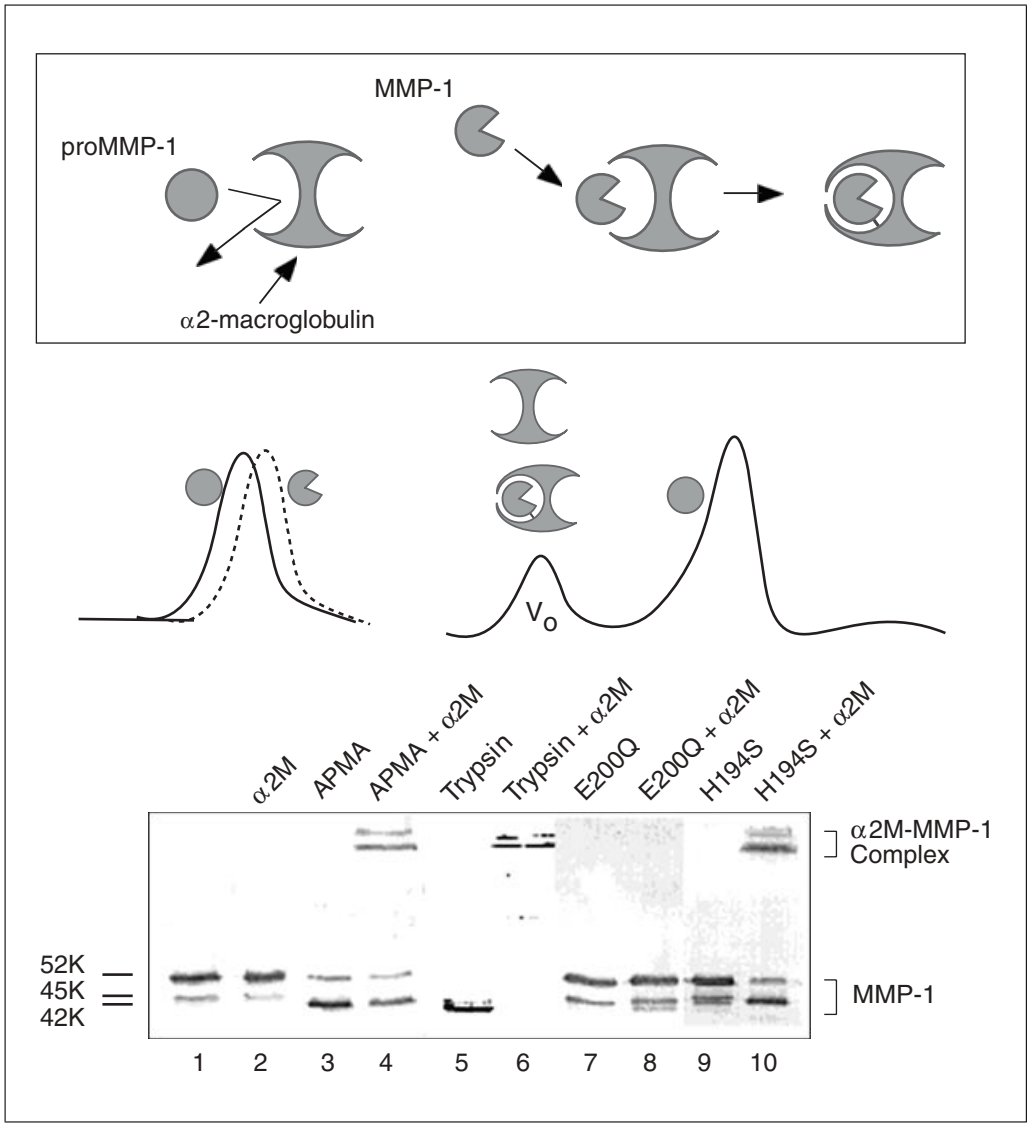

Figure 10.8.5 α2-macroglobulin (α2M) capture. The capture technique is based on the property that proteolytic cleavage of the α2M bait region results in conformational and eventually covalent capture of the attacking proteinase. Because of the large disparity in molecular weight, captured and free froms of the proteinase may be separated either by molecular sieve chromatography (upper panel; Birkedal-Hansen et al., 1976) or by SDS gel electrophoresis (lower panel; Windsor et al., 1994). Covalently bound proteinase is not released and is readily identified by appropriate antibody staining. Latent or inactive proteinases are not captured. The method therefore discriminates between enzyme forms with and without catalytic activity at the moment of testing. The panel shows wild-type and mutant forms of human MMP-1. Samples in lanes 3, 4, and 7 to 10 are pretreated with *p*-aminophenylmercury acetate (APMA). Samples in lanes 5, and 6 were preactivated by trypsin. Modified from Windsor et al. (1994).

temperature, then add 100 μg/ml soybean trypsin inhibitor (added from 1 mg/ml stock). Incubate separately with α2M as described in step 1.

Commercial sources of α2M are available but should always be checked for activity by titration with trypsin using a suitable substrate (Sottrup-Jensen and Birkedal-Hansen, 1989). Alternatively, the inhibitor may be prepared by standard techniques as described by Sottrup-Jensen and Birkedal-Hansen (1989) and Sottrup-Jensen et al. (1983). Activation with trypsin prior to addition of α2M often yields more complete capture than with organomercurials—e.g., NH_2PheHgAc (APMA)—which seem to gradually inactivate α2M. Samples preincubated with organomercurials, however, still show partial capture.

3. Mix with 5× electrophoretic sample buffer (final concentration, 1% w/v SDS, 2.5% v/v 2-ME) without heating, then resolve by by SDS-PAGE using a 10% gel according to Laemmli (Laemmli, 1970; *UNIT 6.1*).

4. Transfer to nitrocellulose paper and stain with appropriate MMP antibody using conventional immunoblotting techniques (*UNIT 6.2*).

Typical results are shown in Figure 10.8.5.

TIMP CAPTURE

ALTERNATE PROTOCOL

Complexes formed with TIMPs are not covalent, although several, but not all, withstand exposure to low concentrations of SDS, as originally observed by DeClerck et al. (1991), who first pioneered this technique. This method detects many but not all activated MMPs that bind TIMPs, including MMP-1 (collagenase-1), MMP-3 (stromelysin-1), MMP-7 (matrilysin), MMP-10 (stromelysin-2), and MMP-13. Detection is most conveniently done by immunoblotting using specific antibodies to the two complex components (MMP and TIMP; Fig. 10.8.6). The method described below is the authors' adaptation of the method of DeClerck (DeClerck et al., 1991). It is based on capture with TIMP-1, but TIMP-2 capture works just as well.

Materials

0.1 to 1.0 mg/ml TIMP-1 (Oncogene Research Products, Chemicon International; also see Bodden et al., 1994) in 50 mM Tris·Cl standard buffer (see recipe), pH 7.4

10.0 mM NH_2PheHgAc (APMA; Sigma) in Tris·Cl standard buffer (see recipe), pH 7.4

5× electrophoretic sample buffer (see recipe, but use only 0.5% w/v SDS)

Antibodies to MMPs and TIMP-1 of interest (Calbiochem, Chemicon International)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Incubate control and activated samples with 40 to 100 μg/ml TIMP-1 (added from 0.1 to 1.0 mg/ml stock) with and without 1.0 mM NH_2PheHgAc (added from 10.0 mM stock) for 90 min at 37°C.

Molecules which are activated by NH_2PheHgAc are captured almost instantly by TIMP-1.

TIMP-1 may be prepared from cultures of fibroblasts or similar cell lines that express fairly high levels of TIMP-1 activity (Bodden et al., 1994). Concentrations of this compound in the range of 0.1 to 1.0 mg/liter may be recovered from the culture medium. The purification scheme is somewhat cumbersome but greatly facilitated by use of antibody-based affinity chromatography techniques.

2. Mix with 5× electrophoretic sample buffer containing 0.5% SDS. Resolve by SDS-PAGE using a 10% gel on ice at 100 V (*UNIT 6.1*).

Note that the SDS concentration of the sample buffer is reduced to 0.1% (final concentration) in order to avoid dissociation of these entirely noncovalent complexes. This change is crucial to the success of the technique.

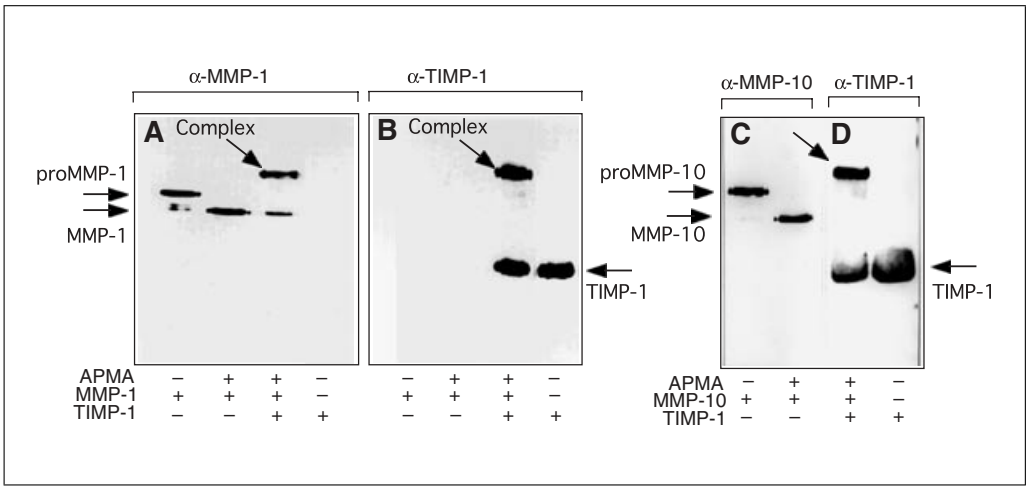

Figure 10.8.6 TIMP capture. (**A**, **B**) are identical panels stained with antibodies to either human MMP-1 or TIMP-1. Capture of activated human MMP-1 gives rise to a new band in the 70-kDa range containing both MMP-1 and TIMP-1 (arrow). (**C**) proMMP-10 and activated MMP-10 stained with antibody to human MMP-10. (**D**) Addition of TIMP-1 to activated MMP-10 results in capture of the enzyme now migrating in a complex with TIMP-1 in the M_r 70-kDa range. Modified from Windsor et al. (1993).

3. Transfer to nitrocellulose and stain adjacent lanes with antibodies to TIMP-1 and to MMP using standard immunoblotting techniques (*UNIT 6.2*).

   Typical results are shown in Figure 10.8.6.

BASIC PROTOCOL 5

FLUORESCENT LABELING OF CRYPTIC CYS-RESIDUE IN MMPs

Most MMP (and ADAM) precursors contain a cryptic thiol group derived from a single, unpaired cysteine residue in the propeptide. This group is coordinately bonded directly to the active site Zn ("cysteine switch") and in this manner plays a significant role in maintaining the catalytic latency of the proteinase precursors. The protocol below permits unmasking and detection of this cryptic thiol group (Fig. 10.8.7). The "switch" opens upon addition of SDS, which allows reaction of the liberated thiol group with a fluorescent maleimide compound (Yamamoto et al., 1977; Lyons et al., 1991).

Materials

MMP-containing samples
20 μM fluorescent maleimide N-(7-(di-methylamino-4-methyl-3-coumarinyl) maleimide (DACM) in Tris·Cl standard buffer (see recipe for buffer; prepare from 1 mM DACM stock in DMSO or ethanol)
2-mercaptoethanol stock in electrophoretic sample buffer (see recipe for buffer): concentration appropriate to obtain 5% final concentration in reaction mixture
Fluorescent lamp
Photographic equipment

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*)

1. Expose companion samples of 50 to 200 μg/ml MMP for 1 hr at room temperature to 20 μM DACM (final concentration) either in the presence or absence of 1% (w/v) SDS.

2. Stop reaction by adding 2-mercaptoethanol (as stock solution of appropriate concentration in electrophoretic sample buffer) to a final concentration of 5% (v/v).

3. Resolve proteins by SDS-PAGE (*UNIT 6.1*).

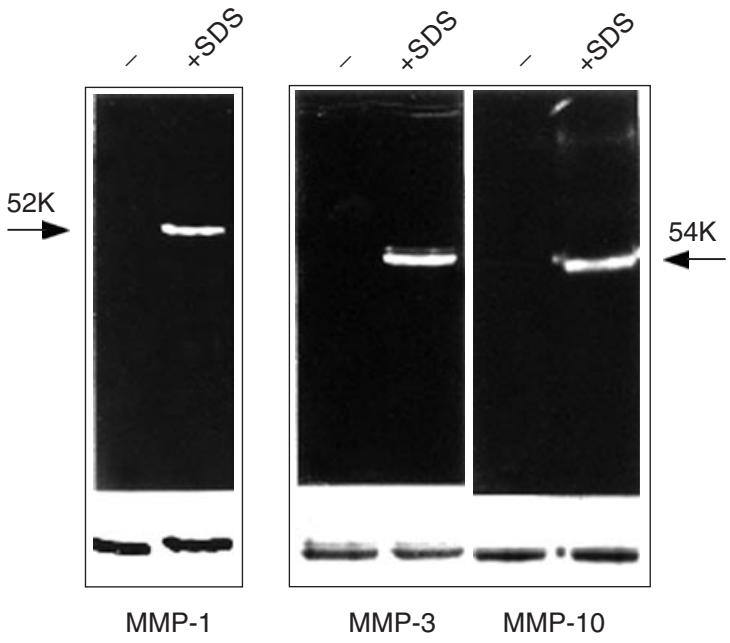

Figure 10.8.7 Fluorescent labeling of propeptide cryptic thiol residue by fluorescent maleimide. The cysteine switch is "closed" in the nascent proenzyme and therefore not reactive with a fluorescent maleimide compound (DACM). Exposure to SDS "opens" the switch and renders the cryptic thiol group reactive with the maleimide resulting in covalent modification of the proenzyme and generation of a readily detectable fluorescent band. Left panel: MMP-1. Right panel, MMP-3 and MMP-10. Lower edge of each panel shows Coomassie blue staining of the same bands. Modified from Windsor et al. (1993).

4. Photograph under long-wavelength UV illumination.

Typical results are shown in Figure 10.8.7.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX*** *2A; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Coomassie blue stain

0.5% (w/v) Coomassie blue R-250
30% (v/v) methanol
10% (v/v) acetic acid
Store up to 6 months at room temperature

Electrophoretic running buffer, pH 8.3

0.025 M Tris base
0.192 M glycine
0.1% (w/v) SDS
Store up to 1 year at room temperature

Electrophoretic sample buffer, 5×

0.2 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
5% (w/v) SDS
20% (w/v) glycerol

continued

0.1% (w/v) bromphenol blue
Store up to 1 year at room temperature

This is the sample buffer used in Basic Protocol 2.

Gelatin solution, 8.7 mg/ml

Add gelatin (bovine skin, Sigma-Aldrich type B6-6269) to 1 M Tris·Cl, pH 8.8 at 8.7 mg/ml. Dissolve by heating to 57°C, then filter through Whatman no. 1 filter paper.

Gel destaining solution

30% (v/v) methanol
10% (v/v) acetic acid
60% (v/v) H_2O
Store up to 1 year at room temperature

Gel washing buffers 1 to 4

Buffer 1:
2.5% (v/v) Triton X-100
3 mM NaN_3
Buffer 2:
2.5% (v/v) Triton X-100
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
3 mM NaN_3
Buffer 3:
2.5% (v/v) Triton X-100
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
3 mM NaN_3
5 mM $CaCl_2$
1 μM $ZnCl_2$
Buffer 4:
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
3 mM NaN_3
5 mM $CaCl_2$
1 μM $ZnCl_2$

Buffers may be stored up to 1 year at room temperature.

Incubation solution

50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.2 M NaCl
5 mM $CaCl_2$
0.02% (w/v) Brij-35
Store up to 1 year at 4°C

Neutralizing buffer (0.2 M naP_i)

Prepare the following stock solutions:
Solution A: 2.78 g NaH_2PO_4 in 100 ml H_2O
Solution B: 5.365 g $Na_2HPO_4 \cdot 7H_2O$ in 100 ml H_2O
Prepare working solutions as follows:
15.2 ml Solution A
64.8 ml Solution B
16.6 ml 5 M NaCl
Add 80 ml 0.1 N NaOH
Store up to 1 year at 4°C

Tris·Cl standard buffer, pH 7.4

50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
0.2 M NaCl
5 mM $CaCl_2$
Store up to 1 year at 4°C

COMMENTARY

Background Information

Dissolution of collagen type I

Substrate. Although collapsing the gel by air drying is advantageous for most purposes, and the resulting collagen film is more similar to the density of collagen in interstitial connective tissues (Fig. 10.8.1), it is possible to seed the cells on top of (or inside) fully hydrated gels and to monitor the process as the cells dissolve their way through the collagen gel. Electron microscopy confirms that hydrated gels are very loose, with the individual fibrils spaced far apart. The collagen content is quite low compared to the liquid phase and accounts for only 0.03% of the mass and for a similarly small volume fraction of the gel.

While use of reconstituted type I collagen fibrils as a substrate offers particular advantages because of its resistance to general proteolysis, it is possible to replace this substrate with other extracellular matrix components. Type II collagen does not form fibrils as readily as does type I but might prove useful after additional refinement of the system. Type III collagen appears to gel adequately for this purpose and may also be used as a substrate. Films and gels of type IV collagen may also be used, as may Matrigel (predominantly composed of laminin), fibrin, and fibronectin. An important variation using fluorescently labeled fibronectin was devised by Chen and coworkers (Chen et al., 1984; Chen and Chen, 1987).

Serum. Serum contains a number of factors expected to either promote or inhibit the proteolytic dissolution of the extracellular matrix including collagen fibrils. The high concentration of α2M (2 to 3 mg/ml or 3 to 4 × 10^{-6} M), which effectively blocks most MMPs in test tube experiments, however, does not inhibit cell-mediated dissolution of the collagen fibril film. Serum also contains plasminogen at a concentration of ~200 μg/ml (2 × 10^{-6} M). Addition of even low concentrations of plasminogen (4 μg/ml; 4 × 10^{-8} M) to serum-free cultures greatly accelerates the rate of dissolution of the collagen fibril film by human foreskin keratinocytes (or other cells) which express urokinase-type plasminogen activator (u-PA) or tissue-type plasminogen activator (t-PA). The mechanism is not quite well understood but may involve a role for plasminogen in the extracellular activation of certain proMMP precursors as an essential step in the dissolution of the substrate.

Cytokines, transcriptional activation. Addition of cytokines, growth factors, and agents such as TPA, which upregulate or induce expression of MMPs, generally accelerates dissolution of the fibril coating dramatically, but since these reagents upregulate a wide range of MMPs, it is not yet possible to determine whether a single MMP or group of MMPs is responsible for this effect.

Inhibition. That dissolution of the collagen fibril coating is mediated by metalloproteinase-dependent mechanisms is readily made evident by synthetic inhibitors. Inclusion of the Zn-chelating agent 1,10-phenanthroline completely blocks dissolution, as do synthetic MMP inhibitors such as BB94, BB2516 (British Biotech), and Galardin. A number of synthetic inhibitors currently exist; some of these may be obtained by directly contacting the pharmaceutical companies in question (British Biotech, Roche Diagnostics, Celltech). Serine proteinase inhibitors such as α1-antitrypsin (α1AT) and soybean trypsin inhibitor, as well as cysteine proteinase inhibitors such as E-64, have no effect on the rate of dissolution. These findings suggest that the process(es) that result in dissolution of the collagen fibrils are absolutely dependent on MMP activity.

Zymography

Gelatin zymography is a fairly straightforward yet very highly sensitive technique as long as heating and reduction are avoided during sample preparation. The method yields discrete, well-resolved, and distinct unstained bands on a blue background, which are clearly visible and easy to photograph and document with transillumination (Fig. 10.8.3). The activity may be quantified by comparison with standard curves of specific purified MMPs (Kleiner and Stetler-Stevenson, 1994), but the rate of lysis varies considerably from MMP to MMP, and the technique is primarily intended

to provide qualitative information. A variation described by Lyons et al. (1991) permits monitoring of real-time progress of the reaction under UV light by use of gelatin labeled by a fluorophore. Although gelatin zymography is highly sensitive, capable of detecting low picogram quantities of MMPs, the assay does not reflect the activity of these proteases present in the sample analyzed. This is because the addition of SDS to the sample prior to electrophoretic separation results in dissociation of many enzyme inhibitor complexes. Therefore, zymography represents an excellent technique for identification of MMP species present in a given sample, but overinterpretation of the results—e.g., assessment of specific activity—is a common pitfall. Casein zymograms develop more slowly, almost invariably require overnight incubation, and tend to produce less sharp bands. (Latent) proenzyme forms also show up because of the "switch"-opening effect of SDS, but these forms do not necessarily acquire full catalytic activity. "Activation" by organomercurials (0.5 to 1.0 aminophenylmercuric acetate in 50 mM Tris·Cl buffer, pH 7.5, for 20 min to 20 hr) before sample preparation often results in higher levels of proteolytic activity but also shifts the M_r of the individual bands because of autolytic cleavage and removal of the propeptide.

α2M capture

Capture techniques permit direct assessment of the ability of various forms of MMPs to bind to natural inhibitors in a manner that resists dissolution by exposure to low concentrations of SDS. Zymographic techniques are not capable of discriminating between latent and catalytically active forms of the enzymes. That, however, can readily be achieved by α2M capture. TIMP capture (see Alternate Protocol) on the other hand does not depend on proteolytic activity and merely requires a correctly folded, but not necessarily catalytically competent, active site (Windsor et al., 1994).

TIMP capture

The method is particularly useful for analysis of the binding capacity of mutants in TIMPs and in MMPs (Windsor et al., 1994; Caterina et al., 1997). It is important to recognize that TIMP binding is not necessarily synonymous with catalytic competence. Mutants of MMP which are correctly folded but devoid of catalytic activity, such as the E200Q mutant of MMP-1 in which the active site glutamate is replaced with glutamine (and therefore catalytically inactive), still form complexes with TIMP-1 fully, as well as the native enzyme (Windsor et al., 1994). TIMP-1 captures both truncated and full-length forms, as long as the "switch" is open (by APMA).

Fluorescent labeling of cryptic Cys residue

The nascent closure of the "cysteine switch" by bonding of the single unpaired propeptide Cys residue to the active-site Zn^{2+} converts a catalytic Zn-binding site to a structural Zn-binding site. In order to monitor the (re)opening of the switch as a preamble to zymogen activation, the authors of this unit reasoned that covalent linkage of a fluorophore to the free thiol group might render this process easily visible and potentially quantifiable. That is indeed the case. The method shows, for instance, that the phenomenon of "switch opening" can be readily visualized in the absence of propeptide cleavage by exposure either to SDS or to EDTA.

Critical Parameters and Troubleshooting

Dissolution of collagen type I

Even for the experienced operator, collagen is not an easy protein to work with. Its preparation and use require meticulous and stringent adherence to the rules and conditions that "work," often with very little leeway for shortcuts and modifications. The most important checkpoint comes after the initial gelling. Unless there is clear and unequivocal evidence of gelling after 2 hr, efforts should be made to identify and correct the problem. Since there is no simple way to measure collagen concentration, the authors have utilized initial dry powder weight from materials stored in refrigerated dessicator jars as a guide. The concentrations mentioned in this unit refer to powder weight under these conditions. It is absolutely necessary that the solution from which the collagen is lyophilized be completely salt-free following extensive dialysis against dilute acetic acid. This problem may be avoided by purchase of commercial preparations of rat or bovine type I collagen, but it is necessary to test the gelling properties of the particular brand in question at the desired concentration and under the desired conditions. After 2 hr of gelation, the gel should be reasonably firm, i.e., it should not disintegrate upon gentle flicking of the plate. If the gel disintegrates during this test, the problem must first be solved before proceeding.

The homogeneity of the gel is also very important. This is best checked following the first

air drying and washing step by staining a newly prepared film with Coomassie blue. This will instantly reveal whether the gel is uniform and homogenous and if it contains particulate matter (which can be removed by centrifugation) or air bubbles. Both must be avoided, and the technique must be improved until each gel is completely uniform and homogenous after staining. It is also important to ascertain after the first washing of the first-time dried gel that salt-crystal deposits (formed during the initial drying phase) have been completely removed by washing. This is most easily checked using the phase-contrast microscope. The gel should look granular but uniform; any trace of crystal patterns is a certain indication of inadequate washing.

Zymography

Gelatin zymography presents few, if any, technical challenges, hence the popularity and universal application of this technique. Because of the longer incubation time required and the lesser sensitivity, casein zymograms often give less distinct and more diffuse bands. Although it has not been widely explored, it is highly likely that a large number of other substrates could be substituted for either gelatin or casein. Reverse zymography, on the other hand, is technically challenging and requires great care and skill as well as considerable practice and experience. The latter method is, however, a uniquely powerful technique to identify discrete MMP-inhibitory bands.

Inhibitor capture

While commercial preparations of α2M are available, the method is critically dependent on the native configuration of the inhibitor. Consequently, the authors rely only on freshly isolated inhibitor. Occasionally, methods which are employed to activate MMPs, such as exposure to organomercurials, adversely affect the inhibitor and render the capture reaction partial rather than complete. In some cases trypsin activation (stopped by soybean trypsin inhibitor) is preferable, but many mutants are highly sensitive to trypsin and rapidly degrade during activation attempts.

Fluorescent labeling of cryptic Cys residue

The method is fairly straightforward, although care must be taken to exclude any chemicals from the solutions that interfere with the Cys-maleimide reaction (e.g., heavy metals, *N*-ethylmaleimide, or iodoacetate). Photographic documentation can be tricky, but usually works well when using reflected UV light.

Anticipated Results

Dissolution of collagen type I

Use of 1- to 2-μm films results in complete dissolution within 1 to 4 days. Initially the cells penetrate the collagen fibril coating in discrete spots, which eventually coalesce to form contiguous zones devoid of collagen fibrils (Fig. 10.8.2). Dissolution of the fibril coating is strictly limited to the area immediately beneath the cell layer and does not extend beyond the boundaries of the cell colony. A similar pattern is observed in the presence of serum or purified plasminogen.

Zymography

When performed correctly, the reverse zymography–stained gel shows discrete, well-resolved bands of TIMPs on a virtually unstained background, indicating that all of the gelatin has been degraded except in and around the TIMP bands (Fig. 10.8.4). While this method yields important information when used in qualitative or semiquantitative fashion, the read-out may be quantified as described by Kleiner and colleagues (Oliver et al., 1997).

As with direct zymography, reverse zymography is a highly sensitive technique that can detect as little as 50 to 100 pg of TIMPs in a given sample (Oliver et al., 1997). However, as with direct zymography, careful interpretation of results is essential. Again, use of SDS-containing sample buffers and electrophoretic separation of the sample results in dissociation of some protease-inhibitor complexes. Thus, the levels of TIMPs present may not accurately reflect the actual free TIMP levels present in the samples analyzed. Alternatively, as described for the TIMP capture assays, not all TIMP-MMP complexes may be dissociated by SDS, and TIMP-binding to an MMP active site does not necessarily reflect proteolytic competency of the enzyme.

α2M capture

Incubation of native α2M with activated proteinases that cleave the bait region result in full or partial capture of the attacking proteinase. Complete capture requires a significant molar excess of inhibitor (with the amount varying from proteinase to proteinase), which may be determined by titration in preliminary experiments. Because of the size difference, captured and uncaptured bands are readily resolved and identified on western blots by staining with anti-MMP antibodies. Latent or catalytically inactive forms are not captured and remain at their usual migration position in the gel.

TIMP capture

Remarkably, most TIMP-MMP complexes survive dilute SDS solutions at room temperature and permit electrophoretic separation of free and complexed forms. The M_r difference (20 to 30 kDa) is sufficient to fully resolve the bands. As with α2M capture, latent forms of MMPs ("switch closed") are not captured, and this method is therefore valuable in distinguishing "switch-open" and "switch-closed" forms before proteolytic excision of the propeptide during activation. The active site, however, does not have to possess catalytic activity, and inactive mutants (if correctly folded) readily form complexes with TIMPs.

Fluorescent labeling of cryptic Cys residue

Removal of Zn^{2+} with EDTA, as expected, also unmasks the cryptic thiol group. Fully converted ("activated") forms of the enzyme which have lost the entire propeptide no longer react. Note, however, that the free thiol group is only a few residues upstream of the ultimate proteolytic processing site. Partially processed forms of the proenzymes therefore may still react with DACM.

Time Considerations

Analysis of the degradation of collagen gels takes ~2 days to prepare the gels and 1 to 4 days for the assay itself. It requires ~2 weeks to prepare rat tail tendon collagen type I and 3 to 4 days to label the collagen with fluorophore.

Direct zymography takes 2 days to complete, while reverse zymography takes 2 days.

α2M and TIMP capture take 1 to 2 days depending on the duration of antibody incubation in immunoblotting.

Fluorescent labeling of the cryptic Cys residue can be completed in a single day.

Preparation of Extracellular Matrices Produced by Cultured and Primary Fibroblasts

Culturing fibroblasts on traditional two-dimensional (2-D) substrates induces an artificial polarity between lower and upper surfaces of these normally nonpolar cells. Not surprisingly, fibroblast morphology and migration differ once suspended in three-dimensional (3-D) collagen gels (Friedl and Brocker, 2000). However, the molecular composition of collagen gels does not mimic the natural fibroblast microenvironment. Fibroblasts secrete and organize the extracellular matrix (ECM), which provides structural support for their adhesion, migration, and tissue organization, in addition to regulating cellular functions such as growth and survival (Buck and Horwitz, 1987; Hay, 1991; Hynes, 1999; Geiger et al., 2001). Cell-to-matrix interactions are vital for vertebrate development. Disorders in these processes have been associated with fibrosis, developmental malformations, cancer, and other diseases.

This unit describes methods for generating tissue culture surfaces coated with a fibroblast-derived 3-D ECM produced and deposited by both established and primary fibroblasts. The matrices closely resemble in vivo mesenchymal matrices and are composed mainly of fibronectin fibrillar lattices. Utilizing in vivo–like 3-D matrices as substrates allows the acquisition of information that is physiologically relevant to cell-matrix interactions, structure, function, and signaling, which differ from data obtained by culturing cells on conventional 2-D substrates in vitro (Cukierman et al., 2001).

These protocols were initially derived from methods described in *UNIT 10.4*, which were modified to obtain fibroblast-derived 3-D matrices and to characterize cellular responses to them. The basic approach is to allow fibroblasts to produce their own 3-D matrix (see Basic Protocol). For this purpose, fibroblasts are plated and maintained in culture in a confluent state. After 5 to 9 days, matrices are denuded of cells, and cellular remnants are removed. Such extraction results in an intact fibroblast-derived 3-D matrix that is free of cellular debris and remains attached to the culture surface (see Figure 10.9.1). The fibroblast-derived 3-D matrices are then washed with PBS and can be stored 2 to 3 weeks at 4°C or up to 3 weeks frozen at −80°C. Moreover, to analyze the effect of matrix pliability on cellular behavior, prepared 3-D matrices can be rigidified by chemical cross-linking (see Support Protocol 1 and *UNIT 17.10*).

Additionally, to evaluate the quality of the fibroblast-derived 3-D matrices, support protocols present a variety of procedures for measuring cell responsiveness to the 3-D matrix microenvironment (see Support Protocols 2 and 3). The rapid cell attachment of fibroblasts plated within the matrix can be quantified. By plating isolated fibroblasts in the 3-D matrix, the acquisition of an in vivo–like spindle-shaped morphology can also be measured. To ascertain whether fibroblasts respond to the 3-D microenvironment when plated within specific (NIH-3T3) matrices, the phosphorylation level of nonreceptor focal adhesion kinase (FAK) pY^{397} can be quantified by immunoblotting (see Support Protocol 4).

This unit will also describe how to mechanically compress the fibroblast-derived 3-D matrices to obtain 2-D substrate controls (see Support Protocol 5). Moreover, a support protocol will illustrate how to solubilize the fibroblast-derived 3-D matrices to produce a matrix-derived protein mixture for additional 2-D coating controls and for subsequent

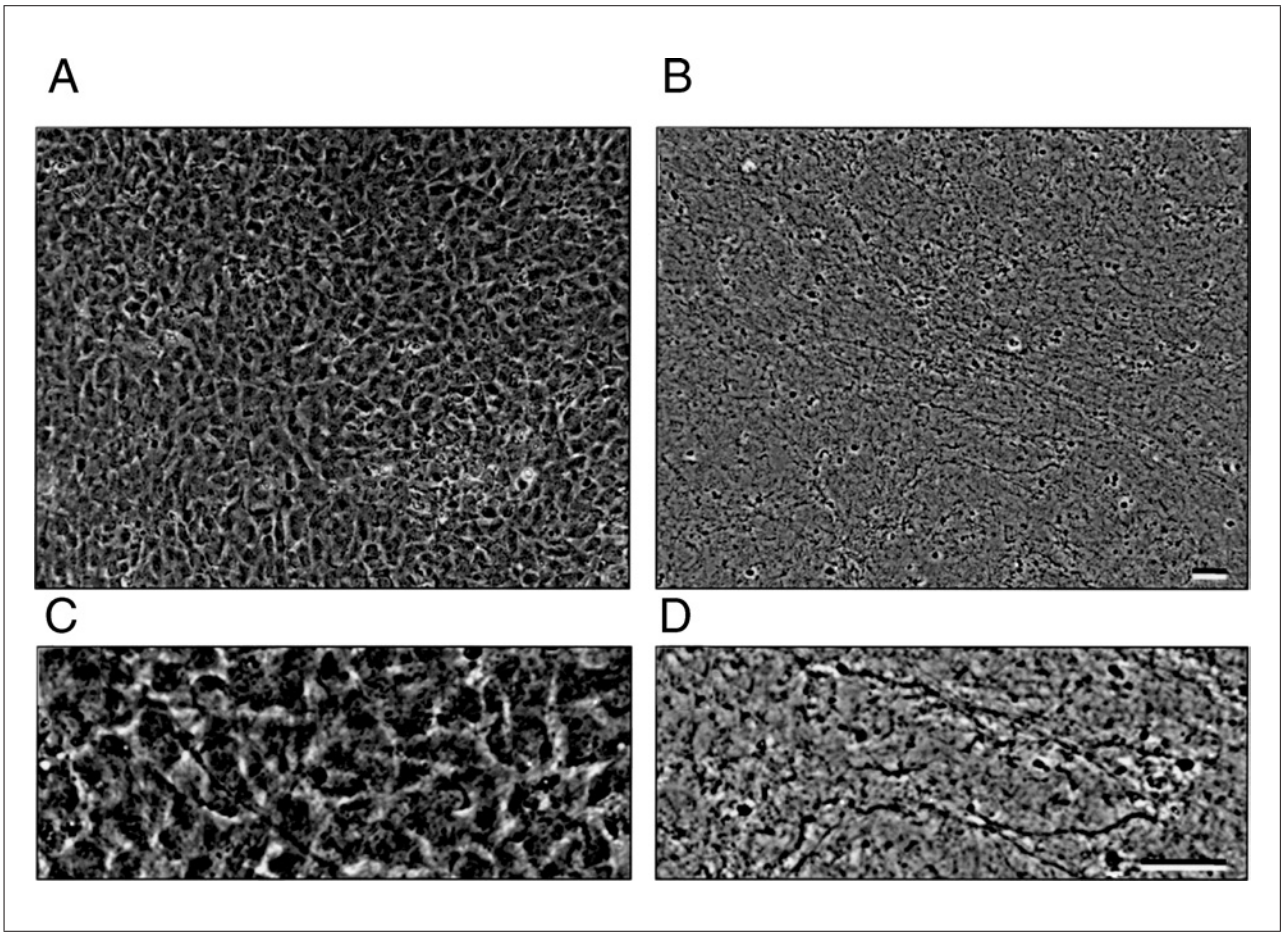

Figure 10.9.1 Fibroblast-derived 3-D matrices before and after extraction process. (**A**) Culture at day 5 prior to matrix extraction. (**B**) The resulting fibroblast-derived 3-D matrix. Panels **C** and **D** are magnified insets from **A** and **B**, respectively. Bars represent 50 μm.

biochemical analysis of the matrices (see Support Protocol 6 and Commentary). Lastly, there is a protocol for isolating primary fibroblasts from fresh tissue samples to produce additional types of fibroblast-derived 3-D matrices (see Support Protocol 7).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic techniques should be used accordingly.

NOTE: All cell-culture incubations should be performed in a 37°C, 10% CO_2 humidified incubator.

BASIC PROTOCOL

PREPARATION OF EXTRACELLULAR MATRICES PRODUCED BY CULTURED OR PRIMARY FIBROBLASTS

NIH-3T3 cells (for primary cell lines see Support Protocol 7) must be routinely cultured in high-glucose Dulbecco's modified Eagle medium supplemented with 10% calf serum, 100 U/ml penicillin, and 100 μg/ml streptomycin unless otherwise specified. Never allow cultured NIH-3T3 cells to become completely confluent while maintaining stock cultures. When cells reach 80% confluence (about once per week), subculture at a 1:20 dilution. However, prior to plating for matrix deposition, NIH-3T3 cells should be adapted to grow in 10% fetal bovine serum rather than calf serum for the cells to adopt an optimal phenotype for matrix production (see Critical Parameters).

Depending on the laboratory equipment available, and the anticipated uses of the fibroblast-derived 3-D matrices, a suitable surface on which the matrices will be produced (e.g., glass-bottom dishes, coverslips, or tissue culture dishes) must be selected as follows:

(1) Disposable glass bottom dishes (MatTek) can be utilized for real-time fluorescent experiments or for quality assessment assays (e.g., cell attachment and cell shape) using an inverted fluorescent microscope (see Support Protocols 1 and 2).

(2) Coverslips can be used for immunofluorescence experiments in which samples are fixed and mounted on microscope slides (see Support Protocol 3), or for mechanical compression of the fibroblast-derived 3-D matrices to be used as control 2-D surfaces (see Support Protocol 5).

(3) Regular tissue culture dishes (e.g., 35-mm diameter) can be used for in vivo observations using an inverted microscope, for matrix solubilization and further characterization, and/or for biochemical analyses (see Support Protocols 5 and 3, respectively). Tissue culture dishes are also used for real-time cell motility analyses (Cukierman, 2005).

Materials

NIH-3T3 cells (ATCC) or primary fibroblasts (see Support Protocol 7)
Confluent medium with fetal bovine serum (FBS; see recipe)
0.25% (w/v) trypsin/0.03% (w/v) EDTA solution (see recipe)
0.2% (w/v) gelatin solution (see recipe)
Ethanol (absolute)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
1% (v/v) glutaraldehyde in PBS (see recipe)
1 M ethanolamine (see recipe)
Matrix medium with ascorbic acid (see recipe)
Extraction buffer (see recipe), 37°C
10U/ml DNase I (Roche) in PBS^+ (see recipe for PBS^+), optional
Penicillin/streptomycin (Invitrogen)
Fungizone (amphotericin B; Invitrogen)

37°C, 10% CO_2 humidified incubator
15-cm dishes plus the specific culture vessels for matrix production
Inverted phase-contrast microscope
6-well tissue culture plates or 35-mm dishes (optional)
22-mm circular high-quality coverslips (Carolina; optional)
Bacterial 6-multiwell petri plates for preparing matrices on coverslips
Parafilm strips
Small, sterile fine-pointed tweezers (e.g., Dumont no. 4), optional

Prepare cell cultures

1. Start with a semi-confluent (80% confluent) culture of NIH-3T3 cells cultured in 10 to 12 ml confluent medium containing fetal bovine serum (see Critical Parameters) or primary fibroblastic cells on a 15-cm culture plate (see Support Protocol 7); aspirate and discard the culture medium.

2. Rinse the cell layer briefly with 1.5 ml of 0.25% trypsin/0.03% EDTA (trypsin/EDTA) per 15-cm dish. Then gently aspirate off the solution.

   This rinse will remove traces of serum that contains trypsin inhibitors.

3. Add enough trypsin/EDTA solution to cover the cell layer, quickly aspirate excess liquid, and observe under an inverted microscope at room temperature until the cells have detached from the culture dish (1 to 3 min).

4. Collect the cells in 10 ml of confluent medium.
5. Add 2 ml of the suspended cells and 10 to 12 ml of confluent medium to a 15-cm plate and culture for 2 to 3 days (until semi-confluent, up to ~80% confluence).

   As many as five 15-cm culture dishes may be used.

Prepare surfaces for matrix deposition

Although not strictly required, both gelatin coating (steps 6 and 7) and cross-linking of gelatin (steps 8 through 11) with glutaraldehyde stabilizes the attachment of the matrices to the culture dish surface and greatly improves final yield. However, the resulting matrices may be thinner than those obtained without gelatin pre-coating and cross-linking. Therefore, matrix thickness should be determined for each fibroblastic cell type and a decision to follow the optional steps should be made for each cell type.

6a. *For tissue culture dishes:* Add 2 ml of 0.2% gelatin solution to a 35-mm tissue culture dish surface to be used for fibroblast-derived 3-D matrix deposition and incubate for 1 hr at 37°C.

   Choose 35-, 60-, or 100-mm dishes to be used in this protocol. For 60- or 100-mm dishes, scale up the volumes of all reagents added from 2 ml to 4 and 8 ml, respectively.

6b. *For coverslips:* Presterilize by flaming the coverslips after dipping in anhydrous ethanol (absolute). Then place coverslip in a tissue culture dish and rinse with PBS. Incubate coverslips in a 0.2% gelatin solution.

7. Aspirate gelatin and add 2 ml PBS.

   When using coverslips, after this rinse, transfer coverslips to individual wells of multiwell bacterial plates.

   When preparing coverslips for 3-D matrix deposition, multiwell bacterial petri dishes are preferred over tissue culture plastic dishes because the fibroblasts do not adhere well to bacterial petri plastic. Consequently, there is preferential fibroblastic growth on pretreated glass coverslips instead of on the surface of the petri plastic, conditions conducive to enhancing matrix production on the coverslip. Placing coverslips on bacterial petri plastic also facilitates lifting the coverslip off the dish surface with tweezers during matrix extraction (see step 19) because any cells growing underneath the glass coverslips are easily dislodged.

8. Aspirate PBS and add 2 ml of 1% glutaraldehyde (prediluted in PBS) to each dish or well and incubate 30 min at room temperature.
9. Wash coverslips or culture dishes three times for 5 min each with 2 ml of PBS.
10. Add 2 ml of 1 M ethanolamine to each dish and incubate 30 min at room temperature.
11. Repeat the PBS washes (step 9).

    This step is a good place to stop if time does not permit cell seeding. Dishes can be left for 1 to 7 days at room temperature under sterile conditions.

12. Aspirate PBS from dishes and replace with 2 ml matrix medium. If the medium appears purple, repeat steps 11 and 12 to remove any trace amounts of ethanolamine.

    At this point, the surfaces are ready to be seeded with matrix-producing fibroblasts.

Allow cells to deposit matrix

13. Repeat steps 1 to 3 to harvest cells from a semi-confluent dish.

    This protocol was developed for NIH-3T3 cells. Nevertheless, other fibroblast cell lines can be used. For example, the same protocol can be followed from this point on using human or other primary fibroblastic cells (see Suppport Protocol 7).

14. Collect cells from each dish in 10 ml of matrix medium, count cells (*UNIT 1.1*), and dilute to a final concentration of 2.5×10^5 cells/ml.

15. Aspirate medium (from step 12) and seed 5×10^5 cells in 2 ml of matrix medium per 35-mm dish and culture for 24 hr.

    Use as many dishes as needed; there should be enough cells for ~100 35-mm plates from each 15-cm semiconfluent dish. Remember to scale up volumes from 2 ml to 4 or 8 ml for 60- or 100-mm plates, respectively.

16. After 24 hr, carefully aspirate the medium from cells and replace with fresh matrix medium containing 50 μg/ml of ascorbic acid.

    For some primary cell lines, adding a ten-fold higher concentration of ascorbic acid on this first addition of ascorbic acid after cell plating can increase matrix thickness. Because the higher ascorbic acid concentration is detrimental for NIH-3T3 cells, whether or not to use this higher dose should be independently determined for each fibroblastic cell type.

17. Ascorbic acid degrades over time in culture, so change medium with freshly made matrix medium every 48 hr for a total of 5 to 9 days after step 16.

    At this time, the matrix should be sufficiently thick to achieve three-dimensionality (≥10 μm, see below). At this point it is ready to be extracted (see Fig. 10.9.1 A).

    Matrices should be extracted after they reach a thickness of at least 10 μm. The time required for each fibroblast cell type to produce a matrix of this thickness may vary. Therefore, this time period must be determined empirically for each cell type.

Remove cells from matrix

18. Carefully aspirate the medium and rinse gently with 2 ml PBS by touching the pipet against the dish wall rather than at the bottom of the dish where the cells are located.

19. Gently add 1 ml of prewarmed (37°C) extraction buffer.

    If coverslips are being used, gently lift the coverslips with the fine-pointed tweezers (or a syringe needle) so that extraction buffer reaches under the coverslip. This step will ensure that the matrix deposited on the coverslip will be separated successfully from the matrix deposited on the bottom of the culture dish. This will facilitate subsequent handling of the coverslips without tearing the delicate matrix.

20. Observe the process of cell lysis using an inverted microscope. Incubate at 37°C until no intact cells are visualized (~3 to 5 min; see Fig. 10.9.1B).

Remove cellular debris

21. Slowly add 2 to3 ml PBS to dilute the cellular debris. Gently pipet the PBS on the side of the dish to avoid disturbing the newly formed matrix. Store dishes overnight at 4°C to avoid disturbing the matrix.

    The above dilution process should be carried out gently to prevent turbulence that may cause the freshly denuded matrix-layer to detach from the surface.

22. As cautiously as possible (using a pipet), aspirate the diluted cellular debris, but without completely aspirating the liquid layer so that the matrix surface remains hydrated at all times.

    Do not attempt to aspirate the whole volume. This will prevent removing the matrix layer.

23. Gently add another 2 ml of PBS and gently aspirate the PBS as described in steps 21 and 22.

24. (*Optional*) If necessary, minimize DNA by treating the matrix with DNase I. Add 2 ml DNase I and incubate 30 min at 37°C.

25. At the end of the incubation, aspirate the enzyme and wash two times with 2 ml PBS.

26. Cover the matrix-coated plates (or coverslips) with at least 3 ml PBS supplemented with 100 U/ml penicillin, 100 μg/ml streptomycin, and 0.25 μg/ml Fungizone. Seal with Parafilm and store for up to 2 or 3 weeks at 4°C.

    For signal transduction assays, store the matrix-coated plates in serum-free medium (see Commentary).

    Matrices can also be stored for at least 3 weeks at −80°C (longer times have not yet been tested) without compromising matrix integrity, when compared with matrices from the same batch stored at 4°C. To store matrices at −80°C, rinse matrix dishes two times with sterile, nanopure H_2O and carefully aspirate all the liquid. Then label dishes to indicate the date of freezing for future reference, seal with Parafilm, and place at −80°C. When needed, thaw matrix dishes at room temperature and rehydrate with PBS prior to use for cell attachment or replating (see Support Protocols 1 and 5).

27. Confirm the integrity of the matrices directly before use. Examine for matrix integrity using an inverted phase-contrast microscope.

    The matrices should be attached to the culture surface and appear similar to the example in Figure 10.9.1B.

SUPPORT PROTOCOL 1

FIXATION OF EXTRACTED MATRICES FOR LACK OF PLIABILITY ANALYSES

For certain experiments designed to analyze the effect of rigidity or pliability of the matrix on cell behavior, it is necessary to chemically rigidify the prepared matrices. To this end, matrices are fixed with 1% glutaraldehyde prior to cell plating and analysis.

Materials

1% (v/v) glutaraldehyde in PBS (see recipe)
Tissue culture dishes or coverslips with matrix
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
1 M ethanolamine (see recipe)
Penicillin/streptomycin
Fungizone
Parafilm

1. Aspirate PBS, add 2 ml of 1% glutaraldehyde (prediluted in PBS) to each tissue culture dish or well, and incubate 30 min at room temperature.
2. Wash coverslips or culture dishes three times, for 5 min each, with 2 ml PBS at room temperature.
3. Add 2 ml of 1 M ethanolamine to each dish and incubate 30 min at room temperature.
4. Repeat the PBS washes (step 2).
5. Cover the matrix-coated plates (or coverslips) with at least 3 ml PBS supplemented with 100 U/ml penicillin, 100 μg/ml streptomycin, and 0.25 μg/ml Fungizone. Seal with Parafilm. Store up to 2 or 3 weeks at 4°C or at −80°C as described for NIH-3T3 matrices (see Basic Protocol, step 26).

ASSESSING THE QUALITY OF FIBROBLAST-DERIVED THREE-DIMENSIONAL MATRICES

The quality of fibroblast-derived 3-D matrices can be tested by one of three assays presented here as support protocols. The first two assays, induction of rapid cell attachment (see Support Protocol 2) and rapid acquisition of spindle-shape morphology (see Support Protocol 3), are based on examination of fluorescently labeled cells plated on 3-D matrices. The prelabeling with a fluorescent dye is required to enhance the observation of cells

within fibroblast-derived 3-D matrices. NIH-3T3 matrix quality can also be assessed in a third assay to check for down regulation of activated FAKpY^{397} when normal fibroblasts are plated within prepared NIH-3T3 matrices (see Support Protocol 4). These are referred to as "re-plated" fibroblasts. To analyze the level of activated [FAKpY^{397}/total FAK] of normal fibroblasts re-plated within these matrices, the ratio of FAKpY^{397}/total FAK is compared to the level of FAKpY^{397}/total FAK of the same cells plated on a traditional fibronectin-coated tissue culture dish, (2-D surface; see Support Protocol 2, cell attachment assay). Typically, a 1.5- to 4-fold reduction in FAK pY^{397}/total FAK in normal fibroblasts replated into NIH-3T3 matrices is observed (Cukierman 2001; see Support Protocol 4).

Cell Attachment Assay

SUPPORT PROTOCOL 2

Human or mouse fibroblasts can be used to evaluate the cell adhesion–promoting activity of the fibroblast-derived 3-D matrices. It has been reported that these in vivo–like 3-D matrices (NIH-3T3) are about six-fold more effective than 2-D substrates in mediating cell adhesion as quantified by a 10-min cell attachment assay (Cukierman et al., 2001). Briefly, cell nuclei are prelabeled to avoid any background staining from DNA debris on the 3-D matrix. The live prelabeled cells are rinsed free of excess dye, trypsinized, and plated on the fibroblast-derived 3-D matrix to be assessed or onto control fibronectin-coated surfaces. After 10 min, nonattached cells are washed away, and attached cells are quantified by counting nuclei.

Materials

Semi-confluent fibroblasts (human or mouse) in a 15-cm dish
Confluent medium with fetal bovine serum (see recipe)
Hoechst 33342 stock solution (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), 4°C and room temperature
Trypsin/EDTA solution (see recipe)
Glass-bottom no. 1.5 dishes (MatTek Corporation): three containing fibroblast-derived 3-D matrix (see Basic Protocol) and three with pre-coated 2-D fibronectin (see recipe)
Fixing solution (see recipe)
15-ml polypropylene conical tubes
Tissue culture centrifuge equipped with rotor suitable for conical 15-ml tubes
Fluorescence inverted microscope equipped with an appropriate camera and set of filters to visualize Hoechst 33342 (see *APPENDIX 1E*)
Image analysis software capable of counting objects (optional)

Label cells

1. Start with a semi-confluent 15-cm culture dish containing fibroblasts (mouse or human); aspirate and discard the culture medium.
2. Add 20 ml of confluent medium containing 40 µl of Hoechst 33342 stock solution (1:500) to the cells. Incubate 15 min at 37°C.

Harvest cells

3. Rinse four times with 10 ml PBS at room temperature, 1 min each rinse.
4. Add enough trypsin/EDTA solution to cover the cell layer, aspirate excess liquid, and observe under an inverted microscope until cells are detached from the culture dish (1 to 3 min).

Prepare cell suspension

5. Collect the cells in 10 ml of confluent medium into a 15-ml polypropylene conical tube and take a sample for counting (*UNIT 1.1*).

6. Pellet the cells by centrifuging 5 min at 100 × *g*, room temperature.
7. Discard the supernatant and gently resuspend the cells with confluent medium to a final concentration of 3.5×10^5 cells/ml.
8. Rotate cells in suspension for 20 min at 37°C.

Allow cells to attach

9. Carefully place a 150-µl drop of cell suspension onto the glass-bottom part of the dishes coated with 3-D matrix or 2-D matrix controls. Incubate 10 min at 37°C.
10. Remove from the incubator and tilt the dishes slightly to dislodge the medium droplet containing unattached cells from the glass portion onto the plastic portion of the dish and then aspirate.
11. Rinse the dishes by slowly adding (to the plastic portion of the dishes) 3 ml of 4°C PBS.

Fix cells

12. Aspirate PBS carefully and add 2 ml of fixing solution. Incubate 20 min at room temperature.
13. Aspirate and add 2 ml PBS at room temperature.

Visualize and analyze attached cells

14. Using an inverted fluorescence microscope with appropriate excitation wavelength and excitation and emission filters (*APPENDIX 1E*), acquire five random images of the nuclei from each one of the six dishes utilizing a 10× or 20× objective and count the nuclei.

    Counting of the nuclei can be done automatically utilizing commercially available image analysis software capable of counting objects (e.g., MetaMorph from Universal Imaging Corporation). If the counting is done automatically, then images should be acquired with a 10× objective. However, if the nuclei are to be counted manually, then a 20× objective is recommended.

    The mean number of cells attached to the fibroblast-derived 3-D matrix should be up to six-fold higher than the number attached to the 2-D matrix control. This result will confirm the quality of the NIH-3T3-derived 3-D matrix (Cukierman et al., 2001).

SUPPORT PROTOCOL 3

Determination of Cell Shape

Human or mouse fibroblasts can be used to evaluate induction of spindle-shaped cell morphology promoted by a good-quality in vivo–like 3-D matrix. A recent report has established that fibroblasts will acquire an in vivo–like spindle-shaped morphology in cell-derived 3-D matrices 5 hr after plating (Cukierman et al., 2001). The protocol consists of prelabeling live fibroblast membranes with a fluorescent dye and incubating the cells on fibroblast-derived 3-D matrices or controls for a period of 5 hr. After this period of time, the fibroblast-derived 3-D matrix promotes a spindle-shaped morphology resembling in vivo fibroblast morphology, thereby confirming the quality of the 3-D matrices.

Materials

Fibroblast-derived 3-D matrix-covered coverslips (see Basic Protocol)
Fibronectin 2-D matrix-coated coverslips (see recipe)
2% (w/v) heat-denatured BSA (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Semi-confluent 15-cm dish of fibroblasts
Trypsin/EDTA solution (see recipe)
Confluent medium with fetal bovine serum (see recipe)

1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) stock solution (see recipe)
Fixing solution (see recipe)
Prolong Gold mounting medium (Invitrogen)

35-mm tissue culture dishes or 6-well plates
Inverted microscope
15-ml polypropylene conical tubes
Tissue culture centrifuge equipped with rotor suitable for 15-ml conical tubes
Fine-point forceps (e.g., Dumont 4)
Glass microscope slides
Fluorescent microscope equipped with digital camera
Image analysis software capable of measuring elliptical Fourier parameters

Block nonspecific cell binding with BSA

1. Cautiously place fibroblast-derived 3-D matrix and control-coated coverslips (matrix face up) into 35-mm tissue culture dishes (or 6-well plates).
2. Block nonspecific cell binding by adding 2 ml of 2% heat-denatured BSA and incubate for 1 hr at 37°C.
3. Rinse all blocked coverslips with 2 ml PBS.

   At this point, coverslips are ready to be seeded with the prelabeled cells.

Label cell membrane with DiI

4. Start with a semi-confluent 15-cm dish of fibroblasts; aspirate and discard the culture medium.
5. Rinse the cell layer briefly with 1.5 ml trypsin/EDTA.

   This rinse will remove traces of serum that contain trypsin inhibitors.

6. Add enough trypsin/EDTA solution to cover the cell layer, aspirate excess liquid, and observe under an inverted microscope until cells are detached from the culture dish (1 to 3 min).
7. Collect the cells in 10 ml of confluent medium containing 4 μg/ml DiI into a 15-ml polypropylene conical tube.
8. Incubate the cells with the dye in suspension by rotating gently for 30 min at 37°C.
9. Pellet the cells by centrifugation 5 min at 100 × *g*, room temperature.
10. Discard the supernatant by aspiration, and gently resuspend the cells in confluent medium to a final volume of 10 ml.
11. Repeat steps 9 and 10 four additional times to remove any remaining free dye.
12. Count cells (*UNIT 1.1*) and dilute (with confluent medium) to a final concentration of 1×10^4 cells/ml.

Plate labeled cells

13. Carefully aspirate PBS from the coverslips in step 3.
14. Add 2 ml of the diluted cell suspension to the dishes containing coverslips and incubate 5 hr at 37°C.

    For fast qualitative analysis, cells can be observed and photographed at the end of 5 hr with an inverted fluorescence microscope (see APPENDIX 1E for wavelength information).

15. Aspirate medium and rinse with 2 ml PBS.

Fix cells

16. Aspirate PBS and fix with 1 ml of fixing solution for 20 min at room temperature.
17. Aspirate fixing solution and rinse with 2 ml PBS.
18. Rinse with 2 ml water to eliminate residual salt.
19. Carefully lift coverslip with fine-point forceps and gently discard excess liquid by touching the edge of the coverslip onto a paper towel.
20. Mount coverslips (cells face down) on a droplet (~20 µl) of Prolong Gold mounting medium placed on a glass microscope slide.
21. Allow mounted samples to dry in the dark for ~1 hr at room temperature.

    At this point, samples are ready for morphometry analysis, or they can be stored overnight in the dark at room temperature before transferring to ≤4°C.

Perform morphometric analysis

22. Acquire fluorescent digital images, slightly over-exposing to visualize the contour of the cells (for wavelength, see *APPENDIX 1E*).

    Use a magnification that will allow visualization of an entire cell in each image. Randomly capture images of at least 12 cells per sample and a minimum of 36 cells per substrate.

23. Perform the measurements for both the length (span of the longest cord) and the breadth (caliper width) of each cell.
24. Calculate the inverse axial ratio by dividing length by breadth.

    The inverse axial ratio corresponds to the elliptical form factor (EFF) morphometric parameter found in the integrated morphometry analysis (IMA) function of MetaMorph software (Universal Imaging Corporation).

    The mean inverse axial ratio induced by a high-quality NIH-3T3-derived 3-D matrix should be about three-fold greater than that induced by the 2-D fibronectin control (Cukierman et al., 2001).

SUPPORT PROTOCOL 4

Lysis of Re-Plated Fibroblasts for Western Blot Analyses

To assure the quality of a batch of NIH-3T3-derived 3-D matrices, the levels of FAK activity (FAKpY^{397}) must be down-regulated at least 1.5 fold (Cukierman et al., 2001) when compared to classic 2-D cultures. This protocol describes how to lyse normal human or murine primary fibroblasts after re-plating within 3-D matrices for biochemical analysis by immunoblotting (see *UNIT 6.2*). In brief, re-plated normal fibroblasts are lysed and subjected to immunoblot analysis. Cell lysate extracts can also be stored for later analyses (see step 11).

Materials

Matrix-coated ≥35-mm dishes (see Support Protocol 2)
Fibronectin-coated ≥35-mm dishes
Cell suspension from confluent cultures of fibroblasts
Confluent medium with fetal bovine serum (see recipe)
Lysis buffer (modified RIPA) reagent (see recipe) supplemented with protease and phosphatase inhibitors (see recipe), ice cold
Normal human or murine fibroblasts re-plated in 3-D matrix dishes (see Basic Protocol, step 18)
Phosphate-buffered saline without Ca^{2+} or Mg^{2+} (CMF-PBS; *APPENDIX 2A*), ice cold
Dry ice/isopropanol bath

5× sample buffer supplemented with β-mercaptoethanol
Anti-FAKpY^{397} and anti-total FAK (see recipes)
Glutaraldehyde-3-phosphate dehydrogenase (GAPDH)

37°C, 10% CO_2 humidified incubator
Cell scraper (Costar, Fisher Scientific)
1.5-ml microcentrifuge tubes (Eppendorf)
Sonicator (e.g., Branson Sonifier 150)
Scion image software beta version 4.03

Additional reagents and equipment for calculating the amount of 5× sample buffer supplemented with β-mercaptoethanol (*UNIT 6.1*) and detecting proteins by immunoblotting (*UNIT 6.2*)

Re-plate fibroblasts within 3-D matrices

1. Block nonspecific binding in 3-D matrices with BSA in a 35-mm dish (or 6-well multiwell dish (see Support Protocol 2, steps 1 and 2).

   When using 2-D substrates, precoat 35-mm dishes with 1 ml of 5 μg/ml fibronectin or other matrix protein (see recipe for pre-coated 2-D fibronectin dishes) for 1 hr at 37°C. Alternatively, use uncoated dishes in PBS for 2-D control substrates.

2. Plate 2 ml of cell suspension at a final concentration of 1×10^5 cells/ml in confluent medium for each dish and incubate 20 hr in a 37°C, 10% CO_2 humidified incubator (see Basic Protocol, steps 1 to 4).

Lyse cells within matrices

3. Supplement 10 ml of ice-cold lysis buffer with protease and phosphatase inhibitors.

4. Carefully aspirate confluent medium from fibroblasts re-plated in 3-D matrix dishes (see Basic Protocol, step 18).

5. Gently add ice-cold PBS and repeat steps 4 and 5 for a total of two PBS washes.

6. Carefully aspirate again and tip the dishes for 1 min to accumulate the excess PBS on one side of the dish (~30° to bench top).

   It is important to remove all traces of PBS to prevent diluting lysates with PBS for the purpose of maintaining a uniform volume of lysate for different samples. This will yield a relatively consistent protein loaded onto SDS-PAGE gels for immunoblotting (see UNIT 6.2).

7. Carefully aspirate the excess PBS to avoid detaching the matrix layer.

8. Place the dishes (usually a 35-mm dish) on ice and add 200 to 300 μl of ice-cold lysis buffer.

   For larger dishes, add a proportionally larger volume of lysis buffer.

9. Incubate on ice for 5 min with gentle rocking.

Collect the lysate

10. Scrape the cells and matrix from the dish with the cell scraper. Then, tilt the dish toward one side and collect the lysate mixture into a 1.5-ml microcentrifuge tube.

11. Sonicate each tube of cell lysate using the remote setting of 3 (medium power) for 30 sec for each tube.

12. Centrifuge the lysates 15 min at 16,100 × *g*, 4°C.

13. Carefully remove the supernatant and transfer to a fresh, labeled tube. If not used immediately, quick freeze the lysates in a dry ice/isopropanol bath and store for 1 to 2 weeks at −80°C.

To quick-freeze cell lysates, prepare a dry ice/isopropanol bath by adding ~100 ml of isopropanol to a 400-ml beaker and placing in an ice bucket containing dry ice pellets in the fume hood. Allow the isopropanol to cool for 30 min. Add 1.5-ml microcentrifuge tubes containing freshly prepared lysates to a tube-rack and lower the rack into the isopropanol so that the lysate volume is completely immersed. The lysates should be frozen almost immediately (smaller aliquots are better). Finally, quickly transfer the tubes to a −80°C freezer. Samples are stable for 1 to 2 weeks. Each individual protein should be tested since there is some variability.

Analyze lysates

14. To analyze the matrix by immunoblotting, calculate the amount of 5× sample buffer supplemented with β-mercaptoethanol (*UNIT 6.1*) that is needed to make a 1× final concentration after addition to the sample; and add that amount to appropriate lysate samples.

15. Analyze signaling proteins by immunoblotting and immunodetection (*UNIT 6.2*) using antibodies to FAKpY^{397} and total FAK.

For analysis of phosphoproteins, incubate primary antibodies with TBST with a final concentration of 5% (w/v) BSA.

For total FAK and other non-phosphorylated protein epitopes, primary antibodies, all secondary antibodies, and for blocking buffer, use 5% (w/v) nonfat dried milk in TBST as the diluent.

16. Scan individual protein bands corresponding to FAKpY^{397} or total FAK and quantify their optical densities using the public Scion image software beta version 4.03 by means of the Gelplot2 macro. To adjust for sample loading, quantify glutaraldehyde-3-phosphate dehydrogenase (GAPDH, 40 kDa) as a total cellular protein control.

The software can be downloaded from the Scion image software Web site at: http://www.scioncorp.com/frames/fr_download_now.htm.

The average protein yield of the matrix and fibroblasitic proteins (lysate) is ~0.5 to 2 mg per 35-mm dish.

PREPARATION OF TWO-DIMENSIONAL CONTROLS

Any given cell response induced by in vivo–like fibroblast-derived 3-D matrices could be due to the three-dimensionality of the matrix, its molecular composition, or a combination of both. The following two support protocols provide methods for obtaining suitable 2-D control matrices with the same molecular composition as the 3-D matrices.

SUPPORT PROTOCOL 5

Mechanical Compression of the Fibroblast-Derived 3-D Matrix

This protocol describes how to apply pressure to the fibroblast-derived 3-D matrix to collapse the matrix to a flat substrate. Mechanical compression of the 3-D matrix ensures that all natural components of the 3-D matrix are present, lacking only the element of three-dimensionality. Briefly, the 3-D sample is compressed using a known weight applied to a given area. The surface that comes into contact with the matrix is covered with a Teflon film to prevent sticking and to avoid tearing the flattened matrix as the weight is retracted.

NOTE: Any other materials fulfilling the same purpose can be substituted.

Materials

Superglue
Absolute ethanol, optional
Fibroblast-derived 3-D matrix on 22-mm circular coverslips
Phosphate-buffered saline (PBS; see *APPENDIX 2A*)
Flat platform large enough to rest on the ring (see Fig. 10.9.2)
Suitable spacer smaller in width than the diameter of the ring but longer in height than the depth of the ring (see Fig. 10.9.2)
12-mm round coverslips (Carolina)
Teflon film: protective overlay composed of: 0.001-in. FEP film, on 0.008-in. vinyl film, with adhesive back (use to cover laboratory bench-tops, Cole-Parmer Instrument Company)
Cork borer (12-mm diameter)
Biological hood equipped with UV light
Stand equipped with a horizontal ring
Lifting laboratory jack
Parafilm
Weight (~158 g)
35-mm dishes
Inverted phase-contrast microscope

Construct weight holder for matrix compression

1. Glue the flat platform to the spacer in such a way that the spacer will protrude slightly beyond the bottom of the ring when the platform is placed on the ring (Fig. 10.9.2).

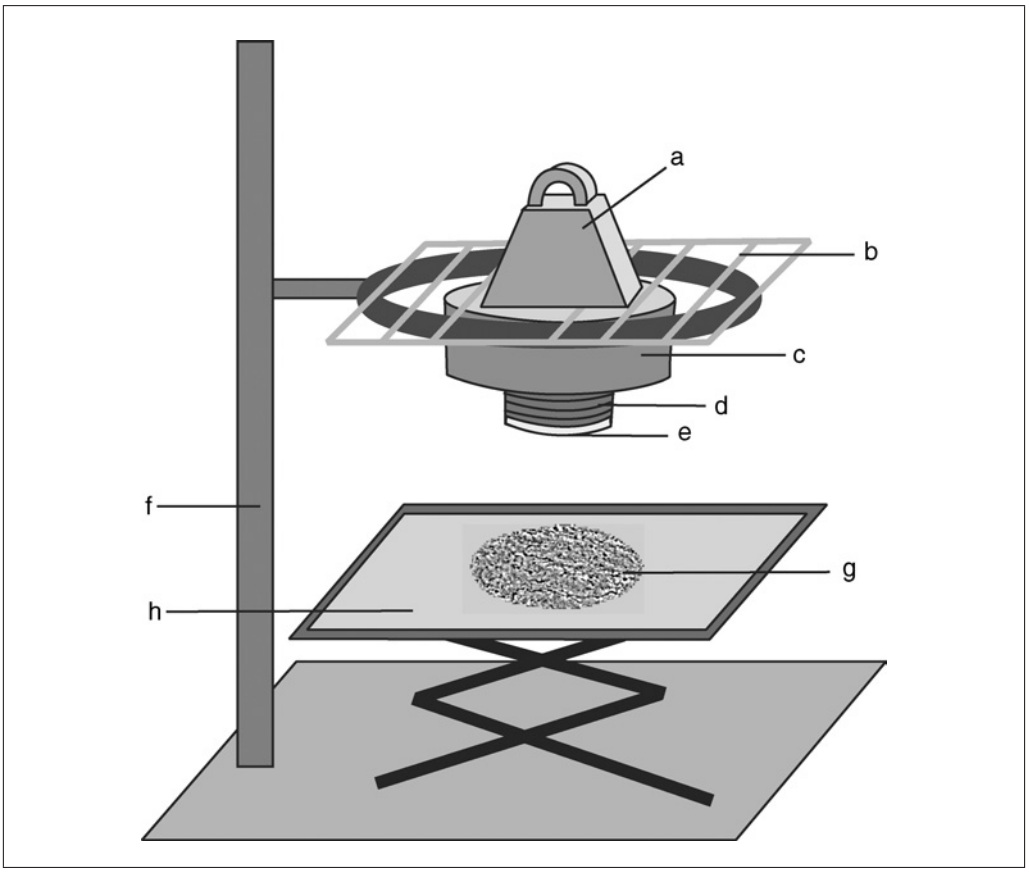

Figure 10.9.2 Diagram showing the components of the mechanical compression device. (a) Weight. (b) Flat platform. (c) Spacer. (d) 12-mm coverslips. (e) Teflon film. (f) Ring stand. (g) Fibroblast-derived 3-D matrix to be mechanically compressed. (h) Lifting laboratory jack.

2. Glue four 12-mm round coverslips to the end of the spacer (one on top of the other) as an extension of the spacer using superglue. Allow enough time for the superglue to completely dry.

   This will facilitate penetration of the coverslip portion into the matrix while avoiding contact between the matrix and the rest of the spacer, and it defines the area of compression.

3. Cut a Teflon circle (12-mm diameter) with the cork borer.

4. Cover the last coverslip with the Teflon film.

5. Sterilize materials by exposing them to a UV light in a biological hood for several hours with the Teflon film facing the light.

   If the compressed matrices are to be in contact with cells for only short periods of time (e.g., for the 10-min cell attachment assay), rinsing the Teflon film with ethanol and air-drying should be sufficient to prevent contamination.

6. Place the glued platform with spacer on the ring portion of the stand with the Teflon facing down.

7. Cover the flat upper surface of the laboratory jack with Parafilm and position the jack under the ring.

8. Set the weight on the platform and level the ring so that the Teflon film is situated parallel to the surface of the jack (see Fig. 10.9.2).

Mechanically compress the 3-D matrix

9. Position the fibroblast-derived 3-D matrix-coated coverslip (matrix face up) onto the jack directly underneath the Teflon film.

10. Slowly raise the laboratory jack until the matrix contacts the Teflon film and the platform rises above the ring. Wait for 2 min.

    At this point, the entire weight should be resting on the matrix, compressing it at a specific weight per unit area.

11. Slowly lower the jack until the platform rests once again on the ring, and the compressed matrix is separated from the Teflon film.

12. Place the coverslip with the compressed matrix into a 35-mm dish. Carefully add 2 ml PBS and examine by phase-contrast microscopy to confirm continued integrity of the compressed matrix.

SUPPORT PROTOCOL 6

Solubilization of Fibroblast-Derived 3-D Matrix

This protocol describes how to solubilize fibroblast-derived 3-D matrix to generate a protein mixture that can be used for subsequent coating of surfaces or biochemical analysis. Briefly, the matrices are treated with a guanidine solution to denature and solubilize the matrix components, thereby producing a liquid mixture that can be stored and used for coating surfaces.

Materials

Fibroblast-derived 3-D matrices on 35-mm dishes (see Basic Protocol)
Solubilization reagent (see recipe)

Cell scraper (e.g., rubber policeman, Costar brand, Fisher Scientific)
1.5-ml microcentrifuge tubes
Rotator at 4°C
Microcentrifuge

Prepare dishes

1. Aspirate PBS from fibroblast-derived 3-D matrix-covered dishes.
2. Tip the dishes for 1 min to accumulate the excess PBS on one side of the dish (~30° to bench top).
3. Aspirate the excess PBS carefully to avoid detaching the matrix layer.

Solubilize matrix

4. Place the dishes on ice and add 300 µl of solubilization reagent. Incubate 5 min on ice.
5. Scrape the dish with a cell scraper toward one side of the dish and pipet the mixture into a 1.5-ml microcentrifuge tube.
6. Add an additional 200 µl solubilization reagent. Rotate 1 hr at 4°C.

Collect solubilized matrix

7. Microcentrifuge 15 min at 12,000 × *g*, 4°C.
8. Transfer the supernatant into a fresh 1.5-ml microcentrifuge tube. Store the solubilized matrix in solubilization reagent indefinitely at 4°C.

The average protein concentration is 1 to 3 mg/ml.

ISOLATION OF PRIMARY FIBROBLASTS FROM FRESH TISSUE SAMPLES

SUPPORT PROTOCOL 7

NIH-3T3 cells are particularly well-suited for mesenchymal cell–derived matrix production because they are homogeneous and provide batch-to-batch consistency. When grown in FBS, their ability to grow at high densities and lack of contact inhibition allows the NIH-3T3 cells to produce a thicker matrix, usually ≥10 µm, which is optimal for cell studies of 3-D cultures (see Critical Parameters). However, other primary fibroblasts and fibroblast cell lines are also suitable for the production of cell-derived matrices. This protocol describes harvesting of primary fibroblasts from fresh tissue samples.

Materials

Fresh tissue samples (murine or human surgical)
Phosphate-buffered saline (PBS; *APPENDIX 2A*) supplemented with antibiotics (see recipe), 4°C
Confluent medium with fetal bovine serum (FBS; see recipe)
Ciprofloxicin (Invitrogen), optional
Trypsin/EDTA solution (see recipe)
60-mm tissue culture dishes
Dissecting scissors, tweezers, and scalpels (Fisher Scientific)
12-well or 6-well tissue culture plates
Sterile laminar flow hood
75-cm^2 tissue culture flasks
Inverted phase-contrast microscope

Prepare tissue samples

1. Rinse tissue samples obtained immediately after surgery (human or murine) three times in a 60-mm tissue culture dish with pre-cooled (to 4°C) PBS supplemented with antibiotics.
2. Aspirate supplemented PBS, finely chop the tissue sample into 1-mm^2 pieces using a sterile scalpel, assisting with sterile tweezers (see Amatangelo et al., 2005).
3. Using sterile dissecting scissors, make multiple scratches into the plastic surface of a 12-well or 6-well tissue culture dish in a star-like configuration.

4. Wash the dish two times with 1 ml (12-well plate) or 2 ml (6-well plate) PBS and gently press tissue pieces into the indentations created by the scratches.

Isolate primary fibroblasts

5. Allow plate to dry for 5 min under the sterile laminar hood.
6. Gently add 1 ml (12-well plate) or 2 ml (6-well plate) confluent medium with FBS to each of the wells, ensuring that the tissue samples remain attached to the scratched surfaces. Incubate 2 to 7 weeks. Replace the confluent medium every other day until primary fibroblasts emerge from the tissue pieces.

   This process normally takes 2 to 7 weeks depending on the tissue source.

7. (*Optional*) As an additional measure to prevent contamination of freshly isolated surgical samples, culture half of the tissue pieces in confluent medium supplemented with 250 ng/ml to 2.5 μg/ml Fungizone and 10 μg/ml ciprofloxacin.
8. After fibroblasts are grown to ~70% confluence in multiwell dishes remove the tissue pieces.
9. Trypsinize fibroblasts with trypsin/EDTA and passage into a 75-cm^2 tissue culture flask (see Basic Protocol, steps 1 to 4).
10. Once fibroblasts reach confluence in a 75-cm^2 flask, harvest and freeze them for future experimental analysis, and/or use them to produce fibroblast-derived matrices between passage 2 and 6 (see Basic Protocol).

    The authors start counting passages once the fibroblasts are initially transferred into a 15-cm dish. The fibroblasts are stable by morphological and biochemical criteria to at least passage 6. Morphological criteria include an elongated cell shape and the shape of the nuclei by Hoechst staining. For tumor-associated fibroblasts, elliptically shaped nuclei typical of myofibroblastic cells have been observed. They have not yet been genetically characterized.

REAGENTS AND SOLUTIONS

Use deionized, distilled water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Anti-FAKpY^{397}

Make a 1:1000 to 1:2500 dilution of anti-FAKpY^{397} (Biosource International or Covance) in 5% (w/v) BSA (Sigma)/TBST (see *UNIT 6.2*; see recipe for TBST). Store up to 12 months at −20°C.

Anti-total FAK

Use a 1:2500 dilution of anti-total FAK (Upstate Cell Signaling Solutions) in 5% (w/v) nonfat dried milk (Carnation, Fisher Scientific)/TBST (see *UNIT 6.2*; see recipe for TBST). Store up to 12 months at −20°C.

Confluent medium with fetal bovine serum

High-glucose Dulbecco's modified Eagle medium supplemented with:
10% (v/v) fetal bovine serum (*APPENDIX 2A*)
100 U/ml penicillin
100 μg/ml streptomycin
Store for 1 month at 4°C

For surgical or fine needle aspirates tissue samples, 250 ng/ml to 2.5 μg/ml Fungizone can be added to the cultures.

Culture medium with calf serum

High-glucose Dulbecco's modified Eagle medium supplemented with:
10% (v/v) calf serum
100 U/ml penicillin
100 μg/ml streptomycin
Store for 1 month at 4°C

DiI solution

Dilute 2.5 mg/ml 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI; Molecular Probes) stock solution in ethanol to 4 μg/ml with confluent medium (see recipe) and sterilize by filtration using a 0.22-μm filter. Store up to 12 to 24 months at –20°C.

Ethanolamine, 1 M

Prepare a 1 M solution of ethanolamine (Sigma-Aldrich) sterile water by adding 0.062 ml of ethanolamine per milliliter of water. Filter sterilize through a 0.2-μm filter unit. Prepare fresh.

Extraction buffer

Phosphate-buffered saline (PBS; APPENDIX 2A) containing:
0.5% (v/v) Triton X-100
20 mM NH_4OH
Store up to 1 month at 4°C

Fixing solution

Into a 50-ml polypropylene conical tube, add:
2 g sucrose
10 ml 16% (w/v) solution paraformaldehyde (EM-grade from Electron Microscopy Sciences)
Phosphate-buffered saline (PBS; *APPENDIX 2A*) to a final volume of 40 ml
Prepare fresh

Gelatin solution, 0.2% (w/v)

Prepare a 0.2% (w/v) gelatin solution in PBS (*APPENDIX 2A*). Autoclave the solution, cool, and filter through a 0.2-μm filter. Prepare fresh.

Glutaraldehyde solution in PBS, 1% (v/v)

Dilute a 25% stock of glutaraldehyde (Sigma) to 1% glutaraldehyde in PBS (*APPENDIX 2A*). Thaw a 10-ml aliquot of the stock and dilute to a final volume of 250 ml in PBS. Filter sterilize through a 0.2-μm filter unit and store in 50-ml aliquots at −20°C.

Heat-denatured BSA, 2% (w/v)

Dissolve 2 g BSA fraction V (Sigma) in 100 ml water and filter sterilize using a low-protein-binding 0.22-μm filter. Store indefinitely at 4°C.

Just prior to use, heat the amount needed 5 min at 65°C or until the solution starts to appear slightly opaque (not milky). Cool to room temperature before using for blocking procedures. Do not store the heat-denatured BSA.

Hoechst 33342 stock solution

Prepare a 2 mM (MW 615.9 g) Hoechst 33342 (bisbenzimide H 33342 fluorochrome, trihydrochloride; Calbiochem) solution in water. Store at 4°C, protected from light.

Lysis buffer (modified RIPA) reagent

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
50 mM NaCl
1% (w/v) deoxycholic acid, sodium salt (Fisher)
48 mM NaF
1% (w/v) glycerol (Fluka)
1% (w/v) Triton X-100 (Sigma)
Adjust to 100 ml with MilliQ H_2O
Store 3 to 6 months at 4°C

Matrix medium with ascorbic acid

Confluent medium (see recipe) containing:
L-ascorbic acid sodium salt (Sigma) at a final concentration of 50 μg/ml
Filter sterilize with a 0.2-μm filter
Prepare fresh

Ascorbic acid should be freshly prepared just prior to use as a 1000× stock concentration of 50 mg/ml in PBS to yield a final concentration of 50 μg/ml. Remove a 5- to 10-ml aliquot of medium, add ascorbic acid, and after filtering, add the ascorbic acid–containing medium back to the total volume of medium. In cases where a 500 μg/ml final concentration of ascorbic acid is added on the first day after cell plating, the stock is diluted only 100-fold instead of 1000-fold (see Basic Protocol, steps 16 and 17).

PBS$^+$

Phosphate-buffered saline (PBS; APPENDIX 2A) containing:
1 mM $CaCl_2$
1 mM $MgSO_4$
Store 6 to 12 months at room temperature

PBS supplemented with antibiotics

Phosphate-buffered saline (PBS; APPENDIX 2A) containing:
100 U/ml penicillin
100 μg/ml streptomycin
2.5 μg/ml Fungizone (amphotericin B; Invitrogen)
10 μg/ml ciprofloxicin
Store 1 to 2 weeks at 4°C

Pre-coated 2-D fibronectin dishes

In phosphate-buffered saline (*APPENDIX 2A*), prepare a 5 μg/ml solution of human plasma fibronectin (see *UNIT 10.5* or Sigma). Immediately add 1 ml per 35-mm tissue culture dish and incubate for 1 hr at 37°C. Remove remaining fibronectin solution and rinse once with PBS. Prepare diluted fibronectin solution fresh for each experiment.

The above procedure can be used with any desired protein for coating dishes or coverslips. If solubilized matrix mixture is to be used (see Support Protocol 6), coat with a 30 μg/ml protein concentration.

Protease and phosphatase inhibitors

1 mM sodium pyrophosphate
1 mM nitrophenol phosphate
5 mM benzamidine
1 mM PMSF
1 mM sodium orthovanadate

continued

Serine/threonine phosphatase cocktail inhibitor 1 (100 μl/10 ml lysis buffer; Sigma)
Tyrosine phosphatase inhibitor cocktail 2 (100 μl/10 ml lysis buffer; Sigma)
Prepare fresh

Solubilization reagent

5 M guanidine containing:
10 mM dithiothreitol
Store indefinitely at 4°C

Tris-buffered saline with Tween (TBST)

10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
150 mM NaCl
0.5% (v/v) Tween-20 detergent (Sigma)
Adjust pH to 8.0 with 12 M HCl
Store up to 2 weeks at 4°C

Trypsin/EDTA solution

2.5 g trypsin
0.2 g EDTA
8 g NaCl
0.4 g KCl
1 g glucose
0.35 g $NaHCO_3$
0.01 g phenol red
Bring up to 1 liter with H_2O
Sterilize by filtration with a 0.2-μm filter and store up to 3 months at −20°C

COMMENTARY

Background Information

Extracellular matrix (ECM) was historically regarded as a passive scaffold that stabilizes the physical structure of tissues. With time, it became evident that the ECM is much more than a simple physical scaffold. The ECM is a dynamic structure capable of inducing (and responding to) a large variety of physiological cell responses regulating the growth, migration, differentiation, survival, and tissue organization of cells (Buck and Horwitz, 1987; Hay, 1991; Hynes, 1999). Integrins are receptors for matrix molecules and can mediate these cell responses by inducing the formation of membrane-associated multi-molecular complexes. These integrin-based structures (cell-matrix adhesions) mediate strong cell-substrate adhesion and transmit information in a bi-directional manner between ECM and the cytoplasm. There are three main cell-to-matrix adhesions. The "focal adhesion" mediates firm linkage to relatively rigid substrates (Burridge and Chrzanowska-Wodnicka, 1996). Focal adhesions cooperate with "fibrillar adhesions" that generate fibrils from pliable fibronectin (Katz et al., 2000; Pankov et al., 2000). Fibroblasts require culture for several days at high cell density to generate 3-D matrices and evolve "three-dimensional-matrix adhesions." The requirements for producing 3-D matrix adhesions include three-dimensionality of the ECM, integrin $\alpha_5\beta_1$, fibronectin, other matrix component(s), and pliability of the matrix (Cukierman et al., 2001). The fibroblast-derived matrix provides an in vivo–like 3-D environment for cultured fibroblasts, thereby restoring their normally nonpolar surroundings. The fibroblast-derived 3-D matrix can be used as a suitable in vitro system to investigate in vivo–like fibroblast-to-matrix interactions, such as 3-D matrix adhesion signaling.

Critical Parameters

The phenotype of cultured NIH-3T3 fibroblasts as monitored by cell morphology is extremely important for the successful preparation of 3-D matrix-coated dishes. The fibroblasts should be well-spread and flat under sparse culture conditions. If elongated cells are commonly observed in the cell population, recloning of the cell line may be necessary to achieve greater phenotypic homogeneity. The NIH-3T3 line obtained from ATCC (ATCC# CRL-1658) has this morphology and produces

an excellent matrix. The NIH-3T3 cells must be maintained routinely as sub-confluent cultures in a medium containing calf serum to retain the correct phenotype. However, if the matrix deposition at confluence is performed in the presence of calf serum, the resultant matrices are thicker but less stable and more likely to detach from the surface than matrices obtained after culture in fetal bovine serum. Therefore, NIH-3T3 cells should be changed to medium containing fetal bovine serum prior to matrix deposition. While the NIH-3T3 cells are being adapted for matrix production in FBS, they take on a more uniform polygonal morphology and are not as contact inhibited as those grown in calf serum. NIH-3T3 cells do not normally take on a very elongated morphology unless they are cultured within 3-D matrices. To pre-adapt the NIH-3T3 cells to fetal bovine serum–containing medium, it is recommended to culture the cells for 15 to 20 passages before plating for matrix deposition.

The Basic Protocol can be modified for other fibroblastic cell lines capable of secreting and assembling fibronectin-based matrices. As described in Support Protocol 7, the authors have adapted this protocol for the isolation of primary fibroblasts obtained from human and/or murine surgical tissue samples. Fibroblasts can be isolated from tissue samples after ~2 to 7 weeks in culture. In some cases, the resulting matrix may be too thick or dense to obtain efficient extraction. In such cases, more prolonged cell extraction may be needed with extensive DNase treatment until no cell debris is detected. The lack of contaminating cellular debris (in the case of NIH-3T3 cells) in the matrices has been confirmed by immunoblotting and immunofluorescence staining for cellular proteins like actin or GAPDH.

Pre-coating surfaces with gelatin promotes fibronectin binding and results in smooth layers of relatively homogenous matrices that will not detach from the surface.

The thickness of NIH-3T3-derived 3-D matrices is measured using a confocal microscope without dehydration of the matrix (no mounting or fixing). The resultant thickness observed varies between 8 and 20 μm. Basic molecular characterization of the matrices revealed the presence (among other molecules) of fibronectin organized in a fibrillar mesh, collagen I and III but not IV, and small traces of non-organized laminin and perlecan.

The integrity of these 3-D matrices must be confirmed prior to every use. This can be accomplished by using phase-contrast microscopy and discarding any matrices that are torn or detached (see Fig. 10.9.1 B). Moreover, if matrices are to be used for short-term signal transduction assays under serum-depleted conditions, then freshly made matrices must be utilized. Matrices that have been stored at 4°C or −80°C (up to 2 to 3 weeks) should be used only after assessment of their integrity by phase-contrast microscopy. Freshly prepared or stored matrices can be used to test the induction of cellular responses in the presence of serum such as attachment, morphology, motility, proliferation, and for immunofluorescence staining. Additionally, biochemical analysis of the 3-D matrix can be assessed by immunoblotting to test for cell responsiveness to three-dimensionality by phospho-FAK down regulation (see Support Protocol 3).

Anticipated Results

The Basic Protocol is based on the ability of densely cultured fibroblasts (start up at ~2.5×10^5 cells/ml) to coat any available tissue culture surface by deposition of their natural matrix, which gradually forms a 3-D matrix. This intact, naturally produced ECM is similar in its molecular organization to mesenchymal fibronectin-based extracellular matrices in vivo (Cukierman et al., 2001). The basic approach is to allow cells to deposit their own ECM followed by removal of cells, while avoiding procedures that may alter or denature the native ECM constituents and supramolecular organization.

One NIH-3T3 semi-confluent (80%) cultured 15-cm dish can yield enough cells to coat 100 35-mm tissue culture dishes.

Time Considerations

The adaptation step after switching NIH-3T3 cell medium to fetal bovine serum for future matrix deposition requires culturing the cells for 15 to 20 passages. This adaptation process could take between 5 and 22 weeks depending on the rate of NIH-3T3 cell proliferation and the dilution factor per passage. The rate of NIH-3T3 proliferation is dependent upon many factors, including the growth-promoting abilities of the fetal bovine serum, which unfortunately is largely batch-dependent. Therefore, the time required for adapting NIH-3T3 cells to growth in FBS should be determined empirically. At this point, the NIH-3T3 cells are between 20 and 25 passages, and can be cultured in FBS for at least 20 to 25 additional passages, resulting in a total of ≥50 passages. After that, their morphology starts to become more

spindle-shaped and, therefore, they can no longer form optimal matrices. When the NIH-3T3 cells become too spindle-shaped, they fail to form uniform monolayers that upon extraction can ultimately produce uneven matrix coverage. Matrix production will require between 5 and 9 days. About 2 to 7 weeks are required from the time of tissue isolation to harvesting primary fibroblasts.

Purification and Analysis of Thrombospondin-1

Thrombosponding-1 (TSP-1) is a trimeric matricellular protein that is expressed by many cells. It contains several different domains that allow it to participate in cell adhesion, cell migration, and cell signaling. Recently, TSP-1 has been shown to activate transforming growth factor-β (TGF-β) and to inhibit both angiogenesis and tumor growth. This unit describes two protocols: the purification of TSP-1 from platelet-rich plasma (see Basic Protocol 1) and the purification of TSP-1 proteolytic fragments (see Basic Protocol 2).

ISOLATION OF THROMBOSPONDIN-1 FROM HUMAN PLATELETS

BASIC PROTOCOL 1

TSP-1 is released from platelet α-granules in response to thrombin and can therefore be readily purified from the supernatant of thrombin-treated platelets. Human platelets can be obtained from the Red Cross or from hospital blood banks. Outdated pheresis units of platelet-rich plasma are a good source of TSP-1. Platelets are separated from plasma and other blood components by a series of centrifugation steps. The isolated platelets are washed repeatedly to remove plasma proteins and the washed platelets are then activated by exposure to thrombin. Next the TSP-1-containing supernatant is passed over a heparin-Sepharose column. Lower-affinity heparin-binding proteins are washed away and the TSP-1 is eluted under conditions of high salt. The TSP-1-containing fractions are pooled, precipitated, and loaded onto a 10% to 20% continuous sucrose gradient and subjected to ultracentrifugation. The gradient is divided into fractions and the protein concentrations are determined by measuring optical density. The level of purity is normally >95% as determined by SDS-PAGE (*UNIT 6.1*).

Materials

Platelet-rich plasma
Baenziger A buffer (see recipe)
Baenziger B buffer (see recipe)
1 M $CaCl_2$ (*APPENDIX 2A*)
1 N NaOH (optional)
Thrombin
Diisopropyl fluorophosphate (DFP)
Heparin-Sepharose CL-6B (Amersham Pharmacia Biotech)
0.15, 0.25, 0.55, and 2.0 M heparin-Sepharose column buffers (see recipe)
Anti-vitronectin immunoaffinity column: prepare in advance according to manufacturer's instructions using an Affi-Gel Hz Immunoaffinity kit (Bio-Rad) and anti–human vitronectin antibody (e.g., GIBCO/BRL)
Ammonium sulfate
10% and 20% (w/v) sucrose gradient solutions (see recipe)

15- and 50-ml centrifuge tubes (conical bottom preferred)
Preparative centrifuge (Sorvall RC-B3 or equivalent) and rotor (H4000 or equivalent)
40-ml Oak Ridge centrifuge tubes
High-speed centrifuge (Beckman J2-MC or equivalent) and rotor (JA-20 or equivalent)
1 × 12–cm chromatography column
Fraction collector and appropriate tubes
Spectrophotometer set at 280 nm
Gradient maker
14-ml ultracentrifuge tubes
Ultracentrifuge (Beckman LM-80 or equivalent) and rotor (SW 41Ti or equivalent)

NOTE: Platelets are temperature sensitive and activated by untreated glass surfaces; therefore, they should be handled at room temperature in plasticware, and centrifuges and buffers should be warmed to room temperature before use.

Prepare platelets

1. Transfer platelet-rich plasma to 50-ml centrifuge tubes (conical bottom preferred) and centrifuge in a Sorvall RC-B3 preparative centrifuge 20 min at 1400 × *g* (2800 rpm in an H4000 rotor), 20°C.

   Pheresis units are preferable, but random donor units of platelet-rich plasma also work well.

2. Carefully pour off the supernatant. Gently resuspend the cell pellet in Baenziger A buffer at a ratio of 15 ml buffer per 2 ml packed cells.

3. Transfer the platelet suspension to 15-ml centrifuge tubes and centrifuge 8 min at 120 × *g* (800 rpm in an H4000 rotor), room temperature.

   Most of the platelets will remain in suspension following this centrifugation, while erythrocytes and leukocytes will pellet.

4. Leaving behind the red cell pellet, carefully transfer the platelet suspension to 50-ml centrifuge tubes (~22 ml per tube).

5. Add Baenziger A buffer to a final volume of 50 ml. Mix by inverting the tube several times and centrifuge 20 min at 1400 × *g* (2800 rpm in an H4000 rotor), 20°C.

Wash platelet pellet

6. Carefully pour off the supernatant. Resuspend each cell pellet in 15 ml Baenziger A buffer and then add buffer to a final volume of 50 ml. Invert the tube to mix and centrifuge 20 min at 1400 × *g* (2800 rpm in an H4000), room temperature. Repeat once.

7. Remove the supernatant and resuspend the pellet in 15 ml Baenziger B buffer. Add sufficient Baenziger B to achieve a ratio of 50 ml buffer per 2 to 3 ml packed cells. Mix the tube by inversion.

8. Add 100 µl of 1 M $CaCl_2$ per 50 ml suspension.

   From this point on, 2 mM calcium must be present at all times to maintain the conformational integrity of the thrombospondin molecule.

9. Check the pH of the suspension using pH paper. Adjust to pH 7.6 by adding 1 N NaOH as necessary.

Activate platelets

10. *Optional:* If the platelets are from outdated units, enhance their response to thrombin by incubating 5 min in a 37°C water bath.

11. Add 50 U thrombin per 50 ml platelet suspension and immediately mix by gentle inversion. Continue mixing 2 to 3 min at room temperature, then place on ice.

    Platelet aggregation should be evident upon examination of the suspension. The platelets will form large clumps and settle to the bottom of the tube, causing the supernatant to appear somewhat clear after 2 to 3 min. Outdated platelets respond more slowly than fresh ones. Outdated units should therefore be mixed for an additional 2 to 3 min.

12. Remove the cellular debris by centrifuging the tubes 5 min at 1400 × *g* (2800 rpm in an H4000 rotor), 4°C. Transfer supernatant to a 40-ml Oak Ridge centrifuge tube.

From this point on the TSP-1-containing supernatant must be kept on ice and all subsequent steps must be performed at 4°C.

13. Add sufficient DFP to achieve a final concentration of 1 mM (i.e., 0.181 µl/ml).

    CAUTION: *DFP is a powerful serum protease inhibitor and is highly toxic. Great care should be taken in its use. DFP is volatile and should be used in a fume hood.*

Isolate TSP-1 supernatant

14. Centrifuge 20 min in a Beckman J2-MC high-speed centrifuge at 34,957 × *g* (17,000 rpm in a JA-20 rotor), 4°C.

15. Transfer the supernatant to a clean 50-ml tube. Place the sample on ice and leave overnight at 4°C.

    This incubation step is necessary to allow formation of fibrin fibrils, which are then removed by centrifugation (step 17). If the supernatants are applied to the heparin-Sepharose column without performing this procedure, the fibrin fibrils will form on the top of the column and the flow rate will be decreased significantly.

Isolate TSP-1

16. Prepare and pour enough heparin-Sepharose CL-6B, according to the manufacturer's instructions, to produce a 5-ml bed volume in a 1 × 12–cm chromatography column. Equilibrate the column with 50 ml of 0.15 M heparin-Sepharose column buffer.

17. Following the overnight incubation (step 15), centrifuge the supernatant 20 min at 1400 × *g* (2800 rpm in an H4000 rotor), 4°C. Transfer the supernatant to a new tube.

18. Load the supernatant onto the equilibrated heparin-Sepharose column at a flow rate of ~3 ml/min.

    The TSP-1 will be immobilized on the column following this step. If necessary, the protocol may be paused at this point; however, the column should be washed extensively with 0.15 M heparin-Sepharose column buffer before pausing. TSP-1 is stable on the column for 3 to 4 days.

19. Connect the column to a fraction collector with appropriate tubes and elute the column with 40 ml of 0.15 M heparin-Sepharose column buffer at a flow rate of ~3 ml/min, collecting twenty 2-ml fractions. Repeat with 0.25 M heparin-Sepharose column buffer.

    Little or no TSP-1 will be present in these first two elutions.

20. Elute TSP-1 by applying 40 ml of 0.55 M heparin-Sepharose column buffer and collect in 2-ml fractions. Determine which fractions contain protein by measuring their absorbance at 280 nm. Calculate the total amount of protein in milligrams using the following formula: total protein = $OD_{280} \times 1.08 \times$ volume.

    After elution, >80% of total protein is TSP-1.

21. Strip the heparin-Sepharose column by applying 100 ml of 2.0 M heparin-Sepharose column buffer. Equilibrate and store the column in 0.15 M heparin-Sepharose column buffer at 4°C.

    The column can be used repeatedly if treated in this manner.

22. Pool the protein-containing fractions and apply to an anti-vitronectin immunoaffinity column.

    Although vitronectin is present in only trace amounts in the TSP-1-containing fraction (<1%), cells adhere strongly to vitronectin, which can pose a problem in certain applications involving purified TSP-1. It is therefore advisable to remove it. The authors are unable to detect vitronectin in the immunoaffinity flowthrough by immunoblotting.

For storage and reuse of the immunoaffinity column, refer to the manufacturer's instructions.

23. Transfer the flowthrough to a 40-ml Oak Ridge tube. Precipitate the protein by adding ammonium sulfate to 40% (w/v). Mix by inverting the tube until the solid is dissolved.

24. Centrifuge the sample 20 min at 34,957 × *g* (17,000 rpm in a JA-20 rotor), 4°C.

    The precipitated protein should form a milky-white pellet following centrifugation. It may be useful to note the orientation of the tube in the rotor to aid in locating the pellet.

25. Carefully pour off the supernatant and briefly leave the tube inverted to drain away all remaining liquid.

26. Resuspend the pellet in sufficient 0.15 M heparin-Sepharose buffer so that the protein concentration is ~1 mg/ml.

    The concentration does not change significantly from the value determined in step 20.

27. Using a gradient maker, prepare 12 ml of a 10% to 20% continuous sucrose gradient in a 14-ml ultracentrifuge tube.

28. Carefully load the protein-containing sample onto the gradient, using no more than 2 mg protein on each gradient in order to achieve good resolution.

    Drawing up the solution into a pipet tip and slowly discharging it by turning the volume adjustment wheel on the pipettor works well. It is important not to disturb the gradient.

    See UNIT 5.3 for more information concerning sucrose gradients.

29. In a Beckman LM-80 ultracentrifuge, centrifuge the gradients 18 hr at 247,605 × *g* (38,000 rpm in an SW 41Ti rotor), 4°C.

30. Fractionate the sucrose gradients into 0.5-ml aliquots. Read the absorbance of each fraction at 280 nm.

    The concentration of TSP-1 in each fraction is determined using the equation $c = A_{280}/\varepsilon l$, *where* ε *is the molar extinction coefficient of TSP-1 (1.08 in* $M^{-1}cm^{-1}$*) and l is the pathlength of the cuvette.*

    TSP-1 is the major peak located in the middle third of the gradient. The peak usually appears in the eighth fraction from the bottom and continues over approximately eight fractions. There is also a minor peak located higher in the gradient that is composed mainly of β*-thromboglobulin. The purified TSP-1 can be frozen directly in the sucrose gradient solution and stored 3 to 5 years at −70°C. If necessary for specific applications, sucrose can be removed by dialysis (APPENDIX 3C).*

BASIC PROTOCOL 2

ISOLATION OF PROTEOLYTIC FRAGMENTS OF TSP-1

The identification of functional sites within larger proteins can be accomplished by producing individual domains for functional studies. The proteolytic digestion of native molecules or the expression of individual domains by recombinant approaches is typically used for this purpose. While the authors were developing the procedure for the purification of TSP-1, it was observed that molecules that lacked the 25,000-Da N-terminal domain were not retained by the heparin-Sepharose column. This observation led to the early identification of the N-terminal domain as a high-affinity heparin-binding site and to the development of a procedure to purify this domain. During the development of the isolation protocol, it was also found that TSP-1 purified in the presence of calcium was distinct from that purified in the presence of EDTA. The removal of calcium from the protein renders some regions much more labile to proteolysis (Lawler and Hynes, 1986). Subsequent sequencing studies revealed that the type 3 repeats are a contiguous set of calcium-binding sites. Removal of calcium causes the type 3 repeats and the adjacent

C-terminal domain to unfold and become more labile to proteolysis. Thus, it is difficult to design a protocol that utilizes proteolysis in order to isolate the type 3 repeats and the C terminus of TSP-1. These domains are either resistant to digestion in the presence of calcium or are readily digested in its absence. In the absence of calcium, the central 70,000-Da core of the protein can be produced by chymotryptic digestion. This structure contains the intrachain disulfide bonds and hence is trimeric with a molecular weight of 210,000 Da. A procedure for preparing the N-terminal heparin-binding domain and the central core region is provided below.

Materials

TSP-1 (see Basic Protocol 1)
TBS (see recipe) containing 2 mM $CaCl_2$
0.5 M EDTA (*APPENDIX 2A*)
Chymotrypsin
Diisopropyl fluorophosphate (DFP)
0.8 × 3–cm column of immobilized soybean trypsin inhibitor (Pierce)
0.8 × 3–cm column of heparin-Sepharose CL-6B (Amersham Pharmacia Biotech)
0.15, 0.25, and 0.55 M heparin-Sepharose column buffers (see recipe)

Centriplus centrifugal filter device (3000-Da cutoff; Millipore)
1.3 × 30–cm column of Sephadex G-200
Fraction collector
Spectrophotometer set at 280 nm

1. Begin with 5 mg purified TSP-1 in 3 ml TBS containing 2 mM $CaCl_2$ on ice. Add 0.5 M EDTA to a final concentration of 5 mM.
2. Dissolve chymotrypsin in TBS to a final concentration of 1 mg/ml and add 50 µl to the sample.

   This gives an enzyme-to-substrate ratio of 1:100 (w/w).
3. Digest 20 hr in a covered ice bucket in a 4°C cold room.

   This approach produces a very reproducible digestion pattern.
4. Terminate the digestion by adding DFP to 1 mM (0.181 µl/ml) and incubating an additional 2 hr on ice.
5. Pass the sample over a 0.8 × 3–cm column of immobilized soybean trypsin inhibitor to remove the chymotrypsin.
6. Collect the flowthrough from the column and apply to a 0.8 × 3–cm heparin-Sepharose column connected to a fraction collector with appropriate tubes.
7. Collect 1-ml fractions while the sample is flowing onto the column and throughout the elution. Elute the column in a stepwise fashion with 20 ml (each) of 0.15, 0.25, and then 0.55 M heparin-Sepharose buffer.

   The 25,000-Da fragment elutes in the 0.55 M heparin-Sepharose buffer. The protein is ~95% pure and can be used directly or concentrated further. Some applications may require dialysis to reduce the salt concentration.

   The 210,000-Da fragment is in the initial flowthrough fractions. It should be dialyzed and purified on a Sephadex G-200 column as described in the following steps.
8. Pool the flowthrough fractions and concentrate to 2 ml using a Centriplus centrifugal filter device.
9. Apply this sample to a 1.3 × 30–cm Sephadex G-200 column equilibrated with TBS at 4°C.

Sephadex G-200 is fragile and care should be exercised to follow the manufacturer's directions for removing fines and for pouring and eluting the column.

