The pTriEX backbone is used for the cloning of the biosensor, and the complete biosensor cDNA can be cut out as a cassette by digesting with *Nco*I/*Xho*I. *Nco*I encodes the start codon, and *Xho*I is placed in-frame immediately following the stop codon after the RhoA GTPase. The pTriEX version of the biosensor allows overexpression in mammalian cells driven by the CMV promoter.

One must beware of the potential toxicity of GTPases upon overexpression (Pertz et al., 2006) and the importance of the relative intracellular concentrations of GTPases and upstream regulators in cells (Michaelson et al., 2001; Del Pozo et al., 2002). We have addressed these issues by using retroviral transduction to stably incorporate low copy numbers of the biosensor DNA using the pBabe expression system (Pertz et al., 2006). Transduced cells are sorted flow cytometrically to obtain low to medium expressors only, so that the biosensor expression level is comparable to endogenous GTPase. We have shown that competition with endogenous effectors of the GTPase is not a significant problem at appropriate biosensor concentrations (Pertz et al., 2006).

In order to address the toxicity of overexpressed biosensor, a tetracycline-inducible retroviral construct based on a pBabe-sin-tet-CMV-puro backbone is used.

Materials

Tet-off stable MEF/3T3 cell system (Clontech)
MEF/3T3 cells transduced with the appropriate construct
10 mg/ml doxycycline stock solution
10 mg/ml puromycin stock solution

10-cm tissue culture dishes
Coverslips coated with fibronectin: immerse glass coverslips 30 to 60 min in 10 μg/ml fibronectin (e.g., Sigma), then rinse three times with PBS (*APPENDIX 2A*) and leave immersed in PBS until use

Additional reagents and equipment for cell culture techniques including trypsinization (*UNIT 1.1*), flow cytometric cell sorting (Robinson et al., 2009), and imaging the RhoA biosensor (Basic Protocol 4)

1. Using the tet-off stable MEF/3T3 cell system (Clontech), repress infected cells using 1 μg/ml doxycycline.

   Refer to user's guide for Clontech tet-off stable MEF/3T3 cell system for this and the following step.

2. Select cells with puromycin up to 10 μg/ml, increasing the puromycin concentration gradually following the infection (2 μg/ml increase per each successive selection cycle).

   "Selection cycle" means that the cells have tolerated that particular puromycin concentration.

3. At the end of selection, induce cells for biosensor expression by removal of doxycycline and replating cells at a sparse concentration (1×10^4 cells per 10-cm tissue culture dish) for 48 hr.

4. Sort cells flow cytometrically (Robinson et al., 2009) to produce nearly 100% biosensor-positive cells. Sort for CFP and YFP using two-color system.

5. Repress the cells again by application of 1 μg/ml doxycycline.

   We routinely maintain repressed cells in 1 μg/ml doxycycline under standard tissue culture conditions.

6. For the induction of the biosensor prior to experiments, detach the cells by brief trypsinization (*UNIT 1.1*) and centrifuge 5 min at $300 \times g$, 24°C. Carefully remove the supernatant and resuspend the cells in medium without doxycycline.

7. Plate the cells sparsely (1×10^4 cells per 10-cm tissue culture dish) without doxycycline and incubate for 48 hr prior to the experiments.

8. At a time point 24 hr after induction (i.e., the plating in step 7), check the cells for fluorescence. Continue incubating the cells under doxycycline-free conditions for an additional 24 hr prior to the assay.

   The total of 48 hr after removal of doxycycline ensures that overexpressors die and only cells with a sustainable expression level survive for the experiment.

9. On the day of the experiment, detach the cells with a brief trypsinization (*UNIT 1.1*).

10. Replate the cells on coverslips coated with fibronectin on the morning of the experiment and allow to adhere for 5 hr prior to imaging (see Basic Protocol 4).

IMAGING THE RhoA BIOSENSOR

BASIC PROTOCOL 4

Imaging is performed with the cells in Ham's F-12K medium without phenol red (see recipe in Reagents and Solutions), supplemented with 2% fetal bovine serum (FBS). For a single-chain design, it is sufficient to simply take a ratio of the FRET emission over the donor emission (Pertz et al., 2006). The two fluorophores will bleach at different rates, so bleaching corrections may be required to counter a bias in the signal over time. Such photobleach corrections are covered in detail elsewhere (Hodgson et al., 2006). Correcting for bleed-through (discussed in Basic Protocol 7) is not required for single-chain biosensors, but can be used to improve dynamic range when the biosensor is bright enough to permit this additional image processing.

This biosensor design preserves upstream regulatory interactions with molecules requiring a free C terminus, such as GDI. While this is an advantage in accurately reflecting cell physiology, it requires that one maintain low, near-endogenous levels of biosensor to minimize perturbation of normal cell physiology. At these low biosensor levels one must be careful to maximize light collection. It is not possible to compensate for low biosensor concentrations simply by increasing irradiation, as this bleaches the biosensor and increases phototoxicity. We routinely use an oil-immersion 40× Olympus UIS2 DIC objective lens with a numerical aperture of 1.3, together with 2 × 2 binning on our cooled CCD camera. We find that using 60× or higher magnification objectives cuts down greatly on light collection while increasing the photobleach rate. The signal intensity scales to the 4th power of the numerical aperture and to the inverse square of the magnification. Therefore, switching from a 1.3 NA 40× DIC objective lens to a 1.42 NA 60× DIC objective lens will result in an ∼37% decrease in signal intensity. It is important to use DIC rather than phase-contrast objective lenses, as the phase objective contains a phase annulus that substantially reduces light transmittance. Neutral-density filters of 0.6 to 1.0 (25% transmittance to 10% transmittance) are used to cut the brightness of the excitation light. It is better to use longer exposure with dimmer excitation rather than shorter, more intense irradiation; this reduces both photobleaching and phototoxicity. We routinely use methods to remove oxygen from the medium to further decrease photobleaching and phototoxicity, such as including the oxygen scavenger OxyFluor (Oxyrase, Inc.), including antioxidants such as vitamin C at 1 mM concentration, and purging the assay medium with argon gas.

The authors of this unit currently use a Roper Photometrics CoolSnapESII camera (*http://www.roperscientific.com/*), which is a Sony ICX285-based interline transfer cooled CCD camera, cooled to 0°C. This camera can be obtained with $<6e^-$ read noise, and $0.1e^-$/pixel/second dark current. The quantum efficiency of the chip is ∼60% for 450- to 625-nm light, and it has a small pixel size (6.45 × 6.45 μm) for good spatial resolution. We routinely use 2 by 2 binning and expose 800 msec for CFP and 400 msec for FRET, with a 10% transmittance neutral-density filter in the excitation light path. These conditions usually result in gray values filling ∼75% of the full 12-bit

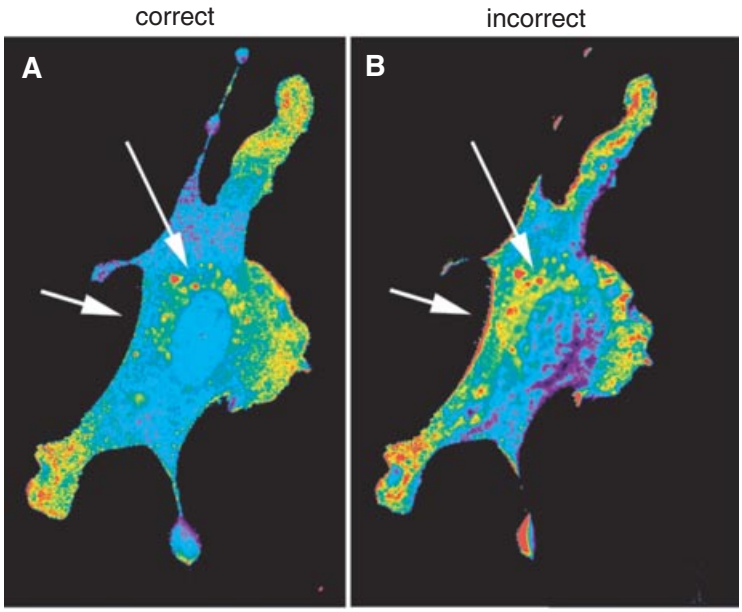

Figure 14.11.3 *x-y* translational image registration artifacts generate features on ratio images. In panel (**A**), a correctly registered ratio image of MeroCBD is shown. Panel (**B**) shows the ratio image from the same cell without registration. In the latter case, the dye image was misaligned by −5 pixels in both x and y directions. The white arrows in both figures point to regions where misalignment produces edge artifacts and other artifactual features. In (B), a lower-ratio rim can be seen on one side of the nucleus, and a higher ratio on the opposite side. Similarly, edge artifacts appear as higher ratio on predominantly one side of the cell, with an artifactually low ratio on the opposite side. For color figure go to *http://www.currentprotocols.com/protocol/cb1411*.

range of camera digitization. We do not recommend the current generation of on-chip amplification-gain CCD (EM-CCD) cameras for biosensor imaging. While these cameras can capture images under extremely dark illumination conditions, the gain circuitry introduces large amount of stochastic noise, which is problematic for ratiometric imaging (Fig. 14.11.3). When mathematical operations are performed on raw images, the stochastic noise adds greatly to the total noise levels in the resulting ratio image. While there are techniques available for signal restoration from acquisition with EM-CCD and other noisy approaches (Wang, 2007a,b), we have found conventional cooled CCD cameras to be sufficient. Other viable options may include back-thinned, back-illuminated cooled CCD cameras with high quantum efficiency. These cameras offer ultra-high quantum efficiency (>90%), but the pixel size is usually large (16 × 16 μm), reducing spatial resolution.

Two identical cameras can be mounted via a beamsplitter to simultaneously acquire the FRET and CFP channels. In such an approach, image registration can be affected by camera orientation as well as the angle of the dichroic mirror (causing rotation, *x-y* translation, image shear, mismatched scale, and mismatched focus). One must carefully mount the cameras to minimize rotational and translational effects, while accounting for the focus differences. Typically, beamsplitters are designed with an adjustable parfocal compensation device that can independently adjust the focusing distance of either camera head. This should be performed empirically to minimize focus difference between the two channels. Rotation, *x-y* translation, shear, scaling difference, and curvatures in the field of view will need to be corrected computationally based on a priori calibration, as described in Basic Protocol 7.

EXPRESSION OF Rac1 FLAIR, DUAL-CHAIN FRET BIOSENSOR FOR Rac1

BASIC PROTOCOL 5

The Rac1 biosensor currently used by the authors of this unit is a modification of an older design, wherein the FRET donor was EGFP-Rac1 and the FRET acceptor was a small binding domain derived from p21-activated kinase 1 (PAK1), labeled with the dye Alexa 546 (Kraynov et al., 2000). We modified this biosensor by replacing the EGFP with the fluorescent protein CyPet, and replaced the Alexa 546 with the fluorescent protein YPet (Fig. 14.11.1C). The new Rac1-FLAIR biosensor is wholly genetically encoded. It has been extensively validated and compared with other designs (Machacek et al., 2009). Unlike the RhoA biosensor above, the donor and acceptor fluorophores are not on the same chain. This improves the dynamic range and hence the sensitivity of the biosensor (in single-chain designs, some residual FRET is usually present even in the off state, so the change induced by activation is not as great as in dual-chain designs). The disadvantage of the dual-chain design is that the two chains do not distribute equally through the cell, necessitating careful bleed-through correction (see Basic Protocol 7). The two designs are prone to different effects on cell physiology and artifacts affecting the activation signal. Controls for the Rac1 FLAIR biosensor indicate that results have not been compromised by the separation of the chains (Machacek et al., 2009), and the sensitivity is, in fact, substantially enhanced.

Expression of the Rac1 biosensor is essentially the same as described for the RhoA biosensor above. The Rac1 biosensor is available from Addgene (*http://www.addgene.org*) in two formats:

1. Mammalian expression and cloning vectors: pECFP-C1 (Clontech) with ECFP replaced by CyPet (pCyPet-Rac1/kanamycin resistance), and pEYFP-C1 (Clontech Inc.) with EYFP replaced by YPet (pYPet-PBD/kanamycin resistance).

2. pBabe-sin-tet-CMV-puro retroviral vector for Tet-On/Off system incorporating the CyPet-Rac1 and YPet-PBD (amp resistance).

Because the donor and acceptor chains are on separate expression constructs, co-transfection/transduction of both components is required.

Materials

Mouse embryo fibroblast (MEF/3T3) cells (Clontech; tet-OFF MEF/3T3)
Rac1 biosensor vector system (see above)
Fugene6 transfection reagent (Roche)
10 mg/ml doxycycline stock solution
Coverslips coated with fibronectin: immerse glass coverslips 30 to 60 min in 10 μg/ml fibronectin (e.g., Sigma), then rinse three times with PBS (*APPENDIX 2A*) and leave immersed in PBS until use

Additional reagents and equipment for cell culture techniques (*UNIT 1.1*), flow cytometric cell sorting (Robinson et al., 2009), and imaging the Rac1-FLAIR biosensor (Basic Protocol 6)

For transient expression

1a. Transfect mouse embryo fibroblast cells (MEF/3T3) using Fugene6 following the manufacturer's protocols. Use a DNA ratio of 3:2 to transfect CyPet-Rac1 and YPet-PBD, respectively, for optimal results in MEF (or COS-7) cells.

It is important to premix the DNA solutions in the correct ratio, then add them to the Fugene-containing medium as a single aliquot. This optimizes correct mixing of both DNA constructs and results in an evenly distributed expression profile 24 hr post-transfection.

2a. Plate cells on fibronectin-coated glass coverslips at a density of 4×10^4 cells/coverslip for 3 to 4 hr prior to imaging.

For stable cell lines

Stable cell lines are preferred to reduce variability in the fluorescence profile from experiment to experiment, as well as for attaining better control of expression levels.

1b. For viral transduction using the pBabe Tet-off system, cotransduce viruses for the donor and acceptor portions of the biosensor according to the manufacturer's instructions.

2b. Select cells for stable incorporation by successively increasing the puromycin concentration, similar to the procedure described for stable RhoA biosensor cells (see Basic Protocol 3, step 2).

3b. Once the stable population is produced, sort the cells flow cytometrically (Robinson et al., 2009) for low to medium brightness, with equal CyPet and YPet fluorescence emission,

4b. Replate the collected fraction with doxycycline (1 μg/ml) to repress the expression until 48 hr prior to experiments.

Examination of varying ratios and levels of expression for each construct have not affected the results of motility studies, but can influence sensitivity and the ease of bleed-through corrections.