10. Apply TBS and collect fifty 1-ml fractions. Measure the OD_{280} of each fraction.

The 210,000-Da fragment is eluted in the molecular weight peak near the void volume of the column. This material can be concentrated using the Centriplus centrifugal filter device (step 8) and should be >95% pure.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Baenziger A buffer

0.102 M NaCl
0.0039 M K_2HPO_4
0.0039 M Na_2HPO_4
0.022 M NaH_2PO_4
0.0055 M glucose
Store up to 2 weeks at 4°C

Baenziger B buffer

0.015 M Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.14 M NaCl
0.005 M glucose
Store up to 2 weeks at 4°C

Heparin-Sepharose column buffers, 0.15, 0.25, 0.55, and 2.0 M

0.015 M Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.002 M $CaCl_2$
0.15, 0.25, 0.55, or 2.0 M NaCl
Store up to 3 weeks at 4°C

The molarity of the buffer refers to the concentration of the NaCl.

Sucrose gradient solutions, 10% and 20% (w/v)

0.015 M Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.14 M NaCl
0.002 M $CaCl_2$
10% or 20% (w/v) sucrose
Store up to 1 week at 4°C

TBS (Tris-buffered saline)

0.015 M Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.015 M NaCl
Store up to 2 weeks at 4°C

COMMENTARY

Background Information

The thrombospondins are a family of extracellular matrix proteins currently consisting of five members, thrombospondins 1 to 4 and cartilage oligomeric matrix protein (COMP). For comprehensive reviews, see Adams (2001) and Chen et al. (2000). These proteins are synthesized by many tissues with patterns of expression that are temporally and spatially regulated. All thrombospondin family members are composed of a series of multidomain structures and have the ability to bind large numbers of calcium ions. Calcium binds to the thrombospondins through a cooperative mechanism that involves a significant conformational change in the protein. Through interactions with molecules on the cell surface and components of the extracellular matrix, the

thrombospondins play a role in cell adhesion, migration, differentiation, and proliferation.

Thrombospondin-1 (TSP-1) was the first member of the gene family to be identified and has been the most extensively characterized. TSP-1 is a large multifunctional glycoprotein with a molecular weight of 420,000 Da, and is a trimer composed of identical subunits each with a molecular weight of 142,000 Da. TSP-1 is expressed by both normal and tumor cells and has a number of domains that allow it to interact with cells and other proteins. These include (1) a heparin-binding domain that interacts with proteoglycans, integrin α3β1, and cell-surface glycosaminoglycans (Clezardin et al., 1997; Merle et al., 1997); (2) three type 1 repeats that interact with CD36, matrix metalloproteinases, fibronectin, and heparan sulfate proteoglycans, and also activate latent TGF-β (Bornstein, 1995; Schultz-Cherry et al., 1995; Crawford et al., 1998); (3) an RGDA sequence within the last type 3 repeat, which interacts with integrin αvβ3; and (4) a C-terminal cell-binding domain that contains a recognition sequence for the integrin-associated protein CD47 (Gao et al., 1996). In this unit, the authors focus on the activities of TSP-1 that involve the type 1 repeats and the interaction of TSP-1 with integrins (Fig. 10.10.1). The interaction of TSP-1 with proteoglycans is discussed in detail in a recent review by Chen et al. (2000).

TSP-1 and transforming growth factor-β

Recently, TSP-1 has been shown to activate transforming growth factor-β (TGF-β) by binding to the latency-associated protein and altering the conformation of TGF-β to make it accessible to its receptor (Schultz-Cherry et al., 1995; Crawford et al., 1998). The region of TSP-1 responsible for TGF-β activation is the amino acid sequence KRFK, which is found at the start of the second type I repeat (Schultz-Cherry et al., 1995; Crawford et al., 1998; Fig. 10.10.1). TGF-β is a 25-kDa homodimeric cytokine and a known tumor suppressor (Markowitz and Roberts, 1996). It is secreted in a latent complex consisting of mature TGF-β, the latency-associated protein, and sometimes an additional latent TGF-β-binding protein. The latent TGF-β-binding protein is thought to target latent TGF-β to sites in the extracellular matrix where it is sequestered until activated. Activation of TGF-β has been demonstrated in vitro by activators such as acids, plasmin, or cathepsin D (Munger et al., 1997). TSP-1 and the αvβ6 integrin have been shown to activate TGF-β in vivo (Crawford et al., 1998; Munger et al., 1999). Activation of TGF-β by TSP-1 was demonstrated in vivo when TSP-1-deficient mice were injected with a peptide containing the sequence KRFK. The lungs of the injected mice became morphologically more similar to wild-type mice and active TGF-β was detected in the bronchial epithelial cells (Crawford et al., 1998). In some contexts, however, TSP-1 does not appear to be a good activator of TGF-β

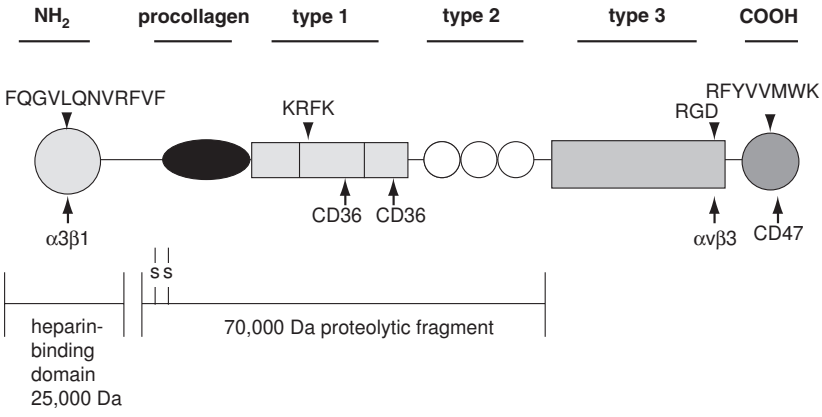

Figure 10.10.1 Representative model of TSP-1 identifying the different structural and functional domains. The binding sites for the various integrins, CD36, and CD47 are indicated below the model. Amino acid sequences that mediate receptor binding and activation of TGF-β are indicated above the model. The proteolytic fragments isolated in the protocol are shown at the bottom. The FQGVLQNVRFVF sequence is a GAG-independent cell binding site and the RFYVMWK sequence is an integrin-associated protein (CD47) binding site.

(Abdelouahed et al., 2000; Grainger and Frow, 2000). These data indicate that post-translational modification or other factors may regulate the ability of TSP-1 to activate TGF-β. Thus, co-expression of TSP-1 and TGF-β does not necessarily mean that TSP-1 will activate latent TGF-β in that tissue.

The role of TSP-1 in angiogenesis and cancer

TSP-1 has been shown to be an effective inhibitor of angiogenesis, tumor progression, and metastasis (Chen et al., 2000; Lawler, 2002). While TSP-1 levels are very low in many tumor cells, expression of TSP-1 is high in the tumor stroma (Brown et al., 1999). Overexpression of TSP-1 in MDA-MB-435 human breast carcinoma cells decreased tumorigenesis and metastasis in vivo (Weinstat-Saslow et al., 1994). Furthermore, the tumors derived from cells formed by a fusion of low-TSP-1-expressing human breast cancer cells and high-TSP-1-expressing normal breast epithelial cells were smaller in nude mice as compared to the tumors formed from the breast cancer cells alone (Zajchowski et al., 1990). Lastly, one group has shown that plasma TSP-1 secreted from primary HT1080 fibrosarcomas in nude mice inhibited growth of experimental metastases (Volpert et al., 1998). Moreover, if the implanted fibrosarcoma cells were transfected with an antisense TSP-1 construct prior to implantation, melanoma cell invasion of the lung was not inhibited.

Recently, the authors have shown that recombinant proteins comprising the second type 1 repeat of TSP-1 and containing the TGF-β activating sequence KRFK inhibited B16F10 tumor growth in mice (Miao et al., 2001). Furthermore, it was observed that treatment with a TGF-β antibody or soluble TGF-β receptor reversed this inhibition, suggesting that TSP-1 activation of TGF-β is part of the inhibitory pathway. By contrast, an effect of TGF-β was not observed with Lewis lung carcinoma because these cells have acquired mutations that have rendered them unresponsive. Vascular density was decreased in both B16F10 and Lewis lung carcinoma tumors treated with the recombinant proteins through a TGF-β-independent mechanism.

In another study, Streit et al. (1999) overexpressed full-length TSP-1 in A431 human carcinoma cells and implanted these cells in the flanks of nude mice. Decreased tumor growth and angiogenesis were observed in tumors expressing TSP-1. Recent work has demonstrated that the KRFK sequence in the second type 1 repeat of TSP-1 is partly responsible for this growth inhibition and the decrease in tumor angiogenesis (K. Yee, unpub. observ.). In another recent study, TSP-1 null mice were crossed with *c*-neu transgenic mice to create a mouse that develops breast tumors and does not express TSP-1. These mice developed tumors that were larger and more vascular than the tumors of mice overexpressing TSP-1 (Rodrídguez-Manzaneque et al., 2001). The authors also determined that the absence of TSP-1 in these tumors resulted in an increase in the amount of active matrix metalloproteinase 9 (MMP-9).

The effects of TSP-1 on endothelial cell migration and angiogenesis have been previously observed by several groups (Tolsma et al., 1993; Dawson et al., 1997; Qian et al., 1997; Iruela-Arispe et al., 1999; Jiménez et al., 2000; Nör et al., 2000). These studies demonstrate that TSP-1 is able to prevent tumor progression in several in vivo cancer models and that one of the ways TSP-1 inhibits tumor growth may be through decreasing tumor angiogenesis. In a different avenue of thinking, many groups have examined MMP-2 and MMP-9 with regards to breast cancer progression (Benaud et al., 1998; Martorana et al., 1998; Remacle et al., 1998; Rudolph-Owen et al., 1998; Lee et al., 2001). MMP-2 and -9 are gelatinases that degrade collagen types IV, V, VII, and X, as well as denatured collagen and gelatin (Dollery et al., 1995). Recently, TSP-1 has been shown to interact with MMP-2 and -9 and inhibit their activation (Bein and Simons, 2000; Rodrídguez-Manzaneque et al., 2001). This interaction is mediated by the type 1 repeats of TSP-1. Therefore, one of the mechanisms through which TSP-1 inhibits both tumor progression and tumor angiogenesis may be due to its ability to inhibit MMP activation and prevent growth factor and cell mobilization.

Angiogenesis is a complex process that involves multiple cell types. TSP-1 does have possible effects on the recruitment of immune cells and on the proliferation and migration of vascular smooth muscle cells. In some assays, these effects can predominate, leading to the conclusion that TSP-1 supports angiogenesis. The preponderance of in vivo data indicates that the anti-angiogenic effects predominate in tumors.

TSP-1 and CD36

CD36 is an integral membrane glycoprotein, a member of the class B scavenger receptor

family, and is located within the caveolae of the cell membrane. It is expressed in many cells including microvascular endothelium, adipocytes, skeletal muscle, dendritic cells, and hematopoietic cells including platelets and macrophages (Febbraio et al., 2001). CD36 is also a receptor for TSP-1 and binds to the specific sequence CSVTCG in the second and third type 1 repeats of TSP-1, while TSP-1 type 1 repeats bind the CD36 LIMP-II Emp sequence homology (CLESH) region of CD36 (Crombie and Silverstein, 1998). This binding initiates a signal that involves the nonreceptor tyrosine kinases *fyn*, *lyn*, and *yes* as well as p38MAPK (Huang et al., 1991). One of the endpoints of this cascade is activation of caspase 3 and endothelial cell apoptosis (Guo et al., 1997; Jiménez et al., 2000; Nör et al., 2000). CD36 signaling is one of the mechanisms by which TSP-1 inhibits angiogenesis and tumor progression (Dawson et al., 1997; Simantov et al., 2001).

The initial work on exploring the anti-angiogenic effect of TSP-1 through CD36 utilized peptides containing the CSVTCG sequence. These peptides inhibited endothelial cell migration and angiogenesis (Iruela-Arispe et al., 1991; Tolsma et al., 1993; Dawson et al., 1999). Antibodies to CD36 also inhibited endothelial cell migration (Dawson et al., 1997) and, in CD36-null mice, TSP-1 did not inhibit angiogenesis in a cornea pocket assay (Jiménez et al., 2000). Therefore, binding of TSP-1 to CD36 on endothelial cells inhibits angiogenesis and tumor progression.

TSP-1 and integrins

Integrins are a family of cell surface receptors composed of both an α and a β subunit (Hynes, 1992). TSP-1, in both soluble and matrix-bound forms, can interact with β1 and β3 integrins; however, the physiological consequences of binding are dependent upon the integrin engaged, the cell type, and in some cases the involvement of accessory proteins.

TSP-1 and β1 integrins

In breast carcinoma cells, α3β1 is essential for chemotaxis towards TSP-1 and cell spreading on an immobilized TSP-1 matrix (Chandrasekaran et al., 1999). This interaction is mediated through binding of the integrin to residues 190 to 201 of the N-terminal region of TSP-1 (Krutzsch et al., 1999). In the presence of a β1-activating antibody, the adhesive properties of the carcinoma cells on TSP-1 are enhanced. This is characterized by rearrangement of F actin filaments into filopodia that terminate at points that are rich in β1 and are in contact with TSP-1. Signaling through the insulin-like growth factor-I receptor (IGF-IR) can also potentiate this adhesion. Recent evidence suggests that IGF-IR signaling activates α3β1 by promoting association with the mitochondrial molecule heat shock protein 60 (Barazi et al., 2002).

Small-cell lung carcinoma cells also bind residues 190 to 201 of TSP-1 through α3β1 (Guo et al., 2000). This interaction stimulates the cells to extend neurite-like processes and differentiate along a neuronal pathway. When epidermal growth factor is added to these cultures, binding to TSP-1 through this receptor also suppresses cell proliferation. This mechanism may be important for the antitumorigenic effects of TSP-1.

In response to loss of cell-cell contact, endothelial cells engage immobilized TSP-1 through α3β1 and are stimulated to adhere to TSP-1 and proliferate (Chandrasekaran et al., 2000). This effect can be induced through disruption of cell contacts through wounding or by inhibiting vascular endothelial (VE) cadherin, indicating a role for TSP-1 in supporting repair of wounded endothelium. However, classically, TSP-1 is known for inhibiting endothelial cell proliferation and angiogenesis (Good et al., 1990). Indeed, endothelial cells exposed to a soluble TSP-1 peptide that recognizes α3β1 have decreased proliferation and motility (Chandrasekaran et al., 2000). These opposing effects on endothelial cells suggest that tight regulation of TSP-1/α3β1 interaction and signaling exists. Recent studies using melanoma cells demonstrated that the ability of TSP-1 to bind α3β1 is altered when TSP-1 is bound to fibronectin (Rodrigues et al., 2001). Conformational regulation of TSP-1 may represent one mechanism by which integrin-mediated cellular responses are controlled.

Activated T-lymphocytes can adhere to intact TSP-1 through α4β1 and α5β1 integrins (Yabkowitz et al., 1993). This may have implications for mediating T cell activation, as stimulation of the ERK pathway by TSP-1 in these cells can be inhibited using anti-β1 function-blocking antibodies (Wilson et al., 1999). A role for TSP-1 in modulating the inflammatory response would not be surprising since TSP-1-deficient mice suffer from inflammatory disease (Lawler et al., 1998).

TSP-1 and β3 integrins

In platelets, it was originally discovered that αvβ3 and, to a lesser extent, αIIbβ3 (GPIIbIIIa) function as adhesion receptors for TSP-1. The recognition site for these integrins is the RGD motif located in the type 3 repeats of TSP-1.

TSP-1 can influence integrin function directly and indirectly through its interaction with nonintegrin receptors. In platelets, binding of the C terminus of TSP-1 to the transmembrane receptor integrin-associated protein (IAP or CD47) leads to assembly of a TSP-1/IAPαIIbβ3 complex on the platelet surface. This complex can further activate αIIbβ3 and cause phosphorylation of focal adhesion kinase, resulting in both augmentation of platelet aggregation and attachment to fibrinogen (Chung et al., 1997). A necessity for G-protein signaling has since been added to this cascade of events (Frazier et al., 1999).

TSP-1/IAPαvβ3 complexes are also important in other cell types. On vitronectin substrates, C32 human melanoma cells are stimulated to spread in response to complex formation (Gao et al., 1996). More recently, an increase in latent TGF-β activation, induced by tamoxifen treatment of breast carcinoma cells, has been shown to be dependent on localization of TSP-1 to the cell surface by this mechanism (Harpel et al., 2001).

Another example of TSP-1 affecting integrin function through cooperation with other receptors occurs in the clearance of apoptotic neutrophils. Here, TSP-1 associates with CD36 on the macrophage surface and αvβ3 associates on the neutrophils where it forms a bridge, allowing the recognition of neutrophils for ingestion (Savill et al., 1992). This process can be modulated on a second exposure of macrophages to neutrophils by ligation of αvβ3, α6β1, and α1β2 (Erwig et al., 1999).

αvβ3 is also expressed on endothelial cells. In sickle cell anemia patients, both αvβ3 in the endothelium (Solovey et al., 1999) and TSP-1 plasma levels are elevated. These proteins have been implicated in recurring vaso-occlusion problems in sickle cell patients caused by exaggerated adhesion of the sickle cell red blood cells (SS-RBCs) to the endothelium. Indeed, it has been demonstrated that TSP-1 enhances adhesion of SS-RBCs to cultured endothelial cells and that antibodies to αvβ3 can block this event (Kaul et al., 2000). It is as yet unknown if this is a direct consequence of TSP-1/αvβ3 association.

Critical Parameters

The response of the platelets to thrombin is a critical factor contributing to the success of the purification procedure. Since platelets become less responsive during storage, the platelet-rich plasma should be processed as soon as possible after collection. Since platelets are temperature sensitive, buffers and centrifuges used in the purification procedure should be warmed to room temperature before beginning the procedure. The platelets should also be handled gently during the resuspension steps to prevent mechanical activation. Moreover, since platelets are activated by untreated glass surfaces, all transfer pipets and tubes should be plastic.

TSP-1 is susceptible to proteolysis following its secretion into the supernatant. It is important to work quickly following the activation step to minimize exposure to proteases secreted from the platelets and the thrombin used for the activation. The supernatant should be treated immediately with DFP following the debris-clearing centrifugation step in order to inactivate these proteases. The supernatant should be kept on ice at all times during the remaining purification steps.

The association of TSP-1 with calcium maintains the confirmation of the molecule. It is therefore essential that calcium be present in all solutions during and subsequent to thrombin treatment. A concentration of 2 mM is recommended.

Troubleshooting

The problem most likely to be encountered in the purification procedure is unresponsive platelets. To remedy this situation the procedure can be performed on a small scale using fresh platelets. This will provide a sense of how the aggregated platelets should appear following thrombin treatment. Another method for assaying platelet responsiveness is to perform electrophoresis on the supernatant from the thrombin-treated platelets. TSP-1 is a major component of the platelet α-granule and should appear as a prominent band running at an apparent molecular weight of 185,000 Da on discontinuous Laemmli SDS gels (*UNIT 6.1*). This anomalously high value for the molecular weight of the subunit is probably due to a decrease in the amount of SDS bound to the large number of negatively charged residues in the type 3 repeats.

Anticipated Results

The purification procedure should result in producing ~200 μg TSP-1 per 100 ml outdated platelet-rich plasma, which is most often >95% pure as determined by SDS-PAGE. There is evidence that some preparations of TSP-1 produced according to this method may contain trace amounts of active TGF-β bound to the TSP-1. It is possible to remove this contaminant by adjusting the pH of the sucrose gradient solutions to pH 11, as TGF-β will dissociate from TSP-1 under alkaline conditions (Murphy-Ullrich et al., 1992; Schultz-Cherry et al., 1994). The pH of the TSP-1-containing fractions should be returned to pH 7.6 immediately following centrifugation.

Whereas the protocol for purifying TSP-1 proteolytic fragments does not require many steps and is reasonably efficient, it is important to bear in mind that the N-terminal domain only represents ~18% of the total mass of the protein. Thus, if one starts with 5 mg total protein, a yield of 400 to 500 μg is appropriate. Since the 210,000-Da fragment represents about one-half of the protein, yields of 1 to 1.5 mg can be expected.

Time Considerations

The purification procedure is extended over a period of 3 days. The amount of time required to perform this procedure will depend in part on the amount of material to be processed. Approximately 3 to 4 hr should be allowed to isolate the TSP-1-containing supernatant (steps 1 to 15). Purification of TSP-1 (steps 17 to 28) will require another 3 to 4 hr. It is possible to leave the TSP-1 bound to the heparin-Sepharose column for a number of days prior to continuing the elution process.

The purification of proteolytic fragments also takes ~3 days. The limited tryptic digestion is done overnight. Elution of the heparin-Sepharose column can be done in ~1 day and the elution of the G-200 column requires another day.

Purification of SPARC/Osteonectin

SPARC (secreted protein acidic and rich in cysteine) is a founding member of the matricellular group of proteins that have been shown to mediate interactions between cells and the extracellular matrix (ECM; Bornstein and Sage, 2002). Other proteins within this family include thrombospondins 1 and 2, osteopontin, tenascins C and X, and Cyr61. Over the last several years, a wealth of data, largely from mice with targeted disruptions of the respective genes, has emerged identifying various targets of the matricellular proteins that influence cell behavior—e.g., growth factors, cell-cycle regulatory proteins, ECM components, adhesion proteins and/or their receptors, cell survival, collagen fibrillogenesis, and immune cell function. In vivo, these effects can be translated into abnormalities in blood vessel morphogenesis and connective tissues, wound healing, bone formation, and responses to various types of injury. Therefore, study of one or more of the matricellular proteins affords insight from a somewhat unusual and underexplored perspective: the interface between the cell surface and the extracellular milieu.

SPARC belongs to a family of several genes, only one other of which, *SC1/hevin*, has been characterized beyond a limited degree (Brekken and Sage, 2000). *SPARC*-null mice exhibit many phenotypic abnormalities that follow logically from the effects of SPARC on cultured cells (i.e., de-adhesion, antiproliferation, interaction with growth factors and ECM, and regulation of collagen production). These characteristics include (1) accelerated dermal wound healing and fibrovascular invasion of sponge implants, (2) reduced foreign body response, (3) thin skin with decreased collagen, which is deposited as small-diameter fibrils, (4) excessive accumulation of adipose tissue, (5) osteopenia, and (6) cataract formation (Bornstein and Sage, 2002). Providing a mechanistic explanation for any one of these phenotypes requires experiments, largely in vitro, with active purified protein in clearly defined assays with quantitative endpoints. This unit presents several protocols for the purification of SPARC (see Basic Protocol and Alternate Protocols 1, 2, and 3), and for the measurement of its biological activity and conformation (see Support Protocols 1 and 2). Since the end product—i.e., natural SPARC or recombinant (rSPARC)—differs according to the source, guidelines for the choice of each protocol, and its advantages and limitations, have been included with the Basic Protocol (purification of SPARC from cultured cells), Alternate Protocol 1 (rSPARC from *E. coli*), Alternate Protocol 2 (rSPARC from insect cells), and Alternate Protocol 3 (SPARC from blood platelets). A method for determining endotoxin levels is presented in Support Protocol 3.

NOTE: To prevent denaturation of SPARC due to adsorption to surfaces, only polypropylene or siliconized glass should be used.

NOTE: All solutions and equiptment coming into contact with live cells should be sterile and a septic technique should be used accordingly

PURIFICATION OF SPARC FROM PYS-2 CELLS

BASIC PROTOCOL

This protocol describes the purification of SPARC from cultured PYS-2 cells. This cell line, originally derived from a mouse parietal yolk sac carcinoma, has been a consistent reproducible source of biologically active SPARC for nearly two decades (Sage and Bornstein, 1995). The following procedure can be applied to most cell culture supernatants and involves essentially three steps: (1) precipitation of culture medium, (2) ion-exchange chromatography, and (3) molecular-sieve chromatography. Advantages of the PYS-2 cell line are its immortality, its high rate of growth, its copious production (secretion) of SPARC, and the presence of few other secreted products in the culture medium. It is also possible to radiolabel SPARC metabolically if desired. A commercial

Contributed by E. Helene Sage
Current Protocols in Cell Biology (2003) 10.11.1-10.11.23

source of SPARC, isolated according to this protocol and of ~80% purity, is available from Sigma-Aldrich.

Materials

50% to 70% confluent PYS-2 cells (see recipe)
DMEM (serum-free; *APPENDIX 2A*)
1100 Ci/mmol (12.5 Ci/ml) [*trans*-^{35}S]methionine/cysteine (ICN; optional)
DMEM minus methionine and cysteine (optional)
0.2 M PMSF stock solution (see recipe)
N-Ethylmaleimide (NEM)
Ammonium sulfate, ultrapure
DEAE buffer, 4°C (see recipe)
NaCl
~2 × 20–cm DEAE column (see recipe)
S-200 buffer (see recipe)
Scintillation fluid (optional)
Sephacryl molecular-sieve column (see recipe)
0.05 M acetic acid

Plastic pipets
50-ml polycarbonate high-speed centrifuge tubes
Low-speed GPKR (Beckman) centrifuge with swinging bucket rotor
High-speed refrigerated centrifuge with GSA (Sorvall) or JA-17 rotors (Beckman) or equivalent
12,000- to 14,000-MWCO dialysis tubing (Spectrapor) or equivalent, prewashed with DEAE buffer
Dialysis clips (optional)
Standard gradient maker (e.g., Amersham Biosciences)
Peristaltic pump
Fraction collector
Lyophilizer
50 or 250 ml centrifuge tubes

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) with autoradiography (*UNIT 6.3*), if appropriate, and determination of protein concentration by spectroscopy (*APPENDIX 3B*)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiments and dispose of wastes in appropriately designated area, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

Collect and precipitate tissue culture medium containing secreted SPARC

1. Replace medium in 20 to 30 dishes or flasks of PYS-2 cells (grown to 50% to 70% confluency) with 12 to 13 ml serum-free DMEM and preincubate 15 min at 37°C. Replace with fresh medium and then incubate 18 to 24 hr.

   If desired, purification can be monitored by adding 500 μCi of 1100 Ci/mmol [^{35}S]methionine to one dish and processing the medium in parallel with nonlabeled medium from the other dishes. Alternatively, if radiolabeled SPARC of high specific activity is required for experimental purposes, [^{35}S]methionine/cysteine can be added to all dishes. When using label, incubate cells in serum-free DMEM lacking methionine and cysteine.

2. Collect the medium from the cell layer by gentle aspiration via plastic pipet and transfer to centrifuge tubes. Remove cellular debris by centrifuging in a clinical (i.e.,

tissue-culture) centrifuge 5 min at 1,000 × *g*, room temperature, or in GPKR centrifuge at 1000 × *g*, 4°C.

3. Pool all supernatants in a siliconized flask. Add 0.2 M PMSF drop-wise with stirring to a final concentration of 0.2 mM, and NEM to a final concentration of 10 mM. Stir on ice until medium reaches 4°C.

   For 100 ml medium, add 0.1 ml PMSF stock solution and 62.5 mg NEM. Take care not to lyse cells in any of these procedures.

4. Add solid ultrapure ammonium sulfate to the medium in an amount equivalent to 50% (w/v) of the starting volume over a period of several hours. Stir 12 to 24 hr at 4°C.

   For 100 ml medium, add 50 g ammonium sulfate, in very small increments (e.g., 1 to 2 g) over several hours (e.g., 3 to 5). This detail is important for maintenance of neutral pH and for efficient precipitation of protein, which consists mainly of laminin 1, type IV collagen, bovine serum albumin (BSA), and SPARC.

   Do not allow the solution to foam by stirring too rapidly, as this indicates the proteins are denaturing.

5. Transfer medium to 50-ml polycarbonate high-speed centrifuge tubes and centrifuge in a high-speed refrigerated centrifuge with JA-17 rotor 30 min at 40,000 × *g*, 4°C. Discard the supernatant. Keep tubes containing pellets on ice or store up to 1 to 2 months at –70°C.

6. Thaw, if necessary, and dissolve each pellet by gentle vortexing in 2 to 5 ml DEAE buffer, 4°C. Pool these solutions and transfer to 12,000- to 14,000-MWCO dialysis tubing, prewashed with DEAE buffer and closed on one end. Rinse each centrifuge tube with 1 ml buffer and add this solution to the bag.

7. Close the open end of the dialysis bag with double knots or dialysis clips, leaving 1 to 2 in. (2.5 to 5 cm) extra space to allow for change in volume. Immerse the bag (containing ~40 ml) in a 500-ml graduated cylinder containing 500 ml DEAE buffer, 4°C. Dialyze with stirring overnight (or 4 to 6 hr), and change the dialysis buffer twice (2 to 3 hr each) for an additional 4 to 6 hr dialysis.

   Wear gloves when handling dialysis tubing to minimize exposure to radioactivity as well as to protect the sample from contamination. Mix bag contents several times by inversion.

8. Remove dialysis tubing, cut tip off carefully (if knotted) or remove clips, and empty contents into one or two 50-ml centrifuge tubes. Clarify the solution by centrifuging in a JA-17 rotor 20 min at 10,000 × *g*, 4°C. If appropriate, retain 10 to 25 µl for scintillation counting and for SDS-PAGE (*UNIT 6.1*) with autoradiography (*UNIT 6.3*), as assessment of starting material.

   The sample is now ready for ion-exchange chromatography.

Chromatograph on DEAE cellulose

9. Prepare gradient buffer B by adding 2.336 g NaCl to 200 ml DEAE buffer (200 mM NaCl final). Fill the front chamber of a standard gradient maker (containing a stir bar or paddle) with 200 ml DEAE buffer (gradient buffer A) and the second chamber with 200 ml gradient buffer B.

   Ensure that the narrow opening between the two chambers is filled with gradient buffer A before adding gradient buffer B. An air block will inhibit flow of B into A.

10. Use a peristaltic pump to add the entire sample onto an ~2 × 20–cm DEAE column, and follow with one to two column volumes DEAE buffer. Discard this eluate, which contains unbound protein.

11. If phenol red (from DMEM) is seen to bind to the resin, wash the column until it is no longer visible, or until the A_{280} of the flowthrough is at baseline.

Phenol red will interfere with the monitoring of the column effluent at 280 nm.

12. Connect the gradient maker to the peristaltic pump for delivery to the column bed. Connect a fraction collector to the column and set to collect 3-ml fractions of eluate in polypropylene or siliconized glass tubes. Elute bound proteins with a linear gradient of 0% to 100% buffer B over ~300 ml.

    All chromatographic procedures must be carried out at 4°C.

    A less complicated alternative to the continuous gradient is the use of two stepwise elutions, the first consisting of 100 ml of 75 mM NaCl in DEAE buffer, followed by 100 ml of 175 mM NaCl in DEAE buffer. SPARC will elute in the second buffer.

13. For radiolabeled SPARC (step 2), monitor the effluent by scintillation counting 20-µl aliquots from alternate fractions suspended in 3 ml scintillation fluid. For nonradiolabeled SPARC, monitor alternate fractions by absorbance at 280 nm.

    SPARC is eluted at 150 to 175 mM NaCl. See Sage et al. (1989) for an example of the elution profile. If the location of the peak containing SPARC is in doubt, individual fractions can be analyzed by SDS-PAGE (UNIT 6.1).

14. Pool fractions containing SPARC, and dialyze the pooled sample (~20 ml) against four changes of 4 liters (each) water over 24 to 48 hr, 4°C (see steps 6 to 8).

    After 24 to 48 hr, a precipitate containing SPARC, together with laminin and traces of BSA, should appear in the dialysis bag. Depending on the concentration of protein and/or the water used (pH 5.5 is optimal), precipitation may fail to occur. In this case, lyophilize the protein (step 16b), redissolve in DEAE buffer at 25% of the original volume, and repeat dialysis and precipitation (steps 14 and 15).

    If the column will be reused, it should be regenerated as described (see Reagents and Solutions).

15. Decant the entire contents of the bag into a centrifuge tube and centrifuge 30 min at 48,000 × *g*, 4°C. Discard the supernatant.

16a. *For immediate use:* Dissolve pellet in 2 ml S-200 buffer, clarify by microcentrifugation for 1 min at top speed or 10,000 × *g*, and proceed to molecular-sieve chromatography (step 18).

16b. *For storage before chromatography:* Resuspend pellet in 2 to 4 ml water, shell-freeze by twirling the tube in dry ice/ethanol to effect freezing of the solution on the sides of the vessel, and then lyophilize. Store up to 1 to 2 months at –70°C. Before use, resuspend in 1 to 2 ml S-200 buffer, stir 4 to 6 hr at 4°C, and clarify the solution by microcentrifugation at top speed for 1 min.

    Shell-freezing increases the efficiency of lyophilization and improves solubility of the protein after storage.

    Pellets from several preparations can be pooled prior to molecular-sieve chromatography.

Purify SPARC by molecular-sieve chromatography

17. Remove buffer from the top of a Sephacryl molecular-sieve column and apply the sample gently onto the resin. Allow the sample (optimally 1 to 2 ml) to flow into the bed. Add 2 to 4 ml S-200 buffer to the top of the column, reconnect the buffer reservoir, and allow effluent to flow by gravity at 8 to 10 ml/hr (0.17 ml/min) by adjustment of the pressure head (i.e., the reservoir containing S-200 buffer above the column).

    It is important not to disturb the column bed during sample loading, as the precision of elution can be affected.

In some cases it may be necessary to use a peristaltic pump, pulling buffer from the bottom of the column, at ~10 ml/hr. If the flow rate is too high, the column will pack too tightly and will cease to flow.

18. Collect 80 fractions of 1 to 1.5 ml each and monitor effluent by absorbance at 280 nm and/or by counting 10 to 25-µl aliquots in 3 ml scintillation fluid.

    The exact position of elution of SPARC will vary with chromatographic parameters (e.g., column size, sample size, flow rate). It is therefore advisable to monitor the column effluent and, if necessary, to check 10 to 25 µl of each fraction by SDS-PAGE (see below). The initial peak (at V_o) contains laminin, whereas the leading shoulder of the peak corresponding to the elution position of SPARC contains most of the BSA.

19. Pool peak fractions corresponding to SPARC (approximately ten fractions, corresponding to 55 to 65 ml total column effluent). Dialyze this pool against four changes of 4 liters of 0.05 M acetic acid each, 4°C, and lyophilize.

    Alternatively, the sample can be stored at –70°C in S-200 buffer without dialysis or lyophilization, or it can be dialyzed directly into another buffer as desired.

20. Determine the concentration of SPARC by absorbance at 280 nm, using the extinction coefficient (ε) 0.838 mg ml^{-1} cm^{-1} (*APPENDIX 3B*).

21. Analyze the purified protein by SDS-PAGE (*UNIT 6.1*) with autoradiography (*UNIT 6.3*). When heating samples at 95°C, use reducing (i.e., 50 mM DTT) and nonreducing conditions.

    For detection using Coomassie blue, from 1 to 5 µg SPARC is recommended; for detection by autoradiography, ~10^4 cpm is recommended. A single broad band, or occasionally a doublet, should be obtained with an apparent M_r of 39,000 (with DDT) or 43,000 (without DDT), the latter co-migrating with an ovalbumin molecular weight standard. The yield of purified SPARC is ~500 µg per 30 maxiplates (150-mm diameter) of PYS-2 cells (2 to 3 × 10^8 cells).

PURIFICATION OF rSPARC FROM *E. COLI*

ALTERNATE PROTOCOL 1

The preceding procedure (see Basic Protocol) allows for the purification of murine SPARC from cultured (tumor) cells. Limitations of a mammalian cell culture system as a protein source are its cost, potential contamination of the product by serum and cellular proteins/proteinases, and the low yield of product. To circumvent these problems, Bassuk et al. (1996a) expressed human rSPARC with a C-terminal histidine tag in *E. coli*. A soluble (monomeric) form and an insoluble (aggregated) form of SPARC were recovered, the latter sequestered in inclusion bodies within the host. Soluble (monomeric) SPARC from *E. coli* is biologically active and can be purified in relatively large quantities with minimal contamination by endotoxin or bacterial proteins. Isolation of the soluble form is accomplished by anion-exchange, nickel-chelate affinity, and gel-filtration chromatographies. Anion-exchange chromatography on DEAE-Sepharose is used as an initial isolation step. Metal-chelate affinity chromatography provides an efficient purification of rSPARC that has been expressed with a $(His)_6$ sequence. Gel-filtration chromatrography separates monomers of SPARC from dimers, trimers, and higher oligomers. This procedure is outlined below. It assumes that a competent strain of *E. coli*—e.g., BL21(DE3)—has been transformed with a SPARC expression plasmid—e.g., pSPARC wt (human)—with a hexahistidine $(His)_6$ sequence at the 3′ end (Bassuk et al., 1996a) and has been propagated and frozen as a glycerol stock.

Additionally, the aggregated form can be unfolded by urea treatment, purified by nickel-chelate affinity chromatography, and renatured by gradual removal of the denaturant. After disulfide bond isomerization, the disaggregated monomers are further purified by

high-resolution gel-filtration chromatography (Bassuk et al., 1996b). As the disaggregation/renaturation procedure is complicated and time consuming, the reader is referred to Bassuk et al. (1996b) for this additional protocol.

Additional Materials *(also see Basic Protocol)*

LB medium with appropriate selective reagents (*APPENDIX 2A*)
E. coli strain transfected with SPARC expression vector (Bassuk et al., 1996a)
Inducing agent (e.g., IPTG; *APPENDIX 3A*)
10 mM sodium phosphate, pH 7.0 (*APPENDIX 2A*)/10% (v/v) glycerol
90 mM sodium phosphate buffer (pH 7.8)/10% (v/v) glycerol/0.2 mM AEBSF, 4°C (see recipe), with and without 0.5 M NaCl
DEAE-Sepharose Fast Flow anion-exchange resin (Amersham Biosciences): equilibrate in 90 mM sodium phosphate buffer (pH 7.8)/10% (v/v) glycerol/0.2 mM AEBSF and allow to settle
5 M NaCl (*APPENDIX 2A*)
0.2 M AEBSF stock solution (see recipe)
Nickel/nitrilotriacetic acid (Ni-NTA) metal-chelate affinity resin (Qiagen)
50 mM sodium phosphate (pH 5.3, 6.0, and 7.8)/0.5 M NaCl/10% (v/v) glycerol (see recipe)
1.6 × 60–cm Superdex 70 column (see recipe)
50 mM Tris·Cl (pH 8.0)/0.15 M NaCl (see recipe)
1× PBS (*APPENDIX 2A*) containing 1 to 4 mM Ca^{2+} (optional)

French press
2 × 20– and 1 × 10–cm chromatography columns
Flow cell coupled to a UV monitor set at 280 nm
Chart recorder
Conductivity meter (optional)
Disposable 10-ml gel-filtration column, sterile (optional)

Additional reagents and equipment for transfecting SPARC expression vector (*APPENDIX 3A*) and for SDS-PAGE on minigels (*UNIT 6.1*)

Extract E. coli

1. Inoculate 1.3 liters LB medium containing appropriate selective reagents with a suitable *E. coli* strain transfected with SPARC expression vector using standard techniques (*APPENDIX 3A*). Grow to midexponential phase (OD_{600} ~0.5) and induce with the appropriate agent.

   Induction of rSPARC in midexponential phase cells is necessary for high levels of expression. The procedure and chemical(s) used depend on the E. coli strain and the vector into which SPARC cDNA is cloned. For example, IPTG was used at a final concentration of 1 mM for SPARC cloned into pET22b vector and transfected into strain BL21(DE3) (Bassuk et al., 1996a).

2. After the cells have been induced, grow an additional 1 to 4 hr.

3. Recover the cells by centrifuging 20 min at 7000 × *g*, room temperature. Discard the supernatant and resuspend the pellet in 20 ml of 10 mM sodium phosphate, pH 7.0, containing 10% (v/v) glycerol. Disrupt by performing two cycles in a French press at 20,000 psi.

   Cells can alternatively be broken open by sonication on ice.

4. Separate soluble from insoluble material by centrifuging 30 min at 10,000 × *g*, 4°C. Decant soluble extract (supernatant) into a separate tube.

Soluble extracts and insoluble pellets at this stage can be stored up to 1 month at –80°C. Refer to Bassuk et al. (1996b) for details on processing pellets for aggregated SPARC.

Perform initial chromatography on DEAE-Sepharose

5. If necessary, thaw the soluble extracts on ice. Dilute to 100 ml with ice-cold 90 mM sodium phosphate buffer (pH 7.8)/10% (v/v) glycerol/0.2 mM AEBSF, 4°C.
6. Add 50 ml settled DEAE-Sepharose Fast Flow anion-exchange resin. Stir gently 12 to 18 hr at 4°C.
7. Pour slurry into a 2 × 20–cm chromatography column, allow to settle, and wash with ~250 ml of 90 mM sodium phosphate buffer (pH 7.8)/10% (v/v) glycerol/0.2 mM AEBSF until the absorbance at 280 nm is <0.01.
8. Assemble a linear gradient (see Basic Protocol 1, step 9) by adding 250 ml of 90 mM sodium phosphate buffer pH 7.8)/10% (v/v) glycerol/0.2 mM AEBSF to the front compartment of a gradient maker, and 250 ml of 90 mM sodium phosphate buffer (pH 7.8)/10% (v/v) glycerol/0.2 mM AEBSF with 0.5 M NaCl (7.3 g) to the other compartment.
9. At 4°C pump gradient onto the column at 3 ml/min. Collect 8-ml fractions and monitor the column eluate with a flow cell coupled to a UV monitor set at 280 nm and a chart recorder set at full scale equal to 1 OD unit.

   It is advisable also to monitor the eluate by conductivity; read every fourth fraction in a conductivity meter (clean probe after each reading). rSPARC elutes at a concentration of 0.10 to 0.25 M NaCl (conductivity of 14 to 20 mmho).

10. Analyze 50-µl aliquots of fractions by SDS-PAGE on minigels (see Basic Protocol and *UNIT 6.1*). Pool fractions containing rSPARC, and adjust solution to 0.5 M NaCl by adding 5 M NaCl.

    In the absence of post-translational modification, rSPARC migrates on an SDS-polyacrylamide gel with an apparent M_r of 34,000 to 38,000 Da after reduction. Adjustment of ionic strength can be monitored easily by conductivity measurement; the final conductivity of the pooled fractions containing SPARC should be equivalent to that of 50 mM sodium phosphate (pH 7.8)/0.5 M NaCl/10% (v/v) glycerol. At this point, fractions can be stored up to 1 month at –80°C.

Perform metal-chelate affinity chromatography

11. Add 0.2 M AEBSF stock solution to the pooled sample to a final concentration of 0.2 mM.
12. Mix sample with a slurry of Ni-NTA metal-chelate affinity resin, using 3 to 5 ml resin per liter original bacterial culture. Adjust pH to 7.8 with 1 N NaOH or 1 N HCl, and stir gently for 1 hr at 4°C.
13. Pour slurry into a chromatography column (e.g., 1 × 10 cm), allow to settle, and wash with ~60 ml of 50 mM sodium phosphate (pH 7.8)/0.5 M NaCl/10% (v/v) glycerol at a flow rate of 0.5 ml/min until the absorbance at 280 nm is <0.01.
14. Pass 15 column volumes of 50 mM sodium phosphate (pH 6.0)/0.5 M NaCl/10% (v/v) glycerol through the column to remove nonspecifically bound proteins (i.e., until A_{280} <0.01).
15. Elute rSPARC from the column with 20 ml of 50 mM sodium phosphate (pH 5.3)/0.5 M NaCl/10% (v/v) glycerol.
16. Store up to 1 month in ~1-ml aliquots at –80°C.

Perform gel-filtration chromatography

17. Apply ~1 ml rSPARC solution onto a 1.6 × 60–cm Superdex 70 column and elute by gravity using 50 mM Tris·Cl (pH 8.0)/0.15 M NaCl buffer at a flow rate of 0.1 ml/min. Collect fractions of 1.25 ml each, monitored at 280 nm.

    Over an elution range of 100 ml, rSPARC monomer elutes between 46 and 50 ml. This should be verified by SDS-PAGE, as should the removal of oligomers (compare migration with and without 50 mM DTT).

18. *Optional:* Perform buffer exchange as needed for experimental design using sterile disposable 10-ml gel-filtration columns. Elute in the buffer of choice (e.g., 1× PBS containing 1 to 4 mM Ca^{2+} for in vitro studies).

19. Store samples up to 3 months at –80°C.

ALTERNATE PROTOCOL 2

PURIFICATION OF rSPARC FROM INSECT (*Sf*9) CELLS

This protocol describes the purification of human rSPARC produced in a baculovirus expression system using insect (*Sf*9) cells (Bradshaw et al., 2000). Advantages of this system over those described above (see Basic Protocol and Alternate Protocol 1) are higher yield of rSPARC, production of protein in a nonbacterial system to minimize contamination by endotoxin (*E. coli*) or serum proteins (mammalian cells), and the potential for post-translational modifications of protein similar to those in mammalian cells.

This protocol assumes that the starting materials are human (or other species) SPARC cDNA (minus the signal sequence) subcloned into a baculovirus expression vector (Pharmingen), *Spodoptera frugiperda* 9 (*Sf*9) insect cells cotransfected with the SPARC expression vector and linearized baculovirus, and high-titer stocks of recombinant virus generated for subsequent infections of *Sf*9 cells grown in suspension in serum-free media (Invitrogen). Information on the latest versions of the *Sf*9/baculovirus expression system is readily available from the Pharmingen instruction manual, *Baculovirus Expression Vector System*, and the Invitrogen manual, *Growth and Maintenance of Insect Cell Lines for Expression of Recombinant Proteins using the Baculovirus Expression System*.

Materials

Sf9 cells (Invitrogen) infected with baculoviral SPARC expression vector, grown in serum-free *Sf*-900 II medium (Invitrogen)
200 mM MOPS, pH 6.5 (see recipe)
10 N NaOH (*APPENDIX 2A*)
Q-Sepharose Fast Flow column (see recipe)
200 and 400 mM LiCl/20 mM MOPS, pH 6.5 (see recipe)
0.1 N acetic acid, 4°C: 0.6 ml glacial acetic acid in 100 ml H_2O
Hanks' buffered saline solution (see recipe)

50-ml conical tube
0.22-µm filter bottle
AktaPrime automated liquid chromatography system (Amersham Biosciences) or equivalent conventional model
10,000-NMWL Ultrafree-15 (Millipore) or Centricon Plus-80 (Amicon) centrifugal filter device
0.22-µm sterile syringe-driven filter

Prepare Sf9 conditioned medium for chromatography

1. Transfer *Sf*9 cells infected at 2 to 4×10^5 cells/ml with baculoviral SPARC expression vector, grown 4 to 5 days in serum-free *Sf*-900 II medium, to 50-ml conical tubes. Centrifuge 45 min at $6000 \times g$, 4°C. Transfer the supernatant to a 0.22-µm filter bottle and discard the cell pellets.

   This system optimizes for the efficient secretion of recombinant protein. It is important to avoid lysis of the cells (and contamination of the medium) during this step.

2. Sterile-filter the supernatant and measure the volume. Add 1/10 vol 200 mM MOPS, pH 6.5, and adjust the pH to 6.5 with 6 N NaOH.

Purify rSPARC by anion-exchange chromatography

3. Pump the sample onto a Q-Sepharose Fast Flow column at a flow rate of 5 ml/min.

4. Using either an AktaPrime automated liquid chromatography system or equivalent conventional model, assemble a continuous linear salt gradient from 200 to 400 mM. Use 200 ml of 200 mM LiCl/20 mM MOPS, pH 6.5, supplied to the buffer valve (AktaPrime System) or front chamber (conventional gradient maker) and 200 ml of 400 mM LiCl/20 mM MOPS, pH 6.5, to the buffer switch valve or rear chamber.

5. Start the gradient pumping at a rate of 5 ml/min and collect 3.5-ml fractions over 300 ml, monitoring the column effluent at 280 nm.

   The fractions can also be checked by SDS-PAGE (see Basic Protocol and Alternate Protocol 1; UNIT 6.1). Human rSPARC produced by Sf9 cells migrates at ~38,000 to 40,000 Da after reduction, and the doublet shifts to a single band of ~36,000 Da in the absence of reducing agent. The doublet is the result of heterogeneous glycosylation (Bradshaw et al., 2000).

Dialyze sample

For dialysis using acetic acid

6a. Pool the fractions containing rSPARC in 12,000- to 14,000-MWCO dialysis tubing and dialyze against three 1- to 2-liter changes (each) of 0.1 N acetic acid, 4°C.

7a. Aliquot the samples according to use. Snap-freeze on dry ice or in liquid nitrogen, lyophilize, and store at –70°C.

   Acetic acid is used when the sample is to be lyophilized and concentrated.

   The above procedure results in rSPARC of ~80% purity by SDS-PAGE. An additional purification step (entailing molecular-sieve chromatography) can be performed after the sample has been lyophilized. Follow the procedure described above (see Basic Protocol, steps 17 to 21). Significant losses of rSPARC (Sf9) should be expected with this procedure, however.

For dialysis using saline solution

6b. Pool the fractions containing rSPARC in 12,000- to 14,000-MWCO dialysis tubing and dialyze against three 4-liter changes (each) of 1× Hanks buffered saline solution (HBSS) containing 1 µM $CaCl_2$. Concentrate in a 10,000-NMWL Ultrafree-15 or Centricon Plus-80 centrifugal filter device to 1 or 2 ml. Filter sterilize using 0.22-µm sterile syringe-driven filter.

   Saline solution is used when the sample is to be used for cell culture.

7b. Aliquot according to use. Snap freeze on dry ice or in liquid nitrogen and store at –70°C.

Analyze SPARC

8. Determine protein content by UV spectroscopy at 280 nm (*APPENDIX 3B*), using the extinction coefficient (ε) 0.838 mg ml^{-1} cm^{-1}. Estimate the purity of SPARC by SDS-PAGE (5 μg/sample lane; *UNIT 6.1*).

The yield is 2 to 4 mg SPARC (~80% purity) per 400 ml of initial Sf9 cell culture suspension (at 2 to 4 × 10^6 cells/ml).

An updated version of the Sf9/baculovirus expression system is now available from Invitrogen. Termed "InsectSelect," it is a virus-free system that relies on expression of protein from a single nonlytic, integrative plasmid transfected into Sf9 or other insect cells, and is claimed to be optimal for secreted proteins.

ALTERNATE PROTOCOL 3

PURIFICATION OF SPARC/OSTEONECTIN FROM TISSUES

SPARC was originally isolated from fetal bovine mineralized bone matrix, of which it is a major noncollagenous component, and was termed osteonectin (Termine et al., 1981). Two other significant sources of SPARC are platelets (osteonectin; Kelm and Mann, 1991) and the Engelbreth-Holm-Swarm (EHS) sarcoma, a murine basement membrane–producing tumor (termed BM-40; Sasaki et al., 1999, and references therein). SPARC, osteonectin, and BM-40 are now recognized as the same protein. Many of the functional properties of SPARC were deduced from biochemical/biophysical studies of the tissue-derived protein, which can be isolated in significantly greater quantities compared to yields typically described from in vitro sources. In this protocol, purification of SPARC from human platelets is described, based on an original report by Kelm and Mann (1990). There are several advantages to using platelets as a source of SPARC: (1) human blood is a readily available source for human SPARC; (2) bovine blood is an excellent source of SPARC and requires neither screening for pathogens nor the rigorous safety procedures associated with the use of human material; and (3) denaturing conditions are not involved (the extraction of osteonectin from bone matrix or EHS tumor includes the use of EDTA and, in some cases, guanidinium·HCl; Termine et al., 1981; Kelm and Mann, 1990; Sasaki et al., 1999). It is important to note, however, that differences have been reported between bone and platelet osteonectin from the same species, notably in the specificity of collagen binding that was attributed to differences in glycosylation (Kelm and Mann, 1991). Investigators interested in tissue-specific modifications of SPARC and their functional implications are encouraged to consult the references cited above. Bovine bone and human platelet osteonectin are available commercially from Calbiochem, although their method of purification is not specified. Haematologic Technologies sells human platelet osteonectin isolated by affinity chromatography on an anti-osteonectin monoclonal antibody column, as well as bovine bone osteonectin isolated from 0.5 M EDTA extracts of demineralized bone. All commercial preparations should be tested for activity in one or more of the assays described (see Support Protocols 1 to 3).

Materials

Platelet-rich plasma or platelet suspension, or informed, nonsmoking, aspirin-free, consenting adult blood donors
0.156 M citrate containing 0.1 M dextrose and 5.0 μM prostaglandin E_1 (Sigma; optional)
0.02 M Tris·Cl, pH 7.6/0.15 and 1.0 M NaCl (see recipe)
Thrombin
Sepharose 4B–AON IgG column (see recipe)
3.0 M NaSCN/0.02 M Tris·Cl (pH 7.6)/0.15 M NaCl (see recipe)
0.05 M NH_4HCO_3

19-G butterfly needles
50 or 250-ml plastic centrifuge bottles with caps
12,000 to 14,000-MWCO dialysis tubing
Lyophilizer

Additional reagents and equipment for thrombin activation of platelets (Kelm and Mann, 1990) and SDS-PAGE (*UNIT 6.1*; also see Basic Protocol, step 22)

Prepare activated platelet supernatant

1a. *For predrawn plasma:* Purchase platelet-rich plasma or platelet suspensions from a local blood bank.

1b. *For in-house drawn plasma:* Draw 480 ml fresh blood from informed, nonsmoking, aspirin-free, consenting adults via 19-G butterfly needles into 0.156 M citrate containing 0.1 M dextrose and 5.0 μM prostaglandin E_1 (to prevent platelet activation). Remove red cells and leukocytes by centrifuging 30 min at 1000 × g, room temperature.

CAUTION: *Appropriate biosafety practices must be followed when working with human blood or blood products. Human blood must be screened for HIV and other infectious viruses. In addition, safety glasses, a double layer of gloves, and protective laboratory clothing should be worn at all times. Use double containment (e.g., place a tube or bag containing blood in a beaker prior to any manipulation) and ensure that all containers including centrifuge bottles are tightly capped.*

2. Centrifuge platelet-rich suspension 30 min at 27,000 × *g*, 4°C, to pellet the platelets. Decant supernatant.

3. Wash platelets with 200 ml of 0.02 M Tris·Cl (pH 7.6)/0.15 M NaCl, centrifuge as in step 2. Resuspend platelets in 50 ml of the same buffer. Count with a hemacytometer and suspend 4.5×10^{10} cells in 50 ml of 0.02 M Tris·Cl (pH 7.6)/0.15 M NaCl. Activate by adding 2.5 U/ml thrombin as described by Kelm and Mann (1990).

4. Transfer to plastic, capped centrifuge bottles and isolate activated platelets by centrifuging 30 min at 25,000 × *g*, room temperature. Discard the pellet using appropriate containment and retain the supernatant.

CAUTION: *Autoclave human products prior to disposal.*

Isolate SPARC/osteonectin by immunoaffinity chromatography

5. Apply platelet supernatant to a Sepharose 4B-AON IgG column (~2 × 20–cm). After the applied solution has permeated the resin, clamp off the column and allow the sample to remain within the column bed for 16 hr at 4°C.

6. Wash the column with 0.02 M Tris·Cl (pH 7.6)/0.15 M NaCl until the effluent shows an A_{280} of 0.01.

7. Wash the column with 0.02 M Tris·Cl (pH 7.6)/1.0 M NaCl until a baseline absorbance is achieved.

8. Elute SPARC/osteonectin with 3.0 M NaSCN/0.02 M Tris·Cl (pH 7.6)/0.15 M NaCl and collect in a single tube or in fractions.

9. Transfer the effluent to 12,000 to 14,000-MWCO dialysis tubing, dialyze against two changes of 2 liters of 0.05 M NH_4HCO_3, and then lyophilize.

Peak fractions of the eluted SPARC can also be dialyzed against 0.02 M Tris·Cl (pH 7.6)/0.15 M NaCl, PBS, or DMEM (minus phenol red), as dictated by the intended use of the purified SPARC, and stored up to 1 month at –80°C. If the NH_4HCO_3 fails to lyophilize completely, redissolve the powder in water, dialyze against 0.01 N acetic acid, and repeat the lyophilization.

It is important to minimize the exposure of SPARC/osteonectin to NaSCN, and to keep all reagents at 4°C during affinity chromatography and dialysis.

10. Determine the concentration of SPARC/platelet osteonectin at A_{280} using the extinction coefficient (ε) 0.838 mg ml^{-1} cm^{-1}.

11. Monitor the purity of SPARC by SDS-PAGE (*UNIT 6.1*; also see Basic Protocol, step 22).

Platelet SPARC/osteonectin should be >80% pure by SDS-PAGE using a Coomassie blue stain. It exhibits an apparent M_r of ~3000 greater than that of bone osteonectin purified according to the same protocol (shown to be due to differences in glycosylation), but is comparable to that reported for SPARC isolated from PYS-2 cell culture media.

Immunoaffinity chromatography typically produces somewhat low recoveries of the protein antigen, albeit in a high state of purity given the minimal steps used in the isolation protocol. The total amount of SPARC/osteonectin in human platelets (prior to affinity purification) was reported by Kelm and Mann (1990) to range from 0.65 to 2.2 μg/10^8 platelets.

ASSAYS FOR THE EVALUATION OF SPARC ACTIVITY

All proteins need to be evaluated, not only for their extent of purity, but also for their activity and conformational integrity. The latter is especially critical in the case of recombinant proteins, which are produced either in biologically "inappropriate" hosts (e.g., SPARC in a prokaryotic system) or at levels that preclude proper processing, folding, and/or editing. Moreover, the importance of post-translational modification to the functions of many proteins is poorly understood. In the case of SPARC, N-linked glycosylation (one site) appears not to be critical for activity, at least in the assays that have been used; however, rSPARC (see Alternate Protocols 1 and 2) has consistently displayed less activity (up to 50%) than SPARC purified from PYS-2 cells (see Basic Protocol; Yost et al., 1994; Bassuk et al., 1996a; Bradshaw et al., 2000). These protocols describe biological assays that test two major effects of SPARC on cultured cells: de-adhesion and inhibition of proliferation. Other assays based on biochemical measurements (e.g., circular dichroism, binding assays) are standard procedures and are discussed elsewhere (see Commentary).

SUPPORT PROTOCOL 1

Proliferation Assay

Endotoxin will inhibit cell proliferation, and endothelial (especially BAE) cells are particularly sensitive. At 10 ng endotoxin/mg SPARC, there should be <10% inhibition of [^{3}H]thymidine incorporation in BAE cells exposed to 60 μg SPARC/ml. To determine the effect of endotoxin on other types of cells, treat the cells with a titration of CSE and measure proliferation.

Additional Materials *(also see Basic Protocol)*

Bovine aortic endothelial (BAE) cells
DMEM/0% and 10% (w/v) FBS (*APPENDIX 2A*)
Purified SPARC (see Basic Protocol or Alternate Protocol 1 to 3) and appropriate control buffer
6.71 Ci/mmol (1 mCi/ml) [methyl-^{3}H]thymidine (PerkinElmer)
10% (w/v) trichloroacetic acid (TCA), ice cold
95% (v/v) ethanol
0.4 N NaOH
Glacial acetic acid
Scintillation fluid

24-well tissue culture plate
15-ml conical tube
Radioactivity warning tape

Additional reagents and equipment for trypsinizing cells (*UNIT 1.1*)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiments and dispose of wastes in appropriately designated area, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

1. Starve a 100-cm dish of confluent bovine aortic endothelial (BAE) cells in serum-free DMEM for 3 to 4 days.
2. Trypsinize cells (*UNIT 1.1*), resuspend in 10 ml DMEM/10% FBS, and centrifuge briefly (i.e., 5 min at 1000 × *g*, room temperature) to pellet.
3. Rinse cells twice with 5 ml serum-free DMEM.
4. In a 24-well tissue culture plate, plate triplicate wells containing 5×10^4 cells in 500 µl (final 1×10^5 cells/ml) of the following solutions, using the same volume for SPARC and buffer:

   Serum-free DMEM (control)
   DMEM/2%FBS containing 5 µg/ml SPARC dissolved in DMEM
   DMEM/2% FBS containing 20 µg/ml SPARC dissolved in DMEM
   DMEM/2% FBS containing buffer alone (control).

   Other buffers compatible with cell culture may be used but not acetic acid.
5. Incubate 16 to 18 hr at 37°C.

   By this time, cells will have begun to synthesize DNA (S phase).
6. Prepare label in a 15-ml conical tube by adding 20 µl (20 µCi) of 6.71 Ci/mmol [methyl-^{3}H]thymidine/ml DMEM. Place 55 µl (1.1 µCi) of this mixture into each well. Swirl plate gently to mix. Label plate with radioactivity warning tape, and incubate 4 hr at 37°C.

   CAUTION: *Perform this step in a laminar-flow hood with absorbent bench pad and radioactive waste receptacle.*
7. Wash each well twice with 500 µl ice-cold 10% TCA, and drain completely.

   CAUTION: *Collect radioactive media and washes for safe disposal.*
8. Wash with 500 µl of 95% ethanol. Remove ethanol and add 500 µl of 0.4 N NaOH per well. Incubate 30 min at room temperature with shaking.
9. Add 100 µl glacial acetic acid to neutralize the solution.

   Extremes of pH can result in precipitation of scintillation cocktail and/or quenching.
10. Place the contents of each well into a collection vial containing 3 ml scintillation fluid. Cap, mix by inversion, and measure cpm in a scintillation counter.

    There should be no precipitate in the vials; check pH if this occurs and adjust to neutrality.

    For rSPARC, expect >70% inhibition of [^{3}H]thymidine incorporation at 50 µg SPARC/ml. For SPARC purified from PYS-2 cells, the effective dose at which 50% inhibition of [^{3}H]thymidine incorporation occurs (ED_{50}) is 20 µg SPARC/ml.

De-adhesion Assay

SUPPORT PROTOCOL 2

This protocol is presented as a rapid, inexpensive, and diagnostic assay for the de-adhesive activity of SPARC on nontransformed cells in vitro. The activity is based on the diminishment of focal adhesions produced by cultured cells. These structures can be distinguished by immunofluorescence staining of vinculin in wedge-shaped structures at the periphery of the cell, which are diagnostic for focal adhesion complexes.

Additional Materials *(also see Basic Protocol)*

One 100-mm dish of nearly-confluent bovine aortic endothelial (BAE) cells, passaged not greater than ten times, grown in DMEM/10% FBS containing appropriate antibiotics
DMEM/2% and 10% FBS (*APPENDIX 2A*)
Purified SPARC (see Basic Protocol and Alternate Protocols 1 to 3) and appropriate control buffer

12-well tissue culture dishes
Phase-contrast microscope (*UNIT 4.1*)

Additional reagents and equipment for trypsinizing cells (*UNIT 1.1*)

1. Trypsinize (*UNIT 1.1*) a 100-mm dish containing a nearly confluent monolayer of bovine aortic endothelial (BAE) cells, passaged greater than ten times, and grown in DMEM/10% FBS containing appropriate antibiotics.

   The size of the dishes is optional and can be adjusted according to the availability of SPARC. Scale the volume of medium as appropriate for size of dish or well.

2. Transfer trypsinized cells to appropriate centrifuge tubes, pellet in a clinical centrifuge 5 min at $1000 \times g$, room temperature, and resuspend in an appropriate volume of DMEM/2% FBS. Plate 5 to 7.5×10^4 cells in triplicate wells of a 12-well tissue culture dish.

3. Add the following solutions to cells in triplicate, using the same volume for SPARC and buffer:

   No addition
   20 µg/ml SPARC
   40 µg/ml SPARC
   Appropriate control buffer.

4. Mix gently and incubate 1 hr at 37°C.

5. Check the plate carefully under a phase-contrast microscope. Examine several representative fields and count the number of cells in the following groups:

   Fully spread cells (group *a*)
   Partially spread cells (group *b*)
   Rounded cells (group *c*).

   Cells to which SPARC has not been added should be attached and beginning to spread. Cells to which SPARC has been added should be less spread (i.e., rounded). If control cells (i.e., no SPARC) have not spread, wait an additional 1 to 2 hr. There should be no toxicity or cell death.

6. Quantify the activity of SPARC according to the rounding index (RI):

   $RI = [(1 \times a) + (2 \times b) + (3 \times c)]/(a + b + c)$

   An RI = 1 represents a culture with only spread cells, whereas a culture with increasing numbers of round cells would approach the maximum, RI = 3.

   A titration curve can be generated using different concentrations of SPARC. Anticipate that different types of cells will show differential sensitivity to SPARC. Cell lines (e.g., 3T3, NRK) and transformed cells typically do not respond to SPARC.

Endotoxin Assay

Endotoxin is derived from gram-negative bacteria (e.g., *E. coli*) and is a commonly encountered contaminant of buffers, columns, and glassware. In addition, soluble (monomeric) SPARC purified from *E. coli* may contain endotoxin. Endotoxin interferes with bioassays for SPARC, so it is necessary to assess samples for the presence of endotoxin.

Materials

Purified SPARC (see Basic Protocol and Alternate Protocols 1 to 3) and appropriate buffer
Limulus Amoebocyte Lysate (LAL) Pyrochrome kit (Associates of Cape Cod) for the Detection and Quantification of Gram-Negative Bacterial Endotoxin:
Pyrochrome LAL reagent
Pyrochrome Reconstitution buffer
Control Standard Endotoxin (CSE)
50% (v/v) glacial acetic acid

Nonpyrogenic 96-well tissue culture plate
Microtiter plate reader

1. Prepare SPARC titrated at 0.2, 1, and 5 µg/ml in DMEM or HBSS. Pipet 50 µl of each into triplicate wells of a nonpyrogenic 96-well tissue culture plate, leaving 16 empty wells for standards and controls (step 5).
2. Tap vial containing Pyrochrome LAL reagent. Remove and discard stopper.
3. Add 3.2 ml Pyrochrome Reconstitution buffer to the LAL reagent. Mix gently but thoroughly. Cover with Parafilm and place for 3 to 5 min on ice. Store on ice up to 3 hr.
4. Prepare standards by adding 2.0 ml water to the vial containing the Control Standard Endotoxin (CSE) to yield 1.0 endotoxin units (EU)/ml endotoxin. Vortex and store on ice.
5. Place 200 µl water in each of five wells in a fresh 96-well plate. Make a five-step serial dilution using a ratio of 1:1 at each step, by adding 200 µl of 1.0 EU/ml endotoxin to the first well, mixing, transferring 200 µl to the next well, and repeating until the series is complete. Pipet 50 µl of each dilution into triplicate wells of the SPARC-containing plate (step 1), and include a 50-µl water-only control.

   The serial dilutions above will result in final concentrations of 0.5, 0.25, 0.125, 0.0625, and 0.0313 EU/ml endotoxin, respectively.
6. Pipet 50 µl of reconstituted Pyrochrome LAL reagent (step 3) into each well, shake on a microtiter plate shaker for 30 sec, and incubate at 37°C for 30 min.
7. Stop reaction by adding 25 µl of 50% glacial acetic acid per well.
8. Measure OD_{405} in a microtiter plate reader. Determine the concentration of endotoxin in the sample by comparison to the curve generated from the standards.

   The expected concentration of endotoxin is <10 ng/mg SPARC, at an estimated level of 10 EU/ng endotoxin. Endotoxin levels range from 5 to 15 EU/ng. The level of endotoxin that affects cells depends on the cell type.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AEBSF (aminoethylbenzenesulfonyl fluoride) stock solution, 0.2 M

Dissolve 4.794 g AEBSF (Calbiochem) in 100 ml water. Make fresh.

DEAE buffer

500 ml 8 M urea stock solution (see recipe)
50 ml 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
448 ml H_2O
1 ml 0.2 M PMSF stock solution (see recipe)
625 mg *N*-ethylmaleimide (NEM)
Adjust pH to 8.0 with 10 N NaOH
Chill to 4°C
Make fresh buffer for each column run

Final concentrations are 50 mM Tris·Cl, pH 8.0, 0.2 mM PMSF, 10 mM NEM, and 4 M urea.

DEAE column

Pack an ~2 × 20–cm column (e.g., Amersham Biosciences) at 4°C with a 20% slurry of DE-52 cellulose (Whatman) equilibrated in DEAE buffer (see recipe). Equilibrate with several column volumes (~70 ml each) DEAE buffer, delivered via a peristaltic pump connected from a reservoir to the bottom of the column (pumping upward ensures more efficient utilization of theoretical plates for ion exchange). The column can be stored at 4°C and reused for several months. After storage, flush the column with several volumes of fresh DEAE buffer immediately before use. To regenerate a DEAE column, pump one column volume of DEAE buffer containing 500 mM NaCl (29.2 g/liter) followed by several column volumes of DEAE buffer until the absorption and conductivity of the elution buffer is restored to baseline (see Commentary).

Columns manufactured by Amersham Biosciences work well, as they are thick walled and are equipped with high-quality fittings that can withstand the pressures delivered by a peristaltic pump.

Hanks' buffered saline solution

0.14 g/l $CaCl_2$ (1.26 mM final)
40 g/l KCl (5.33 mM final)
0.6 g/l potassium phosphate, monobasic (0.44 mM final)
0.1 g/l magnesium chloride, hexahydrate (0.50 mM final)
0.1 g/l magnesium sulfate, heptahydrate (0.41 mM final)
0.35 g/l sodium bicarbonate (4.00 mM final)
0.048 g/l sodium phosphate, dibasic (0.30 mM final)
Store up to 3 months at 4°C

LiCl, 200 mM/20 mM MOPS, pH 6.5

200 ml of 200 mM MOPS, pH 6.5 (see recipe)
80 ml 5 M LiCl
Add H_2O to 1700 ml
Adjust pH to 6.5 with 6 N NaOH
Add H_2O to 2000 ml
Store up to 1 year at 4°C

LiCl, 400 mM/20 mM MOPS, pH 6.5

50 ml 200 mM MOPS, pH 6.5 (see recipe)
40 ml 5 M LiCl
Add H_2O to 480 ml
Adjust pH with 6 N NaOH
Add H_2O to 500 ml
Store up to 1 year at 4°C

LiCl, 2 M/20 mM MOPS, pH 6.5

50 ml 200 mM MOPS, pH 6.5 (see recipe)
200 ml 5 M LiCl
Add H_2O to 480 ml
Adjust pH with 6 N NaOH
Add H_2O to 500 ml
Store up to 1 year at 4 °C

Molecular-weight standards

Molecular-weight standards include a marker for the excluded (outer; V_o) and included (inner; V_i) volume of the column. For V_o, use 500 µl of 0.1% (w/v) blue dextran in S-200 buffer (see recipe). Clarify by centrifugation before applying to the column. For V_i, use 25,000 to 100,000 cpm [^{35}S]methionine or [^{3}H]proline (which can be detected by scintillation counting), or any small protein (M_r <10,000) or peptide that is minimally hydrophobic and nonglycosylated.

MOPS, 200 mM, pH 6.5

41.86 g 3-(*N*-morpholino)propanesulfonic acid (MOPS)
Add H_2O to ~800 ml
Adjust pH to 6.5 with 6 N NaOH
Add H_2O to 1000 ml
Store up to 1 year at 4°C

NaSCN, 3.0 M/0.02 M Tris·Cl (pH 7.6)/0.15 M NaCl

243.24 g sodium isothiocyanate (NaSCN)
20 ml 1 M 0.22-µm-filter-sterilized Tris·Cl, pH 7.5 (*APPENDIX 2A*)
8.766 g NaCl
Add H_2O to ~900 ml
Adjust pH to 7.6 with 6 N NaOH
Add H_2O to 1000 ml
Store up to 1 year at 4 °C

PMSF (phenylmethylsulfonyl fluoride) stock solution, 0.2 M

Dissolve 3.48 g PMSF in 100 ml isopropanol. Store up to several years at 4°C or room temperature.

Add this reagent to aqueous solutions drop-wise while vortexing, or it will precipitate.

PYS-2 cells, 50% to 70% confluent

Using 150-mm tissue-culture dishes or equivalent plastic flasks, grow PYS-2 cells (ATCC CRL-2745) to between 50% and 70% confluence ($7–10 \times 10^6$ cells per plate) in DMEM/10% (v/v) FBS (*APPENDIX 2A*).

Cells undergo >1 population doubling in 24 hr under these conditions.

Q-Sepharose Fast Flow column

Pour a 1.7 × 20–cm column of Q-Sepharose Fast Flow resin (Amersham Biosciences) equilibrated in 200 mM LiCl/20 mM MOPS, pH 6.5 (see recipe). Equilibrate by running two to three column volumes of 200 mM LiCl/20 mM MOPS, pH 6.5 (see recipe), through the resin. After use, strip the column with 100 ml of 2 M LiCl/20 mM MOPS, pH 6.5 (see recipe), and equilibrate with 60 ml of 200 mM LiCl/20 mM MOPS, pH 6.5. Store up to 1 year at room temperature.

S-200 buffer

999 ml Hanks' balanced salt solution (HBSS; see recipe) with Ca^{2+} and Mg^{2+} (Life Technologies and *APPENDIX 2A*)
1 ml 0.2 M PMSF stock solution (see recipe)
Filter sterilize with a 0.22-μm filter
Prepare fresh for each run and keep at 4°C

Calcium is present in HBSS as 0.14 g/liter $CaCl_2$, and magnesium is present as 0.1 g/liter $MgCl_2 \cdot 6H_2O$ and 0.1 g/liter $MgSO_4 \cdot 7H_2O$.

Sephacryl molecular-sieve column

At 4°C, pour an ~1 × 100–cm column (e.g., Bio-Rad) of Sephacryl S-200 (Amersham Biosciences) in a slurry of cold, sterile S-200 buffer (see recipe). Allow column bed to pack slowly but steadily, with controlled elution from the bottom port of the column at ~10 ml/hr (0.17 ml/min), to a bed height of ~95 cm. Run several column volumes (~80 ml each) of S-200 buffer through the packed bed and then calibrate using molecular-weight standards (see recipe). Store in S-200 buffer at 4°C for up to several days prior to use. For longer storage and reuse (up to several months), store in S-200 buffer containing 0.1% (w/v) sodium azide at 4°C. Periodically clean (i.e., remove sample debris from the top of the column up) and flush with fresh S-200 buffer containing 0.1% sodium azide.

Azide must be flushed out completely (monitor at 280 nm) prior to chromatography of SPARC, as azide is toxic to cells and may also interfere with the properties of SPARC.

Sepharose 4B-AON IgG column

Following manufacturer's instructions, pour anti-osteonectin (AON-5031; 20 mg) monoclonal IgG_1 antibody (Haematologic Technologies) coupled to CNBr-activated Sepharose 4B (Amersham Biosciences) into a 5- to 10-ml column, at 4°C. Equilibrate in several column volumes of 50 mM Tris·Cl (pH 8.0)/0.15 M NaCl (see recipe), by gravity flow at 0.1 to 0.5 ml/min. After use reequilibrate column in 0.02 M Tris·Cl, pH 7.6/0.15 M NaCl. Store up to 1 month in that same buffer at 4°C.

Sodium phosphate, 50 mM (pH 5.3, 6.0, or 7.8)/0.5 M NaCl/10% (v/v) glycerol

29.2 g NaCl
5.75 g sodium phosphate dibasic
1.37 g sodium phosphate monobasic
100 ml glycerol
Add H_2O to ~800 ml
Adjust pH to 5.3 or 6.0 with 6 N HCl, or to 7.8 with 6 N NaOH
Add H_2O to 1000 ml
Store up to 1 to 2 days at 4°C

Sodium phosphate, 90 mM (pH 7.8)/10% (v/v) glycerol/0.2 mM AEBSF

10.35 g sodium phosphate dibasic
2.466 g sodium phosphate monobasic
100 ml glycerol
1 ml 0.2 M AEBSF stock solution (see recipe)
Add H_2O to ~800 ml
Adjust pH to 7.8 with 6 N NaOH
Add H_2O to 1000 ml
Store up to 1 to 2 days at 4°C

Superdex 70 column

In the cold (i.e., 4°C), pour a 1.6 × 60–cm column of Superdex 70 gel-filtration resin (Amersham Biosciences) equilibrated in 50 mM Tris·Cl (pH 8.0)/0.15 M NaCl (see recipe). Calibrate using the molecular-weight standards (see recipe) blue dextran (V_o) and [^{3}H]proline (V_i) as described.

Tris·Cl, 0.02 M (pH 7.6)/0.15 and 1.0 M NaCl

20 ml 1 M 0.22-µm-filter-sterilized Tris·Cl, pH 7.5 (*APPENDIX 2A*)
8.77 or 58.44 g NaCl
Add H_2O to ~900 ml
Adjust pH to 7.6 with 1 N NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Tris·Cl, 50 mM (pH 8.0)/0.15 M NaCl

8.76 g NaCl
4.44 g Tris·Cl
2.65 g Tris base
Add H_2O to ~800 ml
Adjust pH to 8.0 with 6 N NaOH
Add H_2O to 1000 ml
Store up to 1 month at 4°C

Urea stock solution, 8 M

Add 1920 g ultra pure urea (Life Technologies) in 2 liters water by dissolving ~200 g at a time. After all urea has dissolved, add water to 4 liters. Filter through Whatman no. 3 paper and store up to 1 month at 4°C.

COMMENTARY

Background Information

The abundance of SPARC in many tissues, and its high levels of secretion by most cells in vitro, belie the difficulty of its recovery as an intact, active protein after purification. SPARC (as osteonectin) was found to be a major non-collagenous component of fetal and adult bone (Termine et al., 1981). In situ hybridization of SPARC by numerous investigators has shown that the mRNA is abundant in most fetal tissues, presumably associated with morphogenesis, growth, and angiogenesis but is somewhat limited in the corresponding adult tissues (for reviews, see Lane and Sage, 1994; Brekken and Sage, 2000; Bradshaw and Sage, 2001). SPARC mRNA and protein are found in relatively high amounts in adult tissues that exhibit continuous turnover (gut epithelium) and remodeling (bone), and are produced in response to injury (wound healing) and certain types of pathologies (tumors, scleroderma). In more quiescent and/or established tissues, however, levels of SPARC are low. Since SPARC affects both the adhesion and proliferation of most normal cells, its association with angiogenesis and other processes requiring cell migration, differentiation, and synthesis of extracellular matrix (ECM) is not surprising.

There are several structural features of SPARC that should be considered in the context of a purification protocol.

1. SPARC is typically a secreted protein with two post-translational modifications that can be troublesome. There are fourteen cysteines, all of which are disulfide-bonded, and the folding and correct formation of disulfide bridges are not trivial in recombinant proteins produced at high levels, especially in yeast and bacteria. This has certainly been the case for SPARC (Yost et al., 1994; Bassuk et al., 1996b). Additionally, secreted SPARC contains a single complex-type carbohydrate chain (N-linked) which is not produced in nonmammalian systems. Interestingly, the carbohydrate has been shown to be variable in mammalian SPARCs—i.e., the carbohydrate from platelet SPARC is different from that from bone. In addition, cultured cells can assemble and process the oligosaccharide side-chain structures differently (Lane and Sage, 1994). It is important to remember that purification of SPARC from tissues such as bone will result in the recovery of nonsecreted SPARC that has unprocessed high-mannose-type oligosaccharide.
2. SPARC binds other proteins, including growth factors. The association of SPARC with albumin (probably through adventitious disulfide interchange) has been troublesome, but can be avoided by the use of serum-free culture (e.g., *Sf*9 cells, *E. coli*, or a serum-independent mammalian cell line). Anticipate that isolation of SPARC from tissues (including platelets) can result in contamination from plasma and tissue fluid components (e.g., albumin) as well as ECM proteins to which SPARC binds (collagen types I, III, IV, V, and thrombospondin 1). Moreover, SPARC also interacts with platelet-derived growth factor (PDGF) AB and BB and vascular endothelial growth factor (VEGF) with a $K_d \cong 10^{-9}$ M. If possible, it is best to avoid these proteins when choosing a source of SPARC, as additional purification steps to remove the contaminants will invariably result in lower yields and loss of activity.
3. SPARC binds to several cations (Cu^{2+}, Fe^{2+}) and has an absolute requirement for Ca^{2+}. The disulfide-bonded EF-hand, a Ca^{2+}-binding loop at the C terminus, is reasonably stable, with a K_d for $Ca^{2+} \cong 10^{-7}$ M, and is thought to serve a structural function. The N terminus, however, contains from five to eight low-affinity ($K_d \cong 10^{-3}$ to 10^{-5} M) Ca^{+2}-binding sites (glutamic acids). Association of Ca^{2+} with this region of SPARC serves to neutralize its excessive negative charge and confers α-helicity to this domain. It is therefore critical that SPARC is not exposed to EDTA or other chelating agents during purification, and that the protein is stored in the presence of 1 to 4 mM Ca^{2+}. One of the assays for native structure of SPARC, circular dichroism (see below), depends on α-helicity as a function of Ca^{2+} binding within this low-affinity site.

Three protocols have been discussed that maximize both the yield and the purity/native structure of either natural or rSPARC. Most cultured cells secrete reasonably high levels of SPARC into the culture medium, an environment in which SPARC is stable over several days at 37°C. Proteolytic degradation of SPARC has rarely been a problem, especially with the judicious use of protease inhibitors, as described in the protocols. Since both human and murine tumor cells can also secrete high levels of SPARC in vitro and in general are more tolerant of low serum (or, preferably, the absence of serum), they are a logical choice for the isolation of nonrecombinant SPARC, especially if they exhibit high rates of growth and secretion (see Basic Protocol).

Advantages of a recombinant protein expression system include the (theoretically) substantially higher yields of protein, as well as the potential of producing mutated versions of the protein. Both the *E. coli* and *Sf*9 cell systems can achieve these goals with respect to SPARC (see Alternate Protocol 1 and 2). Additionally, SPARC from any species for which the sequence is known can be engineered by the polymerase chain reaction (*APPENDIX 3F*) into a suitable expression vector. Disadvantages include potential problems with folding and post-translational modification of rSPARC; however, assessment of purity and activity of the SPARC produced in both *E. coli* and *Sf*9 cells has shown that these are both viable routes for the production of SPARC. Although the activity of rSPARC appears to be ~50% of that of the PYS-2-derived protein, the substantially greater yields may offset this limitation.

Any modification of the primary structure of SPARC must be considered as potentially deleterious to its conformation and/or activity. The $(His)_6$ sequence, tagged onto the C terminus of SPARC to facilitate its purification by metal-affinity chromatography, could affect one or more properties of SPARC (e.g., nuclear translocation, de-adhesion) and should be controlled for in subsequent experiments. As discussed in preceding paragraphs, post-translational differences need to be considered as well—i.e., the lack of carbohydrate in *E. coli* rSPARC (see Alternate Protocol 1), and a dif-

ferent or additional type of glycosylation conferred by *Sf*9 cells (see Alternate Protocol 2).

There may be situations in which the proper SPARC for study will be that isolated from a given tissue (e.g., bone). References have been included (see Alternate Protocol 3) for the extraction of SPARC from this tissue. The use of denaturants and EDTA could be problematic, although renaturation is always an option. Since both platelet and bone SPARC are available commercially (see Alternate Protocol 3), it is advisable to purchase a small amount and to test it according to the parameters required.

Critical Parameters and Troubleshooting

Many of the caveats at various stages of purification of SPARC have been detailed within each protocol. The principal problems are low recovery and poor bioactivity.

Recovery of SPARC depends on several factors, not the least important of which is the output of SPARC in vitro. Despite claims of immortality, transformed or tumor cells do not live forever in culture. Successive passages and cycling of cells on and off serum (or growth in the absence of serum) can affect their eventual viability. Therefore, it is important to monitor the secretion of SPARC over time (this also applies to the production of rSPARC). SPARC is produced optimally by subconfluent cells; at confluence or near-confluence, SPARC is secreted at a reduced rate, and will associate with the cell surface or ECM. Presented below is a list of other possible causes of recovery loss, as well as potential solutions; however, the reader should bear in mind that some losses are indeed unavoidable.

1. Failure of SPARC to redissolve completely in the various buffers used for purification or assay. Clarification of solutions is always recommended.
2. Precipitation of SPARC during freezing or thawing. Snap-freezing on dry ice, and quick-thawing at room temperature, are recommended.
3. Incomplete precipitation during dialysis against water, which can be checked by SDS-PAGE (*UNIT 6.1*) of a small aliquot of the supernatant.
4. Irreversible binding and/or denaturation of SPARC on membrane-type centrifugal concentrators (e.g., Centricons). Losses should be determined if the investigator chooses to concentrate purified SPARC in this manner. There are always new products on the market that claim to minimize this problem.
5. Degradation due to proteolysis by intrinsic proteinases or to bacterial contamination. Protease inhibitors should always be used during purification of SPARC, as described, and bacterial contamination should be minimal if sterile buffers or buffers containing sodium azide (NaN_3) are used.
6. Recovery can be compromised by the use of untreated glass vessels; only polypropylene or siliconized-glass containers should be used. Surface denaturation of SPARC occurs readily, either from adsorption to surfaces or from rapid stirring or overzealous mixing.

Denaturation of SPARC can be minimized with careful handling and attention to a few details.

1. The protein should be stored at –70° or –80°C, not at 4°C and especially not at –20°C.
2. 1 to 4 mM Ca^{2+} should be present in buffers containing SPARC.
3. Stirring of solutions should be steady but not rapid.
4. Purification of the protein should be conducted at 4°C whenever possible.
5. Only reagents (e.g., urea) of the highest purity should be used.
6. Reducing/oxidizing conditions, which can result in the scrambling of disulfide bonds, should be avoided.

Assays for SPARC bioactivity have been described elsewhere (see Support Protocols 1 to 3) and need not be repeated here. However, an important criterion for the correct folding of SPARC is the circular dichroism spectra obtained in the presence and absence of Ca^{2+}. These spectra are relatively easy to perform and interpret. Examples for SPARC purified from PYS-2 cells, *E. coli*, and *Sf*9 cells have been published (Sage et al., 1989; Bassuk et al., 1996a; Bradshaw et al., 2000). The method relies on a characteristic increase of the mean residue ellipticity (θ) at 220 nm as a function of increasing concentrations of Ca^{2+}, indicative of a shift toward α-helicity. SPARC preparations that do not exhibit this transition are likely to be contaminated by other components and/or denatured.

For the use of SPARC in proliferation (i.e., [^{3}H]thymidine incorporation) assays, it is important to measure levels (if any) of contaminating growth factors that could affect the results. Both PDGF and VEGF bind to SPARC (see Background Information) and are anticipated to stimulate the proliferation of smooth muscle cells, fibroblasts (PDGF), and endothelial cells (VEGF). Kits based on ELISA are now available for the detection of these factors;

alternatively, detection could be accomplished by immunoblot analysis after SDS-PAGE of SPARC under reducing conditions (*UNIT 6.2*), although the former method allows for greater sensitivity.

Anticipated Results

Isolation from PYS-2 cells (see Basic Protocol) should yield ~500 µg per 30 maxiplates (150-mm diameter) PYS-2 cells (~10^7 cells/plate). The protein is of high purity (>90% by SDS-PAGE) and retains maximal biological activity. For example, an ED_{50} of 20 µg/ml (0.6 µM) has been defined as an effective concentration for the induction of cell rounding by SPARC.

Yields of rSPARC from *E. coli* and *Sf*9 cells are greater than those from PYS-2 cells (see Alternate Protocols 1 and 2), but are in large part dependent on the efficiency of the expression system (i.e., the particular expression vector, the host and its growth properties, and whether the rSPARC is secreted or retained within the cell). Using a first-generation *Sf*9/baculovirus expression system, the authors' laboratory typically recovers 2 to 4 mg human rSPARC (of ~80% purity) from an initial suspension of ~10^9 cells. The InsectSelect system, which eliminates the need for viral infection, is likely to be an improvement over the earlier version. rSPARC can be purified to ≥80% and displays biological activity in cell rounding and proliferation assays.

The immunoaffinity-based chromatographic purification of SPARC from platelets will theoretically produce a highly purified protein, in reasonable yields, although the amount of SPARC in the starting material (α-granules of platelets) is low, from 0.7 to 2.2 µg/10^8 cells. One limiting factor is the availability of the monoclonal antibody used for the purification. This reagent must not only bind soluble SPARC with relatively and selectively high affinity, but must also release SPARC readily into the elution buffer without compromise of the SPARC or the antibody itself. Moreover, the antibody must function while coupled to an affinity resin. It is therefore important to ensure that a sufficient supply of the antibody is commercially available, as the column will have to be repacked periodically with new affinity-coupled resin. An alternative is to purchase a hybridoma cell line secreting a suitable anti-SPARC IgG that can be propagated in the laboratory.

Time Considerations

The Basic Protocol and Alternate Protocols 1 to 2 each require ~1 week from the time of medium (PYS-2 and *Sf*9 cells) or cell (*E. coli*) collection until the final lyophilization (or buffer exchange) step. Allow 1 to 2 days for the preparation of buffers and columns, and for the washing of columns. PYS-2 cells are usually ready for beginning the collection of medium 24 hr after plating, and medium is removed from the cells 18 to 24 hr later. Similar time frames apply to *E. coli* (grown overnight, diluted to an appropriate density in log phase, and induced) and to *Sf*9 cells (grown in flasks over 3 to 4 days to generate conditioned medium containing rSPARC).

In all the protocols, convenient stopping points have been noted. There is temporal flexibility in the purification process, especially during the dialysis steps.

Analysis of Fibronectin Matrix Assembly

Fibronectin (FN) is one of the most ubiquitous components of the extracellular matrix (ECM). It plays a critical role in organizing ECM structure and influences cell behavior through interactions with cell surface receptors. Many types of cells secrete cellular FN and assemble it into a fibrillar network. Assembly proceeds via a step-wise process in which FN is initially organized into fine cell-associated fibrils and, through continued accumulation of FN, these fibrils are converted into a dense network of detergent-insoluble fibrils. Differential solubility in the detergent deoxycholate (DOC) is the principle for biochemical analysis of FN matrix (DOC-solubility assay).

In this unit, basic methods of detection, quantification, and visualization of the fibrillar FN matrix are described. The Basic Protocol for analysis of the matrix assembly process is based on the DOC-solubility assay and describes isolation and analysis of a FN matrix from cultured cells. Alternate protocols are also provided for analyzing matrix assembly using exogenous FN (see Alternate Protocols 1 and 2) or by metabolic labeling (see Alternate Protocol 3). In addition to biochemical analysis of matrix assembly, Alternate Protocol 4 and Alternate Protocol 5 describe visualization of matrix organization directly by incorporation of fluorescently labeled FN and by indirect immunofluorescence staining, respectively.

Protocols described in this section require cell culture (*UNIT 1.1*), purification of plasma FN (*UNIT 10.5*), metabolic labeling of cells (*UNIT 7.1*), immunoblotting (*UNIT 6.2*), immunoprecipitation (*UNIT 7.2*), and immunofluorescence staining (*UNIT 4.3*).

NOTE: All tissue culture incubations are performed in a humidified 37°C, 5% CO_2 incubator. Some media, e.g., DMEM, require increased levels of CO_2 to maintain the medium at pH 7.4.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique must be used.

ANALYSIS OF MATRIX ASSEMBLY USING A DOC-SOLUBILITY ASSAY

BASIC PROTOCOL

Fibroblasts growing on tissue culture surfaces synthesize FN and assemble it into a fibrillar matrix. The assay is based on the insolubility of stable FN matrix in 2% DOC detergent (McKeown-Longo and Mosher, 1983). Cells are lysed in DOC lysis buffer and centrifuged to separate DOC-insoluble matrix from DOC-soluble material containing cell-associated and intracellular FN. The DOC-insoluble FN is solubilized in a buffer containing 1% SDS. The DOC-soluble and -insoluble fractions are resolved by SDS-PAGE, transferred to nitrocellulose, and analyzed by immunoblotting.

Materials

Sub-confluent (80% confluent) fibroblasts in a 10-cm tissue culture dish
PBS (*APPENDIX 2A*)
Trypsin/EDTA solution (GIBCO, Invitrogen)
Culture medium containing 10% FN-depleted serum (see *UNIT 10.5* for FN-depletion)
DOC lysis buffer (see recipe)
SDS-solubilization buffer (see recipe)
BCA protein assay kit (Pierce Chemical)
2× SDS sample buffer (see recipe)

Contributed by Iwona Wierzbicka-Patynowski, Yong Mao, and Jean E. Schwarzbauer
Current Protocols in Cell Biology (2004) 10.12.1-10.12.10

15-ml screw-cap tube
24-well tissue culture plate
Rubber policeman
1-ml syringe and 26-G, 3/8-in. needle
Additional reagents and equipment for cell culture (*UNIT 1.1*), gel electrophoresis (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

Prepare cell culture

1. Aspirate the medium from a sub-confluent culture of fibroblasts growing on a 10-cm tissue culture dish.
2. Rinse cells with 5 ml PBS to remove any residual serum.
3. Add 2 ml of trypsin/EDTA solution to cell layer and incubate for 1 to 5 min at room temperature.
4. When cells detach from the dish, add 2 ml of culture medium and transfer all cells to a 15-ml screw-cap tube. Count the cell number (*UNIT 1.1*) and centrifuge 5 min at 100 × *g*, room temperature.
5. Resuspend fibroblasts in culture medium containing FN-depleted serum at 2.5 × 10^5/ml (1 ml/well). Plate cells onto a 24-well tissue culture plate and incubate up to 8 hr in an incubator.

   The cell densities for matrix assembly vary for different cell lines and incubation times. The cells should be plated at subconfluency for overnight incubations. For incubations of several hours, cells should be plated almost confluent or touching. Usually, fewer cells are required for fibroblasts than other cell lines for a given surface area. If experiments are done in different-sized tissue culture dishes or wells, the amount of reagents and number of cells need to be scaled up or down accordingly. To avoid the introduction of exogenous FN from serum, FN-depleted serum should be used to supplement the medium instead.

Perform DOC-solubility assay

6. At desired time, aspirate medium from the wells and gently wash the cells with cold PBS.

   The desired time is determined by the purpose of the experiment and cell type used for FN matrix assembly. For cells expressing endogenous FN, it can take 4 to 6 hr to accumulate amounts of DOC-insoluble FN detectable by immunoblotting. DOC-insoluble matrix should be easily detectable in cells cultured overnight.

7. Add 200 µl of DOC lysis buffer to each well and scrape cells off of the dish using a rubber policeman. Collect cell lysate with a 1-ml syringe attached to a 26-G, 3/8-in. needle. To reduce viscosity, pass the cell lysate through the needle five times, transfer to a 1.5-ml microcentrifuge tube labeled "DOC-insoluble," and keep tube on ice.

   The amount of DOC lysis buffer should be adjusted accordingly for different-sized dishes (e.g., 2 ml for 10-cm dish, 1 ml for 6-cm dish, and 0.5 ml for 35-mm dish). Volumes can be adjusted to achieve the desired total protein concentration. Cell lysates should be thoroughly scraped off of the tissue culture surface. Lysates are passed (usually five passes) through a small-gauge needle to shear genomic DNA and reduce the viscosity. This procedure should be carried out without generating air bubbles. Alternatively, viscosity can be reduced by treating the samples with Triton X-100 followed by DNase I as described by Quade and McDonald (1988).

8. Microcentrifuge the lysates in 1.5-ml microcentrifuge tubes 15 min at 14,000 rpm, 4°C.

9. Carefully remove supernatant into a new 1.5-ml microcentrifuge tube labeled "DOC-soluble" and keep on ice.

   In some cases, the pellet of insoluble material is not very obvious, therefore, always mark the side where the pellet will reside after centrifugation. Remove supernatant as completely as possible and keep the pipet tip away from the pellet.

10. Add 25 μl of SDS-solubilization buffer to the insoluble pellet and mix thoroughly.

    It is important to thoroughly dissolve the pellet and to wash the walls of the tube. Do this by pipetting the SDS-solubilization buffer up and down and by vortexing. Scale up or down the volume of SDS-solubilization buffer for different sample sizes (e.g., 62.5 μl for 35-mm dishes). The amount of SDS-solubilization buffer or the concentration of SDS in the buffer can be increased if cells are plated on a protein-rich substrate (such as Matrigel, gelatin, or a 3-D matrix prepared from cultured fibroblasts).

Determine total protein concentrations

11. Estimate protein concentrations for DOC-soluble fractions using a BCA protein assay kit. Follow the manufacturer's instructions.

12. Normalize samples for the same amount of protein by adjusting volume with 2× SDS sample buffer and boil 2 min.

    Protein concentration in the DOC-soluble fraction is proportional to the number of cells in the culture and is used to adjust gel sample volumes on a per-cell basis. In a typical experiment, the total protein concentration ranges from 300 to 800 μg/ml from one well of a 24-well plate. The maximum amount of protein should be electrophoresed to ensure detection of FN (usually 3 to 10 μg/lane). DOC-insoluble sample volume for SDS-PAGE is based on protein concentration in the corresponding DOC-soluble fraction. To detect monomeric FN, samples should be reduced with 0.1 M DTT in the SDS sample buffer.

Analyze samples by immunoblotting

13. Resolve protein samples using a 5% polyacrylamide-SDS gel and transfer proteins to nitrocellulose. Perform electrophoresis and immunoblotting according to protocols described in *UNITS 6.1 & 6.2*, respectively.

    The amount of FN in both fractions can be detected using anti-FN antibodies, followed by secondary antibodies and ECL reagents.

QUANTIFICATION OF MATRIX ASSEMBLY USING ^{125}I-LABELED PROTEIN A

ALTERNATE PROTOCOL 1

Using ^{125}I-labeled protein A to detect FN in immunoblots allows the amount of assembled FN matrix to be quantified. After DOC-soluble and DOC-insoluble fractions are separated by SDS-PAGE and transferred to a nitrocellulose membrane, FN is detected with an anti-FN antibody and secondary antibody followed by radiolabeled protein A. The intensity of the protein band is then measured using a phosphorimager scanner as described below.

CAUTION: Experiments involving radioactive material handling have to be performed by trained personnel and in a designated area to avoid contamination. See *APPENDIX 1D* for safe use of radioisotopes.

Materials

Samples of DOC-soluble and -insoluble FN from cultures (see Basic Protocol, steps 1 to 10)
5% (w/v) BSA in TBS buffer (see *APPENDIX 2A* for TBS)
Primary anti-FN antibody (e.g., HFN7.1, ATCC)
Rabbit secondary antibody (e.g., unconjugated rabbit anti-mouse IgG, Pierce Chemical)

^{125}I-labeled protein A (10 μCi/μg,specific activity; MP Biomedicals)
Buffer A (see recipe)

Plastic wrap
Phosphorimager screen (cassette) and scanner
ImageQuant software

Additional reagents and equipment for gel electrophoresis (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Perform electrophoresis of samples of DOC-soluble and -incoluble FN from cultures and transfer to nitrocellulose according to protocols described in *UNITS 6.1 and 6.2*.
2. Block nitrocellulose with 5% BSA in TBS buffer overnight at 4°C.
3. Dilute primary antibody in 10 ml of 5% BSA in TBS and incubate with nitrocellulose filter for 1 hr at room temperature. Wash three times with 10 ml of 5% BSA in TBS buffer, 10 min each wash. Incubate with rabbit secondary antibody diluted to 1 μg/ml in 10 ml of 5% BSA in TBS 1 hr at room temperature. Wash three times with 10 ml TBS buffer, 10 min each wash.

   For optimal binding of protein A and to amplify the signal from the primary anti-FN antibody, rabbit secondary antibody should be used. The authors usually use unconjugated rabbit anti-mouse IgG (H+L) (Pierce Chemical) to detect monoclonal anti-FN antibodies.

4. Incubate with ~6 μCi of ^{125}I-protein A in 5% BSA in TBS buffer. Wash three times with 10 ml TBS, 10 min each wash.
5. Wrap the nitrocellulose in plastic wrap and place in phosphorimager cassette. Expose to phosphor screen for desired amount of time.

   The time of exposure is empirically determined. Bands can usually be detected after an overnight exposure but weaker signals may require exposure for ≥1 week.

6. Read the screen on phosphorimager scanner. Determine the number of counts associated with each band using ImageQuant software.

ALTERNATE PROTOCOL 2

ANALYSIS OF ASSEMBLY OF EXOGENOUS FN

Some cell lines (e.g., CHO and many tumor cell lines) do not produce significant levels of FN. To assess their matrix assembly capability and to study regulation of the assembly process, the addition of exogenous FN is required. For quantitation purposes, ^{125}I-labeled FN can be included in the exogenous FN.

Materials

Purified plasma FN (*UNIT 10.5*)
^{125}I-labeled FN (~1 μCi/μg; MP Biomedicals; optional)
Additional reagents and equipment for trypsinization and collection of cells, and isolation and analysis of DOC-insoluble and DOC-soluble FN (see Basic Protocol)

1. Prepare purified FN from blood plasma using the protocol described in *UNIT 10.5*.
2. Trypsinize and collect cells following Basic Protocol, steps 1 to 5.
3. Allow cells to attach and spread, usually 60 min at 37°C

4. Add 25 to 50 μg/ml of exogenous FN and incubate for desired amount of time.

   The amount of exogenous FN can be varied and the optimal amount for assembly should be determined empirically. To quantify the amount of FN in the matrix, ^{125}I-labeled FN can be added together with unlabeled FN. Alternatively, cells can be allowed to assemble exogenous FN for a period of time and then ^{125}I-labeled FN can be added for a shorter period. Additional reagents such as activators or inhibitors of matrix assembly can be added along with exogenous FN or at any time during the incubation.

5. Isolate and analyze DOC-insoluble and DOC-soluble FN (see Basic Protocol, steps 6 to 13).

   When ^{125}I-labeled FN is included, the SDS-polyacrylamide gel is dried and directly exposed to a phosphorimager screen (for gel drying, see Alternate Protocol 3).

ANALYSIS OF METABOLICALLY LABELED FN

ALTERNATE PROTOCOL 3

Using metabolically labeled cells for matrix assembly studies allows one to determine the incorporation of endogenous FN over specific time periods and also provides radiolabeled material for quantification. ^{35}S-labeled FN in DOC-soluble and -insoluble fractions are isolated by immunoprecipitation and analyzed using a phosphorimager after resolution by SDS-PAGE.

Materials

Cell cultures for labeling
Culture medium containing FN-depleted serum (see *UNIT 10.5* for FN-depletion)
Labeling medium (see recipe)
^{35}S-methionine (>1000 Ci/mmol)
IP buffer (see recipe)
Protein A–Sepharose beads
35-mm tissue culture dish or 6-well plate
Phosphorimager screen and scanner
ImageQuant software
Additional reagents and equipment for cell preparation (see Basic Protocol), IP protocol (*UNIT 7.2*)

1. Prepare cells according to Basic Protocol, steps 1 to 5.
2. Plate 1×10^6 cells in culture medium containing FN-depleted serum in 35-mm tissue culture dishes or 6-well plates. Let cells attach and spread.

   Alternatively, cells can be plated and allowed to grow until 80% to 90% confluent.

3. Aspirate medium, rinse cells with 2 ml labeling medium minus methionine, and replace with 1 ml labeling medium. Add 25 μCi of ^{35}S-methionine per milliliter of labeling medium and mix well. Incubate cells for desired amount of time.

   The optimal concentration of ^{35}S-methionine depends on cell type and length of labeling. A 24-hr labeling period with 25 μCi/ml of ^{35}S-methionine is typically used to determine assembly competence and FN expression by cells. Shorter labeling times with increased amounts of ^{35}S-methionine can be used (e.g., 50 μCi/ml for 6 to 8 hr or 100 μCi/ml for 2 hr).

4. Remove medium and save for detection of FN in the medium (see *UNIT 10.5*).
5. Wash cells with 2 ml ice-cold PBS.

   The waste PBS should be disposed of in a properly labeled radioactive waste container.

6. Prepare DOC-soluble and -insoluble fractions as described in Basic Protocol, steps 6 and 7, using 500 μl DOC-lysis buffer and 62.5 μl SDS-buffer.

7. Determine protein concentration. Normalize the samples to equal protein concentration in ~125 µl of DOC-soluble sample and 50 µl of DOC-insoluble sample.
8. Adjust volume to 500 µl using stock solutions to give composition of IP buffer.
9. Immunoprecipitate FN from the soluble and insoluble fractions using anti-FN antibody. Follow the IP protocol described in *UNIT 7.2*.
10. Run immunoprecipitated samples on 5% SDS-PAGE. Dry the gel and expose to phosphorimager screen. Scan the intensity of FN bands using a phosphorimager scanner and analyze using ImageQuant software.

Electrophoresis of one-third of the immunoprecipitate is usually sufficient to detect FN in fibroblast matrix. To dry gel, fix in 50% methanol/10% acetic acid solution 30 min at room temperature, rehydrate with several changes of water, place on a sheet of Whatman paper, place on gel dryer, cover with plastic wrap, and dry at 80°C under vacuum.

ALTERNATE PROTOCOL 4

DIRECT DETECTION OF MATRIX ASSEMBLY BY INCORPORATION OF FLUORESCENTLY LABELED FIBRONECTIN

In addition to the biochemical methods, FN matrix assembly can be monitored using fluorescence techniques. Fibrillar matrix can be detected by indirect immunofluorescence staining using antibodies with fluorescent tags (see Alternate Protocol 5) or matrix can be labeled directly by incorporation of fluorescently tagged FN.