BASIC PROTOCOL 6

IMAGING RAC1-FLAIR

Imaging is performed in Ham's F-12K medium without phenol red (see recipe in Reagents and Solutions), supplemented with 2% fetal bovine serum. For emission ratio imaging, the following filter sets (Chroma Technology) are used (for excitation and emission, respectively): CyPet: HQ436/20 (ex), HQ470/40 (em); FRET: HQ436/20 (ex), HQ535/30 (em); YPet: HQ500/20 (ex), HQ535/30 (em). The dichroic mirror ("Quad-Custom," lot no. 511112038; spectra shown in Fig. 14.11.4) was custom manufactured by Chroma

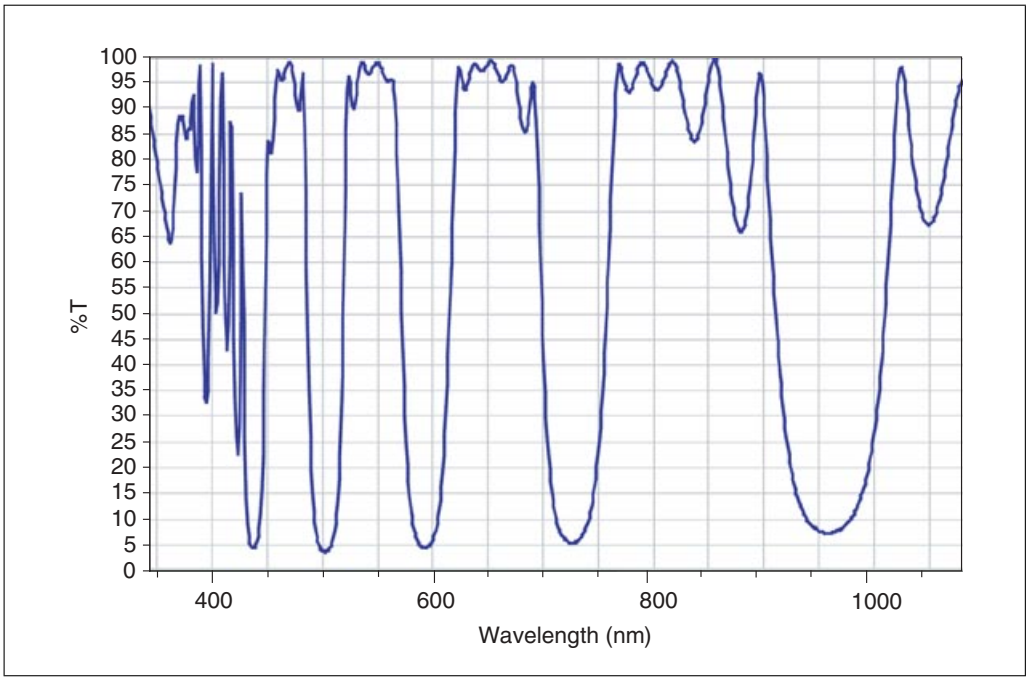

Figure 14.11.4 Transmittance spectra for the "Quad Custom" dichroic mirror (Chroma Technology, lot no. 511112038).

Technology Corp. for compatibility with all of these filter sets. A more recent sputter-coated ET series of dichroic mirrors and band-pass filters from Chroma could be used. For CyPet/YPet imaging or any other ECFP/EYFP-FRET-based imaging, either filter set 59217 (single-band exciters with a dual-band emitter) or set 89002 (all single-band filters) can be used effectively (Chroma Technology). Cells are illuminated with a 100 W Hg arc lamp through a neutral-density filter of 10% transmittance. At each time point, three images are recorded with the following exposure times, typical for the low biosensor concentrations used to minimize cell perturbation—CyPet, 900 msec; FRET (excitation of donor, observation of acceptor emission), 900 msec; YPet, 300 msec—at binning 2 × 2. The image sets have been taken at 10-sec to 10-min intervals. Ideally, one fills ~75% of the total 12-bit dynamic range of the camera for each channel. This produces a good signal-to-noise ratio and does not saturate the dynamic range should any one channel dramatically increase brightness. Imaging is detailed further in the RhoA biosensor section above.

Bleed-through correction for intermolecular biosensors is described in the following discussion of imaging procedures.

IMAGE PROCESSING PROCEDURES

BASIC PROTOCOL 7

Shading correction

The first step in image analysis is to correct for uneven illumination in the field of view. This is present in almost all images, including those taken using flat-field (Plan) corrected objective lenses. In order to correct for shading, one obtains images from fields of view that contain no samples. Images of each fluorescence channel are obtained using the same camera integration times and illumination conditions as are used for the real images that will be corrected. The images for shading correction are acquired following the acquisition of the real fluorescence image sets either by using cell-free areas within the same coverslip or by mounting a fresh coverslip with identical media and mounting conditions. In the latter case, it is convenient to mark a spot in the middle of the fresh coverslip on the side where cells would be present on an actual sample coverslip, so that one can focus on the edge of the spot to find the correct plane of focus. Usually, 20 to 30 shading images are acquired at the appropriate camera integration times and illumination settings for each fluorescence channel. The resulting image set for each channel is averaged to produce a single shade-corrected image for each fluorescence channel. The averaging process is important because each image frame contains stochastic camera noise. This noise can be reduced by averaging many frames of the same field of view. Additionally, images corrected for camera noise are required. These images are obtained by taking an average of multiple exposures (10 frames) of a field of view, but with the illumination shutter completely closed so as to prevent any light from reaching the CCD sensor. This basically captures the electronic and dark current noise associated with each acquisition condition. The noise image is then subtracted from the raw images and the shading images. Once these corrections are made, one simply divides the sample field of view by the corresponding shading image. Here, care must be taken to prevent floating-point errors from the image analysis software. Software including Metamorph (Universal Imaging Co.) and ISEE Inovision (ISee Imaging Systems) do not process floating-point data. Matlab (Mathworks) codes can be written to process images using a multiple decimal-point precision. Metamorph offers a convenient plug-in module for shade correction where a scaling factor can be specified to increase the relative pixel values so that floating-point operation is avoided. One can either scale to the maximum pixel value in the shading image or specify some fixed value. The latter is usually the better choice, as one can specify the same scaling factor (i.e., 1000) for images from both channels of fluorescence, thereby maintaining the relative intensities of the image pairs.

Background subtraction

Because of the flat-field correction, cell-free background areas within the field of view have the same intensities. One can use an area with minimal debris in the field of view as the background. The pixel intensities within such a region are averaged and subtracted from the whole image. Small variations in background can be introduced, e.g., by debris in your field of view. It is important to choose the same background position in each fluorescence image to minimize artifacts. Metamorph offers a convenient plug-in module ("Use region as background") to expedite the process. Using this utility, one can select a background region in the first fluorescence image of a ratio pair, and copy/save the region and paste/load onto the second fluorescence image. When using this Metamorph utility, it is important to note that processing of stack images requires additional considerations. If the region is selected on the top plane and the utility is run for all planes in the stack, the averaged background value from the first plane is subtracted from each of the subsequent planes. In order to work around this problem, the region on the top plane can be saved and loaded onto each of the subsequent planes, and background subtracted. Similarly, the same region can be loaded onto each plane of the fluorescence ratio pair images and processed.

Image masking

Ratio division can introduce noise and hot spots in regions outside of the cell. Furthermore, pixel intensities in the thin, peripheral regions of the cell can be near background levels, making reliable quantitative ratio calculations difficult. In order to limit the area within which ratio calculations are performed, a binary mask can be applied to the cell, setting areas outside of the cell uniformly to zero. The mask can be based on an image of a volume marker (i.e., fluorescent dextran) or a membrane marker in a fluorescence color different from that of the biosensor. This is used to unambiguously specify the true cell boundary in cases where intracellular distribution of the biosensor does not correspond to the cell shape. In the case of most GTPase biosensors, distribution of the biosensors sufficiently delineates the cell boundaries, so this is unnecessary.