Materials

Purified FN (*UNIT 10.5*)
50 mM sodium bicarbonate, pH 8.
Sulfo-NHS-rhodamine *or* fluorescein (Pierce Chemical)
CAPS-NaCl solution
Cell cultures (see Basic Protocol, steps 1 to 4)
Culture medium containing FN-depleted serum (see *UNIT 10.5* for FN-depletion)
PBS/Mg (PBS containing 0.5 mM $MgCl_2$)
3.7% (v/v) formaldehyde in PBS/Mg
0.5% NP-40 (v/v) in PBS/Mg
FluoroGuard (Bio-Rad)
Nail polish

Spectrophotometer
12-mm circular coverslips
24-well plate
Fine-tip forceps
Beakers
Paper towels
Kimwipes
Glass microscope slides

Prepare fluorescently labeled FN

1. Dialyze 1 mg/ml of purified FN in 50 mM sodium bicarbonate, pH 8.5, overnight at 4°C.
2. Immediately prior to use, make 1 mg/ml of sulfo-NHS-rhodamine in distilled water. Add 40 µg of sulfo-NHS-rhodamine per 1 mg of dialyzed FN.
3. Incubate 2 hr on ice in dark.
4. Dialyze the reaction mixture against CAPS-NaCl solution at 4° C. Use two changes of at least a 100-fold excess volume each.

5. Determine protein concentration by reading A_{280} using a spectrophotometer. Store 100-μl protein aliquots for 6 months at −80°C.

Prepare cultures

6. Place 12-mm circular coverslips in the wells of a 24-well plate.

   Sterilize coverslips prior to use by autoclaving.

7. Prepare cells in culture medium containing FN-depleted serum according to Basic Protocol, steps 1 to 4.

8. Plate cells on coverslips in wells of 24-well plates and let them attach and spread for 30 to 60 min.

   Make sure that coverslips are at the bottom of the wells rather than floating in the medium.

9. Add 25 μg/ml of rhodamine-labeled FN and incubate cells at 37°C for desired amount of time.

10. Aspirate medium and gently wash cells with 1 ml PBS/Mg. Fix with 1 ml of 3.7% formaldehyde in PBS/Mg 15 min at room temperature. Aspirate fixing solution and wash three times with 1 ml PBS/Mg.

11. Carefully remove coverslips from wells using fine-tip forceps. Set up three beakers containing 100 ml PBS/Mg. Wash coverslips by dipping several times in each beaker. Do a final wash in 100 ml water. Drain coverslips on a dry paper towel and dry the clean (non-cellular) face of coverslip with a Kimwipe.

    Alternatively, cells can be removed from the well prior to fixation. Place in a humidified chamber (e.g., a Petri dish lined with a moistened paper towel). Gently pipet 25 to 50 μl of fixing solution on top of cells and incubate 15 min at room temperature.

Visualize incorporated labeled FN

12. Place a drop (2 to 4 μl) of FluoroGuard on a glass microscope slide. Carefully place the coverslip with cells face down on top of the FluoroGuard.

13. Seal periphery of the coverslip with nail polish and let dry.

    Properly sealed slides can be stored several months at −20°C.

14. Examine slides with a fluorescence microscope equipped with rhodamine filters.

DETECTION OF MATRIX ASSEMBLY BY INDIRECT IMMUNOFLUORESCENCE STAINING

ALTERNATE PROTOCOL 5

Fibrillar matrix can be detected by indirect immunofluorescence staining using primary anti-FN antibody and secondary antibodies with fluorescent tags.

Materials

Cell cultures
Primary anti-FN antibody
2% (w/v) ovalbumin in PBS/Mg solution
Fluorescein-conjugated or rhodamine-conjugated goat anti-mouse IgG (or anti-rabbit IgG)

Petri dishes
Fluorescence microscope

Additional reagents and equipment for detection of FN matrix (see Alternate Protocol 4)

1. Follow Alternate Protocol 4, steps 6 to 10, except do not add fluorescently labeled FN.

   Exogenous FN can be added to cells if the cell type does not produce FN.

   For detection of intracellular proteins, fixed and washed cells can be permeabilized with 1 ml 0.5% NP40 in PBS/Mg, 15 min at room temperature followed by three washes with 1 ml PBS/Mg.

2. Carefully remove coverslips from wells using fine-tip forceps. Place in a humidified chamber (e.g., a Petri dish lined with a moistened paper towel).

3. Add 25 to 50 μl of diluted primary anti-FN antibodies in 2% ovalbumin/PBS/Mg solution and incubate for 30 min at 37°C.

   The optimal antibody dilution should be determined by the individual user. Typical dilutions are: 1:50 to 1:250 for hybridoma culture supernatant or polyclonal antisera and 1:500 to 1:2000 for ascites fluid or concentrated hybridoma supernatant. Antibody incubations can be done in a 37°C incubator (without CO_2).

4. Wash coverslips by dipping in 100 ml PBS/Mg three times.

5. Incubate cells with 25 to 50 μl of the secondary antibody (e.g., fluorescein- or rhodamine-conjugated goat anti-mouse or rabbit IgG) in 2% ovalbumin in PBS/Mg solution 30 min at 37°C.

6. Rinse and mount the coverslips according to Alternate Protocol 4, steps 12 to 13.

7. Examine coverslips using a fluorescence microscope with appropriate filters.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A

25 mM Tris·Cl, pH 7.5
150 mM NaCl
0.1% (v/v) Tween-20
Store up to 6 months at 4°C

CAPS-NaCl solution

10 mM 3-[cyclohexylamino]-1-propanesulfonic acid (CAPS)
150 mM NaCl
Adjust to pH 11 with 5 N NaOH
Store up to 6 months at 4°C

Cell labeling medium

To cell culture medium without methionine, add non-radioactive methionine (tissue culture–grade) to a final concentration that is 0.1× the amount in normal medium.
Store up to 3 months at 4°C.

DOC lysis buffer

2% (w/v) sodium deoxycholate (from 10% DOC stock solution in dH_2O, kept for months at −20°C)
20 mM Tris·Cl, pH 8.8 (from 1 M Tris·Cl stock solution, pH 8.8, stored at room temperature)

continued

2 mM phenylmethysulfonyl fluoride (PMSF; 0.2 M PMSF in ethanol and stored at −20°C)
2 mM EDTA (from 0.5 M EDTA stock solution, stored at room temperature)
2 mM iodoacetic acid (freshly prepared 100 mM stock in H_2O)
2 mM *N*-ethylmaleimide (freshly prepared 100 mM stock in H_2O)
Prepare fresh

Dissolve any precipitated PMSF in the stock solution by vortexing.

IP buffer

50 mM Tris·Cl, pH 8.8
2.5 mM EDTA
2.5 mg/ml BSA
0.5% (v/v) NP-40
0.5% (w/v) DOC
0.1% (w/v) SDS
Prepare fresh

SDS sample buffer, 2×

200 mM Tris·Cl, pH 6.8
10% (v/v) glycerol
2 mM EDTA
4% (w/v) SDS
0.05% (w/v) bromphenol blue
Store up to 12 months at room temperature

SDS solubilization buffer

1% (w/v) SDS (from 20% SDS stock solution, kept at room temperature)
20 mM Tris·Cl, pH 8.8
2 mM PMSF
2 mM EDTA
2 mM iodoacetic acid (freshly prepared in H_2O)
2 mM *N*-ethylmaleimide (freshly prepared in H_2O)
Prepare fresh

COMMENTARY

Background Information

The extracellular matrix (ECM) is a protein network that acts as a framework for tissue architecture and dynamically regulates many cellular functions such as adhesion, migration, growth, and differentiation. A major component of most matrices, fibronectin (FN) is a multifunctional glycoprotein synthesized by many cell types including fibroblasts, endothelial cells, myoblasts, and astrocytes (Hynes, 1990; Pankov, 2002). In addition to cellular FN produced by cells in tissues, there is a considerable amount of FN in blood plasma. This plasma FN is made by hepatocytes and differs from cellular FN by alternative splicing (Schwarzbauer, 1991). FN is synthesized and secreted as a disulfide-bonded dimer. It is assembled by cells into a fibrillar matrix via a regulated, step-wise process (Schwarzbauer and Sechler, 1999; Wierzbicka-Patynowski and Schwarzbauer, 2003). Initiation of assembly depends on FN binding to cell surface integrin receptors. Once immobilized, dimeric FN is active to participate in FN-FN interactions leading to formation of fibrils. As the process proceeds, short fine fibrils become longer and denser. Initially the integrin-associated fibrils are soluble in deoxycholate (DOC) detergent. As additional FN dimers are assembled, the DOC-soluble pool is converted into DOC-insoluble matrix in which the FN dimers are quite tightly associated into detergent-stable high-molecular weight multimers. (McKeown-Longo and Mosher, 1983).

Thus, conversion from cell-associated fine fibrils to stable matrix can be monitored by analysis of the amounts of FN in these two pools. FN fibril organization can be examined by immunofluorescence staining.

Biochemical and microscopic analyses provide distinct types of information about FN matrix assembly. Immunoblotting of detergent lysates allows quantification of the amounts of FN in DOC-soluble and -insoluble fractions as well as determination of whether matrix FN is intact or has been proteolyzed. Immunofluorescence analyses allow one to follow the progression of FN assembly from fine fibrils to dense, stable matrix as well as to determine the overall distribution of FN in the cell layer.

Critical Parameters

At the time of analysis, cells should be sufficiently dense to ensure optimal conditions for fibril formation between adjacent cells but not so crowded that they are approaching quiescence. Critical steps in the DOC-solubility assay include reducing the viscosity of genomic DNA, gently removing DOC-soluble from the DOC-insoluble fraction after centrifugation, and completely dissolving the DOC-insoluble pellet.

Anticipated Results

Fibroblasts and other cells that synthesize significant levels of FN usually yield a visible amount of DOC-insoluble material within several hours after plating. Cell types that produce very little FN, such as many tumor cell lines, can require incubations as long as 24 hr for isolation of detectable DOC-insoluble FN. To increase the amount of FN available for assembly, cell cultures can be supplemented with exogenous FN allowing detection of FN matrix after much shorter incubation periods. The sensitivity of the DOC-solubility assay is in the nanogram range. Immunofluorescence staining usually shows a bright fibrillar pattern at times corresponding to detectable FN by immunoblotting.

Time Considerations

Time after plating cells is variable depending on the experiment. Performance time for the DOC-solubility assay depends on the number of samples but should be easily completed in 1 to 2 hr. SDS-PAGE and immunoblotting are described in *UNITS 6.1 & 6.2*. Similarly, antibody staining requires ~2 hr for fixation and incubations.

Non-Radioactive Quantification of Fibronectin Matrix Assembly

Fibronectin (FN) matrix assembly is a cell-dependent process that converts soluble FN molecules into elaborate extracellular fibrillar matrices. This process relies on activated integrins, cellular contractility, and unmasking of cryptic fibronectin assembly sites for generation of insoluble fibrils (Geiger et al., 2001). The signaling pathways involved in matrix assembly have just begun to be elucidated (Wierzbicka-Patynowski and Schwarzbauer, 2002), and further studies will require simple and reliable assays for quantification of matrix assembly associated with parallel determinations of the activity of various signaling molecules.

This unit provides a protocol (see Basic Protocol) for non-radioactive determination of the rate of incorporation of biotinylated fibronectin into the insoluble matrix organized by cultured cells. This protocol provides a simple method for quantifying changes in matrix assembly that result from different experimental treatments or conditions with concomitant determinations of the activation state of various signaling molecules that may be involved in the process of matrix assembly. This unit also provides a protocol (see Support Protocol) for biotinylation of purified fibronectin.

QUANTIFICATION OF MATRIX ASSEMBLY USING BIOTINYLATED FIBRONECTIN

BASIC PROTOCOL

This protocol can be applied to nearly all cultured cell lines with little or no modifications. It describes labeling of the matrix assembled by cultured cells with biotinylated fibronectin, followed by isolation of detergent-insoluble fibronectin matrices (see *UNIT 10.12*). Quantification of the incorporated biotinylated FN is performed by electrophoresis (*UNIT 6.1*), electroblotting (*UNIT 6.2*), and detection with peroxidase-conjugated streptavidin. The quantities of intermediate filament proteins present in the detergent-insoluble fractions are determined by immunoblotting for use as the internal controls for isolation efficiency of the detergent-insoluble matrix in each fraction. The detergent-soluble fractions are used to monitor the ability of cells to bind fibronectin under the conditions being tested and to determine simultaneously the activation state of the signaling molecules of interest.

Materials

Fibroblasts (or any cell line of interest)
Dulbecco's modified Eagle medium supplemented with 10% (v/v) fetal bovine serum (DMEM/10% FBS; *APPENDIX 2A*)
Biotinylated fibronectin (see Support Protocol)
PBS (*APPENDIX 2A*), ice cold
DOC extraction buffer (see recipe)
2× SDS sample buffer (*APPENDIX 2A*)
1 M NaF
0.1 M sodium orthovanadate solution (*APPENDIX 1B*)
10 mM leupeptin (*APPENDIX 1B*)
25 mM pepstatin A (*APPENDIX 1B*)
0.2 M phenylmethanesulfonyl fluoride (PMSF; *APPENDIX 1B*)
2× SDS sample buffer (*APPENDIX 2A*)

Contributed by Roumen Pankov and Kenneth M. Yamada
Current Protocols in Cell Biology (2004) 10.13.1-10.13.9

8% (w/v) polyacrylamide separating gels with 4% (w/v) stacking gels (*UNIT 6.1*) or commercially available pre-cast 4% to 12% gradient gels (e.g., Novex) for SDS gel electrophoresis

Prestained protein molecular size standards (e.g., Novex)

Transfer buffer (*UNIT 6.2*)

Ponceau S solution (*UNIT 6.2*)

Tris-buffered saline with 0.1% (v/v) Tween 20 (TTBS; *APPENDIX 2A*)

Blocking solution: TTBS containing 5% (w/v) dry nonfat milk (TTBS/milk)

Streptavidin, horseradish peroxidase (HRP)-conjugated (e.g., Jackson ImmunoResearch)

Enhanced chemiluminescence (ECL) detection reagent (*UNIT 14.2*)

Primary antibody: monoclonal anti-vimentin (e.g., Sigma)

Secondary antibody: horseradish peroxidase (HRP)-conjugated anti-rabbit or anti-mouse antibodies (e.g., Amersham Bioscience)

35-mm tissue culture dishes

Plastic cell scraper (rubber policeman)

23-G needle and 1-ml syringe

1.5-ml microcentrifuge tubes

Micropipettors

Porous electrotransfer pads

Whatman 3MM filter papers cut to gel size

Two nitrocellulose membranes cut to gel size

SDS-PAGE/transfer apparatus (e.g., Bio-Rad, Novex)

Constant-voltage/current power supply (e.g., Bio-Rad)

Flat containers

Rocking shaker

Heat-sealable plastic bags and sealer

Sonicator/ultrasonic processor

Plastic wrap

X-ray film (e.g., Hyperfilm; Amersham Bioscience)

Tube heater (e.g., Thermomixer; Eppendorf) or boiling water bath

Film cassette for X-ray film

X-ray film developer

Additional reagents and equipment for dialysis (*APPENDIX 3C*), tissue culture (*UNIT 1.1*), SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

NOTE: All reagents and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be performed in a 37°C, 10% CO_2 humidified incubator. Use pre-warmed cell culture medium for all treatments.

Prepare and treat cells

1. Plate cells in 35-mm dishes so that after spreading they will be ~90% to 95% confluent, and culture overnight in DMEM/10% FBS.

   Depending on the size of fibroblasts used, the desired confluency can be obtained by plating between 0.25 × 10^6 cells (e.g., primary human fibroblasts) and 0.5 × 10^6 cells (e.g., NIH 3T3 cells).

2. After overnight incubation, wash cells with 1.0 ml DMEM/10% FBS and add 1 ml/plate of the same medium containing 20 μg/ml biotinylated FN.

   Treatment with reagents of interest can be incorporated in this step, which can include chemical compounds, peptides, antibodies, etc. Add an appropriate volume of stock

solution containing the reagent to one plate and the same volume of the solvent (e.g., DMSO) to another plate that will serve as a control. Label each plate.

If the presence of serum in the medium interferes with the action of the tested reagent (e.g., growth factors), replace serum with 1% (w/v) bovine serum albumin during the treatment period.

3. Incubate plates in a tissue culture incubator for 4 hr.

   Depending on the ability of the cells to form fibronectin matrix, this time period can be varied. For example, a 3-hr incubation is sufficient for primary human fibroblasts to incorporate readily detectable quantities of biotinylated fibronectin into the detergent-insoluble fraction, while 4 to 6 hr are necessary for β_1 null GD 25 cells to polymerize enough labeled FN for reliable detection.

4. Aspirate medium and wash cell monolayers three times with 2 ml ice-cold PBS each.

5. Lyse cells in 0.5 ml DOC extraction buffer, scrape plates with plastic scraper, pass the lysate five times through a 23-G needle attached to a 1-ml syringe, and transfer into labeled 1.5-ml microcentrifuge tubes. Keep lysates on ice.

   Shearing DNA by passing lysates through a thin needle is necessary to reduce viscosity and to allow sedimentation of small, insoluble matrix aggregates during centrifugation. Check that the needle is firmly attached to the syringe and gently aspirate and expel lysate from the syringe while avoiding the formation of bubbles.

6. Centrifuge lysates 20 min at 20,000 × *g*, 4°C.

Prepare detergent-insoluble matrix

7. Transfer a 100-µl aliquot of the supernatant into new 1.5-ml microcentrifuge tubes labeled DOC soluble, mix with 100 µl of 2× SDS sample buffer, and leave on ice.

8. Carefully remove the rest of the supernatant, leaving the DOC-insoluble pellet intact.

9. Wash the pellet by resuspending it in 100 µl DOC extraction buffer, pipetting up and down five times with a micropipettor.

10. Centrifuge 10 min at 20,000 × *g*, 4°C.

11. Carefully remove the supernatant and dissolve the pellet in 50 µl of 2× SDS sample buffer.

    Attention should be paid to avoid losing the pellet, which is usually very small and sometimes difficult to visualize.

Analyze samples by SDS-PAGE

12. Boil samples collected at steps 7 and 11 in a water bath for 3 min or heat 5 min on a 95°C heating block.

    The samples can be stored sealed and frozen at least 1 month at −20°C.

13. Cast an 8% polyacrylamide separating gel with a 4% stacking gel (*UNIT 6.1*) or use a commercially available pre-cast 4% to 12% gradient gel.

14. Load 25 µl of each sample/gel lane and a separate lane containing prestained protein standards on the gel.

    Load the set of DOC-insoluble samples first, followed by the set of DOC-soluble samples. Divide the two sets with marker proteins or an empty well, so that after the transfer the two portions of the membrane can be separated. Alternatively, load the two sets of samples on two separate gels.

15. Electrophorese the gel(s) at 150 V until the bromophenol blue dye reaches the bottom of the gel (see *UNIT 6.1*).

Transfer separated proteins from gel to membrane

16. When electrophoresis is complete, remove gel(s) from gel plates, cut off the stacking gel(s), and incubate the separating portion of gel(s) in 50 ml transfer buffer for 15 min.

    Use gloves to handle gels and membranes, since oil from hands can interfere with the transfer.

17. Assemble the transfer sandwich consisting of porous electrotransfer pad, Whatman 3MM filter paper, nitrocellulose membrane, equilibrated acrylamide gel, second Whatman 3MM filter paper, and second pad (Fig. 6.2.1).

    All pads, filter papers, and nitrocellulose membranes should be handled using gloves and pre-wetted with transfer buffer. The transfer cassette should be assembled submerged under the transfer buffer to avoid trapping air bubbles. Keep the orientation of the gel (judged by the position of the prestained protein standards) such that it will ensure the correct order of the samples after transfer onto the nitrocellulose membrane.

18. Place the transfer sandwich into the electroblotting apparatus filled with transfer buffer with the nitrocellulose membrane on the cathode side of the gel. Connect the apparatus to the power supply and transfer proteins for 1 hr at 100 V (constant voltage) with cooling (*UNIT 6.2*).

    Transfer time depends on the size of the proteins, acrylamide percentage, and thickness of gel. The completeness of transfer can be easily judged by the extent of transfer of the prestained protein standards.

19. After completing the electrotransfer, turn off the power supply and disassemble the apparatus and the transfer cassette. Remove the nitrocellulose membranes and stain with 50 ml Ponceau S solution in a flat container for 5 min. Destain membranes with several rinses of distilled water.

    If the two sets of samples were run on the same gel, cut membrane along the well that separates the two sets (see step 14).

    Two membranes can be incubated in the same container by orienting them back to back.

    Staining with Ponceau S does not interfere with subsequent reactions and provides a good estimate of protein loading, separation, and quality of transfer. The amounts of protein in the DOC-insoluble samples will be several-fold lower than the proteins in the DOC-soluble samples, because most cellular proteins are soluble in DOC, whereas only FN and a few other proteins are insoluble.

    The Ponceau S solution can be reused several times.

Probe membranes with streptavidin-HRP and antibodies

20. Rinse membranes one time with TTBS and incubate in 50 ml blocking solution for 30 min at room temperature with gentle shaking.

    Milk proteins in the blocking buffer are used to saturate free protein-binding sites and to prevent nonspecific binding. Do not incubate the membrane >1 hr in blocking buffer, since it has a slight stripping effect and may cause detachment of transferred proteins.

21. Dilute streptavidin-HRP as recommended by the manufacturer in a final volume of 10 ml TTBS containing 3% dry nonfat milk. Place membranes in a heat-sealable plastic bag, add diluted streptavidin-HRP, and seal the bag. Incubate membranes 1 hr at room temperature with gentle shaking.

    Two membranes can be incubated in the same bag by orienting them back-to-back. Remove all air bubbles from the bag before sealing.

22. Remove membranes from the bag and wash them three times, 15 min each, with 50 ml TTBS in a flat container with vigorous shaking.

23. Use the ECL immunodetection protocol (*UNIT 6.2*) to detect biotinylated fibronectin. Incubate membranes with ECL solution for 1 min, remove excess fluid by touching the edge of the membrane held vertically to a horizontal piece of filter paper, wrap membranes in plastic wrap, and expose to X-ray film.

    Do not allow membranes to dry after the exposure.

24. Rinse membranes with 10 ml TTBS.

Probe membranes for control proteins

25. Incubate the membrane containing the DOC-insoluble samples with anti-vimentin antibody, and the membrane containing DOC-soluble samples with anti-actin antibody. Dilute the antibodies according to the manufacturer's recommendations in a final volume of 10 ml TTBS containing 3% dry nonfat milk. Place membrane in a heat-sealable plastic bag, add diluted antibodies, and seal the bag. Incubate membranes for 1 hr at room temperature (or overnight at 4°C) with gentle shaking.

    This second reaction is used as an internal control for the efficiency of matrix isolation and loading of the gels. If primary cells are used in the experiment, they may not express detectable amounts of vimentin. In such cases, a different intermediate filament protein can be used as a marker. The choice of appropriate marker will depend on the origin of the primary cells (see Coulombe et al., 2001).

26. Repeat step 22.

27. Dilute the secondary antibody in a final volume of 10 ml TTBS containing 3% dry nonfat milk according to manufacturer's instructions. Place membranes in a new heat-sealable bag, add diluted antibody, and seal. Incubate 30 to 45 min at room temperature with gentle shaking.

    Either HRP- or alkaline phosphatase–conjugated secondary antibody can be used. HRP-conjugated secondary antibodies can be combined with the high-sensitivity ECL detection system.

    This system allows detection of signals from weak antibodies, although attention should be paid to linearity if accurate quantification of the signal is necessary (see Commentary).

28. Repeat step 22 and detect the secondary antibody using the ECL procedure described in step 23.

    The membrane containing resolved proteins from DOC-soluble fractions can be re-probed again with antibodies recognizing the phosphorylated (activated) forms of different signaling molecules of interest. This step is possible if the molecular masses of the signaling molecules are different from those of fibronectin (250 kD) and actin (45 kD) and if the new signals on the membrane will not interfere with any previous band detected. Alternatively, the remainder of DOC-soluble samples can be used for additional immunoblotting experiments with other antibodies.

Quantify gels

29. Measure the optical density (absorbance) of the signals from biotinylated FN and the antibodies for each sample using densitometry (*UNIT 6.3*) or image processing software (e.g., NIH Image).

30. Normalize the densitometry values from biotinylated FN to the readings for vimentin in the DOC-insoluble fraction and the densitometry readings from biotinylated FN to the readings for actin in the DOC-soluble fraction. Calculate fold or percent changes relative to the control.

SUPPORT PROTOCOL

BIOTINYLATION OF PLASMA FIBRONECTIN

Biotin is a vitamin that binds with high affinity to avidin and streptavidin. Because of its small size (244 Da), it can be used to label proteins without significant risk of affecting their function.

This protocol describes labeling of fibronectin with sulfo-NHS-biotin, followed by a dialysis step to remove unconjugated biotin.

Additional Materials *(also see Basic Protocol)*

Fibronectin (e.g., Sigma or purified as described in *UNIT 10.5*)
Bicarbonate buffer (see recipe)
Sulfo-NHS-biotin (e.g., Pierce)

1. Dialyze 0.5 mg fibronectin against 1 liter of bicarbonate buffer overnight at 4°C or 2 hr at room temperature, change bicarbonate buffer once, and dialyze for an additional 1 hr at room temperature.

   For a 25-sample preparation, 0.5 mg of fibronectin in 0.5 to 1.0 ml will be sufficient.

2. Immediately prior to use, dissolve 0.5 mg sulfo-NHS-biotin in 0.5 ml deionized water.

3. Immediately add 40 µl sulfo-NHS-biotin solution to 0.5 ml of fibronectin solution and incubate 30 min at room temperature on a gently rocking shaker.

   Avoid harsh mixing and foaming, because fibronectin tends to denature and precipitate at the liquid/air interface.

4. Dialyze the biotinylated fibronectin against 1 liter of TBS overnight at 4°C or 2 hr at room temperature, change TBS buffer once, and dialyze for an additional 1 hr at room temperature.

5. Centrifuge fibronectin solution in a microcentrifuge 15 min at maximum speed at room temperature and save the supernatant.

   This step will remove possible precipitates from the solution.

6. Determine protein concentration using BCA assay (*APPENDIX 3H*). Store 200-µl aliquots indefinitely at −70°C. Avoid repeated freeze-thawing.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DOC extraction buffer

1% (w/v) sodium deoxycholate
20 mM Tris·Cl, pH 8.5 (*APPENDIX 2A*)
2 mM *N*-ethylmaleimide, add fresh
2 mM iodacetic acid, add fresh
2 mM EDTA (*APPENDIX 2A*)
50 µM leupeptin (*APPENDIX 1B*), add fresh
50 µM pepstatin (*APPENDIX 1B*), add fresh
1 mM PMSF (*APPENDIX 1B*), add fresh
1 mM sodium vanadate (*APPENDIX 1B*), add fresh
50 mM NaF (*APPENDIX 1B*), add fresh
Prepare fresh

This DOC extraction buffer is based on the work of McKeown-Longo and Mosher (1983).

Bicarbonate buffer

50 mM $NaHCO_3$
100 mM NaCl
Adjust pH to 8.5 with 1 M NaOH if necessary
Store up to 2 weeks at 4°C

COMMENTARY

Background Information

Fibronectin matrices not only provide substrates for cell attachment and tissue organization, but they also regulate migration, cell growth, and differentiation. These matrices are organized by cells from secreted cellular fibronectin and soluble plasma FN from blood, where this glycoprotein is present at high concentrations (300 μg/ml). In vitro, cells polymerize exogenous fibronectin from serum-supplemented culture medium together with the secreted FN (McKeown-Longo and Mosher, 1983). Even cells that do not produce fibronectin are able to form matrices when this molecule is provided exogenously (Sottile and Hocking 2002). This property permits the use of labeled exogenous FN as a tracer during the process of matrix assembly.

Experiments with iodinated fibronectin have shown that shortly (2 to 10 min) after addition to the culture medium, it binds to the cell culture and becomes resistant to simple rinses with buffers that preserve cell viability (McKeown-Longo and Mosher, 1983). Prolonged incubation leads to increased binding and formation of two different fibronectin pools that can be distinguished by their solubility in 1% deoxycholate (DOC). The DOC-soluble pool represents FN bound by cellular receptors and preexisting matrix fibrils, while the DOC-insoluble pool is believed to include bound fibronectin that is incorporated in the matrix through detergent-resistant interactions such as disulfide bonding. Based on the similarities between the incorporation of exogenous and endogenous FN, the quantities of labeled FN in different fractions appear to be proportional to the total amounts of fibronectin present in these fractions. Thus, the ability of cells to bind and organize fibronectin matrix under different conditions where a variety of signaling pathways are affected can be studied by following the relative distributions and quantifying the amounts of labeled (tracer) fibronectin between these two fractions.

Purification of the DOC-insoluble fraction from relatively small amounts of cultured cells very often poses technical difficulties in handling such small and often invisible pellets. Possible losses of part of the DOC fractions will lead to erroneous interpretation of the results. This serious problem can be avoided by a parallel determination of the amount of an intermediate filament protein present in this fraction. Due to their high insolubility, these proteins resist DOC extraction, and their quantities can be used as internal controls for the efficiency of isolation and recovery of the DOC-insoluble fraction.

Radioactive isotopes are widely used for quantification purposes, but this method demands special training, equipment, and disposal of reagents. Substitution of biotinylated fibronectin for radioiodinated fibronectin simplifies the technique while still preserving the necessary level of sensitivity. Moreover, covalently linking *N*-hydroxysulfosuccinimide (NHS)-coupled biotin to fibronectin is a routine and easy procedure. It permits detection of biotinylated FN with avidin through the strongest known noncovalent recognition reaction ($K_a = 10^{15}\ M^{-1}$).

Addition of phosphatase inhibitors to the DOC extraction buffer permits the use of the DOC-soluble fractions for determination of the activity of different phosphorylated signaling molecules by using simple immunoblotting techniques and phosphospecific antibodies, making this method more versatile than the classical DOC solubility assay.

Critical Parameters and Troubleshooting

Several parameters play critical roles for success in the quantification of fibronectin matrix assembly. Incorporation of readily detectable levels of biotinylated fibronectin into the DOC-insoluble fraction is necessary for accurate quantification. This step depends on the ability of the cells being studied to organize matrix, and it can be achieved by optimizing the duration of the labeling period.

Obtaining a high signal-to-noise ratio after immunoblotting is also essential for successful quantification of the amounts of biotinylated fibronectin and changes in signaling pathways. This goal can be achieved by: (1) loading

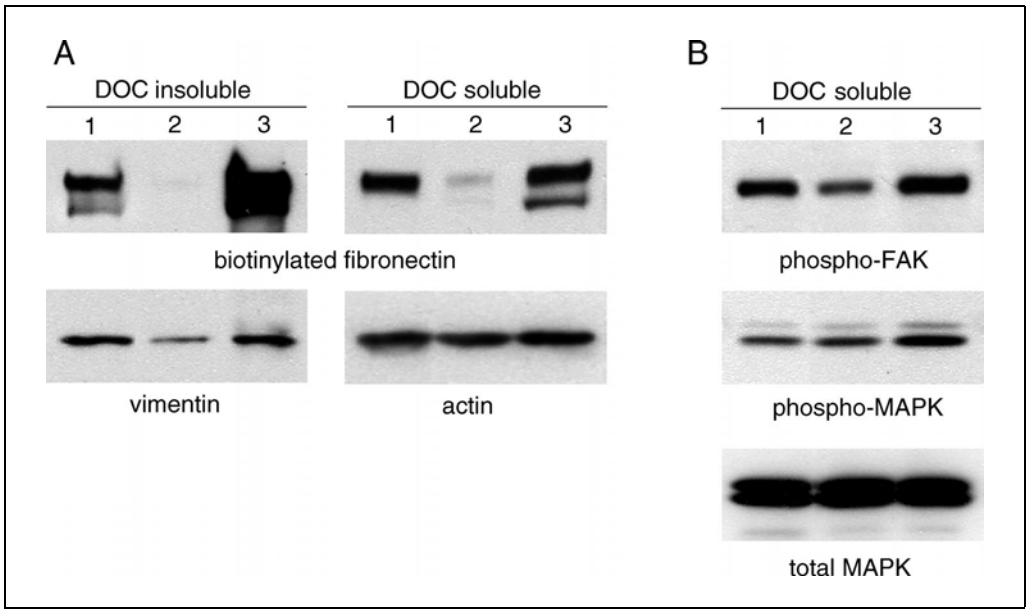

Figure 10.13.1 Determination of matrix assembly by the methods described in this unit. (**A**) Primary human fibroblasts were cultured overnight in normal medium, washed with medium without serum containing 1% BSA, and incubated in the same medium supplemented with 20 μg/ml biotinylated fibronectin without additional agents (lane 1), with 10 μM ROCK inhibitor Y27632 (lane 2), or with 2 μM lysophosphatidic acid (LPA; lane 3) for 4 hr. Deoxycholate (DOC)-insoluble and -soluble fractions were resolved on 4% to 12% gradient polyacrylamide gels, transferred to nitrocellulose membranes, and probed with HRP-conjugated streptavidin for determination of the amount of the incorporated FN (biotinylated fibronectin). The same membranes were re-probed with antibodies against vimentin and actin for determination of the efficiency of purification and gel loading. (**B**) Samples as in (**A**) from the DOC-soluble set were assayed by immunoblotting with antibodies against the activated form of focal adhesion kinase (phospho-FAK), activated form of mitogen-activated protein kinase (phospho-MAPK) and total MAPK for determination of the effect of Y27632 and LPA on the these signaling molecules.

sufficient amounts of proteins from both fractions to ensure trouble-free detection of the biotinylated FN; (2) use of freshly added phosphatase and protease inhibitors to the DOC extraction buffer; (3) use of sufficiently specific antibodies that recognize the phosphorylated but not the unphosphorylated forms of the signaling molecules of interest; and (4) following proper techniques for SDS-PAGE and immunoblotting (see *UNITS 6.1 & 6.2*).

Accurate comparison and quantification by densitometry of the amounts of biotinylated FN as well as the phosphorylation levels of the signaling molecules studied in different samples can be achieved if the detection system is kept in a linear range. That is, loading two times the amount of sample should be reflected in a doubling of signal. The enhanced chemiluminescence (ECL) system should be optimized to obtain linearity by adjustments of the amount of protein loaded on the gel, concentrations of primary and secondary antibody, and X-ray film exposure time. If the weakest signal is detectable and the strongest signal is still within the linear range of the film (e.g., not saturated), then the rest of the samples are also in the linear range and the results can be used for quantification.

Anticipated Results

Typical results expected after performing the Basic Protocol are presented in Figure 10.13.1. Easily detectable amounts of biotinylated FN should be present in the control lanes (Fig. 10.13.1 A, lane 1) in both DOC-insoluble and DOC-soluble sets of samples. Different treatments may have different effects on matrix assembly. In the example presented, blocking cellular contractility with Y27632 strongly decreased both binding of FN to the cells (Fig. 10.13.1 A, DOC soluble, lane 2) and its incorporation into the matrix (Fig. 10.13.1 A, DOC insoluble, lane 2). The opposite effect was observed after stimulation of cellular contractility with lysophosphatidic acid (LPA; Fig. 10.13.1 A, lane 3). Calculation of the differences observed (see Basic Protocol) revealed an 11.5-fold reduction in the incorporation of labeled FN into the DOC-insoluble matrix after treatment with Y27632 and a 4.9-fold

increase after stimulation with LPA. The reduction in the DOC-soluble fraction after treatment with Y27632 was 5-fold, suggesting that this agent may affect not only formation of the matrix, but also initial FN binding to the cell surface.

The decrease in matrix assembly after inhibition of cellular contractility was accompanied by a reduction in the activation of FAK, but not of MAPK (Fig. 10.13.1 B, lane 2), suggesting that in this particular experimental setting, the activity of FAK may be important for matrix assembly. While the effects of agents such as Y27632 and LPA on matrix formation are clear, drawing unambiguous conclusions about the relevant signaling events demands a number of additional experiments. Nevertheless, such initial correlative data between signaling and matrix assembly provide a good starting point.

Time Considerations

The procedure described in the Basic Protocol can be completed in 3 days.

The first day includes the time for cell attachment after plating (overnight); labeling with biotinylated FN (4 hr) and isolation of DOC-soluble and DOC-insoluble fractions (2 hr). The second day comprises SDS-PAGE and electrotransfer (3.5 hr for mini gels); probing with streptavidin-HRP and ECL reaction (2.5 hr); and overnight incubation with the primary antibody. The third day is for completion of the immunoreactions and ECL processing (4 hr).

There are a number of points where the procedure can be interrupted: (1) after preparation of the SDS-PAGE samples; (2) after the electrotransfer (membranes can be stored wet or dry in resealable plastic bags at 4°C); and (3) after completion of the first ECL development (membranes can be stored wet in resealable plastic bags at 4°C).

The procedure described in the Support Protocol can be completed in 1 day if the 2-hr dialysis period is employed, or 36 hr if the overnight dialysis is used.

ABSTRACT

The practice of in vitro three-dimensional (3-D) cell culture has lagged behind the realization that classical two-dimensional (2-D) culture on plastic surfaces fails to mirror normal cell biology. Biologically, a complex network of proteins and proteoglycans that constitute the extracellular matrix (ECM) surrounds every cell. To recapitulate the normal cellular behavior, scaffolds (ECM analogs) that reconstitute the essential biological cues are required. This unit describes the 3-D cell culture and tumor engineering applications of Extracel, a novel semisynthetic ECM (sECM), based on cross-linked derivatives of hyaluronan and gelatin. A simplified cell encapsulation and pseudo-3-D culturing (on top of hydrogels) protocol is provided. In addition, the use of this sECM as a vehicle to obtain tumor xenografts with improved take rates and tumor growth is presented. These engineered tumors can be used to evaluate anticancer therapies under physiologically relevant conditions. *Curr. Protoc. Cell Biol.* 40:10.14.1-10.14.21. © 2008 by John Wiley & Sons, Inc.

Keywords: hyaluronan • semisynthetic extracellular matrix • hydrogel • biodegradable scaffold

INTRODUCTION

This unit describes the use of chemically modified, cross-linkable derivatives of hyaluronan (HA) hydrogels for more physiologically significant in vitro cell culturing and in vivo tumor and tissue engineering applications. Traditional two-dimensional (2-D) culturing conditions lead to aberrant cell behavior that may have limited relevance to in vivo conditions (Roskelley et al., 1994; Weaver et al., 1997; Wang et al., 1998; Cukierman et al., 2001). Mammalian cells do not grow in a physiologically realistic manner on plastic. In vivo, an extracellular matrix (ECM) surrounds the cells in all tissues. The ECM is a complex network of proteins and glycosaminoglycans (GAGs), which form a 3-D microenvironment that plays an integral part in signaling cells to proliferate, migrate, differentiate or invade (Galbraith et al., 1998; Geiger et al., 2001; Lutolf and Hubbell, 2005; Holmbeck and Szabova, 2006).

HA is a major constituent of the ECM and is the only nonsulfated GAG present (Knudson and Knudson, 2001). It is biocompatible and biodegradable, and it performs important biological functions such as stabilizing and organizing the ECM (Fraser et al., 1997; Dowthwaite et al., 1998), regulating cell adhesion and motility (Dowthwaite et al., 1998; Cheung et al., 1999), and mediating cell proliferation and differentiation (Entwistle et al., 1996).

The HA-derived hydrogel (Extracel) discussed in this unit is composed of chemically modified HA containing reactive thiol groups (known as CMHA-S, Glycosil, or Carbylan-S) and chemically modified gelatin containing reactive thiol groups (known as

DOI: 10.1002/0471143030.cb1014s40

Gtn-DTPH or Gelin-S), which are co-cross-linked with polyethylene glycol diacrylate (PEGDA or Extralink) to form a semisynthetic ECM (sECM; Shu et al., 2004, 2006; Prestwich, 2007, 2008). For clarity and consistency in this unit, we will use the names of the commercially available materials.

All three components of the hydrogel are available as lyophilized solids. Once reconstituted, the solutions can be easily pipetted and transferred into multiple formats (including any well size or tissue culture insert), or it can be injected into an animal model. The hydrogel is formed by mixing the chemical cross-linker, Extralink, with either Glycosil only or Glycosil mixed with Gelin-S. Once the cross-linker is added, the mixture will become more and more viscous until a solid hydrogel is formed. The gelation time can be controlled by the user depending upon requirements.

The HA component Glycosil can be cross-linked alone with Extralink, but most mature cell types do not adhere to HA-only hydrogels. Some cancer cells and stem cells will grow and proliferate in HA-only hydrogels, but usually some attachment factor (e.g., gelatin, an RGD peptide, collagen, laminin, or fibronectin) needs to be mixed with the Glycosil prior to cross-linking with PEGDA. The hydrogel retains proteins greater than 70 kDa in size, so even though the ECM-derived proteins are not covalently attached to the hydrogel, they are entrapped and will only be able to diffuse out as the sECM degrades. Growth factors are also retained within the hydrogel in a similar fashion (Cai et al., 2005; Pike et al., 2006; Riley et al., 2006).

Using three basic components to make an sECM simplifies the biological ECM to a consistent, fully defined, experimentally controllable material for research. Because ECM proteins and growth factors can be incorporated into these hydrogels, it is possible to make a fully defined mimic of specific ECMs found in mammalian tissues if the target tissue ECM composition is known. Additionally, since the basic hydrogel can be formed with only Glycosil and Extralink, animal-free hydrogels can also be made.

STRATEGIC PLANNING

For successful use of these protocols, the researcher must be familiar with how to culture the cells of interest in a 3-D environment or be prepared to conduct several experiments to determine the optimal conditions. Cells cultured in 3-D behave differently than those cultured 2-D on tissue culture–treated plastic. At a minimum, the cell morphology and gene expression patterns can change (Bissell et al., 2003). Because cells receive signals from the matrix on which they are grown (even if this matrix is plastic), the composition and stiffness (compliance) of this matrix help determine the growth and functional characteristics of the cells (Yeung et al., 2005; Engler et al., 2006). In the case of naïve mesenchymal stem cells, the matrix stiffness can cause lineage restriction. For fibroblasts, it changes the amount and arrangement of actin stress fibers (Ghosh et al., 2007). For many cell types, the differences when plating on stiff versus compliant surfaces is not yet characterized. Finally, cells respond differently when encapsulated within a hydrogel or when plated on the surface.

For in vitro cell growth, the culture medium and cell seeding density are very important. It is possible to use the optimal tissue culture–plastic culture conditions as a starting point for the hydrogel experiments. However, it is likely that some modification to these conditions will be required. For the in vivo tumor xenografts, the cell density, injection volume, and hydrogel dilution are critical for the experimental outcome (Liu et al., 2007a). The method of making the hydrogel affects its final properties. There are several variations to this general protocol which are discussed in subsequent sections. Prior to using the hydrogels, the following questions need to be addressed:

1. What gelation time is required?

2. Will cells be encapsulated in the hydrogel?

3. Will ECM proteins be incorporated into the hydrogel?

4. Will growth factors be incorporated into the hydrogel?

5. What hydrogel compliance is required?

Based on the answers to these questions, additional steps may be required in the hydrogel preparation. If it is your first time using these HA-derived hydrogels, performing a simple gelation test before starting the first experiment will greatly improve the chances of success. The test takes ~1 hour and will allow you to understand fundamentally how the materials work. A protocol for performing this test is given in Basic Protocol 1.

This unit contains six protocols which detail how to make the HA-derived hydrogels (Basic Protocol 1), vary their compliance (Basic Protocol 2) and composition (Basic Protocol 3), use them for cell growth in vitro (Basic Protocols 4 and 5), and implant them in mice for in vivo experimentation (Basic Protocol 6).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

STANDARD HA-DERIVED HYDROGEL PREPARATION

BASIC PROTOCOL 1

The basic hydrogel, Extracel, is the foundation tool for all the protocols discussed in this unit. Its preparation is required for 3-D cell and pseudo-3-D culture (encapsulation and surface growth) and tumor xenograft experiments. Extracel is composed of Glycosil (thiol-modified HA), Gelin-S (thiol-modified gelatin), Extralink (PEGDA), and degassed, deionized water (DG Water). Glycosil, Gelin-S, and Extralink are available as lyophilized solids. They must be reconstituted using DG Water prior to forming the hydrogel. When reconstituted, they form low-viscosity solutions in phosphate-buffered saline (PBS), pH ~7.4. The hydrogel is formed by mixing all three components together. The gelation time is highly dependent upon the pH of the Extracel solution: the higher the pH, the faster the gelation time. Additionally, depending upon the amount of Extralink used and the concentration of the Glycosil and Gelin-S solutions, gelation will occur in 10 min to >2 hr. Once the Extralink is added there is a time limit on using the hydrogel because it becomes impossible to pipet after the gelation point is reached.

Materials

7.5-ml Extracel Hydrogel Kit (Glycosan BioSystems) containing:
  Glycosil (three 1-ml vials)
  Gelin-S (three 1-ml vials)
  Extralink (three 0.5-ml vials)
  DG Water (one 10-ml vial)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Serum-free cell culture medium

37°C water bath
1-ml syringes with long-tip 20-G × 1½-in. needles, sterile
37°C shaking or rocking incubator
4-ml glass vials

Prepare the gel

1. Remove Glycosil, Gelin-S and Extralink vials from the −20°C freezer and heat them to 37°C (∼30 min).
2. Remove the DG Water from the −20°C freezer and thaw in a 37°C water bath (∼15 min).
3. Under aseptic conditions and using a syringe with the exact amount of liquid, add 1.0 ml DG Water to the Glycosil vial. Repeat for the Gelin-S vial.
4. Incubate both vials horizontally at 37°C, with shaking (for maximum mixing).

   NOTE: *Vigorous shaking will speed up dissolving time.*

   It will take <30 min for the solids to fully dissolve. Solutions will be clear and slightly viscous.
5. Under aseptic conditions and using a syringe with the exact amount of liquid, add 0.5 ml DG Water to the Extralink vial. Invert several times to dissolve.
6. As soon as possible and within 4 hr of making the solutions, mix equal volumes of Glycosil and Gelin-S in a sterile container. Mix by pipetting up and down gently or inverting the vial.
7. To form the hydrogel, add Extralink to the Glycosil + Gelin-S mix in a 1:4 volume ratio (0.25 ml of Extralink to 1.0 ml Glycosil + Gelin-S).

Perform gelation tests with Extracel

8. Follow steps 1 to 5 (above) for standard hydrogel reagent preparation.
9. Add 0.25 ml Glycosil and 0.25 ml Gelin-S to a small glass vial. Pipet up and down to mix.
10. Add 0.125 ml Extralink to the vial and pipet up and down to mix. Record the time.

    The initial solution of Glycosil + Gelin-S + Extralink will be low viscosity (similar to medium).
11. Every few minutes, invert the vial. Record the time at which the hydrogel no longer flows when the vial is inverted.

    As the hydrogel forms, the liquid will become more viscous.

    The gelation time is the difference between the two recorded times. This establishes the maximum length of time you will have to use Extracel after the Extralink is added.
12. Repeat steps 8 to 11, but in addition, add 0.5 ml PBS to the vial of Glycosil + Gelin-S from step 9.

    This gelation time will be substantially longer due to the dilution of the Glycosil and Gelin-S.
13. Repeat steps 8 to 11, but in addition, add 50 µl cell culture medium (no serum or additives) to the vial of Glycosil + Gelin-S in step 9. Pipet up and down to mix.

    This gelation time will be about the same as with the first trial (step 11). This simulates the addition of cells in medium into the hydrogel prior to cross-linking.

    These gelation tests will help the user determine the time constraints for working with Extracel, once the cross-linker Extralink is added to the Glycosil + Gelin-S. They will also help familiarize the user with how the hydrogel is formed, prior to working with it in an experiment.

HA-DERIVED HYDROGEL STIFFNESS VARIATION

As discussed above, hydrogel stiffness can have a dramatic effect on how cells behave in culture. Using the Extracel Hydrogel Kit as per the standard instructions results in a hydrogel compliance of ~100 Pa (J. Vanderhooft, unpub. observ.).

For the HA-derived hydrogels, compliance variation can be achieved in two different ways: (1) varying the concentration of the cross-linker used and (2) varying the concentrations of the Glycosil and Gelin-S solutions.

By increasing the concentration of Extralink, the compliance can be increased to ~500 Pa (Ghosh et al., 2007). Alternatively, diluting the Extracel solutions can decrease it to below the threshold of detection (~20 Pa). Glycosil-only hydrogels cross-linked with Extralink are ~300 Pa. Changing the concentration of Extralink significantly alters the gelation time, as does diluting the Glycosil and Gelin-S solutions. Doubling the Extralink concentration will decrease the gelation time by ~50%. A 2-fold volume dilution will more than double the time for the hydrogel to form.

Materials

7.5-ml Extracel Hydrogel Kit (Glycosan BioSystems) containing:
  Glycosil (three 1-ml vials)
  Gelin-S (three 1-ml vials)
  Extralink (three 0.5-ml vials; purchase additional vials separately, if required)
  DG Water (one 10-ml vial)
Serum-free cell culture medium
Phosphate-buffered saline (PBS; *APPENDIX 2A*), pH ~7.4 and ~7.6

37°C shaking or rocking incubator
37°C water bath
1-ml syringes with long-tip 20-G × $1^1/_2$-in. needles, sterile

Method 1: vary cross-linker concentration

1a. Prepare Glycosil and Gelin-S as in Basic Protocol 1, steps 1 to 4.

2a. Under aseptic conditions and using a syringe with the exact amount of liquid, add the appropriate amount of DG Water to the Extralink vial based on the desired hydrogel stiffness (see Table 10.14.1). Invert several times to mix.

3a. As soon as possible and within 4 hr of making the solutions, mix equal volumes of Glycosil and Gelin-S by pipetting up and down.

4a. To form the hydrogel, add Extralink to the Glycosil + Gelin-S mix in a 1:4 volume ratio (e.g., 0.5 ml Extralink to 2.0 ml Glycosil + Gelin-S).

The gelation time will decrease with the higher Extralink concentration.

For the stiffest hydrogel, there is insufficient Extralink in the standard Extracel 7.5-ml Hydrogel Kit to use all of the Glycosil and Gelin-S. Individual Extralink vials can be purchased, if required.

Table 10.14.1 Amounts of PBS Added to Extralink When Preparing Hydrogels of Different Stiffnesses by Cross-linker Concentration Variation

Condition	Volume PBS (ml)	Notes
A	0.25	Stiffest
B	0.5	Standard
C	1.0	Softest

Table 10.14.2 Amounts (ml) of PBS Added to Hydrogel Reagent Solutions When Preparing Hydrogels of Different Stiffnesses by Hydrogel Component Dilution

	Stiffest ⟶ Softest				
	Standard	A	B	C	D
Glycosil	0.00	0.25	0.50	0.75	1.00
Gelin-S	0.00	0.25	0.50	0.75	1.00
Extralink	0.00	0.13	0.25	0.38	0.50

Method 2: dilute hydrogel solutions

1b. Prepare the hydrogel kit reagents as in Basic Protocol 1, steps 1 to 5 (standard hydrogel reagent preparation).

2b. Based on the desired stiffness of hydrogel, aseptically add (using a syringe) varying volumes of sterile PBS to the prepared 1-ml Glycosil and Gelin-S vials (see Table 10.14.2). Invert to mix.

3b. Also add varying amounts of sterile PBS to the prepared 0.5-ml Extralink vial (see Table 10.14.2). Invert several times to mix.

4b. As soon as possible and within 4 hr of making the solutions, mix equal volumes of Glycosil and Gelin-S by pipetting up and down.

5b. To form the hydrogel, add Extralink to the Glycosil + Gelin-S mix in a 1:4 volume ratio (e.g., 0.5 ml Extralink to 2.0 ml Glycosil + Gelin-S).

The gelation time will increase with the solution dilution.

BASIC PROTOCOL 3

ECM COMPONENT INCORPORATION IN HYDROGELS

Gelin-S provides basic cell attachment sites for cell lines and some primary cell types (Shu et al., 2006; Prestwich et al., 2007). However, several cell types are dependent upon specific ECM components for growth and differentiation. For specific cell performance, matricellular and extracellular proteins (e.g., laminin, collagen, fibronectin, vitronectin, aggrecan, decorin) may be added to Glycosil-only hydrogels by the user (Mehra et al., 2006). These proteins are easily incorporated noncovalently into the hydrogel prior to gel formation and retained there after gel formation because of their size. The following protocol describes how to prepare Glycosil-only hydrogels mixed with a laminin isoform from a particular animal source.

Materials

1-ml vial of Glycosil (Glycosan BioSystems)
0.5-ml vial of Extralink (Glycosan BioSystems)
DG Water (Glycosan BioSystems)
500 μg/ml commercial (e.g., Sigma) or laboratory-prepared laminin stock solution (or other sterile, cellular matrix protein in aqueous solution): prepared according to the manufacturer's instructions, if commercially obtained

37°C water bath
1-ml syringes with long-tip 20-G × 1½-in. needles, sterile
37°C shaking or rocking incubator

1. Remove the Glycosil and Extralink vials from the −20°C freezer and heat them to 37°C (~30 min). Thaw the laminin solution (for commercial product, per the manufacturer's instructions).

For example, it is necessary to thaw Sigma laminin L6274 overnight.

2. Remove the DG Water from the −20°C freezer and thaw in a 37°C water bath (~15 min).
3. Under aseptic conditions and using a syringe with the exact amount of liquid, add 1.0 ml of DG Water to the Glycosil vial.
4. Place the vial horizontally at 37°C, with shaking (for maximum mixing).

   NOTE: *Vigorous shaking will speed up dissolving time.*

   It will take <30 min for the solids to fully dissolve. Solution will be clear and slightly viscous.
5. Under aseptic conditions and using a syringe with the exact amount of liquid, add 0.5 ml of DG Water to the Extralink vial. Invert several times to dissolve.
6. Add 125 µl of commercially obtained or laboratory-prepared laminin to the 1 ml of Glycosil solution. Mix thoroughly.
7. To form the hydrogel, add Extralink to the Glycosil + laminin mix in a 1:4 volume ratio (0.25 ml Extralink to 1.0 ml Glycosil + 0.125 ml laminin).
8. Vary the composition of the hydrogel, as desired, as follows:

   a. Increase or decrease the amount of laminin.
   b. Vary the source of the laminin.
   c. Use other ECM proteins (e.g., a specific type of collagen, fibronectin, vitronectin, decorin) in place of or in conjunction with laminin.

CELL GROWTH ON HA-DERIVED HYDROGEL SURFACE

BASIC PROTOCOL 4

This protocol describes how to make Extracel hydrogels in a 24-well plate format for cell growth on the surface. The protocol can easily be adapted for use with 6-, 12-, 48- and 96-well plates.

Materials

7.5-ml Extracel Hydrogel kit (Glycosan BioSystems)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), sterile
1–2 × 10^4 cells/ml medium suspension of cultured cells of interest: prepared according to standard procedures (e.g., see *UNIT 1.1*)
Cell culture medium with serum
0.05% trypsin EDTA (VWR)
10× collagenase/hyaluronidase (StemCell Technologies)

37°C water bath
1-ml syringes with long-tip 20-G × 1½-in. needles, sterile
37°C shaking or rocking incubator
15-ml sterile, conical tubes
24-well tissue culture plates
Sterile plate-sealing film (e.g., Axy Seal, VWR) and roller
Light microscope (10× magnification)

Coat plates

1. Prepare the hydrogel kit reagents as in Basic Protocol 1, steps 1 to 5 (standard hydrogel reagent preparation).
2. Under aseptic conditions and using a syringe with the exact amount of liquid, add an additional 1.0 ml of sterile PBS to both the Glycosil and the Gelin-S vials. Shake to mix.

3. Under aseptic conditions and using a syringe with the exact amount of liquid, add an additional 0.5 ml of sterile PBS to the Extralink vial. Shake to mix.
4. Transfer Glycosil and Gelin-S solutions into a sterile 15-ml conical tube. Mix for at least 3 min with a 25-ml pipet by pipetting up and down.

   If the Extracel solutions are not well mixed, the hydrogel surface may not be uniform. This can cause variation in how the cells attach and grow on the hydrogel.
5. Remove a 24-well plate from the packaging.
6. Just before use, add the 1.0 ml Extralink to the tube containing Glycosil + Gelin-S. Mix at least 2 min by pipetting with a 25-ml pipet.
7. Pipet 500 µl into each of ten wells. Rock the plate by hand to ensure that the surface of the plate is equally coated.
8. Remove 300 µl from each well using a pipet, leaving 200 µl of hydrogel in each well. Repeat steps 7 and 8 until all wells are coated.
9. Cover each plate with a sterile film. Seal with a roller so that each well is isolated.

   Since these are thin coatings they will dehydrate very easily to form films if they are not completely sealed.
10. Allow gelation to occur on the bench top.

    It will take >2 hr for gelation to occur.
11. Store up to 4 months at 4°C until ready for use. Do not freeze.

Culture cells on the HA-derived hydrogel surface

12. Remove a precoated 24-well plate from storage at 4°C.
13. Allow it to warm to room temperature or place in the incubator to increase the temperature to 37°C prior to plating.
14. Add 500 µl of the cell suspension in medium to each well on top of the hydrogel.

    NOTE: *Cells should be cultured in the same medium as when they are grown on tissue culture–treated plastic. This medium may or may not contain serum, depending upon the cell type.*

    Cell seeding density depends upon the experiment and the cell type. As a rough guideline, follow the cell seeding density used for seeding a tissue culture–treated plastic 24-well plate.
15. Incubate at least 1 hr in a 37°C, 5% CO_2 incubator.
16. Verify cell attachment under the microscope. Once confirmed, add the appropriate amount of medium (0.5 to 1.5 ml) to each well and return the plate to the incubator.
17. Change the medium as required (based on changes in the medium's phenol red indicator) by carefully aspirating off the medium.

    The hydrogel can easily be removed by vacuum aspiration as well, so this must be done gently and carefully.
18. Pipet 1 to 2 ml medium into each well. Try to avoid disrupting the gel.
19. Return the plate to the incubator.

Recover cells from hydrogel surface

20. Aspirate the medium and wash the hydrogel surface with 1 to 2 ml PBS per well.

21. Add 0.5 ml trypsin solution to the hydrogel surface.

    Other products (e.g., Accutase, Detachin, TrypLE) that are gentler than trypsin and are better tolerated by cells can also be used. However, they may also degrade the hydrogel so that recovered cells carry some hydrogel particles with them. If this occurs, then use a 10× collagenase/hyaluronidase solution to digest the remaining hydrogel.

22. Incubate at 37°C until the cells begin to detach (~15 min).

23. Gently tap the plate to loosen the cells.

24. Add 2 ml medium with serum to the hydrogel surface and pipet up and down to get a uniform cell suspension.

25. Transfer the cells to a 15-ml culture tube. Add 8 ml medium with serum (10 ml final volume). Centrifuge the cells 5 min at 120 × *g*, room temperature.

26. Remove the supernatant and replace with 1 to 2 ml fresh medium.

    Cell viability will be similar to that of cells grown on plastic and detached with trypsin.

CELL ENCAPSULATION IN HA-DERIVED HYDROGELS

BASIC PROTOCOL 5

Encapsulating cells in HA-derived hydrogels and growing them in tissue culture inserts is the best way (in the absence of a bioreactor) to mimic in vivo conditions in vitro. This protocol describes how to make Extracel hydrogels in a 24-well plate format, using tissue culture inserts. Other insert formats also work, but the amount of hydrogel used per insert should be varied based on the insert volume.

It is not always necessary to recover cells from the hydrogels. Cells cultured by encapsulating them in tissue culture inserts can be treated like tissue. The hydrogel can be removed from the insert, embedded in paraffin, sectioned, and stained as per standard protocols. Note that small molecule dyes and stains that are less than 70 kDa in size will freely diffuse into the gel.

It is not possible to perform direct antibody staining of cells encapsulated in HA-derived hydrogels because the antibodies are too large to permeate the gel. If embedding, sectioning, and staining is not desirable, then the cells must be recovered from the hydrogel.

Materials

7.5-ml Extracel Hydrogel Kit (Glycosan BioSystems) containing:
10× collagenase/hyaluronidase (StemCell Technologies)
Sterile phosphate-buffered saline (PBS)
~0.4–2 × 10^4 cells/ml medium suspension of cultured cells of interest: prepared according to standard procedures (e.g., see *UNIT 1.1*)
Cell culture medium with and without serum

37°C water bath
1-ml syringes with long-tip 20-G × 1½-in. needles, sterile
37°C shaking or rocking incubator
24-well plate with tissue culture inserts (e.g., 6.5-mm Costar tissue culture–treated polycarbonate membrane polystyrene plates, Corning; 8.0-μm pore size Millicel, Millipore
35-mm sterile petri dishes
Surgical scalpel
15-ml conical centrifuge tube

Encapsulate cells

1. Prepare hydrogel kit reagents as in Basic Protocol 1, steps 1 to 5 (standard hydrogel reagent preparation).
2. Determine the volume of suspension required to obtain the desired seeding density in 2.5 ml of the hydrogel.

   Seeding density varies with cell type, but a typical range is 10,000 to 50,000 cells per insert.

3. Prepare two 24-well plates with tissue culture inserts by removing them from their sterile packaging.
4. Mix 1.0 ml of Glycosil and 1.0 ml of Gelin-S.
5. Centrifuge the volume determined in step 2 for 5 min at 120 × *g*, room temperature, and discard the supernatant. Resuspend the cell pellet in the 2 ml of Glycosil + Gelin-S.
6. Just before pouring the hydrogels, add 0.5 ml of Extralink to Glycosil + Gelin-S with cells. Mix completely by pipetting up and down.

   Once the Extralink is added you have <20 min before the hydrogel forms.

7. Quickly pipet 100 µl of Extracel mix into each insert.

   Do not add medium at this point because this will dilute the hydrogel and prevent it from gelling.

8. Incubate the plates for ~1 hr in a 37°C, 5% CO_2 incubator to allow the Extracel to gel.
9. Remove the plates from incubator and verify that the hydrogel is solid. If so, add 1.8 ml medium (with serum, if required) to each well. Incubate in a 37°C, 5% CO_2 incubator.
10. Change the medium as required:

    a. Move each tissue culture insert to an adjacent empty well.
    b. Aspirate the medium.
    c. Tap each insert carefully to remove the medium above the hydrogel in the insert.

       Aspiration can be used to remove the medium, but, the gel can also easily be removed by vacuum aspiration, so this must be done gently and carefully.

    d. Replace the insert into its original well.
    e. Slowly and carefully pipet 1.8 ml medium into each well.

       Try to avoid disrupting the gel.

    f. Return the plate to the 37°C, 5% CO_2 incubator.

       Cells behave differently when cultured in 3-D than when grown on the surface of a hydrogel or tissue culture–treated plastic. The cells will grow at different rates (typically slower) and have different morphologies (depending upon the hydrogel stiffness and composition). Additionally, the cells are not passaged in the traditional manner. Since the volume of the hydrogel provides a large volume for growth, the cultures can be maintained for many days, even weeks, before the cells become confluent.

Recover encapsulated cells

11. Dilute the 10× collagenase/hyaluronidase 10-fold in the cell culture medium (without serum) used to cultivate the cells.

    Do not use undiluted enzyme because this results in low cell viability.

If using medium that contains serum for culture, make sure to wash the hydrogels with serum-free medium or PBS before starting the digestion process because the serum will inactivate the enzymes. At a minimum, wash hydrogels twice for 1 hr to clear serum).

12. Remove the tissue culture insert from the 24-well culture plate. Place upside down in a petri dish.
13. Remove the membrane by using a surgical scalpel to cut it loose from the insert.

    The membrane will stay attached to the insert, but usually flips up out of the way.

14. Turn the insert right side up and using the back of a 10-µl pipet tip punch the hydrogel out of the insert into the petri dish.
15. Place the hydrogel in a 15-ml conical tube and add 5 ml diluted collagenase/hyaluronidase solution to the hydrogel for each 100 µl of hydrogel.
16. Incubate overnight at 37°C, with gentle shaking.

    At the end of the incubation there will still be some hydrogel left in the tube.

    If the 10-fold dilution of 10× collagenase/hyaluronidase is not satisfactory, try a 5-fold dilution with digestion overnight.

    Be cautious about mechanically breaking up the hydrogel prior to digestion because this can lower cell viability significantly.

17. Centrifuge in the conical tube 5 min at 120 × *g*, room temperature.
18. Aspirate and discard the supernatant.

Wash the cells

19. Add 5 ml PBS to wash the cell pellet.
20. Repeat steps 17 and 18.
21. Resuspend the cell pellet in 5 ml PBS.

    NOTE: *In the PBS you can see any remaining hydrogel.*

22. Centrifuge cell suspension 15 min at 120 × *g*, room temperature.
23. Aspirate and discard the supernatant.
24. Add 5 ml medium and repeat the centrifugation.
25. Aspirate off all medium but ~0.5 ml and resuspend pellet (in the remaining 0.5 ml) in the desired volume of cell culture medium.

HA-DERIVED HYDROGELS FOR TUMOR XENOGRAFTS

BASIC PROTOCOL 6

Clinically relevant cancer models are necessary to improve our ability to successfully treat the disease. Anticancer drug discovery efforts require models that can predictably translate preclinical results to efficacy in human patients. Most commonly used are the human tumor xenograft models, where human cancer cells are injected into immune compromised mice. Typically these cells are injected in serum-free medium or buffer or Matrigel (a tumor-derived basement membrane extract). Poor ‘‘take’’ is often a problem, and many cell lines or patient-derived cells will not form tumors by injection in buffer or medium.

HA-derived hydrogels can be used for the delivery and growth of cancer cells in vivo for the growth of orthotopic and subcutaneous tumors. Using a hydrogel to deliver cancer cells can offer several advantages (Liu et al., 2007a):

The incidence of cancer formation is increased and variability in tumor size is reduced.
The growth of organ-specific cancers is enhanced with improved tumor-tissue integration.
Vascularization is increased and necrosis is reduced in tumors.
Cancer seeding on adjacent tissues or organs is minimized.
The general animal health is improved, leading to better data with fewer animals.

Use the pilot study described below to determine the optimal:

Extracel dilution factor
Cell density
Hydrogel injection volume
Coordination of surgical or injection manipulations with hydrogel handling.

The protocol provided below is based on nine mice with two subcutaneous injections each (see Table 10.14.3), where each experimental condition (cell density and injection volume) has an "$n = 3$" (see Table 10.14.4). Please adjust this protocol (cell density and injection volume, especially) as required, based on experimental requirements and experience.

NOTE: These guidelines describe how to prepare Extracel hydrogels for encapsulation of cancer cells and injection of this suspension into experimental animals ***for research purposes only***.

NOTE: Researchers are responsible for obtaining a valid Institutional Animal Care and Use Committee (IACUC) protocol prior to initiation of any experiments (if applicable). The guidelines below only pertain to the operational use of the Extracel product in order to assist in preparing an IACUC protocol.

Table 10.14.3 Composition of Injections Mixes (μl)

	Glycosil	Gelin-S	Extralink	Cells + medium	Total volume
Six 100-μl injections					
Injection 1: 90% Extracel + 10% cell suspension	250	250	125	63	688
Injection 2: 50% Extracel + 50% cell suspension	130	130	65	325	650
Three 200-μl injections					
Injection 1: 90% Extracel + 10% cell suspension	120	120	60	30	330
Injection 2: 50% Extracel + 50% cell suspension	70	70	35	175	350

Table 10.14.4 Pilot Study Conditions

	Cells/ml	Injection volume (μl)
Mice 1-3	5×10^6	100
Mice 4-6	5×10^7	100
Mice 7-9	5×10^7	200

NOTE: We recommend conducting a benchtop study with Extracel to confirm the Extracel characteristics prior to initiating animal experiments and gain familiarity with handling and timing of use. The gelation time and final hydrogel properties are highly dependent upon the medium used, extent of hydrogel dilution, and final hydrogel pH (see Basic Protocol 1, steps 8 to 13).

NOTE: We ***strongly*** urge researchers to conduct pilot animal studies to optimize experimental conditions and familiarize the researcher with the handling of Extracel prior to doing large-scale animal testing. The pilot study will provide important information on the time course for tumor growth from a given cell line or primary tumor source, optimal injection size, cell concentration, and Extracel dilution.

Materials

Extracel Hydrogel kit (Glycosan BioSystems) containing:
  Glycosil
  Gelin-S
  Extralink
  DG Water
Tumor cells
Cell culture medium (without serum)
Research animals
Iodine and 70% (v/v) ethanol and sterile swabs

37°C water bath
1-ml syringes with long-tip 20-G × $1\frac{1}{2}$-in. needles, sterile
37°C shaking or rocking incubator

Prepare hydrogels

1. Remove Glycosil, Gelin-S, and Extralink vials from the −20°C freezer and heat them to 37°C (~30 min).
2. Remove the DG Water from the −20°C freezer and thaw in a 37°C water bath (~15 min).
3. Under aseptic conditions and using a syringe with the exact amount of liquid, add 1.0 ml of DG Water to the Glycosil vial. Repeat for the Gelin-S vial.
4. Place both vials horizontally at 37°C, with shaking (for maximum mixing).

   NOTE: *Vigorous shaking will speed up dissolving time.*

   It will take <30 min for the solids to fully dissolve. Solutions will be clear and slightly viscous.
5. Under aseptic conditions and using a syringe with the exact amount of liquid, add 0.5 ml DG Water to the Extralink vial. Invert several times to dissolve.

Prepare cells

6. Prepare cells for encapsulation by resuspending them in the relevant sterile cell culture medium (without serum) to the appropriate cell density and volume (5×10^7 cells/ml for 100-µl and 200-µl injections and 5×10^6 cells/ml for 100-µl injections).

   This protocol assumes that a suspension of 100 µl or 200 µl of Extracel + cells will be injected into nine research animals.

   The cell loading and amount of injected Extracel hydrogel used depends upon the application. The amounts discussed in these guidelines are based on published tumor xenograft experiments (Liu et al., 2007a; Prestwich et al., 2007; Prestwich 2008), where a cell concentration of 5×10^7 cells/ml was employed. Lower concentrations may also be effective; however, they will require longer tumor formation times.

Prepare animals and inject cell suspensions

7. Prepare the research animals for surgery as dictated by an approved IACUC protocol and sterilize the sites for surgery with iodine and alcohol swabs.

   For subcutaneous injections, the hydrogel with cells is injected under the skin. It is possible to perform two injections per animal, one on each side.

   For orthotopic (surgically implanted) injections, the animal is opened surgically and the hydrogel with cells injected into the desired location (e.g., onto the pancreas).

8. Add the appropriate volume of cell suspension to the appropriate amount of Glycosil + Gelin-S (see Tables 10.14.4). Mix the resulting suspension by gently vortexing or pipetting.

   The exact time for the hydrogel to become viscous and gel depends on the dilution factor of Extracel and the pH value of the hydrogel solution.

   The pH of medium used to dilute the Extracel and the dilution factor can profoundly affect the gelation time. As provided by the manufacturer, the gelation time is ∼20 min at ambient temperature. However, the greater the dilution factor, the longer the gelation time.

   The pH of Extracel as provided by the manufacturer is controlled to be approximately 7.4 prior to cell encapsulation and further dilution. However, the cell culture medium used can increase or decrease the pH and change the gelation time. For Extracel, a higher pH results in a faster gelation time. For multiple injections, many researchers desire a slower gelation time of 60 or more min. Lowering the pH by 0.1 or 0.2 units, to pH 7.3 or 7.2, combined with dilution with medium, allows researchers to identify an optimal pH/dilution condition for their specific operational needs.

   If stiffer hydrogels are required, increase the concentration of Extralink used or decrease the subsequent dilution factor (or resuspend the initial lyophilized Extracel components in half of the indicated water amounts).

   Extracel hydrogels form by the reaction of thiols in Glycosil and Gelin-S with the acrylate groups of the cross-linker Extralink. Both Glycosil and Gelin-S can form hydrogels in the absence of Extralink via disulfide bond formation; however, this reaction is normally very slow (hours instead of minutes).

9. When the animals are ready for injection of the hydrogel, add the appropriate amount of Extralink to the cells + Glycosil + Gelin-S. Mix the resulting suspension by gently vortexing or pipetting.

   Once the Extralink is added to the Glycosil + Gelin-S + cells, you have between 20 min and 2 hr before the hydrogel forms. Prepare accordingly. If you cannot inject all the animals within this amount of time, consider dispensing aliquots of the cells + Glycosil + Gelin-S into individual injection amounts and adding the Extralink just prior to injection into each animal.

10. Draw the Extracel + cells into a sterile 1-ml syringe with a 20-G needle.

11. Inject the required amount of hydrogel into the research animal at the desired location.

12. After injection, properly care for the research animals and monitor for tumor formation.

COMMENTARY

Background Information

Mammalian tissues are composed of a conglomerate of interconnected cells that perform similar functions within an organism. Cells can interact with each other directly or indirectly, and their activity is modulated by autocrine and paracrine regulatory mechanisms. In epithelial tissues, cells are in close contact with each other. The majority of other tissue types are comprised of cells that are surrounded by a complex network of macromolecules and proteins referred to as the ECM.

Cell culture is a vital tool for basic research in cell biology, drug discovery, drug evaluation processes, and protein biotechnology. Classical tissue culturing techniques were recently proven to be poor mimics of the physiological cellular environment (Bissel et al., 2003, 2005). Currently, two types of 3-D culturing methods are commonly used. One is referred to as 3-D "embedded" cell culture, while the other is known as 3-D "on-top" (Lee et al., 2007). Both methods require an extracellular matrix (ECM) equivalent as the 3-D culturing microenvironment.

At present, the leading ECM equivalent employed for 3-D culture is Matrigel. This is a natural, murine sarcoma–derived product. Its composition includes laminin, collagen, entactin, and growth factors. Matrigel was tested in numerous 3-D cell culturing applications, invasion assays, and tumor xenografts and yielded satisfactory results (Kleinman et al., 1986; *UNIT 12.2*). Nonetheless, Matrigel has drawbacks, the most serious of which pertain to difficulty of use, lack of experimental control of composition, batch-to-batch variability, and lack of utility in translational research for cell therapy (Prestwich, 2007).

A different natural ECM analog, PureCol (consisting of purified type I collagen; Nutracon, *http://www.purecol.nu*), is widely used in cell culture and tissue engineering and as a coating material for medical devices (Elsdale and Bard, 1972; Emerman and Pitelka, 1977; Bell et al., 1979; Schor et al., 1982; Weinberg and Bell, 1986). PureCol has long gelation times (45 to 60 min at 37°C) that make this material unsuitable as a vehicle for 3-D applications. For 3-D encapsulation, the gelation time of PureCol is such that the cells will settle by gravity prior to gelation, so they are not suspended throughout the hydrogel. However, this material is easy to use, has a very long history in cell culture, and is suitable for pseudo-3-D plate coating.

Although naturally derived ECM extracts provide biological recognition and meet key requirements such as presentation of receptor binding ligands and cell-induced proteolytic degradations, they are far from ideal. Issues of limited availability, batch-to-batch variability, pathogen transmission, immunogenicity, technical challenges in handling, and the inability to customize composition and compliance opened the door for a new generation of semisynthetic ECM equivalents.

One such commercially available material is PuraMatrix, a synthetic self-assembling peptide-based material that forms fibrous scaffolds which can be used for 3-D cell embedding or surface plating (Zhang et al., 1995; Holmes et al., 2000; Semino et al., 2003; Bokhari et al., 2005; Yamaoka et al., 2006). This nonanimal-derived material is nonimmunogenic and is suitable for in vivo studies. A major weakness of this material is its preparation protocol; the pH of the initial reagent is 3.0, which strictly limits the time of cell exposure to this environment. Furthermore, the gelation procedure for this material requires extensive handling. For example, the medium needs to be changed three times in 30 min. Increased handling increases the risk of cell culture contamination and thus limits use to small-scale experimental protocols.

In this unit, we introduced an sECM known commercially as Extracel, a hydrogel based on chemically modified hyaluronan (Glycosil) and gelatin (Gelin-S) that are co-cross-linked with polyethylene glycol diacrylate (Extralink). A generic synthetic scheme for this scaffold is presented in Figure 10.14.1. This biomaterial sustains cell growth and proliferation, while eliminating many of the issues posed by other biomaterials. Its preparation protocol is very user friendly and cell friendly and is suitable for large-scale experimental protocols. The gelation times can be adjusted by varying pH or temperature, and the compliance (stiffness) can be altered by adjusting the degree of cross-linking (Ghosh et al., 2007). In addition, its nature overcomes the issue of immunogenicity in in vivo applications (Liu et al., 2004, 2006a,b, 2007a,b; Duflo et al., 2006; Shu et al., 2006; Orlandi et al., 2007; Prestwich et al., 2007). The biological performance of the four aforementioned ECM equivalents both in pseudo-3-D and 3-D cell cultures were recently compared and contrasted (Serban et al., 2008).

Critical Parameters

The critical parameters required for experimental success were mentioned in each of the protocols. Below, we briefly summarize four key factors that can affect the experimental results:

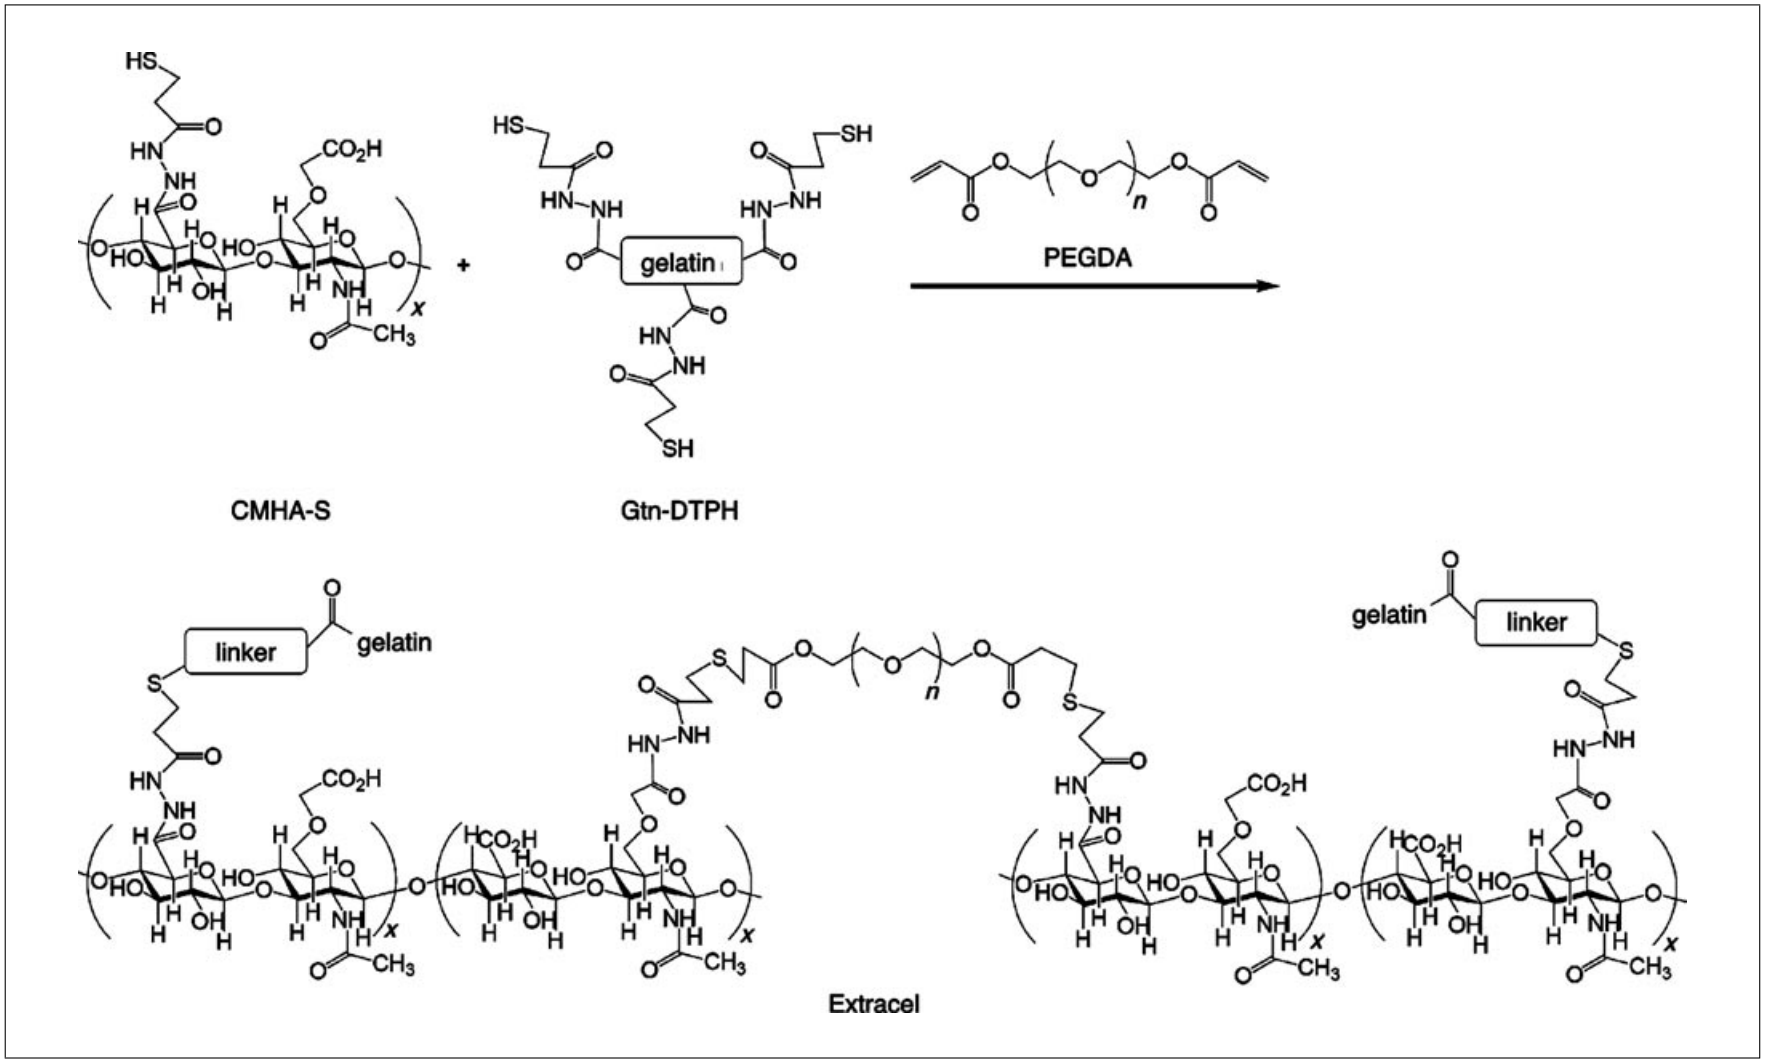

Figure 10.14.1 Generic synthetic scheme for Extracel. Extracel is composed of CMHA-S [thiol-modified hyaluronic acid (HA), trade name of Glycosil], Gtn-DTPH (thiol-modified gelatin, trade name of Gelin-S) and PEGDA (polyethylene glycol diacrylate, trade name of Extralink). In this schematic, "linker" refers to the PEGDA molecule. When mixed together, PEGDA chemically cross-links CMHA-S and Gtn-DTPH to form a hydrogel. *NOTE:* each CMHA-S and Gtn-DTPH molecule has multiple modification sites so that the covalent bonds are formed many times on each HA and gelatin molecule. Reprinted from *Methods*, Vol. 45, Serban, M.A. and Prestwich, G.D., Modular extracellular matrices: Solutions for the puzzle, Copyright 2008 with permission from Elsevier.

Table 10.14.5 Troubleshooting Guide to Working with Hydrogels

Problem	Possible cause	Solution
Hydrogel sets too quickly	High solution pH Extensive handling time High solution concentration	Adjust solution pH to ~7.4 Dilute solutions Aliquot gel components and cross-link near time of use
Hydrogel sets too slowly	Low solution pH Low solution concentration	Adjust solution pH to ~7.4 Reconstitute the lyophilized compounds with less water
Encapsulated cells settle to bottom	High solution dilution	Reconstitute the lyophilized compounds with less water
	Improper cross-linker-to-gel components ratio	Optimize cross-linker-to-gel components ratio
		Add cell suspension to the hydrogel only when mix is becoming viscous
Tumor formation not optimal	Improper solution pH Improper solution concentration	Adjust solution pH to ~7.4 Adjust solution concentrations
	Improper cross-linker-to-gel components ratio	Run a pilot, bench-top experiment to determine optimal hydrogel formulation based on experimental needs

Setup time
Solution pH
Solution dilution factor
Cell seeding density.

The last three factors mentioned can be customized to fit experimental requirements.

The duration of material handling is dictated by the chosen properties of the Extracel components (i.e., higher solution pH leads to faster gelation or lower dilution factor causes faster gelation). Although the protocols provided here are intended to serve as a general guide for experimental setup, it is important to recognize that individual cell types and lines might require optimization. For instance, human tracheal scar fibroblasts were found to prefer a gelatin-rich formulation of Extracel (Serban et al., 2008). Based on individual experimental needs, benchtop studies should be conducted to customize the protocols in order to fit the researcher's needs. These trials should only take a short time (a few hours) and can ensure experimental success.

The cell seeding density should be adjusted accordingly, especially when cell will be 3-D encapsulated. It is important to differentiate between surface (2-D) versus embedded (3-D) culturing. To extrapolate an initial 3-D cell seeding density if the 2-D seeding number is known, simply tripling the cell number is a good starting point. Then, work from this cell density to optimize the cell density for a particular experiment. Using classical analytical methods, cell proliferation or viability for both pseudo-3-D or 3-D culturing conditions can easily be determined. Colorimetric (MTS) assays and staining procedures such as fluorescein diacetate/propidium iodide (FDA/PI) or hematoxylin and eosin (H&E), are perfectly compatible with Extracel.

Troubleshooting

See Table 10.14.5 for troubleshooting hints for these protocols.

Anticipated Results

For cells grown on the surface of Extracel hydrogels (Basic Protocol 4), you should notice cell attachment in ~2 hr. Cells will elicit a morphology consistent with the hydrogel on which they are grown (Fig. 10.14.2). Cell viability should be similar to the classical 2-D culturing conditions.

Cells that are encapsulated in Extracel hydrogels should be homogeneously distributed in the hydrogel in a 3-D environment (you can

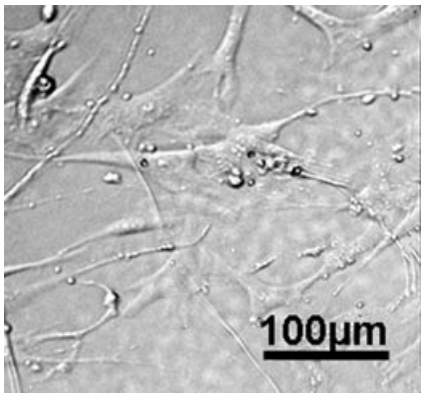

Figure 10.14.2 T31 human tracheal scar AM/Ethidium fibroblasts grown on Extracel. Reprinted from *Acta Biomater.*, Vol. 4, Serban, M.A., Liu, Y. and Prestwich, G.D., Effects of extracellular matrix analogues on primary human fibroblast behavior, *pp.* 67-75, Copyright 2008 with permission from Elsevier.

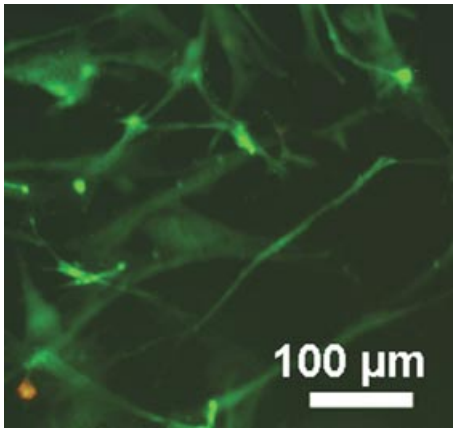

Figure 10.14.3 Calcein-homodimer-1 staining of Extracel-embedded T31 fibroblasts (M.A. Serban, Y. Lue, and G.D. Prestwich unpub. observ.) For color version of this figure see *http://www.currentprotocols.com.*

monitor this microscopically by changing the focal planes; see Fig. 10.14.3). Cell viability should be similar to the classical 2-D culturing conditions.

For tumor xenografts (Basic Protocol 6), both subcutaneous and orthotopic (surgically implanted) injections should result in well localized, vascularized, and differentiated tumors (Fig. 10.14.4 and Fig. 10.14.5). The use of Extracel as a delivery vehicle for tumor engineering leads to increased incidence of cancer formation, reduced variability in tumor size, enhanced growth of organ-specific cancers, improved vascularization, and lower occurrence of core necrosis and adjacent cancer seeding (Liu et al., 2007a).

Time Considerations

The time considerations for hydrogel handling for each of the six protocols were discussed during the process description. Gelling and incubation times are specific to the applications.

Generation of Micropatterned Substrates Using Micro Photopatterning

Andrew D. Doyle[1]

[1]National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, Maryland

ABSTRACT

Micro photopatterning (μPP) has been developed to rapidly test and generate different patterns for extracellular matrix adsorption without being hindered by the process of making physical stamps through nanolithography techniques. It uses two-photon excitation guided through a point-scanning confocal microscope to locally photoablate poly(vinyl) alcohol (PVA) thin films in user-defined computer-controlled patterns. PVA thin films are ideal for surface blocking, being hydrophilic substrates that deter protein adsorption and cell attachment. Because gold substrates are not used during μPP, all live-cell fluorescent-imaging techniques including total internal reflection fluorescence microscopy of GFP–linked proteins can be performed with minimal loss of fluorescence signal. Furthermore, because μPP does not require physical stamps for pattern generation, multiple ECMs or other proteins can be localized within microns of each other. This unit details the setup of μPP. It also provides troubleshooting techniques. *Curr. Protoc. Cell Biol.* 45:10.15.1-10.15.35. © 2009 by John Wiley & Sons, Inc.

Keywords: micro photopatterning • micropatterning • extracellular matrix • two-photon confocal microscopy • photoablation • polyvinyl alcohol • thin film

INTRODUCTION

This unit describes the generation of micropatterned substrates using a direct-writing method known as micro photopatterning or μPP. Micropatterning of extracellular matrix (ECM) components, where ECM proteins are applied to a two-dimensional surface in a specified pattern, has been an important technique for understanding how cells respond and react to their physical surroundings. The most common manner in which to generate micropatterns is through the process known as microcontact printing or μCP, where a physical stamp is used to "ink" ECM patterns onto a gold-coated coverslip (Lehnert et al., 2004). More details about this process can be found in the Background Information section of the Commentary.

While μCP has been refined and can now generate sub micron-sized patterns (Lehnert et al., 2004), it has several limitations. One major limitation is that the patterns of a master cannot be readily changed. This requires a new master for each new pattern or stamp. A second limitation is the use of gold for alkanethiol attachment. Being an electron-dense metal, gold strongly quenches green fluorescent protein (GFP) fluorescence, leaving live-cell fluorescence imaging nearly impossible.

Here, we describe in detail how to generate ECM micropatterned glass-bottomed dishes or coverslips using μPP that bypasses many of the issues associated with other micropatterning techniques (Doyle et al., 2009). This technique utilizes high-powered two-photon (TP) laser excitation channeled through a point-scanning confocal microscope in order to physically ablate or remove a thin film of poly(vinyl) alcohol (PVA). This exposes the underlying glass surface to which ECM proteins can directly attach. PVA's high hydrophilicity and relative inertness make it an optimal candidate for deterring protein

Current Protocols in Cell Biology 10.15.1-10.15.35, December 2009
Published online December 2009 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb1015s45

adsorption to non-ablated regions of the thin film. Furthermore, PVA's high refractive index (~1.5) allows for all fluorescence techniques, including total internal reflection fluorescence (*UNIT 4.12*), even through nonablated regions of the film. In addition, by performing several rounds of μPP in series, multiple proteins can be deposited locally within microns of each other.

STRATEGIC PLANNING

While μPP is a fairly straightforward methodology, it does call for experience and knowledge using a confocal microscope. While the day-to-day processing requires little expense, two important pieces of equipment are necessary: (1) A spincoater to evenly and thinly distribute PVA over the glass surface, and (2) a two-photon laser point-scanning confocal microscope to locally ablate patterns in the PVA thin film. While each piece of equipment is an added expense (spincoater: ~$6,000 to $12,000; Zeiss 510 LSM NLO system: >$500,000) both can be found on most university campuses. Check with Material Science or Bioengineering departments for spincoating devices, and Biology or Physics departments for availability of two-photon confocal systems. Throughout this unit, we refer to the Zeiss 510 LSM NLO system (NLO stands for NonLinear Optics) as the confocal microscope and the AIM software version 4.2, which runs the microscope. It is assumed that the user has basic knowledge using the software in expert mode. Although not described here, it is our view that with slight alterations to these protocols, other two-photon confocal microscope types (i.e., Olympus) could be used to attain local ablation of the PVA thin film.

The process of μPP can be broken down into five stages: (1) glass surface activation, (2) PVA thin film deposition, (3) photoablation, (4) surface quenching, and (5) ECM adsorption. Each part of the process can be a stopping point, with the steps that follow occurring up to several days or even weeks apart. For example, following glass surface activation, dishes/coverslips can be kept desiccated for over month at 4°C, which allows you to generate 30 or more dishes at a time, but other steps can be performed in smaller batches more frequently. Table 10.15.1 shows the longevity of samples after their given stage of processing. The following sections will describe in detail each of the protocols associated with the stages, as well as provide background information and troubleshooting tips.

Table 10.15.1 Longevity of Samples After the Given Stage of Processing

Processing stage	Stability time (days)
Glass surface activation	30+
PVA thin film deposition	7-14
Photoablation	30+
Quenching	30+
ECM adsorption	1-3

BASIC PROTOCOL 1

ACTIVATION OF THE GLASS SURFACE

This protocol describes how to prepare the glass surface for direct conjugation to the PVA thin film. The first order of business is to clean the glass surface of any organic residues through acid washing. This is crucial so the silanes are uniformly distributed over the glass to provide covalent attachment of the PVA thin film. The term "activated glass" or "activation" here refers to adding a reactive aldehyde group conjugated directly to the glass surface, through silanes. The aldehydes can react directly with hydroxyl groups found on the PVA polymer, and hence the thin film generated in later steps is covalently attached

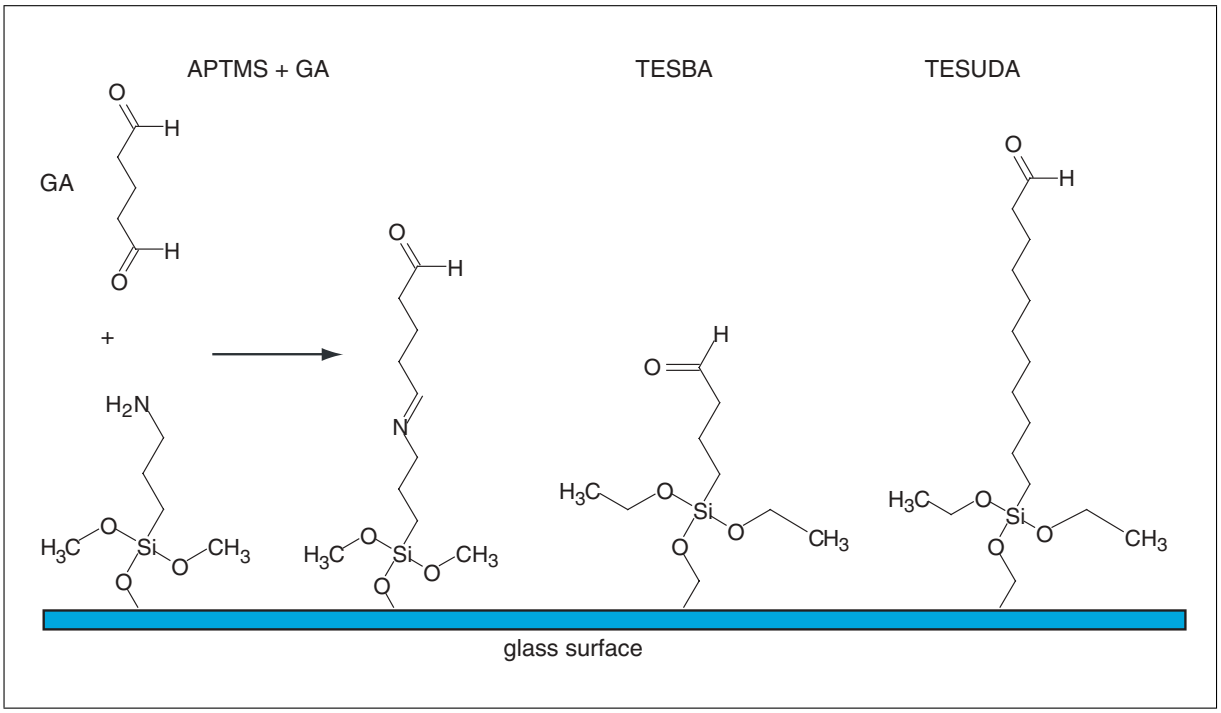

Figure 10.15.1 Schematics of APTMS, TESBA, and TESUDA conjugated to a glass surface. The addition of glutaraldehyde (GA) to APTMS-coated glass results in "activation" by attachment to the free amino group, leaving a free aldehyde to react with PVA during spin coating.

to the glass. The silanes in question are (3-aminopropl)trimethoxysilane (APTMS), triethoxysilylbutraldehyde (TESBA), and 11-(triethoxysilyl)undecanal (TESUDA). The first is an amino-terminated silane, which requires glutaraldehyde for "activation," while the latter two are both aldehyde terminated (Fig. 10.15.1). Protocols for using both types are detailed below. Caution should be used when handling silanes; they can cause severe burns and damage many surfaces.

NOTE: After the completion of each process (i.e., acid washing, silanization, etc.) it is important to visually inspect all dishes under a microscope with a 10× objective to observe if there are any imperfections in the surface. If there are, it is best to discard the affected dishes before any further steps.

Materials

50% (v/v) nitric acid
Deionized or distilled water
200 mM NaOH solution (see recipe)
(3-aminopropyl)trimethoxysilane (APTMS: 97% or higher; Gelest)
50% (v/v) glutaraldehyde (Electron Microscopy Sciences)
Aldex (Waste and Compliance Management)
Drierite (W.A. Hammond Drierite Company)

R-3603 Tygon tubing (Norton Performance Plastics)
1000-µl barrier filter pipet tips
Low-pressure air jet
Fume hood
Thirty MatTek glass-bottomed dishes (P35G-1.5-10-CMatTek)
Carrying tray
Pasteur pipets
Automatic pipettor

2000-ml beaker
Scale
Scintillation vials or other small glass containers
Drying oven
500-ml screw-top container (e.g., Nalgene) or other similar desiccated containers for storage

Prepare the glass surface for silanization

1. Before starting the acid washing, create a compressed air blower using 3 ft of Tygon tubing and a 1000-µl barrier filter pipet tip. Connect one end of the tubing to a low-pressure air jet (commonly found on most laboratory benches). Insert the pipet tip into the other end, tip out.

   Alternatively, this can be attached to a compressed air or nitrogen tank. This will used throughout the process to dry the dishes. Use low pressure for drying, $^1/_4$ to $^1/_3$ of the way open or under 10 psi.

2. In a fume hood, arrange thirty MatTek dishes on a carrying tray.

3. Using a Pasteur pipet fit into an automatic pipettor, add a small amount of 50% (v/v) nitric acid to each dish, just enough to cover the glass area, usually between 300 and 500 µl. Incubate for 25 min at room temperature.

4. After the incubation period has elapsed, place dishes in a large 2000-ml beaker and rinse with deionized or distilled water, under continuous flow for a minimum of 4 hr or overnight.

   Be sure that dishes are not floating.

5. Remove dishes from water and aspirate remaining water from dishes.

6. Arrange dishes on a carrying tray again, add 300 to 500 µl of 200 mM NaOH to each dish, and incubate for 15 min at room temperature.

   This step helps to exchange H^+ residues associating with the glass from the acid washing and neutralizing or replacing them with OH^-, which is more conducive for the binding of the methoxy or ethoxy portion of the silane.

7. Rinse dishes two times, each time with 3 ml deionized or distilled water, then dry under compressed air (device created in step 1).

Silanize glass surfaces

8. Place a scintillation vial on a scale, tare, and weigh out 1% (w/v) APTMS.

   CAUTION: *Silanes corrode metals, plastics, and all organics. Only use glass for transferring and wear chemical-resistant gloves when handling.*

9. Insert a glass Pasteur pipet into the APTMS and tilt container to 45°. Allow capillary action to bring the APTMS into the pipet.

10. Place your gloved finger on the top open-end of the pipet, transfer, and release a total of 100 mg into the tared vial. Add 9900 µl distilled water to the scintillation vial. Replace vial cap, mix gently, and incubate for 1 min at room temperature.

11. Add ~300 to 500 µl of the 1% APTMS solution to each dish, only covering the glass portion. Incubate 5 min at room temperature.

12. Aspirate APTMS and dispose of properly (contact your chemical safety officer for the proper disposal).

13. Rinse two times, each time with 3 ml distilled water over 10 min.

14. Aspirate the water and dry the dishes with compressed air.

15. Replace the dish lids and incubate at 65°C in a drying oven for a minimum of 3 hr.

    This step cures the silanes. They can also be left desiccated at room temperature overnight and achieve the same level of curing.

    Incubation above 65°C leads to warping of the dishes.

Activate amino-terminated silanes with glutaraldehyde

16. Mix 100 µl of 50% glutaraldehyde with 9900 µl distilled water to make a 0.5% glutaraldehyde solution. Add ~300 to 500 µl of the solution to only the glass surface of the silanized dishes. Incubate for 30 min at room temperature.

    To convert this amino-terminated silane (APTMS) into an active aldehyde, glutaraldehyde (a bi-functional aldehyde) is added to react directly with the amino group.

17. Remove the glutaraldehyde solution by aspiration and discard properly in Aldex.

    Aldex is used to inactivate the reactive aldehydes allowing for proper disposal.

18. Rinse dishes three times, each time in 3 ml distilled water over 20 min.

19. Aspirate the water and blow-dry the surface again.

20. Store up to 1 month at 4°C in a desiccated storage container (add Drierite to the container bottom or to a small vial placed inside it).

USING ALDEHYDE-TERMINATED SILANES FOR SURFACE ACTIVATION

ALTERNATE PROTOCOL 1

In order to bypass the glutaraldehyde-activation steps of the Basic Protocol, TESBA or TESUDA, which are already terminated in a reactive aldehyde group, can be used for silanization. Both are triethoxysilanes, which renders them water insoluble and requires ethanol as the solvent.

***Additional Materials** (also see Basic Protocol 1)*

Absolute ethanol (200 proof)
Triethoxysilylbutraldehyde (TESBA) *or* 11-(Triethoxysilyl)undecanal (TESUDA; both from Gelest)

Prepare the dishes

1. Follow steps 1 through 7 of Basic Protocol 1 for acid washing of glass-bottomed dishes.

Silanize the glass surface

2. Place a scintillation vial on a scale, tare, and weigh out 1% (w/v) of either silane.

3. Insert a glass Pasteur pipet into the silanes and tilt container to 45°. Use capillary action to bring the silanes into the pipet.

4. Place your gloved finger on the top open-end of the pipet, transfer and release a total of 100 mg into the tared vial.

5. Add 9900 µl of absolute ethanol to the scintillation vial. Mix gently with the cap on and incubate for 5 min at room temperature.

6. Add ~300 to 500 µl of the 1% silane solution to each dish, only covering the glass portion. Incubate for 5 min at room temperature.

7. Dispose of the silanes properly (contact your chemical safety officer for the proper disposal).

Rinse and dry the silanized dish

8. Flooding the dish, rinse twice, each time with 3 ml absolute ethanol followed by a single rinse with 3 ml distilled water for 2 min.
9. Aspirate the distilled water and dry dishes with compressed air.
10. Replace the dish lids and incubate at 65°C in a drying oven for a minimum of 3 hr.

    This step cures the silanes. They can also be left desiccated at room temperature overnight to achieve the same level of curing.

    Curing at temperatures above 65°C leads to warping of the dishes.
11. Store up to 1 month at 4°C in a desiccated storage container (add Drierite to the container bottom or to a small vial placed inside it).

BASIC PROTOCOL 2

GENERATING POLYVINYLALCOHOL (PVA) THIN FILMS

Here, we describe the mixing of the PVA solution and spincoating it into a thin film on the activated glass dishes. Spincoating is a process by which a solution (in this case PVA) is thinned evenly across a surface using centripetal force. This is often used in the semiconductor industry to apply agents to silicon wafers. A flat glass disc or dish is attached via vacuum suction to a central "chuck" (Fig. 10.15.2). Chucks come in many sizes to fit the size of the disc/dish. The vacuum secures the disc from moving during spinning. Most Spincoaters require a vacuum source (in our case a gel pump) and a source of high-pressure air, (a normal compressed air cylinder). The latter is to keep liquids and other materials from coating the rotor.

Materials

Distilled water
Poly(vinyl) alcohol powder (mol. wt. between 13,000 and 100,000; 98% hydrolyzed minimum; Sigma)
2 N HCl
5 M NaCl

400-ml glass beaker
Stirrer/hot plate
50-ml conical tubes
Scale
Flea Micro magnetic stir bar (VWR)
50-ml Steriflip (0.2-μm pore size)
Gel vacuum pump
High-pressure compressed air source (e.g., compressed air cylinder)
Vortex
5 to 10 MatTek dishes with activated glass surface (Basic Protocol 1 or Alternate Protocol 1)
Pipettor
Spincoater with a chuck capable of accepting 50-mm or smaller items (A WS-400B-6NPP/LITE spincoater from Laurell Technologies shown in Fig. 4.15.2 is used here)
Scintillation vial or 35-mm tissue culture dish
Nalgene 500-ml screw top or other similar containers for storage

Make the PVA solution

The PVA solution can be used repeatedly over a period of 1 week. We recommend making it fresh weekly.

Figure 10.15.2 Laurell Technologies Spincoater with an "activated" MatTek dish in position before spincoating PVA/HCl solution. The chuck (arrow) can be changed according to the size required for the dish/disc being spun.

1. Add ~270 ml of water to a 400-ml glass beaker and begin heating on a stirring hot plate at medium-high heat.
2. Weigh out 2.835 g of PVA into a 50-ml conical tube.
3. With the tube still on the scale, bring the weight/volume up to 50 g with distilled water. Add a stir bar to the conical tube and cap.
4. Loosen the cap of the tube slightly and place the PVA-containing tube into the beaker of hot, near boiling water. Be sure the water line of the beaker is between the 35 to 40 ml lines on the conical tube.

   PVA will not go into solution until it reaches ~90°C.
5. Turn on the stirring mechanism to medium and continue heating until PVA goes into solution, ~10 to 15 min. Have the 50-ml Steriflip ready.
6. Inspect the PVA solution and be sure no PVA crystals/powder remains. When sure, immediately filter the PVA solution into the Steriflip (0.2 μm) using vacuum.

   The PVA must be hot (above 90°C) to filter. Once cooled, the viscosity of the solution increases and makes filtering nearly impossible.
7. Allow the PVA solution to cool to room temperature.
8. Once cooled, transfer 8876 μl to a new 50-ml conical tube. To this, add 1124 μl of 2 N HCl and mix by vortexing.

   This acidified PVA solution can now be used for spincoating.

Spincoat thin films of PVA

9. Retrieve 5 or 6 of the "activated" MatTek dishes that were stored desiccated at 4°C (Basic Protocol 1 or Alternate Protocol 1).

10. Add ~300 to 500 µl of the PVA/HCl solution with a pipettor to the glass surfaces of the dishes and incubate for 5 min at room temperature. Be sure to completely cover the glass area.

11. Center a single dish on the chuck of the spincoater. Follow the manufacturer's instructions for operation. Pull a vacuum and turn on your compressed air. Initiate your spin. When finished, repeat for each dish.

    For spincoating, we have found that a relatively short spin of 40 sec at a high velocity (7000 rpm) works best for generating a thin coating of PVA, with few imperfections. Acceleration of the spincoater is also important: 550 rpm gets the dish up to speed within 18 sec. However, you may need to adjust all variables (time, velocity, and acceleration) to determine which best suits your needs.

12. Add 2 to 3 ml of 5 M NaCl to either a scintillation (no cap) vial or a 35-mm tissue culture dish and place in the storage container.

13. Place dishes within the storage container and incubate a minimum of 2 hr before ablating. Store dishes within the container at 4°C for up to two weeks prior to photoablation.

    High molarity or super-saturated salt solutions are effective in regulating humidity within a closed environment with each salt type maintaining a different relative humidity. For NaCl, it is ~50% to 60%, which is optimal for reducing issues with PVA crystallization, and loss of surface hydrophilicity.

    At this point in the processing, the activated glass surface is now coated with a submicron (between ~100 to 200 nm) thin film of PVA, which will deter protein adsorption and cell attachment (Fig. 10.15. 3).

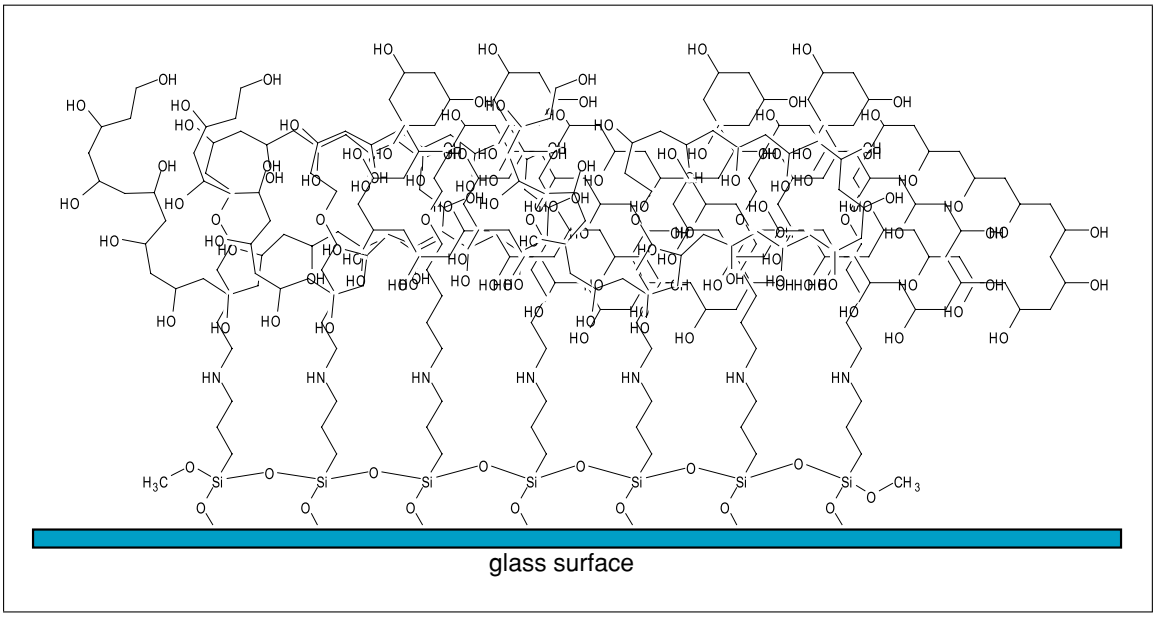

Figure 10.15.3 Representation of the PVA thin film generated on dishes following processing through Basic Protocol 2 using APTMS together with glutaraldehyde as the cross-linker.

PHOTOABLATION WITH TWO-PHOTON CONFOCAL MICROSCOPY

In this section, the actual process of photoablation is described. It is divided into several sections for clarity. First, the configuration settings for the confocal microscope are addressed, followed by the pre-ablation setup and how to generate pattern templates. We then detail how to photoablate single fields of view (FOV), and finally how to automate the process using the Multi Time macro and tiling functions. Throughout this section and the ones that follow, we will often be referring to dialog boxes and buttons within the AIM software. The title of each dialog/button will be **bolded** for easier referencing. For all intents and purposes, the actual photoablation process merely utilizes the intrinsic capabilities of a point-scanning confocal microscope. However, the major difficulty is in setting the proper configurations to elicit localized ablation efficiently. Once configuring is complete, the process can be performed with relative ease.

Materials

Glass cleaner
Immersion oil

Zeiss 510 LSM NLO confocal microscope or later model with 1.5-W minimum tunable two-photon titanium:Sapphire laser, and a 633-nm HeNe2 laser (5 mW power output)
AIM software (Zeiss MicroImaging)
63× oil immersion objective with numerical aperture of 1.3 or higher capable of NLO transmission
PVA thin film-coated MatTek dishes (Basic Protocol 2)

Set up confocal microscope configuration

The following steps are meant to guide you through configuration setup and scan settings that are required for the ablation process. Throughout this section are screen shots of the AIM software (version 4.2) to help in understanding how and where to change settings (indicated by bolded numbers in figures). It is important to note that the direct light path from the TP laser to the confocal scan head should be aligned at least once a month. Ablation efficiency is greatly reduced when mirrors are misaligned. Have a qualified individual align the mirrors (microscope facility director, Zeiss service representative, etc.) at 755 nm before beginning the ablation process.

1. Turn on the confocal microscope and boot the computer. Be sure to turn the two-photon laser from the standby position to the on position.

   There is no need to ignite the mercury arc lamp since it is not used to find the thin film.

2. Open the AIM software in expert mode.

3. Go into the **Acquire** menu and open the Laser window (Fig. 10.15.4, 1; i.e., the inserted numeral 1 in Fig 10.15.4); turn on the 633-nm laser and tune the two-photon to 755 nm.

4. In the same Acquire menu, select **Configuration** (Fig. 10.15.4, 2) to open up the configuration window (Fig. 10.15.5).

5. In Channel Mode, select **Singletrack** or **Multitrack**.

6. For the primary dichroic (Fig. 10.15.5A), select the HFT KP 700/488 (1).

   This allows the near-infrared (NIR) light from the two-photon to be reflected to your sample. While the 633-nm light is not properly matched for the dichroic, it provides back reflection of the glass/thin film interface, similar to backscatter, helping you find the appropriate z-plane for ablation.

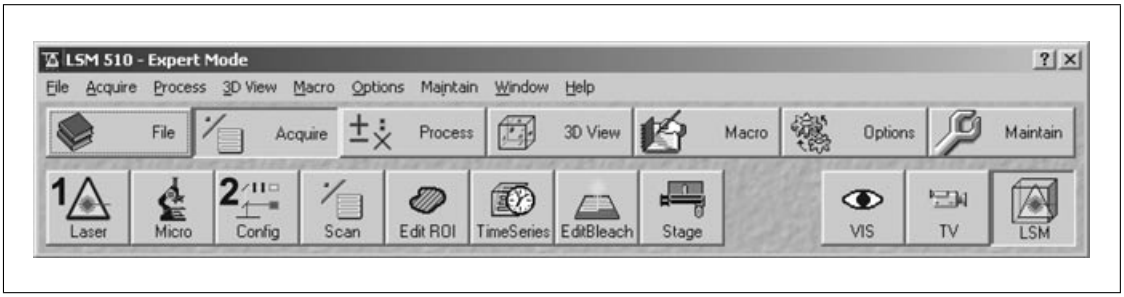

Figure 10.15.4 The LSM 510 AIM software Expert Mode window with the Acquire menu open. All screen shots of the AIM software are courtesy of Carl Zeiss MicroImaging.

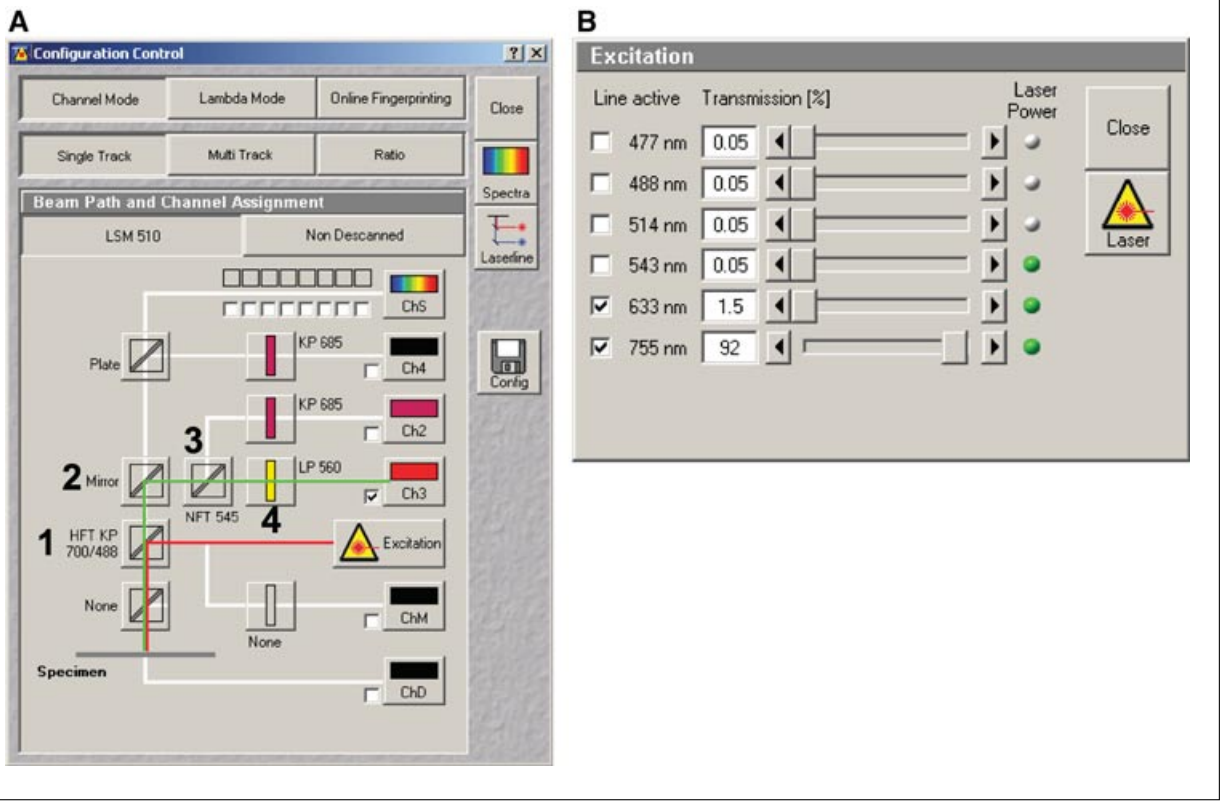

Figure 10.15.5 Configuration Control window screen shot for Zeiss' AIM software (version 4.2). (**A**) Red line depicts the light path from the lasers to the PVA-coated dish, while the green line illustrates the reflected light path from the dish to the channel 3 photomultiplier tube (Ch3). Numbers show the primary dichroic, (1) mirror (2), and filters (3 and 4) required for obtaining a reflected light image of the thin film surface. (**B**) The laser excitation panel with 633-nm and 755-nm TP settings. Courtesy of Carl Zeiss MicroImaging. For color version of this figure go to *http://www.currentprotocols.com/protocol/cb1015*.

7. Select photomultiplier tube or channel 3 (**Ch3**) and set the following filters along the light path illustrated below: **Mirror** (2), **NFT 545** (3), and **LP 560** (4).

8. Set the 633-nm laser to 1.5% power and the 755-nm TP to ~90% by selecting **Excitation**, this opens the Excitation window (Fig. 10.15.5B).

   The percent power is a reflection of the total amount allowed through the AOTF or AOM for the 633-nm HeNe2 and the 755-nm TP, respectively. Using the TP at 90% does not affect the lifetime of the laser.

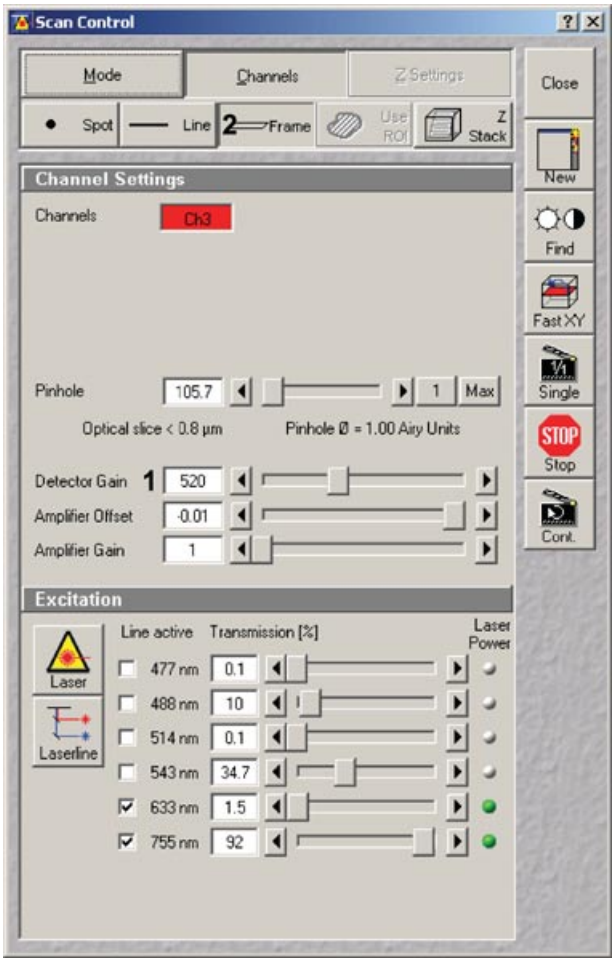

Figure 10.15.6 Scan Control window illustrating the Channels dialog panel. Courtesy of Carl Zeiss MicroImaging.

9. Click on the **Config** button on the middle right-hand side of the window. Save the configuration at this point.

   You may want the title to be basic at this point. Later on, this basic version can be changed and saved to reflect your zoom and scan settings (discussed in the next few steps).

10. Now that you have created and saved the proper basic configuration, open the **Scan** window and select the **Channels** menu (Fig. 10.15.6). Set the detector **gain** to approximately halfway up, in the low 500s (Fig. 10.15.6, 1).

11. Be sure that frame scan is selected (Fig. 10.15.6, 2) and the pinhole is set to 1 Airy for a 63× objective.

12. Select the **Mode** window (Fig. 10.15.7).

    The Mode window is divided vertically into four separate control boxes: (1) objective, line stepping, and frame control, (2) scan speed, (3) pixel depth, scan direction, and averaging, and (4) zoom, rotation, and offset. Because of the complexity of this window, each control box will be addressed in separate steps below.

13. **Objective, line stepping, and frame control** (Fig. 10.15.8): For µPP, this box in the Mode window is important for controlling the pixel size, which will impact the

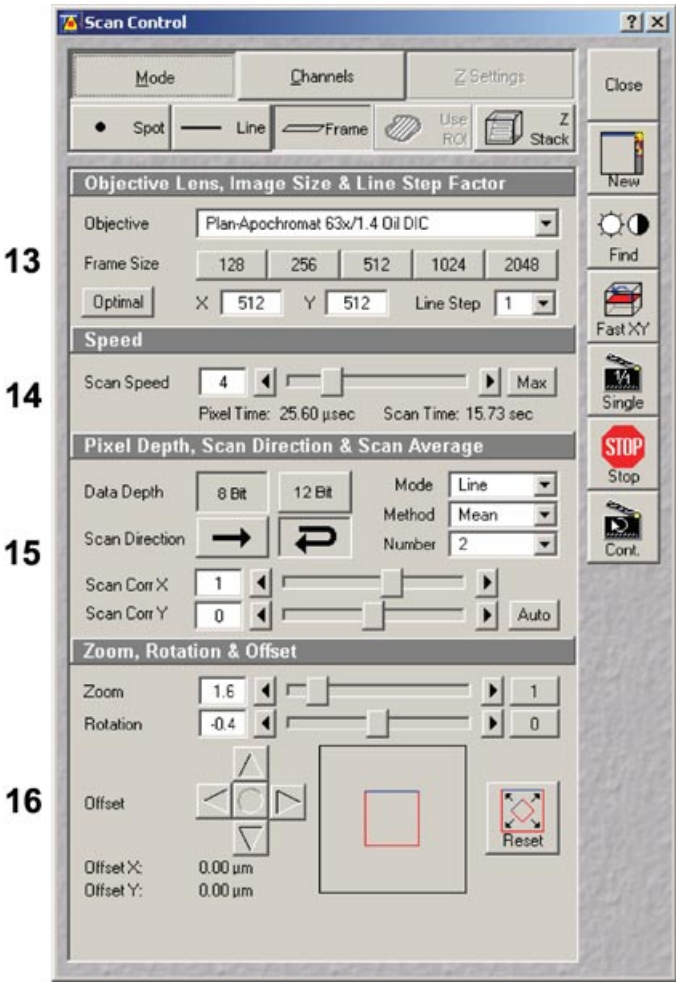

Figure 10.15.7 Scan Control window illustrating the Mode dialog panel. The four boxes within the panel are discussed in detail in the step numbered on the left side of the panel with enlarged images. Courtesy of Carl Zeiss MicroImaging.

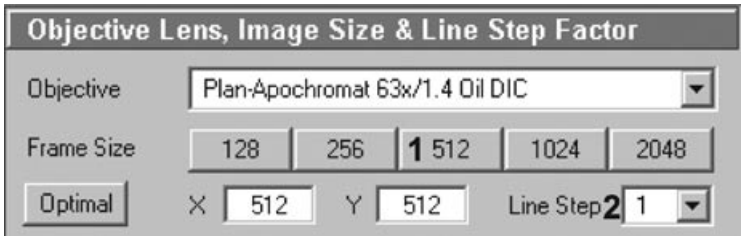

Figure 10.15.8 Objective, line stepping, and frame control box in the Scan control window of the AIM software. Courtesy of Carl Zeiss MicroImaging.

region of interest (ROI) template, how detailed or defined the ablation patterns are, as well as the total scan time (the larger the pixel array the longer the scan time).

We have found that using a 512 × 512 array is a good intermediate (Fig. 10.15.8, 1): fast scanning with a reasonably high level of detail. ***Line step*** *should be 1 (Fig. 10.15.8, 2). Objective can be varied but should have a high numerical aperture (N.A), minimum of 1.0.*

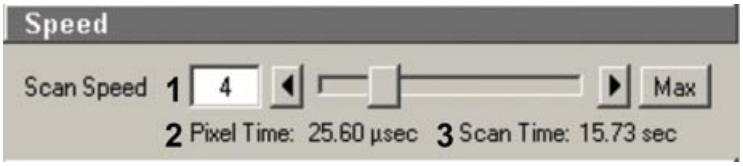

Figure 10.15.9 Scan speed box in the Scan control window of the AIM software. Courtesy of Carl Zeiss MicroImaging.

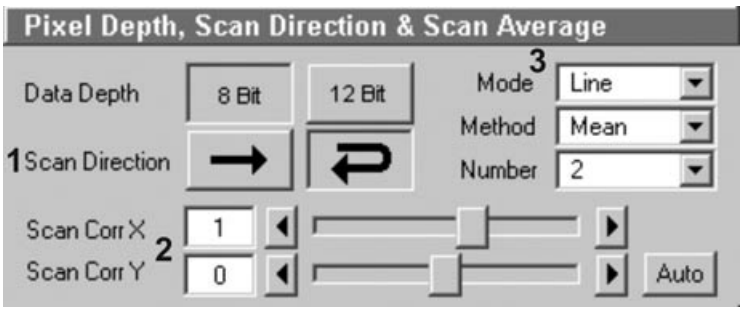

Figure 10.15.10 Pixel depth, scan direction, and averaging box in the Scan control window of the AIM software. Courtesy of Carl Zeiss MicroImaging.

14. **Scan speed** (Fig. 10.15. 9): This sets the relative rate of speed the galvanometric mirrors move and scan the FOV or the ablation area. As scan speed increases (Fig. 10.15. 9, 1), both pixel time and Scan time (Fig. 10.15.9, 2 and 3, respectively) decrease. The Pixel Time (or dwell time) is the amount of time the laser dwells on any given pixel in the FOV. Since efficiency of the ablation process is directly dependent on the total amount of light energy (in µjoules/µm^2), the dwell time is dependent on the total power output of the TP laser (in our case ~1200 mW at 755 nm). A scan speed of 4 using a 63× provides efficient ablation with our setup.

    Scan speed will need to be decreased when the pixel size changes, for instance, when a digital zoom is used to generate smaller patterns with the same objective lens. This will be discussed in later sections.

15. **Pixel depth, scan direction, and averaging** (Fig. 10.15.10): **Scan direction** and **scan average** are equally important here. Choose to reverse scan direction (Figure 10.15.10, 1; reverse arrow). This decreases the scan rate by half when compared to the single direction. When choosing a scan, the correction dialog box is opened. This helps to align the scanning properly (Fig. 10.15.10, 2; see your Zeiss representative or manual for more on how to do this). Scan average (Fig. 10.15.10, 3) provides the same basic function it normally does when imaging: repeated scanning of the same line or frame in the FOV. However, instead of decreasing background noise it adds a second (or more) pass over the area being ablated. For example, increasing this number from 1 to 2 overall doubles the laser dwell time by performing a second pass. It will also double the scan time (from step 14). Leave the scanning in line mode. The method does not matter since you are not saving the image files.

16. **Zoom, rotation, and offset** (Fig. 10.15.11): In this box, you can set the appropriate zoom (Fig. 10.15.11, 1). This is helpful if you want to decrease the size of an entire ROI template. For example, you can generate a circle pattern with a diameter of 10 µm simply by zooming in by 2× with a ROI template containing a circle with a 20-µm diameter. Here it is set to 1.6, which, when using a 63× objective, is equivalent to 100×. This is not an optical or a true digital zoom: the same pixel array is scanned but

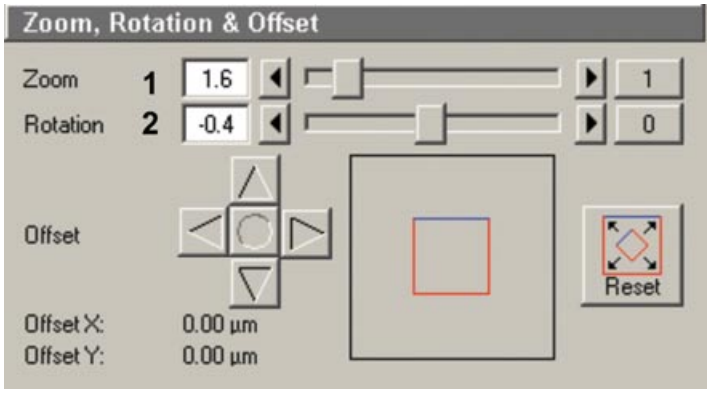

Figure 10.15.11 Zoom, Rotation, & Offset box in the Scan control window of the AIM software. Courtesy of Carl Zeiss MicroImaging.

simply in a smaller region on the galvanometric mirrors. Rotation (Fig. 10.15.11, 2) is important only when generating multiple patterns (same or different) next to each other, and comes into play in later sections when using the automated tiling function. In many confocal microscopes, the galvometric mirrors are slightly offset from the true horizontal or vertical plane of the stage. By correcting the rotation for this offset, larger patterns (i.e., long lanes or lines) can be flawlessly connected and generated. Setting the proper rotation offset is discussed later in Support Protocol 1. FOV offset is normally not changed.

The Zoom function can also go below 1 to 0.7 giving you a larger FOV. However, the rotation dialog will be reset to 0 and cannot be changed.

17. At this point, the confocal configurations are properly set. Save the Configuration again in the Configuration control panel, as you did in step 3 above.

Pre-ablation set up

While the previous section led you through the proper confocal configurations required for efficient ablation of the PVA thin film, this section will guide you through how to find the proper *z*-plane to ablate the thin film, how to align the *z*-plane, and how to generate ROI templates for use in ablation. After these steps, ablation can be performed.

18. Bring your PVA thin film dishes in their container to room temperature. Place the dishes you will be patterning near or on the microscope to allow them to acclimate to the temperature of the confocal microscope since differences in oil, objective, and dish temperature will cause focus drift.

19. Boot the system as before in step 1, turning on the appropriate lasers.

20. Clean the bottom of the dish with glass cleaner thoroughly and dry. Add a small drop of oil directly to the bottom of the dish and place it in the single dish holder.

21. Before proceeding, make sure the stage insert is clean and properly fit into the stage with all adjustment screws up (not contacting the stage plate).

22. After loading the software, load the configuration for ablation saved in previous steps.

23. Bring the 63× objective up to your sample using the course focus knobs until the oil hits the glass.

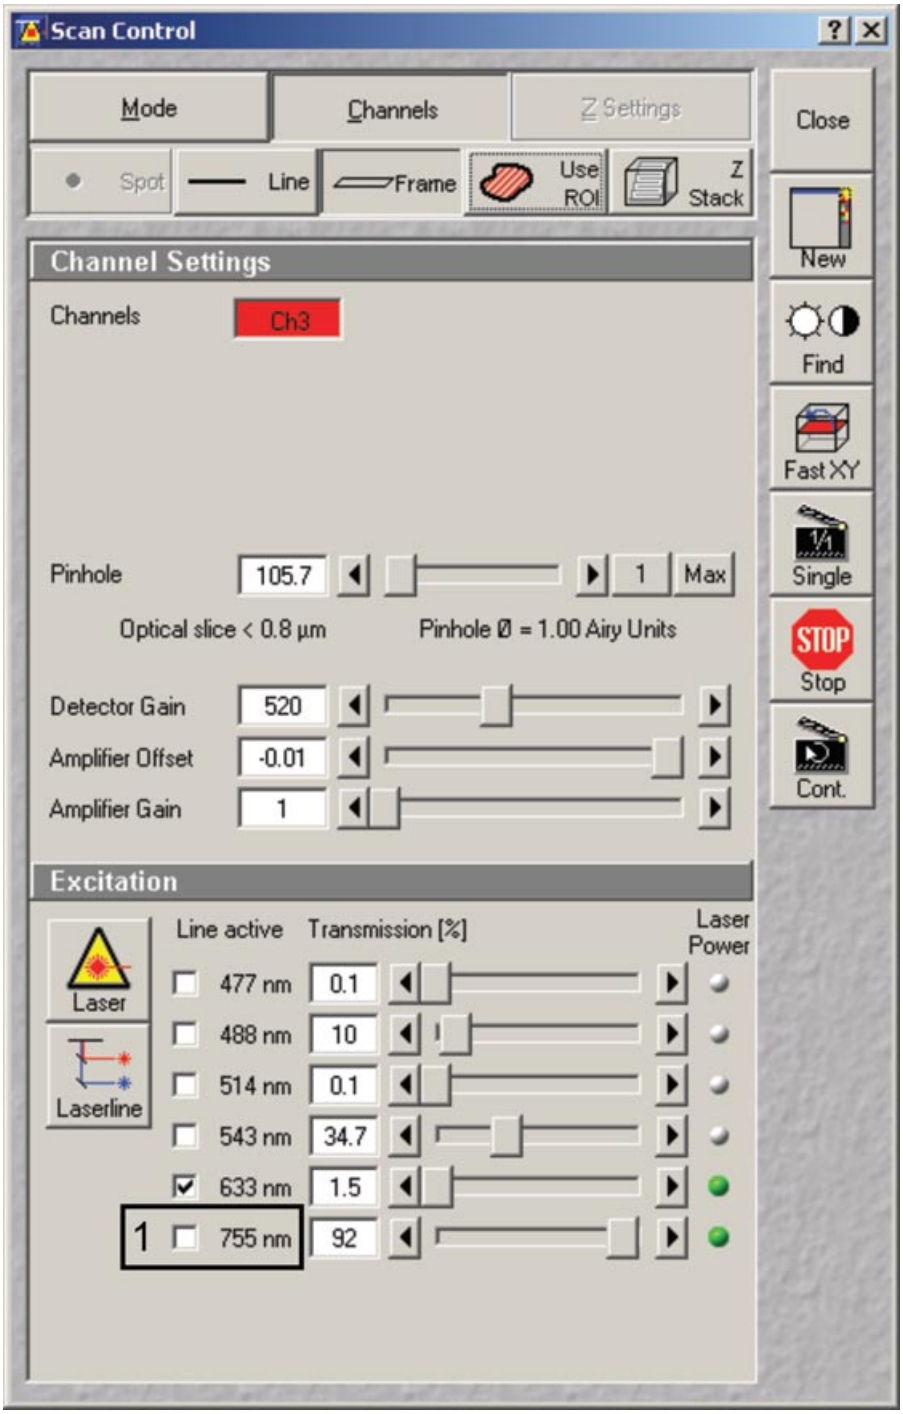

Figure 10.15.12 Scan Control window with Channels panel displayed. Box indicates an unchecked 755-nm laser line. Courtesy of Carl Zeiss MicroImaging.

24. Before using Fast XY to find your sample, be sure to inactivate the 755-nm laser line in the **Scan control** window under the **Channels** panel (Fig. 10.15.12, 1 black box).

    This is imperative since this amount of light will ablate the surface as soon as you reach the focal plane.

25. Using the **Fast XY** function, begin scanning for the PVA thin film surface by rotating the fine focusing knob (up: clockwise on the right-hand side of the microscope). Do

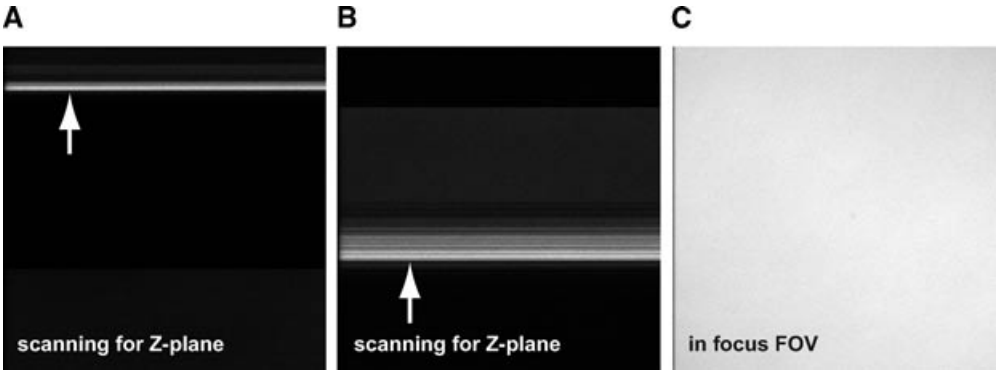

Figure 10.15.13 Reflected light images while trying to find the PVA thin film. (**A,B**) Images were taken while scanning in the *z*-plane. The bright linear areas indicate passing by the glass/PVA thin film (arrows). (**C**) Once found, the field of view (FOV) should appear equally (uniformly) bright if the surface is level.

this at a moderate to fast pace moving 300 to 400 μm in ~10 sec time. While doing this, keep your eye on the monitor. When you reach or pass the focal plane it will appear as a bright line or set of lines on the screen in Fast XY mode (Fig. 10.15.13A,B).

26. Adjust the objective *Z* position until nearly the entire FOV is in focus (Fig. 10.15.13C).

    Once in focus, you may need to adjust the PMT gain up or down depending on the brightness. The brightest z-plane, which is the glass interface, should be near pixel saturation (~255 for an 8-bit image).

27. More often than not, the FOV's brightness is unevenly distributed, such as in Figure 10.15.14A, and requires adjustment since the TP light is maximally absorbed only at the focal plane. To adjust properly you first need to know which corner or edge is low. Adjust the focus so the focal plane is below the glass. Slowly raise the objective until you start to see brightness in the FOV: whichever area appears bright first is low and needs to be raised using the adjustment screws in the stage insert plate (Fig. 10.15.14B). In the example in Figure 10.15.10A, both the upper-right and lower-right adjustment screws need to be turned clockwise, or screwed in to raise the stage up. Perform several half turns. The image should go black, indicating the stage has been adjusted. Refocus with the fine focusing knobs. Repeat this process until the FOV demonstrates even illumination, as in Figure 10.15.13C. This adjustment process should be performed before ablation of any dish. When finished with each dish return adjustments screws to their neutral positions.

28. Wait 5 min for the focus to adjust due to temperature variations, and then refocus to the brightest FOV. Open the **Stage and Focus control** window (Fig. 10.15.15). In the stage control window, set the **Z Focus step** (Fig. 10.15.15, 1) to 0.25 μm.

29. Using the focusing arrows (Fig. 10.15.15, 2), raise the focal plane to 0.75-μm above the brightest FOV. This is the proper height to perform ablations. The FOV should be slightly dimmer. Set this point to zero (**Z**: Fig. 10.15.15, 3).

30. In the stage position box, select **zero** (Fig. 10.15.15, 4). Now you will know the position of your first ablation site.

31. Now that the dish has been leveled, ablation can commence once you have generated a ROI template. In essence, this is the same way you would generate ROIs for FRAPing (Fluorescence Recovery After Photobleaching, *UNIT 21.1*) a sample.

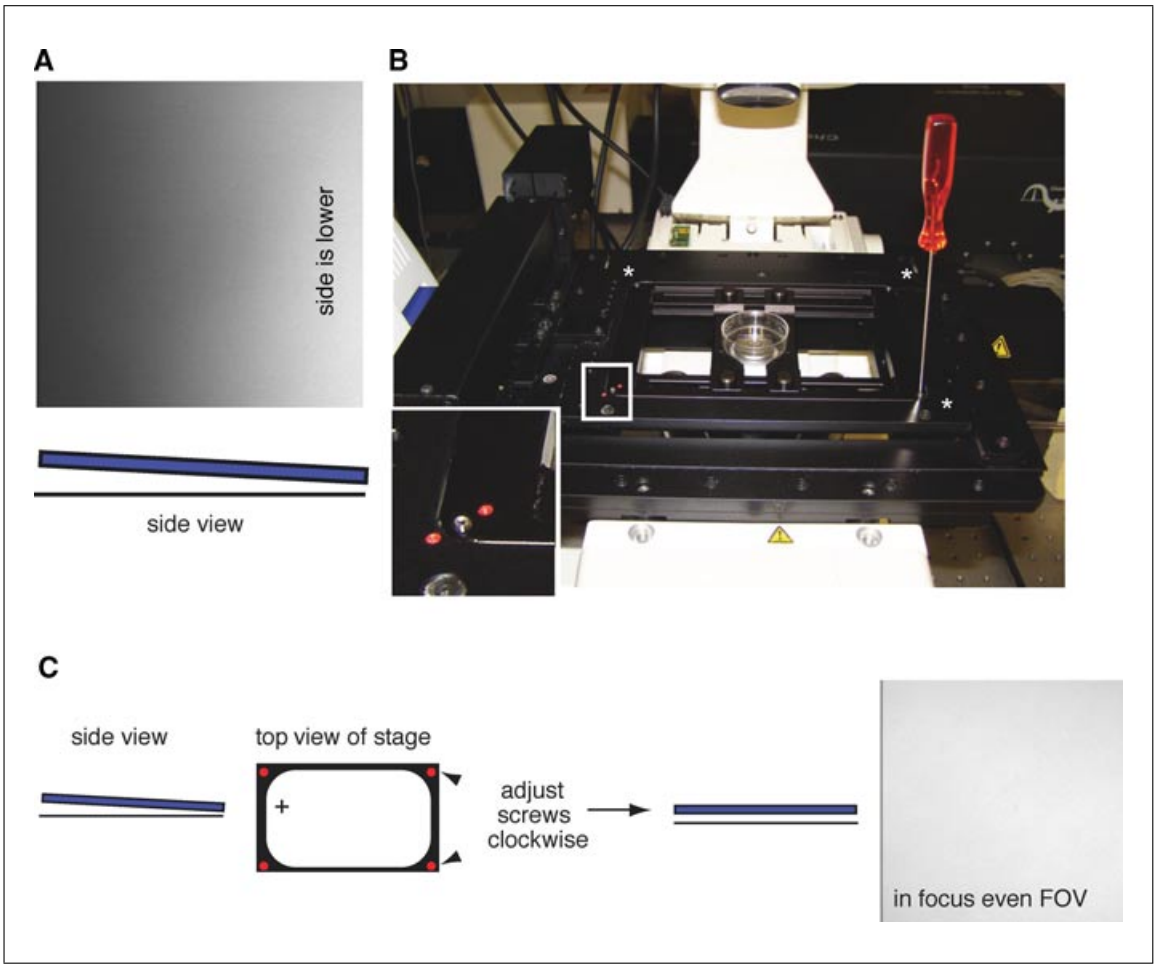

Figure 10.15.14 Dish leveling. (**A**) Reflected light image of a dish that is slightly tilted down on the right, as shown by the increase in brightness as you focus up to the glass surface. Below the image is a cartoon side view representing the glass (gray) with respect to the horizon (black line). (**B**) Image of the confocal stage. Inset shows a magnified view (white box) of one of four adjustment screws in the stage plate. The other adjustment screws are indicated by asterisks. (**C**) Simplified schematic of the tilted dish in (A) and how to correct the tilt by screwing in both right-side adjustment screws, until an in-focus evenly illuminated FOV is attained (right-side of arrow).

32. To generate ROIs, select the **Edit ROI** window (Fig. 10.15.16A,C). The window allows you to generate and save hundreds of different ROIs in a single FOV as templates.

33. To begin, in the Scan Control window select **New** to generate a new image window.

34. From the bottom dialog boxes in the Edit ROI window (Fig. 10.15.16A, 1 and black box), select a shape (i.e., circles, polygons rectangles, etc.). Then draw the shape onto the new image window (Fig. 10.15.16B). Once drawn, the shapes size and location information will appear in the Edit ROI window, checked (Fig. 10.15.16C, 4). From here, you can resize or reposition the shape or uncheck it and remove it.

    Several macros are available free from Zeiss that allow you to repeat a single ROI multiple times on the same window, which is helpful for generating a dot-based matrix, etc. It is also helpful to know the size of a single pixel with the objective and zoom you are using. This can be found by selecting the Info button in the image window (Fig. 10.15.16B, 2).

35. The **X and Y Scaling** (Fig. 10.15.16B, 3) can then be used for pattern spacing and sizing, as well as knowing the size of the FOV, important for moving the stage

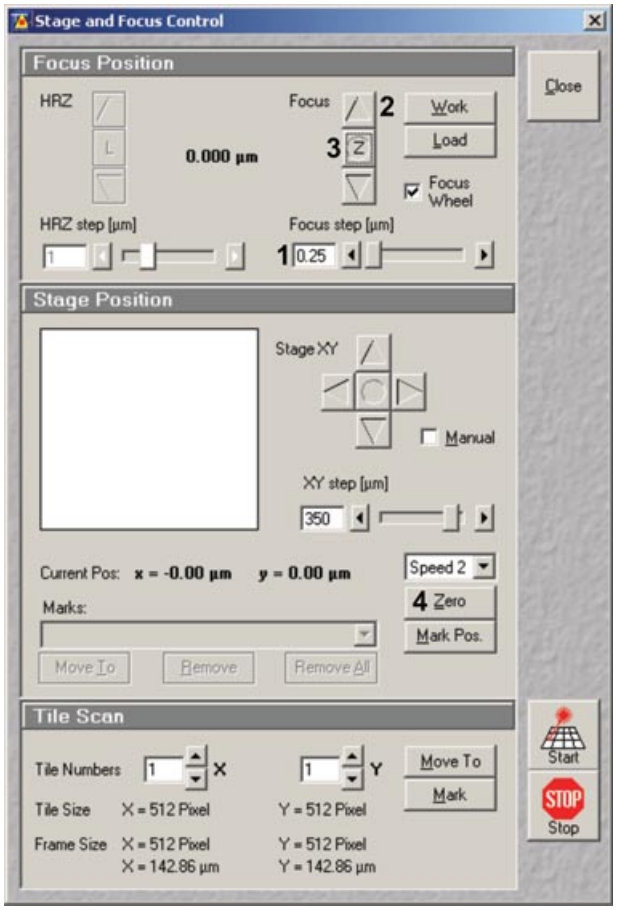

Figure 10.15.15 Stage and Focus Control window in the Zeiss AIM software. 1 indicates the focus step set at 0.25 µm. 2 indicates toggle arrows for focus position. 3 indicates the focus zeroing button. 4 indicates the Stage position zeroing button. Courtesy of Carl Zeiss MicroImaging.

horizontally or vertically when generating larger repeated patterns. Save and name the template when completed.

Photoablate the thin film

36. With the above steps completed, you can now proceed with photoablation. First, check that you are still focused ~0.75-µm above the brightest focal plane and readjust if necessary.

37. In the **Scan control** window under the **Channels** panel, check the 755-nm TP to on.

38. Select the ROI template of your choice from the **Edit ROI** window. In the Scan control window, select the **ROI** button (2nd row from top 2nd from the right, see Fig. 10.15.12).

39. Select **Single** scan button. The ROIs in the template should be slowly scanned from top to bottom, taking ~15 sec with the parameters set and discussed earlier.

    Because of the intense level of light hitting the sample, the ROIs will appear saturated with light (255 on an 8-bit scale).

40. Once the Scan has completed, uncheck the TP 755-nm line in the scan window, deselect the ROI tab, and **Fast XY** scan the FOV to observe the post ablation result as shown in Figure 10.15.17.

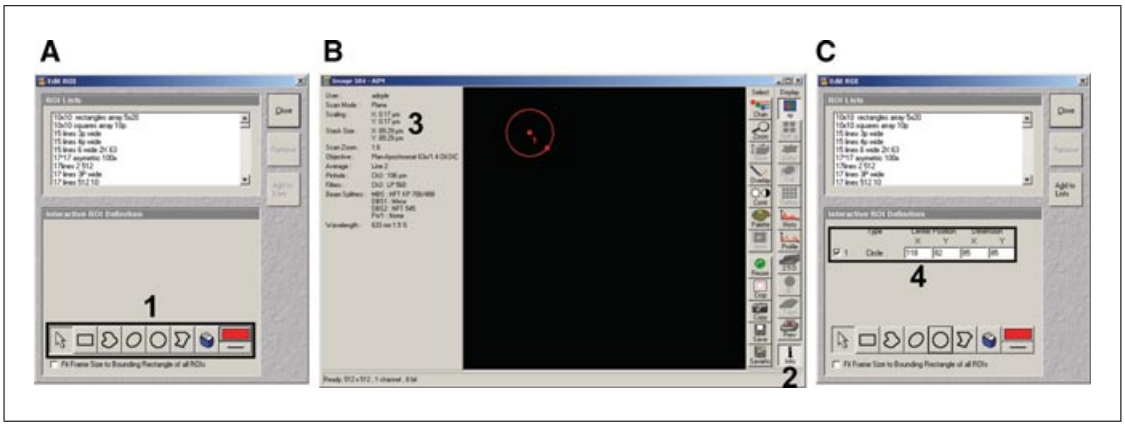

Figure 10.15.16 Edit ROI window and pattern generation. (**A**) Edit ROI window with the shape dialog boxes (1 and black box). (**B**) Example of generating a single circle once the circle dialog button is selected in the Edit ROI window in (A). 2 indicates the information button, which shows on the on the left-hand side of the image window. 3 (upper left) indicates where pixel scaling information can be found. (**C**) Edit ROI with the ROI definitions (4 and black box) for the circle shown in panel (B). Courtesy of Carl Zeiss MicroImaging.

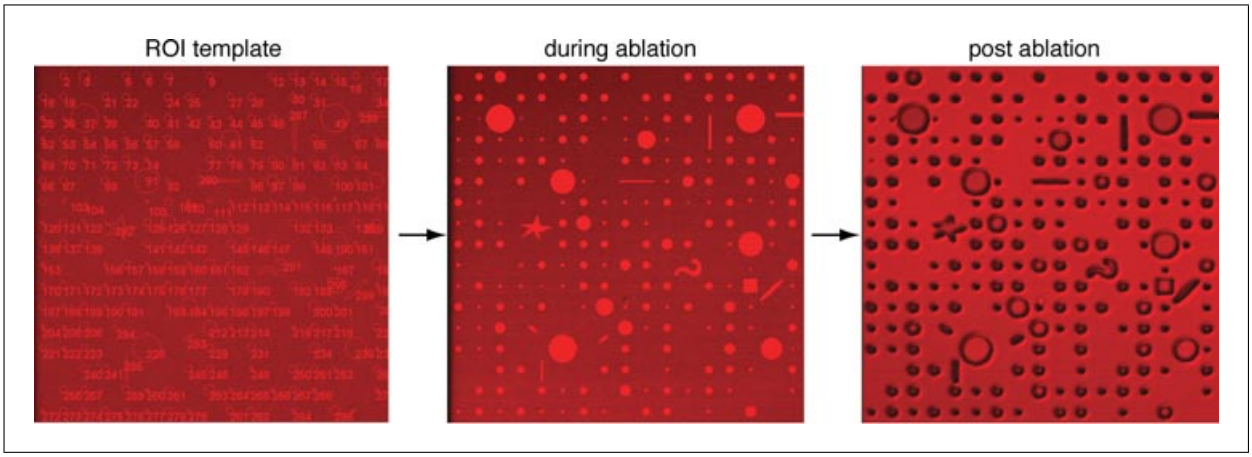

Figure 10.15.17 From template to ablated pattern. The three images representing the ROI template (left), what is observed during the ablation (middle), and the post-ablation pattern (right).

41. To generate multiple FOVs of the same pattern use the **Stage and Focus control** window to move the stage over by setting the *xy* step to exactly one FOV (use the calibrated *xy* information multiplied by your scanning window size, assuming *x* and *y* are equal).

    This works best for dot or separated patterns such as the example illustrated in Figure 10.15.17. However, if using a linear pattern, which needs to be seamlessly continued, we recommend reducing the xy step by 1 or 2 μm to provide an appropriate overlap.

Automate μPP with macro functions

To this point, you should be able to efficiently photoablate PVA thin films for a single FOV. Once the configurations have been set correctly and the ROI templates are generated, there is no true need to sit at the scope moving the stage from place to place if the process can be automated. This can be achieved through the **Multitime macro** in the AIM software. Originally intended for time-lapse imaging, Multitime allows the user to choose multiple locations within the dish. Instead, here we use Multitime to automate the μPP process. An additional feature is the ability to "tile" around a specified point; that is to image an array of images around a single point in a tile or grid-like fashion. The

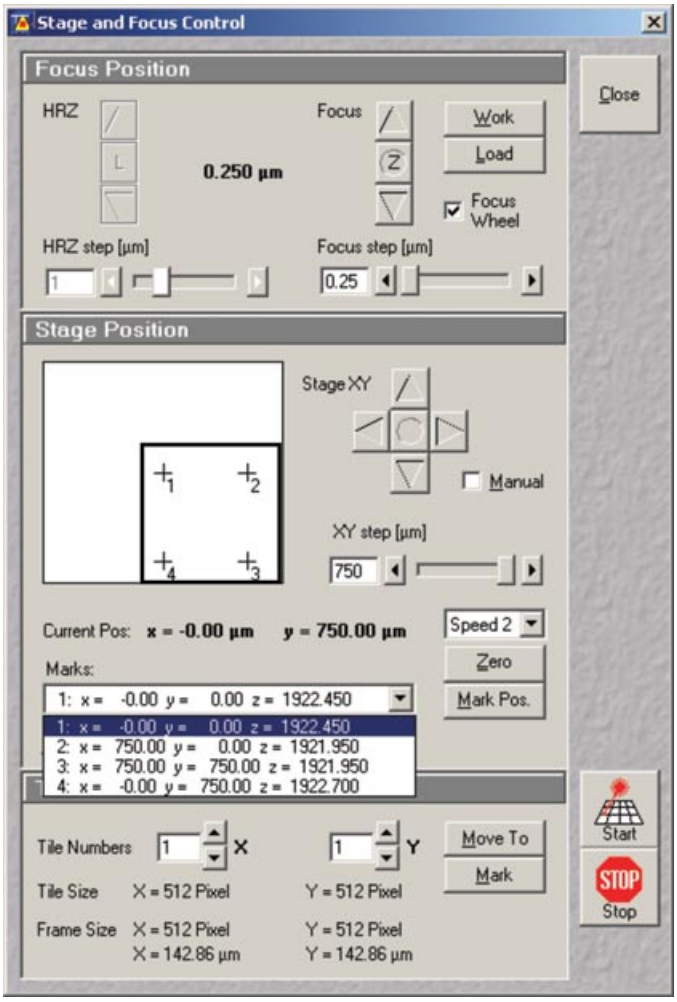

Figure 10.15.18 Using the Stage and Focus Control window to mark multiple tiling positions. The black box indicates four points that were selected for tiling. Courtesy of Carl Zeiss MicroImaging.

next several steps will help you to achieve this automation process. While the Multitime macro has many functions, we are only going through those that directly pertain to automating µPP.

42. After you have found the proper *z*-plane and zeroed your position as in steps 28 to 30, go to the **Stage and Focus control** window (Fig. 10.15.18). In the Stage position box (center), select **Mark Pos.** (Fig. 10.15.18, 1). Keep this window open since you will be referring to it later.

    The example in Figure 10.15.18 shows how this was repeated four times 750-µm apart. Each mark is listed in the dropdown menu below. These marked positions will be used for tiling in the Multitime macro.

    It is helpful to move the stage while in Fast XY mode. Once to the correct xy position, readjust the z-plane to be ~0.75-µm above the brightest FOV then mark the position, but do not zero.

43. Prior to starting, create a new database (**File>New File**) and save it in an appropriate place.

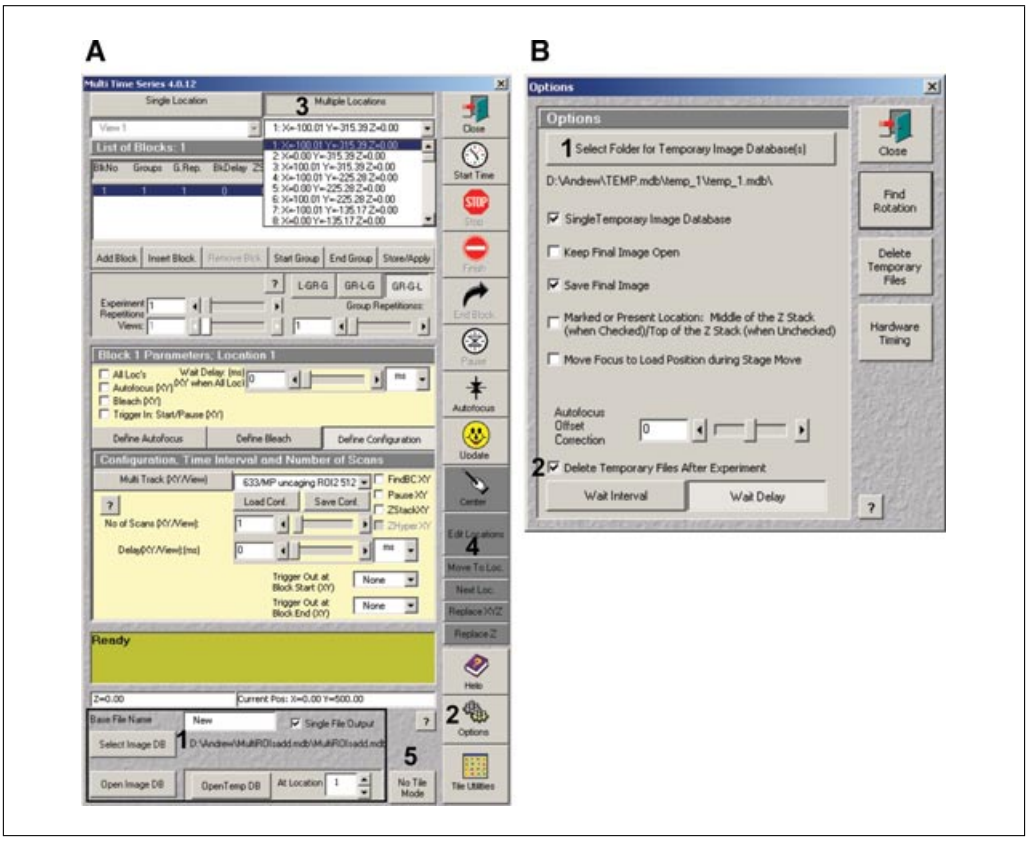

Figure 10.15.19 Multitime macro window (**A**) and the Options window (**B**). The bold numbers indicate the order each step is to be performed. Courtesy of Carl Zeiss MicroImaging.

44. In the main AIM window, select the **Macros** menu. If the Multitime macro does not appear in the window, load it (if unfamiliar with Macros ask your Microscope facility director or your Zeiss representative for help with installation).

45. Open the Multitime window. At the bottom of the window (Fig. 10.15.19A, bottom, 1), select the **Image DB** dialog button to choose the database you generated earlier.

46. From the window buttons on the right-hand side, select **Options** (Fig. 10.15.19A, 2 and 10.15.19B). In the Option window, first create a temporary image database (Fig. 10.15.19B, 1).

    This is where the software saves your ablation images.

47. Next, check the dialog box that says "Delete Temporary files after final experiment" (Fig. 10.15.19B, 2). Close window.

48. From the top of the window, select **Multiple locations** (Fig. 10.15.19A, 3), which will allow you to choose more than one point to scan.

    Steps 44 to 48 in Multitime only need to be performed once. After performing these actions once, Multitime will remember the settings.

49. Next, choose **Edit location** (Fig. 10.15.19A, 4). The edit location window (Fig. 10.15.20A) will allow you to tile around the marked positions from step 42.

50. Under the **Grid** tab, change the *x* and *y* Grid numbers to the appropriate number of FOVs to tile in each plane (Fig. 10.15.20A, 1), and then select **Create Grid Locations** (Fig. 10.15.20A, 2).

    This generates a list of points in the Multiple locations dropdown menu.

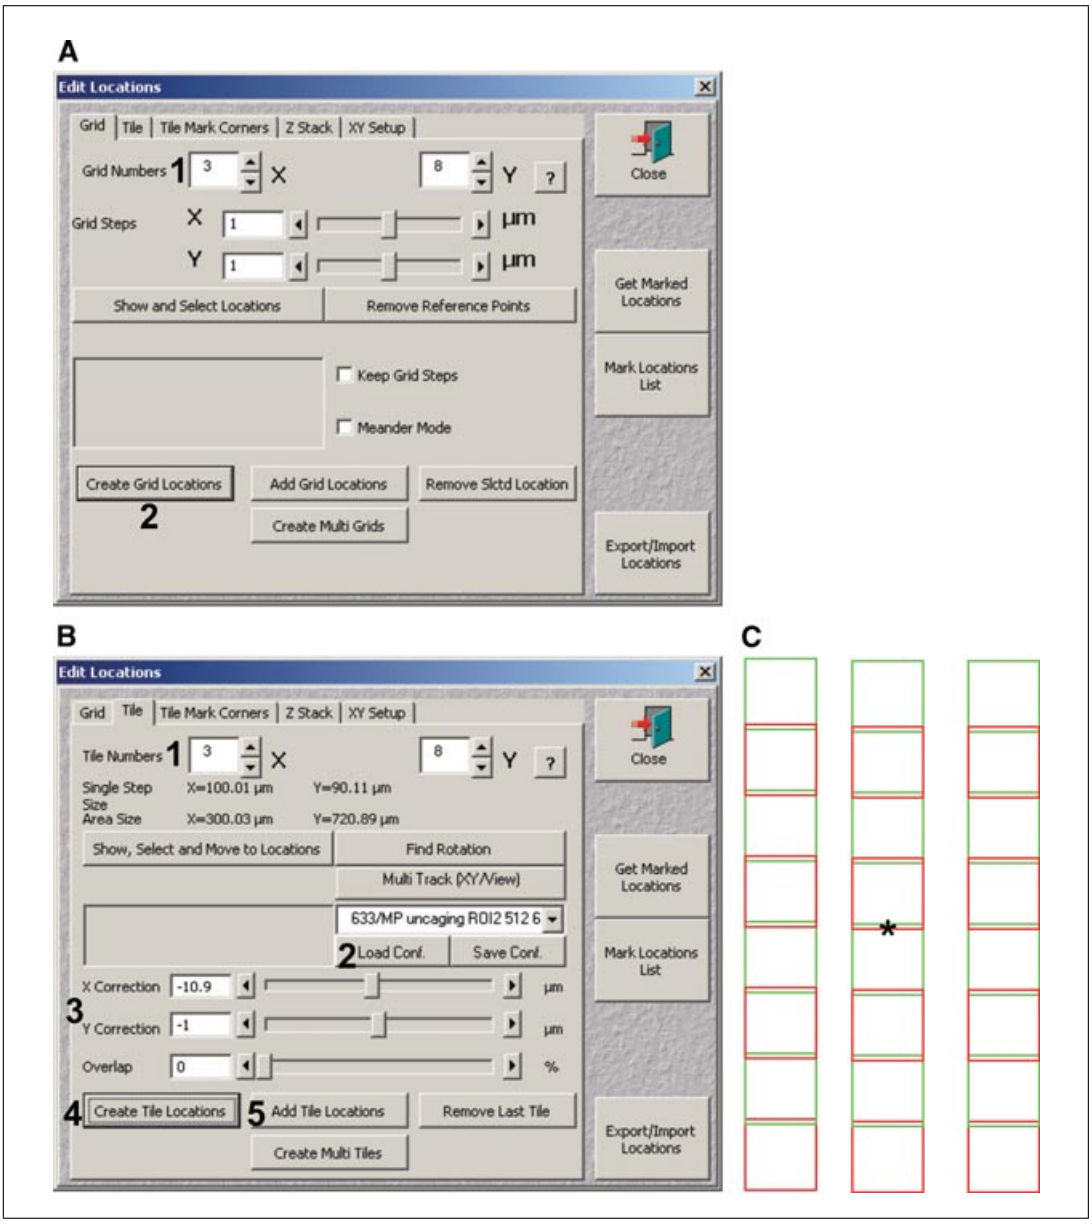

Figure 10.15.20 Tiling with Edit Locations window. (**A**) The Edit Locations window grid tab showing the Grid Numbers dialog (1) and the Create Grid Locations button (2) for grid generation. (**B**) The Edit locations window tile tab with Tile Numbers (1), configuration (2), XY correction (3), and Create Tile Locations (4) highlighted. (**C**) Schematic representation of the tiled grid generated based on the parameters shown in (B). The asterisk represents the marked positions chosen in the Stage and Focus control window. Courtesy of Carl Zeiss MicroImaging.

51. Next, select the **tile** tab (Fig. 10.15.20B). From top to bottom (1), change the **tile numbers** *x* and *y* (Fig. 10.15.20B, 1), (2) select the configuration to be used from the dropdown menu, then load it by hitting **Load Conf.** (Fig. 10.15.20B, 2), and (3) set your **X and Y correction** (Fig. 10.15.20B, 3; used for overlapping or spacing FOVs apart).

52. In the **Stage and Focus control** window, select a position from the dropdown menu, and select **Move To**.

53. Then, back in the **Edit Location** window select **Create Tile Locations** (Fig. 10.15.20B, 4). If more than one location is to be tiled, move to its position then select **Add Tile Location** (Fig. 10.15.20B, 5; after your initial locations all other locations are added in this manner).

54. Go to the **Scan Control** window and select **ROI**.

    IMPORTANT NOTE: *This is very important. If not selected, the Multitime Macro will photoablate the entire FOV.*

55. Select the **No Tile Mode** (Fig. 10.15.19, 5).

    This stops the tiling of the images collected into a larger single image.

56. Select **Start** in the Multitime window.

    You should start seeing Multitime running. At the bottom of the Multitime window, information should begin appearing telling you the position, scan number, and other information. It is helpful to time the process for a single FOV plus the stage movement to estimate your finishing time.

57. Once this Multitime has finished, check several FOVs to be sure the ROI template has been repeated. Close the **Multitime Macro** window.

58. If more patterning is required in the same dish (the same or a different pattern), simply move to a new nonablated region being sure to know your current position with respect to all previously ablated areas.

59. Repeat finding the *z*-plane, reset zero for *x*, *y*, and *z*.

    *The original zero point (0, 0, 0 for x, y, and z, respectively) should now be listed in the **Stage and Focus control** window as something different. For example, if you moved over 2000 μm in x, 0 μm in y, and 1.0 μm in z, the original position should read: $x = -2000.00$ $y = 0.00$ $z = -1.00$.*

DISH QUENCHING

BASIC PROTOCOL 4

Following the photoablation of the PVA thin films, the next step is quenching any unreacted aldehydes. Quenching the thin film is important for three reasons: (1) it reduces any reacted aldehydes leading to a stronger covalent attachment of the thin film to the glass surface; (2) the reduction of the aldehydes, especially if glutaraldehyde is used, decreases autofluoresence in the blue to green wavelengths (490 to 540 nm); and (3) it acts to block any free radicals that may be produced in the thin film during photoablation. Because sodium borohydride is very hygroscopic, we suggest desiccating it at room temperature in small aliquots in microcentrifuge tubes. Use a single tube 4 to 5 times and discard the remainder. The reaction that occurs when $NaBH_4$ comes in contact with water is temperature dependent, being more vigorous as temperature increases.

Materials

μPP-patterned dishes (Basic Protocols 1 through 3)
200 mM ethanolamine buffer (see recipe)
Sodium borohydride solution ($NaBH_4$; see recipe)
1 M NaOH solution (see recipe)
Phosphate-buffered saline (PBS; Hyclone, cat. no. SH30264.02)
Phosphate-buffered saline (PBS) with penicillin/streptomycin and fungizone (see recipe)

Storage containers
Scale
1.5-ml microcentrifuge tubes

1. To each photoablated dish, add 2 ml of ethanolamine buffer after photoablation. Store dishes containing ethanolamine buffer up to 1 month at 4°C in an airtight container.

   The ethanolamine buffer should be added on the same day (preferably within an hour) of photoablation.

2. If photopatterned dishes have been stored at 4°C, allow them to warm at room temperature for 5 min.
3. Weigh out 40 mg of $NaBH_4$ into a single 1.5-ml microcentrifuge tube. Add 1 ml of 1 M NaOH. Triturate several times.
4. To each dish, add 20 µl of the $NaBH_4$ solution mixed in step 3. Replace the dish lid, swirl several times to mix, and incubate up to 8 min at room temperature.

   You should start to see bubbling after 1 to 2 min, which shows the reaction is occurring.
5. Aspirate $NaBH_4$ solution and rinse two times, each time with 3 ml PBS. Add 1 to 2 ml of PBS with penicillin/streptomycin and fungizone. Store up to 1 month at 4°C.

BASIC PROTOCOL 5

ADSORBING EXTRACELLULAR MATRIX AND PLATING CELLS

The final step of µPP is adsorption of an extracellular matrix (ECM) molecule to the photoablated patterns. Here, we describe the attachment of fibronectin to photoablated dishes; however, any other ECM molecule or even growth factors can be absorbed in this fashion. Once the ECM is adsorbed to the surface, it is important to block attachment of other molecules (other ECMs, growth factors, etc.) found in serum using heat-denatured bovine serum albumin (BSA). For fluorescence microscopy techniques where the patterns are invisible, prior direct conjugation of a fluorescent dye to the ECM molecule of choice is helpful for pattern visualization. A general fluorescent dye labeling protocol for N-hydroxy succimidyl ester-based dyes can be found in Support Protocol 2. Pluronic F-127 is a nonionic detergent/surfactant, which is used here to help with blocking nonspecific protein adsorption to nonablated surfaces.

Materials

Fibronectin at 2 mg/ml concentration in PBS or other suitable buffer
Phosphate-buffered saline (PBS) with 0.1% (v/v) pluronic F-127 (see recipe)
µPP patterned dishes (Basic Protocols 1 through 4)
Lyophilized bovine serum albumin (BSA)
Phosphate-buffered saline (PBS; Hyclone, cat. no. SH30264.02)
2 M NaCl solution
Phosphate-buffered saline (PBS) with penicillin/streptomycin and fungizone (see recipe)
NIH/3T3 cells (ATCC) grown to 60% to 70% confluency in a 100-mm diameter dish in 10% CO_2 incubator
Hanks balanced salt solution (HBSS; Invitrogen)
0.5% (w/v) trypsin/EDTA solution (Invitrogen)
NIH/3T3 fibroblast culture medium (see recipe)

Tissue culture hood
37°C waterbath
400-ml beaker
Stirrer/hot plate
Scale
50-ml conical tubes
Glass test tube capable of holding 30 to 50 ml
Flea Micro magnetic stir bar (VWR)
Digital thermometer
Ice in an ice bucket
Vacuum aspirator
Airtight storage container

Benchtop swinging-bucket rotor centrifuge with adapters for 50-ml conical tubes
Inverted microscope equipped with a 10× phase contrast objective

Prepare coating solution

1. Calculate the total amount of fibronectin solution needed for all dishes.

   Because the glass surface only needs to be covered, we use ~100 μl per dish.

2. Next, calculate the volume of fibronectin (at 2 mg/ml) needed to attain the proper concentration (10 μg/ml).

   For example, for four dishes, add 2 μl of 2 mg/ml fibronectin to a microcentrifuge tube followed by 398 μl of PBS with 0.1% pluronic F-127 buffer for a 10 μg/ml solution.

3. Prewarm the concentrated fibronectin solution to ~37°C prior to mixing the solution. Fibronectin is an active molecule, which over time will lose activity when left at 4°C for extended periods. We suggest keeping small aliquots (~20 μl) frozen at −80°C and defrosting and using an aliquot for only 1 week stored at 4°C. Once diluted, the fibronectin solution must be used promptly and cannot be stored.

Coat the dish in the pattern

4. In a tissue culture hood, add 100 μl of the 10 μg/ml fibronectin to each dish, cover, and incubate for 1 hr at 37°C.

5. While waiting, heat 250 ml of water in a 400-ml beaker on the stirrer/hot plate to ~85°C.

Heat-denature BSA

6. Weigh out 0.3 g of BSA in a 50-ml conical tube. Bring volume/weight up to 30 g with PBS.

7. Incubate in a 37°C waterbath until BSA goes into solution, ~15 min.

   This BSA solution should be made fresh and can be used for a maximum of only 1 day.

8. Once the BSA has gone into solution, transfer the 1% BSA solution to a glass test tube and add the stir bar. Next place the test tube in the ~85°C water. Turn on the stirplate to medium.

9. Directly measure the temperature of the 1% BSA solution with the digital thermometer. Set a timer for 3 min. Wait until the solutions temperature reads 83°C and then start the timer. Monitor the temperature over the next 3 min.

   If the solutions temperature goes above 85°C, remove the test tube from the water bath and cool briefly, keeping the temperature a minimum of 83°C.

10. After 3 min, remove 1% BSA solution from the beaker of water and cool in an ice bath until the solution's temperature is below 37°C.

11. After the 1-hr incubation of the fibronectin on the μPP dishes, bring the dishes to the tissue culture hood, aspirate fibronectin, and rinse three times, each time with 3 ml PBS.

Rinse and block

12. Add 2 ml of 2 M NaCl solution to each dish and incubate 5 min at room temperature to reduce nonspecific protein binding.

13. Aspirate NaCl solution, and rinse three times, each time with 3 ml PBS.

14. Add 2 ml of heat-denatured 1% BSA solution (from step 10) to each μPP dish and again incubate for 1 hr at 37°C.

15. Rinse dishes three times, each time with 3 ml PBS, and store in an airtight container in 2 ml of PBS plus penicillin/streptomycin and fungizone until use. Use within 3 days of this last step.

Attach NIH/3T3 fibroblasts to μPP patterns

16. Detach 60% to 70% confluent NIH/3T3 fibroblasts from 100-mm tissue culture dish by rinsing twice, each time with 6 ml of 37°C HBSS.
17. Add 5 ml of 37°C trypsin/EDTA solution and wait 30 to 60 sec.
18. Aspirate excess solution and incubate for 2 to 3 min at 37°C.
19. Add 10 ml of 37°C NIH/3T3 fibroblast culture medium to the dish, triturate, and transfer to a 50-ml conical tube.
20. Centrifuge the cells in the swinging-bucket centrifuge 4 min at 1000 × *g*, room temperature.
21. After centrifugation, aspirate excess medium leaving the cell pellet undisturbed.
22. Tap the tube firmly on the tissue culture hood working area. Add 10 ml of NIH/3T3 fibroblast culture medium to tube, and triturate several times to loosen cell clumps.
23. Add 1 to 2 ml of cells to each μPP dish. Incubate for 10 to 15 min at 37°C, and then check cell attachment to patterns using a 10× phase contrast objective on an inverted microscope.

    When cells begin to attach they should appear phase dense when compared to non-adherent cells.

24. If the proper number of cells is not attached, check dishes every 5 min.
25. When the proper number of cells has attached, gently aspirate the excess and add 1.5 to 2 ml of fresh NIH/3T3 fibroblast culture medium. Incubate for a further 30 min at 37°C before imaging.

SUPPORT PROTOCOL 1

SETTING THE CONFOCAL SCAN HEADS' ROTATION OFFSET

As mentioned earlier in Basic Protocol 3, the *x* and *y* galvanometric scan head mirrors can be slightly misaligned or offset from a true horizontal or vertical plane. This becomes an issue when using the Multitime Macro for tiling: improper scanner alignment will result in the pattern being askew from FOV to FOV. For example, if generating a lined pattern that is meant to be continuous, lines may be offset. The following protocol alleviates this rotation alignment issue. This can be done simply in one of two ways: first, is to use a grid slide supplied by Zeiss for the alignment, and second is to generate a grid of your own using μPP. Both require the same steps. Any differences between the methods are discussed.

Materials

Zeiss 510 LSM NLO confocal microscope or later model with 1.5 W minimum tunable two-photon titanium:sapphire laser, and a 633-nm HeNe2 laser (5-mW power output), and a 543-nm HeNe1 laser (1-mW power output)
AIM software (Zeiss MicroImaging)
PVA thin film–coated MatTek dishes (Basic Protocol 2; for option 1)
Arc lamp
Grid slide, Objektträger (for option 2; Zeiss, cat. no. 474028)
Fluorescent highlighter, any color (for option 2)
Kimwipes

For option 1

1a. Turn on the microscope, the AIM software, and the appropriate lasers for performing μPP.

2a. Load your μPP configuration.

3a. Place a PVA thin film–coated dish on the stage and follow the pre-ablation setup in Basic Protocol 2, steps 18 through 30 in order to find the proper *z*-plane for μPP.

4a. Create a new ROI template in a pattern similar to Figure 10.15.21.

> *The grid and circle pattern help to determine the rotational offset. The spacing of the grid is not important, just that horizontal and vertical lines, as well as curved lines are incorporated into the pattern.*

5a. Being sure to have your zoom set for 1×, photoablate the pattern in the PVA thin film. Save the configuration with the TP 755-nm line unchecked.

6a. In the Focus and Stage control window, mark the position.

For option 2

1b. Turn on the arc lamp followed by the microscope, the AIM software, and the 543-nm HeNe1 laser.

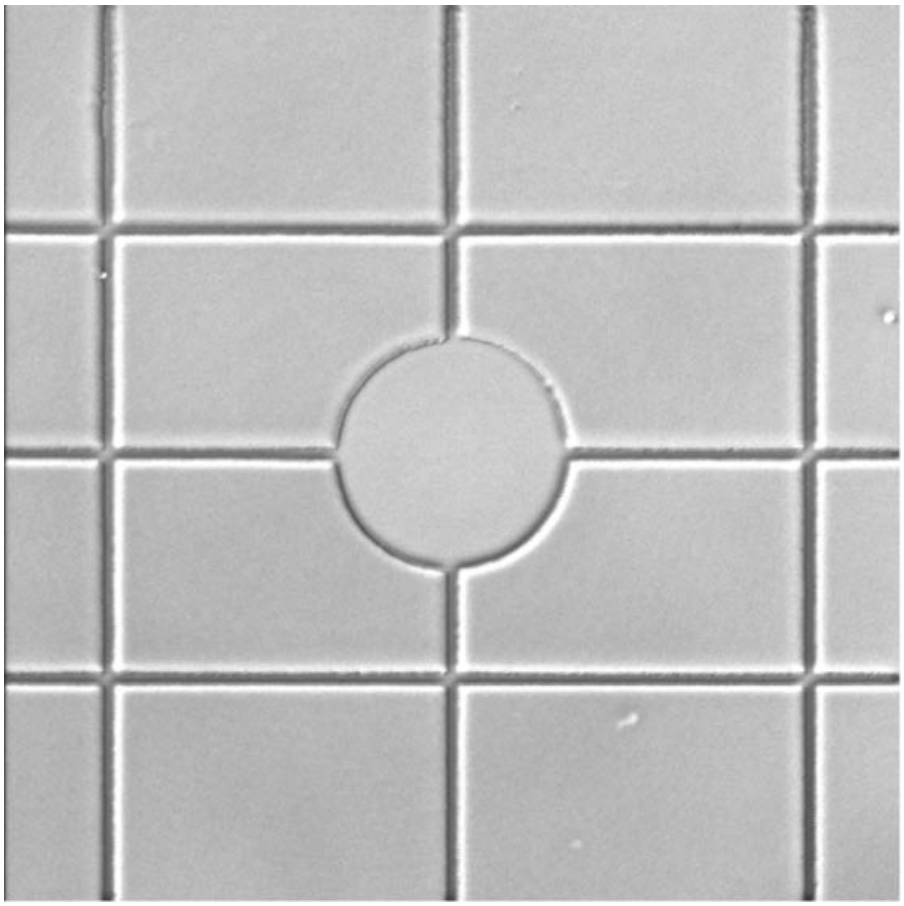

Figure 10.15.21 Microphotopatterned grid used for rotational alignment of the XY galvanometric scanning mirrors in the confocal head with the stage.

Figure 10.15.22 Tile Scan Rotation dialog window in the AIM software. Courtesy of Carl Zeiss MicroImaging.

2b. Select a configuration to image Cy3, Alexa Fluor 543, or Rhodamine dyes.

If needed, ask your microscope facility manager for help.

3b. On the grid slide, locate the grid in the center. Mark the grid with the fluorescent highlighter. Gently wipe off excess with a Kimwipe.

4b. Add a drop of oil over the grid and position the slide properly in the stage holder. Use epifluorescence to find the grid using a 63× 1.4 NA objective. Once the grid is found, switch to LSM mode, and adjust the *z*-plane while in Fast XY. Adjust the settings (PMT gain, laser output, etc.) and save as a new configuration.

5b. Scan the grid pattern until you find a region that contains both the vertical and horizontal lines, as well as part of a curved arc.

The grid pattern usually has a small and large circle pattern.

6b. In the Focus and Stage control window, mark the position.

For options 1 and 2

7. Open the Macros menu and select the Multime Macro. Open the Edit Locations window and select the tile tab (**Macros>Multime>Edit Locations> Tile tab**).

8. Select the configuration you saved in step 5a or 4b for either option and select **load Config.**

9. Select the **Find Rotation** button.

A new window should appear similar to the one shown in Figure 10.15.22.

10. Choose **Calibrate** (Fig. 10.15.22, 1). This should take ~20 sec before a number will appear in the **Rotation [°]** dialog on the left, which represents the rotational offset (Fig. 10.15.22, 2).

11. Go to the **Zoom, Rotation and Offset** box in the **Mode** panel of the **Scan control** window. Use the number found in the **Rotation [°]** dialog for your rotational offset in your μPP configurations. Save the configurations once complete.

SUPPORT PROTOCOL 2

DIRECT FLUORESCENT LABELING OF FIBRONECTIN

For any type of micropatterning including μPP, it is important to know whether the ECM is being adsorbed to the patterns and not nonspecifically. While antibodies can help with this determination, the direct approach is often best, especially when conducting live-cell fluorescence imaging. Below, we detail one method of directly labeling fibronectin with N-hydroxy succimidyl (NHS) ester-based fluorescent dyes. Before proceeding, several items should be noted: (1) NHS ester reactions are pH and temperature dependent, (2) the reactions are hygroscopic and once in contact with aqueous solutions begin reacting immediately, and (3) the ratio of protein to dye is important, with the reaction time being based on this and the parameter (1) above. For every 1 mg of protein, 5 to 10 μg of dye should be used (200:1 or 100:1 ratio). This is slightly below a 10-molar excess

normally suggested for dye-to-protein conjugations. Over-labeling ECM proteins can negatively affect cell attachment and/or migration. If using different starting protein amounts, recalculate the amount of dye to match these ratios. More information about these other types of fluorescent conjugations can be found in "Bioconjugate Techniques" written by Greg Hermanson (Hermanson, 1996).

Materials

NHS-ester-based fluorescent dye of choice (several are available from Invitrogen and Pierce)
Dimethyl sulfoxide (DMSO)
500 to 1000 μl of fibronectin at 2 mg/ml concentration or 2 mg of lyophilized fibronectin
100 mM borate buffer, pH 9.0 (see recipe)

Slide-A-Lyzer (Pierce)
1.5-ml microcentrifuge tubes
Aluminum foil
End-over-end rotating mixer, e.g., Labquake rotating mixer (sometimes termed a rotisserie shaker)
Desalting spin column *or* dye-removal columns capable of ~1 ml volumes (Pierce)
Centrifuge capable of 10,000 × *g* with 15-ml conical tube holders

1. Keep NHS-ester-based fluorescent dyes, which are hygroscopic, in DMSO until use. Dilute the lyophilized dye with DMSO to a concentration of 1 mg/ml. Split into aliquots of ~25 μl. Store at −20°C until use.
2. If starting from lyophilized fibronectin, add 1 ml of 100 mM borate buffer (pH 9.0) to make a 2 mg/ml concentration. If starting from fibronectin in PBS or other buffers (~pH 7.4), dialyze in borate buffer (see *APPENDIX 3C*).
3. Warm 2 mg/ml fibronectin to room temperature prior to reacting with NHS ester dyes.
4. Defrost NHS-ester dye (1 mg/ml concentration) prior to opening the tube since it will absorb moisture from the air.
5. Add 1 ml of fibronectin (2 mg/ml, in borate buffer) to a 1.5-ml microcentrifuge tube.
6. Add 10 to 20 μl of the concentrated dye (1 mg/ml) to the fibronectin solution. Close the tube and wrap with aluminum foil.
7. Incubate 1 hr at room temperature on an end-over-end mixer at ~8 rpm.

   For other ECM molecules, it is recommended that the reaction be incubated at 4°C for 2 hr.

8. After 1 hr, remove unreacted dye using either a desalt spin column or dye removal column and follow the manufacturer's protocol.

   Alternatively, gel filtration or dialysis of the unreacted dye can be performed.

USING MULTIPLE ECM PROTEINS WITH μPP

SUPPORT PROTOCOL 3

One advantage of μPP over other patterning techniques is the ability to repeat the process after an initial photoablation, quenching, ECM adsorption, and blocking. This allows placement of different ECMs within microns of each other at the subcellular levels (Fig. 10.15.23). It is crucial here to use 0.1% pluronic F-127 for protein dilution, as well as for rinsing steps to deter nonspecific protein adsorption. The following protocol details the process.

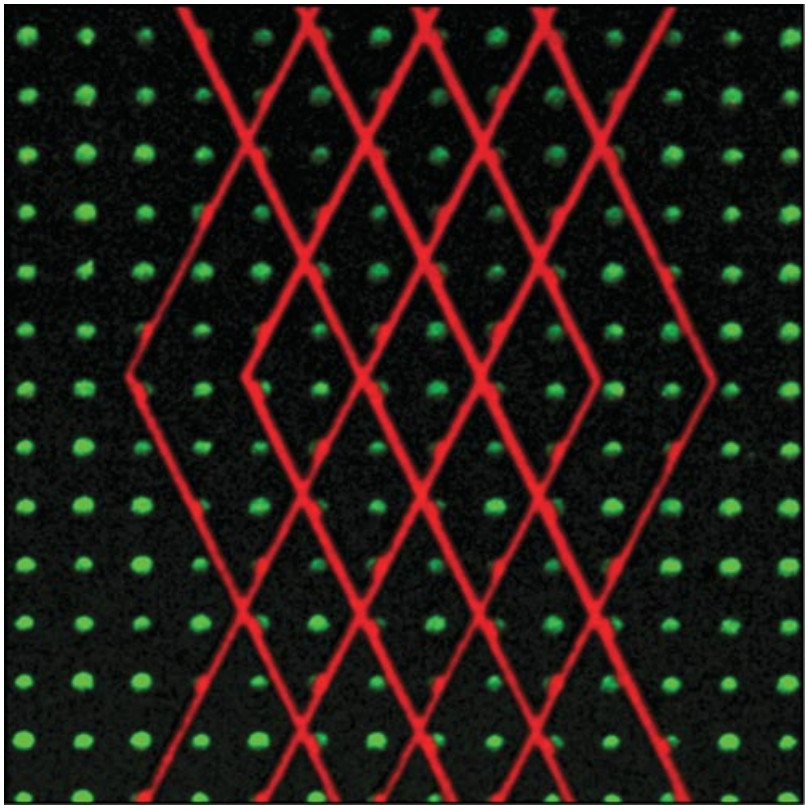

Figure 10.15.23 Dual ECM patterns by performing μPP twice in series. A first ablation was performed followed by quenching, ECM adsorption, and blocking. A second round of ablation was done is the presence of the second ECM. Green dots are fibrinogen and red lines are vitronectin. Dots are spaced 5-μm apart. For color version of this figure go to *http://www.currentprotocols.com/protocol.cb1015*.

Additional Materials *(also see Basic Protocol 3)*

Two different, fluorescently labeled ECM molecules/growth factors at the proper final concentration (user defined)
1% (w/v) heat-denatured BSA solution (prepare fresh and keep <1 day)
Phosphate-buffered saline (PBS) with 0.1% pluronic F-127 (see recipe)

PVA thin film–coated MatTek dishes (Basic Protocol 2)
Permanent marker
AIM software (Zeiss MicroImaging)

1. Prior to photoablation (Basic Protocol 3), mark a single side of a PVA thin film–coated dish along the edge of the attached coverslip.
2. Align the marked edge with the front of the microscope stage.
3. Proceed with rest of the photoablation procedure.

   This part can be automated.

4. Continue with the full coating, blocking, and cell plating process through Basic Protocol 5, substituting a fluorescently labeled protein during the adsorption step (step 4 of Basic Protocol 5).

   We suggest that this first labeled protein have a fluorophore in the visible range of emission, between 510 and 610 nm. Far red dyes such as Cy5, Alexa Fluor 633 and 647, or Dylight 649 are not recommended for this first stage.

5. After blocking the fluorescently labeled protein with 1% heat denatured BSA (step 14, Basic Protocol 5), perform a second photoablation, if desired.

   Here there are several options that may depend on the first adsorbed protein: (1) the surface of the film can be dried using compressed air immediately before photoablation, (2) the surface can be left in PBS, or (3) the second fluorescently labeled protein can be added to the surface. The photoablation process can still occur in solution (options 2 and 3); however, due to the presence of water, its efficiency can be reduced.

6. Align the marked side of the photoablated dish with the front of the stage. Use epifluorescence to scan the area(s) of the dish for the first photoablation site.

7. Once found, realign the dish to the best of your ability by hand. Fast XY scan the FOV using the most suitable configuration for the fluorophore used.

8. While scanning, make the fine alignment adjustments using the rotation dialog box in the Mode panel of the Scan control window. To help with this, open the Edit ROI window and choose the ROI template that was used to generate the first pattern. Leave the Edit ROI window open without selecting the ROI tab in the Scan control window, and continue scanning.

   This keeps the ROI template visible while scanning a full FOV.

9. Manually or using the Stage and Focus control window, align the ROI template over the fluorescent patterns. If using the same pattern, offset the template from the original position in either the *x* or *y* planes, or both.

   The amount of offset will depend on the original ROI.

10. Load the μPP photoablation configuration into the AIM software. Photoablate single FOVs at a time.

    We recommend this step not be automated.

11. Once finished, follow steps 6 through 8 in Basic Protocol 5, substituting PBS with 0.1% pluronic F-127 for PBS.

12. Following each protein added to the photoablated dish, block the surface with 1% heat-denatured BSA to prevent nonspecific protein attachment.

    Quenching with sodium borohydride is only required after the initial photoablation. Requenching will reduce fluorophore fluorescence and is not recommended.

13. Repeat the process (steps 3 through 5), if needed.

14. Plate cells on the surface as in steps 16 through 25 of Basic Protocol 5.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Borate buffer, 100 mM, pH 9.0

3.092 g boric acid (powder 99.5%; Sigma)
Add distilled water to 400 ml
Add several solid NaOH pellets at a time while mixing until the pH is ~9.0
Add distilled water to 500 ml
Filter sterilize using a 0.2-μm filter
Store up to 6 months at room temperature

Ethanolamine buffer, 200 mM

4.88 g ethanolamine hydrochloride ($EtOHNH_3$, crystalline form, 99%; Sigma)
Add sodium phosphate buffer (see recipe) to 250 ml
Filter sterilize using a 0.2-μm filter
Store up to 6 months at room temperature

NIH/3T3 fibroblast culture medium

440 ml Dulbecco's modified Eagle's medium (DMEM, high-glucose modified; Hyclone)
5 ml penicillin/streptomycin (10,000 U/μg per ml each, respectively; Invitrogen)
50 ml bovine calf serum (BCS; Hyclone)
Sterile filter using a 0.2-μm filter
Store up to 1 month at 4°C

Phosphate-buffered saline (PBS) with 0.1% pluronic F-127

199 ml phosphate-buffered saline (PBS; Hylcone)
1 ml of 20% pluronic F-127 in DMSO (Invitrogen)
Mix well on a stirplate
Sterile filter
Store up to 2 months at room temperature

Warming to ~37°C during mixing will help mix the solutions.

Phosphate-buffered saline (PBS) with penicillin/streptomycin and fungizone

490 ml DPBS/modified containing calcium and magnesium (Hyclone)
5 ml Amphotericin B (250 μg/ml; Invitrogen)
5 ml penicillin/streptomycin (10,000 U/μg per ml each, respectively; Invitrogen)
Mix and store up to 6 months at 4°C

Sodium borohydride solution

40 mg sodium borohydride ($NaBH_4$, hygroscopic powder; Sigma)
1 ml of 1 M NaOH (see recipe)
Mix well
Prepare fresh each time.

Sodium hydroxide, 1 M

20 g NaOH pellets
Distilled water to 500 ml
Mix well
Filter sterilize and store up to 6 months at room temperature

Sodium hydroxide solution, 200 mM

50 ml of 1 M NaOH solution (see recipe)
200 ml of distilled water
Mix well
Filter sterilize
Store up to 6 months at room temperature

Sodium phosphate buffer, 100 mM (pH 8.0)

6.90 g sodium phosphate monobasic (NaH_2PO_4)
Add distilled water to 400 ml
Add several solid NaOH pellets at a time while mixing until pH is ~8.0
Add distilled water to 500 ml
Filter sterilize using a0.2-μm pore-size filter
Store up to 6 months at room temperature

COMMENTARY

Background Information

Micropatterning using self-assembled monolayers

Micropatterning of ECM molecules originated by using self-assembled monolayers (SAMs) of alkanethiolates attached to gold-coated surfaces (Singhvi et al., 1994; Mrksich et al., 1996). The alkanethiol molecules consist of a sulfhydryl end terminal, a middle spacer, which is normally an ethylene-glycol backbone, and a head group that differs from the end terminal. Sulfhydryls or thiols have a high affinity for electron-dense gold and they bind, leaving the head groups pointing upward away from the gold surface. By changing the head group of the alkanethiol to a hydrophobic methyl (CH_3) or a hydrophilic hydroxyl (OH) group, the surface chemistry is altered; this will promote or deter ECM protein adsorption, respectively. Traditionally, in order to physically isolate hydrophobic from hydrophilic regions on a two-dimensional surface, a "rubber stamp" is generated that can physically ink the hydrophobic alkanethiol onto a gold surface. The remaining regions are backfilled with a hydrophilic alkanethiol, and finally an ECM protein can be added, which will only attach to the patterned hydrophobic regions of the surface. This process, known as microcontact printing (μCP), relies mostly on nanolithography techniques to generate a silicon "master" mold from which the polydemetylsiloxyane (PDMS) stamp is created (Singhvi et al., 1994).

Poly(vinyl) alcohol properties

As alluded to earlier, PVA is a highly hydrophilic polymer. It consists of a carbon backbone and hydroxyl groups located on every other carbon. PVA comes in varying molecular weights (mol. wt.), from as low as 6000 to >100,000 Da. PVA is generated from the hydrolysis of poly(vinyl) acetate. The percent hydrolysis that is listed with most PVAs defines the total amount of poly(vinyl) acetate hydrolyzed to PVA. The percent hydrolyzed should be as high as possible and is related to its hydrophilicity, with 98% to 99% being ideal for this application. With regards to the mol. wt., the larger the PVA monomer, the thicker the thin film becomes. We have found that using any of the molecular weights between 13,000 and 100,000 in a 5% solution can be used for μPP. Interestingly, after ablation of a high mol. wt. PVA film, the patterns remain visible via phase contrast and DIC imaging after submersion in buffer. This is not the case with 13,000 mol. wt. PVA, although labeling with fluorescent ECM proteins confirms proper local ablation (A.D.D., unpub. observ.). Because of this, low-molecular-weight PVA thin films are generally better for higher resolution fluorescence microscopy, and high mol. wt. PVA is helpful for visualizing the ECM patterns at lower magnifications.

Photoablation with two-photon microscopy

The process of photoablation is based on the ability of the PVA polymer to absorb light in the ultraviolet (UV) range (100 to 380 nm; Matsumoto et al., 1958). Other large polymers that have the ability to form a hydrogel such as polyacrylamide and polyethylene glycol can undergo photolytic degradation (Chen et al., 2003; Yamato et al., 2003). Two-photon femto-second pulse lasers mimic UV wavelengths using 720- to 760-nm light, and can excite UV-based fluorophores such as DAPI, coumarin, and Hoechst. For more information on properties and the process of two-photon excitation and confocal microscopy, we suggest reviewing *UNITS 4.5 & 4.11* on confocal and two-photon excitation microscopy, respectively. Absorption of UV light can initially result in polymerization of many polymer solutions (Du, 2007). However, continued exposure can disrupt primary bonds; in PVA's case the –OH bond to the carbon backbone. Further exposure results in a breakdown of the carbon backbone itself. With μPP, we use this property of PVA to locally breakdown or ablate the thin film, exposing the underlying glass to which ECM proteins can later be adsorbed.

Critical Parameters and Troubleshooting

The key elements during the multi-step μPP process requiring consideration are: (1) the PVA conjugation to the glass surface, (2) how the PVA thin film is stored, and (3) several parameters associated with the two-photon laser for proper photoablation. Many other troubleshooting tips are found throughout the text, where they are directly pertinent to the protocols.

Improper cleaning and/or activation of the glass surface can result in thin film detachment. Checking dishes for debris during each phase of the processing is important and should not be overlooked.

The PVA thin films need to be hydrated. PVA hydrogels can undergo crystallization

when dehydrated (Peppas and Merrill, 1977). While this process greatly increases their tensile strength, it greatly reduces their hydrophilicity from removal of hydroxyl groups and, hence, PVA's ability to deter protein adsorption and cell attachment is compromised. This will have no effect on the photoablation process, however. Critical times where dehydration can greatly affect the thin film are initially after spincoating, when the macromolecular monolayer may still be reacting with the activated glass surface. Short-term exposure to dry conditions such as during the photoablation on the microscope is tolerated.

Many issues stem from proper maintenance of the two-photon laser. We found that the amount of fluorescently labeled fibronectin attached to a given area is highly dependent on the total amount of light energy reaching the PVA thin film (Doyle et al., 2009). Small alignment issues of the two-photon source with the confocal scan head will greatly reduce the light throughput to your sample, and can result in improper photoablation within the whole field of view or just a part of it. If the two-photon system is heavily used by multiple users, more frequent mirror alignments should be performed. Other issues with uneven photoablation can arise from focus drift, bubbles in the immersion oil, and an uneven FOV. Another issue to factor into proper photoablation is the tuning of the TP laser. Technically speaking, the two-photon absorption of a given wavelength should be the same between different two-photon sources. However, there can be variation in the best or most suitable wavelength to maximize wavelength absorption. As it is recommended by most experts, you should test several wavelengths until the best one is found for your particular two-photon source to illuminate, or in this case photoablate, your sample. Starting with 755 nm, tune the Ti:Sapphire laser up or down ten nanometers at a time. Photoablate a simple pattern such as a field of same-sized dots at the particular wavelength, and then document the time taken and whether the ablation was efficient (complete removal of the PVA thin film) or not (only partial removal). Partial photoablation of patterns, where the PVA thin film is not completely removed from the glass surface, can lead to an inability of ECM protein adsorption and, hence, can affect cell attachment and/or migration.

Anticipated Results

It is expected that after generating the PVA thin film dishes and creation of the configurations and ROI templates, you should be able to generate micropatterns to which ECM or other proteins of interest can readily adsorb. Once patterns have been produced, you should find that cells should readily attach to patterns, especially linear structures (lines and lanes). There should be limited autofluorescence from the dish surface and all fluorescence microscopy techniques, from TIRF to spinning-disk confocal and two-photon confocal microscopy, should be effortlessly performed.

Time Considerations

As described in the Strategic Planning section, the many different parts of μPP can be performed not only on separate days, but weeks, if not months, apart between glass activation (Basic Protocol 1) and ECM adsorption/cell attachment (Basic Protocol 5). It is best to plan accordingly. For example, activating 30 dishes or more depending on your usage should be enough for 4 weeks. However, it is not prudent to continue all 30 dishes through the thin film deposition stage (Basic Protocol 2), unless you can process 30 dishes in a single week. Furthermore, how many of the 30 dishes can be used in a 1 to 3 day period after ECM adsorption needs also to be considered. Preplanning for dish need and usage will decrease your issues at key steps. One important time consideration is between formation of the PVA thin film through spincoating and the addition of the ethanolamine buffer after photoablation. Although as rare as this would occur, a short time (<2 hr) between these two steps could cause release of the thin film from the glass surface due to a lack of covalent attachment. Hence, the ethanolamine buffer should be added as soon as practical after spincoating.

Preparation of Hydrogel Substrates with Tunable Mechanical Properties

Justin R. Tse[1] and Adam J. Engler[1]

[1]Department of Bioengineering, University of California, San Diego, La Jolla, California

ABSTRACT

The modulus of elasticity of the extracellular matrix (ECM), often referred to in a biological context as "stiffness," naturally varies within the body, e.g., hard bones and soft tissue. Moreover, it has been found to have a profound effect on the behavior of anchorage-dependent cells. The fabrication of matrix substrates with a defined modulus of elasticity can be a useful technique to study the interactions of cells with their biophysical microenvironment. Matrix substrates composed of polyacrylamide hydrogels have an easily quantifiable elasticity that can be changed by adjusting the relative concentrations of its monomer, acrylamide, and cross-linker, bis-acrylamide. In this unit, we detail a protocol for the fabrication of statically compliant and radial-gradient polyacrylamide hydrogels, as well as the functionalization of these hydrogels with ECM proteins for cell culture. Included as well are suggestions to optimize this protocol to the choice of cell type or stiffness with a table of relative bis-acrylamide and acrylamide concentrations and expected elasticity after polymerization. *Curr. INTRODUCTION

The extracellular matrix (ECM) provides both mechanical support for surrounding cells and a variety of biochemical and biophysical signals that influence cellular behavior. These are largely the result of the ECM composition that includes adhesive glycoproteins, fibrous matrix proteins, proteoglycans, and glycosaminoglycans (Badylak, 2005). These signals are coupled in the body and together they create a 3-dimensional microenvironment for cell growth (Cukierman et al., 2001). In particular, the modulus of elasticity E, or "stiffness," is a characteristic of the ECM that certain anchorage-dependent cells can sense and respond to with a variety of cellular processes (Discher et al., 2005). E of a material represents the intrinsic resistance of organs and tissues to stress, and in its simplest mathematical form can be expressed as the tensile stress, σ, or force applied per unit area, divided by the resultant strain, ε, or relative change in length (Discher et al., 2005). Though highly nonlinear (Fung, 1993), at the physiologically appropriate strains, the degree of stiffness varies dramatically between tissues: brain (E_{brain} ~0.1-1 kPa) is clearly softer than striated skeletal muscle (E_{muscle} ~8-17 kPa), which is less stiff than precalcified bone ($E_{precalcified\ bone}$ = 25-40 kPa; Engler et al., 2006). At the cellular level, such changes in substrate elasticity have been observed to influence several cellular behaviors, including cell proliferation, locomotion, adhesion, spreading, morphology, striation, and even differentiation of stem cells (Pelham and Wang, 1997; Wang et al., 2000; Flanagan et al., 2002; Engler et al., 2004b, 2006; Khatiwala et al., 2006; Reinhart-King et al., 2005; Discher et al., 2009). That said, these properties are not static within the body; they are often displayed in highly complex gradients, such as those of stiffness at tissue interfaces. In vitro, the variation of E across a substrate has been shown to elicit directly cell migration or "durotaxis" in fibroblasts and vascular smooth muscle cells (Lo et al., 2000; Wong et al., 2003), indicating again that intrinsic matrix properties can influence cell behavior. Moreover, they are coupled, meaning that both mechanics and biochemical signals can

[a]This table shows the relative concentrations of acrylamide and bis-acrylamide and their expected modulus of elasticity after polymerization in water. Acrylamide and bis-acrylamide can be kept premixed in solution for weeks to months at 4°C. At least 3 hydrogels per sample and 50 indentations per hydrogel were assessed for these measurements.

jointly influence cells, e.g., stem cells differentiate in response to an appropriately compliant material, but only when coupled to the right matrix ligand (Rowlands et al., 2008).

To study these affects in isolation and together, this unit describes the fabrication of hydrogel substrates of a defined *E* for the culture of cells. Basic Protocol 1 describes procedures for fabricating hydrogels of a constant *E*, termed statically compliant hydrogels, and of a gradient *E*, termed radial-gradient hydrogels, onto glass coverslips from non-biodegradable polyacrylamide. Basic Protocol 2 describes a technique to covalently coat the matrix substrate with an ECM protein, while the Support Protocol describes how to create an apparatus to make radial-gradient hydrogels. Table 10.16.1 provides expected *E* values after polymerization of various ratios of acrylamide and bis-acrylamide solutions.

FABRICATION OF STATICALLY COMPLIANT MATRIX SUBSTRATES OF VARYING STIFFNESS

BASIC PROTOCOL 1

Several different types of polymers, including both nonbiodegradable and biodegradable types, can be used to fabricate matrix substrates of varying stiffness. Here, we introduce a simple method to create matrix substrates from polyacrylamide (PA) with a tunable elasticity. Besides producing statically compliant hydrogels, this technique can be adapted to produce hydrogels with a gradient of elasticity (Alternate Protocol). PA offers several important advantages for its application as a biomaterial for cell culture. (1) The modulus of elasticity of the substrate can be varied by changing relative concentrations of acrylamide and bis-acrylamide (Pelham and Wang, 1997). (2) The surface chemistry of PA can be kept constant while changing its mechanical properties (Pelham and Wang, 1997; Khatiwala et al., 2006), a characteristic whose importance is highlighted by a study demonstrating the dependence of cell spreading on ligand density (Engler et al., 2004a). (3) PA is generally nonfouling, meaning that the adsorption of serum proteins or the nonspecific binding of cell surface receptors is typically negligible. As a result, only adhesive molecules chosen to be covalently attached to the surface of the gel can serve as ligands for cell attachment (Georges and Janmey, 2005). (4) The pore sizes of the gel are on the order of 100 nm, preventing cells (~15 μm in diameter) and their extensions, such as growth cones (~5 μm in diameter) from entering the substrate (Flanagan et al., 2002). (5) Immunofluorescence is made possible at high magnifications because of the thin, translucent quality of PA gels.

PA gels are produced in this protocol by mixing various acrylamide and bis-acrylamide concentrations and inducing free radical polymerization. A table of expected modulus of elasticity values given the input concentrations of acrylamide and bis-acrylamide is provided (Table 10.16.1), while we also include a plot in Figure 10.16.3 that presents the spatial elasticity gradient possible using the gradient gel method detailed here. PA gel modulus of elasticity was quantified using atomic force microscopy (AFM), which is a nano-indentation method of calculating elasticity. This technique has been extensively detailed elsewhere (Rotsch et al., 1999; Rotsch and Radmacher, 2000).

Materials

0.1 M NaOH
Distilled H_2O
3-Aminopropyltriethoxysilane (APES)
0.5% (v/v) glutaraldehyde in phosphate-buffered saline (PBS; Cellgro, cat. no. 46-013-CM)
Dichlorodimethylsilane (DCDMS)
40% (w/v) acrylamide stock solution (Sigma-Aldrich, cat. no. A4058)
2% (w/v) bis-acrylamide stock solution (Sigma-Aldrich, cat. no. M1533)
Phosphate-buffered saline (PBS), optional
Tetramethylethylenediamine (TEMED)
10% (wv) ammonium persulfate (APS)

25-mm circular coverslips (for 6-well plate)
Hot plate
35-mm petri dish(es)
Kimwipes
25 × 75–mm glass slides
Vacuum desiccator
Vortex mixer
6-well plate, optional

Prepare amino-silanated coverslip(s)

1. Place 25-mm coverslip(s) on a hot plate and add 500 µl of 0.1 M NaOH to the coverslip so that the solution covers the entire glass surface.

2. Heat the coverslip with solution at ~80°C until the liquid is evaporated.

   The solution should not boil, and there should be a thin semi-transparent film of NaOH remaining on the coverslip(s) after evaporation.

3. Repeat step 1 by diluting the NaOH by adding 500 µl of distilled H_2O to the coverslip and heating the solution at 80°C until the film of NaOH is uniform.

   This step should be performed if and only if steps 1 and 2 resulted in a non-uniform film.

   A uniform film of NaOH is important for uniform gel attachment.

4. Place coverslip(s) in a nitrogen-filled tent. Add 200 µl of APES to the surface of the coverslip(s). Allow 5 min for the APES to react.