To produce the binary mask, all fluorescence image stacks (dye and EGFP channels, or ECFP and FRET/Citrine-YFP channels) are intensity thresholded. If the shade correction and background subtraction have been performed correctly, this is a straightforward process (i.e., using the Threshold Image command in Metamorph). With properly processed images, the histogram distribution is such that there will be a large peak in the zero-pixel-intensity position, followed by a spread of non-zero pixels in the image histogram distribution (Fig. 14.11.5). Inclusive thresholding is manually performed by trial and error, observing which setting appropriately includes the cell pixels and excludes the surrounding pixels (i.e., using the Metamorph Threshold Image function). For a 16-bit image, the upper bound needs to be set at 65,535, the maximum value for 16-bit dynamic range. When processing a series of images from a time-lapse study, it is important to check the low-end threshold value selected using the first plane ($t = 0$ time point) against the last image plane ($t =$ end). Photobleaching will shift the low-end intensity distribution downward, resulting in under-selection of cell area at later times. In order to work around this problem, threshold values are determined through one of two methods: (1) thresholding is performed for later time points of the data stack, resulting in a relaxed thresholding for earlier time points; or (2) the data stack is histogram-equalized for the lowest intensity value using the Metamorph Equalize Light function, setting the equalization for "minimum" via the "addition" option, then producing the binary mask using the equalized data stack and then applying the resulting binary mask to the original non-equalized data stack. The latter approach produces better masking precision without resulting in relaxed selection in the earlier time points. Once the threshold values are set, a binary mask can be produced based on the selected inclusive threshold (in Metamorph, the Clip tab within the Threshold Image module is used to produce a binary mask in

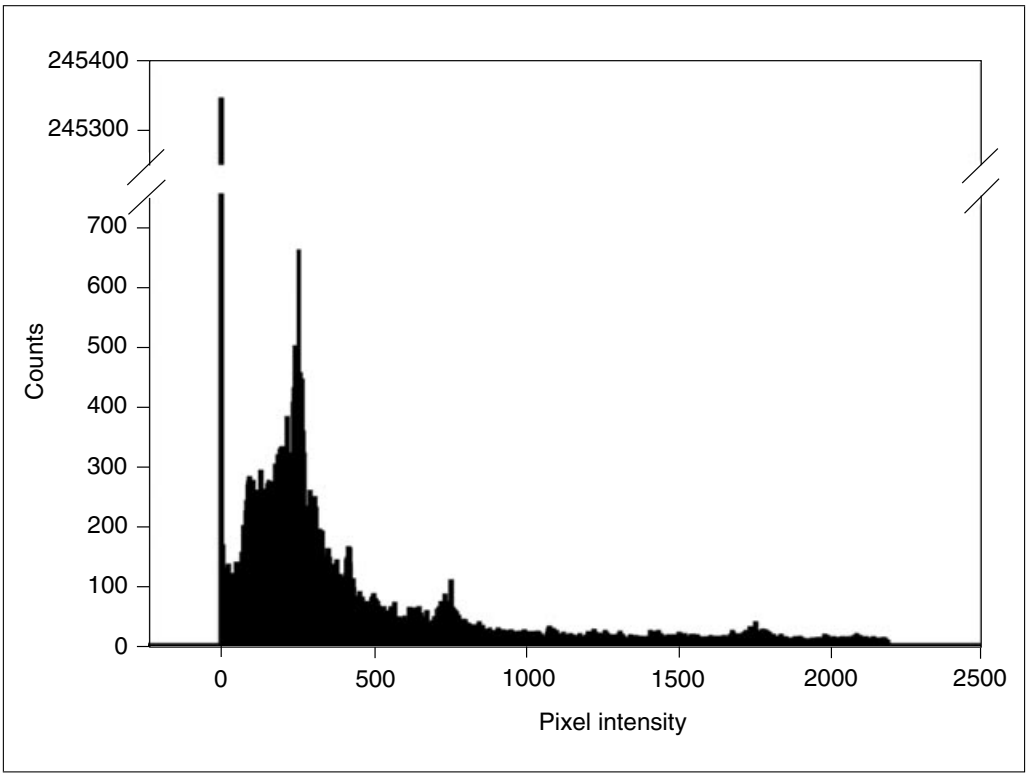

Figure 14.11.5 A representative histogram from a shade-corrected and background-subtracted image, prior to masking. The prominent histogram peak at zero intensity is followed by a continuous distribution of pixels at a range of positive intensity values. Threshold masking to remove pixels of too low an intensity is performed using this histogram. One maximizes selection of pixels from within the cell while removing pixels outside the cell, including noise around the periphery.

16-bit). This will produce a binary mask where regions outside the threshold selected area are uniformly zero, while inside is 65,535. Divide the binary mask with a constant (65,535) to produce a true binary mask containing the value one inside the masked region and zero outside (Arithmetic function in Metamorph). Binary masks produced for each fluorescence channel are multiplied into the corresponding fluorescence image stacks to produce the masked fluorescence image stacks prior to automated image registration.

Automated image registration

The ratio calculation requires a division of one image by another. It is essential that the fluorescence ratio image pair be perfectly aligned prior to division. There are a host of potential sources for misalignment: placement of optical filters, dichroic turret movement, *x-y-z* stage movement, temperature fluctuations and ambient vibration, and sub-pixel misalignment. Figure 14.11.3 indicates the result of misalignment on ratiometric analysis. The edge artifacts in the form of high ratio values on one side and low ratio values on the other, as well as similar symmetrical artifacts within the cell, provide clues that image misregistration has occurred. Sub-pixel registration routines are available in most image processing-software. For some experiments, only manual registration will suffice, but in many cases, especially when there are subcellular structures with clearly defined edges, automated registration is possible. The authors of this unit developed an automated method for image registration based on normalized cross-correlation technique (Shen and Price, 2006). A modified version of this routine, based on the Matlab program, applicable for registration of up to three channels of fluorescence image sets, is provided at *http;//www.currentprotocols.com/protocol/cb1411* (files `regAny2.m` and `regFCY2.m`).

The Matlab routine for processing the 2-channel data set is `regAny2.m` and for the 3-channel data set is `regFCY2.m`. The `regAny2.m` will take individual tiff files with the running number index and align the FRET channel with respect to the CFP channel to an accuracy of 1/20th of a pixel (maximum pixel shift allowed = 10 whole pixels). Similarly, the `regFCY2.m` will align the FRET and YFP channels against the CFP channel. In both cases, the relative displacements in *x* and *y* are recorded on a frame-by-frame basis for an entire time series, and the median values of the distance displacements in *x* and *y* are applied to the whole time series at the end of the routine. This mode of registration is based on the assumption that the majority of the channel misalignment will stay constant for the duration of a single time-lapse experiment. If individual *x-y* displacements are corrected on a frame-by-frame basis, we have observed an unacceptable level of jitter in the final movie playback. Detailed requirements for the naming convention, file formats, etc., are listed within the headers of the programs. One tip for making this program run faster and more smoothly is to crop the cell image as tightly as possible (ensuring for all timepoints that the cell stays within the region of interest selected and cropped), making sure both channels to be aligned are cropped using the same cropping factor. This will minimize the computational load required to translationally align the images, as there will be fewer total pixels to compute the cross-correlation coefficients compared to processing the entire field of view.

Image shear, rotation, and scaling correction

Two separate cameras can be used to simultaneously acquire the two images required for ratio imaging (CFP and FRET, or EGFP and dye). This can be valuable when rapid image sequences are required, or when rapid changes in cell shape or biosensor distribution can produce motion artifacts. For simultaneous imaging with two cameras, one uses a beam splitter and appropriate filters and dichroic mirror to direct different wavelengths to each camera. Differences in positioning of the two cameras can produce image misalignment other than the straightforward *x-y* translation encountered with one camera. Such additional misalignments include shear, rotation, and scaling between the two images. These problems primarily arise from imperfect mounting of the cameras and the dichroic mirrors in the beam splitter. Alignment should first be optimized manually, but an automated solution based on a priori calibration is required to sufficiently correct these effects. We present here a polynomial-based method for a priori calibration. Figure 14.11.6 shows calibration grid images and ratiometric images of RhoA activity before and after the correction. It is clear that manually aligning one corner of the grid leads to misalignment of the far corner. The software for Matlab consists of two parts (*http://cuurrentprotocols.com/protocol/cb1411*, files `morphPrep.m` and `morph.m`): (1) a priori calibration software `morphPrep.m`, used to determine the coordinate transformation control points; and (2) the transformation program `morph.m`, which applies a 3rd-order polynomial-based coordinate transformation using the calibrated control points. We find it best to apply these corrections prior to image masking and *x-y* translational alignment. For calibration, one can use a grid-type stage micrometer imaged in bright-field, or microbeads coated with fluorophores to simulate fluorescence imaging conditions. Imaging of the calibration specimen should be performed at the end of an experiment (be careful not to move the two cameras during the imaging experiment!). This correction method is not applicable to a majority of cases where a single camera and filter wheel are used to acquire multiple images in succession. However, in some cases fluorophores of very different wavelengths can scale differently due to the behavior of chromatically corrected optics (i.e., ECFP versus Cy-7). This method can be used effectively to correct for such issues if a priori calibration is performed.