   If a nitrogen tent is unavailable, this step can be done in the fume hood. Since APES will react with the oxygen in the air, use 250 µl of APES to compensate for the loss of reactivity. A thin film will likely result on the surface of the APES solution and additional washing cycles in step 6 may be necessary to remove it.

5. Rinse the coverslip(s) with distilled H_2O under the distilled H_2O tap to ensure both the top and bottom of the coverslip(s) is rinsed.

   It is important to completely rinse off the unreacted APES, for it will create an orange-brown precipitate with glutaraldehyde (see step 8) that fluoresces under UV light and can thus interfere with immunostaining techniques.

6. Place the coverslip(s) in distilled H_2O into a petri dish and rinse the coverslips twice, each time in ~10 ml (or enough to immerse the coverslip) distilled water for 5 min each.

7. Aspirate the second distilled H_2O wash solution and add ~10 ml (or enough to immerse the coverslip) of 0.5% glutaraldehyde in PBS. Let the solution stand for 30 min.

8. Aspirate the solution and dry the coverslips with a Kimwipe, by allowing the coverslips to dry naturally in air, or by blowing nitrogen on them.

   The amino-silanated coverslips remain viable for 48 hr. However, to prepare radial-gradient hydrogels, it is best to use the amino-silanated coverslips immediately after they are created to ensure uniform gel attachment.

Prepare chloro-silanated glass slide(s)

9. Using separate glass slides, spread about 100 µl of DCDMS onto each slide in the fume hood. Ensure that the solution coats the entire surface of the slides. Allow to react for up to 5 min before removing the excess DCDMS with a Kimwipe and rinse 1 min under distilled H_2O.

Prepare statically compliant hydrogel(s)

10. Mix acrylamide and bis-acrylamide to their desired concentrations in either distilled H_2O or PBS.

    See Table 10.16.1 for concentrations and corresponding elastic modulus.

    The elastic moduli will be slightly lower if the solutions are made in water, due to gel swelling when placed in cell culture media. This effect can be directly measured by AFM or other mechanical techniques.

    Acrylamide and bis-acrylamide can be kept together in solution for weeks to months, though the sterility of the stock solution should be closely maintained by filter sterilization.

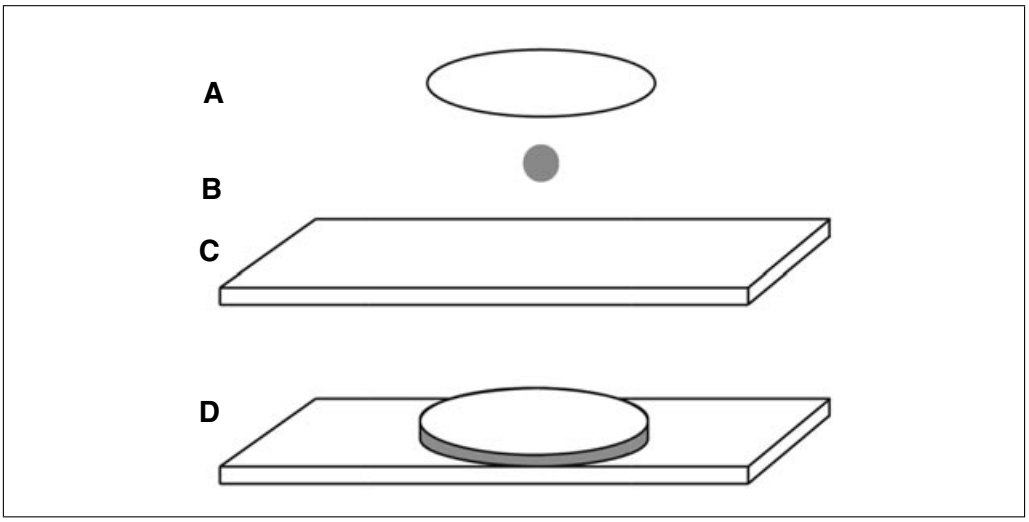

Figure 10.16.1 Exploded schematic of the setup for statically compliant PA hydrogels. The gel-glass composite includes (**A**) the amino-silanated coverslip, (**B**) polymerizing solution, and (**C**) chloro-silanated glass slide (C). (**D**) The completed setup is shown.

If not sterile, contaminants from the gel could adversely affect cell culture and induce infections.

11. Degas the mixture under strong vacuum for 15 min to exhaust the solution of dissolved oxygen.

    Dissolved oxygen in the solution will act as a sink for the subsequent free radical polymerization. Degassing the solution not only speeds up polymerization but ensures more uniform polymerization as well.

12. Add 1/100 total volume of APS and 1/1000 total volume of TEMED to gel solutions.

13. Vortex the polymerizing solution.

14. Quickly pipet 25 µl of the gel solution (see Fig. 10.16.1B) onto the treated side of the chloro-silanated glass slide(s) (see Fig. 10.16.1C) and add the amino-silanated coverslip(s) with the treated side down (see Fig. 10.16.1A).

    See Figure 10.16.1D for how the completed glass-gel-coverslip composite should appear.

    Essentially, the setup resembles a "sandwich" in which the polymerizing solution sits in between the chloro-silanated glass slide and the amino-silanated coverslip.

15. Allow the gel to polymerize for 5 to 30 min. Monitor the unused solution to determine when the solution is fully polymerized.

    Shorter polymerization times may result in insufficient polymerization of all available monomers and may cause the mechanical properties of the hydrogels to vary from the values noted here.

16. Remove the bottom glass slide and discard. Place the top coverslip-gel composite in a 35-mm petri dish or 6-well plate in PBS or dH_2O depending on what was used to dilute the acrylamide. Make sure that the gel-coated side faces up.

17. To remove unpolymerized acrylamide rinse twice, each time for 5 min in PBS or distilled H_2O depending on what was used to dilute the acrylamide.

    These hydrogels can be stored for long periods of time without losing any of their mechanical properties. To store them, immerse the hydrogels in water or PBS to keep them hydrated and store them at 4°C.

ALTERNATE PROTOCOL

FABRICATION OF RADIAL-GRADIENT MATRIX SUBSTRATES OF VARYING STIFFNESS

Radial-gradient hydrogels can be fabricated by photoinitiated polymerization as this technique allows for spatial control over the mechanical properties of the material. Among the commercially available photoinitiators, 1-[4-(2-hydroxyethoxy)-phenyl]-2-hydroxy-2-methyl-1-propanone, also known as Irgacure 2959, is commonly used for gel encapsulation and other photopolymerization reactions (Fedorovich et al., 2009). However, there are several limitations to using Irgacure 2959 that affect the maximum attainable polymerization rate, including its low solubility in water and its relatively narrow excitation spectrum. Nevertheless, we found that Irgacure 2959 as a photoinitiator is sufficient in producing spatial gradients of stiffness for our hydrogels. A detailed study on the kinetic properties of Irgacure 2959 and a novel photoinitiator that can be applied for this technique can be found in Fairbanks et al. (2009).

In this polymerization system, UV light of the appropriate wavelength catalyzes the free radical polymerization of acrylamide and bis-acrylamide by cleaving the Irgacure 2959 molecules into free radicals. While the mechanism for polymerization is similar to that of the fabrication of statically compliant hydrogels, UV light and Irgacure 2959 serve as the catalyst and the free-radical donor for the reaction, respectively, instead of TEMED and APS. The photomask filters the exposure of the UV light and creates a gradient of UV light intensity, which will result in a spatial gradient of polymerization rate. Because the polymerization reaction is stopped before completion by removing the UV light source, a polymer with a gradient of cross-linking density, or elasticity, is created through this process.

While the fabrication of statically compliant PA hydrogels is relatively straightforward, there are many parameters that need to be adjusted before the gradient gel can be created. These parameters include UV intensity, wavelength, and exposure time as well as distance from the UV light source, photoinitiator concentration, gel thickness, photomask grayscale, and acrylamide and bis-acrylamide concentration. Because of variations in the UV light source and photomask, several trials by the user are necessary optimize the protocol. It is recommended to only vary the UV exposure time and the acrylamide and bis-acrylamide concentrations while keeping the other parameters constant.

Materials

40% (w/v) acrylamide stock solution (Sigma-Aldrich, cat. no. A4058)
2% (w/v) bis-acrylamide stock solution (Sigma-Aldrich, cat. no. M1533)
Distilled water *or* phosphate-buffered saline (PBS; Cellgro, cat. no. 46-013-CM)
Irgacure 2959 (Ciba)

Vacuum desiccator
Gradient gel apparatus
Photomask
254-nm UV light source
Chloro-silane-treated 25 × 75–mm glass slides (Basic Protocol 1)
APES-coated glass coverslips (Basic Protocol 1)
35-mm petri dish(es) *or* 6-well plates

1. Mix acrylamide and bis-acrylamide to their desired concentrations in distilled H_2O or PBS.

   See Table 10.16.1 for concentrations and corresponding elastic modulus. The corresponding elastic modulus represents the maximum elastic modulus for the gradient gel. In our setup, we used a concentration of 10% acrylamide and 0.3% bis-acrylamide to obtain a gradient with a range of ~1 kPa to 14 kPa. Often, the range of the gradient is limited by the diffusion of acrylamide monomers during polymerization. These concentrations can be adjusted to obtain a desired range. However, some optimization will be necessary.

2. Add Irgacure 2959 at a concentration of 0.5% (w/v).

   It is best to use this solution immediately after mixing and to remake a new solution for each batch of gels because the initiator, Irgacure 2959, reacts slowly with the acrylamide and bis-acrylamide due to incidental light exposure.

   Irgacure 2959 is relatively insoluble in water; the solution can be placed in a warm water bath to speed up dissolving.

   As with the statically compliant gels, sterility is important for longer-term culture. Filter sterilization of all solutions is recommended.

3. Degas the mixture under strong vacuum for 60 min to speed up polymerization.

   Because the polymerization time is a function of both the amount of UV exposure and the concentration of dissolved gas in solution, it is important to remove all dissolved gases that may limit the free radical polymerization.

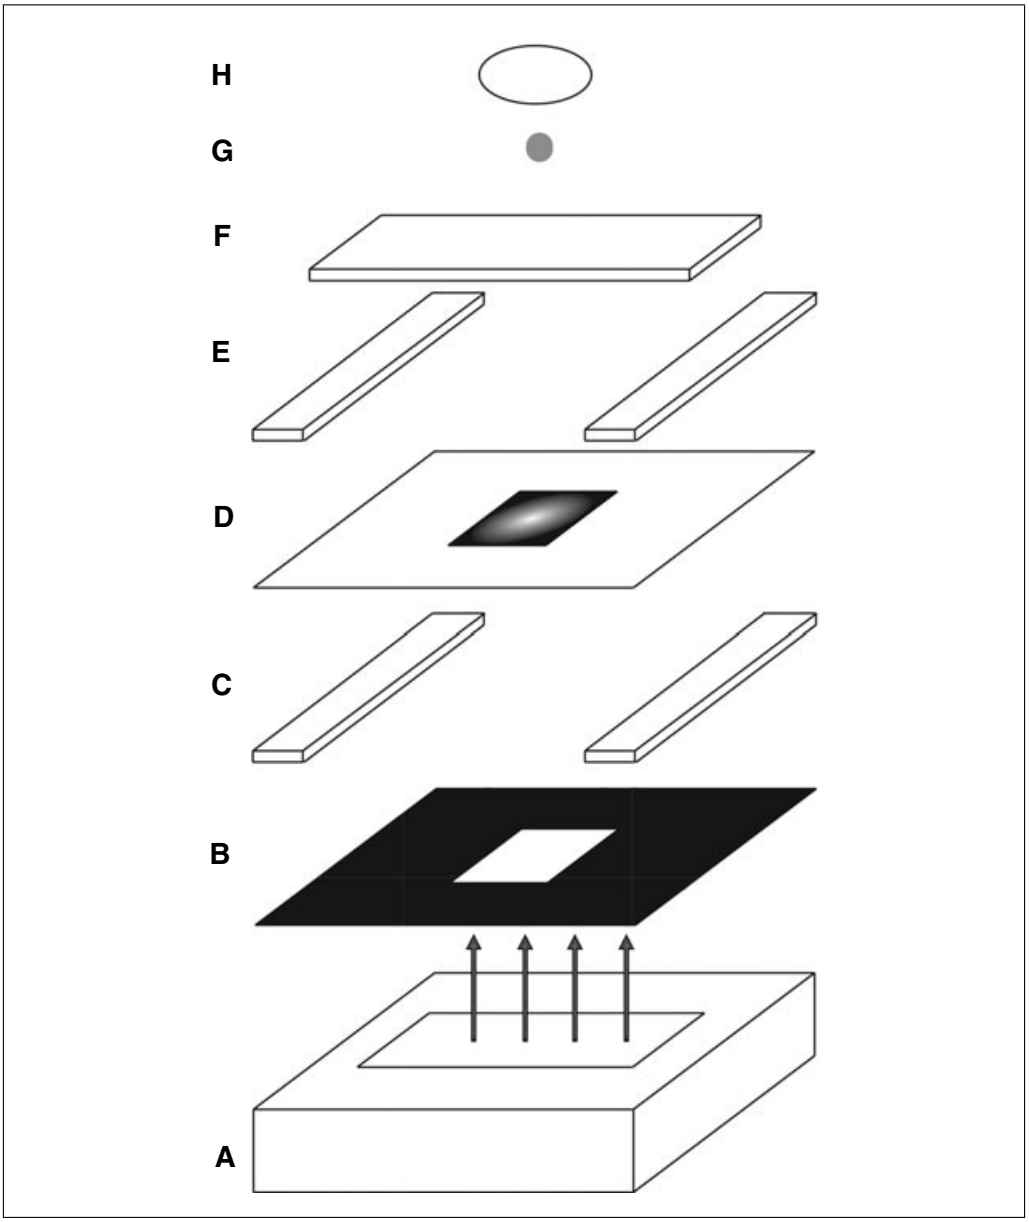

Figure 10.16.2 Exploded schematic of the setup for radial-gradient hydrogels. The setup includes (**A**) the UV light box, (**B**) negative photomask, (**C** & **E**) spacers, (**D**) photomask, (**F**) chloro-silanated glass slide, (**G**) polymerizing solution, and (**H**) amino-silanated coverslip.

4. Set up in the gradient-gel apparatus (Support Protocol 1) by placing the negative photomask on the UV light box (see Fig. 10.16.2A and B), the photomask on top of the UV light box (see Fig. 10.16.2D), and the chloro-silanated glass slide on top of the photomask (see Fig. 10.16.2D). Use spacers as necessary to separate each component (see Fig. 10.16.2C and E).

   The distance between the photomask and the chloro-silanated glass slide should be minimized to ensure the greatest resolution. For our setup, the distance was kept within 1 mm.

5. Pipet 30 µl of the gel solution (see Fig. 10.16.2G) onto the treated side of the chloro-silanated glass slide (see Fig. 10.16.2F) as set up in the gradient-gel apparatus (Support Protocol 1) and add the amino-silanated coverslip (see Fig. 10.16.2H) with the treated side down.

   To maintain the same approximate gel thickness as that of the statically compliant hydrogels, slightly more gel solution is added to compensate for the incomplete polymerization that takes place at the edge of the gels.

   It is possible to make thicker gels by increasing the volume of gel solution added to the chloro-silanated glass slide. However, the thickness of the gel introduces another parameter to the gradient elasticity as thicker gels allow greater diffusion of monomers in the x-y plane during polymerization, effectively decreasing the range of stiffness.

6. Turn on the UV light for the desired exposure time.

   The amount of UV light exposure can be varied to produce a desired gradient range. Since UV intensity, distance, photomask quality, and other parameters differ for each setup, it is important to optimize this parameter to produce the desired range. For our setup and gradient range, we used a polymerization time of 3 min 30 sec.

   Fig. 10.16.3 shows the spatially elastic gradient that can be obtained by using this technique.

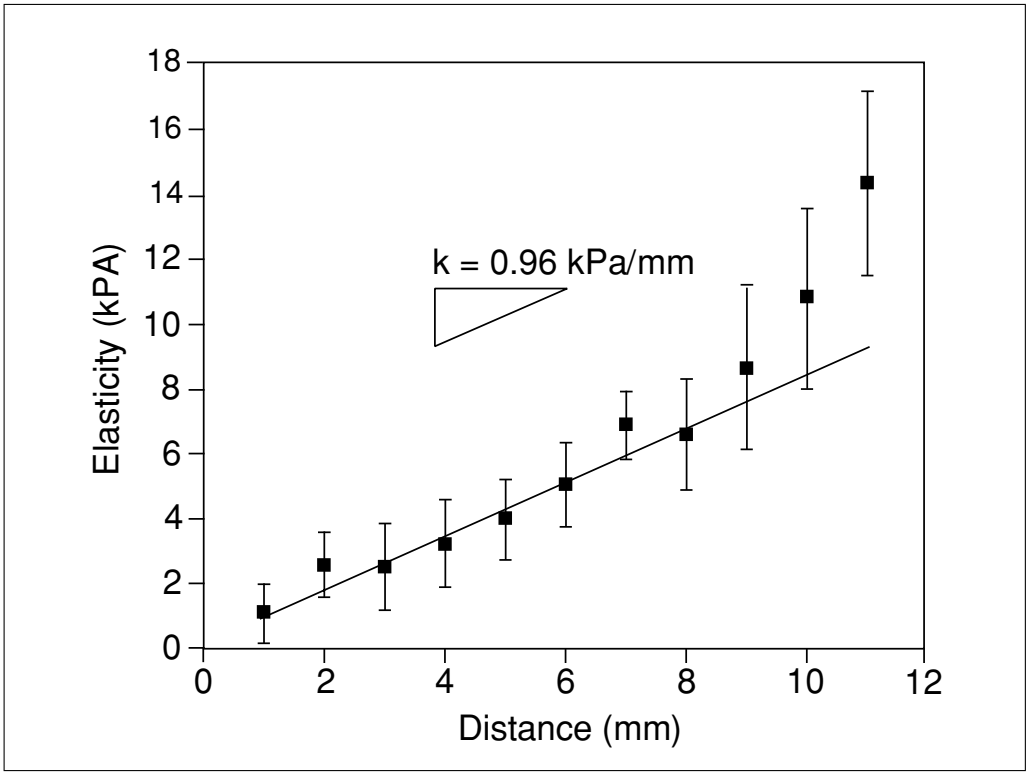

Figure 10.16.3 Spatial map of the elasticity (kPa) versus distance from the center of the gel (mm) characterized by AFM that can be obtained by fabricating the radial-gradient hydrogel detailed in the Alternate Protocol. The PA hydrogels represented in the figure were cast on coverslips of 25-mm diameter.

7. Remove the bottom glass slide and discard. Place the top coverslip-gel composite in a 35-mm petri dish or 6-wll plate in PBS or distilled H_2O depending on what was used to dilute the acrylamide. Make sure that the gel-coated side faces up.

8. Rinse twice to remove unpolymerized acrylamide with 2 ml PBS or distilled H_2O depending on what was used to dilute the acrylamide.

These hydrogels can be stored for long periods of time without losing any of their mechanical properties. To store them, immerse the hydrogels in water or PBS to keep them hydrated and store them at 4°C.

PREPARATION OF MATRIX PROTEIN SUBSTRATES OF VARYING STIFFNESS FOR CELL CULTURE

BASIC PROTOCOL 2

For many synthetic materials, before cell attachment can take place, an ECM protein coating is needed to promote adhesion. However, polyacrylamide hydrogels do not readily adsorb proteins, and thus it is essential to covalently bind proteins to the gel to ensure efficient cell attachment (Pelham and Wang, 1997). In this protocol, sulfo-SANPAH, a heterobifunctional protein cross-linker, is used to covalently bind proteins to the polyacrylamide substrates. Sulfo-SANPAH contains a nitrophenylazide group that is most photoreactive at wavelengths of 320 to 350 nm toward polyacrylamide. Exposure of the gel in a solution of Sulfo-SANPAH with a UV light source at 365 or 320 nm covalently links the sulfo-SANPAH to the polyacrylamide hydrogel. The *N*-hydroxysuccinimide ester in sulfo-SANPAH can then react with the primary amines of proteins to complete the attachment of proteins to the surface of the gel. Figure 10.16.4 shows a schematic of the steps in the functionalization of the PA hydrogel. Although not detailed here, an alternative conjugation method would be to incorporate 6-((acryloyl)amino) hexanoic acid into the gel solution of Basic Protocol 1 as it polymerizes. Reinhart-King and coworkers have successfully employed such a technique where the hexanoic acid copolymerizes into the gel and displays an *N*-hydroxysuccinimide ester for amine-containing protein binding (Reinhart-King et al., 2008). Carbodiimide has also been employed, though details may be found elsewhere (Grabarek and Gergely, 1990).

One of the concerns with ECM protein coatings is the variability of the ligand density among the different substrates and homogeneity of the ligand coating. With regards to this protocol, data suggests that the ligand is the limiting reagent in this reaction, and thus, the surface density of the ligand can be varied by changing the concentration of the ligand (Gaudet et al., 2003). This directly affects key cellular properties, e.g. cell spreading (Engler et al, 2004a). On the other hand, the surface chemistry of the matrix stays constant while the mechanical properties of the substrate are varied. Pelham and Wang (1997) report that the relative surface concentration of collagen varied $<3\%$ among the substrates, regardless of the modulus of elasticity, and several other studies confirm this observation (Wang et al., 2000; Khatiwala et al., 2006; Rowlands et al., 2008). Importantly, two gels of differing acrylamide/bis-acrylamide concentration but similar mechanical properties can bind similar amounts of matrix protein. To optimize the hydrogel coating protocol to the end user's specific proteins and conditions, such a check is necessary. Verification schemes used by Pelham and Wang (1997), as well as other groups, to confirm that relatively uniform protein attachment occurred, are also detailed here.

Finally, there are several choices of ECM proteins for PA hydrogel conjugation. Common ECM proteins include collagen I, collagen IV, laminin, and fibronectin. While these proteins can effectively promote cell attachment, the choice of the ECM protein is important as both integrin signaling and substrate elasticity are cues that affect cell

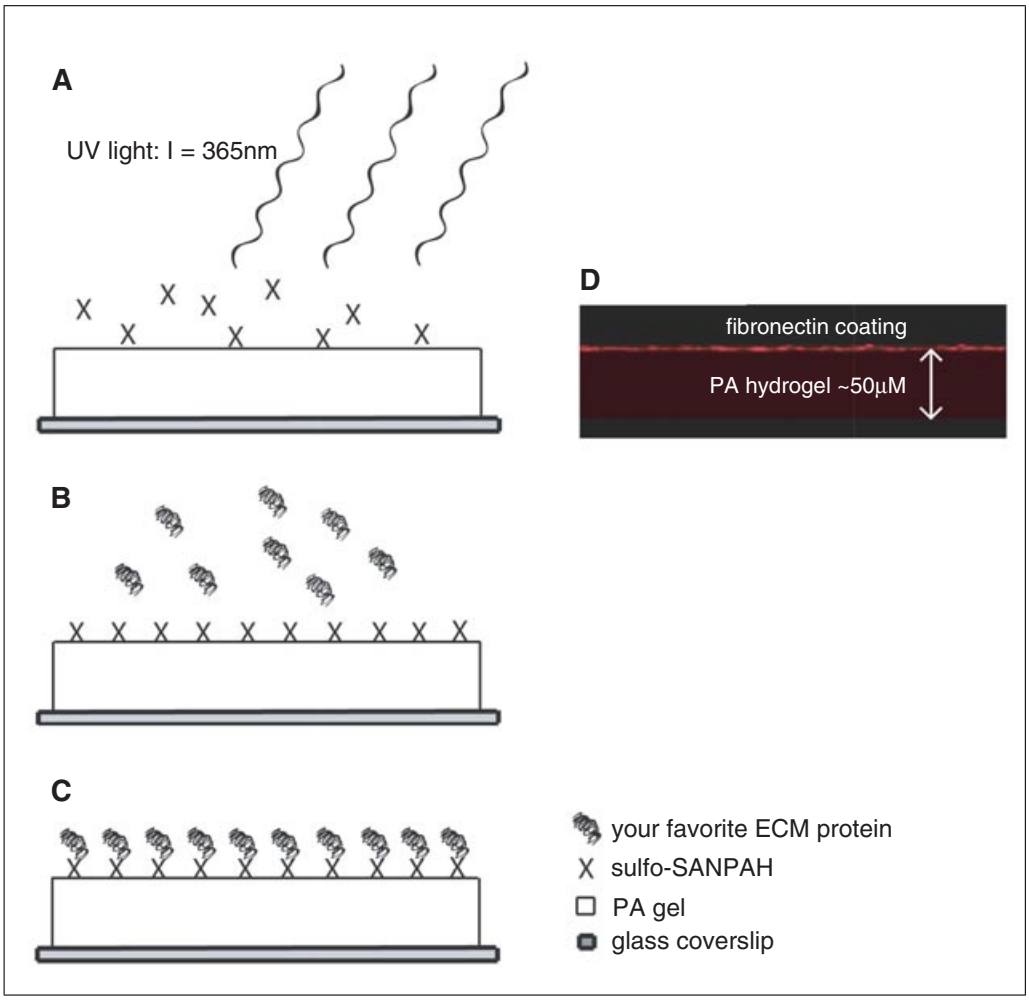

Figure 10.16.4 Schematic of the functionalization procedure for PA hydrogels. (**A**) The surface becomes activated upon addition of sulfo-SANPAH to the PA hydrogel, a reaction catalyzed with 365-nm UV light. (**B**) Overnight attachment of your favorite ECM protein in a 50 mM HEPES solution, pH 8.5. (**C**) Completed functionalization of your favorite ECM protein to the PA hydrogel. (**D**) Confocal cross-sectional fluorescence image of a 34-kPa PA hydrogel functionalized with rat fibronectin, demonstrating that the ECM protein represents a relatively uniform, thin layer of the PA hydrogel. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb1016*.

behavior (Rehfeldt et al., 2007). For example, while culturing mesenchymal stem cells (MSCs) on relatively stiff substrates promotes osteogenic differentiation of mesenchymal stem cells when collagen I (Engler et al., 2006) or fibronectin is bound (Rowlands et al., 2008), the use of collagen IV and laminin, proteins found in low concentrations in bone, on these same substrates does not result in any osteogenic marker expression (Rowlands et al., 2008). Nevertheless, because collagen I is the most abundant type of collagen found in the body, it is often used as a default surface coating for a variety of cell types (Badylak, 2005). The optimal choice of ECM protein or combinations of proteins thus depends on what will best mimic the in vivo microenvironment of the specific cell type.

Materials

PA hydrogels (Basic Protocol 1 or Alternate Protocol)
0.2 mg/ml sufosuccinimidyl-6-(4′-azido-2′-nitrophenylamino)-hexanoate (sulfo-SANPAH; Pierce Biotechnology)

50 mM HEPES buffer, pH 8.5, filter sterilized
ECM protein(s) of choice
Distilled H_2O *or* phosphate-buffered saline (PBS; Cellgro, cat. no. 46-013-CM), sterile

320-nm or 365-nm UV light source
37°C tissue culture incubator

1. Remove dH_2O or PBS from the petri dish with coverslip-gel composite.
2. Add ~500 µl of sulfo-SANPAH solution to the gel surface or enough to cover the entire gel.

   Complete coverage is necessary to ensure even protein coating.

   Sulfo-SANPAH is light-sensitive and should be shielded from light until use.

3. Place the gel in the 365-nm UV light source at a distance of ~3 in. and expose for 10 min.

   Repeat as necessary should insufficient protein bind, or if the coating does not appear uniform using the methods detailed below.

   See Figure 10.16.4A for schematic of the attachment of sulfo-SANPAH to the PA hydrogel, catalyzed by 365-nm UV light.

4. Rinse with 2 ml 50 mM HEPES at least two to three times to eliminate excess sulfo-SANPAH.

   The HEPES solution should be filter sterilized to ensure that the hydrogels remain as sterile as possible.

5. Add an appropriate amount of ECM protein to 50 mM HEPES, and incubate this solution with the gel overnight at 37°C.

   Due to the aqueous instability of the sulfosuccinimidyl ester, conjugation should start immediately upon activation.

   Ensure that the protein used in the conjugation has a primary amine group in it. Most extracellular matrix proteins contain such a reactive group. The end user should optimize the density of ligand coating for the specific cell type used.

   If making larger gels, placing the gel on a rocker plate can ensure that the solution remains well mixed and evenly coats the gel.

   For our setup, we employ concentrations of 0.10 mg/ml for collagen and 10 µg/ml of fibronectin or laminin, which have previously been shown to promote optimal cell behavior in smooth muscle cells (Engler et al., 2004a), fibroblasts (Rajagopalan et al., 2004), and epithelial cells (Williams et al., 2008), respectively. Increasing the collagen concentration within the solution to enhance binding may cause the collagen to precipitate or form a gel once heated to a physiological temperature. When the hydrogels are used for cell culture, media proteins will not continue to attach to unlinked sulfo-SANPAH sites because the reaction will only take place when the pH is 8.5, and media pH is usually 7 to 7.4.

   It is critically important that, for successful conjugation of the protein to the PA gel, the protein solution not precipitate. Given the relatively high pH of 8.5 for the reaction, collagen will have a tendency to precipitate. To avoid this, we suggest adding HEPES buffer to the concentrated collagen stock solution slowly, with vigorous vortexing.

   See Figure 10.16.4B,C for schematic of the overnight attachment of an ECM protein to the sulfo-SANPAH at the surface of the PA hydrogel.

6. Rinse with 2 ml distilled H_2O or PBS, depending on what was used to dilute the acrylamide.

7. To verify binding amounts, we suggest either using fluorescently labeled (Engler et al., 2004c; Rowlands et al., 2008) or radioactively labeled (Rajagopalan et al., 2004) protein to relate the measured signal to the amount of protein from reference standards. Alternatively, antibody-coated bead binding (Lo et al., 2000) or enzyme-linked immunosorbent assays (ELISA) may be used to confirm protein binding.

   Using fluorescently bound proteins may be most effective as they will also enable detection of uniform protein coating. Fluorescently labeled proteins can be added at up to a 1:9 ratio to unlabeled protein in step 5 of this protocol. When observing the gel with a confocal microscope, it will be possible to confirm that functionalization was confined to the top surface of the gel and that it does not vary in intensity by more than 10% (see Fig. 10.16.4D, Rowlands et al., 2008, or Winer et al., 2009).

   If there is an intensity variation of more than 10%, additional functionalization steps using sulfo-SANPAH should performed, i.e., repeat steps 1 to 4 of this protocol prior to adding protein in step 5. Alternatively, increasing sulfo-SANPAH concentration is not advisable, as it will reach its solubility limit.

8. After confirmation of protein binding, or in parallel cultures, add 1 ml of sterile distilled H_2O or PBS to the petri dish or well and place in the tissue culture hood for 30 min under UV for sterilization.

9. Plate cells using standard tissue culture techniques. For isolated cells with only cell-ECM contacts, plate cells at $<10^4$ cells/cm^2 in their standard medium.

SUPPORT PROTOCOL

CONSTRUCTION OF A GRADIENT-GEL APPARATUS

The construction and setup of the gradient-gel apparatus is presented here. The three main components of the apparatus are the gradient and negative photomasks and the UV light source. Photomask design can simply be made using the gradient tool in Adobe Photoshop and by adjusting the percent gray-scale or using silvered glass etching techniques in a microfabrication facility. Given that the former is a much more accessible technology, we will focus our discussion here to desktop versions for photomask generation. For our particular setup, we use a radial-gradient of 0% to 70% gray-scale, with the center at 0% and the edge at 70% gray-scale. While the gray-scale range can be modulated to any value, 70% was chosen as the maximum gray-scale because a higher value blocked efficient polymerization. The 0% to 70% range allows us to achieve a maximal range of elasticity of the gel associated with a maximal range of gray-scale. Because the edges of the photomask would transmit the least amount of light, the PA hydrogel would be expected to show the least polymerization and thus the lowest modulus of elasticity at the edge of the gels. This radial-gradient design is beneficial because it is easy to find the lowest attainable modulus of elasticity by monitoring the amount of time required for the edge of the hydrogel to just complete polymerization. Our setup uses a small UV light box, which typically emits UV light at 254-nm and 365-nm. It is acceptable to use a UV wavelength outside the optimal Irgacure 2959 absorbance peak of 280 nm with the precaution that longer UV exposure time is needed to deliver the same results. The negative photomask is essentially a black screen that blocks out all excess light by transmitting only an area of light the size of the actual photomask.

While the setup of the gradient-gel apparatus can be altered so that the light box is on top, it is important for the relative order of each component to stay the same. Figure 10.16.2 shows an exploded diagram of our apparatus that illustrates how the UV light should transmit through the chloro-silanated glass slide first before reaching the polymer solution. This order would initiate polymerization at the interface between the polymer solution and the chloro-silanated glass slide allowing the gel surface to receive the most UV light.

Materials

Laser printer
Nitrocellulose film
Photomask design
4 mil transparency film
Negative photomask design
254-nm UV light box
Spacers

1. Create photomask by printing out the desired pattern at 1200 dpi using a laser printer onto nitrocellulose film (see Fig. 10.16.2D as an example).

   For our photomask design, the center of the photomask had a gray-scale intensity of 0%, while the edge photomask had a gray-scale intensity of 70%. The photomask design can be created using the gradient tool in Adobe Photoshop.

   The photomask should be the same dimensions as the gel itself.

   Nitrocellulose film was chosen for the photomask material because it transmits UV light at a wavelength of 254 nm. Typical commercially purchased transparency films do not transmit UV light below ~300 nm due to the presence of benzene rings of the poly(ethylene terephthalate) of the material that absorb at these wavelengths.

2. Print out the negative photomask design at 1200 dpi onto 4 mil transparency film using a laser printer (see Fig. 10.16.2B).

   The negative photomask design should be a black print that would transmit UV light in the shape of the photomask.

3. Place the negative photomask on top of the 254-nm UV light box (see Fig. 10.16.2A and B), separated by spacers (see Fig. 10.16.2B).

4. Place the nitrocellulose paper with printed photomask on top of the negative photomask (see Fig. 10.16.2D).

5. Because nitrocellulose paper is sticky, use spacers to avoid contact between the negative photomask and the chloro-silanated glass slide (see Fig. 10.16.2E).

6. Align the negative photomask so that the area of light that is transmitted is directly below the photomask.

7. Proceed to the Alternate Protocol to continue the preparation of radial-gradient hydrogels.

COMMENTARY

Background Information

PA gels were originally used for the separation of proteins in gel electrophoresis as PA is both nearly inert and has tunable cross-linking density. For the same reasons, PA gels can be useful for cell culture techniques, as varying these concentrations results in a quantifiable stiffness known as the modulus of elasticity that cells can sense and respond to. The application of polyacrylamide gels to cell culture was first developed in 1997 to study the responses of 3T3 fibroblasts and rat kidney epithelial cells to mechanical properties of the substrate (Pelham and Wang, 1997). While this protocol uses PA as the polymer of choice, other materials, such as polydimethylsiloxane, (PDMS), polyethylene glycol (PEG), and hyaluronic acid (HA) are some of the other synthetic and natural substrates with a tunable elasticity that may be used for cell culture (Rehfeldt et al., 2007). The application of this protocol allows one to study how matrix elasticity can affect cell locomotion, focal adhesion structure, cytoskeleton, differentiation, and other potential mechanosensitive cellular processes. Recently, the interest in the effects of matrix elasticity has prompted other researchers to develop

methods to fabricate hydrogels with mechanical properties that oscillate or change with time, temperature, and/or pH (Kaehr and Shear, 2008).

Critical Parameters and Troubleshooting

PA gradient-gel

The greatest challenge to fabricating a PA matrix with a gradient of elasticity is finding the correct set of parameters that can reliably reproduce the gradient. There are many parameters that can affect the modulus of elasticity of the gradient gel. The parameters include the UV bulb intensity, UV light wavelength, distance from the UV light box, Irgacure 2959 concentration, gel thickness, photomask gray-scale range, acrylamide and bis-acrylamide concentration, and UV exposure time. Because even minute changes in the setup can affect the final values of the gradient gel, it is necessary for the researcher to optimize these parameters to create the desired results. It is recommended to vary the UV exposure time and the acrylamide and bis-acrylamide concentrations, keeping all other parameters constant. To increase the range of the modulus of elasticity, increase the relative acrylamide and bis-acrylamide concentrations. To increase the modulus of elasticity of the hydrogels, increase the UV exposure time. There are several references to measure the modulus of elasticity of the gels by AFM (Domke and Radmacher, 1998; Rotsch et al., 1999; Rotsch and Radmacher, 2000).

Gel attachment

When separating the chloro-silanated glass slide from the gel, the gel may not be completely attached to the amino-silanated coverslip, resulting in uneven gel attachment. This is especially common when creating the gradient-gels, in which the polymerization starts on the side of the gel facing the chloro-silanated glass slide. To ensure uniform gel attachment, make sure that the glass slide is freshly coated with DCDMS and that the amino-silanated coverslips are used as quickly as possible after preparation.

Gel thickness

Another obstacle in the fabrication of the hydrogels is uneven gel thickness. Uneven gel thickness usually results from completing the protocol on a tilted surface, causing the polymer solution to aggregate to one side. To ensure uniform gel thickness, make sure that a flat surface is chosen to complete the protocol.

Anticipated Results

Support Protocol. A basic gradient-gel apparatus that can be assembled in a few minutes and used repeatedly for the fabrication of gradient-gels.

Basic Protocol 1. The researcher should observe that the amino-silanated glass coverslips are hydrophilic while the chloro-silanated glass slides are hydrophobic. After gel attachment, a translucent PA gel of ~50 μl should be uniformly attached to the amino-silanated glass coverslip. The modulus of elasticity of the statically compliant hydrogels should match the values found in Table 10.16.1 and can be confirmed by using AFM analysis.

Basic Protocol 2. After overnight incubation with the ECM protein, the surface of the hydrogel should have covalent linkages to the protein. The researcher can confirm protein attachment by using immunofluorescent staining such as that employed by Rowlands and coworkers (Rowlands et al., 2008) or with bead assays as with Lo and coworkers (Lo et al., 2000). If one uses the conditions described in this unit, the surface concentration of the ligand should be ~340 to 450 molecules per μm^2 (Gaudet et al., 2003).

Time Considerations

Support Protocol. The gradient-gel apparatus can be completed within 1 hr.

Basic Protocol 1. It takes ~15 min to prepare NaOH-coated glass coverslips, which can be stored indefinitely. The rest of the preparation of the chloro-silanated glass slides and amino-silanated glass coverslips takes ~50 min. The steps that complete the attachment of the statically compliant PA hydrogel takes ~40 min. For the radial-gradient hydrogel, it generally takes ~15 min for the Irgacure 2959 with acrylamide and bis-acrylamide to completely dissolve and ~60 min to degas. Each gel then takes a few minutes to polymerize, depending on the acrylamide and bis-acrylamide concentration and the desired gradient.

Basic Protocol 2. The set up and UV exposure to cross-link the sulfo-SANPAH to the PA hydrogel takes ~20 min. The attachment of the ECM protein to the PA hydrogel can be completed overnight. Finally, before plating cells, the PA hydrogels should be sterilized for 30 min by placing them in the tissue culture hood under UV.

Engineering Three-Dimensional Collagen Matrices to Provide Contact Guidance during 3D Cell Migration

Paolo P. Provenzano,[1,2] Kevin W. Eliceiri,[2] David R. Inman,[2] and Patricia J. Keely[2]

[1]Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, Washington
[2]University of Wisconsin, Madison, Wisconsin

ABSTRACT

Cell invasion requires that cells navigate complex three-dimensional matrices in vivo. Topological cues are provided and three-dimensional cell migration and invasion facilitated by the alignment of collagen fibers proximal to tumors. In order to better understand the molecular mechanisms by which cells recognize and migrate along aligned matrices, in vitro assays are needed that recapitulate topological features of the in vivo matrix. Here, we describe two approaches for creating aligned three-dimensional collagen matrices, both dependent and independent of cell-mediated alignment. Approaches to quantify alignment and visualize the collagen matrix relative to the cells by second-harmonic generation are included. These assays are readily adaptable to a variety of cells and biological questions related to three-dimensional cell migration. *Curr. Protoc. Cell Biol.* 47:10.17.1-10.17.11. © 2010 by John Wiley & Sons, Inc.

Keywords: collagen alignment • three-dimensional cell migration • invasion

INTRODUCTION

Cell migration is an essential process in which physical and chemical cues are provided by the extracellular matrix (ECM; Lauffenburger and Horwitz, 1996; Petrie et al., 2009). Contact guidance from topographical features (Teixeira et al., 2003; Doyle et al., 2009) or three-dimensional (3D) microenvironments (Guido and Tranquillo, 1993; Dickinson et al., 1994; Dallon et al., 1999; Provenzano et al., 2008a) is the phenomenon by which the ECM provides directional cues that influence cell orientation and migration direction. In 3D collagen matrices, contact guidance from collagen fibers regulates cell migration via anisotropy in the local microenvironment (Dickinson et al., 1994; Provenzano et al., 2008a), with cells migrating preferentially along aligned collagen fibers.

In this unit, basic methods for engineering 3D collagen matrices to generate contact guidance cues are presented. The matrices closely resemble architectures observed in vivo (Provenzano et al., 2006). Utilizing in vivo–mimicking ECM conditions facilitates the acquisition of physiologically relevant information, while permitting manipulation of the system within a manageable experimental window. Therefore, to achieve this, two basic methods for generating 3D migration/invasion assays with defined architecture are described. The first system, described in Basic Protocol 1 makes use of placing cell-seeded collagen gels (CSCGs) or tissue explants into collagen matrices in a defined manner to create collagen architectures via cell contraction–mediated collagen reorganization. The second protocol (Basic Protocol 2) describes methods to align collagen matrices during matrix polymerization using a magnetic field. The aligned matrices may then be oriented and combined to develop 3D migration assays in which the cells face different contact guidance cues.

DOI: 10.1002/0471143030.cb1017s47

NOTE: All solutions and equipment used during the protocols must be sterile for use with cell culture. Likewise, all procedures should be performed in a sterile tissue culture hood with proper aseptic technique used throughout the protocols.

NOTE: Collagen matrix polymerization times should be optimized for each individual's laboratory conditions. Moreover, parameters may need to be adjusted to accommodate different cell types, experimental designs, and collagen matrix concentrations.

BASIC PROTOCOL 1

PREPARATION OF A 3D MIGRATION ASSAY USING NESTED CELL-SEEDED COLLAGEN GELS

Cell-seeded collagen gels (CSCGs) placed into an encasing matrix will contact and reorganize the matrix to generate regions of collagen alignment and regions of non-alignment that provide contact guidance cues for motile cells. In this assay, cells are seeded into collagen matrices to make plugs that are then inserted into an encasing collagen matrix. Over time, cells reorganize the matrix and invade into the newly organized encasing matrix.

Materials

Sub-confluent epithelial or fibroblast cells on a standard tissue culture dish/flask
Culture medium of choice for the chosen cell type
Phosphate-buffered saline (PBS) or serum-free culture medium
Trypsin/EDTA solution (Cellgro)
Rat tail collagen (BD Biosciences)
0.1 M HEPES buffer in 2× PBS

15-ml screw-cap conical tubes
96-well ultra-low adhesion culture plate (Corning)
37°C cell culture incubator
28-G syringe needle
1000-μl pipets with the tips cut off
6-well culture dishes (Corning ultra-low attachment plates work very well, but other more standard plates may be substituted as needed)

Additional reagents and equipment for counting the cells (*UNIT 1.1*) and optical imaging (Support Protocol)

Detach and count cells

1. Aspirate the cell culture medium from the culture dish containing sub-confluent cells. Rinse the cells with PBS or serum-free culture medium to remove residual serum. Aspirate buffer/medium from the dish.

   The volume of PBS or serum-free medium will depend on the size of the culture plate, as discussed in step 2.

2. Add 2 to 3 ml of trypsin/EDTA solution to the cell dish and incubate for ∼3 to 5 min (or until sufficient cell detachment is achieved) at room temperature. Use gentle agitation of the dish, if necessary, to detach cells.

   The concentration of the trypsin/EDTA solution may depend on the chosen cell line and the volume of trypsin/EDTA that is necessary will depend on the size of the culture dish. In general, the lowest concentration and volume of trypsin/EDTA solution that results in sufficient cell detachment within 10 min should be used. Furthermore, any cell culture reagent that adequately detaches the cells of interest may be substituted for trypsin/EDTA solution.

3. After the cells detach from the dish, transfer the cell-containing trypsin/EDTA solution to a 15-ml screw-cap conical tube and add 2 vol of culture medium for every one volume of trypsin/EDTA solution to the tube. Centrifuge the tube 3 to 5 min at 300× *g*, 4°C, to pellet the cells.

4. Discard the supernatant and resuspend the cells in 1 to 2 ml of culture medium. Count the cells (*UNIT 1.1*).

Prepare cell-seeded collagen gels (CSCGs)

5. Determine the volume of cell-containing medium that contains at least 150,000, but no more than 500,000 cells.

   The number of cells per CSCG may be adjusted for cell type and experimental design, but in general <150,000 cells do not adequately fill the CSCG with cells, while cell numbers >500,000 cells/CSCG are commonly too cell dense.

6. Calculate the volume of collagen mixture needed for the experiment.

   The amount of collagen added will depend on the desired final concentration of the collagen matrix and the initial concentration (in mg/ml) of the collagen solution. The volume of neutralizing HEPES buffer solution will be equal to the volume of collagen solution. Add regular culture medium to achieve the final volume. In our hands, 1 to 2 mg/ml collagen matrices have worked very well for MDA-MB-231 and T47D breast carcinoma cells. Therefore, as an example, to make a 2 mg/ml collagen matrix from a 10 mg/ml initial stock of collagen, add 200 μl of collagen solution, 200 μl of HEPES buffer solution, and 600 μl of culture medium for every ml of matrix solution needed. The 600 μl of culture medium includes the volume of culture medium needed to add the correct number of cells. For each CSCG, 150 to 250 μl (150-μl CSCGs work very well but larger volumes may used to accommodate more cells, i.e., 250 μl for 500,00 cells) of the collagen/HEPES/medium mixture is added to a well within the 96-well plate.

   Since the collagen solution is very viscous, pipet very carefully, allowing adequate time for the collagen solution to enter and exit the pipet. After releasing the collagen solution from the pipet allow the remaining volume to pool in at the bottom of the pipet tip and then clear the pipet again. In addition, make extra solution to ensure that enough CSCGs can be poured for the experiment.

7. In a new conical tube, add the calculated volume of collagen solution to an equal volume of 100 mM HEPES buffer (in 2× PBS). Add culture medium and culture medium containing cells to achieve the correct final volume and cell number per CSCG.

   All solutions should be kept on ice until the mixture is pipetted to the culture plate.

8. Pipet 150 to 250 μl of the collagen mixture (containing cells as described in step 6) to an individual well in the 96-well culture plate.

9. Allow the collagen matrix to polymerize for 20 min at room temperature, then at least 2 hr but not more than 16 hr in a cell culture incubator at 37°C (Fig. 10.17.1A).

Implant CSCGs into the encasing matrix

10. Gently detach the CSCG from the sides of the culture plate well using a fine needle, such as 28-G syringe needle. Insert the needle at the side of the CSCG, touching the well wall, and while maintaining contact with the wall, move the needle along the perimeter of the CSCG (Fig. 10.17.1B). Gently shake and tap the plate to help detach the CSCGs from the culture well surfaces.

11. Using a 1000-μl pipet with the tip cut off to increase the opening diameter (Fig. 10.17.1C), gently pull the CSCG up out of the culture well.

    The CSCG should never enter the pipet. The CSCG should remain suspended below the entrance to the pipet tip (Fig. 10.17.1D).

12. Suspend the CSCGs in culture medium in a tissue culture plate for 20 min to allow the matrix to contract.

    Allow ample room in the culture plate for the CSCGs to float without coming into contact with one another (Fig. 10.17.1E,F).

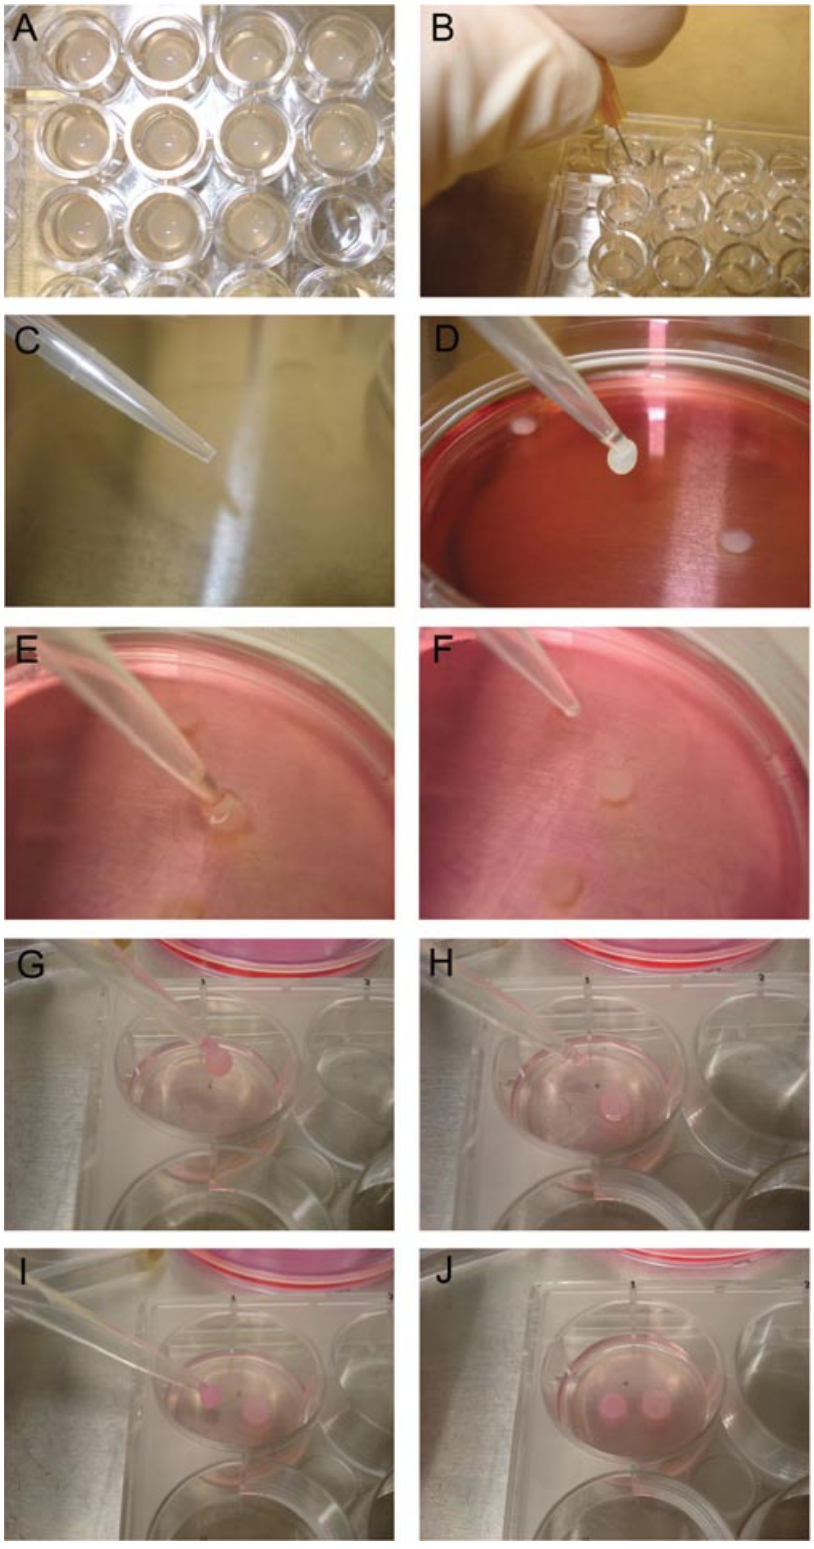

Figure 10.17.1 Key steps in Basic Protocol 1. (**A**) Polymerized CSCGs in a 96-well plate. (**B**) Detaching CSCGs from the culture dish wall. (**C**) A 1000-μl pipet with the tip cut off. (**D**) Transferring the CSCG from the culture well with care taken not to pull the CSCG into the pipet. (**E**) Placing the CSCG into a culture plate. (**F**) Floating the CSCG in culture medium with care not to allow multiple CSCGs to contact one another. (**G-J**) Placing CSCGs into the encasing matrix.

13. During step 12, make an additional collagen mixture for the encasing matrix.

    For each well of a 6-well tissue culture plate, 1.5 ml of 2 mg/ml collagen mixture is needed.

14. Add 1.5 ml of the collagen mixture to a well of the 6-well plate. Allow the collagen matrix to polymerize for ~10 to 15 min at room temperature.

    This step helps ensure that the CSCG will not directly rest on the bottom of the culture dish and attach to the bottom surface. By placing the CSCG into a matrix that is just starting to polymerize, and is therefore less fluid, the CSCG becomes suspended in the encasing matrix.

15. Place the CSCGs into the encasing matrix, making sure that the CSCGs does not sink to the bottom of the culture dish. Place the CSCGs 7 mm apart (from edge to edge) along the maximal diameter midline of the well (Fig. 10.17.1G-J).

    A custom reference grid may be placed under the well to help facilitate placement.

16. Allow the collagen matrix to polymerize undisturbed at room temperature for at least 20 min. After the matrix has sufficiently polymerized to allow movement of the plate without disturbing the CSCG placement, move the plate to the cell culture incubator at 37°C.

17. Sixteen to 24 hr after matrix construction, detach the encasing matrix and float the matrix in 2 ml cell culture medium.

    Detach the matrix from the culture dish by gently inserting a small pipet tip on the side of the matrix (while touching the well wall with the pipet tip). Gently move the tip around the perimeter of the matrix while maintaining contact with the well wall. Place the pipet tip at the side of the well and gently pipet 2 ml of medium into the well, under the matrix. Gently rotate the plate to detach the matrices and float them in the medium. Extreme care must be taken during this step so that the CSCGs do not tear away from the encasing matrix.

18. Incubate the nested CSCGs for one to several days, changing the medium every 3 days or for more even stimulation change 25% of the medium daily.

    We find that collagen alignment can be observed within the first 24 hr, but that collagen alignment is maintained and enhanced over 6 to 10 days.

19. Analyze three-dimensional cell migration/invasion with optical imaging (see Support Protocol)

    A single-plug nested assay can be employed as well (Grinnell et al., 2006; Provenzano et al., 2006; Miron-Mendoza et al., 2008), but does not provide the consistent contact guidance cues as the alignment is more distributed in random locations around the plug. However, this assay still provides a very good 3D migration assay, particularly for cancer biology studies where the CSCG can simulate an epithelial mass where carcinoma cells invade into the collagenous stroma. Likewise, more than two CSCGs can be employed to create more complex architectures.

PREPARATION OF ALIGNED COLLAGEN MATRICES TO CONSTRUCT A 3D MIGRATION ASSAY WITH DEFINED CONTACT GUIDANCE CUES

BASIC PROTOCOL 2

One limitation of the nested-plug assay, above, is that it does not readily allow separation of signaling events that lead to an aligned matrix from those necessary to migrate along a matrix that is already aligned. Here, we describe an approach to create a pre-aligned collagen matrix [as presented in Provenzano et al. (2008b) and adapted from Guo and Kaufman (2007)], which provides cells with contact guidance cues from perpendicular, parallel, and/or unaligned matrices. This approach allows one to address the question of which molecular events are specifically necessary for recognizing the topography of the matrix and mediating contact-guided 3D cell migration.

Materials

Sub-confluent epithelial or fibroblast cells on a standard tissue culture dish/flask
Culture medium of choice for the chosen cell type
Trypsin/EDTA solution (Cellgro)
Rat tail collagen (BD Biosciences)
0.1 M HEPES buffer in 2× PBS

Rectangular mold (~1- × 3-in.) *or* Nunc multidish, 4-well rectangular
1.5-μm diameter streptavidin-coated iron oxide beads (Bangs Labs, cat. no. BM551)
Cylindrical magnet (~2G; McMaster, cat. no. 5862K32)
37°C culture incubator
Small spatula *or* cell scraper

Additional reagents and equipment for detaching and counting cells and preparing collage solution (Basic Protocol 1) and optical imaging (Support Protocol)

Detach and count cells

1. Detach and count cells as described in steps 1 to 4 of Basic Protocol 1.

Prepare rectangular CSCGs

2. In a new conical tube, add the appropriate volume of collagen solution (as described in step 6 of Basic Protocol 1) needed to make 2.5 ml (for every two samples) of a mixture that will generate matrices with a final collagen matrix concentration of 2.0 mg/ml. Add an equal volume of 100 mM HEPES buffer (in 2× PBS). Add culture medium and culture medium containing cells to achieve the correct final volume and cell number per CSCG.

   At least 2 million cells per 2.5 ml matrix should be included. This number may vary by cell type and experimental question, but in general a smaller number of cells will not sufficiently fill the CSCG and the cell distribution at the CSCG-aligned matrix interface will be uneven.

3. Pipet the collagen mixture into a rectangular mold (~1 × 3 in.) or culture dish (Nunc 4-well rectangular multidishes work very well), and allow the matrix to polymerize for at least 2 hr at 37°C. During this time, move forward with step 4.

   While herein rectangular CSCGs are described and they have worked well, in general, any CSCG geometry that is needed to satisfy the final assay architecture may be substituted. Moreover, the size of the assay can be scaled as needed. However, the matrix volume should be optimized for each condition.

Generate aligned collagen matrices

4. In a new conical tube, add the appropriate volume of collagen solution (as described in step 6 of Basic Protocol 1) needed to make 2.5 ml of a mixture that will generate matrices with a final collagen matrix concentration of 2.0 mg/ml. Add an equal volume of 100 mM HEPES buffer (in 2× PBS). Add culture medium and then streptavidin-coated iron oxide beads (1.5-μm diameter) to achieve the correct final volume with a bead concentration of 0.1 mg/ml.

5. Pipet the collagen mixture (containing magnetic beads) into a rectangular dish with the same geometry as the dish used in step 3.

6. Place the cylindrical magnet underneath the culture well with the poles of the magnet along the long axis of the gel mold, in the direction of alignment, to align the collagen matrix during collagen fibrillogenesis at room temperature for 20 min.

   The culture plate well should be slowly translated over the magnet continuously, along the direction of alignment, during the first 10 min with each pass taking ~15 sec of the polymerization period in a single direction. If multiple matrices are being generated, an

array of magnets can be employed. In this case, four magnets can be separated by plastic so that a magnet is below each well (in the case of a Nunc 4-well plate). Note that care must be taken when handling the magnets as they will strongly attract or repel (depending on their orientation to one another) and can cause injury.

7. Place the culture dish, with the magnets remaining underneath the wells, in a cell culture incubator at 37°C for an additional 60 min.

Implant aligned matrices CSCGs into the encasing matrix

8. Remove the CSCG(s) and aligned matrices from the incubator. Using a small spatula or cell scraper, carefully lift each CSCG from the culture plate and float the matrix in culture medium for 20 min.

9. During step 8 make an additional collagen mixture for the encasing matrix at 2 mg/ml.

   The volume of the encasing matrix will depend on the choice of final geometry.

10. Cut a CSCG and an aligned matrix into two equal pieces and then pipet a thin, evenly distributed, volume of encasing matrix onto the culture plate. Immediately place the CSCG at the center of the dish and place the aligned matrices parallel and perpendicular to the CSCG. Gently pipet the encasing matrix over CSCG and aligned matrix pieces to achieve the configuration shown in Figure 10.17.2.

    The aligned matrices should be pressed directly against the CSCG with no space between the matrices at the CSCG/aligned matrix interface. Care should be taken so that the thin volume of collagen mixture at the bottom of the plate is not pushed between the CSCG and the aligned matrices. Likewise, when pipetting the encasing matrix, care should be taken not to flow an excess amount of collagen into the interface. Note that the CSCGs

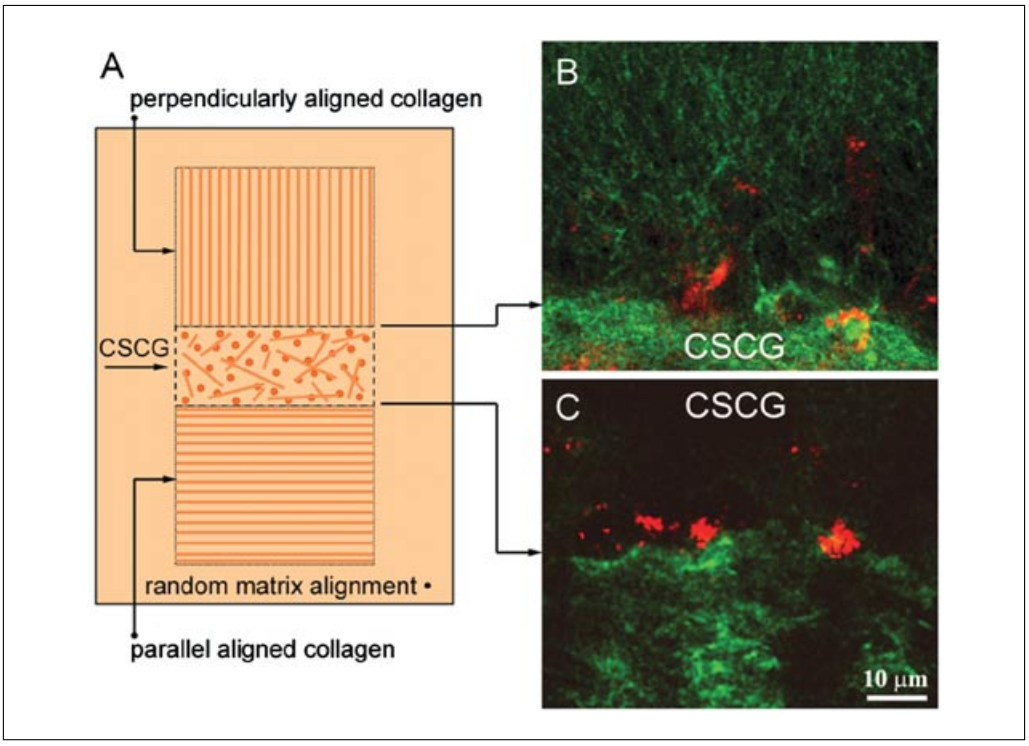

Figure 10.17.2 (**A**) Diagram illustrating 3D migration/invasion assay described in Basic Protocol 2. In the assay, collagen is magnetically aligned and aligned collagen matrices are connected to the CSCG so that the collagen alignment is either perpendicular (**B**) or parallel (**C**) to the CSCG boundary. Collagen is shown in green and cells in red. Reproduced from Provenzano et al., 2008a with permission. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb1017*.

and aligned collagen matrix can be carefully cut and shaped to achieve the desired architecture as shown in Figure 10.17.2. However, care should be taken to prevent an uneven surface from being placed against the CSCG.

11. Culture for one to several days, changing the medium every 3 days or for even more stimulation change 25% of the medium daily.

12. Analyze 3D cell migration/invasion with optical imaging (see Support Protocol)

SUPPORT PROTOCOL

IMAGING COLLAGEN MATRIX ALIGNMENT AND CELL MIGRATION WITH MULTIPHOTON EXCITATION AND SECOND-HARMONIC GENERATION MICROSCOPY

A number of multiphoton laser-scanning microscopy (MPLSM) systems are now commercially available that can be used to image collagen and the cells in the assays described above. Custom systems are also commonplace and the reader is encouraged to examine the references included in this unit for additional details (e.g., Denk 1990; Diaspro 2002; Condeelis 2003; Mohler 2003; Zipfel 2003; Provenzano 2006, 2008a, 2008b; Lee 2009).

The magnetic beads used in Basic Protocol 2 scatter light and can overload the microscope detector if care is not taken. Begin imaging with a low power or detector gain until it is determined how the beads will influence the microscope setup.

Multiphoton laser-scanning microscopy, MPLSM (Denk et al., 1990), is an optical sectioning technique where excitation is restricted to the plane of focus because the probability of two or more photons simultaneously exciting a fluorophore outside the focal volume is extremely low, significantly reducing phototobleaching by not exciting the out-of-focus-plane tissue volume [for detailed reviews of MPLSM and second-harmonic generation (SHG) see Diaspro and Sheppard, 2002; Mohler et al., 2003; Zipfel et al., 2003; Helmchen and Denk, 2005; Provenzano et al., 2009a. Detailed protocols for live-cell imaging and SHG, including equipment considerations, are provided in *UNITS 19.7 & 4.15*, respectively]. With MPLSM, the excitation wavelengths are long, typically 650- to 1050-nm excitation for 2- and 3-photon excitation, which has practical advantages for being able to excite a wide range of fluorophores (both endogenous and engineered) while facilitating deeper penetration into tissues, since the longer wavelengths are less prone to scatter. Additionally, MPLSM is advantageous due to its ability to produce second-harmonic generation signals useful for imaging fibrillar collagen. As such, MPLSM has emerged as a popular and powerful tool for analyzing cells and the extracellular matrix under live culture conditions.

To image the collagen matrix of the three-dimensional migration assays described in Basic Protocols 1 and 2, we image the live cell constructs with MPLSM (as described in Provenzano et al., 2006, 2008a,b) at an 890-nm excitation wavelength to simultaneously generate SHG signals from fibrillar collagen and endogenous fluorescence from the metabolite FAD (Provenzano et al., 2008a). Since SHG signal is found at exactly half of the excitation wavelength, SHG signals and endogenous fluorescence are separated with a 445-nm narrow-band-pass filter and a 464-nm long-band-pass filter (TFI Technologies), respectively. Collagen fiber orientation is examined at regions of the CSCG-encasing or -aligned matrix interface and at the level of the single cell using a Nikon CFI Plan Apo 60× water-immersion lens (NA = 1.2). The number of cells invading into the collagen gel is collected within three focal plains (center ± 30 μm) in regions of interest. Alternatively, full *z*-stacks can be created in regions of interest.

Alternative approaches for imaging 3D cell migration in collagen matrices exist. For instance, confocal reflectance microscopy has been used to successfully image the collagen matrix (Hegerfeldt et al., 2002). In combination with confocal reflectance or MPLSM, live cells can be imaged while expressing fluorescent proteins (Hegerfeldt et al., 2002;

Provenzano et al., 2009b). Furthermore, the cells in 3D constructs can be imaged with transmitted or phase-contrast light microscopy. In samples fixed with paraformaldehyde the distribution and number of cells that have migrated out of the CSCG can be analyzed following staining for cellular components, such as the nucleus (Grinnell et al., 2006; Miron-Mendoza et al., 2008), while MPSLM can be used to image cells and collagen in fixed samples as well (Gehler et al., 2009). Note that when studying cell migration in the context of 3D collagen matrix architecture, as is the case in both Basic Protocols, a method to image the collagen matrix in regions of interest for cell migration must be included, as changes in the organization of collagen strongly influence cell behavior.

COMMENTARY

Background Information

In three-dimensional microenvironments in vivo, cell migration plays a fundamental role in numerous physiologic and pathological processes, including tissue morphogenesis and cancer metastasis (Condeelis and Segall, 2003; Friedl and Gilmour, 2009). In vivo, alignment of collagen fibers has been shown to facilitate gland development (Ingman et al., 2006) and carcinoma cell invasion (Provenzano et al., 2006), while endothelial tube formation in three-dimensional constructs in vitro also shows a dependence on collagen matrix alignment (Lee et al., 2009). Therefore, in order to recapitulate matrix architecture associated with invasion into the collagenous stroma in intact tumors (Provenzano et al., 2006), we engineered 3D collagen matrix assays for studying contact guidance in vitro (Provenzano et al., 2008a). The first assay makes use of the cells themselves to generate contact guidance cues through cell contraction-mediated matrix reorganization, while the second assay pre-aligns the collagen matrix to facilitate separation of signals associated with 3D migration and motility events from those needed to reorganize the collagenous ECM.

Live-cell imaging with MPLSM has emerged as a powerful tool for studying cell migration in 3D microenvironments not only due to it ability to image endogenous fluorescence in live unlabeled cells, but also due to its ability to simultaneously image the collagen matrix. The use of SHG to image collagen fibers in 3D volumes provides novel insight into how the stromal ECM influences cell behavior. Furthermore, it also provides a means to understand how the cell influences matrix architecture under both normal and pathological conditions. While other techniques are valuable and can often be used in conjunction with MPLSM (i.e., imaging live cells with transmitted light, fixing samples after imaging to stain for specific features, etc.), MPLSM is unique in its ability to noninvasively image deep into 3D collagen environments and concurrently image cells and collagen with high resolution and good viability.

Critical Parameters and Troubleshooting

The ability of cells to contract a collagen matrix and cause the realignment (Basic Protocol 1) is dependent in part on the stiffness of the matrix, and in part on the ability of the cells to generate a contractile force. We have found that a 2 mg/ml collagen gel works well for many cell types including MDA-MB-231 cells, NMuMG cells, mouse embryonic fibroblasts, and mammary tumor explants. Dramatically increasing the collagen concentration of the encasing matrix may diminish the extent of the collagen rearrangement, and consequently may alter 3D cell migration. However, stiffer matrices may be useful for highly contractile cells, or when one wants to determine if changes in signaling events have altered cellular contractility (Gehler et al., 2009). In addition, the density of cells in the CSCG can influence the time course of collagen reorganization and cell migration. Our interests have revolved around simulating carcinoma cells invading into the collagenous stroma. As such, we have utilized a high cell density within the CSCGs; however, lower cell densities may be used if desired. The optimal cell density for a specific experimental condition should be optimized by each investigator. Finally, if the CSCG is detaching from the encasing matrix, lengthening the time of CSCG contraction before implantation may reduce pulling away from the encasing matrix. Alternatively, using low-adhesion culture plates can help facilitate detachment of the encasing matrix with the CSCG from the culture plate reducing the need to agitate the plate. Lastly, increasing the collagen density of the CSCG relative to the encasing matrix can help reduce detachment.

Anticipated Results

Cells migrate preferentially through collagen aligned perpendicular to the CSCG. In addition, cells migrate efficiently through aligned collagen matrices in the direction of alignment. With the assay described in Basic Protocol 1, the cells exert contractile forces on the matrix between the CSCGs, aligning the collagen matrix (collagen fibers oriented ~90° relative to the CSCG boundary). In regions 90° from the CSCG-CSCG axis (i.e., the "top" and "bottom" of the CSCG) collagen is oriented parallel to the CSCG boundary, likely due to collagen being pushed during growth expansion of the CSCG. Moreover, due to force balance resistance to contraction, in regions in the "back" (i.e., 180° from the interface nearest to the other CSCG) collagen is also reorganized perpendicular to the CSCG. This provides a valuable control to discount the possibility that cell migration from one explant to another in regions of alignment is being driven by contact guidance and not being driven exclusively by chemoattraction between the two CSCGs. Likewise, in pre-aligned matrices (Basic Protocol 2), cells are expected to migrate preferentially into the collagen matrix with alignment perpendicular to the CSCG.

Time Considerations

After cells are detached from the culture plate for seeding into CSCGs, the steps should be performed decisively so that the cells do not remain in suspension for prolonged periods of time. In addition, care must be taken to ensure that the collagen matrices are adequately polymerized before transferring out of the culture, so that matrix integrity is maintained. Likewise, in step 14 of Basic Protocol 1, the time should be optimized so that the matrix is neither under or over polymerized, so that the CSCG can easily flow into the matrix, but does not immediately drop to the bottom of the culture dish. Overall, once optimized, the entire assembly procedure for Basic Protocol 1 can be performed in 1 to 2 hr, depending on the number of samples being constructed. Basic Protocol 2 takes ~2.5 hr to assemble, with additional time required as the number of samples increases.

Migration into the aligned collagen regions in both protocols begins within 24 hr and continues for days. The exact time will depend on the cell lines used as well as the dimensions of the assay and the matrix conditions. However, following migration over 14 days is not uncommon. It is worth noting, however, that in prealigned matrices, cells that migrate into the matrix can remodel the matrix and in some regions reduce alignment while promoting alignment in other regions. As such, time points for these experiments are typically shorter (~12 to 72 hr) to limit the influence of cell-mediated matrix remodeling. Longer times may be used, but changes in matrix architecture should be noted as they may influence the migration pattern.

ABSTRACT

The use of in vitro three-dimensional (3-D) collagen matrices to mimic an in vivo cellular environment has become increasingly popular and is broadening our understanding of cellular processes and cell-ECM interactions. To study cells in in vitro 3-D collagen matrices, both cellular proteins and the collagen matrix must be visualized. In this unit, the authors describe the protocol and provide troubleshooting for immunolabeling of cells in 3-D collagen gels to localize and visualize cellular proteins with high-resolution fluorescence confocal microscopy. The authors then describe confocal reflection microscopy as a technique for direct imaging of 3-D fibrillar collagen matrices by discussing the advantages and disadvantages of the technique. They also provide instrument settings required for simultaneous imaging of cellular proteins with fluorescence confocal imaging and 3-D collagen fibrils with confocal reflection microscopy. Additionally, the authors provide protocols for a "cell sandwiching" technique to prepare cell cultures in 3-D collagen matrices required for high-resolution confocal imaging. *Curr. Protoc. Keywords: three-dimensional collagen matrix • collagen type I • Nutragen • confocal reflection microscopy • immunostaining of three-dimensional cell samples • invasion

INTRODUCTION

The research of the last decade shows that cells can sense chemical composition of the extracellular matrix (ECM) and its physical properties such as dimensionality, stiffness, and architecture. The use of in vitro 3-D collagen matrices to mimic in vivo cellular environments has become increasingly popular, and broadens our understanding of cell growth, survival, migration, and cell-ECM interactions that occur in vivo under physiologically normal and diseased conditions. To study cellular processes and cell-ECM interactions in an in vitro 3-D collagen matrix, both cellular proteins and the 3-D collagen matrix need to be visualized. Cellular protein localization and dynamics can be visualized using fluorescence microscopy of living cells expressing proteins of interest as a chimera tagged with green fluorescent protein (GFP) or a GFP variant, or of fixed cells immunostained with fluorescently labeled antibodies. The collagen matrix can be visualized through second harmonic generation using multiphoton microscopy, by directly incorporating fluorescently labeled collagen molecules/monomers into polymerized collagen fibrils and using fluorescence microscopy or confocal reflection microscopy.

In this unit, the authors describe the protocol for immunolabeling of cells in 3-D collagen gels to localize and visualize cellular proteins with high-resolution fluorescence confocal microscopy (see Basic Protocol 1). The protocol for fluorescence confocal microscopy of cellular proteins is designed for simultaneous direct imaging of 3-D collagen matrices with confocal reflection microscopy, in order to visualize cell-ECM interactions (see Basic Protocol 2). The authors also provide protocols for preparing cell cultures in 3-D

collagen matrices, which are required for high resolution confocal imaging (see Support Protocols 1 and 2).

STRATEGIC PLANNING

In Vitro Three-Dimensional Collagen Type I Matrices

The in vitro 3-D collagen type I matrix is a convenient system that allows for the mimicking of the in vivo 3-D ECM of connective tissue, where collagen type I is a predominant ECM molecule. However, the modeling of an in vivo environment means taking into consideration (1) the preparation method of collagen type I used, (2) collagen concentration, and (3) conditions for 3-D collagen matrix polymerization. These factors determine the characteristics of 3-D collagen matrix produced, which affect how cells interact with the collagen matrix, and thus result in distinct cell morphology and cellular protein localization.

First, an in vitro 3-D fibrillar collagen matrix is a meshwork of collagen fibrils polymerized from collagen molecules or monomers. Collagen fibril formation occurs when soluble collagen is brought to physiological conditions of neutral pH and warmed to 20° to 37°C (Williams et al., 1978; Gelman et al., 1979). Conversely, collagen solution is prepared by solubilizing native fibrillar collagen at pH 2 and at a temperature reduced to 4°C. The native collagen type I molecule contains nonhelical amino acid sequences on the C- and N- ends that are called telopeptides. These C- and N- telopeptides aid in collagen fibril alignment and provide sites for the cross-linking of collagen fibrils in 3-D ECM (Eyre et al., 1984). Depending on the conditions of collagen monomer preparation from native fibrillar collagen, telopeptides can be preserved or removed from the collagen molecule. Thus, acid extraction of native fibrillar collagen with hydrochloric or acetic acid preserves telopeptides, whereas extraction of collagen with pepsin cleaves off telopeptides. It has been shown that cells cultured in reconstituted collagen matrices that lack telopeptides do not require proteases for matrix transmigration (Packard et al., 2009; Sabeh et al., 2009). Therefore, it is important to remember that the choice of the matrix could determine cell morphology and behavior as well as cellular protein localization and dynamics.

Second, the concentration of collagen monomers used to polymerize fibrillar collagen networks determines the density of the matrix and pore size. It has been proposed that the cells can undergo mesenchymal-ameboid transitions that allow for protease-independent cell transmigration through matrices of low density and high pore size, where cells squeeze through pores in the matrix (Even-Ram and Yamada, 2005). However, for the cell to navigate through a dense fibrillar collagen network, it needs to employ proteases to cleave collagen fibrils, which facilitate the squeezing of the cell body through the narrow pores (Sabeh et al., 2009).

Third, morphology of collagen fibrils and alignment of collagen microfibrils in reconstituted collagen matrices depends on ionic strength, pH, temperature, and amount of phosphate (Williams et al., 1978). The conditions selected for production of 3-D collagen matrices are usually experimentally convenient and produce reconstituted fibrils that mimic native fibrils but do not exactly recreate the morphology and alignment of native collagen fibrils. To avoid possible heterogeneity in results due to changes in collagen fibril morphology, one needs to follow the same conditions for 3-D collagen matrix assembly in each experiment.

"Cell Sandwiching" in A Three-Dimensional Collagen Matrix

High-resolution fluorescence microscopy requires the use of 63× and 100× high numerical aperture oil-immersion objectives that have a working distance in the range of 100 to 200 μm. The working distance of the objective is defined as the distance from

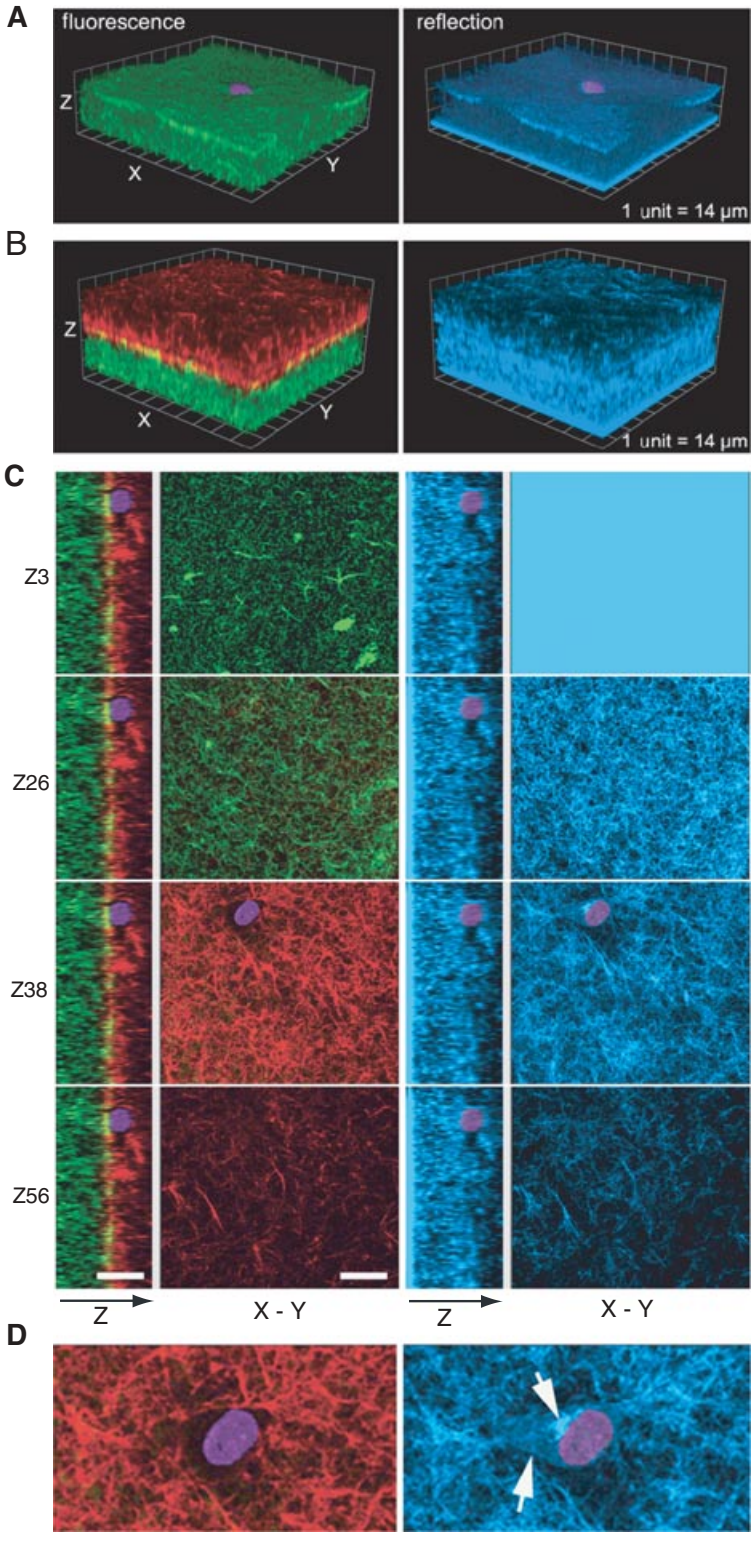

Figure 10.18.1 *(legend appears on next page)*

the front lens element of the objective to the closest surface of the coverslip when the specimen is in sharp focus. The working distance of the objective defines how deep into a 3-D collagen matrix one can image, i.e., it sets the limit on the distance of the cell to be examined with microscopy from the coverslip. The coverslip has its own thickness that is defined by the coverslip number (0.085 to 0.130 mm for number 0; 0.15 mm for number 1.0; 0.17 mm for number 1.5). Therefore, when subtracting the thickness of the glass coverslip from the working distance of the objective, one can estimate how far from the coverslip the cells can be located in the 3-D collagen matrix in order to be imaged with an inverted microscope. With the number 1 coverslip, which has a thickness of ~150 μm and a working distance of the objective of ~200 μm, one can image cells located in the range of 0 to ~50 μm away from the coverslip and deep into the 3-D collagen matrix. To position cells at the required distance from the coverslip and suspended in the 3-D collagen matrix, the authors of this unit developed conditions for "sandwiching" cells between two layers of collagen as described in Support Protocol 2. The authors used collagen conjugated to either fluorescent dye AlexaFluor 568 or AlexaFluor 647 to demonstrate the assembly of a 3-D collagen sandwich (Fig. 10.18.1). Using conditions provided in Support Protocol 2, the first collagen layer polymerized is between 30 and 35 μm in thickness. Cells plated on top of the first layer are consequently initially located at a distance from the glass coverslip that is suitable for high-resolution imaging. The second layer is polymerized on top of the first collagen layer and locks the cells in a 3-D collagen environment. Using collagen labeled with two different colors for labeling the two collagen layers demonstrates that collagen molecules from the second layer also penetrate into the first layer and bind to collagen fibrils in the first layer. This initiates fibril formation for the second collagen layer, ensuring that two collagen layers are "stitched" together with no free spaces in between (Fig. 10.18.2). The cells transmigrating within the 3-D collagen matrix move with different directions and angles relative to the glass surface of the coverslip and form large free spaces or tunnels. The alternative to the cell-sandwiching technique is mixing cells in collagen reconstituted to pH 7 before polymerizing collagen into a 3-D fibrillar matrix. The authors have found, however, that when using this latter procedure, many cells end up sinking through the matrix to the glass and then attaching to the glass coverslip. The cells that remain in the 3-D collagen matrix are usually situated at different distances from the glass coverslip, and are often too deep in the 3-D matrix to be imaged with high-numerical-aperture objectives.

Figure 10.18.1 *(appears on previous page)* Comparing fluorescence and reflection confocal microscopy for imaging of three-dimensional collagen sandwiches. (**A**) Assembly of a 3-D collagen sandwich involves polymerization of first collagen layer on glass surface, plating of the cells on this collagen layer, and (**B**) polymerization of the second collagen layer to encapsulate cells in a 3-D environment. The authors used collagen of two colors: one labeled with AlexaFluor 568 (in green) and another labeled with AlexaFluor 647 (in red) to demonstrate cell sandwiching between two collagen layers. Fluorescence microscopy was employed to visualize both collagen layers labeled with fluorescent AlexaFluor dyes (green and red). The collagen from the second layer penetrates into the first layer and stitches both layers together. The overlay of both layers is seen as yellow when green and red fluorescent dyes colocalize. Reflection confocal microscopy was used to visualize the collagen matrix of the sandwich (in blue). Cell nuclei were labeled with Hoechst (in magenta). (**C**) A series of X-Y slices through 3-D collagen sandwich taken at different Z-distances from the glass surface. Light reflected and scattered by the glass coverslip obscures images of collagen 3 μm in proximity to the glass surface in reflection confocal microscopy (Z3). Scale bar = 28 μm. (**D**) Light reflected from the cellular membranes contributes the cell outline to the image of collagen fibers (arrows). For color figure go to *http://www.currentprotocols.com/protocol/cb1018*.

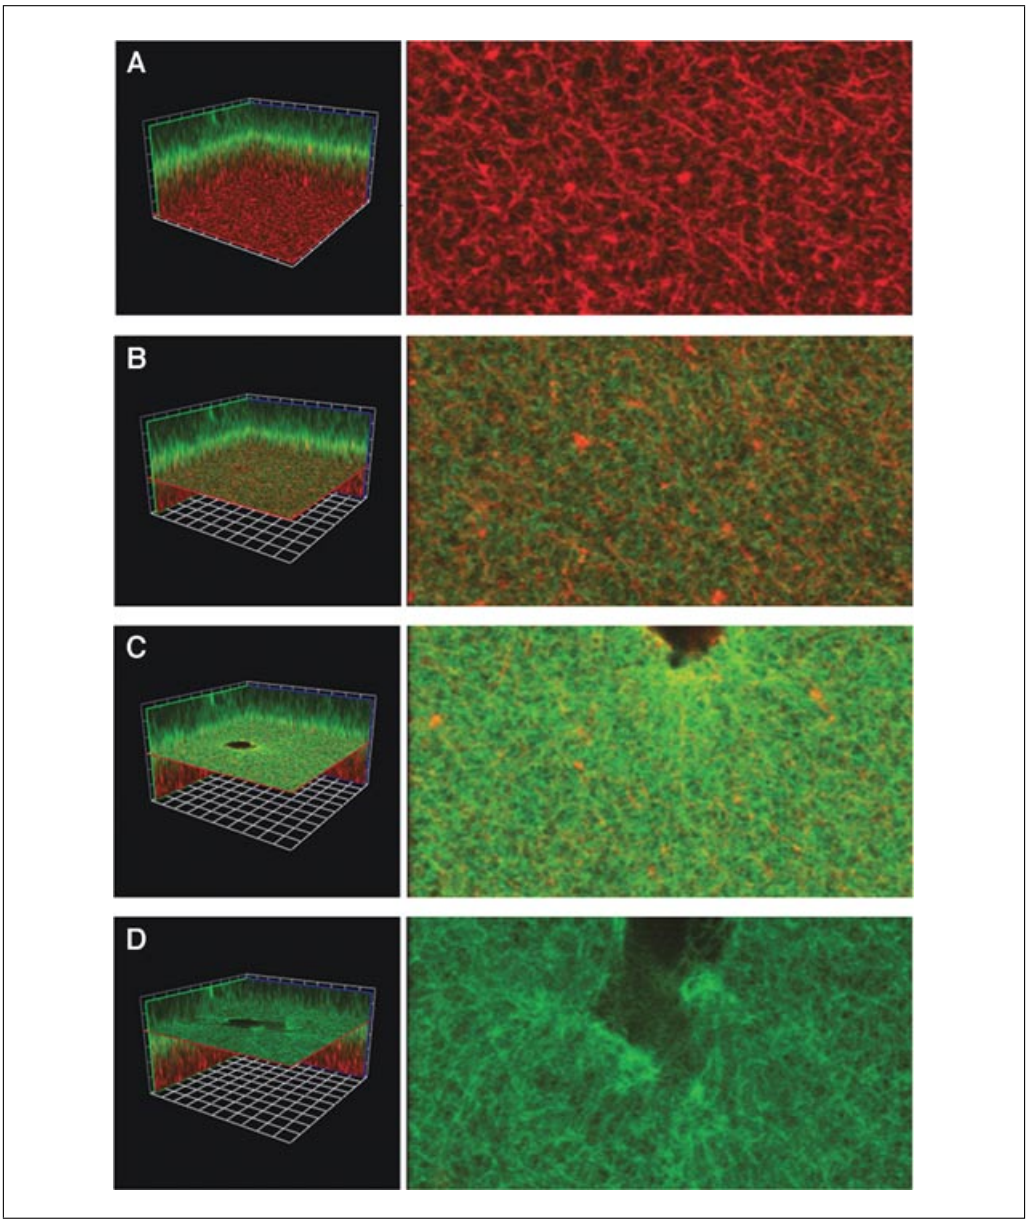

Figure 10.18.2 Morphology of collagen fibers in three-dimensional collagen sandwich. The authors used collagen labeled with AlexaFluor 647 (in red) to polymerize the first collagen layer, and collagen labeled with AlexaFluor 568 (in green) to polymerize the second collagen layer of a 3-D sandwich. X-Y slices taken at different Z-distances from the glass demonstrate that collagen from the second layer penetrates into the collagen of the first layer (**A**) and initiates collagen fibrils for the second layer of the three-dimensional collagen sandwich (**B**). The collagen fibers close to the glass surface appear straight (A and B), possibly from experiencing the tension from the stiffness of the glass. The collagen fibers of the second layer at a distance of about 30 μm and greater from the glass surface appear more wavy and relaxed (**C** and **D**). Unit size for the XYZ projection is 10 μm. For color figure go to *http://www.currentprotocols.com/protocol/cb1018*.

When culturing cells in an in vitro 3-D collagen system, one should test several conditions to establish what incubation time is appropriate for the cell line being studied, and for the collagen concentration to polymerize into a 3-D collagen matrix. Different cell types have different requirements regarding the time required to establish cell polarity and begin migrating within 3-D collagen matrices. The speed of cell migration within a 3-D collagen matrix depends on the density of the collagen matrix.

Microscope Instrumentation

Fluorescence imaging of cells in 3-D collagen matrices with simultaneous direct imaging of fibrillar collagen using reflection microscopy requires a laser scanning confocal microscopy system. Commercial confocal microscopes are equipped with multiple lasers and several photomultiplier tube detectors, which allow for simultaneous multilaser excitation, imaging of several different fluorophores, and confocal reflection imaging. Commercial laser scanning confocal systems include the Zeiss LSM510 and 710 META and NLO versions, Olympus FluoView, Leica TCS SPE, and Nikon Eclipse.

Confocal Reflection Microscopy

ECM fibers that differ in refractive index from their surroundings can reflect light. Laser-scanning confocal microscopy in reflection mode allows for the collection of reflected or back-scattered light from collagen fibers for each confocal plane, generating 3-D structural details of ECM that is not labeled with a fluorochrome (Fig. 10.18.1). Imaging of an unlabeled collagen 3-D matrix provides many advantages, by saving time and resources required for collagen labeling with fluorescent dye, by eliminating the issue of photobleaching that exists for fluorescently labeled collagen matrices, and by allowing for the use of unmodified collagen matrix for cell culture. Confocal reflection microscopy is easily combined with simultaneous fluorescence confocal imaging and does not require any additional modifications of the confocal microscope hardware. However, confocal reflection microscopy also has some limitations that need to be taken into account when preparing a sample for imaging. First, images of Z-planes in the proximity of 3 μm from the glass surface of the coverslip are obscured by bright uniform or nonuniform sources of background, which are caused by light reflection from the coverglass and interference from the optical pathway (Fig. 10.18.1C; Z3). Second, the intensity and contrast of the fibers diminish with the depth of the focus, due to laser light scattering and refraction (Fig. 10.18.1C; compare intensities of Z26, Z38, and Z56). The authors have found that the optimal range for confocal reflection imaging of collagen matrices is between 10 and 60 μm from the surface of the coverslip, and 10 to 60 μm deep into the 3-D collagen matrix. Third, cellular membranes, including the plasma membrane, Golgi, and endocytic vesicles, can also reflect light, contributing to the intensity of light reflected from the cell to the image of collagen fibers (Fig. 10.18.1D). The authors have found that the longer cells are incubated in the dense three-dimensional collagen matrices, the more the cells degrade and internalize collagen, which results in an increase in the number of endocytic vesicles that reflect laser light and contribute to the confocal reflection image.

BASIC PROTOCOL 1

IMMUNOLABELING CELLS IN THREE-DIMENSIONAL COLLAGEN MATRICES FOR IMMUNOFLUORESCENCE MICROSCOPY

This method describes how to fix and label samples of cells cultured in in vitro three-dimensional collagen type I matrices with fluorescently tagged antibody. Authors successfully applied this method of fixation and immunolabeling to different cell lines cultured in 3-D collagen type I matrices: fibroblasts, carcinoma, melanoma, and fibrosarcoma cell lines. The authors have used this protocol for immunolabeling of cells embedded in collagen matrices of different collagen type I concentrations that varied from 1.3 mg/ml to 6.5 mg/ml.

This method produced comparable immunostaining when different sources of collagen type I were used to prepare 3-D collagen matrices for cell culture. The authors used this protocol for the labeling of cells cultured in pepsin-extracted bovine collagen type

I that was devoid of telopeptide sequences, such as VITROGEN 100 (a former product of Cohesion; this product is now available as PureCol from INAMED Biomaterials) and Nutragen (a former product of INAMED Biomaterials), as well as collagen with intact telopeptide sequences, such as acid-extracted rat tail collagen type I (BD Biosciences), and mouse tail collagen type I (prepared by authors).

This protocol was developed for immunolabeling of 3-D collagen samples polymerized in the LabTek 8-well chambered coverglass systems that call for small volumes (400 μl) and allow for conserving antibodies. However, authors also used this protocol for immunolabeling of 3-D collagen samples polymerized in MatTek dishes (MatTek Co.) by scaling up all the reagents for volumes in the range of 1 to 2 ml.

Materials

4% (w/v) paraformaldehyde/5% (w/v) sucrose in PBS (see recipe)
Sample of cells in 3-D collagen gel polymerized in LabTek 8-well chambered coverglass (Support Protocol 2)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), filtered through a 0.22-μm filter
0.5% (v/v) Triton X-100 in PBS (see recipe)
Blocking solution (see recipe)
PBS/Tween (see recipe)
Primary antibody solution (see recipe)
Secondary antibody solution (see recipe)

Additional reagents and equipment for confocal microscopy (*UNIT 4.5*)

Fix the sample

1. Place the solution of 4% paraformaldehyde/5% sucrose in PBS in a water bath and preheat to 37°C.

2. Retrieve a sample of cells in 3-D collagen gel polymerized in LabTek 8-well chambered coverglass from the 37°C tissue culture incubator.

   Do not keep cell samples sitting at room temperature. Start fixing cell samples as described in the next step as soon as possible. Many cell lines are sensitive to temperature shifts. Keeping cell samples at temperatures that are lower than 37°C may cause cells to retract cellular protrusions. This will result in changes in cell morphology and, as a result, in altered immunostaining patterns for cellular proteins.

3. Gently aspirate cell culture medium from the well without damaging the 3-D gel, and slowly add 400 μl of the 4% paraformaldehyde/5% sucrose in PBS to the side of the well to fix the 3-D cell sample.

   Authors recommend using short glass Pasteur pipets attached to vacuum aspiration systems. Fit a 1000-μl plastic pipet tip without a filter on the Pasteur pipet and adjust the vacuum to a low setting to provide gentle aspiration. Always tilt the LabTek chamber to one side while aspirating to accumulate most of the liquid at one corner of the well where one inserts the pipet tip. Keep the pipet tip close to the well wall to avoid sucking up the matrix. Always leave about 25 μl of liquid above the matrix to ensure that you do not touch the matrix with the pipet tip, which can damage the matrix.

4. Incubate 20 min at room temperature.

5. Gently aspirate 4% paraformaldehyde/5% sucrose in PBS and wash the cell sample with 400 μl of PBS three times, each time adding and aspirating the liquid as described in step 3.

   Always add liquids slowly and to the side of the well to prevent damaging the 3-D matrix.

6. Aspirate PBS and add 400 μl of the 0.5% Triton X-100 in PBS to permeabilize the cells for immunostaining of the intracellular proteins. Incubate 10 min at room temperature.

7. Gently aspirate Triton X-100 solution from the well and wash sample with 400 μl of PBS in two short washing steps and one long washing step. For short washing, simply aspirate the liquid from the well and add fresh PBS; for long washing, add fresh PBS and incubate the sample for 30 min at room temperature.

   It is crucial to get rid of all the Triton X-100 in order to stop the permeabilization process and to ensure that it will not interfere with staining.

   At this point the sample can be stored at 4°C for ~1 week. Seal the LabTek chambered dish with Parafilm to prevent liquid evaporation and cell sample drying.

Stain the cells

8. Gently aspirate PBS and add 400 μl of blocking solution to the well to block the sample and prevent nonspecific binding of the antibodies. Incubate 30 min at room temperature.

9. Wash the sample with 400 μl of PBS/Tween one time.

10. Aspirate PBS/Tween and add 300 μl of primary antibody solution and incubate for 90 min at room temperature.

    Authors decrease the volume of the antibody solutions to 300 μl in order to spare the antibody used for the immunolabeling.

    One can use monoclonal or polyclonal antibody against the cellular proteins of interest. Refer to Critical Parameters and Troubleshooting on how to choose the right concentration of the antibody for immunostaining of 3-D samples. The primary antibody directly labeled with fluorochrome can also be used instead of the combination of primary antibody followed by fluorescently-conjugated secondary antibody.

    For the purposes of this unit, authors used phalloidin-AlexaFluor 488 to immunostain actin cytoskeleton, and mouse monoclonal anti-phosphotyrosine 4G10 primary antibody (Upstate Biotechnology) followed by donkey anti-mouse Cy5-conjugated secondary antibody (Jackson ImmunoResearch) to identify sites of tyrosine phosphorylation in carcinoma cells invading 3-D collagen matrix (Figure 10.18.6).

11. Wash the sample with 400 μl of PBS/Tween three times, each time incubating the sample for 10 min at room temperature.

12. Apply 300 μl of secondary antibody solution to the sample and incubate 60 min at room temperature.

13. Wash the sample with 400 μl of PBS/Tween three times, each time incubating the sample for 10 min at room temperature.

14. Wash with PBS three times for 10 min each.

15. Add 400 μl PBS to give the final sample.

Visualize the sample

16. Examine the sample with confocal microscopy (*UNIT 4.5*).

    At this stage, storage of the sample depends on the affinity of the antibody used for immunostaining. The sample is in the liquid and if stored, it will lose fluorescence labeling by many antibodies due to molecular diffusion, resulting in an increase of the background signal. Therefore, it is recommended that one proceed promptly to confocal microscopy after immunolabeling is complete. For some high-affinity antibodies, the sample can be stored overnight at 4°C and examined in the morning the next day. The possibility of sample storage needs to be determined by testing each antibody preparation.

COLLAGEN PREPARATION FOR THREE-DIMENSIONAL COLLAGEN MATRICES

Aliquot and neutralize collagen in the tissue-culture hood to prevent collagen contamination.

Materials

10× DMEM with phenol red (see recipe)
10× reconstitution buffer (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), filtered through a 0.22-μm filter
2 N NaOH
2 N HCl
9.44 mg/ml solution of collagen type I in 0.02 N hydrochloric acid (from BD Biosciences)
ColorpHast pH-indicator strips with pH range 6.5–10.0 (EMD Biosciences, *http://www.emdchemicals.com/*)

Prepare reagents

1. Defrost aliquots of 10× DMEM and 10× reconstitution buffer on ice.
2. Pre-chill microcentrifuge tubes, PBS, 2 N NaOH, and 2 N HCl that will be used for collagen preparation, on ice.
3. Calculate the amount of collagen that is needed for the experiment.

   Always calculate 20% more to account for pipetting difficulties due to the high viscosity of collagen.

   If a positive-displacement pipet is available to aliquot the viscous collagen solution, then the calculated volume of collagen solution should be used without additional 20% of collagen volume.

   To prepare a sample of cells sandwiched in three-dimensional collagen type I in one well of the LabTek 8-well chambered coverglass, as described in Support Protocol 2, one will need 150 μl of collagen at the final concentration required for 3-D matrix preparation. For the example, the authors used collagen at 2.5 mg/ml final concentration to prepare 3-D collagen sandwiches. If multiple wells of the LabTek chambered coverglass to be used, then the amount of the collagen needs to be adjusted accordingly.

Prepare collagen

4. Pipet the required amount of stock collagen solution into a prechilled microcentrifuge tube. Keep the tube with collagen on ice during the subsequent steps.
5. First, add 10× DMEM at one-eighth of the volume of collagen solution added, and mix by slowly and gently pipetting up and down. Observe the change in color of phenol red of DMEM.

   The phenol red will change from red to yellow, indicating that the pH of collagen solution is acidic.

6. Second, add 10× reconstitution buffer at one-eighth of the volume of collagen solution added, and mix by slowly and gently pipetting up and down.

   The phenol red will change from yellow to light pink, indicating that the pH of the collagen solution is shifting to basic.

   As an example, to neutralize 400 μl of rat tail collagen stock, add 50 μl of 10× DMEM and 50 μl of 10× reconstitution buffer.

   Always pipet the collagen solution up and down slowly and gently without introducing air bubbles. Harsh pipetting can cause collagen to precipitate and form clumps. Always keep the tube with collagen solution on ice, since a change in the pH of collagen solution to neutral, and an increase in temperature will induce polymerization of collagen fibrils.

7. Use a pH paper strip to measure the pH of the neutralized collagen: pipet a small drop of neutralized collagen on the strip of pH paper, and, using the color scale, determine the pH of the neutralized collagen solution.

   The pH must be in the range of 7.1 to 7.4. Use the ice-cold solution of 2 N NaOH or 2 N HCl to adjust the pH if needed. Add the solution of NaOH or HCl in small portions, mix gently by pipet, and re-measure pH with pH paper.

8. Incubate the neutralized solution of collagen on ice for 3 to 5 min to allow the pH of the solution to equilibrate.

9. Microcentrifuge collagen solution 3 min at 10,000 rpm, 4°C, to get rid of air bubbles.

10. Re-measure the pH of the neutralized collagen solution to ensure that it falls in the range between 7.1 and 7.4. If needed, adjust pH again, as described in step 7, using the ice-cold solution of 2 N NaOH or 2 N HCl, and then repeat steps 8 to 9.

Dilute collagen solution

11. Depending on the final concentration of the collagen that one needs to use, calculate a dilution ratio of neutralized collagen solution and PBS. Use ice-cold PBS to dilute neutralized collagen.

    Mix collagen and PBS solution slowly and gently by pipetting up and down—collagen can clump if this procedure is performed with haste.

    As an example, the following calculations can be used for preparing 2.5 mg/ml collagen solution from 400 μl of 9.44 mg/ml collagen stock. First, add 100 μl of 10× DMEM and 10× reconstitution buffer mixture to neutralize the collagen solution. This brings the collagen concentration to 7.56 mg/ml. Next, dilute the neutralized collagen with PBS in 1:2 dilution by mixing 500 μl of neutralized collagen with 1000 μl of ice-cold PBS in order to obtain a collagen solution with a final concentration of 2.5 mg/ml.

12. Microcentrifuge collagen solution 3 min at 10,000 rpm, 4°C, to get rid of air bubbles.

    Keep neutralized collagen solution on ice and use within 1 hr. Do not store it.

SUPPORT PROTOCOL 2

POLYMERIZATION OF COLLAGEN THREE-DIMENSIONAL GELS AND PREPARATION OF THREE-DIMENSIONAL CELL CULTURE

Perform all steps of the protocol under the tissue-culture hood to prevent bacterial contamination of the sample.

Materials

Neutralized solution of rat tail collagen diluted to a final concentration of 2.5 mg/ml (Support Protocol 1)
Cell culture medium
Cell suspension (e.g., MDA-MB-231 breast cell carcinoma line; ATCC no. HTB-26) at 1.25×10^4 cells/ml in cell culture medium
LabTek 8-well chambered coverglass (borosilicate no. 1.0 coverglass; Nunc, cat. no. 155411)
37°C, 10% CO_2 cell culture incubator
Tissue culture microscope with 10× objective and phase-contrast optics

Prepare collagen gel on coverglass

1. Place LabTek 8-well chambered coverglass on ice and allow it to chill. Keep neutralized solution of rat tail collagen on ice.

2. Warm cell culture medium in a 37°C water bath.

3. Drop 15 μl of ice-cold neutralized collagen solution on the glass surface of the well of the LabTek chambered coverglass, and, with gentle strokes, spread the collagen solution on the glass surface using the pipet tip. Keep LabTek chambered coverglass on ice while spreading collagen.