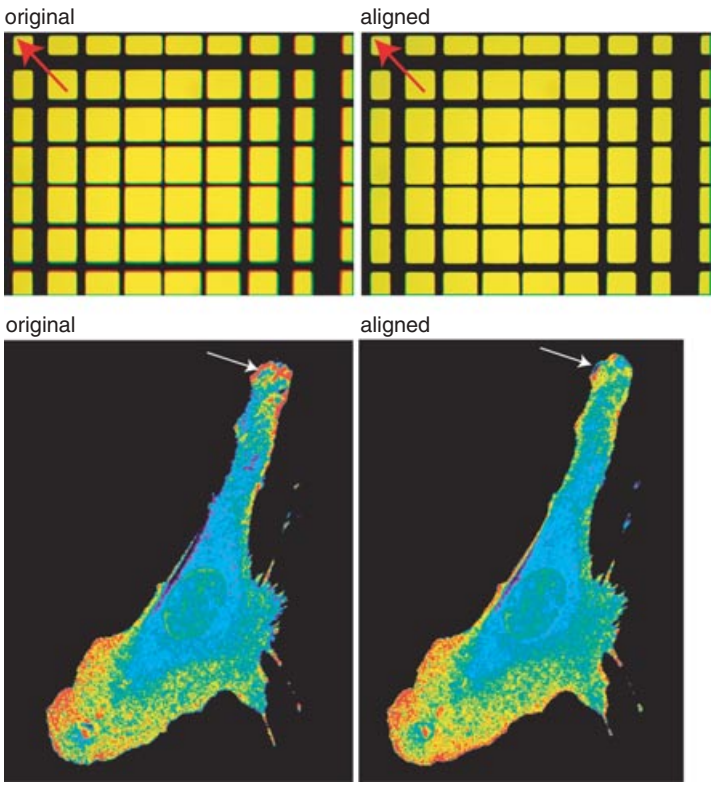

Figure 14.11.6 Image shear between two cameras creates artifacts in ratio images. In the upper panels, calibration grid images from two cameras are overlaid with and without shear correction (red arrow: two channels aligned relative to the corner indicated). In the lower panels, the ratios of RhoA biosensor readouts from the two camera channels are shown with and without shear correction. A peripheral ruffle shows a large artifactual feature when correction is not applied (white arrow). For color figure go to *http://www.currentprotocols.com/protocol/cb1411*.

Ratio calculation

The masked and registered images are divided to produce a ratio image. For meroCBD, the dye image is divided by the EGFP image. For the FRET sensors, the FRET channel is divided by the donor image. The floating point error consideration is important in this step; for software that does not carry out floating point calculations, all numbers must be multiplied by a constant. This converts decimal portions of intensity values to larger numbers, so that they are not truncated or otherwise modified prior to division. In the Metamorph Arithmetic module, a scaling factor of 1000 is specified as a multiplication factor during the ratio calculation. A smaller factor (10 to 100) can be used. However, this is not recommended since it tends to produce a non-smooth histogram distribution (Fig. 14.11.7). The same scaling factor should be used when comparing ratio calculations from different experiments with the same biosensor.

Ratio images are scaled and often displayed as a pseudocolor map to reflect the range of ratio values within the image. Many methods are used for this, and the range of values within an image cannot readily be used to determine the dynamic range of the biosensor. For example, the lowest and highest pixel intensities are often not included in the scaling, as these can be due to spurious artifacts or noise. If one chooses to eliminate the lowest and highest 1% of pixel intensities, a 99-fold change is shown within the image. Eliminating the lowest and highest 5% reduces this to a 20-fold change.

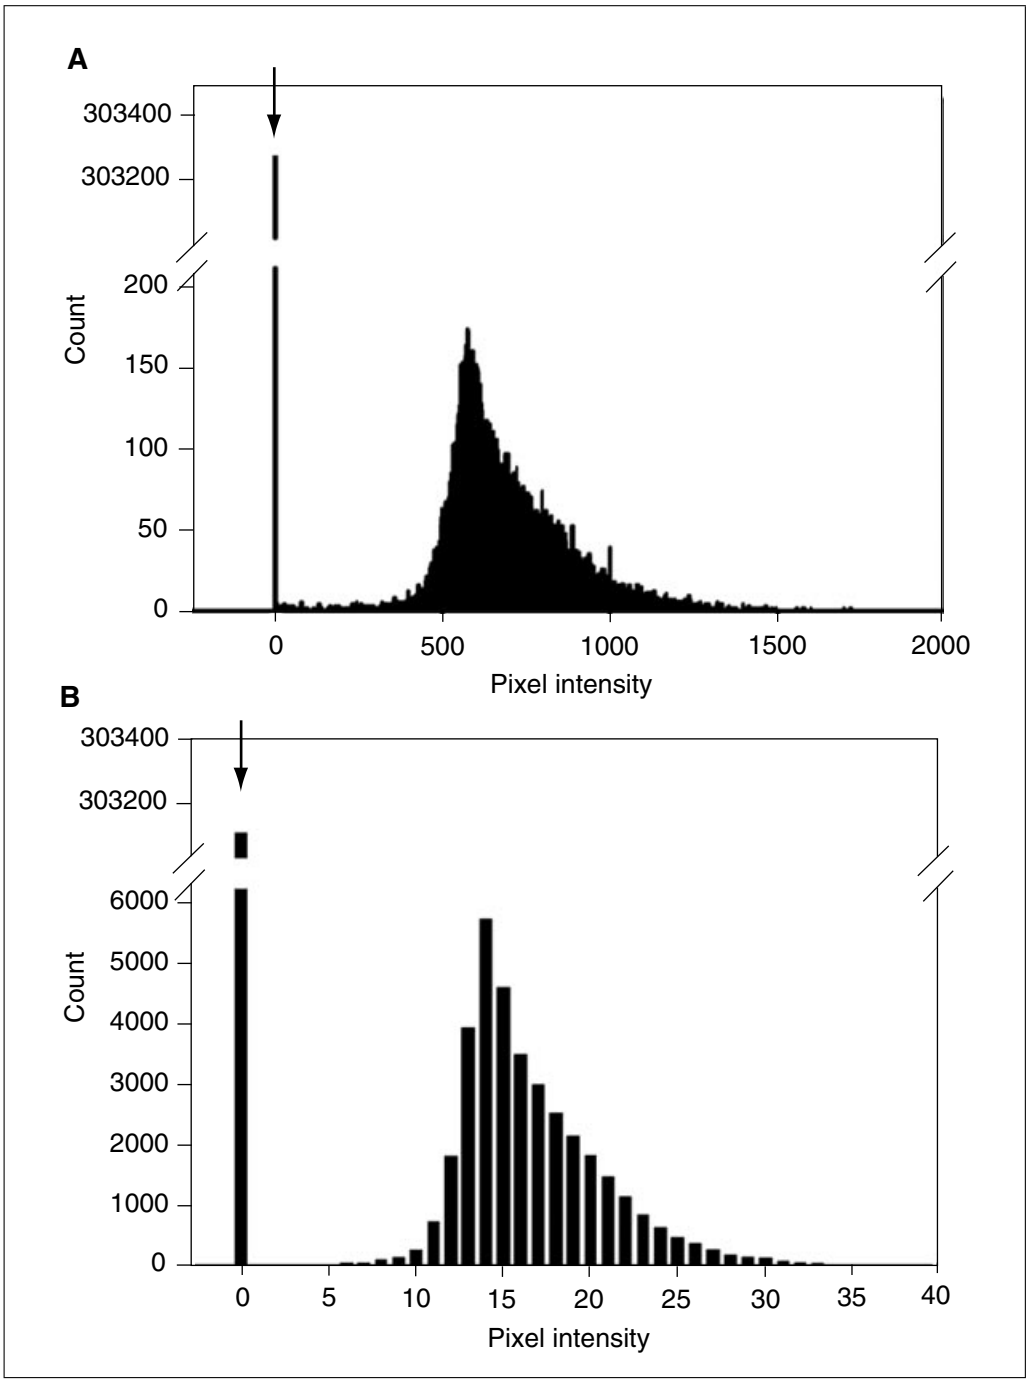

Figure 14.11.7 Effect of the multiplication factor during ratiometric calculation. In panel (**A**), using a scaling factor of 1000 produced a smooth histogram distribution in a ratio image. Panel (**B**) shows the same ratio image with the scaling factor of 25. Though the general distribution pattern is similar, the histogram distribution in (A) retains higher bit-depth resolution.