   There are eight chambers in each LabTek 8-well chambered coverglass. All eight of them can be used to prepare separate 3-D collagen cultures by following this protocol and assembling individual "collagen cell sandwiches" in each well.

4. Place LabTek coverglass in a 37°C, 10% CO_2 cell culture incubator for 25 min to allow collagen to polymerize and form fibrillar meshwork.

5. Use a tissue culture microscope equipped with 10× objective and phase-contrast optics to confirm formation of fibrillar collagen matrix.

   Neutralized collagen is a transparent viscous solution. Warming neutralized collagen to 37°C triggers polymerization of collagen fibrils, which result in formation of fibrillar matrix. Collagen fibrils are detectable with phase microscopy as a network of the fine filaments.

   Slight changes in pH or temperature affect the rate of collagen polymerization as well as the size of collagen fibrils. The concentration of collagen used for matrix polymerization also affects the size of collagen fibrils. It is required that one monitor fibril formation with phase-contrast microscopy to confirm polymerization of fibrillar collagen and to ensure consistency in the size of collagen fibrils. Plating cells on a collagen matrix that did not polymerize well will result in cell adhesion to the glass bottom of the well, detachment of the collagen matrices from the glass, and floating of the matrices.

   While polymerizing collagen matrix, do not allow matrix to dry. Dry matrix becomes opaque in appearance to the naked eye. Drying of collagen matrices changes the physical properties of the matrix, which affects its cellular response.

Prepare cells

6. During the time of collagen polymerization, detach cells to be examined, count them, and prepare cell suspension of 1.25×10^4 cells/ml in cell culture medium.

   Cell density should be adjusted for each cell line and for the requirements of the experimental design. It will vary depending on the size of the cells, on the cells' ability to grow and divide in 3-D collagen matrix, and on the duration of cell incubation in 3-D collagen matrices.

7. Retrieve LabTek coverglass system from the incubator and place it on a Kimwipe under the hood.

   Place LabTek coverglass system on a Kimwipe to avoid direct contact with a cold surface, since decrease in temperature can destabilize the collagen matrix at the glass surface, resulting in the matrix detaching and floating.

8. Add 400 μl of cell suspension on top of the polymerized collagen layer.

   Add cell suspension slowly to the well with polymerized collagen matrix, and always pipet to the side of the well to prevent damaging the matrix.

9. Incubate LabTek coverglass in a 37°C, 10% CO_2 for 30 min, allowing cells to attach to the collagen matrix.

10. Use tissue culture microscope equipped with 10× objective to check if cells are attached to the matrix.

    Place LabTek coverglass on microscope stage, focus on the cells, and, while examining cells under the microscope, gently shake the LabTek coverglass system. If cells are attached, they will move together with the matrix and will not float in the culture medium.

11. Retrieve LabTek coverglass system from the incubator and place it on the Kimwipe under the hood. Gently aspirate cell culture medium from the well.

Use Pasteur pipet equipped with 1000-μl pipet tip for liquid aspiration from the well. Always place pipet tip on the wall of the well above the matrix and tilt the LabTek coverglass system to gather all the liquid in the corner where the pipet tip is inserted.

Prepare the sandwich

12. Coat adherent cells with a layer of collagen by applying 80 μl of collagen dropwise on top of the cells adherent to the first collagen layer.

13. Place LabTek coverglass system in the 37°C, 10% CO_2 incubator and incubate for 30 min to polymerize the second layer of fibrillar collagen.

14. Confirm collagen layer polymerization with phase-contrast microscopy.

15. Retrieve LabTek coverglass system from the incubator and place it on the kimwipe under the hood. Gently add 400 μl of cell culture medium (preheated to 37°C) to the well.

16. Place LabTek coverglass system into the 37°C, 10% CO_2 incubator and incubate for 24 hr to allow cells to establish polarity and start migrating in the 3-D collagen matrix.

Incubation time for cells in 3-D matrices should be established experimentally and will depend on cell type, density of the matrix, and experimental design.

BASIC PROTOCOL 2

SIMULTANEOUS FLUORESCENCE CONFOCAL IMAGING OF CELLS AND CONFOCAL REFLECTION IMAGING OF COLLAGEN IN IN VITRO THREE-DIMENSIONAL GELS

Here the authors provide general procedures for configuring the confocal microscope hardware for simultaneous fluorescence and reflection imaging of three-dimensional collagen samples. They also provide practical suggestions on image acquisition and analysis.

Materials

Immersion oil

Sample of cells in three-dimensional collagen gel polymerized in LabTek 8-well chambered coverglass and immunostained for proteins of interest (Basic Protocol 1)

Inverted confocal microscope equipped with high NA 63× and/or 100× oil immersion objectives (also see *UNIT 4.5*)

Emission filters for specific emission wavelength of chromophores conjugated to anti-bodies used for immunostaining (Chroma, Omega, or available from confocal microscope manufacturer)

Image analysis software

Additional reagents and equipment for confocal microscopy (*UNIT 4.5*)

1. Clean the microscope objective with cleaning solution provided by the manufacturer using lens paper.

A 63× 1.4 NA or 100× 1.4 NA oil immersion objective is recommended for high-resolution imaging. Presence of oil or a dirty objective can result in the formation of interference patterns that deteriorate image quality.

2. Apply one small drop of the immersion oil on the objective lens.

3. Place the LabTek chamber with the specimen on the microscope stage and focus on the sample.

4. Configure confocal microscope hardware for simultaneous imaging in fluorescence and reflection modes.

   Conventional confocal systems with three photomultiplier (PMT) detectors allow for the use of two channels for simultaneous fluorescence imaging of two different fluorophores, and one channel for reflection imaging. To set a configuration for confocal reflection imaging, simply use a separate laser line to illuminate the sample and collect all the light reflected from the sample to the separate PMT detector. Do so by putting no emission filter in front of the detector, or by using a band-pass emission filter that collects the light of the wavelength used to illuminate the sample. Any laser line or PMT can be used for confocal reflection imaging; however the variations in reflection signal intensity and contrast may occur depending on the laser light intensity and PMT sensitivity. In Figures 10.18.3 to 10.18.5, authors present configuration settings that they have used for simultaneous fluorescence imaging with 488-nm and 633-nm laser lines, and reflection imaging with a

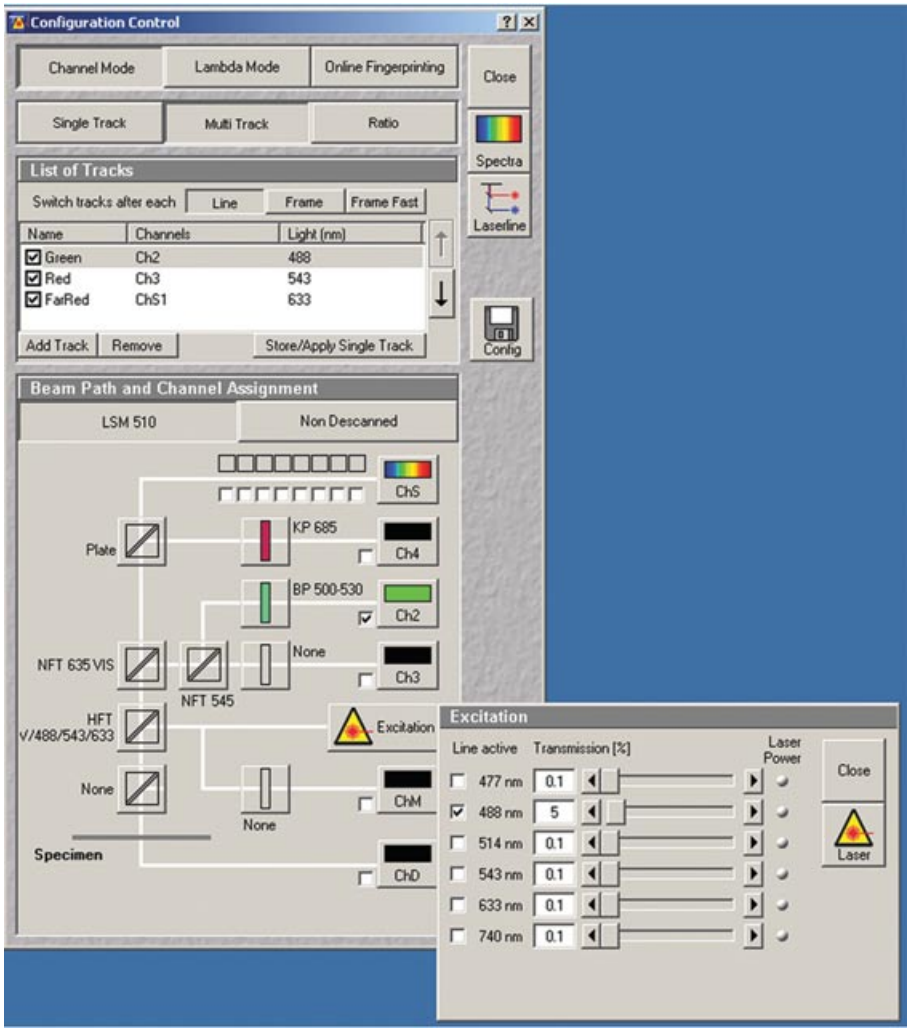

Figure 10.18.3 Configuration for fluorescence imaging with 488-nm excitation for three-channel simultaneous fluorescence, and reflection confocal microscopy with the Zeiss510 NLO imaging system.

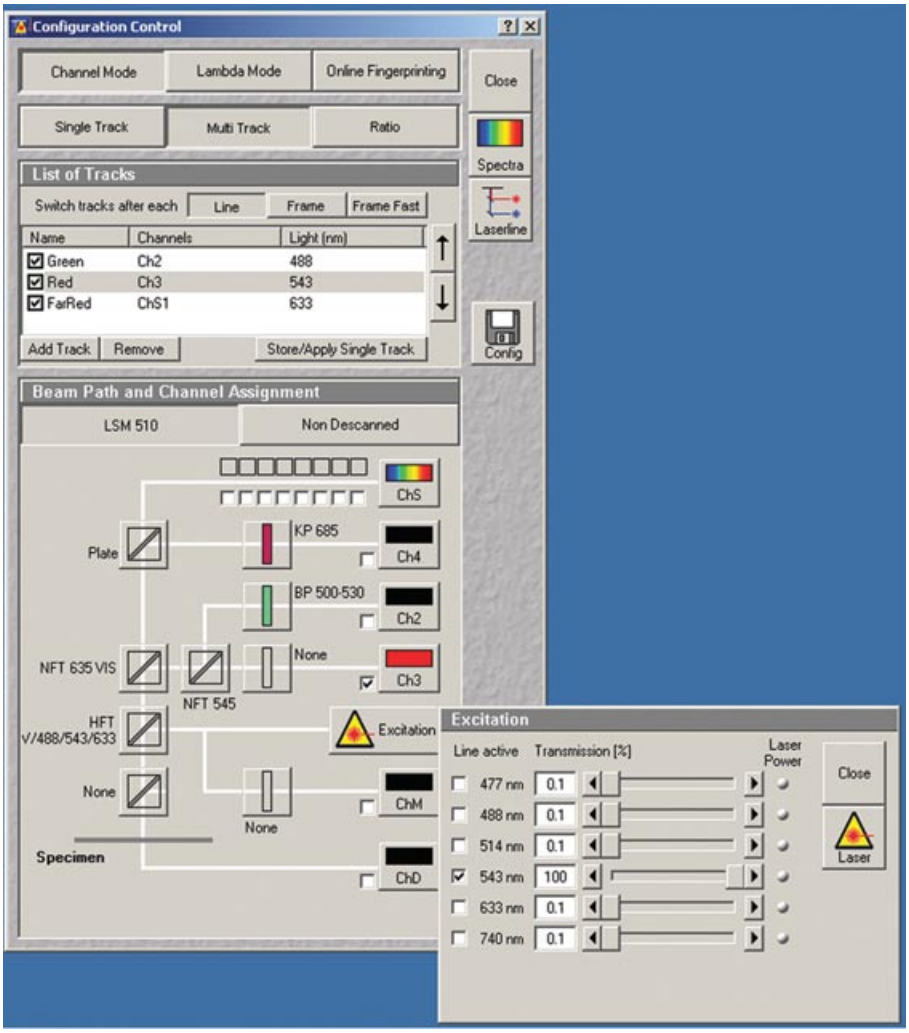

Figure 10.18.4 Configuration for reflection imaging with 543-nm excitation for three-channel simultaneous fluorescence, and reflection confocal microscopy with the Zeiss510 NLO imaging system.

543-nm laser line with a Zeiss510NLO system equipped with META detector. For detailed discussion on the principles and practice of confocal microscopy, see UNIT 4.5.

5. Initiate image acquisition.

Image acquisition is specific to the particular question being addressed, and should be developed by the researcher accordingly. A single confocal plane or Z-stacks of multiple confocal planes can be acquired to demonstrate the localization of the protein/proteins being studied in the cell, colocalization of the proteins, and/or cell interaction with the collagen three-dimensional matrix. Acquiring Z-stacks of whole 512×512 images takes a matter of minutes, and timing depends on the image-acquisition settings such as the number of confocal planes, the speed of acquisition, and the number of scans being averaged.

When acquiring Z-stacks, consider the following: (1) the reflection signal from the collagen matrix attenuates with the increase in three-dimensional volume being imaged, and therefore the differences in collagen matrix intensities will be greater between the first and last Z-slices, with the increase in distance between them; (2) increasing the size of the Z-stack and using low scan speed and a high number of scans for averaging, which is required for a contrast image, can result in photobleaching of some of the fluorophores used for cell immunostaining. To obtain the best image, one can consider selecting the

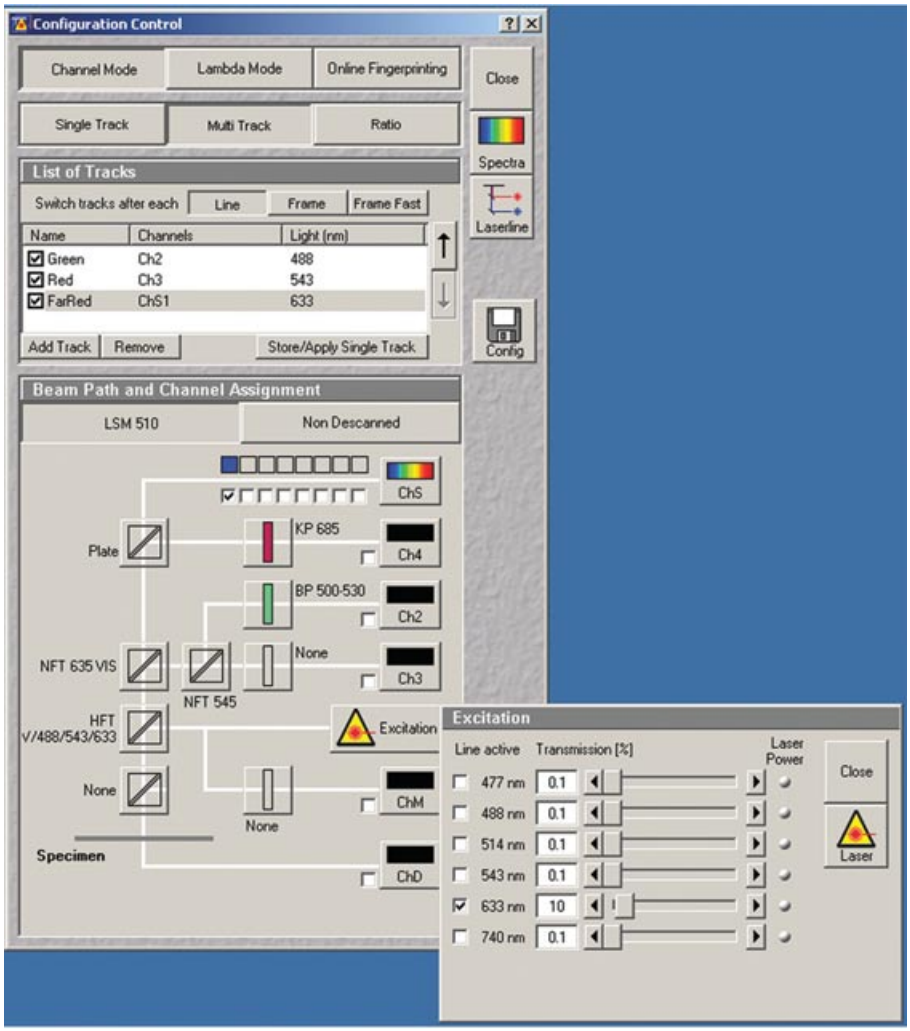

Figure 10.18.5 Configuration for fluorescence imaging with 633-nm excitation for three-channel simultaneous fluorescence, and reflection confocal microscopy with the Zeiss510 NLO imaging system.

region of interest (ROI) for imaging smaller three-dimensional volume with oversampling of Z-slices for the best three-dimensional image reconstruction.

6. Record and store an image.

7. Proceed with image visualization and analysis.

   Image analysis usually depends on the question being addressed by the researcher and the way the data needs to be presented to visualize the experimental result (Fig. 10.18.6). There are many commercial and free software packages available for image visualization and analysis. Among them the most popular are: MetaMorph (Molecular Devices), Volocity (PerkinElmer), AutoQuant (MediaCybernetics), and ImageJ (a free, stand-alone software available through NIH, http://rsbweb.nih.gov/ij/). The MetaMorph package offers great presentation, manipulation, and image analysis of single Z-planes; however its three-dimensional image reconstruction function is inferior to that of the Volocity and AutoQuant software, or ImageJ plug-ins. Commercial laser-scanning confocal imaging systems usually come with software that incorporates three-dimensional image reconstruction of different degrees of complexity depending on the manufacturer.

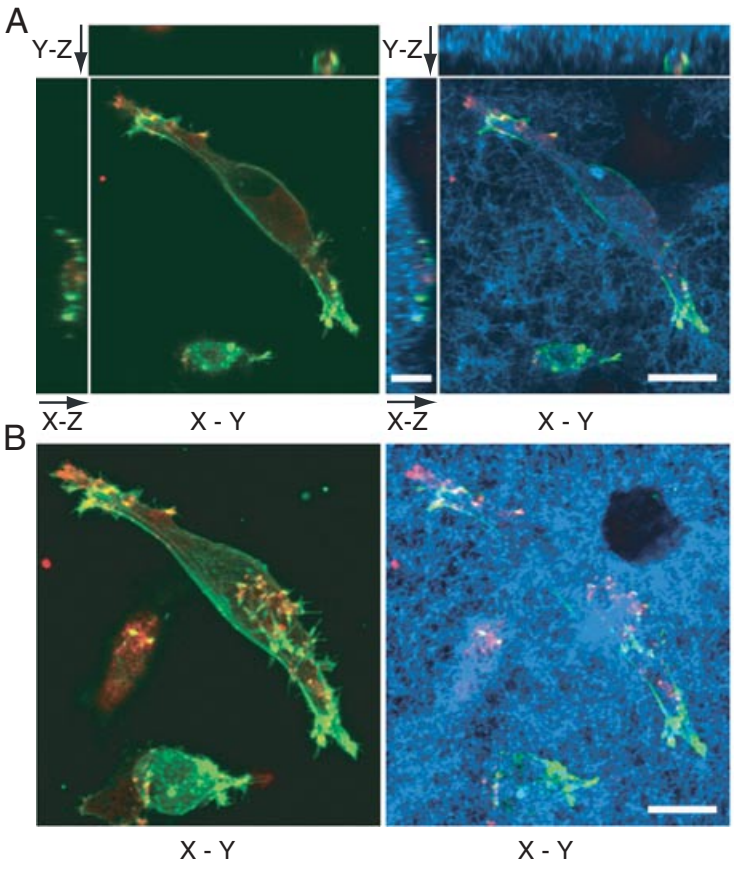

Figure 10.18.6 Breast carcinoma cells transmigrating through the three-dimensional collagen matrix. The actin cytoskeleton was labeled with phalloidin-AlexaFluor 488 (green) and the sites of tyrosine phosphorylation were labeled with anti-phospho-tyrosine primary antibody, followed by secondary Cy5-conjugated antibody (red). Collagen matrix was imaged with reflection confocal microscopy (blue). Images were acquired with a 63× 1.4 NA oil objective. Volocity software was used for image presentation as XYZ projections (**A**) and extended focus (**B**). Scale bars = 19 μm. For color figure go to *http://www.currentprotocols.com/protocol/cb1018*.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking solution

Prepare a fresh solution of 20% (v/v) donkey serum in 1× M.O.M. blocking reagent from the VECTOR M.O.M. Immunodetection kit (Vector Laboratories). Always make this solution fresh and do not store.

Collagen type I, 9.44 mg/ml, in 0.02 N hydrochloric acid

Obtain solution from BD Biosciences. Always keep the solution of collagen on ice. Refrigerate collagen solution up to 6 months at 4°C and never freeze.

There are several different commercially available sources of collagen type I. The protocol for 3-D cell culture polymerization can be used with any mouse tail collagen, commercially-available rat tail collagen type I (BD Biosciences; cat. no. 354249) or PureCol bovine type I collagen (INAMED).

DMEM, 10×, with phenol red

Dissolve DMEM powder (Invitrogen) into 0.1 volume (i.e., one-tenth that recommended by the manufacturer) of distilled water to make a 10× solution. Centrifuge 5 min at 13,000 × *g* to remove all the precipitate. Collect supernatant and filter it through a 0.22-μm vacuum filter to sterilize. Aliquot collected supernatant (500 μl) and store at up to 1 year at −20°C.

Always defrost fresh aliquot on ice before preparing 3-D collagen gels.

A precipitate will form; however this is normal because DMEM does not dissolve completely in this reduced amount of water. The loss of the DMEM components during precipitate formation does not effect the preparation of the neutralized collagen solution.

Paraformaldehyde, 4% (w/v)/sucrose, 5% (w/v)

Prepare a fresh solution of 4% (w/v) paraformaldehyde (electron microscopy grade) and 5% (w/v) sucrose in PBS (see *APPENDIX 2A* for PBS). Filter the solution through a 0.22-μm vacuum filter. Store up to 2 weeks at room temperature. Preheat this solution to 37°C on water bath before fixing cells.

PBS/Tween

Prepare a fresh solution of 0.05% (v/v) Tween 20 in PBS (*APPENDIX 2A*). Put stir bar into a bottle with the solution and stir on magnetic stirring plate until all the Tween 20 is dissolved. Filter the solution through a 0.22-μm vacuum filter. Prepare fresh.

Primary antibody solution

Prepare a fresh solution of primary antibody at 20 μg/ml final concentration in M.O.M. diluent of VECTOR M.O.M. Immunodetection kit (Vector Laboratories). Always make this solution fresh and do not store. To prepare M.O.M. diluent, mix 80 μl of M.O.M. (from the kit) in 1 ml of PBS (*APPENDIX 2A*).

Reconstitution buffer, 10×

Dissolve 2.2 g of sodium bicarbonate and 4.8 g of HEPES in 100 ml of distilled water. Filter through a 0.22-μm vacuum filter to sterilize, then aliquot (500 μl) and store up to 1 year at −20°C. Always defrost fresh aliquot on ice before preparing 3-D collagen gels.

Secondary antibody solution

Prepare a fresh solution of fluorescently-conjugated secondary antibody (Jackson ImmunoResearch), appropriate for the primary antibody used, in PBS/Tween (see recipe) containing 5% donkey serum. Use twice the concentration of secondary antibody that is recommended by the manufacturer. Prepare secondary antibody as recommended by the manufacturer and then dilute the amount required for immunostaining of the antibody in PBS/Tween (see recipe) containing 5% donkey serum. Always make this solution fresh and do not store.

Triton X-100, 0.5% (v/v) in PBS

Prepare 0.5% solution of Triton X-100 in PBS (see *APPENDIX 2A* for PBS) by diluting 10% stock solution of Triton X-100 in PBS, with stirring. Filter the solution through a 0.22-μm vacuum filter. Store up to 2 weeks at room temperature.

COMMENTARY

Background Information

Cellular processes and their underlying signaling events have been studied extensively in two-dimensional (2-D) cell models where cells are plated on glass, plastic, or 2-D non-fibrillar matrices representing different ECM ligands absorbed on glass/plastic surfaces. However, the flat and rigid 2-D surface neither represents the intricate topography of fibrillar matrices nor conveys physico-elastic properties of the in vivo ECM. Recent advances in comparing cell growth and function on different culture surfaces, as well as the efforts made to design model systems that mimic physiological in vivo conditions, have provided strong evidence that matrix topography, stiffness/rigidity, dimensionality, and composition are essential for reproducing physiological patterns of cell adherence, migration, cytoskeleton organization, signal transduction, differentiation, and cellular response to extracellular cues (Even-Ram and Yamada, 2005; Pedersen and Swartz, 2005; Schindler et al., 2006; Petrie et al., 2009). Therefore, 3-D in vitro models have become widely used for the studies of cellular biology.

Collagen type I is the most abundant fibrous protein of interstitial ECM. For that reason, it is commonly used for in vitro 3-D assays to study various cell types and different cellular processes, such as cell migration, invasion, angiogenesis, differentiation, and many others. Although reconstituted three-dimensional collagen type I cannot completely recreate in vivo ECM, it provides the structural integrity of a 3-D environment and basic cell adhesion functions (Pedersen and Swartz, 2005).

Microscopy is the most informative way to study cells embedded in 3-D collagen matrices. Confocal microscopy allows for optical sectioning of 3-D samples, enabling identification of cellular protein localization in differential cellular compartments as well as its relationship to the fibrillar ECM. Time-lapse confocal imaging provides valuable information on dynamics of cellular processes; however, this method requires the expression of cellular proteins tagged with green fluorescent protein (GFP) or GFP variants. Confocal microscopy of fixed and immunolabeled cellular proteins provides valuable information on endogenous proteins that supplements and verifies the understanding of cellular processes identified with the expression of exogenous GFP–tagged proteins. The biggest advantage of applying laser-scanning confocal microscopy to imaging of 3-D collagen cell samples is that it facilitates the simultaneous fluorescence imaging of cellular proteins and reflection imaging of the 3-D fibrillar ECM. Reflection imaging allows for studies and visualization of intact unmodified fibrillar matrix, eliminating any effect of matrix perturbation on the cell. Applying high-resolution confocal imaging for cellular imaging in 3-D collagen matrices sets limitations on 3-D sample preparation with regard to working distance of an objective. The cells need to be distanced from the glass coverslip to be accessible for imaging with a high-numerical-aperture objective. Plating cells in 3-D collagen matrix at the depth required for high-resolution imaging can be achieved with "cell sandwiching" between two collagen layers (Support Protocol 2).

Critical Parameters and Troubleshooting

Immunostaining of cells in three-dimensional collagen matrix

The choice of which antibody is used for immunostaining of cells embedded in 3-D collagen matrix is extremely important and may require some modification of the immunostaining protocol to accommodate differences in antibody affinity. To achieve successful immunostaining of 3-D samples, it is highly recommended to first test the antibody for immunostaining using 2-D cell samples. Simply plate cells on glass coverslips or, if required, coverslips precoated with the ECM molecule that facilitates cell adhesion, and then incubate cells to allow them to adhere. Next, fix the cells with 4% glutaraldehyde/5% sucrose in PBS for 20 min. If the antibody is to be used for immunostaining of intracellular proteins, permeabilize cells with 0.5% Triton X-100 in PBS for 10 min. Then, proceed with immunolabeling of the cell sample using the primary and secondary antibodies. If immunostaining of the cells in the 2-D cell sample gives a weak signal, using that antibody combination will result in poor staining of the cells in 3-D collagen gels. The described protocol for immunostaining of cells in 3-D collagen gels requires double the amount of the primary and secondary antibodies used for immunostaining of the cells in the 2-D cell system. This is necessary to achieve a sufficient concentration of the antibody required for immunolabeling, since in 3-D collagen gels, the solid fraction of

the fibers is about 1% by mass while the other 99% consists of water (Pedersen and Swartz, 2005). If a low-affinity antibody is to be used for immunolabeling of three-dimensional collagen samples, the authors recommend tripling the amount of the primary antibody or increasing incubation time for the labeling. It is crucial to remember that increasing the thickness of the 3-D collagen gels will require increasing incubation times for the primary and secondary antibodies to diffuse through the 3-D matrix.

Controls

It is recommended that the binding specificity of the primary and secondary antibodies be checked by performing the following controls. (1) Perform immunostaining of the 3-D collagen samples with the secondary antibody only to check for specificity of the secondary antibody. (2) Use GFP chimeras of the protein being studied to compare and confirm the pattern of endogenous protein localization in cells cultured in 3-D collagen gels. (3) If available, use specific protein knock-out cells to test for the specificity of the primary antibody.

Sample fixation and permeabilization

Immunostaining of different intracellular proteins may require different conditions for sample fixation and permeabilization to obtain the best immunostaining and, as a result, the best confocal image. This rule applies to immunostaining of samples in two- as well as three-dimensional in vitro systems. As alternatives to the provided protocol, one might consider testing several conditions for fixation and permeabilization by varying the duration of permeabilization with Triton X-100, or by combining fixation and permeabilization in one step. For immunostaining of some of the focal adhesion proteins, the authors have used the following fix/permeabilize protocol: permeabilize cells with 4% paraformaldehyde/5% sucrose/0.5% Triton X-100 in PBS for 5 min at room temperature, and then fix with 4% paraformaldehyde/5% sucrose in PBS for 20 min at room temperature. One should keep in mind that the variations in fixation/permeabilization procedures followed by the same immunolabeling protocol could yield differences in protein immunostaining patterns. This could be due to the effect of the fixation and permeabilization on the retention and accessibility of the protein being labeled, or the sample-penetration capacity for the antibody.

"Cell sandwiching" in three-dimensional collagen

Proper polymerization of the cells between two collagen layers is important in positioning cells at the distance from the glass that allows for confocal imaging with high-numerical-aperture objectives. If it is difficult to focus on the cells with 63× or 100× objectives, then the working distance of the objective does not permit viewing the cells. In this case, consider switching to a low-magnification objective that has a long working distance to assess the distance of the cells from the glass, by acquiring a Z-stack using reflection microscopy. Then, measure the distance between the first Z-slice with the image of the matrix at the glass surface, which will have a high background of light scattered from the glass, and the Z-slice with the image of the reflection from the cell body. This measurement, performed for several cells in the different parts of the 3-D sample, will give an approximation of the thickness and uniformity of the first collagen layer polymerized on the glass surface. To correct for collagen layer thickness, determine if spreading of the collagen solution on the glass surface of the coverglass system pre-chilled on ice is sufficient. If it is required to make the collagen layer thinner to match the working distance of the objective, then the amount of collagen used for polymerization of the collagen layer can be slightly decreased. Alternatively, select a high-numerical-aperture objective with a longer working distance. Also, in some cases, it becomes impossible to focus on the cells because the 3-D collagen matrix is detached from the glass surface and floats in the medium. Such samples are not suitable for imaging. Usually, 3-D collagen matrices detach from the glass for the following reasons. (1) The first layer was not well polymerized before plating cells on it. Always use phase microscopy to check for collagen fibril formation when preparing the sample as described in the protocol. (2) The sample underwent harsh treatment resulting from applying excessive suction forces when aspirating solutions from the well, or from dropping solution on top of the matrix instead of letting it drip and flow on the side wall of the well.

Anticipated Results

Support Protocols 1 and 2

Bringing collagen solution to a physiological pH of 7.1 to 7.4 will allow for polymerizing fibrillar collagen for 3-D collagen matrix using the "cell sandwiching"

technique. Polymerizing cells between two collagen layers should result in a cell sample in the 3-D collagen matrix suitable for high-resolution confocal microscopy.

Basic Protocol 1

Immunolabeling of the cells in a 3-D collagen matrix should result in a sample that is ready for fluorescence confocal imaging of the cellular proteins being studied.

Basic Protocol 2

Simultaneous fluorescence and reflection confocal imaging of the 3-D cell sample will result in collecting images of fluorescently labeled cellular proteins with fluorescence microscopy and unperturbed collagen matrix with reflection confocal microscopy. Z-stacks collected with confocal microscopy will allow for 3-D image reconstruction. The typical confocal immunofluorescence image is presented in Figure 10.18.6.

Time Considerations

Support Protocol 1

Preparation of the solution of collagen required for polymerization of 3-D collagen matrices should take about 60 min. It is important to remember that neutralized collagen can be stored on ice for only 1 hr; therefore it is recommended that the cell suspension be prepared right away, and that the Support Protocol 2 follow immediately.

Support Protocol 2

It takes about 2 hr to prepare the sample of cells in 3-D collagen matrix using the "cell sandwiching" technique described in Support Protocol 2. In addition, it will take at least 16 hr of incubation at 37°C to allow cells to polarize and start migrating in the 3-D collagen matrix. The total incubation time for this for the cell line being studied must be determined by the researcher.

Basic Protocol 1

All steps of this protocol, starting with the 3-D collagen cell sample fixation and finishing with immunolabeling, takes ~6.5 hr. It is required that confocal imaging commence after immunolabeling of the sample is complete. To avoid a lengthy day, authors recommend splitting the protocol into two groups of steps that can be accomplished over a 2-day period. First, perform fixation and permeabilization of the sample (steps 1 to 7) on the first day. After step 7 is complete and the sample has been washed with PBS, it can be stored overnight at 4°C. On the second day, proceed with blocking and immunostaining of the sample with primary and secondary antibodies (steps 8 to 15), followed by confocal microscopy of the sample.

Basic Protocol 2

Acquisition of Z-stacks of whole 512×512 images takes a matter of minutes; therefore 2 to 3 hr are required for image acquisition. Another 1 to 2 hr are required for data analysis and image presentation.

Overview of Eukaryotic In Vitro Translation and Expression Systems

EARLY HISTORY

Today, the protocols and commercial systems for expressing gene products in vitro are well known to molecular biologists and researchers in many other fields. The present-day systems have been steadily improved in efficiency and convenience over their early predecessors. The earliest in vitro translation extracts, developed in the 1960s, were central to the breaking of the genetic code. The late 1960s and early 1970s saw the emergence of a variety of translation extracts prepared from different sources, such as Krebs II ascites cells, CHO cells, rat and mouse liver, and HeLa cells. Most of these systems faithfully translated viral and eukaryotic mRNA pools but were limited in their efficiency and by the competitive translation of endogenous mRNAs. One system that overcame these limitations was the efficient wheat germ–based expression system (Roberts and Paterson, 1973). Another system based on lysates of rabbit reticulocytes that was being developed during this period would eventually become the most widely used option. In 1968, this reticulocyte system was improved through the addition of hemin (Adamson et al., 1968; Zucker and Schulman, 1968), which allowed a steady rate of translation for 60 min. However, these early systems contained high levels of globin mRNA, which made detection and quantification of added mRNA products difficult at best. One approach to this problem was to create a reconstituted system from fractions of reticulocyte lysate from which reticulocyte mRNA had been removed (Schreier and Staehelin, 1973). Unfortunately, the reconstituted fractionated system primed with added mRNAs did not retain high activity.

IMPROVED SYSTEMS

In 1976, Pelham and Jackson described a breakthrough protocol consisting of a micrococcal nuclease treatment to destroy endogenous mRNA followed by addition of EGTA to remove the Ca^{2+} required for nuclease activity (Pelham and Jackson, 1976). This system produced the low background of fractionated systems and yet, in contrast to those systems, exhibited remarkably high activity and an exceptional response to added mRNA. In addition, the nuclease-treated reticulocyte translation system exhibited much lower nuclease activity than the wheat germ system and could therefore generate much larger full-length gene products—up to 200 kDa. The system also retained the translational regulatory responses of the parental lysate. The system became more widely used and was continuously improved through the 1980s. Refinements included addition of exogenous calf liver tRNA to complement the limiting endogenous tRNA population strictly suited for globin expression, optimization of Mg^{2+} and K^{+} ion concentrations, addition of ribonuclease inhibitors (such as RNasin) and protease inhibitors, and inclusion of sugars to maintain reducing potential (Jackson and Hunt, 1983; Jagus, 1987). Concurrently, the wheat germ system was also improved through the use of high spermidine concentrations and the addition of human placental RNase inhibitor, facilitating efficient translation of high-molecular-weight proteins (Morch et al., 1986). Many translational mechanisms were investigated and defined using these systems.

With the growing availability of cloned genes, one of the most important advancements of in vitro expression during this period was the development of a system capable of synthesizing large quantities of gene-specific mRNA (Melton et al., 1984). Genes cloned behind a phage polymerase promoter, such as the T7 or SP6 promoter, could produce mRNA transcripts through incubation of linearized DNA templates with the appropriate polymerase and reaction conditions. Capped (or uncapped) transcript mRNAs were then added to the in vitro expression systems, resulting in expression of a single gene product, rather than expression from viral genomes or mRNA pools (Krieg and Melton, 1984). In vitro translation of transcripts from cDNAs allowed the identities of many cloned genes to be verified. An added bonus of this method is that any desired mutant protein can be generated simply by altering the DNA template (Struhl, 1989).

The efficiency of this in vitro translation method was increased by maximizing the amount of RNA produced for a given amount of DNA template (Milligan et al., 1987; Gurevich et al., 1991), allowing products of the transcription reaction to be added to a cell-free translation system without prior purification of the RNA (Andrews, 1989). The greatest im-

Contributed by Rosemary Jagus and Gregory S. Beckler

Current Protocols in Cell Biology (1998) 11.1.1-11.1.13

provement in RNA yields involved uncapped transcripts, as new vectors were introduced that could create transcripts that did not need to be capped before they could be translated. The vectors pTM1 (Moss et al., 1990) and pCITE (Novagen) place the 5′ untranslated leader region (UTR) of encephalomyocarditis virus (EMCV), which contains an internal ribosome entry site (IRES), upstream of the initiation codon to facilitate cap-independent translation in the reticulocyte system.

NEWER SYSTEMS AND APPROACHES

Continuous-Flow Systems

The late 1980s and the 1990s witnessed an evolution in the use of translation expression systems, from studies of translation mechanisms and simple verification of expected gene products toward the rapid and efficient production of larger quantities of functional proteins. Continuous-flow cell-free (CFCF) systems designed to work for tens of hours and produce hundreds of micrograms of synthesized protein were introduced in the late 1980s (Spirin et al., 1988). Use of the CFCF systems described by Spirin remains technically challenging, requires expensive flow cells, and has yet to demonstrate consistent results. For these reasons such systems have not been widely utilized, although they hold great potential for the production of gene products that are too toxic for production in vivo. Successes have been reported with CFCF systems involving simpler devices such as dialysis tubes, which have been used for prokaryotic systems (Davis et al., 1996; Kim and Choi, 1996) and a wheat germ system (K.J. Rothschild, pers. comm.). These dialysis tube–based systems are able to produce from hundreds of micrograms to >1 mg of expressed protein per milliliter of reaction. Another group has reported the use of affinity ligands to continuously remove the protein products, thereby improving translation efficiency (Marszal and Scouten, 1996).

Coupled Eukaryotic Systems

In 1992, the first eukaryotic coupled transcription/translation batch systems were introduced; these allowed direct expression from DNA containing cloned genes positioned behind T7, T3, or SP6 promoters in rabbit reticulocyte lysate or wheat germ extracts (Craig et al., 1992; Thompson et al., 1992). Transcription and translation reactions exhibit very different requirements for monovalent and divalent cations. The conditions that give optimal activity of the coupled system are closer to those needed for translation; although transcription is relatively inefficient in the coupled reaction, sufficient RNA is produced to saturate the protein synthetic capacity of the system. The fidelity and efficiency of expression in the coupled system is high. Unexpectedly, the coupling of transcription with translation often results in greater protein production (Jagus, 1993). Moreover, the ability to generate and utilize cloned DNA and the products of PCR reactions, rather than purified mRNA, has generated a multitude of new applications (Beckler, 1998—see Internet Resources).

Incorporation of Non-Natural Amino Acids

One primary advantage of in vitro translation is the ability to manipulate expression easily by adding exogenous compounds directly to the reaction. Incorporation of non-natural amino acids into synthesized proteins is a powerful tool for the creation of novel or mutant proteins. A technique for incorporating epsilon-amino-modified lysines into proteins synthesized in rabbit reticulocyte lysate has been described by Johnson et al. (1976). Charged tRNA complexes containing epsilon-modified lysines, such as biotinylated lysines, can be added to the translation reactions and the modified lysines will be incorporated into the synthesized protein. Biotinylated proteins can be detected nonisotopically using streptavidin–alkaline phosphatase or horseradish peroxidase conjugates (Kurzchalia et al., 1988; Hoeltke et al., 1995); these detection systems became commercially available in 1993 (Beckler and Hurst, 1993). Other groups developed alternative site-directed non-native amino-acid replacement (SNAAR) using nonsense codon suppression methods to introduce non-natural amino acids at specific sites (Noren et al., 1989). These approaches use RNA ligase to ligate in vitro–transcribed amber tRNA lacking the 3′ terminal pCpA from the acceptor stem to a chemically acylated pCpA-X, where X can be almost anything, such as a fluorescent, spin-label, or isotopic group (Noren et al., 1990).

NEW APPLICATIONS

The PCR revolution, the genome sequencing projects, and the plethora of techniques available to look at differentially expressed genes have led many researchers to ask what a particular gene of interest codes for, what function it has, and with what other gene products

it interacts. Many basic questions centered on understanding this "genetic output" are being answered using in vitro expression approaches. The following applications are made possible or desirable due to the current ease with which a particular gene or gene segment can be amplified through PCR, with concurrent incorporation of a phage polymerase promoter, such as the T7 promoter (Kain et al., 1991). The PCR-generated DNA can be expressed in a eukaryotic coupled transcription/translation reaction and the activity of the translated product(s) assessed using an in vitro assay.

Molecular Interactions

Protein-protein interactions

One of the most popular current applications of coupled eukaryotic systems is the detection of protein-protein interactions. Often, researchers will use an in vitro approach to verify or confirm results obtained in vivo, for example using the yeast two-hybrid approach (Boyd et al., 1995; see *APPENDIX 3*). To define the region of protein-protein interaction, a series of constructed deletion mutants or occasionally specific point mutants are synthesized in vitro and compared to full-length wild-type proteins.

Fusion-tag approach. Additions to the native gene product in the form of a fusion "tag" can be extremely useful if specific antibodies are not available. [^{35}S]Methionine-labeled proteins can be synthesized in coupled reactions in vitro from either full-length cDNAs or deletion mutants. These radioactive proteins can be used to detect interactions with suspected protein partners that have been expressed as GST, His-tag, or epitope-tagged (*UNIT 5.2*) fusion proteins and purified after expression in *Escherichia coli* (Chinnaiyan et al., 1995). Fusion proteins can be bound to an affinity matrix along with the radioactive protein with which they interact (Cowell and Hurst, 1996; Sharp et al., 1997). The bound radioactive proteins are then eluted and analyzed by SDS-PAGE (*UNIT 6.1*) or immunoblot (western) analysis (*UNIT 6.2*).

Immunoprecipitation. Another approach involves detection of a radioactive fusion partner by immunoprecipitation (*UNIT 7.2*) using antibodies against a particular antigenic domain. For example, an influenza hemagglutinin (HA) epitope incorporated in the carboxyl terminus of an in vitro–expressed protein can be immunoprecipitated using anti-HA antibodies (Benedict and Clawson, 1996). Alternatively, if an antibody against one of the partners is available, detection can be accomplished by coimmunoprecipitation (Leng et al., 1995; Sharp et al., 1997). Again, the bound radioactive proteins are eluted and analyzed by SDS-PAGE or immunoblot analysis. A variation on this analysis method utilizes in vitro–coupled expression of several proteins simultaneously. The relative protein expression levels can be controlled by varying the concentrations of each DNA construct. For instance, using cDNAs for chicken NF-κB p105, NF-κB p100, c-Rel, and v-Rel, cotranslated in vitro, and protein complex detection by immunoprecipitation with specific antiserum, it has been shown that one of the complexes in v-Rel-transformed spleen cells can be reconstituted in vitro (Sif and Gilmore, 1993).

Far western analysis. A direct detection method for identifying protein-protein interaction is the so-called "far western" analysis. In this approach, radioactive proteins are synthesized in vitro and then used as "probes" to detect binding to membrane-bound renatured proteins directly (Johnston et al., 1996).

Isolation of protein complexes by capture of biotinylated lysine residues. One drawback of fusion-protein techniques is the need to make the fusion protein construct. Another approach that obviates the need to develop novel constructs is to to incorporate non-natural amino acids, such as biotinylated lysines, into in vitro–translated proteins. This approach can be taken with any gene containing lysine codons. Incorporation of non-natural amino acids does not significantly alter the efficiency of polypeptide synthesis, and usually incorporation of biotinylated lysines does not affect the function of the protein. This approach has been used to develop a novel method for capturing protein complexes that associate with biotinylated Rab5, a member of the Rab family of GTP-binding proteins (Sanford et al., 1995). The ability to bind biotinylated lysine tightly to streptavidin-linked agarose can be utilized to capture in vitro–synthesized biotinylated Rab5. A promising and potentially powerful modification of the biotinylated-lysine capture technique for detection and gentle purification of in vitro–generated polypeptides, using photocleavable (PC) biotin, has recently been described (Rothschild et al., 1997). In a recent example, the nascent PC-biotin-labeled polypeptides were captured using streptavidin-coated magnetic beads, and after a short exposure to UV, the native polypeptide was released (with 70% to 95% efficiency) with no remaining "tags" (Olejnik et al., 1995, 1998; Rothschild et al., 1997).

Protein folding, chaperonins, and luciferase. Another emerging area utilizing in vitro systems to define protein-protein interactions is the field of protein folding and chaperonin interactions. Researchers have combined the advantages of in vitro expression with the power of instantaneous reporter gene product assays. The folding of polypeptides emerging from ribosomes has been analyzed using firefly luciferase as a model protein (Frydman et al., 1994; Frydman and Hartl, 1996). The growing polypeptide interacts with a specific set of molecular chaperones, including Hsp70, the DnaJ homologue Hsp40, and the chaperonin TRiC. The ordered assembly of these components on the nascent chain forms a high-molecular-mass complex that allows the cotranslational formation of protein domains and the completion of folding once the chain is released from the ribosome.

Real-time translation/folding assays

A novel approach has been developed using a wheat germ system in which the components for the luciferase enzymatic assay have been added directly to the translation reaction and monitored continuously in real time (Kolb et al., 1994). To demonstrate that luciferase exhibits cotranslational folding, the activity of translation products produced from wild-type mRNAs was compared with that of products produced from mutant mRNAs lacking stop codons to prevent release of the polypeptide from the ribosome. Luciferase was shown to be completely folded and enzymatically fully active immediately upon release from the ribosome (Kolb et al., 1994). However, no luciferase activity was observed while full-length luciferase remained attached to the ribosome as a peptidyl-tRNA, probably because the C-terminal portion of the enzyme is masked by the ribosome and/or ribosome-associated proteins. The investigators demonstrated that the ribosome-bound enzyme acquires enzymatic activity when its C-terminus is extended by at least 26 additional amino acid residues (Makeyev et al., 1996). The results demonstrate that the acquisition of the final native conformation by a nascent protein can occur as the protein is being synthesized and that folding does not require release of the protein from the ribosome.

Macromolecular assembly and frameshifting

Many in vivo translational control mechanisms are faithfully replicated in vitro. In addition, a variety of macromolecular complexes can be expressed and properly assembled in vitro. For example, an in vitro synthesis and assembly system for the protypical type D retrovirus, Mason-Pfizer monkey virus (M-PMV), has been developed utilizing rabbit reticulocyte reactions expressing M-PMV–Gag precursor polyprotein precursors as the result of two ribosomal frameshift events (Sakalian et al., 1996). The frameshift efficiency in vitro is identical to that observed in vivo. These polyproteins assemble to form immature retrovirus capsids indistinguishable from those formed in the host cell cytoplasm. More importantly, this system can be utilized in combination with anti-Gag antibodies to search for potential inhibitors of retrovirus assembly.

Protein-DNA interactions

The electrophoretic mobility shift assay (EMSA) is a widely used procedure to detect DNA binding sites for proteins or protein complexes, such as transcription factors. In this technique in vitro–generated proteins with putative DNA-binding activity are combined with an oligonucleotide containing a target consensus sequence site, and changes in DNA migration due to the bound protein are detected by PAGE. Either partner can be radiolabeled (usually 5′-end-labeled [^{32}P]DNA is used) and with proper controls, the translation extract containing the synthesized candidate binding factor can be used directly (Lee and Chang, 1995). Many researchers investigating transcription-factor binding use coupled wheat germ rather than rabbit reticulocyte translation systems, as wheat germ extract does not contain endogenous transcription factors such as NFκB (Sif and Gilmore, 1993). If the reticulocyte system must be used, it is possible to remove endogenous DNA-binding proteins from the reticulocyte system by a rapid method using biotinylated DNA and streptavidin-conjugated magnetic beads (Ebel and Sippel, 1995).

Protein-RNA interactions

Protein-RNA interactions can also be studied with in vitro translated proteins. To demonstrate the direct interaction of the U1 snRNP-A protein with SV40 late mRNAs, [^{35}S]Met-labeled U1 snRNP-A fusion protein containing a g10 epitope tag was synthesized in vitro, mixed with ^{32}P-labeled in vitro transcribed RNA, and immunoprecipitated. Coprecipitating RNAs were extracted and analyzed by PAGE (Lutz and Alwine, 1994).

Characterization of molecular environments

In vitro expression systems have also been utilized extensively to understand the molecular environment of nascent polypeptides as they are translated and translocated, including the very nature of the ribosome "tunnel" the polypeptide passes through. These approaches utilize the incorporation of non-natural amino acids containing photoactivatable cross-linking groups or fluorescent groups.

Photo-cross-linking. Studies of a secretory protein utilizing the incorporation of modified Lys-tRNAs containing a photoreactive cross-linker group, with subsequent photo-cross-linking, revealed a sequential passage of the transmembrane domain through three different proteinaceous environments, and helped define the multistep process of cotranslational integration of a nascent protein into the endoplasmic reticulum membrane (Do et al., 1996).

Fluorescent quenching. Fluorescent probes incorporated into nascent secretory proteins using modified Lys-tRNAs have been used to report on the ability of various-sized quenching agents to enter the endoplasmic reticulum pore and quench fluorescence. (Hamman et al., 1997).

Membrane association. The features within the N-terminal membrane-targeting domain of the cyclic AMP phosphodiesterase RD1 that are required for membrane association have been analyzed using in vitro expression of deletion mutants of RD1-CAT chimeras. Radioactive products were generated in vitro, incubated with membranes, and then identified in either the membrane pellets or soluble supernatant fractions (Smith et al., 1996).

Characterization of transmembrane domains. The G protein–coupled receptors involved in signal transduction across the plasma membrane have been viewed as having seven transmembrane helices and a three-dimensional structure similar to that of bacteriorhodopsin. These receptors appear to insert into membranes using signal-anchor sequences followed by stop-transfer sequences. Hydropathy plots and various experimental techniques have been used to predict the seven membrane domains, yet no one technique has allowed a direct demonstration. In vitro translation in the presence or absence of microsomal membranes was used not only to determine the presence of independent signal-anchor and stop-transfer sequences, but also to identify the amino acid sequences accounting for transmembrane folding (Bayle et al., 1997a,b). This method used constructs containing the N-terminal region of the gastric H^+/K^+ ATPase or the N-terminal region of the cholecystokinin-A (CCK-A) receptor, coupled via a linker region to the last 177 amino acids of the beta subunit of the gastric H^+/K^+ ATPase. The latter contains five potential N-linked glycosylation sites. Translation of the mRNA encoding one, two, or more putative transmembrane domains in the absence or presence of microsomes allowed determination of signal-anchor or stop-transfer properties of the putative transmembrane domains from the molecular weight shift after SDS-PAGE. Translation of segments of the gastric H^+/K^+ ATPase provided evidence for only seven transmembrane segments, but coupled with other data established a ten-membrane-segment model. The CCK-A receptor showed the presence of six of the seven transmembrane segments postulated for this protein. This technique provides a useful addition to methods of determining membrane domains of integral membrane proteins, but must in general be combined with other methods to establish the number of transmembrane alpha helices.

MOLECULAR FUNCTION

Functional Genomics

Ribosomal display for cell-free protein evolution

Ribosomal display is an emerging technology for performing cell-free protein evolution in vitro as an alternative to phage display. This approach utilizes the cell-free system to transcribe a DNA library, translate the mRNA pools, and, using a variety of techniques, retain the proteins and their encoding mRNAs attached to the ribosomes. The protein-mRNA-ribosome complexes are screened for binding to a target and the retained mRNA is amplified using RT-PCR, with the resulting DNA used for another round of selection. Initially the technique utilized the prokaryotic *E. coli* coupled transcription/translation system to generate large libraries of peptides used for receptor-ligand screening (Mattheakis et al., 1994). This system was improved to allow folding of whole proteins into their native structure while on the ribosome (Hanes and Pluckthun, 1997). The first eukaryotic-based system, centered around a rabbit reticulocyte coupled transcription/translation system, used antibody-ribosome-mRNA (ARM) complexes for rapid selection to monitor the evolution of antibody combining sites (He and Taussig, 1997). ARMs carrying single-chain (VH/K) binding frag-

ments specific for progesterone have been selected using antigen-coupled magnetic beads. Selection simultaneously captured the genetic information as mRNA, making it possible to generate and amplify cDNA by single-step RT-PCR on the ribosome-bound mRNA for further manipulation. Using mutant libraries, antigen-binding ARMs were enriched by a factor of 10^4- to 10^5-fold in a single cycle, with further enrichment in repeated cycles. Such an approach has obvious potential for the selection of receptors or peptides from libraries.

An interesting cell-free system for performing evolution studies in vitro has been developed to find reaction conditions in which isothermal RNA amplification would occur simultaneously with coupled transcription and translation (Joyce, 1993). After unsuccessfully testing wheat germ extracts and coupled *E. coli* systems, investigators were able to operate the "two" reactions simultaneously using the rabbit reticulocyte coupled transcription/translation system. This system can be used to perform laboratory "evolution" by putting selective pressure on functional protein products necessary for RNA amplification.

In vitro expression cloning (IVEC)

To a considerable extent, as the era of functional genomics dawns, the current scientific focus is shifting from genomic bioinformatic analyses as such to the development of approaches to understand gene-product function. A new alternative approach to functional gene identification utilizes the manipulative ability, speed, and convenience of eukaryotic coupled transcription/translation. In vitro expression cloning (IVEC) consists of adding small cDNA plasmid pools (of 50 to 100 clones per pool) directly into a rabbit reticulocyte coupled transcription/translation system. The resulting protein pools can be used to identify cDNAs rapidly on the basis of almost any biochemical property for which an assay can be developed (King et al., 1997; Lustig et al., 1997). The first report of this technology detailed the screening of a total of ~500 pools of cDNAs encoding ~12,000 proteins and identification of 105 pools with potential positives. Twenty mitotically phosphorylated proteins were identified by incubating in vitro protein pools with interphase *Xenopus laevis* egg extracts and identifying phosphorylated protein targets from their altered SDS-PAGE migration (Stukenberg et al., 1997). Interestingly, while fifteen of the identified phosphorylated proteins share sequence similarity with proteins previously characterized, the other five are novel. This approach has also been used to screen 100,000 cDNA clones to identify gelsolin as a substrate of caspase-3 protease, demonstrating that gelsolin is an effector of morphological changes in apoptosis (Kothakota et al., 1997). This technology appears to be an effective bridge connecting genomics and proteomics.

Molecular Characterization Studies

Enzymatic activity and mutation analysis

In vitro expression can be used to analyze synthesized proteins, whether wild-type or mutant, for enzymatic activity. While deletion mutation analysis is useful for defining protein- or DNA-binding regions, site-specific mutation analysis can be useful for understanding and modifying enzymatic activity. In one study, the hypothesis that histidine 21 of diphtheria toxin A subunit is important in ADP-ribosyltransferase activity was tested by mutagenizing codon 21 to encode all possible amino acids. The products were translated in vitro in a reticulocyte coupled transcription/translation system and analyzed for ADP-ribosylating activity, resulting in the determination that histidine 21 does not play a major role in diphtheria toxin catalysis (Johnson and Nicholls, 1994). In vitro systems offer substantial advantages over in vivo systems in terms of safety and expression efficiency for toxin expression.

Another group expressed a cDNA encoding a large (110-kDa) six-transmembrane protein, type IV adenylyl cyclase (ACIV), in a coupled transcription/translation system with the same specific enzymatic activity as baculoviral-produced ACIV (Warner et al., 1995). Interestingly, the in vitro–generated ACIV was very stable and demonstrated linear activity for 90 min at 30°C, which is much longer than impure samples (<15 min) and somewhat longer even than pure adenylate cyclase (1 hr). Use of such a system may provide a good first screen for identifying interesting mutants or producing active chimeric constructs of topologically complex proteins like ACIV.

Similarly, generation of in vitro–translated aromatase in the presence of canine pancreatic microsomes gives rise to an active enzyme when supplemented with recombinant P_{450} reductase (Pancharatnam et al., 1996). The in vitro–made enzyme has properties equivalent to those of aromatase in tissue extracts. This use of the coupled transcription/translation systems may provide a general procedure for examining structure/function relationships

among the cytochrome P_{450} superfamily of enzymes without the need for transient or stable transfection studies.

Post-translational modifications

A number of post-translational activities have been extensively analyzed using in vitro expression systems. For example, rabbit reticulocyte lysate contains proteolytic, phosphorylation, myristylation, farnsylation, isoprenylation, and adenylation activities (Glass and Pollard, 1991; Hancock, 1995). With the addition of canine microsomal membranes, methylation, glycosylation, and signal-sequence cleavage activities can be studied (Walter and Blobel, 1983; also see *UNIT 11.4*). A reticulocyte lysate assay for studying the post-translational modifications of Ras proteins has described the analysis of a number of different modifications (Roy et al., 1997).

Proteolytic cleavage analysis

For many years, in vitro expression systems have been used to study viral and cellular proteolytic activity. Examples include characterization of the autoprocessing cascade of HSV-1 (Godefroy and Guenet, 1995) and of the expression of a 250-kDa polyprotein that results in detectable self-cleavage products when expressed in a coupled transcription translation system, but is incompletely processed in a standard mRNA-based translation system (Hemmer et al., 1995). Recent work has described an in vitro assay to activate the hepatitis C virus N2-3 protease post-translationally and methods to study the effects of several common inhibitors on the enzymatic activity (Pieroni et al., 1997).

Antisense regulation

Antisense oligonucleotides have been shown to inhibit gene expression at either the transcriptional or translational level (Curcio et al., 1997). The mechanism for translational inhibition is thought to involve activation of RNase and is currently a target of intense investigation. Attempts to rationally design effective antisense RNAs have yet to yield consistent results, giving rise to the use of an empirical approach using randomized oligonucleotide arrays to identify ideal candidate antisense oligonucleotides (Lima et al., 1997; Milner et al., 1997). An in vitro reticulocyte lysate coupled transcription/translation system has been established for rapid screening of antisense oligodeoxyribonucleotides to determine which are the most effective in arresting mRNA translation (Chen et al., 1997). The potential for heteroduplex formation of an oligonucleotide has been shown to correlate closely with inhibition of translation in vitro.

Development of antiviral agents

The rapid reticulocyte coupled transcription/translation screening system has been applied to the identification of antisense oligodeoxynucleotides capable of inhibiting hepatic D viral replication (Chen et al., 1997). Other groups developing specific viral inhibitors have utilized in vitro expression to test different target regions with modified oligonucleotides (peptide nucleic acid and phosphorothioate oligonucleotides; Alt et al., 1997; Koppelhus et al., 1997). Additional studies have shown the circular 2′-deoxyribo-oligonucleotides to be potent inhibitors of luciferase expression in an in vitro coupled transcription/translation system (Azhayeva et al., 1997).

Ligand binding for identification of novel orphan receptors

The binding of ligands to in vitro–synthesized receptors can be an important aspect of identifying new receptors. For example, a search for novel "orphan" nuclear receptors and ligands cloned and characterized a novel estrogen receptor (Kuiper et al., 1996). Saturation ligand-binding and ligand-competition assays of the in vitro–expressed clone allowed this novel receptor to be distinguished from one previously cloned.

Characterization of antiserum

In studies utilizing antiserum, immunoprecipitation of in vitro–synthesized proteins can be used to demonstrate the specificity of the antiserum (Murrell et al., 1995).

Studies of Molecular Structure

Understanding of integral membrane protein function is currently limited by the difficulty of producing three-dimensional crystals. A method has been developed for probing conformational changes in proteins in which Fourier-transform infrared-difference spectroscopy is combined with amber suppression to insert a single isotopic label into a specific site within in vitro–synthesized polypeptides that fold into their native structure (Sonar, 1994). Unlike earlier methods using site-directed mutagenesis, this does not disrupt the protein structure. It should be applicable to a wide range of proteins, including those involved in enzyme catalysis, ion transport, and signal transduction.

Diagnostic Detection

Protein truncation test

Perhaps the fastest-growing application of coupled transcription/translation systems has been for the diagnostic detection of genetic diseases, a predominantly DNA-dominated arena. The protein truncation test (PTT), sometimes referred to as the in vitro–synthesized protein truncation (IVSP) assay, was first reported in 1993 as a rapid method for detecting translation-terminating mutations in the very large gene responsible for Duchenne muscular dystrophy (Roest et al., 1993) and in the familial adenomatous polyposis (APC) gene responsible for a type of hereditary colon cancer (Powell et al., 1993). In these and other diseases, such as hereditary breast cancer (Hogervorst et al., 1995), 70% to 95% of the mutations that cause disease result in a truncated gene product. In the PTT, genomic DNA or mRNA is first purified from the patient's blood or tissue. This is subjected to either RT-PCR or PCR with concurrent incorporation of a T7 promoter and an optimal translation initiation sequence surrounding the desired start codon. Often, when the source mRNA is limiting, a second nested PCR reaction is required. Large exons are amplified from genomic DNA while smaller exons are amplified together from mRNA, and the gene is segmented into overlapping amplified fragments. The amplified DNA is added directly into a coupled transcription/translation reaction, and translation-terminating mutations are detected as faster-migrating bands after SDS-PAGE analysis. The main advantages of the PTT include the ability to scan large (2- to 3-kb) DNA or RNA segments quickly and the fact that the method detects only disease-causing mutations, avoiding the fruitless evaluation of silent polymorphisms. A disadvantage has been that the interpretation of real results can be complicated by the presence of internally translated protein products and other nonspecific bands. The PTT has been improved through addition of reporter-tag sequences in the 5′ primer, and by the design of overlapping segments, gel parameters, and methods to prevent nonsense-mediated mRNA decay (Rowan and Bodmer, 1997; Garvin, 1998). A recent review comparing PTT to other detection methods describes it as the first choice for mutation screening (Frayling and Rowan, 1997). Perhaps the most unusual example of the power of this method for detecting previously unknown mutations was provided by a new discovery by the Kinzler and Vogelstein groups that uncovered a novel mechanism for producing germline mutations with resulting predisposition to colon cancer (Laken et al., 1997). IVSP screening analysis of a patient with a family history of colon cancer was found to produce truncated gene products, yet sequence analysis of the DNA revealed only an T-to-A transversion resulting in a lysine-for-isoleucine substitution. The truncation thus appeared to be an in vitro phenomenon caused by the transversion. However, further work revealed that this mutation creates a small hypermutable region of the gene, resulting in secondary, truncating mutations. It appears this region contains unusual secondary structure that is incorrectly processed by both the polymerases present in human cells and the phage polymerases used in the IVSP reaction. This finding has led to the development of a specific genetic screen which has demonstrated that this mutation is present in 6% of Ashkenazi Jews.

An approach similar to PTT has been applied to screening of the expression of the simian immunodeficiency virus (SIV) *nef* gene in the course of disease progression in macaque monkeys (Switzer and Heneine, 1995). SIV undergoes constant evolution, and an intact *nef* gene is important to maintain the high viral loads required for disease progression to AIDS in SIV-infected macaques. The coupled transcription/translation system has been used as a screening tool to examine the reading frames of SIV *nef* genes for the presence of premature stop codons. The screen has been further simplified by using a colony PCR step to simultaneously screen for correct recombinants and generate the T7-tagged PCR products required for analysis. Demonstrating the reliability of this technique, a 100% correlation was found between the results from coupled transcription/translation and the sequence analysis of 47 *nef* clones. This approach is much faster, cheaper, and less labor-intensive than conventional gene sequencing techniques.

Drug Screening and Pharmacology

The use of in vitro systems for high-throughput drug screening (HTS) is an emerging area in which there are few publications to date. However, this is not reflective of the intense activity in this area. A number of pharmaceutical companies are currently evaluating and developing in vitro screening protocols; material from company press releases was used for some of the descriptions below.

Screening for pharmacological agents

The in vitro luciferase folding/chaperonin assay described earlier has been extended to understanding the role of heat-shock factors, such as Hsp90. It is now understood that disruption of folding pathways can result in proteolytic degradation. Several groups are currently using this information to ascertain the pharmacological activities of benzoquinone ansamycins, such as geldanamycin (Schneider et al., 1996; Thulasiraman and Matts, 1996). These potentially medically important compounds were first identified as interesting because of their ability to inhibit tyrosine kinase activity. This ability appears to be due to their interaction with Hsp90, which prevents correct folding of tyrosine kinases and is followed by their proteolytic degradation. Other potentially important drugs affecting protein folding through inhibition of chaperonin function could be identified using this approach.

High-throughput screening for translation-inhibiting compounds

Viruses contain a number of different genetic elements used for promoting viral expression at the expense of host mRNA translation. Several groups are currently developing screens using in vitro expression of gene constructs containing a viral element—such as the 5′ UTR that can harbor an internal ribosome entry site—followed by a firefly or *Renilla* luciferase gene. Chemical or antibiotic libraries can be screened for specific translation-inhibiting effects. The viral element can be placed between the firefly and *Renilla* luciferase genes, with translation of the first gene relying on normal cap-dependent initiation. Use of the two luciferase genes allows normalization of the second reporter behind the viral element. Compound efficacy can be assessed rapidly (<30 sec) by assaying light output for both the reporter and the luciferase control. As a variation on this theme, RiboGene has reported that they are developing a high-throughput screen capable of screening several hundred thousand compounds for the ability to diminish or block the required ribosomal frameshifting that occurs during translation of the HIV *gag-pol* mRNA. This screen utilizes a reporter gene in which luciferase (and light) is produced only when the frameshift occurs.

Other Applications

A highly sensitive immunoassay, known as the ultrasensitive expression immunoassay (USEI), was developed based on a "solid-phase" coupled transcription/translation system described by Christopoulos and Chiu (1995). A DNA fragment encoding firefly luciferase is biotinylated and complexed with streptavidin. Biotinylated specific antibodies are used to quantify antigen immobilized on microtiter wells. After completion of the immunoreaction, streptavidin-DNA complex is bound to the immunocomplex. Subsequent expression of the solid phase–bound DNA by a coupled transcription/translation reaction produces luciferase. As few as 3000 molecules of DNA label can detect a minimum of 50,000 antigen molecules. The luminescence is a linear function of the number of antigen molecules in a range extending over 3 orders of magnitude. The high sensitivity achieved results from the combined amplification due to transcription/translation and the substrate turnover. The same investigators developed a similar approach for DNA detection (Chiu and Christopoulos, 1996). A denatured target DNA is hybridized to two probes, one biotinylated and one labeled with digoxigenin. The DNA label contains the firefly luciferase coding sequence downstream from a T7 RNA polymerase promoter. The target DNA (200 bp) is denatured and hybridized simultaneously with two oligonucleotide probes. One probe is immobilized in microtiter wells, via the digoxigenin/anti-digoxigenin interaction, and the other is biotinylated. After hybridization is complete, the hybrids are reacted with a streptavidin-luciferase-DNA complex. Subsequently, the solid phase–bound DNA is expressed by coupled transcription/translation. This system too is very sensitive due to the coupled transcription/translation system, and the resulting luminescence is linearly related to target DNA levels for between 5 and 5000 amol. Because the assay is performed in microtiter wells and avoids membrane hybridization and blotting, it can be adapted to automatable HTS detection.

A sensitive nonradioactive method for detecting eukaryotic nuclear extract transcription products has been developed using in vitro synthesis of mRNAs encoding the firefly luciferase gene. Transcriptional activity can be assessed by using vectors containing the luciferase gene (downstream of a range of different promoters) upstream of the nuclear extract transcription reactions and using the resulting transcripts to program a rabbit reticulocyte translation system. When the translation reaction products are tested using the sensitive luciferase assay, there is a linear relationship between transcriptional activity and light gener-

ated. This approach can be used either to test the transcriptional activity of the nuclear extract with regard to specific promoters or to compare promoter strengths in different extracts (Ayoubi and Van de Ven, 1995).

THE FUTURE OF IN VITRO TRANSLATION SYSTEMS

Although the process of translation—or coupled transcription/translation—is complex, the use of convenient, rapid in vitro expression systems for many different applications is simple. The emergence of the eukaryotic coupled systems, combined with the standard molecular biology techniques of PCR and RT-PCR, has produced an explosion of new applications in such diverse fields as diagnostic detection, HTS for anti-HIV drugs, screening applications for functional genomics, and ribosomal display methods for evolving novel binding partners. For rapid generation of high levels of in vitro–translated protein, continuous-flow systems currently hold more promise than concrete utility, although their practicality appears to be improving. Development of coupled transcription/translation systems from the hyperthermophilic *Archaea* may improve CFCF methodology, since these coupled systems should be more stable and longer lasting than systems derived from mesophilic organisms. The ability to manipulate both the reaction and the end product of in vitro translation systems can be expected to generate even more useful and novel tools and applications in the future.

In Vitro Translation

This unit describes the production and use of the two most widely employed eukaryotic in vitro translation systems—those derived from rabbit reticulocytes (see Basic Protocol 1) and from wheat germ (see Basic Protocol 2). These systems are useful for the production of proteins from mRNA isolated from eukaryotic cells or tissues or from mRNAs transcribed in vitro from cloned cDNAs that contain promoters for bacteriophage RNA polymerases. Also described is a time-saving variation that combines transcription and translation in a one-tube reaction (see Basic Protocol 3).

Although in vitro translation systems were developed primarily for the identification of mRNAs and the characterization of their products, the systems have been widely used for the identification of viral genes and the verification of cloned cDNAs. More recently, the systems have found a plethora of applications, including generation of protein variants that can be assayed for function in vitro (mutagenesis combined with expression-PCR), analysis of molecular interactions, characterization of molecular function, screening for mutants in disease states (protein truncation test), and high-throughput drug screening (see *UNIT 11.1*). The systems can be used to translate mRNAs attached to polysomes (see Alternate Protocol 1), purified from tissues or cell lines (see *APPENDIX 3*), or transcribed in vitro (see Support Protocols 1 and 2). Depending on the application, the systems can be used as small or large static reactions, in continuous-flow mode, and with either nonradioactive, radioactive, or modified amino acids (see Alternate Protocol 2 and Support Protocols 3 and 4).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

PRODUCTION AND USE OF mRNA-DEPENDENT CELL-FREE TRANSLATION SYSTEM FROM RABBIT RETICULOCYTES

BASIC PROTOCOL 1

Experimentally induced anemia results in increased accumulation of circulating reticulocytes. Treatment of rabbits with phenylhydrazine, which oxidizes red blood cell membranes, leads to premature lysis of these cells and induction of reticulocytosis. A number of variations on the phenylhydrazine protocol given here have been used successfully. However, since the translation machinery is lost as reticulocytes mature into red blood cells, it is extremely important that the treatment program be standardized to give high reticulocyte counts. It is good practice to keep rabbits for 1 week before starting to inject them to ensure a healthy starting condition. Ideally, the rabbits should weigh 3 kg. Reticulocyte count should be monitored by drawing blood from the marginal vein of the ear and examining cells stained with Brilliant Cresyl Blue. The interval between the last injection and bleeding allows the rabbits to clear the toxic products of phenylhydrazine from the circulation and increases the hematocrit and, hence, the yield of lysate.

Processing should be conducted as quickly as possible to produce a lysate of high protein-synthetic activity. If the need for lysate is high, it is possible to process five to ten rabbits at a time, since this should not increase processing time significantly. However, it is probably prudent to become familiar with the procedure with one or two rabbits before tackling ten. If processing more than one rabbit, the blood should be pooled prior to processing. If the need for lysate is low or occasional, it is probably better to purchase whichever commercially available system is most suitable. The activity of the translation systems should be tested after preparation and compared to that of previous batches or of

Current Protocols in Cell Biology (1998) 11.2.1-11.2.25

commercially available systems such as those provided by Amersham, Boehringer, Novagen, or Promega. The system described below can be used to translate mRNA purified from tissues or cells (see *APPENDIX 3*) or polysomes (see Alternate Protocol 1), or from in vitro–transcribed mRNAs, which can be uncapped (see Support Protocol 1) or capped (see Support Protocol 2) depending on the application and the choice of expression vector.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Female New Zealand white rabbits, 2 to 3 kg
2.5% (w/v) phenylhydrazine (see recipe)
100 mg/ml ketamine hydrochloride
20 mg/ml xylazine hydrochloride
500 U/ml heparin in sterile water (store at −20°C)
70% ethanol
0.4 mg/ml sodium pentobarbital
Reticulocyte wash buffer I (see recipe), with and without 1 U/ml heparin (from 500 U/ml stock)
Reticulocyte wash buffer II (see recipe)
Diethylpyrocarbonate-treated water (DEPCW; *APPENDIX 2A*), sterile
100 mM $CaCl_2$ (*APPENDIX 2A*)
1 mM hemin hydrochloride (see recipe)
200 U/ml creatine phosphokinase (see recipe)
15,000 U/ml *Staphylococcus aureus* nuclease S7 (see recipe; prepare fresh)
200 mM EGTA (see recipe)
5 mg/ml calf liver tRNA (see recipe)
2 M KCl/10 mM magnesium chloride (K/Mg; see recipe)
1 mM amino acids minus methionine (see recipe)
[^{35}S]Methionine, translation grade (e.g., NEN Life Sciences or Amersham)
20 to 40 U/µl RNasin ribonuclease inhibitor (Promega) or equivalent
1 M phosphocreatine (see recipe)
Translation substrate: mRNA purified from cells or tissues (see *APPENDIX 3*) *or* uncapped or capped in vitro transcript (see Support Protocols 1 and 2)
5% and 10% trichloroacetic acid (TCA; see recipe)

60-ml disposable syringes
1-ml syringes
60-ml spring for 60-ml syringes
No. 16 and 1.5-in.-long no. 20 Huberpoint needles (Fisher)
Liquid nitrogen
Glass-fiber filters (e.g., Whatman GFC or equivalent)
Liquid scintillation counter and scintillation fluid

Prepare reticulocytes

1. Each day for 5 days, at the same time in the late afternoon, inject immature female New Zealand white rabbits (2 to 3 kg) subcutaneously in the interscapular region with 0.25 ml/kg of 2.5% phenylhydrazine hydrochloride using no. 20 Huberpoint needles.

   The weight of the rabbit is only a good guide for dosage with younger rabbits, since the drug does not equilibrate with adipose tissue.

2. Allow rabbits to recover for 2 days. Monitor reticulocyte count.

3. Early in the morning of day 8, inject rabbits intramuscularly in the thigh with 15 to 20 mg/kg ketamine hydrochloride and 5 mg/kg xylazine hydrochloride using a no. 20 Huberpoint needle.

4. Coat the inside of a spring-loaded 60-ml syringe with 0.1 ml of 500 U/ml heparin and attach to a no. 16 Huberpoint needle. When the rabbit is completely unconscious, lay it on its back and spray the thorax with 70% ethanol. With the spring attached to the syringe, push the plunger in completely and insert the needle under the sternum, pointing towards the heart.

   Use of the spring-loaded syringe takes most of the skill requirement out of blood collection by heart puncture. Once inside the thoracic cavity, the spring will prevent the syringe plunger from withdrawing. When the needle punctures the heart, the pressure of blood will allow the syringe to fill unassisted, a clear indication that the heart has been reached.

   The combination of ketamine hydrochloride and xylazine hydrochloride anesthetizes the rabbit and relaxes the muscles while maintaining heart rate, blood pressure, and ventricular function. It is preferable to sodium pentobarbital, which decreases blood oxygen and can result in lower translation activity in the lysates prepared from isolated reticulocytes as well as death of the rabbit before bleeding is complete. Note that ketamine/xylazine anesthesia abolishes the righting reflex, but does not affect the toe-web pinch reflex.

5. Recoat inside of syringe with 0.1 ml heparin and repeat bleeding procedure in same rabbit until no more blood can be extracted.

   It should be possible to withdraw between 60 and 100 ml blood from each rabbit.

6. After bleeding, euthanize each rabbit by injecting intraperitoneally with 200 mg/kg sodium pentobarbital.

Wash reticulocytes

7. Discharge blood into ~5 vol reticulocyte wash buffer I containing 1 U/ml heparin. Collect the cells by centrifugation for 10 min at 1400 × *g*, 4°C. Remove the supernatant by gentle suction and discard.

   When discharging blood from the syringe into the wash buffer, remove needle first to avoid rupturing the reticulocytes.

   After centrifugation the supernatant should be clear and pale straw-colored. Any redness in the supernatant suggests that the reticulocytes have not pelleted or lysis has occurred.

8. Wash twice by resuspending in ~5 to 10 vol reticulocyte wash buffer I without added heparin and centrifuging 10 min at 1400 × *g*, 4°C, discarding the supernatant each time.

   The washes are to remove serum (including clotting factors) and heparin, which is inhibitory to protein synthesis. Use maximum possible rinse volumes or at least 5 times the volume of blood collected. Reticulocyte wash buffer I contains 7.5 mM $MgCl_2$ to stabilize the reticulocyte cell membrane, along with 1 mM glucose to prevent the reticulocytes from becoming depleted of ATP and reducing equivalents. Some published procedures call for removal of the "buffy coat," the fluffy layer of white cells that sediment on top of the heavier reticulocytes, to prevent contamination by ribonucleases contained in the white cells. In practice, however, the white cells will not lyse under the conditions used to lyse reticulocytes, so their removal is unnecessary, and it reduces the yield of reticulocytes obtained.

9. Wash once with reticulocyte wash buffer II. Centrifuge as in step 7. Remove as much supernatant as possible to avoid carryover of salts into the lysate.

   Reticulocyte wash buffer II used in the final rinse is lacking the Mg^{2+} contained in reticulocyte wash buffer I. This is to prevent carryover into the reticulocyte lysate, since protein synthesis can be inhibited by Mg^{2+} at higher concentrations.

Prepare lysate

10. Transfer the cell pellet to a sterile graduated cylinder and record the volume of packed cells. Add 1.5 vol sterile DEPCW. Stir on ice for 5 min to maximize lysis.

11. Centrifuge 20 min at 20,000 × *g*, 4°C, to remove cell membranes and mitochondria. Decant the supernatant, and snap-freeze a few aliquots as "parent lysate" to compare with the mRNA-dependent lysate (MDL). Subject the rest to endonuclease treatment.

    The parent lysate is useful to provide an indication of how much incorporation to expect in a cell-free translation system working at maximum efficiency/capacity. It is also useful if the MDL is not very active and it is necessary to determine whether the problem came from the reticulocyte lysate prep itself or arose during the endonuclease treatment. In addition, the parent lysate can be used to optimize each batch for K^+, Mg^{2+}, and hemin concentrations.

12. To each 25 ml of lysate, add:

    250 µl 100 mM $CaCl_2$
    500 µl 1 mM hemin hydrochloride
    250 µl 200 U/ml creatine phosphokinase
    250 µl 15,000 U/ml nuclease S7.

    Incubate 15 min at 20°C.

13. Add 250 µl of 200 mM EGTA to chelate the Ca^{2+} and inactivate the nuclease. Add 250 µl calf liver tRNA (5 mg/ml). Snap-freeze 500-µl aliquots and store in liquid nitrogen.

    After nuclease treatment, the lysate is referred to as mRNA-dependent lysate or MDL. This preparation should produce between 30 and 40 ml MDL per rabbit. This is sufficient for 600 to 800 50-µl assays.

    Calf liver tRNA is added not because endogenous tRNA is hydrolyzed by endonuclease, but because the composition of reticulocyte tRNA is related to the amino acid composition of globin and may not always support the production of full-length proteins.

    Translation systems from reticulocytes retain activity for years when stored in liquid nitrogen. At −70°C, loss of activity is discernible and the lysate can only be used for 3 to 4 months. Storage at −20°C is not recommended.

14. Test each batch of MDL produced for translational activity by performing steps 15 to 20 using a suitable test RNA (mRNA purified from cells or tissues or transcribed in vitro).

    A good test transcript is that produced from Promega's pGEM-luc DNA, since a functional assay measuring luciferase activity can be used. This has the advantage of not requiring a radioactive amino acid and ensures that only full-length polypeptides are scored.

Translate mRNA

15. Remove reagents from storage and place on ice. Rapidly thaw MDL by hand warming and place on ice.

16. Assemble the following reaction components in a 0.5- to 1.5-ml sterile microcentrifuge tube (for 50 µl):

    2.5 µl K/Mg
    2.5 µl amino acid mixture minus methionine
    2.5 µl [^{35}S]methionine
    0.35 µl 20 to 40 U/µl RNasin
    0.5 µl 1 M phosphocreatine
    0.5 µl 200 U/ml creatine phosphokinase

continued

0.5 µl 1 mM hemin hydrochloride
35 µl MDL
0.5 to 2 µl (~0.5 µg) mRNA substrate
Nuclease-free water to 50 µl final.

Mix by gentle vortexing and, if necessary, microcentrifuge 5 sec to return reaction mix to bottom of tube.

The reaction volume can be modified from 10 µl to 1 ml depending on application. Capped microcentrifuge tubes should be used to avoid changes in reaction volume.

Include a control reaction without added template to assess if any translation products are arising from undegraded endogenous mRNA. Note that the composition of the reaction described above is optimal for MDL prepared as described in the preceding steps. The preparation of commercially available MDL may vary, and the manufacturer's recommendations for use should be followed.

Increased expression levels may be obtained by optimizing Mg^{2+} and K^{+} concentrations for a particular mRNA species. The mRNA used may be purified from cells or tissue or transcribed in vitro from cDNAs downstream of a phage polymerase promoter. Unfractionated cytoplasmic RNA preparations contain 90% to 95% rRNA and translate very poorly.

If synthesizing a recombinant protein such as an enzyme for functional analysis, higher protein levels can be achieved by substituting 1 mM nonradioactive methionine (2.5 µl/50-µl reaction) for [^{35}S]methionine.

17. Incubate 30 min to 1 hr at 30°C.
18. Determine amount of radioactivity incorporated into TCA-precipitable material by diluting 1 to 2.5 µl of the reaction in 1 ml ice-cold water and adding 1 ml of 10% TCA. Heat the mixture 10 min at 95°C to discharge aminoacylated tRNAs, then cool on ice.
19. Collect precipitated protein by vacuum filtration onto glass-fiber filters. Rinse with 5% TCA, and dry filters under an infrared lamp. Measure radioactivity by liquid scintillation spectroscopy.
20. Use remaining incubation mix for assay of function or analysis by SDS-PAGE (*UNIT 6.1*).

PRODUCTION AND USE OF mRNA-DEPENDENT CELL-FREE TRANSLATION SYSTEM FROM WHEAT GERM

BASIC PROTOCOL 2

In this procedure, wheat germ extract is prepared by grinding wheat germ in an extraction buffer, then centrifuging the resulting paste to remove cell debris. Endogenous amino acids and plant pigments that are inhibitory to protein synthesis are removed by gel filtration. Although the level of endogenous mRNA is low compared to that in untreated reticulocyte lysate, the response to added mRNAs is improved by treatment with calcium-dependent micrococcal nuclease with subsequent addition of sufficient EGTA to chelate the free calcium. The most important consideration in preparing wheat germ extract of high translational activity is to find a good batch of fresh commercial wheat germ low in endosperm-rich fragments. There can be considerable variability in the quality of wheat germ from one manufacturer and the activity of the resulting cell-free translation system, depending on growth conditions and conditions at harvest.

The wheat germ system can be used with all the alternative methods described for use of the reticulocyte system (see Support Protocols 1 and 2; see Alternate Protocols 1 and 2). It can also be used as a coupled transcription/translation system (see Basic Protocol 3).

Materials

Wheat germ
Wheat germ extraction buffer (see recipe; prepare fresh)
100-ml Sephadex G-25 column (Amersham Pharmacia Biotech) preequilibrated in extraction buffer
100 mM $CaCl_2$ (*APPENDIX 2A*)
1 mM hemin hydrochloride (see recipe)
200 U/ml creatine phosphokinase (see recipe)
15,000 U/ml nuclease S7 (see recipe; prepare fresh)
200 mM EGTA (see recipe)
5 mg/ml calf liver tRNA (see recipe)
50 mM ATP (see recipe for 4NTP mixture)
50 mM GTP (see recipe for 4NTP mixture)
50 mM and 1 M magnesium acetate
20 to 40 U/µl RNasin ribonuclease inhibitor (Promega) or equivalent
1 mM amino acids minus methionine (see recipe)
1 M potassium acetate
1 M phosphocreatine (see recipe)
10 mCi/ml [^{35}S]methionine (1000 Ci/mmol)
Translation substrate: mRNA purified from cells or tissues (see *APPENDIX 3*) *or* uncapped or capped in vitro transcript (see Support Protocols 1 and 2)
Diethylpyrocarbonate-treated water (DEPCW; *APPENDIX 2A*)
Sterile, RNase-free glass powder (see recipe)

Prepare wheat germ cell-free translation system

1. Working at 4°C with all components and apparatus prechilled, grind 5 g wheat germ with 5 g sterile glass powder and 22.5 ml wheat germ extraction buffer to give a smooth paste. Centrifuge for 10 min at 30,000 × *g*, 4°C.

2. Remove top 20 ml of supernatant and load onto a 100-ml Sephadex G-25 column preequilibrated in extraction buffer. Use ~100 ml of the same buffer for elution.

   A low-molecular-weight inhibitor of protein synthesis and a deep yellow pigment are removed by the column.

3. As soon as all the extract has penetrated into the column, follow with 100 ml of extraction buffer. Collect 2.5-ml fractions and measure A_{260} by spectrophotometry (see *APPENDIX 3*). Pool the highest-absorbance fractions (which are also the most opaque fractions), usually fractions 20 to 30.

4. Let pooled fractions stand 5 min on ice, then centrifuge 10 min at 23,000 × *g*, 0°C. Carefully remove upper 20 ml.

   A high-molecular-weight inhibitor of protein synthesis aggregates as the column fractions incubate on ice. This will disperse if temperature rises above 4° or 5°C.

5. Add the following per 20 ml of lysate:

   200 µl 100 mM $CaCl_2$
   400 µl 1 mM hemin hydrochloride
   200 µl 200 U/ml creatine phosphokinase
   200 µl 15,000 U/ml nuclease S7.

   Incubate 15 min at 20°C.

6. Add 200 µl of 200 mM EGTA per 20 ml (to chelate Ca^{2+} and inactivate the nuclease).

7. Add the following per 20 ml of lysate:

   200 µl 5 mg/ml calf liver tRNA
   625 µl 50 mM ATP
   125 µl 50 mM GTP
   37.5 µl 1 M magnesium acetate.

   Mix, then snap-freeze in 200- to 500-µl aliquots and store in liquid nitrogen.

8. Test each batch of wheat germ extract produced for translational activity prior to use (see Basic Protocol 1, step 14).

Translate mRNA

9. Remove reagents from storage and place on ice. Rapidly thaw wheat germ extract by hand warming and place on ice.

10. Assemble the following reaction components in a 0.5- to 1.5-ml sterile microcentrifuge tube (50 µl):

    25 µl wheat germ extract
    1 µl 20 to 40 U/µl RNasin
    4 µl amino acid mix minus methionine (or other amino acid, as appropriate)
    3.75 µl 1 M potassium acetate
    1 µl 50 mM magnesium acetate
    2.5 µl 10 mCi/ml [^{35}S]methionine (1000 Ci/mmol)
    0.5 to 2 µl mRNA substrate (to give ~0.5 to 1 µg)
    DEPCW to 50 µl.

    Mix by gentle vortexing and, if necessary, microcentrifuge 5 sec to collect the reaction mix in the bottom of the tube.

    Include a reaction without added template to measure any background incorporation from endogenous mRNA. Note that the composition of the reaction described above is optimal for wheat germ extract prepared as described above. Preparation of commercially available wheat germ extract may vary, and the manufacturer's recommendations for use should be followed.

    Increased expression levels may be obtained by optimizing Mg^{2+} and K^{+} concentrations for a particular mRNA species. As with MDL, the mRNA used may be purified from cells or tissue (see APPENDIX 3) or transcribed in vitro from cDNAs downstream of a phage polymerase promoter (see Support Protocols 1 or 2).

11. Incubate 1 to 2 hr at 25°C.

12. Use 1.0 to 2.5 µl of reaction mixture for determining radioactivity incorporated into TCA-precipitable material (see Basic Protocol 1, steps 18 and 19). Use remainder for assay of function or analyze by SDS-PAGE (*UNIT 6.1*).

IN VITRO PROTEIN SYNTHESIS IN COUPLED TRANSCRIPTION/TRANSLATION SYSTEMS

BASIC PROTOCOL 3

Transcription of cDNA clones by bacteriophage RNA polymerases may be carried out simultaneously with translation in a single reaction by adding DNA directly to the translation system along with the appropriate RNA polymerase (T3, T7, or SP6). This adaptation obviates the need for three prior reactions: (1) linearization of DNA, (2) in vitro transcription, and (3) 5′ capping and methylation of mRNA. Optimization of the conditions for the combined reactions are closer to those required for in vitro translation than transcription. Under the conditions outlined, transcription is relatively inefficient, but sufficient levels of trancripts are produced to saturate the protein synthetic capacity

of the system. The reaction buffer is modified to provide the NTPs and additional Mg^{2+}, with the Mg^{2+} concentration being the critical parameter.

Materials

2 M KCl/10 mM $MgCl_2$ (K/Mg; see recipe)
Amino acid mixture minus methionine (see recipe)
25× transcription/translation buffer (TX/TL buffer; see recipe)
10 mCi/ml [^{35}S]methionine (1000 Ci/mmol)
20 to 40 U/µl RNasin ribonuclease inhibitor (Promega) or equivalent
1 M phosphocreatine (see recipe)
200 U/ml creatine phosphokinase (see recipe)
1 mM hemin hydrochloride (see recipe)
mRNA-dependent lysate (MDL; see Basic Protocol 1, step 14, or see Basic Protocol 2, step 8)
Plasmid DNA, at ≥0.1 mg/ml (*APPENDIX 3*)
Appropriate bacteriophage RNA polymerase (e.g., T3, T7, or SP6)
Diethylpyrocarbonate-treated water (DEPCW; *APPENDIX 2A*)

1. Remove reagents from storage and place on ice. Rapidly thaw MDL by hand warming and place on ice.

2. Assemble the following reaction components in a 0.5- to 1.5-ml sterile microcentrifuge tube (50 µl):

   2.5 µl K/Mg
   2.5 µl amino acid mixture minus methionine
   2.0 µl 25× TX/TL buffer
   2.5 µl 10 mCi/ml (1000 Ci/mmol) [^{35}S]methionine
   0.35 µl 20 to 40 U/µl RNasin
   0.5 µl 1 M phosphocreatine
   0.5 µl 200 U/ml creatine phosphokinase
   1 µl 1 mM hemin hydrochloride
   25 µl MDL
   0.5 to 2 µl plasmid DNA (to give ~0.5 µg)
   RNA polymerase to give 600 to 1000 U/ml
   DEPCW to 50 µl.

   Mix by gentle vortexing, and if necessary microcentrifuge 5 sec to return reaction mixture to bottom of tube.

   Note that the amino acid mix minus methionine and [^{35}S]methionine can be replaced by complete amino acid mix and biotinylated lysine-tRNA. Alternatively, if synthesizing a recombinant protein such as an enzyme for functional analysis, higher protein levels can be achieved by substituting 1 mM nonradioactive methionine for [^{35}S]methionine (2.5 µl/50-µl reaction).

   Ensure that all ethanol is removed from DNA before adding to the reaction. The smaller the volume of DNA added to the reaction, the less likely it will be that a nonspecific inhibitor of protein synthesis will be introduced. Include a control incubation to which no DNA has been added. The reaction volume can be modified from 10 µl to 1 ml depending on application. Capped microcentrifuge tubes should be used to avoid changes in reaction volume.

3. Incubate 1 hr at 30°C.

4. Analyze as for the noncoupled system (see Basic Protocol 1, steps 18 to 20).

Best results are obtained with DNA from which all contaminating RNAs are removed by a method that does not involve RNase. However, miniprep DNA prepared by a variety of methods (see APPENDIX 3) has proved to be quite adequate. Optimal production of proteins appears to be obtained with ~1 μg plasmid DNA/100 μl reaction volume, although this varies somewhat with the purification method. However, adequate levels of product may be obtained with 0.1 μg plasmid DNA/100 μl reaction. Circular plasmid DNA gives the best results although linearized versions of most plasmids can be translated. Best results will be obtained from constructs containing the EMCV 5′ UTR and a 3′ poly(A)$^+$ sequence.

PRODUCTION OF UNCAPPED IN VITRO TRANSCRIPTS

SUPPORT PROTOCOL 1

Transcripts produced in vitro can be used in place of purified mRNA in either the reticulocyte or wheat germ translation systems. To produce high levels of uncapped mRNA, transcription reactions containing 4 mM of each nucleotide triphosphate (NTP) are used since the production of mRNA is proportional to the amount of NTP in the reaction up to this concentration (Milligan et al., 1987). Yields are also increased by the inclusion of 0.01% Triton X-100 and BSA (Milligan et al., 1987). The transcript yield is measured by the inclusion of trace amounts of radiolabeled NTP (usually [α-^{32}P]CTP). The percentage of [α-^{32}P]CTP incorporated is measured, and the total amount of CTP is calculated based on the ratio of labeled to unlabeled nucleotide. From that the amount of RNA synthesized is determined. For translation of uncapped transcripts, the efficiency of translation will be increased by using the cDNA of interest in a vector that places an internal ribosome entry site (IRES) upstream of the initiation codon to generate a mRNA that is processed via cap-independent translation. Suitable vectors for achieving this include pCITE from Novagen and the commercially unavailable pTM1 (Moss et al., 1990).

The transcripts produced by in vitro transcription can be used in place of purified mRNA in any of the basic protocols. The integrity of the RNA should be verified by agarose gel electrophoresis prior to use. Because high concentrations of RNA are produced, sufficient RNA to saturate the translation system can be added in such a small volume that prior cleanup is not necessary, as long as the free Mg^{2+} is titrated out after completion of the transcription reaction.

Materials

Diethylpyrocarbonate-treated water (DEPCW; *APPENDIX 2A*), sterile
5× modified transcription buffer (MTB; see recipe)
12.5 mM 4NTP mix (see recipe)
1 M $MgCl_2$ (*APPENDIX 2A*)
250 mM DTT (see recipe)
[α-^{32}P]CTP (3000 Ci/mmol) in tricine, diluted in DEPCW to 10,000 to 50,000 cpm/μl
20 to 40 U/μl RNasin ribonuclease inhibitor (Promega) or equivalent
Plasmid DNA or PCR product containing appropriate phage polymerase promoter (see *APPENDIX 3*), linearized using a restriction enzyme that generates 5′ protruding ends, at 0.2 to 0.5 mg/ml concentration
20 U/μl RNA polymerase (SP6, T3, or T7; Promega)
0.5 mg/ml yeast tRNA (carrier for TCA precipitation)
5% trichloroacetic acid (TCA; see recipe)
0.5 M EDTA (*APPENDIX 2A*)
RQ1 RNase-free DNase (Promega)
TE buffer, pH 8 (*APPENDIX 2A*)
1:1 (v/v) TE-saturated phenol/chloroform
24:1 (v/v) chloroform/isoamyl alcohol

7.5 M ammonium acetate
100% and 70% ethanol

Dry ice/ethanol bath
Glass-fiber filters (e.g., Whatman GFC or equivalent)
Liquid scintillation counter

Produce uncapped transcripts

1. Remove reagents from storage and place on ice.
2. Assemble the following reaction components, in the order listed, in a 1.5-ml sterile screw-cap microcentrifuge tube at room temperature (50 µl total):

   14.7 µl DEPCW
   10 µl 5× MTB
   16 µl 12.5 mM 4NTP mix
   0.8 µl 1 M $MgCl_2$
   2 µl 250 mM DTT
   2.5 µl 20 to 40 U/µl RNasin
   1 µl 10,000 to 50,000 cpm/µl [α-^{32}P]CTP (200 to 1000 cpm/µl final)
   1 µl 0.2 to 0.5 mg/ml linearized DNA
   2 µl 20 U/µl appropriate RNA polymerase (800 U/ml final).

   Mix by gentle vortexing and microcentrifuge 5 sec to collect the reaction mix in the bottom of tube.

   Care should be taken in the choice of restriction enzyme for linearizing the DNA, since templates containing 3′ protruding ends allow the transcription of RNA from these sites. Enzymes such as BamHI and NcoI, which produce 5′ protruding ends, are good choices, whereas those such as Apa I, Sac I, and PstI that generate 3′ protruding ends should be avoided.

3. Place 1-µl spots of the mixture onto two glass-fiber filters and allow filters to dry; meanwhile, incubate remainder of reaction mixture 30 min to 1 hr at 37°C.
4. After the reaction incubation is over, pipet duplicate 1-µl samples of the transcription mixture into 100 µl of 0.5 mg/ml yeast carrier tRNA and add 2 ml of 5% TCA on ice. Collect precipitate on glass-fiber filters by vacuum filtration and allow to dry.
5. Determine total radioactivity (total cpm/µl) of pre- and postincubation samples on filters by liquid scintillation spectroscopy.

   Dividing the value for the second sample by that for the first gives the percentage of [α-^{32}P]CTP incorporated into the transcript. These reactions give between 25% and 30% incorporation of [α-^{32}P]CTP, which means that 50 to 60 nmol of CTP and ~200 to 240 nmol of RNA (depending on coding sequence) are made. Based on 0.33 µg/nmol, between 70 and 80 µg RNA is produced in a 50-µl reaction, giving enough RNA for ~50 50-µl translation assays (assuming some losses during cleanup). Once this has been determined for a particular DNA preparation, scale up the reaction 10-fold to give a greater supply of transcript for use in cell-free translation reactions.

6. Add EDTA to 10 mM final (from 0.5 M stock) to chelate free Mg^{2+}, and store at −20°C (good for several months).

   The reaction mix can be used directly in in vitro translation reactions without further processing. When using frozen reaction mix, warm briefly to 37°C prior to direct use in translation reactions (at 0.5 to 1 µl per 50-µl reaction). Alternatively, the transcripts can be purified from the reaction mix as follows.

   Because high concentrations of RNA are produced, sufficient RNA to saturate the translation system can be added in such a small volume that prior cleanup is not necessary, as long as the free Mg^{2+} is titrated out after completion of the transcription reaction.

Optional: Purify transcripts by phenol/chloroform extraction and ethanol precipitation

7. Add 1 U RQ1 DNase/µg template DNA and incubate 15 min at 37°C.
8. Add 200 µl TE buffer to the reaction mixture, then extract with 250 µl of 1:1 (v/v) TE-saturated phenol/chloroform. Vortex 1 min, then microcentrifuge 5 min at maximum speed, 4°C.
9. Transfer the upper (aqueous) phase to a fresh tube and repeat extraction with 250 µl of 24:1 (v/v) chloroform/isoamyl alcohol.
10. To the final aqueous phase, add 0.5 vol of 7.5 M ammonium acetate and 2.5 vol of 100% ethanol. Place mixture in dry ice/ethanol bath for 10 min. Microcentrifuge 5 min at maximum speed, 4°C.
11. Aspirate supernatant and wash pellet with 1 ml of 70% ethanol. Dry under vacuum and resuspend in a volume of DEPCW that will give ~1 mg/ml transcript. Store at −85°C.

Dilution of the transcription reaction is only necessary to avoid large losses when dealing with small volumes. For scaled-up reactions, this dilution is not necessary.

Equivalent or higher levels of uncapped transcripts can be produced using kits from Ambion, Novagen, or Promega.

It is possible that some double-stranded RNA (dsRNA) may be produced during in vitro transcription reactions from promiscuous binding of the polymerase. This will not be removed by the usual cleanup procedures, but it can be kept to a minimum provided the DNA is not linearized with restriction enzymes that generate 3′ protruding ends. If significant dsRNA is produced in the reaction, this will lead to activation of endogenous PKR, the dsRNA-activated kinase that phosphorylates and downregulates the translation factor eIF2. Higher levels of translation products may be generated by including additives that prevent PKR activation or eIF2α phosphorylation. These include 2 to 10 mM 2-aminopurine, high levels (10 µg/ml) of dsRNA such as poly(I)·poly(C), or 100 to 200 pmol/ml of the vaccinia virus K3L gene product, the pseudosubstrate of eIF2α.

PRODUCTION OF CAPPED IN VITRO TRANSCRIPTS

SUPPORT PROTOCOL 2

The production of capped transcripts is more expensive and more challenging than the production of uncapped transcripts and may not be necessary for the translation of many RNAs. Because of the presence of a cap analog as well as the lower concentration of transcripts generated, the reaction mix cannot be used directly in cell-free translation systems but must be purified prior to use.

Additional Materials *(also see Support Protocol 1)*

5× transcription buffer (TB; see recipe)
10 mM each ATP, CTP, UTP, and GTP (see recipe for 4NTP mixture)
10 mM ^{7}m(5′)Gppp(5′)G (cap analog; Amersham, Pharmacia Biotech)

1. Remove reagents from storage and place on ice.
2. Assemble the following reaction components, in the order listed, in a 1.5-ml sterile screw-cap microcentrifuge tube at room temperature (50 µl total):

13.375 µl DEPCW
10 µl 5× TB
5 µl *each* 10 mM ATP, CTP, and UTP
0.625 µl 10 mM GTP
2.5 µl 10 mM ^{7}m(5′)Gppp(5′)G

continued

1 µl 10,000 to 50,000 cpm/µl [α-^{32}P]CTP (200 to 1000 cpm/µl final)
2 µl 250 mM DTT
2.5 µl 20 to 40 U/µl RNasin
1 µl 0.2 to 0.5 mg/ml linearized plasmid DNA
1 µl 20 U/µl appropriate RNA polymerase (400 U/ml final).

Mix by gentle vortexing and microcentrifuge 5 sec to collect reaction mixture in bottom of tube.

The cap analog is present at a higher concentration than GTP, which is rate limiting for transcription. This ensures that the majority of transcripts are initiated with the cap analog. The cap analog is not used internally to any significant extent.

3. Place 1-µl spots of the mixture onto two Whatman GFC filters and allow filters to dry; meanwhile, incubate reaction mixture 45 min at 37°C.
4. After the 45-min incubation, pipet duplicate 1-µl samples of the reaction mixture into 100 µl of 0.5 mg/ml yeast carrier tRNA and add 2 ml of 5% TCA on ice. Collect precipitate on glass-fiber filters by vacuum filtration and allow to dry.
5. Determine total radioactivity (cpm/µl) of the pre- and postincubation samples on filters by liquid scintillation spectroscopy.

   Dividing the value for the second sample by that for the first gives the percent of [α-^{32}P]CTP incorporated into the transcript.

6. Add another 0.625 µl of 10 mM GTP and 1 µl of 20 U/µl RNA polymerase. Continue incubation for 45 min, then determine percentage of [α-^{32}P]CTP incorporated as in step 5.

   As the reaction proceeds, the GTP concentration falls, although the concentration of m^7(5′)Gppp(5′)G does not decrease significantly. The late addition of more GTP allows more synthesis to occur without affecting the use of the cap analog for initiation. These conditions allow 18% to 22% incorporation of CTP, which is equivalent to 9 to 11 nmol CTP, 36 to 44 nmol RNA, and 12 to 15 µg RNA. Between 75% and 90% of these trancripts are capped. This gives enough RNA for ~10 50-µl translation assays (assuming some losses during cleanup).

7. Stop reaction with RQ1 DNase and purify by phenol extraction and ethanol precipitation (see Support Protocol 1, steps 7 to 11).

ALTERNATE PROTOCOL 1

TRANSLATION OF POLYSOMAL mRNAs FROM CELLS AND TISSUES

Translation of polysome-bound mRNAs in vitro provides a means to assess in vivo recruitment of mRNAs. Polysomes or subfractions of polysomes either in a free or membrane-associated state have long been a source of mRNAs that can be translated in vitro with the aid of rabbit reticulocyte lysate or other cell-free fractions. The translation of polysomal mRNAs allows a finer assessment of changes in gene expression than can be determined by studying the changes in mRNA steady-state levels or transcriptional activity.

The method described here involves gentle lysis of the cells with the nonionic detergent Nonidet P-40 (NP-40) and isolation of polysomes by ultracentrifugation. The polysome fraction contains ribosomes, mRNA, and associated proteins, but translation is suspended in the elongation process. Translation can resume in vitro in a translation system that provides all other requirements. In vitro translation of the polysome-bound mRNA fractions in the presence of [^{35}S]methionine allows quick assessment of what mRNAs are being utilized in the cell by a variety of methods using a radioactive amino acid (e.g.,

methionine) or biotinylated lysine-tRNA. The translation products arise not just from translation runoff of polysomes, but also by reinitiation. Sufficient product can be produced to allow identification of the translation products by immunological techniques or even sequencing.

Materials

10× cell lysis buffer (see recipe; prepare working solution fresh before use)
1 M 4-(2-aminoethyl)benzenesulfonyl fluoride hydrocholoride (AEBSF)
8 mg/ml aprotinin
2 mg/ml leupeptin
250 mM DTT (see recipe)
20 to 40 U/µl RNasin ribonuclease inhibitor (Promega) or equivalent
0.5 M EDTA (*APPENDIX 2A*)
10% Nonidet P-40 (NP-40)
Diethylpyrocarbonate-treated water (DEPCW; *APPENDIX 2A*), sterile
10 mg/ml cycloheximide
Cells from which the polyribosomes are to be isolated
PBS (*APPENDIX 2A*), ice-cold liquid *and* frozen to a slurry
Sucrose buffer (see recipe; prepare fresh)
HEPES/KCl buffer (see recipe)

Beckman polyallomer thick-walled tubes
Beckman TL100 centrifuge and TLA100.3 rotor

Additional reagents and equipment for in vitro translation (see Basic Protocols 1, 2, and 3)

Prepare lysis buffer and cells

1. Prepare two batches of complete lysis buffer by adding the following to 100 µl of 10× cell lysis buffer on ice:

   1 µl 1 M AEBSF
   1 µl 8 mg/ml aprotinin
   1 µl 2 mg/ml leupeptin
   4 µl 250 mM DTT
   10 µl 20 to 40 U/µl RNasin
   2 µl 0.5 M EDTA.

   Add 40 µl of 10% NP-40 to one tube. Adjust final volume in each tube to 1 ml with DEPCW. Keep tubes on ice.

2. Add 1 µl of 10 mg/ml cycloheximide per milliliter of cell medium to be used. Incubate 5 min at 37°C.

   Incubation with cycloheximide prior to cell harvest piles up mRNAs in polysomes, increasing the yield of polysome-bound mRNA and increasing the translational activity. The cycloheximide is washed away during sedimentation of the polyribosomes and so does not prevent translation of the polysome-bound mRNAs in a cell-free translation system.

Lyse cells

For cells in suspension:

3a. To ~1 × 10^8 cells and add an equal volume of a frozen slurry of PBS to reduce temperature rapidly. Centrifuge 7 min at 1200 × *g*, 4°C.

4a. Aspirate supernatant carefully. Resuspend cells in 10 ml ice-cold PBS and transfer to a sterile 15-ml conical centrifuge tube. Centrifuge as in step 3a, and discard supernatant.

5a. Resuspend cells in 1 ml PBS and transfer to 1.5-ml microcentrifuge tube. Microcentrifuge 10 sec at 4°C. Aspirate supernatant and discard.

6a. Resuspend pellet in 0.5 ml complete lysis buffer without NP-40 (from step 1); vortex very gently. Add 0.5 ml complete lysis buffer with 0.4% NP-40 to cells and mix by pipetting up and down. Incubate on ice for a maximum of 10 min to allow cells to lyse.

For cells grown in monolayers:

3b. Remove medium from 10 × 100–mm plates (~1×10^8 cells) and place on metal blocks sitting in an ice bath.

4b. Rinse twice with ice-cold PBS, tilting plates after final rinse to ensure complete removal of PBS.

5b. Add 500 µl complete lysis buffer with NP-40. Incubate 5 min on ice to allow cells to lyse. Incubate on ice for a further 5 min.

6b. Scrape lysate into appropriate-sized microcentrifuge tubes.

The number of cells needed and exact lysis conditions may need to be determined for each cell type or cell line used. Since mRNAs remain in a cytoplasmic fraction, they may be contaminated with RNase, although association with polysomes seems to afford protection from degradation.

Isolate polysomes

7. Microcentrifuge 10 min at maximum speed, 4°C.

8. Layer supernatant over a 400-µl cushion of sucrose buffer in a Beckman polyallomer thick-wall tube. Centrifuge 50 min at 125,000 × *g* (80,000 rpm in Beckman TL100 centrifuge with TLA100.3 rotor), 4°C.

Use of a sucrose pellet traps any contaminating cell membranes that may carry ribonuclease or protease activity.

9. Aspirate supernatant and discard. Invert pellet on a laboratory wipe to remove last traces of supernatant.

The remaining polysomal pellet should be clear and slightly straw-colored.

10. Snap-freeze immediately on dry ice. Store in liquid nitrogen (good for use 1 to 2 years).

Translate polysomal bound mRNA

11. Resuspend polyribosomal pellet in 50 µl HEPES/KCl buffer.

The volume in which the polysomes are resuspended may need to be modified depending on polysome yield.

12. For a 50-µl translation reaction, combine components as described in Basic Protocol 1, step 16, or Basic Protocol 2, step 10, substituting the resuspended polysomes (1 to 4 µl) for mRNA. Adjust the final volume appropriately and incubate 1 hr at 30°C.

Alternatively, to allow capture of the newly synthesized proteins, include 1 to 2 µl biotinylated lysine-tRNA in the reaction mix. Similarly, if biotinylated lysine-tRNA is used, 1 mM methionine may be substituted for [^{35}S]methionine to give nonradioactive products. This decision should reflect anticipated use and detection method. This reaction can be scaled up (e.g., to 1 ml) to allow the isolation of sufficient biotinylated translation product for sequencing. For scaleup, optimization of the nonradioactive lysine concentration is important so that lysine is not limiting but the majority of polypeptide chains still contain biotinylated amino acids.

13. Analyze by SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*) or by immunoblotting (*UNIT 6.2*), as appropriate.

IN VITRO TRANSLATION WITH BIOTINYLATED AMINO ACIDS

ALTERNATE PROTOCOL 2

Biotinylated lysine residues can be used for detection of proteins synthesized in cell-free translation systems, obviating the need for [^{35}S]methionine or other radioactive amino acids. These residues are provided as precharged biotinylated lysine-tRNA complexes in which the biotin moiety is linked to lysine by a spacer arm at the ε-amino group. Biotinylated lysine-tRNA is available commercially as Transcend tRNA (Promega) and the Biotin-Lysine-tRNA Set (Boehringer Mannheim).

The modified amino acid is added to the in vitro translation reactions along with the amino acid mixture, which may or may not contain unmodified lysine depending upon the amount of incorporation of biotinylated lysine desired. The protein products are subjected to SDS-PAGE (*UNIT 6.1*) and electroblotted for immunoblot analysis (*UNIT 6.2*). The proteins are detected by binding either streptavidin–alkaline phosphatase (streptavidin-AP) or streptavidin–horseradish peroxidase (streptavidin-HRP) conjugate, followed by colorimetric or chemiluminescent detection, respectively. The sensitivity is equivalent to that achieved with [^{35}S]methionine incorporation and autoradiographic detection, with the advantage that no radioisotope handling, storage, or disposal is required. Furthermore, lysine is more highly represented in proteins than methionine (average lysine content is 6.6% compared to 1.7% for methionine).

The biotin tag is stable for at least 12 months as lysine-tRNA and within synthesized proteins. In addition, the use of biotinylated lysine incorporation can open up some new applications, since the protein product can be captured with streptavidin affinity chromatography, using either immobilized streptavidin-agarose columns (see Support Protocol 3) or streptavidin-linked magnetic beads (see Support Protocol 4).

Additional Materials *(also see Basic Protocols 1 and 2)*

mRNA-dependent lysate (see Basic Protocol 1, step 14, or see Basic Protocol 2, step 8)
Biotinylated lysine-tRNA complex (Promega's Transcend tRNA, or Boehringer Mannheim's Biotin-Lysine-tRNA Set) at 0.5 µg/µl (12 pmol/µl)
Amino acid mix, complete (see recipe)
Streptavidin-alkaline phosphatase (streptavidin-AP) or streptavidin-horseradish peroxidase (streptavidin-HRP)
Optional: Streptavidin-linked magnetic beads (Dynal) *or* capture resin such as Streptavidin MagneSphere Paramagnetic Particles or Softlink Soft Release Avidin Resin (Promega), Dynabeads M-280 Streptavidin (Dynal), or Streptavidin Magnetic Particles, Streptavidin, immobilized (gel suspension; Boehringer Mannheim)
Additional reagents and equipment for production and use of reticulocyte lysate (see Basic Protocol 1) or wheat germ lysate (see Basic Protocol 2) for in vitro translation, SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

Translate biotinylated proteins

1. Remove reagents from storage and place on ice. Rapidly thaw MDL by hand warming and place on ice.

2. Combine components for a 50-µl translation reaction (see Basic Protocol 1, step 16, or see Basic Protocol 2, step 10), substituting 2 µl of 0.5 µg/µl biotinylated lysine tRNA (1 µg; 24 pmol) for [^{35}S]methionine and complete amino acid mix for amino acids minus methionine. Adjust final volume appropriately.

   Complete amino acid mix is used rather than amino acids minus lysine because lysine represents a significant percentage of amino acids; thus, since the reticulocyte contains only ~7 to 10 µM lysine, without lysine supplementation the amount of protein produced will be reduced. Alternatively, it is possible to increase the incorporation of biotinylated lysine by using amino acid mixtures minus lysine, but the total yield of protein may be less.

Biotin labeling of proteins containing few lysines can be increased by doubling the amount of biotinylated lysine-tRNA added, increasing the specific activity of the biotinylated form.

3. Incubate reaction mixture 1 hr at 30°C.

   The translation reaction mix can be stored for several months at −20° to −85°C prior to analysis. Optionally, detection can be enhanced by capturing the biotinylated protein from a larger volume of translation reaction (see Support Protocols 3 and 4) prior to performing the analysis outlined in steps 4 and 5.

   Reticulocyte lysate contains one minor streptavidin-binding protein that migrates at 100 kDa; some batches also contain an additional streptavidin-binding protein of ~45 kDa. Comparison with the no-template control will distinguish the endogenous streptavidin-binding protein(s) from the expressed product.

4. Analyze reaction mixture by SDS-PAGE (*UNIT 6.1*) and transfer to PVDF membrane (*UNIT 6.2*).
5. Detect with streptavidin-AP or streptavidin-HRP using either chemiluminescent or colorimetric substrates (*UNIT 6.2*).

SUPPORT PROTOCOL 3

CAPTURE OF BIOTINYLATED PROTEINS WITH STREPTAVIDIN-AGAROSE

After in vitro translation, the biotinylated proteins may be captured from the translation reaction using streptavidin immobilized on agarose. This technique can be used to increase the sensitivity of detection methods, and provides a quick and easy way to isolate translation products for a number of downstream applications.

Materials

Translation reaction mixture (see Alternate Protocol 2, step 3)
Softlink Soft Release Avidin Resin (Promega), washed with 5 vol TBS at 40°C
TBS (*APPENDIX 2A*)
2× SDS-PAGE sample buffer (see recipe)

1. Add 10 µl of translation reaction mixture to 20 µl TBS. Incubate 5 to 10 min at 30°C.
2. Add 40 µl of Softlink Soft Release Avidin Resin, prewashed with TBS, to the reaction mix and incubate for 1 hr at 4°C with periodic stirring.
3. Briefly microcentrifuge, or let stand to allow resin to settle.
4. Wash the pellet three to five times with TBS.
5. Elute the bound proteins from the resin by adding 20 to 50 µl of 2× SDS-PAGE sample buffer and heating 5 min at 95°C to release biotinylated protein from beads.

   The protein is now ready for analysis (see Alternate Protocol 2, steps 4 and 5).

SUPPORT PROTOCOL 4

CAPTURE OF BIOTINYLATED PROTEINS WITH MAGNETIC BEADS

Another, rapid method of isolating biotinylated proteins from the other reticulocyte proteins in the translation mix is the use of streptavidin-linked magnetic beads. These beads consist of small metallic particles coated with streptavidin. The biotinylated protein binds the streptavidin, and the beads are removed and recovered by exposing them to a magnetic field. After elution, the protein of interest is relatively pure and may be analyzed by immunodetection, SDS-PAGE, or other methods.

Materials

Translation reaction mixture (see Alternate Protocol 2, step 3)
2× biotin/streptavidin binding buffer (2× BSBB; see recipe)
Streptavidin-linked magnetic beads (e.g., Dynabeads M-280 Streptavidin, Dynal; or MagneSphere Paramagnetic Particles, Promega)

10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
2× SDS-PAGE sample buffer (see recipe)
Magnetic tube holder

1. Add an equal volume of 2× BSBB to translation reaction mixture in a microcentrifuge tube. Bring the total volume up to 250 µl with 1× BSBB. Add 10 to 50 µl of streptavidin-linked magnetic beads equilibrated in BSBB.
2. Incubate with rotation 30 min at 4°C.
3. Place microcentrifuge tube in magnetic holder for 2 min to capture the magnetic beads.
4. Carefully aspirate supernatant away from magnetic beads bound to side of tube.
5. Wash magnetic beads twice with 500 µl of 1× BSBB and once with 10 mM Tris·Cl, pH 8.0, using magnetic holder to separate magnetic beads from wash buffer. Remove supernatants. Resuspend magnetic beads between washes by gentle vortexing.
6. After removal of final supernatant, add 50 µl of 2× SDS-PAGE sample buffer.
7. Incubate 5 min at 95°C to release biotinylated proteins from beads.

The protein is now ready for analysis (see Alternate Protocol 2, steps 4 and 5).

Other methods of capturing biotinylated proteins using streptavidin-coated magnetic beads are also possible; consult the section on Biomagnetic Techniques in Molecular Biology in the Dynal Technical Handbook, 2nd ed. (Dynal, 1995)

REAGENTS AND SOLUTIONS

Use deionized, Milli-Q-purified water in all recipes and solutions except for transcription buffers and reagents for transcription reactions, which should be made with diethylpyrocarbonate-treated Milli-Q-purified water (DEPCW). Storage time for solutions kept at 4°C apply only if sterility is maintained. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Amino acid mixes

Amino acid:	*Quantity:*
Alanine	13.35 mg
Arginine	31.5 mg
Asparagine	22.5 mg
Aspartic acid	20 mg
Cysteine	26.25 mg
Glutamine	22 mg
Glutamic acid	22 mg
Glycine	11.25 mg
Histidine	31.35 mg
Isoleucine	19.5 mg
Leucine	39 mg
Lysine	27.3 mg
Methionine	15 mg
Phenylalanine	24.75 mg
Proline	17.25 mg
Serine	15.75 mg
Threonine	17.85 mg
Tryptophan	30.6 mg
Tyrosine	27 mg
Valine	33 mg

Add water to 80 ml. Adjust pH to 7.2 with 1 N KOH, then add water to 100 ml. Filter sterilize and store in 1-ml aliquots up to 2 years at –20°C.

continued

This yields 100 ml of a stock solution containing 3 mM leucine and valine, 1 mM methionine, and 1.5 mM each of the other 18 amino acids.

For amino acids minus valine, leucine, lysine, or methionine, prepare as described except omit the appropriate amino acid.

***Biotin/streptavidin binding buffer (BSBB), 2×** (10 ml)*

Components:	*Concentration of 2× stock:*
100 µl 1 M Tris·Cl, pH 8.0	10 mM
5 ml 4 M NaCl	2 M
20 µl 500 mM EDTA	1 mM
4.88 ml DEPCW	

Prepare stock solutions with DEPCW and autoclave. Store 2× BSBB up to 6 months at 4°C.

Calf liver tRNA, 5 mg/ml

250 mg calf liver tRNA
DEPCW to 50 ml
Filter sterilize and store in 1-ml aliquots up to 2 years at −20°C

***Cell lysis buffer, 10×** (10 ml)*

Components:	*Final concentration of 10× stock:*
1 ml 1 M Tris·Cl, pH 7.4	0.1 M
1 ml 1 M $MgCl_2$	0.1 M
5 ml 2 M KCl	1 M
3 ml DEPCW	

Prepare stock solutions of reagents for this recipe with DEPCW and autoclave. Divide 10× buffer into 1-ml aliquots and store up to 2 years at −20°C.

Prepare complete lysis buffer from 10× cell lysis buffer stock immediately before use in the preparation of polysome-bound mRNA (see Alternate Protocol 1).

Creatine phosphokinase, 200 U/ml

500 U creatine phosphokinase
1.25 ml 100 mM KCl
20 mM HEPES-KOH (see recipe), pH 7.2
1.25 ml glycerol
Store in 500-µl aliquots up to 1 year at −20°C

Glycerol prevents the enzyme from freezing at −20°C.

DTT, 250 mM

Add 154 mg DTT to 4 ml ice-cold deaerated water. Filter sterilize and snap-freeze in 25- to 250-µl aliquots. Store up to 1 year at −20°C.

Once an aliquot is thawed for use, discard residual solution.

EGTA, 200 mM

7.6 g EGTA
H_2O to 100 ml
Adjust pH to 7.0 with 1 N NaOH
Autoclave
Store up to 6 months at 4°C

***Glass powder** (for production of wheat germ extract)*

Suspend glass powder (Sigma) in at least 20 vol water. Add 1 ml DEPC per liter. Stir at room temperature overnight in a loosely covered container. Autoclave for 45 min. Allow glass powder to settle, remove supernatant, and dry in oven at 185°C.

Hemin hydrochloride, 1 mM

Mix:
65 mg hemin hydrochloride (Sigma)
2 ml 100 mM KOH
Sufficient 100 mM Tris·Cl, pH 7.8, to adjust pH to 7.8
Then add:
20 ml sterile H_2O
80 ml ethylene glycol
Store in light-proof bottle up to 2 years at −20°C

HEPES-KOH, pH 7.2, 1 M

238.3 g HEPES, free acid
H_2O to 800 ml
Adjust pH to 7.2 with 10 N KOH
Add water to 1 liter
Filter sterilize
Store in 1-ml aliquots up to 2 years at −20°C

HEPES/KCl buffer *(10 ml)*

Components:	*Final concentration:*
100 µl 1 M HEPES-KOH, pH 7.2	10 mM
1 ml 1 M KCl	100 mM
20 µl 1 M $MgCl_2$	2 mM
2 µl 500 mM EDTA	0.1 mM
40 µl 250 mM DTT (see recipe)	1 mM
8.84 ml DEPCW	

Prepare all stock solutions of reagents for this recipe with DEPCW and filter sterilize. Prepare solution as described above, then store 1-ml aliquots up to 1 year at −20°C. Add 7 µl/ml RNasin RNase inhibitor (Promega) just prior to use.

Used for resuspension of polysomes.

KCl/10 mM $MgCl_2$ (K/Mg), 2 M

14.9 g KCl
0. 214 g $MgCl_2$
H_2O to 100 ml
Autoclave
Store in 1-ml aliquots up to 1 year at −20°C

Modified transcription buffer (MTB), 5× *(10 ml)*

Components:	*Concentration of 5× stock:*
2 ml 1 M Tris·Cl, pH 8.1	200 mM
300 µl 1 M $MgCl_2$	30 mM
500 µl 1 M NaCl	50 mM
200 µl 250 mM spermidine	5 mM
250 µl 10 mg/ml BSA	250 µg/ml
200 µl 2.5% Triton X-100	0.05%
6.55 ml DEPCW	

Prepare all stock solutions of reagents for this recipe with DEPCW and autoclave or filter sterilize as appropriate. Store 1-ml aliquots of 5× MTB up to 1 year at −20°C.

See Milligan et al. (1987) for discussion of this solution.

4NTP mixture, 12.5 mM

50 mM single-nucleotide stocks (ATP, CTP, GTP, and UTP): Transfer 500 mg of each to a separate sterile 50-ml tube. Add DEPCW to appropriate volume. Check pH of each stock by pipetting 1 µl onto pH paper, and adjust by adding 1 N NaOH drop by drop until pH reaches 7.5. Filter sterilize and store in 1-ml aliquots up to 1 year at −20°C.

10 mM single-nucleotide stocks: Dilute 1/5 in DEPCW. Store in 500-µl aliquots up to 1 year at −20°C.

12.5 mM 4NTP mix: Mix 2.5 ml each of 50 mM ATP, CTP, GTP, and UTP stocks (10 ml total). Store in 500-µl aliquots up to 1 year at −20°C.

Nuclease S7, 15,000 U/ml

Add 1 ml water to lyophilized *Staphylococcus aureus* nuclease S7 enzyme to obtain a concentration of 15,000 U/ml. Make fresh for each use, and discard residual solution.

Used at 1/100 dilution.

Phenylhydrazine, 2.5% (w/v)

Dissolve 5 g phenylhydrazine (Sigma) in 200 ml deaerated sterile 0.85% NaCl and adjust to pH 7.0 with 1 N NaOH (the solution should be a pale straw color, not brown). Store single-use aliquots in air-tight, light-proof containers up to 3 months at −20°C.

Once an aliquot is thawed for use, discard residual solution.

Phosphocreatine, 1 M

Dissolve 0.255 g phosphocreatine in ice-cold water to 1 ml. Snap-freeze in 25- to 250-µl aliquots and store up to 2 weeks at −20°C.

Once an aliquot is thawed for use, discard residual solution.

Reticulocyte wash buffer I

100 ml 10× reticulocyte wash buffer II (see recipe)
7.5 ml 1 M $MgCl_2$
10 ml 100 mM glucose
H_2O to 1 liter
Store up to 1 year at 4°C

Reticulocyte wash buffer II, 10×

38.5 g NaCl
1.875 g KCl
H_2O to 500 ml
Autoclave and store up to 1 year at 4°C

Before use, add 100 ml of 10× stock and 5 ml of 1 M HEPES-KOH, pH 7.2, to 900 ml sterile H_2O.

SDS-PAGE sample buffer, 2× (50 ml)

Components:	*Concentration of 2× stock:*
12.5 ml 1 M Tris·Cl, pH 6.8	250 mM
3 g SDS	6%
2.3 g DTT	300 mM
5 ml 2-mercaptoethanol	1.4 M
500 µl 2% bromphenol blue	0.02%
20 ml glycerol	20%
H_2O to 50 ml	

Filter and store in 1-ml aliquots up to 1 year at −20°C. Once an aliquot has been thawed for use, discard residual solution.

Sucrose buffer *(for cushion; 10 ml)*

Components:	*Concentration:*
3.42 g sucrose	1 M
1 ml 1 M KCl	100 mM
100 µl 1 M $MgCl_2$	10 mM
2 µl 0.5 M EDTA	0.1 mM
100 µl 1 M Tris·Cl, pH 7.4	10 mM
DEPCW to 10 ml	
Filter sterilize	
Use fresh	

Transcription buffer (TB), 5× *(10 ml)*

Components:	*Concentration of 5× stock:*
2 ml 1 M Tris·Cl, pH 7.5	200 mM
300 µl 1 M $MgCl_2$	30 mM
500 µl 1 M NaCl	50 mM
250 µl 10 mg/ml BSA	250 µg/ml
400 µl 250 mM spermidine	10 mM
6.55 ml DEPCW	

Prepare all stock solutions of reagents for this recipe with DEPCW and autoclave or filter sterilize as appropriate. Store 1-ml aliquots up to 1 year at −20°C.

Transcription/translation (TX/TL) buffer, 25× *(10 ml)*

Components:	*Concentration of 25× stock:*
1.4 ml 1 M HEPES-KOH (see recipe), pH 7.2	140 mM
400 µl 1 M $MgCl_2$	40 mM
200 µl 250 mM spermidine	5 mM
8 ml 12.5 mM 4NTP mix (see recipe)	10 mM each

Prepare all stock solutions of reagents for this recipe with DEPCW and autoclave or filter sterilize as appropriate. Store 1-ml aliquots at −20°C.

Trichloroacetic acid (TCA), 5% and 10%

Weigh reagent bottle containing TCA and record weight full. Wearing rubber gloves, goggles, and plastic apron, add water and dissolve by shaking closed container. Pour solution into measuring cylinder, record weight of bottle empty, calculate amount of TCA used, and adjust volume to obtain a 10% solution. Dilute part of solution to 5% with an equal volume of water. Store both solutions in brown plastic bottles.

This method prevents burns from TCA crystals.

Wheat germ extraction buffer *(50 ml)*

Components:	*Final concentration:*
5 ml 1 M potassium acetate	0.1 M
100 µl 1 M magnesium acetate	2 mM
1 ml 1 M HEPES-KOH, pH 7.2 (see recipe)	20 mM
8 µl 250 mM spermidine	40 µM
35.9 ml DEPCW	

Prepare all stock solutions of reagents for this recipe with DEPCW and autoclave or filter sterilize as appropriate. Make buffer fresh, and immediately prior to use, add 200 µl of 250 mM DTT stock (1 mM final).

COMMENTARY

Background Information

Choice of system

The two most widely used eukaryotic in vitro translation systems are the mRNA-dependent reticulocyte lysate (Pelham and Jackson, 1976), an adaptation of an earlier mRNA-independent reticulocyte system (Adamson et al.,1968; Zucker and Schulman, 1968), and the wheat germ system developed by Roberts and Paterson (1973) with later refinements (Morch et al., 1986; Van Herwynen, 1990).

Perhaps the first question a researcher will have is "Which system should I use?" Both systems are very active and express a large range of polypeptide sizes. The most obvious advantages of the wheat germ system are its ease of preparation and its low cost. In addition, no animal use is required. With the inclusion of spermidine and RNase inhibitor in the reaction and supplementation with calf liver tRNA, an earlier drawback of the wheat germ system, its lower ability to translate high-molecular-weight proteins, has been overcome (Morch et al., 1986; Van Herwynen, 1990; Van Herwynen and Beckler, 1995). Furthermore, the wheat germ extract readily translates mRNA preparations containing contaminating double-stranded RNA or oxidized thiols, which are inhibitory in the reticulocyte system. It is also the system of choice for expressing eukaryotic transcription factors, since it does not contain endogenous counterparts (Mercurio et al., 1993).

However, the wheat germ system exhibits rather narrow ionic requirements that are very sensitive to the nature of the mRNA to be translated and can require optimization for each template used. Overall, the reticulocyte system remains the most highly used and the most widely available commercially.

The choice of system should be determined by the nature of the mRNA to be translated and the chosen assay or required function for the expressed protein. Items to consider include whether the protein will fold better in one system versus the other, whether there are endogenous enzymes available for post-translational modifications required for activity of the translation product, whether there are endogenous activities or compounds that interfere with a functional assay, and whether there are endogenous streptavidin-binding proteins that could interfere with detection of biotinylated products. Based on the above considerations, use of the reticulocyte translation system may be advantageous for studies of post-translational modification, including the use of microsomal membranes (*UNITS 11.3 & 11.4*). The reticulocyte system is also better for high-level expression using constructs containing the encephalomyocarditis 5′ untranslated leader region (EMCV 5′ UTR) and for nonisotopic detection using biotinylated lysine-tRNA. Conversely, the wheat germ system is preferable for studies of eukaryotic transcription factors, real-time assays monitoring low levels of luciferase, and cross-linking and fluorescent detection assays involving incorporation of non-natural amino acids. However, there are exceptions to all these generalizations.

To couple or not

The development of coupled eukaryotic transcription/translation systems had allowed direct expression from DNA containing cloned genes positioned behind T7, T3, or SP6 promoters in rabbit reticulocyte lysate or wheat germ extracts (Craig et al, 1992; Thompson et al., 1992). The availability of the coupled systems necessitates another choice—the production of mRNA prior to the translation reaction versus the use of DNA directly using the coupled system. In most cases the coupled system is more convenient, faster, and produces greater protein yields. Unless there is a problem with termination of the mRNA sequence, circular DNA can be used in the coupled system, obviating the need for linearization and subsequent clean-up of DNA. Interestingly, even though the coupled system does not use capped mRNA, several groups have reported the coupled system still produces greater protein yields than optimized expression from capped mRNA (Jagus, 1993). The eukaryotic coupled systems are much more forgiving of DNA purity than their sister prokaryotic (*E. coli*) coupled systems. Most common commercially available DNA purification systems will provide adequate DNA purity. In many cases where PCR DNA is used, the PCR reaction mix can be added directly to the coupled transcription/translation system without purification, although care should be taken not to add too much DNA (Renshaw-Gregg and Guiltinan, 1996).

On a cautionary note, when coexpressing more than one gene in a coupled transcription/translation system, care should be taken that no inhibitory antisense mRNA is generated from the use of dual opposable promoter vectors (i.e., T3/T7 or SP6/T7). If vectors using dual opposable promoters are used in such an

instance, linearization of the DNA 3′ to the gene of interest will prevent the problem.

Critical Parameters

One of the most common questions of researchers expressing gene products in vitro is "How much protein will the system generate?" Unfortunately, there is no simple answer. A multitude of factors will affect the final protein yield, some of them outside the researcher's control. Almost all researchers will be most interested in the translation of transcripts synthesized in vitro from cloned cDNAs using the bacteriophage promoters such as those for T3, T7, and SP6 RNA polymerases (Melton et al., 1984; Milligan et al., 1987). There are now a number of improved commercial systems for generating high levels of mRNA from linearized DNA (e.g., Ambion, EpiCenter, Novagen, and Promega).

The highest yields of transcripts are obtained for uncapped mRNA. Production of uncapped transcripts is also cheaper, since the cap analog needed to produce capped trancripts is expensive. This makes it advantageous to use a vector that places a 5′ UTR, allowing cap-independent translation, upstream of the initiation codon. Such vectors include pCITE (Novagen) and pTM1 (Moss et al., 1990), which use the internal ribosome entry site (IRES) of EMCV to promote cap-independent translation. The addition of the EMCV 5′ viral IRES has been shown to increase the expression of luciferase 16-fold over a control luciferase construct without the sequence (Beckler, 1992). Interestingly, the EMCV IRES sequence does not enhance translation in the wheat germ translation system and is actually detrimental. Alternatively, high expression levels can be achieved with uncapped mRNA by optimizing salt concentrations.

To generate well-translated in vitro transcripts, care must be taken not only in the choice of vector but also in the design of the construct. For instance, the sequence surrounding the AUG start should be optimized to match the so-called "Kozak" consensus sequence of A/GCCAUGG to provide optimal translation initiation (Kozak, 1989). Similarly, the 5′ UTR of the mRNA should not contain any significant secondary structure that may retard migration of the ribosome from the 5′ cap to the initiation codon (Kozak, 1988). In general, it is safer not to include any 5′ UTR sequences from the cDNA of interest since they may be inhibitory to translation. It is preferable to choose a vector that provides a 5′ UTR that will ensure good translation (such as pCITE and pTM1) and to clone in at an *Nco*I or *Nde*I restriction site that becomes the initiation codon.

However, when transcripts requiring cap-dependent translation are used, decreasing the distance of the initiation codon from the 5′ cap can reduce translational efficiency (Kozak, 1991a). Conversely, inclusion of long 5′ sequence that cannot form secondary structures has been shown to increase translational efficiency through the buildup of small ribosomal subunits in the 5′ UTR (Kozak, 1991b). Addition of an artificial 30-nucleotide poly(A)$^+$ sequence to the 3′ end of an mRNA has also been shown to boost expression 7-fold (Beckler, 1992). Note that in mRNA templates containing an added 3′ poly(A)$^+$ tail, increasing mRNA concentration will decrease translation due to titration of poly(A)$^+$ binding protein, which is involved in translation initiation.

Enhancement additives

For the rabbit reticulocyte system, a variety of factors lead to the activation of protein kinases that phosphorylate the α-subunit of initiation factor eIF2. This leads to a cessation of translation initiation. Hemin is always added to reticulocyte systems to prevent activation of the heme-sensitive eIF2α kinase. The addition of 5′-cAMP (1 to 10 mM) may also stimulate translation by preventing eIF2α kinase activation (Gross et al., 1988). Glucose-6-phosphate or 2-aminopurine (0.5 mM) may also stimulate translation by a variety of mechanisms (Jagus and Safer, 1981; Jackson et al., 1983; Michelson et al., 1984; Gross et al., 1988). The addition of eIF2α homologues, such as the K3L gene product from vaccinia virus or the vaccinia virus double-stranded RNA binding protein (the E3L gene product), to the reticulocyte system can prolong the linear rate of translation, resulting in increased protein yields (reviewed by Jagus and Gray, 1994; Clemens and Elia, 1997). If the codon usage of the open reading frame contains rare codons, or is from an organism using a different genetic code (such as trypanosomes), it may be desirable to add exogenous tRNA purified from the source organism.

Optimization of ionic conditions

Optimization of Mg^{2+} and K^+ can enhance the translation of a particular transcript (Beckler, 1992; Beckler et al., 1995). Mg^{2+} is the most critical component of the translation reaction to optimize because the Mg^{2+} optimum is very narrow: small changes in Mg^{2+} concentration can dramatically affect the efficiency and fidel-

ity of translation (Beckler, 1992). In addition, each RNA transcript exhibits a unique Mg^{2+} optimum. Capped mRNAs generally require a higher K^+ concentration than uncapped mRNAs (Kemper and Stolarsky, 1977). mRNAs containing the 5′ UTR of EMCV also require higher K^+ concentrations (Jackson, 1991). The form and concentration of K^+ salts is also important for initiation at the correct site; more efficient and accurate translation is achieved using potassium chloride rather than potassium acetate (Jackson, 1991). Uncapped mRNAs produced in in vitro transcription reactions are also translated with greater fidelity using the chloride rather than the acetate (Jackson, 1991).

Anticipated Results

As stated above, there is no simple expectation of protein yield in the cell-free translation systems. The reticulocyte lysate should contain between 25 and 30 A_{260} units of ribosomes, or 250 to 300 pmol per ml. Using the MDL with added mRNA in a reaction in which the MDL constitutes 70% of the reaction volume (i.e., 175 to 200 pmol ribosomes/ml), under optimal conditions and saturating levels of globin mRNA, the yield will be up to 1 mol globin/mol ribosome/min at 37°C (Jagus, 1987). This works out to be 262.5 to 300 pmol/50-µl reaction/30-min incubation, or 3.5 to 4.25 µg globin. Globin mRNA is translated very efficiently. The expression level of other mRNAs will vary, depending on the integrity and purity of the mRNA and on all the characteristics of mRNA structure known to affect translatability (outlined above; see Critical Parameters).

In the coupled system, the MDL is usually used at 50% of the final reaction mix, but the yield per ribosome has the same or higher potential. However, the purity of the DNA, type of vector, and design of the construct will all have an impact. Similarly, use of enhancement additives can increase the yield by allowing translation to continue for longer.

Estimating expected yields when using biotinylated amino acids is more difficult, since in this case precharged biotinylated lysine-tRNA competes with endogenous lysine-tRNA, which is continuously recharged, so that specific activity of the biotinylated lysine-tRNA decreases throughout the incubation. With biotinylated lysine-tRNA it is difficult to determine the percent incorporation of biotinylated lysines into a translated protein. However, using 15 pmol biotinylated NBD-[^{14}C]lysine-tRNA per 25-µl reaction, supplemented with amino acid mix minus lysine, ~50% of the biotinylated NBD-[^{14}C]lysine was incorporated into protein (Crowley et al., 1993). This is much less yield than is seen using conventional radioisotope labeling, but in this circumstance, lysine was limiting and use of a complete amino acid mix increases both protein yield and detection (Beckler and Hurst, 1993).

Time Considerations

The time taken for in vitro translation reactions will vary depending on which system is used, the source of mRNA, the detection method, and whether a coupled system is used. Assuming that the source of mRNA consists of trancripts generated in vitro from a DNA template, then ~4 hr will be needed for synthesis and purification of the mRNA, 1 to 1.5 hr for the translation reaction, and ~7 to 12 hr for analysis by SDS-polyacrylamide minigels and fluorography, assuming a 4- to 8-hr exposure of the autoradiogram. This gives a total of ~12 to 16 hr. In comparison, use of the coupled system requires only 8 to 12 hr (Thompson et al., 1992).

If standard fluorographic detection is replaced by analysis using phosphoimaging, the time can be reduced by 2 to 6 hr. If fluorographic detection is replaced by the use of biotinylated lysine-tRNA immunodetection, the time can be cut down by 3 to 8 hr. If speed of production of translation product is a critical factor, the system of choice would be a coupled reticulocyte system purchased as a kit. If detection of the protein product is the only experimental need, the use of biotinylated lysine-tRNA with detection using avidin or streptavidin conjugated to alkaline phosphatase coupled with colorimetric detection is the fastest choice (Beckler and Hurst, 1993).

In Vitro Analysis of Endoplasmic-Reticulum-to-Golgi Transport in Mammalian Cells

This unit describes in vitro reconstitution of vesicular trafficking from the endoplasmic reticulum (ER) to the Golgi apparatus in mammalian cells. The assays outlined here allow for the examination of factors that are required for and/or regulate the budding of vesicles from the ER and the subsequent fusion of these vesicles with the Golgi. The assays are based on the ability to follow the movement of a temperature-sensitive mutant of vesicular stomatitis virus–encoded glycoprotein (VSV-G ts045) as it moves out of the ER and through the Golgi. VSV-G ts045 is retained in the ER at the restrictive temperature (39.5°C), which allows for synchronized movement of this protein out of the ER upon switching to the permissive temperature (32°C). Transport is measured by following the maturation of two asparagine-linked oligosaccharide chains on VSV-G as the protein moves from the ER to the *cis*-Golgi and subsequently to the medial/*trans*-Golgi.

The first transport assay (see Basic Protocol 1) measures the movement of VSV-G in semi-intact cells (SICs). SICs are a population of cells that have lost their cytosolic contents due to mechanical perforation of the plasma membrane, but that retain their subcellular organelles. SICs prepared from normal rat kidney cells infected with VSV ts045 faithfully reconstitute vesicular transport upon addition of rat liver cytosol and ATP. The organelles in SICs are accessible to exogenous factors ranging in size from small molecules to large proteins, allowing the effects of different factors on the extent and rate of transport from the ER to the Golgi to be determined. Alternatively, the protocol can be modified to isolate and measure ER-to-*cis*-Golgi transport alone, using clone 15B CHO cells infected with the temperature-sensitive virus VSV ts045 (see Alternate Protocol).

The second transport assay uses microsomes isolated from VSV-infected mammalian cells (see Basic Protocol 2), and is similar to the SIC assay in that it involves a single incubation that reconstitutes ER-to-Golgi transport. A more detailed two-stage protocol allows for ER-derived vesicles to be formed in vitro (see Basic Protocol 3) and used in a separate second-stage reaction that measures fusion with purified Golgi membranes (see Basic Protocol 4). This microsome-based two-stage assay allows vesicle formation and the budding reaction to be studied as separate biochemical events from the targeting and fusion reactions. Furthermore the ER-derived vesicles can be purified and examined as separate entities (see Basic Protocol 3).

The unit also presents Support Protocols for preparing the necessary reagents for these assays. Preparation of microsomal membranes and Golgi membranes is described (see Support Protocols 1 and 4, respectively).VSV ts045 is propagated to generate a high-titer stock (see Support Protocol 2), which is then used as the source of virus for preparation of both SICs and microsomes. Cytosol from rat liver (see Support Protocol 3) is used in each transport assay, and is gel-filtered for use in fusion reactions of ER-derived vesicles with Golgi membranes.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

NOTE: All culture incubations should be performed in a humidified 5% CO_2 incubation unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

NOTE: VSV stocks and samples should be treated with bleach prior to disposal.

BASIC PROTOCOL 1

RECONSTITUTION OF ER-TO-GOLGI TRANSPORT IN SEMI-INTACT CELLS

This first protocol describes the infection of normal rat kidney (NRK) cells with VSV ts045, the labeling of infected cells with ^{35}S, and the mechanical perforation of these cells by hypotonic swelling to generate labeled SICs. The labeled SICs are then used in a reaction that reconstitutes transport of VSV-G ts045 from the ER to and through the Golgi in a cytosol-, ATP-, and temperature-dependent manner. The progress of VSV-G is measured by following the acquisition of endoglycosidase H (endo H) resistance by the N-linked oligosaccharide side chains of VSV-G, which increases with time as the protein moves through the Golgi. The endo H–sensitive and endo H–resistant forms of VSV-G are separated by SDS-PAGE and quantified, and transport is expressed as the percentage of VSV-G in the endo H–resistant form.

Materials

Normal rat kidney (NRK) cells
Alpha minimal essential medium (α-MEM), serum-free and with 5% (v/v) FBS (*APPENDIX 2A*)
VSV ts045 stock (~2×10^9 pfu/ml; see Support Protocol 2)
1 mg/ml actinomycin D in ethanol
Methionine-deficient labeling medium (see recipe)
[^{35}S]Methionine (~11 mCi/ml, 1175 Ci/mmol; Trans^{35}S-label, ICN Biomedicals)
20 mM unlabeled methionine (tissue culture grade; Sigma)
Perforation buffer (see recipe), ice cold
Swelling buffer (see recipe), ice cold
1% (w/v) trypan blue
Rat liver cytosol (see Support Protocol 3)
1 M HEPES acid, pH 7.4
0.1 M magnesium acetate
1 M potassium acetate
10× Ca^{2+} buffer (see recipe)
20× ATP-regenerating system (see recipe)
40 mM UDP-*N*-acetylglucosamine
Endo H buffer (see recipe)
75 mU/ml endoglycosidase H (endo H; Boehringer Mannheim) in 0.1 M sodium acetate, pH 5.6
4× SDS sample buffer (*APPENDIX 2A*)
Fluorographic enhancement solution: 125 mM salicylic acid (sodium salt), pH 7.0, in 30% (v/v) methanol

Culture incubator at 32°C
Water baths at 32°, 37°, and 39.5°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and for autoradiography and densitometry (*UNIT 6.3*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

Infect and label NRK cells

1. Grow NRK cells to confluency on 100-mm tissue culture dishes.
2. Prepare an infection cocktail containing (per dish) 0.9 ml serum-free α-MEM, 0.1 ml of VSV ts045 stock (final ~2×10^8 pfu/ml), and 5 µl of 1 mg/ml actinomycin D (final 5 µg/ml).

Table 11.3.1 Reaction Mix for ER-to-Golgi Transport Assay in Semi-Intact Cells

Solution	Volume in mix (µl)	Final concentration
SICs[a]	5	
Rat liver cytosol	5	3 mg/ml
1 M HEPES acid, pH 7.4	1	25 mM
0.1 M magnesium acetate	1	2.5 mM
1 M potassium acetate	2	50 mM
10× Ca^{2+} buffer	4	1×
20× ATP-regenerating system	2	1×
40 mM UDP-*N*-acetylglucosamine	0.5	0.5 mM
Water	To 40 µl (final)	

[a]Abbreviation: SICs, semi-intact cells.

3. Add 1 ml infection cocktail per dish and rock continuously (or by hand at 5-min intervals) for 45 min in a 32°C culture incubator, ensuring even distribution of the infection cocktail.
4. Add 5 ml α-MEM with 5% FBS to each dish and incubate at 32°C for 3 hr and 40 min.
5. Move the cells to a 39.5°C water bath and wash three times with 3 ml methionine-deficient labeling medium. Incubate the cells in 3 ml methionine-deficient labeling medium 15 min at 39.5°C.
6. Remove labeling medium, replace with 1.5 ml methionine-deficient labeling medium supplemented with 100 µCi [^{35}S]methionine, and incubate 10 min at 39.5°C with occasional rocking.
7. Add 30 µl of 20 mM unlabeled methionine and incubate 2 min at 39.5°C.

   It is essential that the temperature does not drop below 39.5°C at any point during this procedure to ensure that all of the ^{35}S-labeled VSV-G remains in the ER.

Perforate labeled cells

8. Transfer cells to ice and wash three times with 5 ml ice-cold perforation buffer.
9. Cover cells with 5 ml ice-cold swelling buffer and allow cells to sit on ice for 10 min.
10. Aspirate swelling buffer, add 3 ml ice-cold perforation buffer, and immediately scrape the cells with a rubber policeman.
11. Transfer cells to a 15-ml polypropylene tube and pellet by centrifugation at 800 × *g*, 3 min at 4°C.
12. Wash the pellet in 3 ml ice-cold perforation buffer and recentrifuge.
13. Resuspend in 200 to 300 µl ice-cold perforation buffer.
14. Determine the extent of perforation by mixing 10 µl SICs with 1 µl of 1% trypan blue on a cover slip and examining by light microscopy.

    The trypan blue–stained nuclei identify the perforated cells. There should be 90% to 95% perforated cells.

    SICs should be used immediately (i.e., stored no more than 1 hr on ice).

Reconstitute ER-to-Golgi transport

15. Prepare each reaction mix in a microcentrifuge tube as shown in Table 11.3.1. Perform reactions in duplicate along with two negative controls: complete reaction mix incubated on ice and reaction mix without cytosol, incubated at 32°C.

16. Vortex gently 3 sec and incubate 90 min in a 32°C water bath.
17. Pellet SICs by microcentrifuging 20 sec at 16,000 × *g*, 4°C.
18. Resuspend pellet in 20 µl endo H buffer.
19. Boil 5 min, microcentrifuge briefly, and cool. Add 40 µl of 75 mU/ml endo H (3 mU) in 0.1 M sodium acetate, pH 5.6.

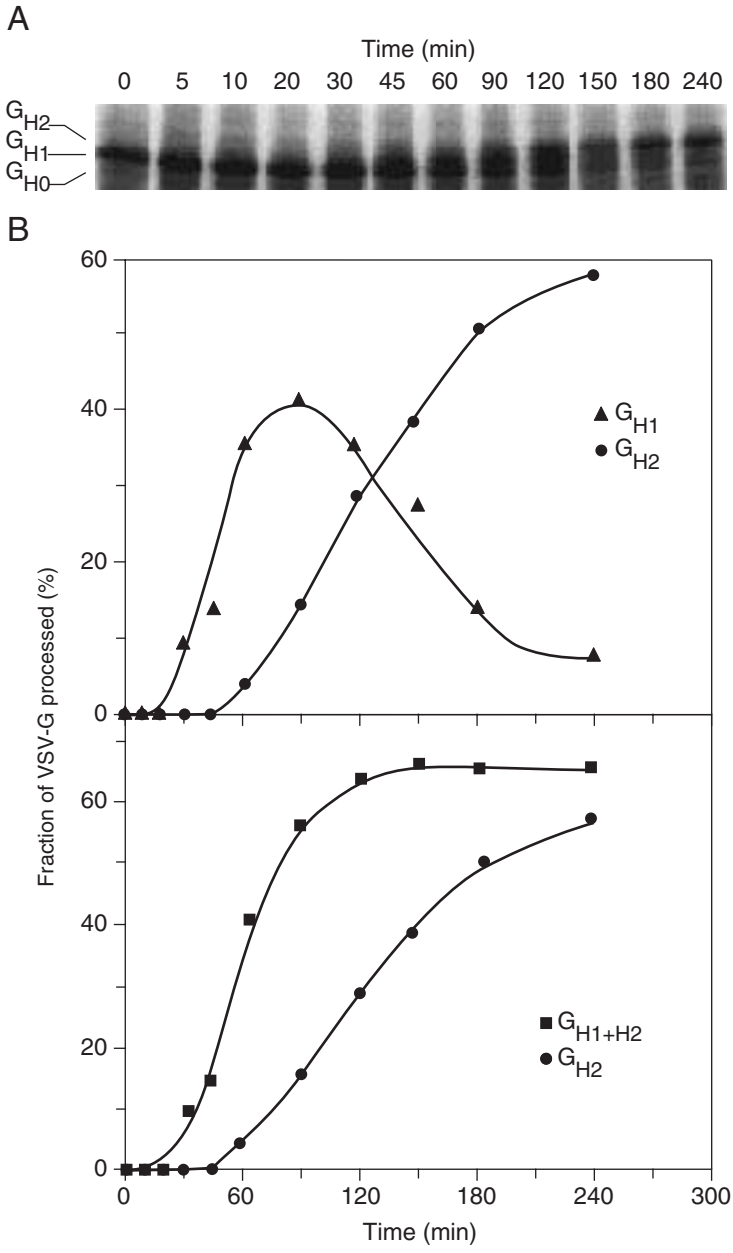

Figure 11.3.1 (**A**) Time course of ^{35}S-labeled VSV-G transport in semi-intact NRK cells, analyzed by endo H digestion. At the early time points, only G_{H0} is detected. G_{H1} appears as a transient intermediate and is replaced by G_{H2} as transport proceeds. These bands reflect discrete intermediates in VSV-G processing (see Background Information and Fig. 11.3.3). (**B**) Kinetics of VSV-G transport in semi-intact NRK cells as measured by the appearance of the G_{H1} and G_{H2} forms of VSV-G. Reprinted from Schwaninger et al. (1991) with permission from the American Society for Biochemistry and Molecular Biology.

20. Incubate overnight in a 37°C water bath.

21. Stop reaction by adding 20 µl of 4× SDS sample buffer, and separate the endo H–sensitive and endo H–resistant forms of VSV-G on a large 6.75% (w/v) polyacrylamide gel (*UNIT 6.1*).

22. Treat the polyacrylamide gel with fluorographic enhancement solution 20 min at room temperature. Dry the gel and autoradiograph (*UNIT 6.3*) at −80°C.

    Alternatively, expose the gel to a Phosphoimager screen.

23. Quantitate the intensities of the different forms of VSV-G by densitometry (Fig. 11.3.1; see *UNIT 6.3* for densitometry).

RECONSTITUTION OF ER-TO-*cis*-GOLGI TRANSPORT IN SEMI-INTACT CELLS

ALTERNATE PROTOCOL

It is sometimes desirable to separate ER-to-*cis*-Golgi transport from ER-to-*cis*-Golgi/medial-Golgi transport. This can be accomplished in an assay using the CHO cell line Clone 15B. These cells cannot process VSV-G oligosaccharide side chains beyond the $Man_5GlcNAc_2$ (Man_5; endo D_s in Fig. 11.3.3) form, due to a lack of the enzyme *N*-acetylglucosaminetransferase I (GlcNAc T I). The Man_5 form is uniquely sensitive to endoglycosidase D (endo D), and therefore the acquisition of endo D sensitivity is a measure of ER-to-*cis*-Golgi transport exclusively.

Additional Materials *(also see Basic Protocol 1)*

Clone 15B chinese hamster ovary (CHO) cells (ATCC)
Endo D buffer (see recipe)
0.5 mU/µl endoglycosidase D (endo D; Boehringer Mannheim)

1. Grow Clone 15B CHO cells to confluency on 100-mm tissue culture dishes and prepare VSV-infected, ^{35}S-labeled SICs (see Basic Protocol 1, steps 2 to 14).

2. Prepare each reaction mix in a microcentrifuge tube as shown in Table 11.3.1, except omit the UDP-*N*-acetylglucosamine. Perform reactions in duplicate along with two negative controls: complete reaction mix incubated on ice and reaction mix without cytosol, incubated at 32°C.

3. Vortex gently 3 sec and incubate 90 min in a 32°C water bath.

4. Pellet SICs by microcentrifuging 20 sec at 15,000 × *g*, 4°C.

5. Resuspend pellet in 60 µl endo D buffer containing 0.5 mU endo D.

6. Incubate the reaction overnight in a 37°C water bath.

7. Analyze results (see Basic Protocol 1, steps 21 to 23; see Fig 11.3.2).

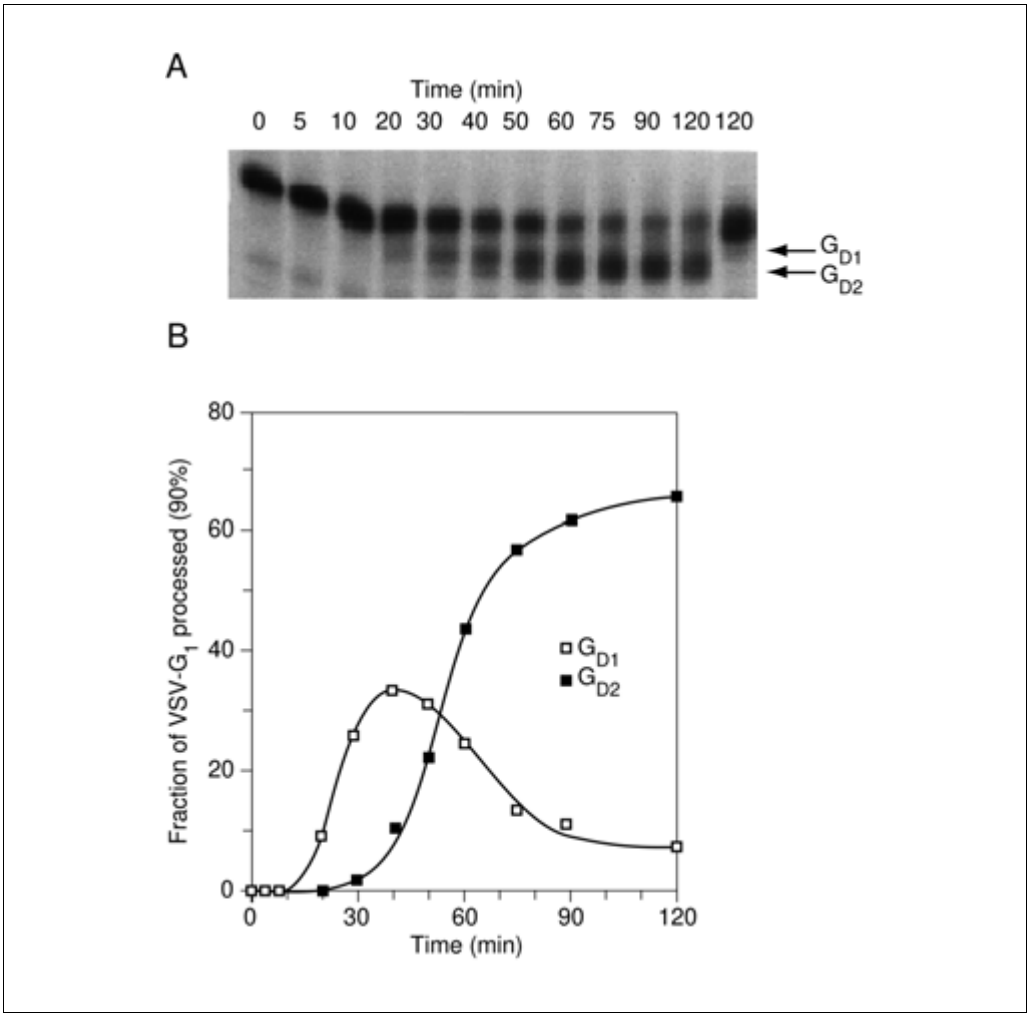

Figure 11.3.2 (**A**) Time course of ^{35}S-labeled VSV-G transport in semi-intact Clone 15B CHO cells, analyzed by endo D digestion. Clone 15B CHO cells are missing the enzyme GlcNAc T I, which is required for development of endo H resistance. At the early time points only G_{H0} is detected. Only G_{D2} is detected under standard SDS-PAGE conditions, although G_{D1}, which is produced when the first of the N-linked oligosaccharides is processed to the endo D–sensitive form, can sometimes be seen as an intermediate by running the dye front off the end of the gel to improve resolution. Reprinted from Schwaninger et al. (1991) with permission from the American Society for Biochemistry and Molecular Biology. (**B**) Kinetics of VSV-G transport as measured by the appearance of the G_{D1} and G_{D2} forms of VSV-G.

BASIC PROTOCOL 2

IN VITRO RECONSTITUTION OF ER-TO-GOLGI TRANSPORT IN MAMMALIAN MICROSOMES

This protocol describes a simple reaction that reconstitutes ER-to-Golgi transport in a microsomal fraction isolated from VSV-infected NRK cells. This assay is similar to the SIC assay in that it is cytosol-, ATP-, and temperature-dependent, and because transport is also measured by assessing the endo H resistance of the VSV-G oligosaccharide side chains.

Materials

Microsomes (see Support Protocol 1)
Rat liver cytosol (see Support Protocol 3)
1 M HEPES acid, pH 7.4
0.1 M magnesium acetate
1 M potassium acetate

Table 11.3.2 Reaction Mix for In Vitro ER-to-Golgi Transport Assay and for In Vitro Formation of ER-Derived Vesicles

Solution	Volume in mix (µl)	Final concentration
Microsomes	7.5	0.5-1 mg/ml
Rat liver cytosol	7.5	4.5 mg/ml
1 M HEPES acid, pH 7.4	1	25 mM
0.1 M magnesium acetate	1	2.5 mM
1 M potassium acetate	1.4	35 mM
10× Ca^{2+} buffer	4	1×
20× ATP-regenerating system	2	1×
2.5 M sorbitol	3	187.5 mM
40 mM UDP *N*-acetyl glucosamine	1	1 mM
Water	To 40 µl (final)	

10× Ca^{2+} buffer (see recipe)
20× ATP-regenerating system (see recipe)
2.5 M sorbitol
40 mM UDP-*N*-acetylglucosamine
Endo H buffer (see recipe)
75 mU/ml endoglycosidase H (endo H; Boehringer Mannheim) in 0.1 M sodium acetate, pH 5.6.
4× SDS sample buffer (*APPENDIX 2A*)
Anti-VSV-G monoclonal antibody p5D4 (Kreis, 1986)
Horseradish peroxidase (HRP)–conjugated secondary antibody
Water baths at 32° and 37°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and densitometry (*UNIT 6.3*)

1. Prepare each reaction mix as described in Table 11.3.2 and vortex gently. Perform reactions in duplicate, using an additional complete reaction incubated on ice as a negative control.

   The final concentration of potassium acetate in the assay should be 70 to 80 mM, with ~45 mM supplied by the microsomes and cytosol. The addition of other components to the assay may require altering the amount of potassium acetate added, so that the final concentration in the assay remains at 70 to 80 mM.

2. Transfer the reaction to a 32°C water bath and incubate 60 to 90 min.
3. Stop reaction by placing the tube on ice. Collect membranes by centrifuging 10 min at 20,000 × *g*, 4°C (e.g., in a Beckman TLA 100.3 rotor). Remove the supernatant by aspiration.
4. Resuspend pellet in 20 µl endo H buffer.
5. Boil 5 min, microcentrifuge briefly, and cool. Add 40 µl of 75 mU/ml endo H (3 mU) in 0.1 M sodium acetate, pH 5.6.
6. Incubate in a 37°C water bath overnight.
7. Stop reaction by adding 20 µl of 4× SDS sample buffer, and separate the endo H–sensitive and endo H–resistant forms of VSV-G on a large 6.75% (w/v) polyacrylamide gel (*UNIT 6.1*).

8. Transfer the proteins to nitrocellulose at 40 V for 6.5 to 10 hr in Tris/glycine/methanol transfer buffer, and immunoblot (*UNIT 6.2*) using the anti-VSV-G monoclonal antibody p5D4 and an HRP-conjugated secondary, each at 1:10,000 in BLOTTO. Quantitate the intensities of the different forms of VSV-G by densitometry (Fig. 11.3.1; see *UNIT 6.3* for densitometry).

   In this protocol only the G_{H0} and G_{H1} forms are seen.

BASIC PROTOCOL 3

IN VITRO FORMATION AND ISOLATION OF ER-DERIVED VESICLES

This protocol describes an in vitro reaction that generates VSV-G-containing ER-derived vesicles from VSV-G-containing microsomes. After incubation in the presence of cytosol and ATP at 32°C, the ER-derived vesicles are separated from the microsomal membranes by differential centrifugation. The ER-derived vesicles are harvested by high-speed centrifugation, and the amount of VSV-G in the high-speed pellet is determined by SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*). This gives a direct measure of the vesicle budding reaction. Timed reactions are used to examine the rate and/or extent of budding.

This protocol also describes a method for purifying the ER-derived vesicles by immunoprecipitation using an antibody against the C terminus of VSV-G. The protein constituents of the purified vesicles can then be examined by SDS-PAGE and immunoblotting. Alternatively, the ER-derived vesicles can be isolated and retained for use in a second-stage fusion reaction (see Basic Protocol 4).

Materials

Microsomes (see Support Protocol 1)
Rat liver cytosol (see Support Protocol 3)
1 M HEPES acid, pH 7.4
0.1 M magnesium acetate
1 M potassium acetate
10× Ca^{2+} buffer (see recipe)
20× ATP-regenerating system (see recipe)
2.5 M sorbitol
Resuspension buffer (see recipe), ice cold
1× SDS sample buffer (*APPENDIX 2A*)
Anti-VSV-G monocolonal antibody p5D4 (Kreis, 1986)
Horseradish peroxidase (HRP)–conjugated secondary antibody
p5D4-Dynabeads: p5D4 coupled to M-500 Dynabeads (Dynal; see manufacturer's instructions)
Immunoprecipitation buffer (see recipe)
FBS (*APPENDIX 2A*)
100 mM EDTA (adjust to pH 8.0 with KOH)
Transport buffer (see recipe)

Water bath at 32°C
Magnetic microcentrifuge tube holder

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and densitometry (*UNIT 6.3*)

1. Set up a 40- to 100-µl reaction for each desired time point as described in Table 11.3.2, except omit the UDP-*N*-acetylglucosamine. For a negative control, perform one complete reaction on ice.

   To determine the rate of budding, use 40-µl reactions with time points ranging from 0 to 60 min at 10-min intervals. To immunoprecipitate vesicles, perform three 10-min, 100-µl

reactions. For a two-stage transport assay (see Basic Protocol 4), use one 10-min, 100-µl reaction.

2. Incubate the reactions in a 32°C water bath, stopping each reaction at the appropriate time point by placing the tube on ice for 2 min.
3. Collect membranes by centrifugation at 135,000 × *g* for 10 min, 4°C (e.g., in a Beckman TLA 100.3 rotor).
4. To resuspend pellets, add 40 to 90 µl ice-cold resuspension buffer, resuspend by repeated pipetting, leave on ice for 10 min, and continue pipetting.

   The membranes are very difficult to resuspend, but can be completely resuspended by this method.

5. Add 0.1 to 0.2 vol of a salt mix so that the final concentration of potassium acetate is 150 mM and that of magnesium acetate is 2.5 mM. Mix by pipetting and microcentrifuge immediately at 16,000 × *g* for 5 min at 4°C.
6. Retain 80% of the medium-speed supernatant (MSS) and carefully aspirate the remainder away from the medium-speed pellet (MSP).

To determine the rate/extent of budding

7a. Centrifuge the MSS at 135,000 × *g* for 10 min, 4°C (e.g., in a Beckman TLA 100.3 rotor). Aspirate the supernatant very carefully or remove it using a yellow pipet tip. Keep the high-speed pellet (HSP).

8a. Resuspend the MSP in 50 µl of 1× SDS sample buffer and the HSP in 40 µl of 1× SDS sample buffer.

9a. Separate the proteins by loading 10 to 20 µl of each resuspended pellet on a 7.5% (w/v) polyacrylamide minigel (*UNIT 6.1*). Transfer the proteins to nitrocellulose and immunoblot for VSV-G (*UNIT 6.2*) using the anti-VSV-G monocolonal antibody p5D4 and an HRP-conjugated secondary, both at 1:10,000 in BLOTTO. Quantify signals by densitometry (*UNIT 6.3*) and determine the ratio of VSV-G in the HSP compared to total VSV-G in the HSP plus the MSP.

To purify vesicles by immunoprecipitation

7b. Mix 150 to 350 µl MSS from a 10-min time point with 1×10^7 p5D4-Dynabeads in a final volume of 372 µl immunoprecipitation buffer. Add 20 µl FBS (final 5%) and 8 µl of 100 mM EDTA (final 2 mM), and mix by continuous rotation at 4°C for 2 hr.

   Coupling of antibodies to the beads is performed exactly as described in the manufacturer's instructions.

8b. Wash beads four times with 500 µl immunoprecipitation buffer, collecting the beads each time with a magnetic tube holder.

9b. Solubilize vesicles on the beads into 1× SDS sample buffer by boiling 5 min and analyze the proteins by SDS-PAGE (*UNIT 6.1*).

To use vesicles in a second-stage fusion reaction

7c. Prepare an HSP from a 100-µl, 10-min reaction as described in step 7a.

8c. Resuspend the HSP in 25 µl transport buffer and keep on ice for stage 2 (see Basic Protocol 4).

   Each 100-µl budding reaction is sufficient for duplicate 50-µl fusion reactions.

SUPPORT PROTOCOL 1

PREPARATION OF MICROSOMAL MEMBRANES FROM NRK CELLS

This protocol describes the preparation of microsomes from VSV-infected NRK cells. These microsomes are used in the microsome-based transport assay (see Basic Protocol 2) and as the source of ER-derived vesicles for a more detailed two-stage assay (see Basic Protocols 3 and 4).

Additional Materials *(also see Basic Protocol 1)*

PBS (*APPENDIX 2A*), ice cold
Homogenization buffer I (see recipe)
100× PIC (see recipe)
Potassium acetate buffer (see recipe)
Transport buffer (see recipe)
1-ml ball-bearing homogenizer (Balch and Rothman, 1985)
Culture incubator at 39.5°C

NOTE: The method described below is for a twelve-dish microsome preparation.

Infect and collect cells

1. Grow NRK cells to confluency on twelve 150-mm tissue culture dishes.
2. Prepare an infection cocktail containing (per dish) 4.5 ml serum-free α-MEM, 0.5 ml VSV ts045 stock (final ~2×10^8 pfu/ml), and 25 µl of 1 mg/ml actinomycin D (final 5 µg/ml).
3. Add 5 ml per dish and rock continuously (or by hand at 5-min intervals) for 45 min in a 32°C culture incubator, ensuring even distribution of the infection cocktail.
4. Add 20 ml α-MEM with 5% FBS to each dish and incubate in a 39.5°C culture incubator (restrictive temperature) for 3 hr and 40 min.
5. Place each dish on ice. Immediately aspirate the medium and wash the cells with 10 ml ice-cold PBS.
6. Add 5 ml homogenization buffer I and scrape the cells using a rubber policeman. Transfer the cells to three 50-ml polypropylene tubes on ice, pooling cells from four dishes into each tube. Repeat the scraping procedure once.

Prepare membranes

7. Centrifuge at 720 × *g* for 3 min at 4°C and remove the supernatant by aspiration.
8. Resuspend each cell pellet in 0.9 ml homogenization buffer I with 1× PIC. Homogenize each by three complete passes through a 1-ml ball-bearing homogenizer.
9. Pool all cell homogenates and add an equal volume of homogenization buffer I with 1× PIC. Divide the diluted homogenate into six 1-ml aliquots in 1.5-ml microcentrifuge tubes.
10. Centrifuge at 720 × *g* for 5 min at 4°C.
11. Transfer each postnuclear supernatant to a 15-ml polypropylene tube. Add 0.5 vol potassium acetate buffer and mix.
12. Divide into 0.8- to 1-ml aliquots in 1.5-ml microcentrifuge tubes, and microcentrifuge at 12,000 × *g* for 2 min, 4°C.
13. Remove the supernatant by aspiration and resuspend all pellets in a total volume of 1 ml transport buffer with 1× PIC. Transfer 0.5 ml into each of two microcentrifuge tubes.

14. Microcentrifuge at 12,000 × *g* for 2 min, 4°C.

15. Resuspend the microsomal pellets in 6 to 8 vol transport buffer with 1× PIC. Pool the microsomes, divide into 50- to 100-µl aliquots, freeze in liquid nitrogen, and store at −80°C.

    In a typical twelve-dish preparation, 1 to 1.5 ml of resuspended microsomes (at 3 to 5 mg protein/ml) is obtained.

    These microsomes can be stored for several months without the loss of transport activity.

PROPAGATION OF VSV ts045

SUPPORT PROTOCOL 2

Stocks of VSV ts045 are prepared from infected baby hamster kidney cells to provide material for these protocols.

Materials

Baby hamster kidney (BHK) cells (ATCC)
Glasgow minimal essential medium (G-MEM; Life Technologies)
Tryptose phosphate broth (TPB; Sigma)
FBS (*APPENDIX 2A*)
TD buffer (see recipe)
Vesicular stomatitis virus (VSV) ts045 stock (Indiana serotype; multiplicity of infection = 0.1; ATCC)
Culture incubator at 32°C

1. Grow BHK cells to a confluent monolayer on 100-mm tissue culture dishes in G-MEM containing 10% (v/v) TPB and 5% (v/v) FBS.
2. Wash cells with TD buffer.
3. Add 10 ml G-MEM/10% TPB containing ~10^6 plaque forming units (pfu) of VSV ts045 stock.
4. Incubate 36 to 48 hr (until cells begin to round) in a 32°C culture incubator.
5. Remove medium, which now contains the amplified virus, and centrifuge at 720 × *g* for 10 min at 4°C.
6. Divide the supernatant into 100-µl aliquots, freeze in liquid nitrogen, and store indefinitely at −80°C.

    Generally the yield of virus is 1-2 × 10^9 pfu/ml. The viral stock can be refrozen twice without significant loss of titer.

FUSION OF ER-DERIVED VESICLES WITH GOLGI MEMBRANES

BASIC PROTOCOL 4

This protocol describes an assay that measures the fusion of ER-derived vesicles with purified Golgi membranes. The vesicles are made in vitro, isolated, and incubated at 32°C with rat liver Golgi membranes in the presence of cytosol and ATP. The acquisition of endo H resistance by the VSV-G oligosaccharide side chains is measured to follow fusion and expressed as the percentage of VSV-G in the endo H–resistant form.

Materials

ER-derived vesicles (HSP; see Basic Protocol 3, step 8c)
Desalted rat liver cytosol (see Support Protocol 3)
Enriched rat liver Golgi membranes (see Support Protocol 4)
1 M HEPES acid, pH 7.4
0.1 M magnesium acetate
10× Ca^{2+} buffer (see recipe)

Table 11.3.3 Reaction Mix for Fusion of ER-Derived Vesicles With Golgi Membranes

Solution	Volume in mix (µl)	Final concentration
HSP[a]	10	
Desalted rat liver cytosol	8	4 mg/ml
Golgi membranes	4	1.5 mg/ml
1 M HEPES acid, pH 7.4	1.25	25 mM
0.1 M magnesium acetate	1.25	2.5 mM
10× Ca^{2+} buffer	5	1×
20× ATP-regenerating system	2.5	1×
40 mM UDP *N*-acetylglucosamine	1.25	1 mM
2.5 M sorbitol	3.6	180 mM
Water	To 50 µl (final)	

[a]Abbreviation: HSP, high-speed pellet.

20× ATP-regenerating system (see recipe)
40 mM UDP-*N*-acetylglucosamine
2.5 M sorbitol
Endo H buffer (see recipe)
75 mU/ml endoglycosidase H (endo H; Boehringer Mannheim) in 0.1 M sodium acetate, pH 5.6
4× SDS sample buffer (*APPENDIX 2A*)
Anti-VSV-G monoclonal antibody p5D4 (Kreis, 1986)
Horseradish peroxidase (HRP)–conjugated secondary antibody
Water bath at 37°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and densitometry (*UNIT 6.3*)

1. Prepare each reaction mix as described in Table 11.3.3. Perform reactions in duplicate and include two negative controls: a complete reaction incubated on ice and a reaction without Golgi membranes, incubated at 32°C.

   Note that desalted rat liver cytosol is used in this assay.

2. Incubate in a 32°C water bath for 75 min.
3. Stop reaction by transferring the tubes to ice.
4. Collect membranes by centrifuging at 135,000 × *g* for 10 min, 4°C (e.g., in a Beckman TLA 100.3 rotor).
5. Resuspend pellet in 20 µl endo H buffer.
6. Boil 5 min, microcentrifuge briefly, and cool. Add 40 µl of 75 mU/ml endo H (3 mU) in 0.1 M sodium acetate, pH 5.6.
7. Incubate overnight in a 37°C water bath.
8. Stop reaction by adding 20 µl of 4× SDS sample buffer, and separate the endo H–sensitive and endo H–resistant forms of VSV-G on a large 6.75% (w/v) polyacrylamide gel (*UNIT 6.1*).
9. Transfer the proteins to nitrocellulose at 40 V for 6.5 to 10 hr in Tris/glycine/methanol transfer buffer and immunoblot (*UNIT 6.2*) using the anti-VSV-G monocolonal antibody p5D4 and an HRP-conjugated secondary, both at 1:10,000 in BLOTTO. Quantify the

intensities of the different forms of VSV-G by densitometry (Fig. 11.3.1; see *UNIT 6.3* for densitometry).

In this protocol only the G_{H0} and G_{H1} forms are seen.

PREPARATION OF RAT LIVER CYTOSOL

SUPPORT PROTOCOL 3

Rat liver cytosol is required as an additive for the transport assays. The first part of this protocol describes steps used for cytosol preparation and is performed in the same manner for each type of assay. For use in the ER-vesicle-to-Golgi fusion assay (see Basic Protocol 4), it must also be desalted by gel filtration, as described in the second part of the protocol.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Male Sprague-Dawley rats
PBS (*APPENDIX 2A*), ice cold
Cytosol buffer (see recipe), ice cold
100 mM ATP
100× PIC (see recipe)

40-ml Dounce homogenizer with type A (tight-fitting) and type B (loose-fitting) glass pestles
Cheesecloth
Sephadex G-25M/PD-10 column (Pharmacia Biotech)

Prepare rat liver cytosol

1. Sacrifice two male Sprague-Dawley rats. Remove the livers and weigh them.

   Two livers should have a wet weight of 15 to 20 g. The age of the rats does not seem to affect yield or performance of the preparation.

2. Wash tissue three times with 50 ml ice-cold PBS and twice with 50 ml ice-cold cytosol buffer.
3. Add 3 vol (vol/gram wet weight of liver) ice-cold cytosol buffer supplemented with 1 mM ATP and 1× PIC, and cut the tissue into small pieces on ice using scissors.
4. Transfer the diced tissue to a homogenizer in a cold room and homogenize by hand using 10 strokes with a type B pestle (loose) followed by 10 strokes with a type A pestle (tight).
5. Filter the homogenate through cheesecloth into a beaker on ice.
6. Centrifuge the filtered homogenate at 12,000 × *g* (e.g., in a Beckman JA-20 rotor) for 10 min, 4°C.
7. Transfer the supernatant to appropriate centrifuge tubes (e.g., for a Beckman SW41 rotor) and centrifuge at 150,000 × *g* for 90 min, 4°C.
8. Remove the overlying lipid layer by aspiration and retain the remaining supernatant (cytosol).
9. Divide the cytosol into 250-µl aliquots, freeze in liquid nitrogen, and store up to 6 months at −80°C.

   This cytosol is ready for use in Basic Protocols 1 and 2 and in the Alternate Protocol.

   The normal protein concentration of the cytosol is 25 to 30 mg/ml. Two livers should provide ~150 aliquots (30 to 40 ml).

Prepare gel-filtered (desalted) cytosol

10. In a cold room, remove the caps from a Sephadex G-25M/PD-10 column and equilibrate the column with 25 ml ice-cold cytosol buffer supplemented with 1× PIC.
11. Add exactly 2.5 ml cytosol to the top of the column.
12. Allow the eluent to flow through the column until it stops, and discard the flow-through.
13. Elute the proteins with exactly 3.5 ml ice-cold cytosol buffer supplemented with 1× PIC.
14. Divide the filtered cytosol into 100-µl aliquots, freeze in liquid nitrogen, and store up to 6 months at −80°C.

Gel-filtered cytosol is used for Basic Protocol 4.

SUPPORT PROTOCOL 4

PREPARATION OF GOLGI MEMBRANES FROM RAT LIVER

Rat livers are used as a source for Golgi membranes, which are purified by sucrose-density fractionation of liver homogenate.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Male Sprague-Dawley rats
Homogenization buffer II (see recipe), ice cold
100× PIC (see recipe)
Sucrose solutions in 10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*): 0.5 M (refractive index 1.3575), 1.0 M (1.3815), 1.1 M (1.3865), 1.25 M (1.3939), and 2.35 M (1.4464)
Dilution buffer (see recipe)
Transport buffer (see recipe)
Homogenizer (Potter-Elvehjem tissue grinder, size C) and Teflon pestles with 0.026-in. (66-mm) and 0.012-in. (30-mm) clearance
Cheesecloth
Refractometer
18-G needle

Prepare postnuclear supernatant

1. Remove the livers from two sacrificed male Sprague-Dawley rats, place on adsorbent paper, and weigh them.

   The two livers should have a wet weight of 15 to 20 g. The age of the rats does not seem to affect yield or performance of the preparation.

2. Place tissue in a beaker, add 5 vol (w/v) ice-cold homogenization buffer II with 1× PIC, and cut the livers into small pieces using scissors.
3. Transfer the diced tissue to a homogenizer and homogenize using a mechanical drive at a speed of 1000 rpm. Use 3 passes with a pestle of 0.026-in. clearance and 3 passes with a pestle of 0.012-in. clearance.
4. Filter the homogenate through cheesecloth into a beaker on ice. Wash the residue on the cheesecloth with 10 ml ice-cold homogenization buffer II.

5. Centrifuge the filtered homogenate at 1450 × *g* (e.g., in a Beckman JA-20 rotor) for 10 min, 4°C.
6. Collect the supernatant.

Separate membrane fractions

7. Layer 30-ml portions of supernatant on top of 8 ml of 1.25 M sucrose solution (e.g., in Beckman SW28 tubes).
8. Centrifuge at 112,000 × *g* (25,000 rpm in a Beckman SW28 rotor) for 90 min, 4°C.
9. Remove the top layer by aspiration and collect the membranes from the 0.5 M/1.25 M interface using a Pasteur pipet.
10. Use a refractometer to determine the sucrose concentration and adjust to 1.2 M (refractive index = 1.3915) by adding 2.35 M sucrose.
11. Place 13-ml portions of this membrane fraction at the bottom of SW28 tubes and overlay with 10 ml of 1.1 M sucrose, 10 ml of 1.0 M sucrose, and 5 ml of 0.5 M sucrose.
12. Centrifuge at 112,000 × *g* (25,000 rpm in a Beckman SW28 rotor) for 2.5 hr, 4°C.
13. Recover the band at the 0.5 M/1.0 M interface using an 18-G needle.
14. Divide into ~300-µl aliquots in 1.5-ml microcentrifuge tubes and add 4 vol dilution buffer.
15. Microcentrifuge at 16,000 × *g*, 4°C, for 10 min.

    After this centrifugation the membranes smear along the side of the tube rather than forming a compact pellet.

16. Aspirate the supernatant and resuspend the membranes gently with 0.5 ml transport buffer.
17. Pool the membranes from the two tubes and repeat microcentrifugation (as in step 15).
18. Resuspend membranes in a total of 4 ml transport buffer. Divide into 75- to 100-µl aliquots, freeze with liquid nitrogen, and store up to 3 months at −80°C.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

NOTE: The pH of all buffers is adjusted with KOH, where appropriate.

ATP-regenerating system, 20×

12 ml 46 mM ATP, pH 7.0 (20 mM final)
12 ml 233 mM creatine phosphate (100 mM final)
4 ml 700 U/ml creatine phosphate kinase (100 U/ml final)
Divide into 100- to 200-µl aliquots
Store up to 3 or 4 months at −80°C

Ca^{2+} buffer, 10×

20 mM HEPES acid, pH 7.4
50 mM EGTA
18 mM $CaCl_2$
Store up to 6 months at 4°C

Cytosol buffer

25 mM HEPES acid, pH 7.4
125 mM potassium acetate
Store up to 6 months at 4°C

Dilution buffer

25 mM HEPES acid, pH 7.2
87.5 mM potassium acetate
1.25 mM magnesium acetate
Store up to 6 months at –20°C

Endo D buffer

50 mM sodium phosphate, pH 6.2
5 mM EDTA
0.2% (v/v) Triton X-100
Store up to 6 months at –20°C

Endo H buffer

0.1 M sodium acetate, pH 5.6
0.3% (w/v) SDS
Store up to 1 month at 4°C
Add 20% (v/v) 2-mercaptoethanol just before use

Homogenization buffer I

20 mM HEPES acid, pH 7.4
375 mM sorbitol
Store up to 6 months at –20°C

Homogenization buffer II

10 mM Tris·Cl, pH 7.4
0.5 M sucrose
5 mM EDTA
5 mM EGTA
1× PIC (see recipe)
Prepare fresh

Immunoprecipitation buffer

20 mM HEPES acid, pH 7.4
150 mM potassium acetate
0.25 M sucrose
0.1% (w/v) BSA
Prepare fresh from stock solutions stored up to 1 week at 4°C

Methionine-deficient labeling medium

Methionine-deficient labeling medium (Sigma)
1× leucine (200× solution, 79 mM; tissue grade culture; Sigma)
1× lysine (200× solution, 80 mM; tissue grade culture; Sigma)
20 mM HEPES acid, pH 7.2
Store up to 1 year at 4°C

Methionine-deficient labeling medium is minimal essential medium (MEM) with Earle's salts and L-glutamine (but without L-leucine, L-lysine, L-methiodine, or sodium bicarbonate).

Perforation buffer

50 mM HEPES acid, pH 7.2
90 mM potassium acetate
Store up to 6 months at 4°C

Potassium acetate buffer

20 mM HEPES acid, pH 7.4
210 mM potassium acetate
3 mM magnesium acetate
Store up to 6 months at –20°C

Protease inhibitor cocktail (PIC), 100×

1 mg/ml leupeptin
1 mg/ml chymostatin
0.05 mg/ml pepstatin A
0.05 M phenylmethylsulfonyl fluoride (PMSF; *APPENDIX 2A*)
Prepare in water fresh before use from stock solutions stored at –20°C

Resuspension buffer

20 mM HEPES acid, pH 7.4
0.25 M sucrose
Store up to 6 months at –20°C

Swelling buffer

10 mM HEPES acid, pH 7.2
18 mM potassium acetate
Store up to 6 months at 4°C

TD buffer

138 mM NaCl
5 mM KCl
25 mM Tris base
0.4 mM Na_2HPO_4
Prepare fresh

Transport buffer

20 mM HEPES acid, pH 7.4
250 mM sorbitol
70 mM potassium acetate
1 mM magnesium acetate
Store up to 6 months at –20°C

COMMENTARY

Background Information

The transport of proteins along the early secretory pathway is mediated by small vesicles that bud from the ER and subsequently fuse with the Golgi apparatus (Palade, 1975). A number of biochemical assays have been developed to study ER-to-Golgi transport in vitro in mammalian cells (Beckers et al., 1987; Rowe et al., 1996) and yeast (Rexach and Schekman, 1991). The assays described in this unit allow the biochemical events of ER-to-Golgi trafficking to be studied in mammalian cells and for the role of distinct components involved in these events to be elucidated.

The assays are based on a viral glycoprotein that is transported to the cell surface in infected cells along the same pathway as endogenous plasma membrane proteins. The assays take advantage of a temperature-sensitive mutant of vesicular stomatitis virus (VSV ts045; Lafay, 1974), which encodes a glycoprotein (VSV-G ts045) that suffers from a thermoreversible folding defect. At the restrictive temperature (39.5°C), VSV-G ts045 is retained in the ER because it is misfolded. Switching to the per-

missive temperature (32°C) corrects the misfolding and triggers transport from the ER. The ability to turn on transport selectively allows the synchronized movement of VSV-G ts045 to be followed through the early secretory pathway.

The ability to retain VSV-G ts045 in the ER and control its release makes this protein an ideal reporter molecule. In theory, however, any cargo protein could be used and the assays described here could be modified to study any protein of interest. The limiting factor is the ability to distinguish cargo protein (coming from the ER during the assay) from protein that is already present in transport vesicles and the Golgi at the beginning of the assay.

The transport of VSV-G is monitored by assessing the maturation of two N-linked oligosaccharide side chains on VSV-G as the protein moves from the ER to and through the Golgi. The processing of the oligosaccharide side chains of VSV-G is a complex process and the formation of different forms of oligosaccharides can be manipulated in vitro (Davidson and Balch, 1993). In the protocols described here, four different forms of VSV-G can be distinguished (Fig. 11.3.1 and Fig. 11.3.2). In the ER, VSV-G exists in a high-mannose form ($Man_9GlcNAc_2$; G_0; Fig. 11.3.3). In the *cis*-Golgi, α-1,2-mannosidase I (Mann I) trims G_0 to the $Man_5GlcNAc_2$ (G_D) form. The oligosaccharide side chains of G_0 are resistant to cleavage by the enzyme endoglycosidase D (endo D), while G_D is uniquely sensitive to endo D. Under standard SDS-PAGE conditions, only a single G_D form is detected (G_{D2}). However a second G_D form (G_{D1}) can be seen by running the dye front off the end of the gel to improve resolution (Fig. 11.3.2). G_{D1} is a transient intermediate formed when only one of the VSV-G N-linked oligosaccharide side chains is processed.

G_D is further processed by *N*-acetylglucosaminetransferase I (GlcNAc T I) and α-1,2-mannosidase II (Mann II) in the *cis* and medial compartments of the Golgi to the G_{H1} and G_{H2}

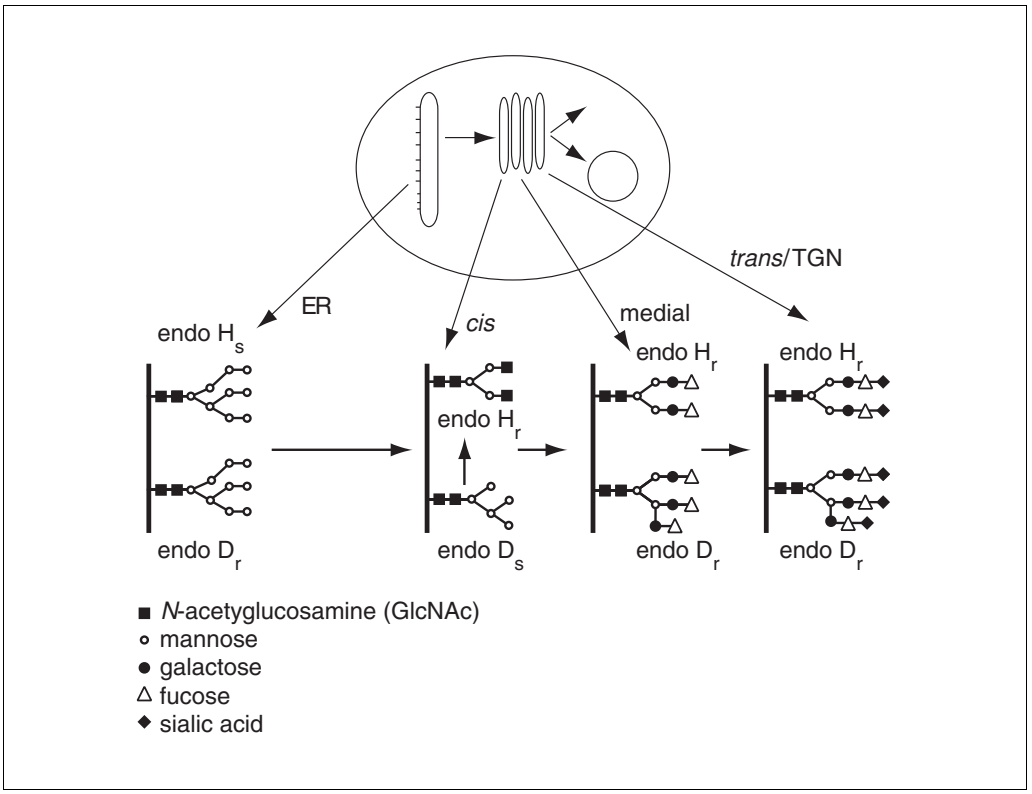

Figure 11.3.3 A schematic representation of the different oligosaccharide side chain processing forms of VSV-G. G_{H0} is the ER Man9 form, which is endo H sensitive (endo H_s) and endo D resistant (endo D_r). G_D is formed in the *cis*-Golgi by trimming G_{H0} to the Man_5 form, which is endo D sensitive (endo D_s). This is the only intermediate in the oligosaccharide processing of VSV-G that is sensitive to endo D and cannot normally be detected in wild-type cells due to its transient formation. Further processing of G_D in the *cis*-Golgi generates G_{H1}, which is endo H resistant (endo H_r). In the medial Golgi, G_{H1} is processed to the G_{H2} form, which is also endo H resistant (endo H_r), but which migrates more slowly than G_{H1} in SDS/polyacrylamide gels. TGN, *trans*-Golgi network.

forms. G_{H1} and G_{H2} are both resistant to endoglycosidase H (endo H), while G_0 is sensitive to endo H. Under the conditions described here, G_{H1} is a transient intermediate in the pathway, and after 90 min almost all VSV-G is in the G_{H2} form. Each oligosaccharide processing form of VSV-G has a unique mobility during SDS-PAGE, allowing for a direct quantitative assay for transport (Beckers et al., 1987).

Because Clone 15B CHO cells lack the enzyme GlcNAc T I (Gottlieb et al., 1975), there is no further processing of G_D as the protein moves through the Golgi in these cells. Therefore the appearance of the G_D form is a measure of transport from the ER to the *cis*-Golgi, and the alternative semi-intact cell assay using Clone 15B CHO cells should be used when one wants to study ER-to-*cis*-Golgi trafficking exclusively.

Further processing of VSV-G that involves the addition of galactose, sialic acid, and additional GlcNAc residues (to generate a complex form of VSV-G, $G_{complex}$) occurs in the medial and *trans*-Golgi network (TGN), and cannot be measured using the protocols described here. However, the protocols can be modified to measure delivery of VSV-G to the TGN (Davidson and Balch, 1993).

The first protocol describes the semi-intact cell (SIC) assay, which is a relatively quick and simple way to determine the effect of any particular factor on the extent and/or rate of transport of protein from the ER to the Golgi. This assay has been used to show that GTP and ATP hydrolysis, Ca^{2+}, members of the Rab protein family, as well as general trafficking proteins such as *N*-ethylmaleimide-sensitive factor (NSF) and soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs) are required for ER-to-Golgi transport. The use of immunodepleted cytosols, the addition of transdominant mutants, and the use of neutralizing antibodies to inhibit transport are the main approaches used to show a role for a particular protein in transport.

The SIC assay can be separated into three distinct kinetic stages (Fig. 11.3.4). The first stage, in which there is no processing of VSV-G oligosaccharide side chains, represents vesicle formation and subsequent budding and targeting of the vesicles. The second stage, in which there is a progressive increase in side chain processing, represents fusion of ER-derived vesicles with the Golgi. A plateau of processing defines the third stage, which presumably represents the maximum capacity of the SIC assay

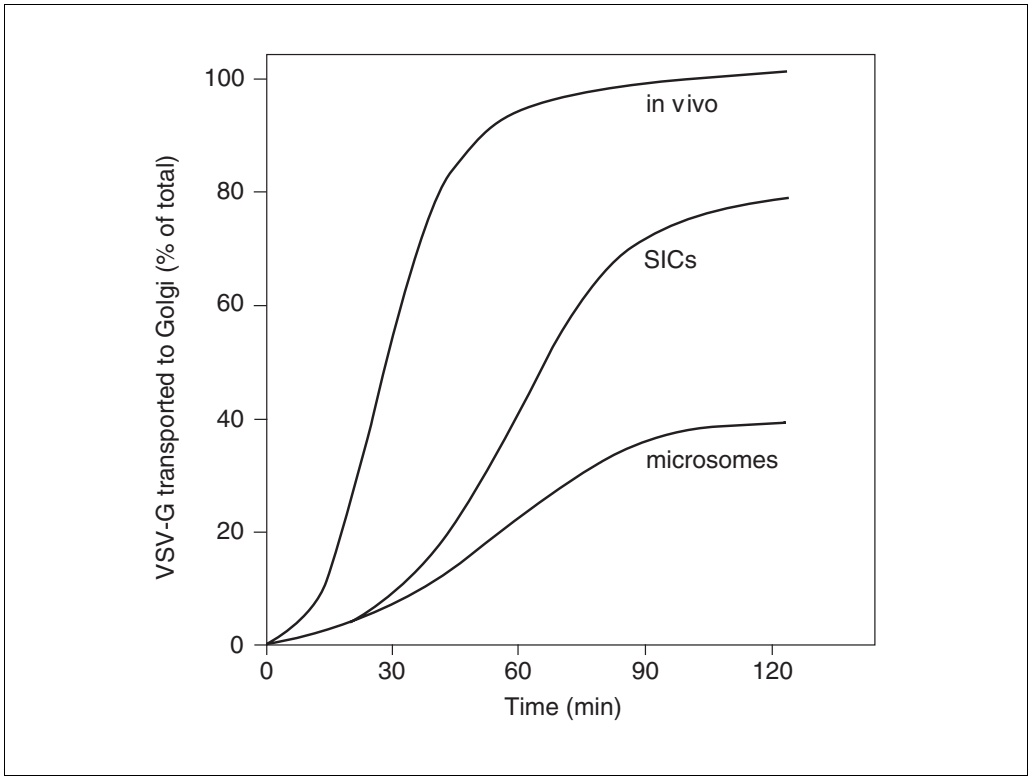

Figure 11.3.4 Comparison of the rates and extent of VSV-G transport from the ER to the Golgi apparatus measured either in vivo, in SIC preparations, or reconstituted using the microsome-based protocol.

to support ER-to-Golgi transport. Modifying this protocol to involve the timed addition of inhibitors during the incubation period can allow the investigator to assign a role of a particular factor to the early or late stages of transport. Furthermore, by accumulating transport intermediates with a reversible inhibitor, the requirements for further transport can be examined upon removal of the inhibitor.

The SIC assay cannot, however, accurately define a role for any factor in the separate biochemical events of ER-to-Golgi transport. The microsome-based assay described here was developed to allow for this. The protocol is a one-stage reaction in which ER-derived vesicles are formed, targeted, and allowed to fuse with Golgi membranes already present in the microsomal fraction. This assay is essentially the same as the SIC assay, except that its overall efficiency is lower (Fig. 11.3.4). It is used mainly to confirm that the microsome and cytosol preparations are competent to reconstitute ER-to-Golgi transport.

The more detailed two-stage assay allows for vesicle formation and budding, targeting of ER-derived vesicles, and fusion with the Golgi to be studied independently. This allows the investigator to accurately assign a role for any particular factor to a distinct biochemical event. Similar assays have been developed in the yeast system for studying both ER-to-Golgi transport (Rexach and Schekman, 1991) and vacuolar inheritance (Conradt et al., 1994). These assays have proved to be powerful tools in determining the order of the distinct biochemical events that are involved and the role of general trafficking proteins in these events.

The first stage of the two-stage assay involves vesicle formation in vitro. When used on its own, this assay allows for the factors involved in vesicle budding from the ER to be studied, as the appearance of VSV-G in the high-speed pellet (HSP) is a direct measurement of vesicle formation. The ER-derived vesicles can also be studied as separate entities by immunopurification using anti-VSV-G antibodies. This allows the protein constituents of the vesicles to be determined. The combination of the first-stage vesicle formation reaction with a separate second-stage fusion reaction allows the targeting and fusion events involved in ER-to-Golgi transport to be studied independently of vesicle formation and budding and independently of each other. The relative contributions of vesicular components, cytosolic factors, and Golgi components to the separate biochemical events can be determined using this assay.

Critical Parameters

All assays described in this unit are based on the synchronized movement of the ts045 mutant of VSV-G from the ER. To keep VSV-G ts045 in the ER, it is essential that the temperature does not drop below 39.5°C during the preparation of SICs and microsomes.

The preparation of SICs by mechanical perforation of hypotonically swollen cells produces a yield of 90% to 95% SICs for the cell lines used routinely in the authors' laboratory. The swelling procedure can be adjusted to achieve maximum perforation of other cell lines by changing the swelling time, the composition of the swelling buffer, or the degree of adherence to the tissue culture plate. In general, cells that adhere weakly require longer swelling times, while strongly adherent cells may not even require swelling before scraping. As an alternative to scraping, perforation can be performed using nitrocellulose stripping, which tears pieces of the plasma membrane away from the surface of the cell. Transport can then be assayed in the cells that remain attached to the nitrocellulose, or the cells that remain on the plate can be harvested by gentle scraping for an assay in suspension. In all cases, the degree of perforation can be determined by assessing trypan blue staining of the nuclei of perforated cells.

The preparation of microsomes with high budding activity is dependent on the homogenization conditions. The ball-bearing homogenizer breaks the cells efficiently, giving a high yield of membranes with high budding activity. The use of other types of homogenizers is not recommended.

In the microsome-based assay, the separation of budded vesicles from the microsomes is achieved by differential centrifugation. The largest reaction volume that does not require alterations in the centrifugation conditions is 100 µl. Larger reaction volumes may change the sedimentation properties of the membranes; therefore, the centrifugation conditions for larger reaction volumes should be characterized empirically.

Sodium ions inhibit both the SIC assay and the microsome-based assay. The pH of all buffers used in these assays is therefore adjusted with KOH, rather than NaOH. Any protein added to the assays should first be dialysed against 25 mM HEPES acid, pH 7.2, containing 125 mM potassium acetate. If it is necessary to add a component in any buffer not described

Table 11.3.4 Troubleshooting Guide

Problem	Possible cause	Solution
High percent transport in cytosol-free control in SIC assay	Poor perforation of cells	Determine percent perforation; optimize protocol for the specific cell line
	Cytosol not completely washed out of cells	Incubate cells on ice 10 min after perforation[a]
Cannot resuspend membranes completely in preparing ER-derived vesicles[b]	Concentration and/or pH of resuspension buffer are incorrect	Check concentration of sucrose using a refractometer; check pH
	Salts added before resuspension	Use salt-free resuspension buffer and add salts only after complete resuspension
No transport in SIC assay; no budding in microsome assay	Sodium ions in reaction	Adjust pH of all solutions with KOH; dialyze additives against 125 mM potassium acetate, 25 mM HEPES, pH 7.2
No fusion in second-stage fusion reaction	Sodium ions and/or sucrose in reaction	Make sure that sucrose has not been used instead of sorbitol

[a]See Basic Protocol 1, step 12.
[b]See Basic Protocol 3, step 4.

here, the effects of this buffer on the assay should be determined. See Table 11.3.4 for a brief troubleshooting guide.

Anticipated Results

The preparation of SICs from NRK, BHK, and CHO cells by scraping results in the perforation of 90% to 95% of cells. The percentage of perforation should be determined using trypan blue staining, particularly if other cell lines are to be used (see Critical Parameters).

The typical result obtained for the SIC assay is shown in Figure 11.3.1. The amount of VSV-G transported is determined by comparing the amount of the endo H–resistant form with the total amount of VSV-G in the reaction. The appearance of the different forms of VSV-G is the same after immunoblotting to measure transport in the two-stage assay, as is shown in Figure 11.3.1 for ^{35}S-labeling in the SIC assay.

In the SIC assay, 65% to 70% of VSV-G is transported after 60 to 90 min. Transport efficiency is lower in the microsome-based assay, where 35% to 40% of VSV-G is transported after 60 to 90 min (Fig. 11.3.2).

Stage 1 of the two-stage microsome assay allows for the rate of budding to be measured. Under standard conditions, VSV-G appears in the HSP after ~5 min, peaks at between 10 and 20 min, and then decreases over time. The amount of VSV-G in the HSP depends on the budding activity of the microsomes as well as on the fusion competence of the membranes in the reaction. In general, 15% to 20% of the VSV-G is found in the HSP at the peak time point. In stage 2 of the two-stage assay, 35% to 40% of the VSV-G in the HSP appears as the endo H–resistant form after 75 to 90 min (Fig. 11.3.2).

The purification of ER-derived vesicles using immunoprecipitation allows 25% to 30% of the VSV-G in the medium-speed supernatant (MSS) to be isolated with 2.5 to 5 µg p5D4 antibody/10^7 beads. This represents only ~5% of the total starting VSV-G. In general, therefore, the MSS from three 100-µl budding reactions (stage 1) are pooled for every immunoprecipitation reaction.

Time Considerations

The SIC assay and the microsome-based assay take 3 days from beginning the experiment to analyzing the data. The actual hands-on time for the SIC assay is 4.5 hr for infection of the cells and 3 to 3.5 hr from the preparation of SICs to the addition of endo H. The hands-on time for the microsome-based assay is considerably shorter, requiring only 2 to 2.5 hr on the first day. Digestion is done overnight (minimum 16 hr). The polyacrylamide gel (200 × 150 × 1.5 mm) takes 4 to 5 hr to run. For ^{35}S analysis, the gel is incubated in fluorographic enhancement solution for 20 min, dried for ~1 hr, and exposed to film overnight. For the microsome-based assay, the endo H–treated proteins are transferred to nitrocellulose overnight (6.5 to 10 hr total transfer time), and immunoblot analysis is done the next day.

The budding reaction (stage 1) and the immunoprecipitation of vesicles can be done in one day. Preparation of the MSS, MSP, and HSP requires ~1.5 to 2 hr. Immunoprecipitation requires 2 hr, with an additional 30 to 45 min for washing the beads. A minigel takes ~1 hr to run, and the proteins are transferred to nitrocellulose for 1 hr. Immunoblot analysis takes 3 to 4 hr.

The two-stage assay also takes a total of three days, with 1.5 to 2 hr for stage 1 and ~2 hr for stage 2, both on the first day. After the addition of endo H, the time required is the same as for the microsome assay.

Cotranslational Translocation of Proteins into Canine Rough Microsomes

This unit describes the isolation of small vesicular fragments of rough endoplasmic reticulum (ER), known as "rough microsomes" (RMs), and their use in cell-free protein translocation assays. By faithfully reproducing the events associated with the transport of proteins into the ER, a cell-free assay provides a tool for analyzing ER targeting signals, signal-sequence cleavage, N-linked glycosylation, and membrane-protein biogenesis. Because translocation has been shown to be a strictly cotranslational process, purified RMs are added directly to wheat germ or rabbit reticulocyte translation reactions that are programmed with appropriate mRNAs (see *UNITS 11.1 & 11.2*). A variety of post-translational treatments are then performed to facilitate interpretation of the results of the translocation reaction. Finally, the proteins in the reaction mix are resolved by SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*). Translocation or membrane insertion of the translation product is indicated by mobility shifts due to signal-sequence cleavage and glycosylation, or by cofractionation with membrane components.

This unit describes the use of RMs isolated from canine pancreas (see Support Protocol 1) in cotranslational translocation assays and optional post-translational treatments (see Basic Protocol). Also included are methods of processing and purifying RMs that optimize their compatibility with in vitro translation reactions (see Support Protocols 2 and 3).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

TRANSLOCATION INTO CANINE ROUGH MICROSOMES

BASIC PROTOCOL

In this protocol secreted, lumenal, and integral membrane proteins are translocated cotranslationally into RMs that are added to rabbit reticulocyte or wheat germ translation reactions. Because many proteins contain an N-terminal, ~20- to 30-amino-acid "signal sequence" that is removed by signal peptidase as the protein is transported into the RMs, translocation can often be assessed simply by looking for a slight increase in mobility on polyacrylamide gels in the presence of RMs (see Fig. 11.4.1). Proteins that are translocated into RMs are also resistant to protease digestion. The extent of N-linked glycosylation can be assessed by looking for a retardation of mobility on polyacrylamide gels that can be reversed by the addition of glycosidases. Finally, the integration of membrane proteins can be analyzed by testing for resistance to alkaline extraction.

Although a standard cotranslational translocation reaction is performed to analyze the transport of all proteins, a variety of different post-translational treatments can be used to generate additional information about protein topology and protein modifications. Because these treatments are applicable only to specific classes of proteins and only in certain experimental situations, the investigator should assess in advance which, if any, of these optional treatments (steps 5, 6, and 7) will be appropriate. Studies by Hansen et al. (1986) and Gafvelin et al. (1997) illustrate the utility of these post-translational treatments.

Current Protocols in Cell Biology (1998) 11.4.1-11.4.11

Materials

Wheat germ *or* reticulocyte translation mix (see *UNIT 11.2*)
1 eq/µl RM solution (see Support Protocol 1)
mRNA encoding a protein of interest
mRNA encoding a control cytoplasmic protein
Buffer C (see recipe)
30% trichloroacetic acid (TCA; store at 4°C), ice cold
For optional steps:
  20 mg/ml proteinase K (store at −20°C)
  Nonionic detergent: e.g., 20% Triton X-100 or Nonidet P-40 (NP-40; store at −20°C)
  25% sodium dodecyl sulfate (SDS; store at room temperature)
  1 M dithiothreitol (DTT; *APPENDIX 2A*)
  Buffer D (see recipe)
  Endoglycosidase H (purchased as solid or stock solution)
  100 mM sodium carbonate, pH 11.5, ice cold
  Glacial acetic acid
1× SDS sample buffer (*APPENDIX 2A*)

Water bath or heating block, 26° or 30°C and (for optional step) 100°C
Tabletop ultracentrifuge and rotor (e.g., Beckman TLA 100.2 rotor; for optional step)

Additional reagents and solutions for in vitro translation (*UNIT 11.2*) and one-dimensional SDS-PAGE (*UNIT 6.1*)

1. Determine the number and total volume of in vitro translation reactions that are required for a given experiment (*UNIT 11.2*). Keeping all reagents on ice, make a master translation mix of the components that are going to be needed in all reactions (e.g., wheat germ extract, radioactive amino acids). Pipet the appropriate amount of master mix into each reaction tube, including tubes to be used for control reactions.