Ratio calculations for intermolecular FRET biosensors

In the case of intermolecular FRET biosensors such as the biosensor for Rac1, a bleed-through correction is required. Images for the bleed-through correction should be obtained routinely as part of each experiment, so that variations in the microscope system over time do not come into play. Control cells expressing either CyPet alone or YPet alone are used to determine how much light bleeds through into channels where it is not desirable. For example, CyPet excitation is used to generate FRET. However, when this is done, some light emitted from CyPet itself appears in the FRET emission channel.

This bleed-through must be quantified so that it can be subtracted out in real experiments. For this correction, intensity is measured using the CyPet excitation and CyPet emission channels, then measured again under the same exposure conditions using the CyPet excitation and YPet emission channels that will be used to monitor FRET. This reveals what percentage of the intensity measured using the direct CyPet fluorescence channels would also appear in the FRET channels. Bleed-through coefficients determined in this way are the coefficients α and β in the following equation:

$$R = \frac{\mathrm{FRET_t} - (\alpha \times \mathrm{CyPet}) - (\beta \times \mathrm{YPet})}{\mathrm{CyPet}}$$

Equation 14.11.3

where R is the ratio, $\mathrm{FRET_t}$ is the total FRET intensity as measured, α is the bleed-through of CyPet into FRET channel upon CyPet excitation, β is the bleed-through of YPet into FRET channel upon CyPet excitation of YPet, and CyPet is the total CyPet intensity as measured. Bleed-through into the CyPet channel (denominator) is negligibly small. By calculating the linear slope of the relationship between FRET and CyPet intensities upon CyPet excitation of cells expressing only the CyPet, the bleed-through parameter α can be determined. Similarly, by relating bleed-through into the FRET channel upon CyPet excitation of cells expressing only the YPet, the bleed-through contribution of YPet excitation by CyPet excitation into the FRET channel β can be determined. For our microscope and exposure conditions, the α parameter was found to be routinely within 0.4 and 0.5 and the β parameter to be $\sim$0.2. These are dependent on the optical configuration of the microscope used. We provide a convenient Matlab routine, `BT_AB.m` for calculating the α and β parameters from raw images and associated shading images (*http://www.currentprotocols.com/protocol/cb1411*; file `BT_AB.m`), utilizing a segmentation based on the K-means clusters method (Shen and Price, 2006). The ratio of corrected FRET over CyPet can be calculated and used as a measure of Rac1 activation.

In time-lapse experiments, CyPet and YPet photobleach at different rates. The ratio can be corrected for photobleaching as described elsewhere (Hodgson et al., 2006). Briefly, by algebraic manipulation, Equation 14.11.3 can be rearranged to:

$$R = \frac{\mathrm{FRET_t}}{\mathrm{CyPet}} - \beta \frac{\mathrm{Ypet}}{\mathrm{CyPet}} - \alpha = \Gamma - \beta \times \Psi - \alpha$$

Equation 14.11.4

where Γ is the fraction representing total FRET intensity over total CyPet intensity, and Ψ is the fraction representing total YPet intensity over total CyPet intensity, and both α and β are bleed-through constants described before. By taking double exponential fits of the decays of both Γ and Ψ, the correction function, $\bar{R}^{-1}$, can be calculated as outlined previously (Hodgson et al., 2006). We provide a convenient routine, `PB5.m`, that takes the masked and registered image sets (CyPet, YPet, and FRET) plus the a priori–determined α and β parameters, and calculates the photobleach-corrected ratio R and corrected FRET, which is represented by the numerator of Equation 14.11.3 (see *http://www.currentprotocols.com/protocol/cb1411*; file `PB5.m`). These codes are available for download from the Hahn lab Web page and from the Current Protocols Web site (*http://www.currentprotocols.com/cb1411*). Also included are the Matlab routines `SubpixShift.m`, `subalign.m`, `kmeanst.m`, and `maxArray.m`,which are required functions that are called from within the routines described above.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ham's F-12K, phenol red-free

Inorganic salts
7530.00 mg/liter NaCl
285 mg/liter KCl
106 mg/liter $MgCl_2 \cdot 6H_2O$
393 mg/liter $MgSO_4 \cdot 7H_2O$
135 mg/liter $CaCl_2$
218 mg/liter $Na_2HPO_4 \cdot 7H_2O$
59 mg/liter KH_2PO_4
2500.00 mg/liter $NaHCO_3$
0.8 mg/liter FeSO4·$7H_2O$
2 μg/liter $CuSO_4 \cdot 5H_2O$
0.14 mg/liter $ZnSO_4 \cdot 7H_2O$

Amino acids
17.8 mg/liter L-alanine
421.3 mg/liter L-arginine HCl
30 mg/liter L-asparagine·H_2O
26.6 mg/liter L-aspartic acid
70.04 mg/liter L-cysteine HCl·H_2O
0 mg/liter L-cystine
29.4 mg/liter L-glutamic acid
15 mg/liter glycine
41.9 mg/liter L-histidine HCl·H_2O
7.9 mg/liter L-isoleucine
26.2 mg/liter L-leucine
73.1 mg/liter L-lysine HCl
8.9 mg/liter L-methionine
9.9 mg/liter L-phenylalanine
69.1 mg/liter l-proline
21 mg/liter L-serine
23.8 mg/liter L-threonine
4.1 mg/liter L-tryptophan
10.9 mg/liter L-tyrosine
23.4 mg/liter L-valine

Vitamins
0 mg/ml L-ascorbic acid
0.07 mg/ml biotin
0.48 mg/ml D-calcium pantothenate
13.96 mg/liter choline chloride
1.36 mg/liter cyanocobalamin
1.32 mg/liter folic acid
18 mg/liter inositol
0.04 mg/liter nicotinamide
0.06 mg/liter pyridoxine HCl
0.04 mg/liter riboflavin
0.21 mg/liter thiamine HCl
0.21 mg/liter DL-thioctic acid

continued

Other compounds
1260.00 mg/liter glucose
0 mg/liter linoleic acid
4 mg/liter hypoxanthine·Na
0 mg/liter phenol red
0.3 mg/liter putrescine
220 mg/liter sodium pyruvate
0.7 mg/liter thymidine

Lysis buffer

50 mM sodium phosphate buffer, pH 7.6 (*APPENDIX 2A*)
300 mM NaCl
10% (w/v) glycerol
5 mM $MgCl_2$
2 mM 2-mercaptoethanol (omit where indicated in protocol)
1 mM PMSF (omit where indicated in protocol)
Store up to 12 months at 4°C

Storage buffer

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
50 mM NaCl
5 mM $MgCl_2$
10% (w/v) glycerol
Store up to 12 months at 4°C

COMMENTARY

Background Information

Biosensors have become valued tools in cell biology, with commercial software and specifically designed microscopes greatly enhancing their accessibility and ease of use. It is important to apply this software with an understanding of the variables that can affect biological conclusions. Final images are sensitive to subtle changes in image-processing procedures, or the use of biosensors under conditions that affect cell biology. The authors of this unit hope that the procedures outlined here, for three different biosensor designs, can be a guide for proper application of new biosensors to shed light on previously invisible protein dynamics.

Rac1 FLAIR is an intermolecular FRET biosensor, frequently referred to as a dual-chain sensor. The use of a dual-chain design significantly enhances the sensitivity of the biosensor in comparison with single-chain FRET biosensors. The latter usually show substantial FRET even when the biosensor is in the off state; the two fluorophores are never fully separated. With the Rac1 sensor, the dynamic range, the difference between the on and off states, is enhanced. There is a downside to the dual-chain approach. The two components of the biosensor distribute differently in the cell, necessitating additional steps in image processing. Both single-chain and dual-chain biosensors are potentially perturbed by competition from native protein ligands; the dual-chain sensor may be more likely to produce false negatives, as it may be more sensitive to ligands that compete for the GTPase-binding fragment, while the steric bulk of the single-chain sensor may prevent it from reaching all sites normally accessed by the GTPases. The issue of competition and its effect on biosensor readout is complex and beyond the scope of this unit. We recently completed a careful study of the effects of varying the concentration of each component of the dual-chain Rac1 biosensor. This did not appreciably alter the results of our cell protrusion studies (Machacek et al., 2009).

Factors affecting FRET efficiency

FRET is sensitive to both the distance and orientation of the two fluorophores in a biosensor. When fluorophores are sufficiently far apart or have orthogonal dipole orientations, excitation of the donor leads simply to donor emission, rather than to FRET. However, when the distance is sufficiently small, and orientation enables sufficient dipole coupling, excitation energy is transferred from the donor

to the acceptor, leading to decreased donor emission and increased emission from the acceptor. This produces a characteristic FRET excitation/emission spectrum, different from that of the donor or the acceptor alone.

GFP mutants optimized for FRET in living cells have shown impressive improvements. Mutants incorporate different trade-offs between brightness, FRET efficiency, photostability, and pH dependence of fluorescence characteristics (Heikal et al., 2000; Miyawaki and Tsien, 2000). Enhanced brightness improves the overall signal-to-noise ratio in cells, but is not always an improvement if it comes at the cost of FRET efficiency or photostability (Nguyen and Daugherty, 2005). The Cyan and Yellow fluorescent proteins (CFP and YFP), and their brighter, pH-stable versions Cerulean and Venus (Miyawaki and Tsien, 2000; Rizzo and Piston, 2005), are relatively fast-maturing, bright GFP mutants that have proven useful in many FRET biosensors. More recent mutants with improved FRET efficiency (Nguyen and Daugherty, 2005) include CyPet and YPet, which exhibit 6- to 7-fold greater FRET efficiency than the original CFP-YFP pair, though more recent findings indicated that this particular pair may be more prone to dimerization (Nguyen and Daugherty, 2005; Ohashi et al., 2007).

FRET efficiency is quantified by the Förster equation:

$$R_0 = \left[8.8\times10^{23} K^2 n^{14} Q_d J\right]^{1/6}$$

Equation 14.11.5

where R_o is the Förster distance (distance at which energy transfer is 50% efficient) and K^2 is the dipole orientation factor, a function of the donor emission transition moment and the acceptor absorption transition moment. K^2 = 2/3 is generally assumed when fluorophore rotation can occur about the bond attaching the fluorophore to the protein (Lakowicz, 1999). Q_d is the fluorescence quantum yield of the donor in the absence of acceptor, n is the refractive index of the medium, generally assumed to be 1.4 for proteins (dos Remedios and Moens, 1995), and J is the spectral overlap integral, indicating the extent of overlap between the donor fluorescence emission spectrum and the acceptor excitation spectrum (Lakowicz, 1999).

In FRET biosensors, activation of the targeted protein leads to a change in the distance and/or orientation of the fluorophores. FRET efficiency is exquisitely sensitive to distance between fluorophores (varies as the inverse 6th power of the distance between the fluorophores):

$$E = \frac{R_0^6}{\left(R_0^6 + R^6\right)}$$

Equation 14.11.6

where E is FRET efficiency, R_o is the Förster distance, and R is the actual distance (Lakowicz, 1999). Changes in the relative angular orientations of the dipoles produce a lesser but nonetheless important effect; the dipole orientation factor K^2 can be assumed to be 2/3 only when both fluorophores are free to rotate isotropically during the excited-state lifetime. A change in the fixed angle of the fluorophores in different biosensor states affect FRET because K^2 can change between 0 and 4 (Lakowicz, 1999; dos Remedios and Moens, 1995). The effects of fluorophore separation (linear displacement) versus angular reorientation cannot be readily separated in live-cell studies, so FRET changes are not used to precisely determine distances between proteins in cells. Rather, the extent of FRET produced by fully activated versus inactive target protein is determined, and these endpoints are used to interpret FRET signals in vivo.

Critical Parameters and Troubleshooting

The critical parameters for setting up a microscope system for time-lapse biosensor imaging will not be discussed here, as the relevant protocols above deal with these in detail. For successful biosensor imaging, critical components are production of clean and functional biosensor at optimal dye labeling efficiency in the case of meroCBD, and optimal expression levels and cell health in the case of genetically encoded biosensors. The proper maintenance of cells before and after microinjection will significantly affect cell survival during time-lapse imaging in the case of MeroCBD. We have found that careful attention to deoxygenating the imaging medium, using reagents including Oxyrase/Oxyfluor, has a significant effect in minimizing photobleaching as well as photodamage to cells from irradiation. To this end, use of low-intensity light for a longer duration of exposure is much preferred, rather than a short exposure with a full intensity of excitation light.

The choice of imaging medium is an important consideration when imaging FRET biosensors. Background fluorescence from the

medium is a significant issue at the wavelengths used. We have performed a quantitative comparison of various media available commercially (data not shown), and concluded that Ham's F-12K medium without phenol red (Kaighn, 1973; Robey and Termine, 1985; see Reagents and Solutions) is a good choice. Unfortunately, this medium is no longer commercially available. The published formulation can be found in Reagents and Solutions.

Anticipated Results

Biosensors for Rho family GTPases should provide sensitive and high-resolution data of activation of GTPases in living cells. Typically, only 40% to 60% of the CBD-EGFP is recovered as purified meroCBD, due to some denaturation/precipitation during labeling and loss during gel filtration. The final eluate concentration is usually 120 to 140 μM. Labeling efficiency under these conditions varies between a dye/protein ratio of 0.7 and 0.9. The meroCBD solution is divided into 15- to 20-μl aliquots and stored at –80°C. Flash-freezing using liquid N_2 or dry ice appears to increase precipitation during microinjection. Alternatively, meroCBD may be kept at 4°C for up to 1 week.

The single-chain RhoA and bimolecular Rac1 biosensor transduction using retrovirus usually results in a nearly 100% positive population following FACS sorting. FACS sorting with relatively tight gates is used to isolate a low-expression-level population that results in biosensor expression levels of ~20% to 30% of endogenous protein. For microscopy imaging, the typical time resolution can be in the order of seconds, limited only by the user's microscope system configuration. The spatial resolution can be theoretically at the optical limit of light microscopy in *x* and *y*; however, due to low levels of injection/expression that are preferred so as to not impact the biological processes of interest, binning may be required to increase sensitivity. The 2 × 2 binned dataset obtained using a 40× DIC oil-immersion objective lens will be on the order of 320-nm spatial resolution in *x* and *y*. The dynamic range of the biosensor ratio readout for meroCBD can be on the order of 1:3 to 1:6, that of genetically encoded single-chain RhoA biosensor can be on the order of 1:1.5 to 1:2, and that of genetically encoded bimolecular Rac1 biosensor can be on the order of 1:7 to 1:20. Dynamics of the resulting ratio readouts should be carefully interpreted, keeping in mind the potential sources of artifacts, including misalignment of the ratio pair and motion artifacts if using single camera-based imaging approach. These artifacts will significantly skew the resulting ratio and impact spatial as well as temporal ratiometric readouts.