   Making a master mix considerably diminishes pipetting errors and reduces the number of pipetting steps needed to set up the reactions. It is a good idea to include separate control reactions lacking mRNA and lacking RMs. Because translocation of proteins into RMs is often highly efficient, small reaction volumes (e.g., 10 µl) are generally sufficient. Small-scale reactions should be performed in 0.5-ml microcentrifuge tubes. Larger reaction volumes can be used in cases where reactions are to be divided for post-translational treatments (e.g., digestion with endoglycosidase H).

2. Add 0.1 to 1 eq of RMs (0.1 to 1 µl of solution) per 10 µl of translation mix to each reaction; for RM-free control reactions, add an equivalent volume of buffer C instead. Then add appropriate amounts of mRNA (or, for RNA-free controls, buffer C). Incubate the reactions 40 to 60 min at 26°C for wheat germ reactions, or 30°C for rabbit reticulocyte translations.

   Generally 10 to 50 ng of an efficiently translated mRNA per 10 µl of translation mix will give a good signal, but higher amounts can also be added.

   The concentration of RMs that is added to the reaction is generally not critical, but in some cases it may be necessary to determine an optimal concentration empirically. Use one that promotes efficient translocation of a given protein and has a minimal inhibitory effect on the translation reaction. Addition of an equimolar amount of an mRNA that encodes a cytoplasmic protein (e.g., globin) to each reaction serves as a good control.

3. Stop the reactions by transferring the tubes to an ice bath.

4. If post-translational treatment(s) of the samples (e.g., protease digestion) are desired, proceed to steps 5, 6, and/or 7. Otherwise, precipitate the proteins by adding 1 vol of 30% TCA and incubating 10 min on ice; then proceed to step 8.
5. *To show that a protein or domain has been transported into the RM lumen (optional):*
   a. Add proteinase K to 100 µg/ml (final concentration). Incubate separate aliquots in the presence and in the absence of 0.5% to 1% nonionic detergent for 30 to 60 min at 0°C.
   b. Stop the protease digestion by adding 2 mM PMSF (final). Incubate an additional 15 min at 0°C.
   c. Precipitate proteins with 30% TCA (see step 4).

      As an additional control, addition of detergent will lyse the RMs and expose a translocated protein to protease digestion. Optionally, addition of 1 mM $CaCl_2$ to the samples prior to protease digestion can help to stabilize the membranes and may increase the yield of protease-protected protein.
6. *To remove N-linked carbohydrates from translocated proteins (optional):*
   a. Add 2% SDS and 75 mM DTT (final concentrations). Boil samples for 3 min.
   b. Dilute samples 20-fold in buffer D and add 1 µg/ml endoglycosidase H (final). Incubate 12 to 16 hr at 37°C.
   c. Precipitate proteins using 30% TCA (see step 4).

      Although endoglycosidase H is most commonly used, other glycosidases that remove N-linked carbohydrates (e.g., endoglycosidase F) can be substituted.
7. *To test for membrane integration (optional):*
   a. Dilute translation reactions 100-fold with ice-cold 100 mM sodium carbonate, pH 11.5. Incubate 30 min on ice.
   b. Centrifuge 30 min at 360,000 × g_{av} (100,000 rpm in a Beckman TLA 100.2 tabletop ultracentrifuge rotor), 4°C.
   c. Carefully remove the supernatant and neutralize with glacial acetic acid. Precipitate proteins with 30% TCA (see step 4).
   d. Meanwhile, dissolve the pellet, containing ribosomes and membrane fragments, directly in 1× SDS sample buffer (this can be run on an SDS-polyacrylamide gel without further manipulation).

   After the centrifugation, integral membrane proteins will be found in the pellet but soluble proteins will be found in the supernatant.

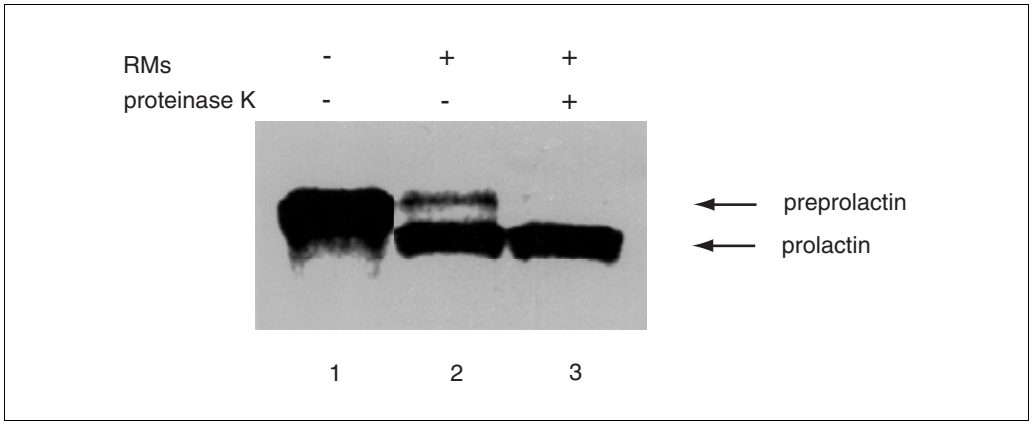

Figure 11.4.1 Translocation of preprolactin into canine pancreatic RMs. An mRNA encoding bovine preprolactin was translated in a wheat germ extract in the absence of microsomes (lane 1) or in the presence of RMs (lanes 2 and 3). After the translation was stopped, proteinase K was added to the sample shown in lane 3.

8. Pellet precipitated proteins by microcentrifuging 5 min at full speed, 4°C. Remove supernatant carefully. Boil in 1× SDS sample buffer for 3 to 5 min or until the pellet is dissolved.

   If the TCA is not removed carefully, the samples may remain acidic (the bromphenol blue in the sample buffer will turn yellow). This problem can be remedied by adding small amounts of 1 M Tris base.

9. Assess protein translocation and modification by SDS-polyacrylamide gel electrophoresis (*UNIT 6.1*).

   The gel shown in Figure 11.4.1 illustrates how protein translocation can be assessed by this method. In the absence of RMs, an mRNA encoding bovine preprolactin directs the synthesis of a 26-kDa protein (lane 1). In the presence of microsomes, efficient translocation of the preprotein results in the removal of the signal sequence and the production of the faster-migrating prolactin form (lane 2). In the presence of proteinase K, essentially all of the prolactin is protected from digestion, but residual untranslocated preprolactin is degraded (lane 3).

SUPPORT PROTOCOL 1

PREPARATION OF RMs FROM CANINE PANCREAS

This protocol describes the isolation of RMs from canine pancreas. The extremely high yield, purity, and translocation competence of RMs obtained from canine pancreas makes it an ideal source for these vesicles. In the method described here, the cells of the pancreas are first disrupted by homogenization. Then nuclei, secretory granules, plasma membranes, and mitochondria are removed to produce a "post-mitochondrial supernatant" containing Golgi and vesicular fragments of ER produced by shearing. The RMs are pelleted through a discontinuous sucrose gradient and resuspended in a buffer that is compatible with their use in protein translocation assays.

NOTE: All steps in this protocol (except dissection and centrifugation) should be performed in a cold room at 4°C. Because it is important to work as quickly as possible after dissecting the pancreas and to keep the tissue cold, all solutions should be prechilled and all equipment and glassware should be placed in the cold room in advance.

Materials

Buffer A (see recipe), ice cold
Dog (e.g., beagle weighing 10 to 12 kg)
Buffer B (see recipe), ice cold
Buffer C (see recipe), ice cold
1% (w/v) SDS (*APPENDIX 2A*), ice cold
Liquid nitrogen

Dissecting tools: small scissors, regular and fine forceps, scalpel (with new blade)
Small plastic cutting board
Single-edge razor blades (at least 5)
Potter-Elvejhem-style tissue homogenizer (e.g., B. Braun Biotech) with 60-ml cylinder and matched Teflon plunger
50-ml polycarbonate or polypropylene centrifuge tubes (~28.5-mm diameter)
Medium-speed centrifuge and rotor (Sorvall SS-34 or Beckman JA20, or equivalent)
25 × 89–mm (26-ml) polycarbonate ultracentrifuge bottles with tops
10-ml glass syringe fitted with a round-tipped pipetting needle
Ultracentrifuge and rotor (Beckman Ti 50.2 or equivalent)
60-ml Dounce homogenizer fitted with type A pestle

Homogenize the pancreas

1. Cover work area with absorbent plastic-coated bench covering. Place ~100 ml ice-cold buffer A (enough to keep the tissue covered) in a 250-ml glass beaker and immerse in ice until fully chilled.

2. Sacrifice the dog, then make a large ventral incision into the abdominal cavity and isolate the pancreas. Dissect the pancreas as quickly as possible and immediately transfer it to the beaker of ice-cold buffer A.

   The pancreas is an elongated, lobulated, pinkish-gray organ that runs along the small intestine and stomach. To locate it, displace the liver and find the stomach. The pancreas will reside at the junction of the stomach and descending duodenum. Grasp the pancreas and gradually detach it from other tissues. The portion of the pancreas that is attached to the duodenum ("right lobe") is most accessible and should be detached first. Generally it is helpful to have a second person keep the pancreas exposed by holding or pushing away other organs.

   If available, tissue can be obtained from dogs that are used as research subjects in other projects. Most common anesthetics, methods of sacrifice, and experimental manipulations that do not affect pancreatic function are compatible with the isolation of translocation-competent RMs. It is absolutely essential, however, to remove the pancreas as quickly as possible after sacrifice to avoid tissue necrosis and degradation of ER components that are required for protein translocation. Provided that the animal is in good health, age and sex do not appear to have a significant effect on the isolation of RMs. Because the weight of the pancreas correlates with the size of the animal, the largest quantities of RMs are obtained from large dogs.

3. Rinse the pancreas in fresh ice-cold buffer A to remove blood and other debris. Place the pancreas on a piece of Parafilm. Using a scissors and fine forceps, remove major blood vessels and adipose and connective tissues from the pancreas.

   The Parafilm will help to visualize fat and connective tissue that is connected to the pancreas. It is critical to clean the pancreas carefully because extraneous tissues can interfere with effective homogenization. It is also important, however, to work rapidly to minimize necrosis of the pancreas.

4. Weigh the pancreas (keeping it in a chilled beaker) and mince finely using fresh razor blades. Change razor blades often as they become dull.

   The pancreas of a 10- to 12-kg dog typically weighs 20 to 30 g.

5. Place the tissue pieces in a clean beaker and add a volume of ice-cold buffer A equal to four times the weight of the pancreas.

6. Stir the tissue pieces and buffer together to create a uniform mixture. Homogenize 60-ml aliquots of the mixture using a motor-driven Potter-Elvejhem-style instrument.

   Five complete up-and-down strokes is generally sufficient to break the cells effectively. It is essential to avoid significant heating of the homogenate during this step; for this reason instruments in which the homogenizer cylinder fits into a container that can be filled with ice (e.g., the unit made by B. Braun Biotech) are recommended.

Isolate RMs

7. Pour the homogenate into a clean beaker and mix well, then transfer to 50-ml centrifuge tubes. Centrifuge 10 min at $700 \times g_{av}$ (3000 rpm in a Sorvall SS-34 or Beckman JA-20 rotor), 4°C.

8. Carefully remove the fat layer at the top of each centrifuge tube by aspiration, then pour the supernatants into a clean beaker. Mix the pooled supernatants well and transfer to clean 50-ml centrifuge tubes. Centrifuge 10 min at $8000 \times g_{av}$ (10,000 rpm in a Sorvall SS-34 or Beckman JA-20 rotor), 4°C.

9. Pour the "post-mitochondrial" supernatants into a clean beaker.

The pellets that are formed after the second centrifugation step are very soft, so pour off the supernatants carefully.

10. Pipet 16 ml of the pooled supernatants (cell extract) into 25 × 89–mm (26-ml) polycarbonate ultracentrifuge bottles.

11. Fill a 10-ml glass syringe fitted with a round-tipped pipetting needle with 8 ml ice-cold buffer B. Underlay the cell extract with this buffer. Close the bottles and centrifuge 2.5 hr at 145,000 × g_{av} (40,000 rpm in a Beckmann 50.2 Ti rotor), 4°C.

In this centrifugation step the RMs should form a tight pellet. If substantial degradation of microsomal proteins and attached ribosomes occurs during the preparation, a tight pellet will not be formed; such samples should be discarded.

12. Remove the top layer carefully by aspiration and discard. Next, remove the broad cloudy band at the interface, which is enriched with Golgi. Finally, remove the buffer B cushion.

13. Add a few milliliters of ice-cold buffer C to each tube and resuspend the pelleted RMs with a rubber policeman. Transfer the resuspended pellets to a 60-ml Dounce homogenizer. Collect residual RMs by washing the tubes with a few more milliliters of buffer C.

The total volume of buffer C used to resuspend the RMs should not exceed 80% of the initial weight of the pancreas. The large off-white pellets will be resuspended as large clumps that require further dispersal.

14. Disperse the RMs in the Dounce homogenizer using five complete up-and-down strokes. Transfer the RMs to a clean 100-ml graduated cylinder.

15. Remove two 10-µl aliquots and add each to 1 ml ice-cold 1% SDS; wipe off the the pipet tip before adding its contents to the SDS solution, because a considerable volume will stick to the outside. Pipet back and forth several times to transfer all of the RMs from inside the tip.

16. Read the absorbance of each sample at 280 nm. Using the average of the two readings, adjust the concentration of the microsomes to 50 A_{280} U/ml.

By definition this solution contains one equivalent (eq) of RMs per microliter.

17. Split the RMs into aliquots of an appropriate size and freeze in liquid nitrogen.

After adjusting the concentration of RMs as described here, the final yield should be ~1 to 1.5 ml per gram of pancreas. The RMs can be frozen and thawed at least several times without loss of activity, so a single aliquot can be used for multiple experiments.

SUPPORT PROTOCOL 2

PREPARATION OF EDTA-STRIPPED ROUGH MICROSOMES

When RMs are added to reticulocyte lysate translations, a high background of polypeptide synthesis can sometimes result from the readout of mRNAs that are attached to membrane-bound polysomes. To solve this problem, membrane-bound ribosomes can be removed by a simple EDTA treatment.

NOTE: All steps in this protocol should be performed in a cold room at 4°C. All solutions should be prechilled and all equipment and glassware should be placed in the cold room in advance.

Additional Materials *(see Support Protocol 1)*

Crude RM fraction (see Support Protocol 1)
Buffer C (see recipe)/50 mM EDTA, ice cold
Buffer C/0.5 M sucrose, ice cold

1. Add 1 vol buffer C/50 mM EDTA to a crude RM fraction. Incubate 15 min at 0°C.
2. Place sucrose cushion, consisting of buffer C/0.5 M sucrose, that is approximately half the volume of the RM mixture, into an ultracentrifugal tube. Carefully load the RMs over the sucrose cushion using a pipet, holding the pipet against the side of the tube to avoid disturbing the cushion. Centrifuge 1 hr at 145,000 × g_{av} (40,000 rpm in a Beckmann 50.2 Ti rotor), 4°C.
3. Resuspend the pelleted membranes to half their original volume in buffer C (without EDTA or sucrose). Disperse the vesicles in a Dounce homogenizer (see Support Protocol 1, steps 13 and 14) and transfer to a graduated cylinder.
4. Adjust to the original volume with buffer C. The stripped RMs are now ready to be used or stored.

PREPARATION OF COLUMN-WASHED ROUGH MICROSOMES

SUPPORT PROTOCOL 3

Occasionally batches of RMs can inhibit in vitro translation reactions. This problem can be solved by separating the RMs from ribosomes and other contaminants using a gel filtration column.

NOTE: All steps in this protocol should be performed in a cold room at 4°C. All solutions should be prechilled and all equipment and glassware should be placed in the cold room in advance.

Additional Materials *(also see Support Protocol 1)*

Sepharose CL-2B resin (Pharmacia Biotech)
Buffer E (see recipe), ice cold
Crude RM fraction (see Support Protocol 1)
Chromatography column of volume equivalent to ten times the volume of RMs to be treated
Ultracentrifuge and rotor (Beckman 45 Ti rotor or equivalent)

1. Prepare a Sepharose CL-2B column with a column volume equivalent to ten times the volume of RMs to be treated. Equilibrate with several column volumes buffer E.
2. Load RMs onto Sepharose CL-2B column.
3. Collect fractions that represent the void volume.
4. Pool the turbid fractions and centrifuge 30 min at 85,000 × g_{av} (35,000 rpm in a Beckman 45 Ti rotor), 4°C.
5. Resuspend the pelleted membranes to half their original volume in buffer C.
6. Disperse the vesicles in a Dounce homogenizer (see Support Protocol 1, steps 13 and 14) and transfer to a graduated cylinder.
7. Adjust to the original volume with buffer C. The washed RMs are now ready to be used or stored.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****. Adjust the pH of all stock solutions with acetic acid.*

Buffer A

50 mM triethanolamine, pH 7.5
50 mM potassium acetate, pH 7.5
6 mM magnesium acetate
1 mM EDTA
250 mM sucrose
1 mM DTT (added immediately before use; *APPENDIX 2A*)
0.5 mM PMSF (added immediately before use; *APPENDIX 2A*)

Store solution without DTT and PMSF indefinitely at 4°C.

Preparation of one canine pancreas requires 500 ml of buffer A.

Buffer B

50 mM triethanolamine, pH 7.5
6 mM magnesium acetate
1 mM EDTA
1.3 M sucrose
1 mM DTT (added immediately before use; *APPENDIX 2A*)
0.5 mM PMSF (added immediately before use; *APPENDIX 2A*)

Store solution without DTT and PMSF indefinitely at 4°C.

Preparation of one canine pancreas requires 100 ml of buffer B.

Buffer C

50 mM triethanolamine, pH 7.5
250 mM sucrose
1 mM DTT (added immediately before use; *APPENDIX 2A*)

Store solution without DTT indefinitely at 4°C.

Preparation of one canine pancreas requires 100 ml of buffer C.

Buffer D

50 mM triethanolamine, pH 7.5
1.5 mm magnesium acetate
1 mm EDTA
1 mM DTT (added immediately before use; *APPENDIX 2A*)

Store solution without DTT indefinitely at room temperature.

Buffer E

100 mM sodium citrate, pH 5.5
0.5 mM PMSF (added immediately before use; *APPENDIX 2A*)

Store solution without PMSF indefinitely at room temperature.

COMMENTARY

Background Information

Pioneering studies conducted by Palade and co-workers in the 1960s demonstrated that proteins that travel through the secretory pathway in mammalian cells are synthesized on endoplasmic reticulum (ER)–bound ribosomes and are translocated across the ER membrane (Palade, 1975). The subsequent discovery that the transport of proteins across the ER membrane, and the associated modifications, can be reproduced in vitro by adding rough microsomes (RMs) to heterologous cell-free translation reactions (Blobel and Dobberstein, 1975; Katz et al., 1977) was a remarkable breakthrough. These studies led to the development of methods for assessing protein translo-

cation (signal-sequence cleavage, glycosylation), formulation of the "signal hypothesis" (the idea that proteins contain sequence information that earmarks them for transport into the ER), and molecular dissection of the transport process itself.

Current understanding of the molecular mechanism whereby proteins are targeted to and translocated across the ER membrane has been derived largely from experiments in which canine pancreatic RMs have been added to wheat germ translation reactions. In early studies it was shown that a soluble ribonucleoprotein complex called the signal recognition particle (SRP) is required for protein transport into RMs. SRP recognizes the signal sequences of secreted proteins as they emerge from translating ribosomes (Walter and Blobel, 1981) and then targets ribosome-nascent chain complexes to the ER via an interaction with the ER-bound SRP receptor. Because SRP binds only to signal sequences that are part of a nascent polypeptide chain, protein translocation does not occur if microsomes are added post-translationally. The interaction between SRP and the SRP receptor facilitates release of the nascent chain (Gilmore et al., 1982; Meyer et al., 1982) and its insertion into a proteinaceous translocation channel comprised of the heterotrimeric Sec61p complex and an auxiliary protein called TRAM (Görlich et al., 1992; Görlich and Rapoport, 1993). Available evidence suggests that the translocation channel has properties associated with gated ion channels (Simon and Blobel, 1991; Crowley et al., 1994). During translocation, signal sequences are cleaved by the hexameric signal peptidase complex (Evans et al., 1986) and N-linked sugars are attached by the heterotrimeric oligosaccharyl transferase (Kelleher et al., 1992).

In addition to providing information about protein localization in vivo and insight into the mechanism of protein transport, the translocation assay described here has many other applications. Because signal-sequence processing occurs faithfully in vitro, N-terminal sequencing of the mature portion of a protein can be used to locate the signal-sequence cleavage site. For the large class of proteins that do not have an N-terminal signal sequence, deletion analysis can be performed to identify targeting sequences, as demonstrated, for example, by the work of Spiess and Lodish (1986). In addition, protease protection analysis following the insertion of membrane proteins can be used to study the topology of membrane proteins, which often cannot be deduced from the primary amino acid sequence (see, for example, Lipp and Dobberstein, 1986; Gafvelin et al., 1997).

Although canine pancreas is the most common source of RMs used in protein translocation studies, translocation-competent RMs have also been derived from a wide variety of other tissues including sheep pancreas (Kaderbhai et al., 1995), rat liver (Bielinska et al., 1979), ascites tumor cells (Bielinska et al., 1979), hen oviduct (Das et al., 1980), and *Drosophila* embryos (Brennan et al., 1980). Translocation-competent microsomes have also been obtained from *Saccharomyces cerevisiae* (Hansen et al., 1986), but these vesicles promote a post-translational, SRP-independent translocation reaction. Attempts to isolate translocation-competent microsomes from pig, rat, fish, and cow pancreas have not been successful (Kaderbhai et al., 1995; P. Walter, pers. comm.). At least in some of these cases it appears that the presence of high concentrations of endogenous ribonucleases destroys the integrity of the RMs. The ability to isolate translocation-competent RMs from different sources may facilitate the analysis of tissue-specific protein translocation or protein modification phenomena.

Most methods for isolating RMs are based on the observation that the attachment of ribosomes to rough ER imparts an especially high density to vesicles derived from that organelle. This high density facilitates purification of RMs on a discontinuous density gradient. In the method described here, RMs are pelleted through a 1.3 M sucrose layer whereas "smooth" microsomes, comprised mostly of Golgi and smooth ER, float at the interface between the low- and high-sucrose layers. This method works well for the isolation of RMs from specialized secretory organs such as the pancreas in which a very large percentage of the total membrane is rough ER. In a successful preparation, >90% of the high-density pellet is comprised of RMs; contamination with free ribosomes and other cellular components is minimal. Alternatively, RMs can also be purified by flotation on a very high-density (2 M) sucrose layer (Mechler and Vassalli, 1975; Behrens et al., 1996). This also yields highly purified RMs, but has the disadvantage that the vesicles may be recovered in a larger volume than desired and may require concentration by centrifugation. This method may be particularly useful in cases where pelleting the RMs would lead to unwanted contamination with free ribosomes or other cellular components.

Critical Parameters and Troubleshooting

It is essential to homogenize the pancreas effectively to obtain a good yield of RMs. Although it is neither necessary nor practical to remove all of the connective tissue and fat associated with the pancreas, excess extraneous tissue can interfere with homogenization. A good way to minimize this problem is to mince the pancreas as finely as possible before homogenization. Pieces of pancreas that prove difficult to disrupt can be removed from the homogenizer and minced again. In pelleting RMs through a sucrose cushion, the rotor and the size of the centrifuge bottles are not critical. It is important, however, to have a 2:1 to 3:1 ratio of cell extract to sucrose cushion to ensure a good separation of the large RM pellet from the smooth microsome interface.

It is very likely that pancreatic RMs obtained at the expected yield (see Support Protocol 1) will work well in translocation assays. Because the efficiency of translocation and glycosylation of different proteins can vary (see Anticipated Results), a new batch of RMs should be tested for activity using a protein that is known to be a good translocation/glycosylation substrate (e.g., preprolactin or influenza hemagglutinin). Sometimes RMs can inhibit translation or give rise to a high background of unwanted protein synthesis, but these problems can generally be eliminated by pretreating the RMs (see Support Protocols 2 and 3). Translocation assays can also be difficult to interpret if the translation reaction itself is inefficient. The optimization of translation conditions is discussed in *UNIT 11.2*.

Anticipated Results

Many but not all proteins are translocated across or inserted into canine RMs with high efficiency (50% to 100%). A few secreted proteins, in particular those that contain unusual signal sequences, are translocated very poorly under the conditions described here (Belin et al., 1996). It is possible that proteins in this class require as yet unidentified tissue-specific factors to promote their translocation.

Whereas signal-sequence cleavage is extremely effective in vitro, the efficiency of core glycosylation is much more variable. In some cases only a small fraction of translocated protein is glycosylated. Because glycosylation is often incomplete, several different partially modified forms of a protein that has multiple glycosylation sites may be observed on polyacrylamide gels. Post-translational treatment of translocation reactions with protease (see Basic Protocol, step 5) will reduce the translational background and may facilitate the visualization of weakly glycosylated forms.

A single pancreas from a 10- to 12-kg dog should weigh 20 to 30 g and yield a high-density pellet that is >90% rough microsomes with minimal contamination from free ribosomes and other cellular components. This preparation yields sufficient rough microsomes for many thousands of small-scale assays (using 1 µl of microsomes per reaction).

Time Considerations

The preparation of canine RMs (Support Protocol 1) can be completed in ~5 to 6 hr. The time required depends in part on the size of the pancreas; it takes longer to process a larger amount of tissue. Dissection of the pancreas, homogenization, and preparation of the post-mitochondrial supernatant requires ~1.5 to 2 hr of continuous work. Glassware and buffer C should be chilled during the subsequent 2.5-hr centrifugation step, but otherwise no work is required. Resuspension of the RMs and adjustment of the RM concentration should require <1 hr of hands-on time.

The time required to perform cotranslational translocation assays and post-translational treatments varies widely. A simple experiment involving a small number of reactions may be completed in 1.5 to 2 hr. The reactions can be assembled in <10 min. After a 40- to 60-min incubation period, an additional 20 min is required to precipitate and collect the proteins. A complex experiment with a large number of samples and different post-translational treatments may require a couple of hours of hands-on work plus incubation times (endoglycosidase H digestion usually requires an overnight incubation). The individual components of the translation and translocation reaction are very stable at 0°C, so the length of time required to assemble the reactions is not a concern. In addition, the incubation time for the translation-translocation reaction is not critical. These reactions are limited by the duration of the protein synthesis reaction, which is generally ~60 min. Shorter incubations will produce a lower signal but otherwise will give essentially the same results. After proteins are precipitated, samples may be left on ice for several hours. After the proteins are pelleted and the TCA is removed, the pellets are stable at −80°C for at least 1 week.

Both EDTA stripping of RMs (Support Protocol 2) and column washing of RMs (Support

Protocol 3) should take ~2 hr, although the time required for the latter procedure will depend to some extent on the flow rate of the column.

In Vitro Analysis of SV40 DNA Replication

The early studies of bacterial DNA replication provided a platform for constructing the theory of eukaryotic DNA replication. In the absence of well-defined origins of DNA replication, however, study of the eukaryotic DNA replication was almost impossible until the efficient cell-free system that supported replication from the SV40 origin of replication was developed. The system was designed to bypass the de novo replication initiation by providing SV40 origin of replication and viral initiator protein T antigen in the presence of replication-competent extract. Replication is carried out completely by cellular proteins in the presence of the viral helicase T antigen and viral origin–containing plasmid. Replication initiates at the replication origin, which is recognized by T antigen, and proceeds bilaterally in a semiconservative manner. Many cellular replication proteins have been identified through study of the SV40 replication system.

This unit outlines general methods for in vitro SV40 DNA replication and product analysis, including incorporation of nucleotides by binding to DE81 paper (see Basic Protocol) and visualization of products after alkaline denaturing gel electrophoresis (see Alternate Protocol); methods for growing a large suspension culture for the extract (see Support Protocol 1) and for preparing a replication-competent S100 cell extract from 293 cells (see Support Protocol 2); support information for the expression of T antigen in insect cells (see Support Protocol 3); and procedures for purifying T antigen from baculovirus-infected insect cells (see Support Protocol 4) and preparing the Pab419 immunoaffinity column used for the purification (see Support Protocol 5).

IN VITRO REPLICATION OF PLASMIDS BEARING SV40 ORIGIN SEQUENCES

BASIC PROTOCOL

This protocol is used to study in vitro SV40 replication. The reaction consists of a mixture of T antigen and replication-competent S100 cell extract in the presence of SV40 origin–containing plasmid and [α^{32}P]ATP. Radiolabeled reaction products are analyzed by liquid scintillation counting. The reaction products can also be analyzed by agarose gel electrophoresis and autoradiography (see Alternate Protocol).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

Materials

5× replication buffer (see recipe)
Supercoiled SV40 origin–containing DNA template
2 U/µl creatine phosphokinase in 10 mM Tris·Cl, pH 8.0/50% (w/v) glycerol
Recombinant T antigen (see Support Protocol 4)
[α^{32}P]dATP (800 or 6000 Ci/mmol; final volume 0.0125 ml)
Replication-competent S100 cell extract (see Support Protocol 2)
DE81 paper (Whatman)
0.5 M Na_2HPO_4
100% ethanol
Scintillation cocktail

Contributed by Yi-Ling Lin and Anindya Dutta
Current Protocols in Cell Biology (1999) 11.5.1-11.5.12

1. Set up a reaction in a microcentrifuge tube containing:

   10 µl 5× replication buffer
   300 ng supercoiled SV40 origin–containing DNA template
   0.1 µl 2 U/µl creatine phosphokinase
   0.7 µg T antigen
   0.05 µl [α^{32}P]dATP (~200 to 1000 cpm/pmol)
   5 to 20 µl replication-competent S100 cell extract
   H_2O to 50 µl.

   Incubate 1 hr at 37°C.

   A negative control without T antigen should be included in the reaction, and the result should be treated as a baseline. Titration of the S100 is recommended to obtain optimal conditions for the reaction. Trichloroacetic acid precipitation can also be used for quantification of incorporated radioactivity.

   Because the volume of reagents in a single replication reaction is often minute, it can be helpful to make a master mix before setting up the reactions. The specific activity is determined as follows (where 125 pmol is the amount of dATP present in one-tenth input):

   cpm of one-tenth input from master mix for each reaction ÷ 125 pmol

   The replication assay can also be done with purified replication proteins, protein fractions, or combinations instead of the S100 cell extract. The reaction buffer and conditions for SV40 replication remain the same.

2. Stop the reaction by placing tubes on ice.

   The sample can then be analyzed for incorporation of radioactivity and by agarose gel electrophoresis and autoradiography (see Alternate Protocol).

3. Draw a grid of 1 × 1-cm squares on a sheet of DE81 paper and label the squares accordingly.

4. Spot 5 µl (one-tenth of output) of each reaction on the corresponding 1 × 1–cm square of DE81 paper.

   Do not allow the spots to dry.

5. Wash DE81 paper successively three times with 0.5 M Na_2HPO_4, once with double-distilled water, and once with 100% ethanol, 5 min per wash.

6. Dry paper with hair dryer or table lamp. Cut and put the squares in scintillation vials.

7. Add liquid scintillation cocktail. Count the radioactivity on squares. To determine specific activity of dATP, spot one-tenth of master mix on a square and count without washing; then calculate specific activity as described in step 1.

8. Determine the amount of dAMP incorporated in each reaction (in picomoles) using the following formula:

   [(cpm of the DE81 square) × 10] ÷ specific activity.

ALTERNATE PROTOCOL

ANALYSIS OF DNA REPLICATION REACTION PRODUCTS BY ALKALINE DENATURING AGAROSE GEL

Reaction products can also be analyzed by alkaline denaturing agarose gel electrophoresis to visualize the replicated DNA. Alternatively, one can analyze the replication products using a regular TAE or TBE agarose gel; however, the size range of nascent DNA products cannot be appreciated when using a nondenaturing gel.

Additional Materials *(also see Basic Protocol)*

3× stop solution (see recipe)
20 mg/ml high-quality glycogen (Life Technologies)
5 M NaCl (*APPENDIX 2A*)
TE buffer, pH 8.0 (*APPENDIX 2A*)
Agarose
1 N NaOH
0.5 M EDTA (*APPENDIX 2A*)
2× alkaline loading buffer (see recipe)
Alkaline running buffer, made fresh (see recipe)
7% trichloracetic acid (TCA)

Additional reagents and equipment for phenol/chloroform extraction and ethanol precipitation of DNA (*APPENDIX 3*), agarose gel electrophoresis (*APPENDIX 3*), and autoradiography (*UNIT 6.3*)

1. Perform in vitro replication reaction (see Basic Protocol, step 1).
2. Add ⅓ vol of 3× stop solution to the replication reaction. Incubate the reaction 30 min at 37°C for protein digestion.
3. Dilute the reaction volume to 100 µl with water. Remove the proteins by phenol/chloroform extraction.
4. Precipitate the DNA by adding 1 µl of 20 mg/ml high-quality glycogen (as carrier) and 250 µl of 100% ethanol.
5. Microcentrifuge 10 min at room temperature or 4°C, discard supernatant, and dissolve the DNA pellet in TE buffer.
6. Make a 1% (w/v) alkaline agarose gel: dissolve agarose in water by microwaving, cool the gel to 50°C, and add 1 N NaOH and 0.5 M EDTA to final concentrations of 30 mM and 1 mM, respectively.

   Do not microwave agarose with NaOH, as this will prevent the gel from solidifying.
7. Add 1 vol of 2× alkaline loading buffer to tube and add the DNA samples. Run gel at 2 to 7 V/cm in freshly made alkaline running buffer.
8. Stop electrophoresis when xylene cyanol has migrated two-thirds of the length of the gel (12 to 14 hr). Neutralize gel in 7% TCA 30 min at room temperature.

   Do not shake, as this may allow the solution to splash, contaminating the shaker with isotope.
9. Vacuum dry gel at low temperature (60°C) and autoradiograph (see *UNIT 6.3*).

PREPARING 293 CELL SUSPENSION CULTURE

SUPPORT PROTOCOL 1

This protocol provides guidance for expanding cells from a small-scale monolayer to a large-scale spinner culture for S100 cell extract. The cells are split to 1×10^5 cells/ml whenever the concentration reaches $0.5–1 \times 10^6$ cells/ml and are periodically checked for viability and density.

Materials

Ten 10-cm plates of confluent 293 cell culture
DMEM with 5% (v/v) calf serum
Joklik's medium (JRH Bioscience) with 5% (v/v) calf serum

Additional reagents and equipment for trypsinizing monolayer cells (*UNIT 1.1*), counting cells, and assessing viability (*UNIT 1.1*).

1. Trypsinize 10-cm plates of confluent 293 cells (*UNIT 1.1*). Resuspend the trypsinized cells from ten 10-cm plates in variable amount of medium.
2. Pool cells together and determine cell count by hemacytometer.
3. Inoculate cells at a density of 1×10^5 cells/ml in suitably sized spinner flask, and maintain as suspension culture in Joklik's medium.

   A good way to check if the cells are maintained as a suspension culture is to examine a drop of the culture under a light microscope: The cells should be individualized and round.

4. Monitor cells regularly (every 3 days) for viability (by Trypan blue; see *UNIT 1.1*) and density.
5. When cell density reaches 1×10^6 cells/ml, split cells by adding Joklik's medium directly to the growing cells to adjust their density to 1×10^5 cells/ml. Change to a bigger container when culture exceeds the recommended volume of the flask. Repeat this step several times, until there are enough cells for a 10-liter inoculation.
6. Split each 10-liter culture into one 8-liter and one 2-liter spinner culture. Check cell viability and density regularly (every 3 days).
7. When the cell density reaches 1×10^6 cells/ml, harvest the 8-liter culture for S100 cell extract, and split the 2-liter culture for another round of 10-liter inoculation (2 liters + 8 liters).

   Maintain a 2-liter suspension culture of 293 cells to significantly shorten the time required for preparation of lab stock S100.

SUPPORT PROTOCOL 2

PREPARATION OF A REPLICATION-COMPETENT S100 CELL EXTRACT

This protocol describes how to make replication-competent cytosolic cell extracts from an exponentially growing 293 suspension culture. The replication-competent S100 cell extract is used to provide replication factors in the reaction mix.

Materials

8 liters mid-log-phase 293 cells (see Support Protocol 1)
PBS (*APPENDIX 2A*), 4°C
Hypotonic lysis buffer (see recipe), 4°C
5 M NaCl
Protein assay dye reagents (Bio-Rad)

IEC PR7000 and rotor or equivalent
IEC Clinical centrifuge or equivalent
40-ml Dounce homogenizer (type B pestle)
RC5B Sorvall centrifuge with SS34 rotor
Beckman ultracentrifuge with SW 55.1 rotor

Harvest cells

1. Harvest cells from 8 liters of mid-log-phase 293 cells at 0.5–1×10^6 cells/ml by centrifuging cells in six 1-liter centrifuge bottles 20 min at $1000 \times g$, 4°C, in an IEC PR7000 or equivalent.
2. Carefully decant supernatant, and add more 293 cell culture to the centrifuge bottles until all culture has been pelleted. Carefully decant supernatant until a small amount of medium is left.

3. Resuspend pellets with residual medium, and transfer suspension into several 50-ml centrifuge tubes.
4. Centrifuge in an IEC Clinical centrifuge or equivalent 10 min at 1000 × *g*, 4°C, and resuspend each pellet with 15 ml cold PBS. Combine resuspended pellets and repeat centrifugation until all cells fit in one tube.

   This normally yields about a 10-ml cell pellet.

Lyse the cells

5. Resuspend the pellet with an equal volume (~10 ml) of freshly prepared hypotonic buffer, 4°C. Pellet the cells in the Clinical centrifuge for 10 min at 1000 × *g*, 4°C, and remove the supernatant.
6. Resuspend pellets in an equal volume of hypotonic buffer, 4°C, and incubate 10 min on ice to swell the cells.
7. Lyse cells by 30 strokes of Dounce homogenizer (with a type B pestle) on ice. Incubate the lysate 30 min on ice.

   The cell lysis may be checked under a microscope.

8. Transfer the lysate into a 30-ml Corex tube, and centrifuge in an SS34 rotor of a Sorvall RC5B centrifuge 10 min at 17,000 × *g*, 4°C. Save both supernatant and pellet. Store the pellet (which contains the nuclei) at −70°C.

   This pellet contains nuclear proteins, which are useful for many other purposes.

9. Measure the volume of the supernatant, and adjust the concentration to 0.1 M NaCl with 5 M NaCl. Divide the supernatant into several SW55.1 Beckman ultracentrifuge tubes, and centrifuge 1 hr at 100,000 × *g*, 4°C.

   Replication factor C (RF-C) is unstable in low salt.

10. Measure protein concentration of the extracts by Bio-Rad protein assay dye reagent, and divide into desired (~500-µl) aliquots. Snap freeze the extract and store at −70°C.

    This protocol usually yields 5 to 10 ml extract, with a protein concentration of 20 to 30 mg/ml. For the assay to work, the protein concentration of the extract must be ≥10 mg/ml.

EXPRESSION OF RECOMBINANT T ANTIGEN

SUPPORT PROTOCOL 3

Insect cells infected with recombinant T antigen baculovirus are used to express T antigen, which is then purified by immunoaffinity chromatography (see Support Protocol 4). The recombinant virus is not commercially available; however, most researchers will share cells.

Materials

Insect cells (Hi-five cells, Invitrogen)
Grace's medium with 10% fetal bovine serum (FBS)
Recombinant T antigen baculovirus stock, high titer
Serum-free medium

1. Seed ten 150-mm tissue culture plates with 2×10^7 Hi-five cells per plate.

   Alternatively, if starting with fewer cells, split them into ten 150-mm plates and grow until 80% confluent.

2. Add fresh Grace's medium to make up a final volume of 25 ml per plate before infection. Infect cells with high-titer recombinant T antigen baculovirus stock to achieve a multiplicity of infection (MOI) of 5 for optimal protein production.

   The amount of medium is not important, as long as the cells are resuspended evenly.

3. Incubate cells 2 days at 27°C. Check for signs of infection (cytopathologic effect) 24 to 48 hr later.

   Cytopathologic effects are usually visible by 24 hr after infection.

4. Two days after infection, harvest cells by scraping them off plates with a rubber policeman. Pellet and wash cells once with serum-free medium and store at −70°C.

   The pellet can be stored 6 months to 1 year.

SUPPORT PROTOCOL 4

IMMUNOAFFINITY PURIFICATION OF T ANTIGEN

In this protocol, recombinant T antigen is purified by immunoaffinity chromatography from insect cells (Hi-five cell, Invitrogen) infected with a recombinant baculovirus containing the T antigen gene.

NOTE: All the steps in this protocol must be carried out at 4°C. Use cold buffers with proteinase inhibitor added fresh throughout.

Materials

1 ml Sepharose CL-4B (Amersham Pharmacia Biotech) column packed in a 3-ml syringe plugged with siliconized glass wool
Pab419–protein A–Sepharose (Pab419-PAS) immunoaffinity column (see Support Protocol 5)
T antigen lysis buffer (see recipe), 4°C
Insect cell pellet containing recombinant T antigen (see Support Protocol 3)
Wash buffer 1 (see recipe), 4°C
Wash buffer 2 (see recipe), 4°C
Elution buffer (see recipe), 4°C
Protein assay dye reagent (Bio-Rad)
Dialysis buffer (see recipe), 4°C
0.1 M sodium borate, pH 9.0
0.5 M piperazine-*N,N′*-bis(2-hydroxypropanesulfonic acid) (PIPES), pH 7.0, 4°C
Dialysis tubing

1. Link a 1-ml Sepharose CL-4B column (for nonspecific absorption) serially to a Pab419-PAS column so the eluate from the former loads onto the latter. Equilibrate both columns with 10 ml T antigen lysis buffer.

   When using the Pab419-PAS column for the first time, pre-elute it with 20 ml elution buffer to remove any noncovalently coupled antibody.

2. Resuspend cell pellet containing recombinant T antigen in 5 to 10 vol (based on pellet volume) of ice-cold T antigen lysis buffer. Let cells stand 30 min on ice to lyse, mixing occasionally.

3. Clear lysate from cellular debris by centrifuging 30 min at 8000 × *g*, 4°C.

4. Load the cleared lysate onto the Sepharose CL-4B column, and collect flowthrough from the Pab419-PAS column. Repeat the loading once, and collect and save the flowthrough.

   Repeat the loading after disconnecting from the Sepharose CL-4B column. The second flowthrough is collected and saved in case the column condition is bad and most of the protein is still in the flowthrough.

5. Uncouple the columns, and wash the Pab419-PAS column with 100 ml wash buffer 1 followed by 50 ml wash buffer 2.
6. Elute T antigen from the Pab419-PAS column with 10 ml freshly prepared elution buffer. Collect 0.25-ml fractions in tubes containing 25 µl of 0.5 M PIPES, pH 7.0, to neutralize each fraction immediately. Determine T antigen concentration using Bio-Rad protein assay dye reagent.

   It is important to prepare the elution buffer fresh for immediate use. It is also important to add PIPES immediately to the fractions to neutralize the pH. This prevents T antigen from being inactivated owing to the high pH elution used in this protocol.
7. Pool the peak fractions, and dialyze the protein overnight at 4°C against 1 liter dialysis buffer. Divide protein into 100-µl aliquots, and snap freeze at −70°C.
8. Regenerate the Pab419-PAS column with 10 ml elution buffer, and wash with 10 ml of 0.1 M sodium borate, pH 9.0.

   The 100-µl aliquots can be further divided into 10-µl aliquots for the first time they are thawed to prevent repeated freeze/thaw cycles.

   The Pab419-PAS column can be reused four to five times and has a shelf life of ≥1 year at 4°C. Make a fresh Sepharose CL-4B column each time.

PREPARATION OF Pab419 IMMUNOAFFINITY COLUMN

SUPPORT PROTOCOL 5

Purification of T antigen requires an immunoaffinity column in which mouse ascites Pab419 antibody is coupled to protein A–Sepharose (PAS). The immunoabsorbent is stabilized by cross-linking with dimethylpimelimidate. Pab419 ascites is not commercially available; however, most researchers will share the Pab419 hybridoma. A commercial laboratory can produce the ascites.

NOTE: Most of the steps in preparing an immunoaffinity column can be performed at room temperature, because both the antibody and protein A–Sepharose are fairly stable. The column is stable for up to 1 year when stored at 4°C.

Materials

Pab419 ascites
Protein A–Sepharose (PAS; 1 ml packed volume) equilibrated in coupling buffer
Coupling buffer (see recipe)
Coupling buffer with 0.5% (v/v) NP-40 (4.2 ml of 10% NP-40 in 100 ml buffer)
0.1 M sodium borate, pH 9.0
400 mM dimethylpimelimidate (freshly prepared)
0.2 M ethanolamine, pH 8.0
0.2% sodium azide
5-ml syringe plugged with silanized glass wool

1. Mix 1.6 ml Pab419 ascites with 1 ml PAS in a 15-ml tube. Bring volume to 10 ml with coupling buffer, and incubate in a rotating wheel 1 hr at room temperature.

   Spinning down the particulate matter of ascites before mixing with the antibody prevents the column from clogging in later steps. Antibody sources other than ascites can be used but should be concentrated to 1 to 10 mg immunoglobulin/ml for best results.

   The reaction mix can be incubated at 4°C, 4 to 5 hr or overnight, if necessary.
2. Wash off the unbound antibody with three 10-ml washes of coupling buffer followed by five 10-ml washes of coupling buffer with 0.5% NP-40.
3. Equilibrate beads with five 10-ml washes of 0.1 M sodium borate, pH 9.0. Bring up the volume to 9 ml with 0.1 M sodium borate, pH 9.0.

Cross-linking with dimethylpimelimidate must be performed above pH 8.3. Check the pH of the sodium borate solution before use.

4. Remove 100 µl resuspended beads (~10 µl packed beads) and retain separately.

   This sample serves as a check for antibody conjugation before the cross-linking step, as described in step 5.

5. Add 1 ml freshly made 400 mM dimethylpimelimidate to the larger tube of beads (final concentration = 40 mM) and incubate 1 to 2 hr, room temperature, on a rotating wheel or rocker. Remove 100 µl resuspended beads after cross-linking, but before adding ethanolamine.

   Cross-linking efficiency can be determined by comparing the antibody released from the PAS beads before and after cross-linking by boiling the beads in Laemmli's buffer and conducting SDS-PAGE (UNIT 6.1). If the cross-linking took place efficiently, little antibody will be released from the beads after cross-linking compared to before cross-linking.

6. To stop the reaction, wash beads with two 15-ml washes of 0.2 M ethanolamine, pH 8.0, and then incubate 2 hr in 10 ml of 0.2 M ethanolamine, room temperature, on a rocker.

7. Transfer resuspended beads to a 5-ml syringe plugged with silanized glass wool, and wash with 20 ml of 0.1 M sodium borate, pH 9.0.

   The beads can be stored stably at 4°C in 0.1 M sodium borate, pH 9.0/0.2% sodium azide for more than 1 year.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Alkaline loading buffer, 2×

60 mM NaOH
2 mM EDTA
6% (w/v) Ficoll (type 400; Amersham Pharmacia Biotech)
0.05% (w/v) bromocresol green
0.08% (w/v) xylene cyanol FF
Store at 4°C; stable ≥1 year

Alkaline running buffer

30 mM NaOH
1 mM EDTA, pH 8.0
Prepare fresh before use

Coupling buffer

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
150 mM NaCl
5 mM EDTA
0.1% (v/v) NP-40
Store at room temperature; stable ≥1 year
Add 1 mM DTT and 1 mM PMSF before use

Dialysis buffer

10 mM PIPES, pH 7.0
0.1 mM EDTA
5 mM NaCl
10% glycerol
Store at room temperature; stable ≥1 year
Add 1 mM DTT and 1 mM PMSF before use

Elution buffer

56.5 µl triethylamine
2 ml glycerol
H_2O to 20 ml
Prepare fresh before use

Hypotonic lysis buffer

20 mM HEPES, pH 8.0
5 mM KCl
1.5 mM $MgCl_2$
Store at room temperature; stable ≥1 year
Add 1 mM DTT and 1 mM PMSF before use

Replication buffer, 5×

150 mM HEPES, pH 7.8
2.5 mM DTT
35 mM $MgCl_2$
20 mM ATP
1 mM each CTP, GTP, and UTP
0.125 mM dATP
0.5 mM each dCTP and dGTP
0.6 mM TTP
200 mM creatine phosphate
Adjust pH to 7.4 to 7.8 with 10 N NaOH
Store in −20°C freezer; stable ≥1 year

Stop solution, 3×

20 mM EDTA
0.3% (w/v) SDS
20 µg pronase
Store in −20°C freezer; stable ≥1 year

T antigen lysis buffer

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
150 mM NaCl
1 mM EDTA
10% (v/v) glycerol
0.5% NP-40
Store at room temperature; stable ≥1 year
Add 1 mM DTT and 1 mM PMSF before use

Wash buffer 1

50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
0.5 M LiCl
1 mM EDTA
10% (v/v) glycerol
Store at room temperature; stable ≥1 year
Add 1 mM DTT and 1 mM PMSF before use

Wash buffer 2

10 mM PIPES, pH 7.4
5 mM NaCl
1 mM EDTA
10% glycerol
Store at room temperature; stable ≥1 year
Add 1 mM DTT and 1 mM PMSF before use

COMMENTARY

Background Information

The SV40 replication system was established in 1984 by Li and Kelly (1984). It provides the first biochemical tool for studying eukaryotic DNA replication. By providing an SV40 replication origin in plasmid form and the initiator protein (and helicase) T antigen in the presence of a replication-competent extract, the system can replicate the plasmid. This approach bypasses difficulties posed by the absence of known cellular initiation proteins and origins of replication.

The mechanisms of SV40 replication have been extensively studied and are summarized here. T antigen initiates the replication of the SV40 origin–containing plasmid by recognizing the replication origin, which is a single 64-bp core origin DNA sequence from the SV40 virus. The DNA is unwound with the assistance of cellular replication protein A (RPA). Synthesis of a primer RNA and the first Okazaki fragment is carried out by the DNA polymerase α/primase complex after the unwinding. Both RPA and replication factor C (RF-C) interact with polymerase α/primase and stimulate lagging-strand DNA synthesis (Tsurimoto and Stillman, 1991a,b). RPA functions as a stabilizer of single-stranded DNA during the replication process. Saturating amounts of RPA, however, block polymerase α and arrest the DNA synthesis after laying down the first Okazaki fragment. Proliferating cellular nuclear antigen (PCNA), RF-C, and ATP then interact with the polymerase α/primase and form a primer recognition complex. At this stage, polymerase δ recognizes the 3′ end of the first Okazaki fragment. RF-C loads PCNA onto the DNA; the latter forms a sliding clamp (Mossi et al., 1997), which interacts with polymerase δ (Lee et al., 1991) and results in the formation of a highly processive holoenzyme that efficiently replicates the leading-strand DNA. DNA polymerase α/primase, together with RPA, RF-C, and PCNA, continue the cycles of priming and DNA polymerization on the lagging strand, producing primer fragments that are extended into Okazaki fragments by DNA polymerase δ. The completion of lagging-strand DNA synthesis requires the processing of Okazaki fragments. RNase HI removes most of the RNA at the 5′ ends of the Okazaki fragments, but flap endonuclease 1 (FEN-1) is required to remove the last monoribonucleotide. After dissociation of cleaved RNA, DNA ligase comes in and seals the nick (Turchi et al., 1994). Thus the DNA replicates bidirectionally from the origin; polymerase δ continuously synthesizes the leading strand from the 3′ end of the first Okazaki fragment, and the DNA polymerase α/primase complex synthesizes the Okazaki fragments along the lagging-strand template by translocating away from the replication fork in a discontinuous manner. It is believed that similar replication mechanisms exist in cellular chromosomes, except that unknown initiation proteins and origins of replication are involved.

Assays representing various stages of SV40 DNA replication are useful in studying the replication mechanism, including origin binding by T antigen (Borowiec and Hurwitz, 1988), origin DNA untwisting (Dean and Hurwitz, 1991), DNA unwinding (Dean et al., 1987; Wold et al., 1987; Dutta and Stillman, 1992; Goetz et al., 1998), RNA primer formation (Murakami et al., 1992), primer DNA formation (Bullock et al., 1991; Denis and Bullock, 1993), and interactions between various replication factors (Dornreiter et al., 1993). The details of these protocols can be found in the cited literature.

The dependence of viral initiation proteins in the SV40 system makes it difficult to study issues related to chromosomal replication initiation. The *Xenopus* in vitro replication system has some advantages over the SV40 system in this regard, because it relies totally on cellular proteins and replicates only once in the cell cycle. Yet this model is not as easily manipulated as the SV40 system. Furthermore, because both are in vitro systems that depend on cellular extracts, possible participation of insoluble cellular components such as nuclear membrane, nuclear matrix, and chromatin cannot be properly determined. Recent introduction of an in vivo mammalian replication system (Krude et al., 1997) has provided a third approach to the study of DNA replication at the biochemical level. The synthesis of knowledge acquired from all three types of in vitro reactions will probably best illuminate the biochemistry of DNA replication.

Critical Parameters

It is important to have an active cell lysate and an active T antigen for the SV40 replication assay. The cells for the replication extracts must be monitored regularly for their viability. Antifungal reagents such as amphotericin B may be needed to avoid fungal contamination in the

long-term culture. The extracts have to be made and frozen on the day of harvesting for optimal reactions. An active lysate must have a protein concentration ≥10 mg/ml. Repeated freezing and thawing of T antigen and S100 extract inactivates the reaction; therefore, store the proteins in small aliquots. The pH of the replication buffer is a key issue for a successful SV40 replication reaction. It is necessary to measure the pH of the replication buffer after adding nucleotides (which are usually very acidic) unless prebuffered nucleotides are used.

Troubleshooting

When incorporation of the nucleotides is poor, four possible causes must be suspected: low protein concentration of the extract, repeated freezing and thawing of the extract, inactive T antigen, and acidic replication buffer. Low yield of T antigen or inactive T antigen is usually the result of improper immunoaffinity column preparation. Check the antibody conjugation and cross-linking procedures by running an SDS-PAGE, as suggested in Support Protocol 5. Also pre-elute the column before using it the first time.

Anticipated Results

The yield of T antigen from ten 150-mm plates with a 1-ml Pab419 column is ~2 to 3 mg. The 8-liter 293 suspension culture usually yields 5 to 8 ml replication-competent S100 cell extract, with a concentration of 20 to 30 mg/ml. A total of 10 to 15 µl of this extract usually gives maximal incorporation for a 50-µl SV40 replication reaction. A total of 60 to 100 pmol nucleotide is usually incorporated in a 50-µl reaction replication. Nucleotide incorporation decreases substantially when the conditions are not optimal.

Time Considerations

When it is started from one monolayer plate, the protocol takes ~3 to 4 weeks to produce enough cells for the replication competent S100 cell extract. The harvesting of cells and preparation of the extract usually takes 1 day. Insect cells infected with T antigen baculovirus are ready to be harvested 2 days after infection, and the resulting cell pellet can be stored at −70°C before purification. Preparation of the Pab419 immunoaffinity column with mouse ascites takes ~4 to 5 hr; most of the steps can be performed at 4°C when a longer incubation time is preferred. T antigen purification procedures take ~2 to 3 hr. The SV40 replication reaction takes ~2 hr to set up and finish. The products can be stored at −20°C for a few days before quantification and gel analysis. Between 1 and 2 hr are required for quantification of incorporated nucleotides for 10 to 20 reactions by the DE81 paper procedure. Alkaline gel analysis of the replication products usually takes 12 to 14 hr plus time for autoradiography.

In Vitro Transcription

Growth, differentiation, and development in eukaryotic organisms are largely regulated at the level of transcription. To gain an understanding of the molecular mechanisms of transcriptional regulation, it is necessary to utilize an in vitro transcription system by which the identity and function of various factors can be elucidated. The initial development of cell-free extracts from HeLa cells, capable of accurate initiation of transcription by RNA polymerase II, was an important advance in the analysis of gene regulation (Dignam et al., 1983; Manley et al., 1980). Since then, several extracts have been prepared, using diverse sources ranging from cultured mammalian (HeLa) cells (Dignam et al., 1983; Manley et al., 1980) to *Drosophila* embryos (Heiermann and Pongs, 1985; Soeller et al., 1988; Kamakaka et al., 1991), and yeast (Lue and Kornberg, 1987; Woontner and Jaehning, 1990), which mediate accurate initiation of basal and activated transcription. These extracts have been utilized to isolate and characterize the various general, as well as sequence-specific, transcription factors. The extracts have also been used to elucidate the detailed molecular mechanisms of transcription initiation in eukaryotes.

This unit describes an in vitro transcription reaction (see Basic Protocol) using either a mammalian (HeLa) cell extract (see Support Protocol 1) or a *Drosophila* embryo extract (see Support Protocol 2 or Alternate Protocol). This reaction is capable of transcribing from naked DNA or chromatin templates. Upon completion of transcription, the products are analyzed by primer extension analysis (see Support Protocol 3).

NOTE: All reagents used for these protocols should be high-quality molecular biology grade and should be RNase- and DNase-free. Likewise, all plasticware should be RNase-free, and great care should be taken to minimize contamination by RNases (*APPENDIX 2A*).

IN VITRO TRANSCRIPTION REACTIONS WITH NUCLEAR EXTRACTS

BASIC PROTOCOL

In this protocol, the nuclear extract is preincubated with a plasmid template containing an RNA polymerase II promoter to form preinitiation complexes at the promoter. Transcription is initiated by the addition of a mixture of ribonucleotide-5′-triphosphates (rNTPs) and is allowed to proceed for 30 min. After completion of the reaction, a stop solution is added. The RNA transcripts are deproteinized and precipitated. The transcripts can then be analyzed by primer extension analysis (see Support Protocol 3), S1 nuclease protection analysis of RNA, or runoff transcription assays.

NOTE: This protocol describes the conditions for 25-µl reactions. However, this reaction can be scaled up to accommodate various experimental parameters as described below.

Materials

Nuclear extract (see Support Protocol 1, Support Protocol 2, or Alternate Protocol)
10% (w/v) polyvinyl alcohol (PvOH; mol. wt. 10,000; Sigma)
10% (w/v) polyethylene glycol (PEG; mol. wt. 15,000 to 20,000)
1 M HEPES (potassium salt), pH 7.6 and 8.0, adjusted with KOH
200 ng/µl plasmid DNA template in TE buffer, pH 8.0 (*APPENDIX 2A*)
5 mM ribonucleotide-5′-triphosphates (rNTPs; see recipe)
Transcription stop solution (see recipe)
0.3 M sodium acetate
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (PCIAA), equilibrated with 10 mM Tris·Cl, pH 7.5
75% and 100% ethanol
30° and 37°C water baths

Contributed by Rohinton T. Kamakaka and W. Lee Kraus
Current Protocols in Cell Biology (1999) 11.6.1-11.6.17

Prepare transcription reaction mix

1. Thaw a sufficient number of aliquots of nuclear extract for the experiment quickly in an ice-water bath. Also thaw aliquots of 10% PvOH, 10% PEG, and 5 mM rNTPs.

   Keep all reagents on ice once thawed.

2. Prepare the following mix (multiplying the quantities by the number of tubes to be used in the assay):

   2.5 µl 10% PvOH
   2.5 µl 10% PEG
   0.5 µl 1 M HEPES (potassium salt), pH 8.0.

3. For each sample, combine the following reagents on ice, in the order listed, in a 1.5-ml microcentrifuge tube, mixing after each addition:

   6.0 µl H_2O
   5.5 µl PvOH/PEG/HEPES mix (from step 2)
   10.0 µl nuclear extract (or optimal amount determined empirically)
   1.0 µl 200 ng/µl DNA template (or optimal amount determined empirically).

   The water can be added to the PvOH/PEG/HEPES mix in step 2, to decrease the amount of pipetting. Purified transcription factors or column fractions from chromatographic purifications can be added at this step in addition to the extract in place of some or all of the water, if desired.

   The optimal amount of nuclear extract for each application will have to be determined empirically, but it typically ranges from 5 to 15 µl. If <10 µl of nuclear extract is used, the volume should be brought up with TM buffer containing 0.1 M KCl; if >10 µl of nuclear extract is used, the volume of the water should be reduced.

   The DNA template should be double-banded on CsCl gradients (see APPENDIX 3). The optimal amount of DNA template per reaction will also have to be determined empirically. It may range from 30 to 300 ng, depending on the strength of the promoter. A good starting point is 200 ng. The DNA is present in TE buffer, pH 8.0.

   The reaction for each set of experimental conditions should be performed in duplicate to compensate for any pipetting errors or loss of sample. Additionally, an internal reference plasmid can be added, if desired.

4. Incubate 15 min at room temperature (~21°C) to allow the formation of preinitiation complexes.

5. Prepare the rNTP mix just before use by combining:

   0.5 µl 1 M HEPES (potassium salt), pH 7.6
   2.5 µl 5 mM rNTPs
   4.5 µl H_2O.

Perform reaction

6. Initiate transcription by adding 2.5 µl of the rNTP mix prepared in step 5 to the incubated reaction from step 4. Incubate 30 min at 30°C.

   To confirm that the RNA was synthesized by RNA polymerase II, and not some other polymerase, inhibition with α-amanitin should be performed as a control. To do this, add 1 µl of 100 µg/ml α-amanitin (in water; also see APPENDIX 1B) to the reaction mix to give a final concentration of 4 µg/ml α-amanitin. RNA polymerase II is inhibited by 0.5 µg/ml α-amanitin; RNA polymerase III is inhibited by 200 µg/ml α-amanitin; and RNA polymerase I is resistant to α-amanitin.

7. Stop the reactions by adding 100 µl transcription stop solution. Mix well and incubate 10 min at 37°C.

Isolate transcripts

8. Add 250 µl of 0.3 M sodium acetate to each sample.
9. Extract each sample with 400 µl of 25:24:1 PCIAA. Transfer the aqueous phase from each tube to a new 1.5-ml microcentrifuge tube.
10. Add 1 ml of 100% ethanol and mix well. Microcentrifuge each sample 15 min at maximum speed, room temperature, to collect the RNA in the pellet.
11. Carefully aspirate the liquid from the small white pellets and add 400 µl of 75% ethanol to each tube. Microcentrifuge 5 min at maximum speed, room temperature.
12. Carefully aspirate all the liquid from the pellets. Dry the pellets in a rotary evaporator (e.g., a SpeedVac). Store the samples at −20°C, or proceed immediately with the primer-extension analyses (see Support Protocol 3).

PREPARATION OF A NUCLEAR EXTRACT FROM HELA CELLS

SUPPORT PROTOCOL 1

This protocol describes the preparation of a nuclear extract from HeLa cells and is based largely on the protocol described by Dignam et al. (1983). HeLa cells are incubated in a hypotonic buffer to swell them by osmotic action. The swollen cells are disrupted by Dounce homogenization, and the nuclei are collected in a pellet by centrifugation. The nuclei are then incubated in a high-salt buffer to extract the soluble proteins, including the transcription factors and RNA polymerase II, without lysing the nuclei. The nuclei are removed from the extract by centrifugation, and the extract is subjected to ammonium sulfate precipitation to concentrate the transcription factors and to remove histone H1 (a repressor of transcription). Finally, the precipitated proteins are collected by centrifugation, dissolved in buffer, dialyzed into a low-salt buffer, and used for transcription.

NOTE: This protocol describes the preparation of a HeLa nuclear extract from 12 liters of HeLa cell suspension culture (i.e., all volumes listed in the protocol below are based on an original culture volume of 12 liters). However, the preparation can be scaled up or down.

Materials

~5–8 × 10^5 cell/ml suspension culture of HeLa cells grown in spinner flasks
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Freezing buffer (see recipe)
Glycerol
PBS (*APPENDIX 2A*) containing 1 g/liter $MgCl_2$
Hypotonic buffer (see recipe)
High-salt buffer (see recipe)
Powdered ammonium sulfate
TM buffer (see recipe) with and without 0.1 M KCl

Beckman JS-4.2 and SW-28 and Sorvall GSA and SS-34 rotors (or equivalents) and appropriate centrifuge bottles and tubes
40-ml Wheaton Dounce homogenizer with loose (B) pestle (or equivalent)
Insulated magnetic stir plate
Coffee bean grinder or mortar and pestle
Dialysis tubing (12,000 to 14,000 MWCO)
Conductivity meter (optional)

Additional reagents and equipment for dialysis (*APPENDIX 3*)

NOTE: Perform all procedures at 4°C (i.e., on ice and in a cold room) using precooled solutions, glassware, and equipment. Perform all centrifugations at 4°C with precooled rotors. All low-speed centrifugations are done in a low-speed centrifuge (e.g., Sorvall RC-5) while high-speed centrifugations are done in an ultracentrifuge.

Isolate HeLa cell nuclei

1. Centrifuge 12 liters of HeLa cells grown under standard conditions (~5–8 × 10^5 cell/ml) in spinner cultures for 15 min at 1800 × *g*, 4°C, in a large, low-speed preparative rotor (e.g., Beckman JS-4.2).

2. Resuspend the cell pellets in PBS (25 to 50 ml for each liter of original culture volume), combine, and centrifuge again as in step 1 in one or two bottles.

   If cells are not to be used immediately, add glycerol and freeze as in steps 3 and 4. Alternatively, the cells can be used immediately without freezing, in which case collect the cells from the spinner culture by centrifugation as in the previous steps and proceed directly to step 5.

3. Resuspend the cell pellets in 2 ml of freezing buffer for each liter of original culture volume and add glycerol to 20% (v/v), taking into account the original glycerol concentration of the freezing buffer (30% v/v), the volume contributed by the cells, and the final volume of the cell suspension.

4. Freeze the cells in aliquots in 50-ml plastic, conical tubes in liquid N_2 and store at −80° to −100°C.

5. Thaw HeLa cells (if frozen) from 12 liters of culture in an ice water bath as quickly as possible. Centrifuge 10 min at 1400 × *g* (3000 rpm in a Sorvall GSA rotor), 4°C, add 200 ml of PBS containing 1 g/liter $MgCl_2$, then centrifuge again at 1400 × *g*. Aspirate the supernatant from the loose cell pellet and wash again in the same manner.

   This protocol can be readily scaled up or down by a factor of two (i.e., for preparations from 6 to 24 liters of cells).

6. Aspirate the supernatant from the washed cell pellet and resuspend the cells in 60 ml hypotonic buffer. Incubate the cells on ice 15 min to allow them to swell.

7. Lyse the cells by 12 strokes in a Dounce homogenizer (with loose "B" pestle). Centrifuge the cell lysate 8 min at 3000 × *g* (5000 rpm in a Sorvall SS-34 rotor), 4°C, to collect the nuclei in the pellet.

   Cell lysis can be monitored under a microscope by staining an aliquot of cells with trypan blue (UNIT 1.1), which stains the nuclei of lysed cells. Aim for 90% cell lysis.

   Work quickly after lysis of the cells to minimize the leakage of transcription factors from the nuclei.

8. Aspirate the supernatant and resuspend the isolated nuclei in a total final volume of 20 ml hypotonic buffer. Pool into one tared SS-34 tube and centrifuge 8 min at 3000 × *g*, 4°C. Aspirate the supernatant and weigh the nuclei.

   A typical yield of nuclei from a 12-liter culture of HeLa cells is ~12 g.

Prepare a high-salt nuclear extract

9. Resuspend the nuclei in 70 ml high-salt buffer and transfer to a 200-ml glass beaker. Stir the suspension slowly in an ice-water bath on an insulated magnetic stir plate for 30 min.

10. Transfer the suspension to thick-walled tubes for a Beckman SW-28 rotor. Balance the tubes and centrifuge 60 min at 100,000 × *g* (25,000 rpm in an SW-28 rotor), 4°C.

    A swinging bucket rotor is preferable to a fixed-angle rotor for this centrifugation step. With a fixed angle-rotor, undesirable shearing of the nuclei can occur.

11. Collect the supernatants into a graduated cylinder and measure the volume (expect 70 to 75 ml).

Precipitate the extract

12. Transfer the pooled supernatants to a 200-ml glass beaker. Start stirring the suspension slowly in an ice-water bath on an insulated magnetic stir plate. Slowly, over a 15 to 20 min period, add 0.33 g powdered ammonium sulfate per ml of supernatant (final saturation 55% at 0°C). After all the ammonium sulfate has been added and has dissolved, let the mixture stir for an additional 25 to 30 min.

    Pulverize the ammonium sulfate by using a coffee bean grinder or a mortar and pestle no more than 5 to 10 min before use. Powdered ammonium sulfate is hygroscopic and cannot be weighed accurately when it is wet.

13. Centrifuge the mixture 20 min 35,000 × *g* (17,000 rpm in an SS-34 rotor), 4°C. Remove the supernatants by aspiration, trying to remove as much of the liquid as possible.

14. Dissolve the pellets in a total final volume of 5 to 6 ml TM buffer and pool into one tube.

    The pellets from the ammonium sulfate precipitation are difficult to dissolve. For best results, add ~1.5 ml of TM buffer to each pellet. Then, pipet up and down gently to dislodge and resuspend the pellets. After pooling, use ~1 ml of buffer to rinse the tubes and the pipet, and add the rinse to the sample. The solution will be milky white after the pellets are dissolved.

Dialyze the extract

15. Desalt the extract by dialysis (*APPENDIX 3*) in 12,000 to 14,000 MWCO dialysis tubing as follows:

    1 hr versus 2 liters TM buffer
    1 hr versus 2 liters TM buffer containing 0.1 M KCl
    2 hr versus fresh change of TM buffer (2 to 4 liters) containing 0.1 M KCl.

    The dialysis is complete when the conductivity of the sample is the same as the conductivity of the dialysis buffer. If a conductivity meter is not available, it should be possible to assume complete or near-complete dialysis with this scheme.

16. Transfer the extract from the dialysis bag and centrifuge 10 min at 12,000 × *g* (10,000 rpm in an SS-34 rotor), 4°C, to remove any insoluble material. Divide the supernatant into aliquots, freeze in liquid N_2, and store at −80° to −100°C.

    If desired, save an aliquot of the extract for determination of the protein concentration by the Coomassie blue binding assay. A convenient aliquot size for in vitro transcription experiments is 150 to 200 µl. Avoid multiple freeze-thaw cycles.

    The yield is ~7 ml of HeLa extract from 12 liters of cells.

SUPPORT PROTOCOL 2

PREPARATION OF HIGH-SALT *DROSOPHILA* EXTRACTS

Two transcription extracts that are highly active for transcription in vitro can be prepared from *Drosophila* embryos (also see Alternate Protocol). Transcription extracts from *Drosophila* are particularly attractive for studies on transcriptional regulation because: (1) they are highly active and (2) many mechanisms of activation have been conserved between mammals and flies with various transcription factors being easily interchangeable in vitro. Furthermore, *Drosophila* embryos are inexpensive compared to cultured cells. Finally, *Drosophila* transcription extracts allow the use of in vitro–reconstituted chromatin as the template for transcription studies (Kamakaka et al., 1991).

This protocol is based on the method of Soeller et al. (1988) and Parker and Topol (1984). It involves the purification of nuclei from 0- to 12-hr *Drosophila* embryos, followed by extraction of nuclear proteins such as transcription factors and histones using a high-salt buffer. After removal of the cellular debris, the transcription factors are precipitated with ammonium sulfate (which, incidentally, removes nonspecific inhibitors of transcription such as histone H1). The precipitated proteins, after solubilization, are desalted by gel filtration, resulting in an active transcription extract. This extract is a rich source of both general and sequence-specific transcription factors which can be purified by further chromatography steps.

NOTE: This protocol is for use with ~100 g of embryos. The preparation, however, can be scaled up or down.

Materials

Drosophila cultures
Molasses/agar plates (see recipe)
Bleach (5.25% sodium hypochlorite) diluted 1:1 in distilled H_2O (store at room temperature)
Embryo wash solution: 0.7% (w/v) NaCl/0.04% (v/v) Triton X-100 (store at room temperature)
Disruption buffer (see recipe)
Resuspension buffer (see recipe)
4 M ammonium sulfate, pH 7.0
Solid ammonium sulfate
HEMG containing 0.1 M KCl (see recipe)

Embryo collection apparatus (construct according to Fig. 11.6.1) and paint brush
Nylon mesh (Tetko, #3-70/43 and 3-500/49) and interlocking rings for constructing embryo collection apparatus
Yamato LH-21 homogenizer (Thomas)
4 pieces of Miracloth (9 in. × 9 in.; Calbiochem)
GSA, 45-Ti, and SS-34 rotors (or equivalents) and appropriate centrifuge bottles and tubes
40-ml Wheaton Dounce homogenizer with a B pestle and 15-ml homogenizer with A pestle
Rotating mixer
Coffee grinder
5 × 22–cm G-25 SF desalting column (430 ml; Pharmacia Biotech)
Conductivity meter

Additional reagents and equipment for growing *Drosophila* (Goldstein and Fyrberg, 1994)

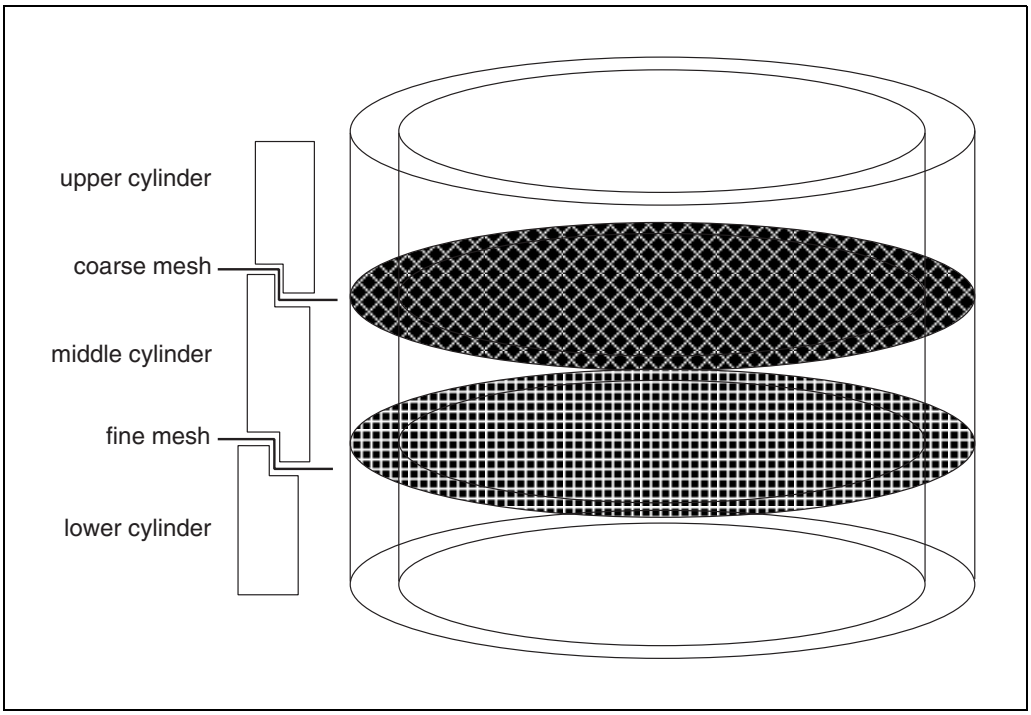

Figure 11.6.1 The embryo collection apparatus consists of three interlocking rings, which hold two nylon meshes of different porosity. The coarse mesh (Tetko 3-500/49) is placed between the upper and middle cylinders to collect any dead flies and large particulate material. The fine mesh (Tetko 3-70/43) is placed between the middle and lower cylinders to collect the embryos but allow the yeast to flow through. The dimensions of this apparatus can vary; 3-in. high, 10-in. diameter segments work well.

NOTE: Perform all procedures at 4°C (i.e., on ice and in a cold room) using precooled solutions, glassware, and equipment. Perform all centrifugations at 4°C with precooled rotors.

NOTE: The use of frozen embryos or embryos stored >3 days results in transcription extracts of a very poor quality.

Collect embryos

1. Grow wild-type flies at 25°C and 70% humidity in population cages (Goldstein and Fyrberg, 1994). Collect the embryos onto molasses/agar plates.

   Embryos collected between 0 and 12 hr after fertilization will be used. The plates can be stored for up to 3 days at 4°C (Biggin and Tjian, 1988).

2. Harvest 0- to 12-hr embryos in embryo collection apparatus (Fig. 11.6.1). Wash the embryos off the molasses/agar plates onto the coarse mesh of the collection apparatus in a sink, using a paint brush and running distilled water. Once all the embryos are collected, remove the upper cylinder and the coarse mesh containing the dead flies and particulate matter.

3. Remove large foreign particles, if present, in the embryos, and wash well in the collection apparatus consisting of the middle and lower cylanders to remove the yeast.

4. Move the apparatus containing the embryos into a Nalgene tub. Pour 3 liters of 1:1 bleach/distilled water into embryo collection apparatus in the Nalgene wash tub and swirl to mix. Dechorionate the embryos by soaking 90 sec in the bleach. Lift the embryos in the bleach solution out of the tub and allow the bleach solution to drain away.

   Do not soak embryos for >90 sec.

5. Quickly, rinse with 1 liter embryo wash solution by pouring embryo wash solution directly into embryo collection apparatus and swirling to mix.
6. Rinse with 1 to 3 liters water to remove excess embryo wash solution and bleach.
7. Dry the embryos to a moist cake by placing paper towels under the fine nylon mesh of the embryo collection apparatus to absorb excess water.
8. Weigh the embryos in a tared beaker.

Homogenize embryos

9. Add 3 ml disruption buffer per gram of embryos and stir with a rod to disperse the embryos evenly. Disrupt embryos with a single passage through the Yamato LH-21 homogenizer at 1000 rpm.
10. Pour the homogenate into a funnel lined with 1 layer Miracloth over a GSA bottle. After the liquid in each funnel has flowed into the GSA bottle, wash the debris remaining in the Miracloth with additional disruption buffer (2 ml per g of embryos).

    The final volume of disruption buffer should be ~5 ml/g embryos.

    Depending on the volume of the homogenate, between one and four funnels are used.

    Once the embryos are homogenized, work quickly—proteins can leak out of the nuclei into the buffer solution.

11. Centrifuge 15 min at 10,000 × *g* (8000 rpm in a GSA rotor), 4°C, to collect the nuclei in a pellet. Carefully decant the supernatant (the pellet will be very loose). Wipe lipids from the walls of the centrifuge bottles with Kimwipes.

    Try to remove as much lipid as possible.

12. Resuspend the nuclei in 3 ml disruption buffer per gram of embryos by swirling carefully. Do not resuspend the yellow yolk, which sticks very tightly to the bottle. Transfer nuclear suspension to a Dounce homogenizer.
13. Use a 40-ml Dounce homogenizer with a B pestle to disperse the nuclei. Transfer to clean GSA bottles.
14. Centrifuge again as in step 11. Carefully decant the supernatant, and wipe the lipids from the walls of the centrifuge bottles.
15. Resuspend the nuclei in 1 ml resuspension buffer per g embryos. Use a 40-ml Dounce homogenizer with a B pestle to break up clumps of nuclei (three strokes of the Dounce are sufficient).
16. Measure the volume accurately with a 250-ml graduated cylinder and transfer to 45-Ti bottles. Add a quantity of 4 M ammonium sulfate equivalent to 1/10 vol of the liquid in 45-Ti bottles to each bottle. Mix by inversion, then rotate 20 min on a rotating mixer.

    The final ammonium sulfate concentration is 0.364 M = 9% saturation at 20°C.

17. Centrifuge the lysed nuclei 1 hr at 142,400 × *g* (35,000 rpm in 45-Ti rotor), 4°C.
18. During the centrifugation, make the following preparations:
    a. Pulverize solid ammonium sulfate crystals in a coffee grinder.
    b. Prepare ice bath over a magnetic stirrer for ammonium sulfate precipitation.
    c. Begin to equilibrate the G-25 SF desalting column with 2 column volumes of HEMG containing 0.1 M KCl at 400 ml/hr.

Precipitate proteins

19. Remove supernatant from the lysed nuclei with a pipet. Avoid lipid globules on the top of the tube.

    It is normal for the solution to become cloudy upon standing.

20. Accurately measure the volume of the combined supernatants. Transfer the liquid to a 400-ml beaker containing a magnetic stirrer, placed in the previously prepared ice bath. Slowly (over a period of ~5 min) add 0.3 g pulverized ammonium sulfate/ml liquid. Stir for an additional 15 min.

    The final ammonium sulfate concentration is 2.26 M = 56% saturation at 20°C.

21. Centrifuge ammonium sulfate precipitate 20 min at 27,000 × *g* (15,000 rpm in an SS-34 rotor), 4°C. Decant supernatant, and drain pellets well.

    The supernatant is a good source for histone H1.

22. Resuspend pellets in 0.1 ml HEMG containing 0.1 M KCl per g embryos. Use a 15-ml Dounce homogenizer with an A pestle to disperse protein clumps.

23. Centrifuge the resulting mixture 10 min at 12,000 × *g* (10,000 rpm in an SS-34 rotor), 4°C, to remove insoluble material.

Desalt extract

24. Apply the protein extract to an equilibrated G-25 SF desalting column. Run the column at 400 ml/hr, and monitor the absorbance at 280 nm. Collect 1-min fractions (~7 ml).

    In ~20 min, the protein peak will elute from the column, the protein peak will be followed by a salt peak.

25. Check the protein concentrations of the peak fractions with the Coomassie blue binding assay (*APPENDIX 3*), then measure the conductivity of the last protein fraction that is to be pooled.

    If the conductivity of this fraction is identical to that of HEMG containing 0.1 M KCl (i.e., 20 mS/cm), then the desalting is complete. Dilute 20 ml of sample in 5 ml distilled water, and measure the conductivity of the resulting solution. 80 mS/cm corresponds to an extract of 20 mS/cm. If the conductivity does not match then use a larger column or dialyze the sample.

26. Pool the peak protein fractions, and centrifuge the solution 10 min as in step 23 to remove insoluble debris. Avoid the lipids at the top of the tubes.

27. Quick-freeze the extract in a 50-ml polypropylene screw-cap tube in liquid N_2 and store at −100°C.

    Typically 100 g of embryos will yield ~40 to 50 ml of high-salt transcription extract.

PREPARATION OF THE SOLUBLE NUCLEAR FRACTION FROM ISOLATED DROSOPHILA EMBRYO NUCLEI

ALTERNATE PROTOCOL

An alternative protocol for the preparation of *Drosophila* transcription extracts, based on the method of Kamakaka et al. (1991), has the advantages of speed, removal of nonspecific inhibitors of transcription, and allowing the preparation of extracts from very few embryos (extracts can be made from between 10 and 150 g of embryos, and quantities are simply scaled proportionately). This method involves the isolation of nuclei in a relatively low-salt buffer followed by a high-speed centrifugation of the nuclei in a small volume

to maximize the concentration of transcription factors while avoiding the extraction of nonspecific inhibitors of transcription.

Additional Materials *(also see Support Protocol 2)*

HEMG20 containing 0.1 M KCl (see recipe)
Ultracentrifuge with SW-28 rotor

1. Prepare nuclei (see Support Protocol 2, steps 1 to 14).
2. Resuspend the nuclei in 1 ml resuspension buffer per gram of embryos. Disperse nuclei in a 40-ml Dounce homogenizer with a B pestle (three strokes of the Dounce should be sufficient).
3. Transfer the entire suspension of nuclei into one tared GSA bottle.
4. Centrifuge 10 min at 10,000 × *g* (8000 rpm in GSA rotor), 4°C.
5. Decant the supernatant and weigh the bottle to determine the mass of the nuclei.
6. Add 0.5 ml per gram of nuclei of HEMG20 containing 0.1 M KCl.

   Example: if there are 10 g nuclei, then add 5 ml HEMG20 containing 0.1 M KCl.

7. Resuspend the pellet by shaking and swirling the nuclei (do not use a homogenizer). Place the suspension on ice for 15 to 60 min.
8. Centrifuge mixture 1 hr at 100,000 × *g* (24,000 rpm in SW-28 rotor), 4°C.

   It is important to always use a swinging-bucket rotor for the preparation of the soluble nuclear fraction to reduce shearing of chromatin.

9. After centrifugation, observe the four distinct layers, which will appear from top to bottom as follows:
   a. A thin gray-white lipid layer. Remove this with a spatula and discard.
   b. A yellow liquid layer, which comprises ~50% of the total volume of the tube and is the soluble nuclear fraction. Remove this extract with a pipet and transfer into a 50-ml screw-cap polypropylene tube.
   c. A gray liquid layer. Avoid the gray layer below the extract as this is enriched in transcription inhibitors and nucleases and phosphatases.
   d. At the bottom, a solid off-white layer of nuclear material which includes DNA, scaffold etc.
10. Quick-freeze the extract (step 9, substep b, above) in 50-ml polypropylene screw cap tube in liquid N_2 and store at −100°C.

    Usually, 100 g of embryos will yield 20 g of wet nuclei, which will then yield ~15 ml of the soluble nuclear fraction.

SUPPORT PROTOCOL 3

PRIMER EXTENSION ANALYSES OF IN VITRO TRANSCRIPTION PRODUCTS

This protocol describes primer extension analyses of in vitro transcribed RNA products. First, a short (~25 base) DNA oligonucleotide is end labeled with [γ-^{32}P]ATP by T4 polynucleotide kinase. Next, the radiolabeled oligomer is annealed to the RNA products from the in vitro transcription reactions, and the primers are extended with reverse transcriptase. Finally, the primer extension products are analyzed by denaturing-polyacrylamide gel electrophoresis.

Materials

~25-base DNA oligonucleotide complimentary to the RNA products from the in vitro transcription reactions
T4 polynucleotide kinase
150 µCi/µl [γ-^{32}P]ATP (7000 Ci/mmol; ICN Biomedicals)
2.5 M ammonium acetate
10 mg/ml glycogen
100% ethanol
1× TE buffer, pH 8.0 (*APPENDIX 2A*)
25:24:1 (v/v/v) phenol/chloroform/isoamyl alcohol (PCIAA), equilibrated with Tris·Cl, pH 7.5
3 M sodium acetate
5× annealing buffer (see recipe)
RNA product (e.g., from Basic Protocol)
Primer extension mix (see recipe)
50 U/µl Moloney murine leukemia virus (MMLV) reverse transcriptase
Formamide loading buffer (FLB; see recipe)
8% urea-polyacrylamide sequencing gel
1× TBE buffer (*APPENDIX 2A*)

37°, 58°, 70°C, and boiling water baths
Whatman 3MM filter paper

Additional reagents and equipment for primer synthesis, agarose gel electrophoresis, DNA elution, ethanol precipitation, DNA quantification, primer labeling (*APPENDIX 3*), and phosphorimaging or autoradiography (*UNIT 6.3*)

NOTE: All reagents used for this protocol should be high-quality molecular biology reagents. All procedures should be performed at room temperature unless otherwise noted. All microcentrifugations are done at maximum speed.

CAUTION. When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out experiment and dispose of waste in appropriately designated areas, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

Radiolabel DNA oligonucleotide

1. Design, synthesize, and purify a DNA oligonucleotide primer ~25 bases in length (*APPENDIX 3*).

   The oligo should produce a primer-extension product 100 to 150 bases in length (from the 5′ end of the annealed oligo to the transcription start site). The oligo should be gel purified on high-percentage (~10%) polyacrylamide gels run in 1× TBE, eluted, ethanol precipitated, dissolved in water, and quantified. Oligonucleotides with an annealing temperature of ~58°C should be designed.

2. Make a working dilution of the primer at 2.5 pmol/µl.

3. In a 1.5-ml microcentrifuge tube, radiolabel 5 pmol (2 µl) of the primer (*APPENDIX 3*). Use T4 polynucleotide kinase according to the manufacturer's specifications (in a 20-µl reaction) in the presence of 2 µl of 150 µCi/µl [γ^{32}P]ATP. Incubate the reaction at 37°C for 1 hr.

   CAUTION: *Great care should be taken, and appropriate shielding used, when labeling with [γ-^{32}P]ATP. All bench surfaces, pipettors, tube racks, hands, and forearms should be carefully monitored with a Geiger counter (see APPENDIX 1D).*

Precipitate DNA

4. Add 100 µl of 2.5 M ammonium acetate. Heat the reaction to 70°C for 15 min to inactivate the T4 polynucleotide kinase.
5. Allow the tube to cool to room temperature, then add 2 µl of 10 mg/ml glycogen and 375 µl of 100% ethanol to precipitate the radiolabeled primer. Mix by vortexing.

   When vortexing to mix the radioactive solutions or to dissolve precipitated primer in this protocol, use careful, gentle vortexing, avoiding contact of the liquids with the inside of the tube lid. This will minimize leakage of radioactive material from the tube and reduce contamination of the microcentrifuge and the investigator's hands.
6. Microcentrifuge the ethanol precipitates 15 min. Carefully remove the ethanol supernatant from the pellet with a pipet and discard in an appropriate waste container. Add 100 µl TE buffer, pH 8.0, and dissolve the pellet by vortexing.
7. Add 100 µl PCIAA and mix by vortexing. Microcentrifuge the tube 5 min to separate the organic and aqueous phases. Remove the upper (aqueous) phase and transfer to a new 1.5-ml microcentrifuge tube.
8. Add 10 µl of 3 M sodium acetate and 300 µl of 100% ethanol to precipitate the radiolabeled primer. Mix by vortexing, and microcentrifuge 15 min.
9. Carefully remove and discard the ethanol supernatant. Dry the pellet 10 min at room temperature.

   Do not dry the pellets under vacuum or they will be very difficult to dissolve.
10. Dissolve the pellet in 150 µl TE buffer, pH 8.0 (to a final concentration of 0.033 pmol/µl), by vortexing. Store the radiolabeled primer at −20°C.

    Primers labeled in this manner may be stored under these conditions for 2 to 3 weeks pending primer-extension analyses.

Perform primer extension

11. Thaw an aliquot of radiolabeled primer complementary to the in vitro transcription RNA products. Make a mix containing 10 µl of 1× annealing buffer (2 µl of 5× annealing buffer and 8 µl TE, pH 8.0) and 0.25 µl of labeled primer (~8 fmol) for each sample to be analyzed in the assay.
12. Add 10 µl of this primer extension annealing mix to each tube of RNA product. Dissolve the RNA by vortexing.
13. Heat the samples to 70°C for 2 min, then incubate 40 min at 58°C to anneal the primer to the RNA product/template.

    The optimal annealing conditions will vary depending on the length and G+C content of the primer.
14. Microcentrifuge the samples quickly to collect condensation from the insides of the lids to the bottoms of the tubes, and allow the samples to cool to room temperature.
15. Add 40 µl primer extension mix and 0.5 µl MMLV reverse transcriptase combined just before use and mix by gentle vortexing. Incubate 40 min at 37°C.
16. Add 225 µl of 100% ethanol. Mix the samples by gentle vortexing and microcentrifuge 15 min.
17. Remove the ethanol supernatant and dry the pellets in a rotary evaporator (e.g., SpeedVac). Dissolve the pellets in 6 µl FLB. Store samples at −20°C or proceed immediately with denaturing polyacrylamide gel electrophoresis.

    Avoid storage of the primer extension products for more than 2 or 3 days before gel analysis.

Analyze the products

18. Pour a standard 8% urea-polyacrylamide sequencing gel (*APPENDIX 3*). Boil the primer extension samples 4 min in a water bath. Run the samples on the gel in 1× TBE until the bromphenol blue tracking dye is 3 to 5 cm from the bottom of the gel.

    A 25-base primer will run in the vicinity of the bromphenol blue tracking dye on an 8% sequencing gel.

19. Dry the gel on a piece of Whatman 3MM paper. Subject the dried gel to phosphorimaging analysis or autoradiography (*UNIT 6.3*).

    If the aim of the experiment is to quantify the amount of primer-extension product, fixing the gel in 10% acetic acid for 15 min is recommended. Prior to fixation of the gel, cut the gel to remove the free primer. Fixation of a gel with the free primer band results in the diffusion of the primer during fixation which increases the background.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Annealing buffer, 5×

10 mM Tris·Cl, pH 7.8 (*APPENDIX 2A*)
1 mM EDTA
1.25 M KCl
Store up to 6 months at –20°C

Disruption buffer

15 mM HEPES (potassium salt), pH 7.6
10 mM KCl
5 mM $MgCl_2$
0.1 mM EDTA
0.5 mM EGTA
350 mM sucrose
Store up to 1 month at 4°C
Just before use add:
1 mM DTT
1 mM sodium metabisulfite
0.2 mM PMSF (also see *APPENDIX 1B*)
1 mM benzamidine

Formamide loading buffer (FLB)

80% formamide
10 mM EDTA
1 mg/ml xylene cyanol
Store up to 6 months at –20°C

Freezing buffer

50 mM Tris·Cl, pH 7.9
30% glycerol
1 mM EDTA
0.5 mM DTT
Prepare fresh at 4°C

HEMG containing 0.1 M KCl

25 mM HEPES (potassium salt), pH 7.6
100 mM KCl

continued

12.5 mM $MgCl_2$
0.1 mM EDTA
10% (v/v) glycerol
Store up to 1 month at 4°C
Just before use add:
1.5 mM DTT
1 mM sodium metabisulfite
0.1 mM PMSF (also see *APPENDIX 1B*)
1 mM benzamidine

HEMG20 containing 0.1 M KCl

25 mM HEPES (potassium salt), pH 7.6
100 mM KCl
12.5 mM $MgCl_2$
0.1 mM EDTA
20% (v/v) glycerol
Store up to 1 month at 4°C
Just before use add:
1.5 mM DTT
1 mM sodium metabisulfite
0.1 mM PMSF (also see *APPENDIX 1B*)
1 mM benzamidine

It is also possible to use 0.4 M potassium glutamate monohydrate (Sigma), instead of 0.1 M KCl, for the preparation of "nuclei juice."

High-salt buffer

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10% (w/v) sucrose
0.42 M KCl
5 mM $MgCl_2$
0.1 mM EDTA
20% (v/v) glycerol
Store up to 1 month at 4°C
Just before use add:
2 mM DTT
0.2 mM PMSF (also see *APPENDIX 1B*)
1 mM benzamidine

The 0.42 M KCl in the high-salt buffer can be substituted with 0.42 M NaCl, if desired.

Hypotonic buffer

10 mM Tris·Cl, pH 7.9 (*APPENDIX 2A*)
10 mM KCl
0.1 mM EDTA
0.1 mM EGTA
Store up to 1 month at 4°C
Just before use add:
2 mM DTT
0.2 mM PMSF (also see *APPENDIX 1B*)
1 mM benzamidine
2 µg/ml aprotinin
2 µg/ml leupeptin
0.75 mM spermidine
0.15 mM spermine
2 µg/ml pepstatin

Molasses/agar plates

100 ml water
14.6 ml molasses
3.6 g fine-ground agar

Autoclave, pour into styrofoam meat trays, and let set. Just before use, spread the top with thick yeast paste (prepared by mixing Red Star yeast with water to a consistency that can be easily spread but is not so thin that the flies get stuck, approximately that of canned tomato paste). Store up to 1 week at 4°C.

Primer extension mix (1 ml)

Evaporate 62.5 µl of 2 mg/ml actinomycin D in ethanol to dryness. Add to this 886 µl water followed by 62.5 µl of 1 M Tris·Cl, pH 8.3. Vortex to dissolve actinomycin D. Add 12.5 µl of 100 mM $MnCl_2$ (do not use a 1 M stock). Add 3.5 µl of each 10 mM dNTP (14 µl total). Vortex again. Finally, add 25 µl of 0.5 M DTT.

Resuspension buffer

15 mM HEPES (potassium salt), pH 7.6
110 mM KCl
5 mM $MgCl_2$
0.1 mM EDTA
Store up to 1 month at 4°C
Just before use add:
2 mM DTT
1 mM sodium metabisulfite
0.2 mM PMSF (also see *APPENDIX 1B*)
1 mM benzamidine

Ribonucleotide-5′-triphosphates (rNTPs), 5 mM

Dilute 100 mM stocks of each rNTP (Amersham Pharmacia Biotech) in buffer (the authors use 20 mM sodium phosphate buffer, pH 7.5, but others—including potassium phosphate, Tris, and HEPES—would work) such that each nucleotide is at a final concentration of 5 mM. Store up to 1 year at −70°C

TM buffer

50 mM Tris·Cl, pH 7.9 (*APPENDIX 2A*)
0.1 M KCl (omit where specified)
12.5 mM $MgCl_2$
1 mM EDTA
10% (v/v) glycerol
Store up to 1 month at 4°C
Just before use add:
1 mM DTT
0.1 mM PMSF (also see *APPENDIX 1B*)
1 mM benzamidine
1 mM sodium metabisulfite

Transcription stop solution

20 mM EDTA, pH 8.0
0.2 M NaCl
1% (w/v) SDS
0.25 µg/µl glycogen
Store up to 1 month at room temperature

COMMENTARY

Background Information

In general, transcription extracts are prepared from whole cells or nuclei by the extraction of factors using high salt concentrations—e.g., 0.42 M NaCl or 0.36 M ammonium sulfate (Dignam et al., 1983; Manley et al., 1980). These extracts are a rich source of general transcription factors, as well as some sequence-specific factors, and they are capable of accurate initiation of transcription from eukaryotic promoters mediated by RNA polymerase II. Results from several laboratories have demonstrated that addition of sequence-specific factors during the transcription reaction results in activated transcription in a binding site–dependent manner. Typically, most of these high-salt extracts utilize between 2% and 5% of the DNA template in a single round of transcription, and most systems allow two to three rounds of transcription. Unfortunately, these high-salt extracts are also a rich source of transcription repressors such as the histones (Croston et al., 1991) and other nonspecific DNA-binding proteins which inhibit elevated amounts of transcription in vitro. Removal of these inhibitors is important in order to dissect the exact mechanisms of transcription activation by sequence-specific factors (see, e.g., Croston et al., 1991).

Use of low-salt nuclear extracts avoids the extraction of certain transcription repressors such as the histones. The low-salt extract is therefore very efficient in template usage, and, depending on the promoter, it is possible to use up to 20% of the template per round of transcription with the possibility of multiple rounds of transcription (Kamakaka et al., 1991). The absence of histones in the extract makes it particularly useful in the transcriptional analysis of reconstituted chromatin templates (Kamakaka et al., 1993). Since the soluble nuclear fraction is prepared with low-salt buffers, it can be used directly in in vitro reactions without desalting.

Critical Parameters

The protocol for preparation of transcription extracts involves the isolation of nuclei followed by extraction of the factors using either high-salt buffers or high-speed centrifugation.

The most critical consideration after nuclear isolation speed is that all subsequent steps be performed at 4°C as rapidly as possible.

During the high-speed centrifugation, the authors have noticed that use of a fixed-angle rotor generates extracts of very poor quality; hence it is recommended that only a swinging-bucket rotor be used.

In the authors' experience, dilute extracts are inefficient for in vitro transcription reactions.

The use of sterile, high-grade reagents and clean glassware is critical.

High-salt extracts, in general, are more efficient in extracting both general and sequence-specific factors from nuclei. However the method is more tedious (taking 7 to 10 hr) and it is impractical to generate extracts from very small quantities of material. The soluble nuclear fraction does not suffer from these problems.

Anticipated Results

Extracts with a protein concentration of between 10 and 30 mg/ml are expected, and these extracts are usually competent for transcription.

All of these extracts should be initially tested for transcription competence using well characterized eukaryotic promoters and sequence-specific transcription activators. The adenovirus major late promoter should be used to test the HeLa extract while the Kruppel promoter is recommended for the *Drosophila* extract. Gal4-VP16 is a potent transcription activator that can be used with promoter templates containing binding sites for Gal4 with the HeLa and *Drosophila* extracts. In studies carried out in the authors' laboratory RNA synthesis has been monitored by primer extension analysis of the RNA (see Kamakaka et al., 1991). Generation of a primer extension product of a specific size is an indication of a functional extract.

Extraction of 12 liters of HeLa cells should provide 7 ml of active extract. Extraction of 100 g of *Drosophila* embryos should provide 40 to 50 ml high-salt extract or 15 ml soluble nuclear extract.

Time Considerations

The in vitro transcription reaction takes 1 to 2 hr and analysis by primer extension another 2 to 3 hr. Preparation of the HeLa extract requires 11 hr (~6 hr to make the extract from frozen cells with an additional 4 to 5 hr for dialysis and freezing). Preparation of the *Drosophila* embryo high salt extract requires 8 to 9 hr and the soluble nuclear extract requires 4 to 5 hr.

Nuclear Import in Digitonin-Permeabilized Cells

The development of the nuclear import assay in permeabilized cells in 1990 was a windfall for the examination of the mechanism of nuclear import. This assay (see Basic Protocol) has been used to detect and examine the factors required for import of nuclear substrates and has lately been adapted for the study of nuclear export as well. This unit will primarily deal with how to analyze the nuclear import of a substrate in an in vitro system. These experiments generally have two goals: first, to demonstrate that a given protein is imported into the nucleus and second, to define the particular sequence (termed the nuclear localization sequence or NLS) in the protein which is responsible for that localization. The nuclear import assay as described here uses *Xenopus* ovarian cytosol as a source of import factors to support import of fluorescent substrate into the nuclei of cells in which the plasma membrane has been permeabilized with digitonin (see Basic Protocol). The presence or absence of import substrate within the nuclei is subsequently detected by fluorescence microscopy.

More challenging than the nuclear import assay itself is generating the reagents necessary to perform the assay. This includes generation of the fluorescent nuclear import substrate and production of cytosol to support nuclear import of that substrate. Production of *Xenopus* ovarian cytosol is described here (see Support Protocol 1). It is a simple, dependable, and inexpensive procedure which does not require a relatively large tissue culture capability. Many laboratories instead use HeLa cytosol or reticulocyte lysate (*UNIT 11.2*) as a source of import factors.

Two protocols are given for production of fluorescent nuclear import substrate controls. The first protocol (see Support Protocol 2) describes how to make TRITC-BSA-NLS, which consists of bovine serum albumin (BSA) that is made fluorescent by coupling to rhodamine (for ease of detection) and then chemically coupled to NLS peptides to confer nuclear localization. A more recent version of import substrate (developed by Dr. Manfred Lohka; see Support Protocol 3) is a fusion protein composed of green fluorescent protein (GFP), glutathione *S*-transferase (GST), and an NLS. The recombinant import substrates have the advantage of containing a specific number of NLSs (one) and fluorophores (one) per molecule. This is not true of chemically conjugated import substrates which, due to the method of their production, are a heterogeneous population. However, the recombinant substrate has not been used as extensively and is therefore not as thoroughly characterized as the chemical conjugates.

Finally, the method of detection of imported substrate must be adapted to the protein in question. There are three common alternatives. First, if the protein has been cloned, it can be fused to GFP and its import assayed directly, assuming the total molecular weight of the substrate is greater than ~50 kDa. Second, the protein can be made fluorescent by direct conjugation to a fluorophore. Third, the protein can be detected by indirect immunofluorescence microscopy (see *UNIT 4.3*).

NUCLEAR IMPORT ASSAY IN ATTACHED HELA CELLS

BASIC PROTOCOL

The following protocol describes a nuclear import assay using a known NLS-containing substrate. The HeLa cell plasma membrane is permeabilized with digitonin, and soluble cellular components are washed away. These soluble components include proteins and nucleotides required for nuclear import to occur. The components are therefore added back to the permeabilized cells in the form of *Xenopus* ovarian cytosol, ATP, and GTP.

Contributed by Mary Shannon Moore and Eric D. Schwoebel

Current Protocols in Cell Biology (2000) 11.7.1-11.7.17

There are two choices of positive control substrate (see Support Protocols 2 and 3), both of which have the same basic properties: (1) the substrate is fluorescent to aid in detection and, (2) the substrate contains an NLS directing import into the nuclei. This substrate is mixed with the cytosol and nucleotide, and added to the cells. The import reaction is allowed to continue for 15 min, and is stopped by addition of cold buffer and fixation.

Materials

70% ethanol
30,000 cell/ml suspension of HeLa cells (ATCC CCL-2) in complete DMEM/10% FBS
DMEM/10% FBS (see recipe)
1× transport buffer (TB; see recipe), ice cold
Digitonin working solution (see recipe), ice cold
Import reaction mixture (see recipe)
Paraformaldehyde working solution (see recipe), ice cold
p-phenylendiamine mounting medium (see recipe)
Clear nail polish

12-mm circular glass coverslips (Fisher) sterilized by autoclaving
24-well tissue culture plates
Whatman 3 mm filter paper
Fine-tipped forceps with large radius curved shanks (e.g., Dumont #7, Fine Science Tools)
Fluorescence microscope

NOTE: All solutions and equipment coming into contact with tissue culture cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All tissue culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Prepare HeLa cultures