Time Considerations

Preparation of meroCBD requires 3 days, including the dye-labeling reaction and post-reaction purification. Cells plated on fibronectin-coated coverslips are usually ready for microinjection within 3 hr following plating. Microinjection of live cells on coverslips is typically performed within 10 min, followed by a 30-min to 1-hr recovery prior to imaging experiments. The process of viral transduction can be performed, taking 1 week, while preparation of stable cell lines containing the genetically encoded biosensor can take up to 2 weeks, including the FACS sorting. Genetically encoded biosensors will require 48 hr after removal of doxycycline from the medium to induce expression prior to imaging experiments. Imaging experiments using the biosensors can be as long as the biological process of interest, but are usually limited to ~2 hr for meroCBD experiments, and can be extended to overnight for genetically encoded biosensors. The post-imaging data processing will require ~10 min per data set.

Analysis of Arf GTP-Binding Protein Function in Cells

Lee Ann Cohen[1] and Julie G. Donaldson[1]

[1]Laboratory of Cell Biology, NHLBI, National Institutes of Health, Bethesda, Maryland

ABSTRACT

This unit describes techniques and approaches that can be used to study the functions of the ADP-ribosylation factor (Arf) GTP-binding proteins in cells. There are six mammalian Arfs and many more Arf-like proteins (Arls), and these proteins are conserved in eukaryotes from yeast to humans. Like all GTPases, Arfs cycle between GDP-bound, inactive and GTP-bound active conformations, facilitated by guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs) that catalyze GTP binding and hydrolysis, respectively. This unit describes approaches that can be taken to examine the localization and function of Arf and Arl proteins in cells. A simple protocol for measuring activation (GTP-binding) of specific Arf proteins in cells using a pull-down assay is also described. Approaches that can be taken to assess function of GEFs and GAPs in cells is described. *Curr. Protoc. Cell Biol.* 48:14.12.1-14.12.17. © 2010 by John Wiley & Sons, Inc.

Keywords: Arf • GTP-binding proteins • guanine nucleotide exchange factors • GTPase-activating proteins

INTRODUCTION

The ADP-ribosylation factor (Arf) family of guanine nucleotide binding proteins were originally identified and named for their ability to act as cofactors during cholera toxin–catalyzed ADP-ribosylation of Gαs. Subsequently, six mammalian and three yeast Arf proteins were identified, and Arf1 was found to specifically associate with the Golgi complex and regulate vesicle trafficking between the endoplasmic reticulum (ER) and Golgi complex (Donaldson and Jackson, 2000; D'Souza-Schorey and Chavrier, 2006). Arfs are conserved 175 to 183 amino acid G proteins that have defined and nearly identical Switch I and Switch II effector domains. All Arfs are co-translationally myristoylated at the amino terminus, and this modification is required for Arfs to interact with membrane surfaces, regulators, and effectors. Thus, addition of epitope tags onto Arf proteins must be made at the carboxyl terminus to retain biological activity. Arfs 1 through 5 reversibly associate with the Golgi complex and cycle into the cytosol during GTP-binding and GTP-hydrolysis, respectively. Arf6, on the other hand, appears to spend more time associated with membranes while GDP-bound (D'Souza-Schorey and Chavrier, 2006).

In their active, GTP-bound form, Arfs modify membrane surfaces by recruitment of coat proteins that sort membrane proteins into forming vesicles, and by stimulating the activity of lipid-modifying enzymes (e.g., phosphatidylinositol 4-phosphate 5-kinase and phospholipase D) that lead to production of phosphatidylinositol 4,5-bisphosphate and phosphatidic acid, respectively (Donaldson and Jackson, 2000; D'Souza-Schorey and Chavrier, 2006). Through these activities, Arfs mediate membrane trafficking in cells. Most of the studies on Arfs have concerned the function of Arf1 at the Golgi complex and Arf6 at the plasma membrane in standard tissue culture cell lines. Specific localization and functions for the other Arf proteins and assessment of Arf function in specialized cells and tissues have yet to be determined. Basic Protocol 1 describes ways to examine

localization and function of Arf or Arl proteins in cells in culture. Cells expressing wild-type or mutant Arfs can be examined for effects on a cellular function of interest. If an Arf is involved in a particular physiological process or membrane trafficking step, it is often desirable to be able to determine what fraction of a particular Arf is in the active, GTP-bound state. Basic Protocol 2 describes a simple assay to determine the amount of active Arf in cells.

Arf proteins cycle between GTP-bound, active and GDP-bound, inactive forms. This cycle is regulated by GEFs that catalyze GDP release and GTP binding, and GAPs that catalyze GTP hydrolysis and return to the GDP-bound form. There are over 15 GEFs and 24 GAPs expressed in mammalian cells, and although the Arf specificities and functions for some of these regulators are known, for many, their specificities, localization, and function have not been evaluated. There are several families of Arf GEFs whose members all share the catalytic Sec7 domain and then differ in other domains. The BIG and GBF GEFs are large proteins that are localized to the Golgi and are sensitive to inhibition by the drug brefeldin A (BFA). The ARNO/Cytohesin, EFA6, and BRAG families of Arf GEFs localize to the cytosol and plasma membrane, and are not inhibited by BFA (Casanova, 2007). There are also many Arf GAP families of proteins that contain the catalytic Arf GAP domain. Arf GAPs also contain many other domains that function to regulate and recruit GAP to membranes as well as domains that serve as scaffolding platforms to recruit other Arf effectors. In this sense, Arf GAPs may be effectors as well as signal terminators (Inoue and Randazzo, 2007). Since there are many more GEFs and GAPs than there are Arfs, there is much to learn about the function of these proteins, and approaches to assessing their cellular function is presented in Basic Protocol 3.

STRATEGIC PLANNING

Although the Arf proteins are ubiquitously expressed, high-affinity, specific antibodies to examine the localization and function of endogenous proteins are not available. Hence, the transient expression of Arf proteins is a useful tool for examining Arf function in cells. Expression of the wild-type Arf protein is a practical way to determine how an Arf localizes and behaves in a cell since expression of the wild-type protein, especially at low levels, does not usually cause a strong phenotype by itself, presumably because the Arf can cycle between GDP-bound inactive and GTP-bound active forms. Due to the importance of the amino terminal myristoyl group for biological function, epitope tags, if used, should be placed at the carboxyl terminus of an Arf protein. A number of tags have been appended to the carboxyl terminus of Arf proteins including peptide tags like HA, myc, FLAG, and also fluorescent proteins like green fluorescent protein (GFP) and red fluorescent proteins (RFP). Small epitope tags are not benign, however, and in many cases they are highly charged. Thus, it is important to consider the consequence of each tag when examining Arf function in cells. Although antibodies are not available that can detect endogenous Arfs, which might be expressed at low levels, commercial antibodies are available that can detect over-expressed Arf proteins (in particular, for Arf1 and Arf6); thus, the behavior of an epitope-tagged over-expressed Arf protein can be compared to that of an untagged over-expressed Arf protein.

When over-expressed, Arfs1–5 typically have a prominent localization at the Golgi complex that can be verified by co-staining cells with antibodies to Golgi-resident proteins. Arfs1–5 also have a substantial cytosolic pool, which represents an inactive pool of the molecules. Because Arfs1–5 are released into the cytosol upon GTP hydrolysis, it is important to realize that they can be recruited to extra-Golgi sites as part of their activation cycle. There are reports of Arf1 at the plasma membrane and on peripheral endosomal structures. Arf6 is not localized to the Golgi, and instead localizes to the plasma membrane and on endosomal structures. In some cells, like HeLa cells, Arf6 is

mostly localized on membranes, whereas in other cells types, Arf6 expression shows a significant cytosolic pool. The cytosolic pool can be considered inactive, but Arf6 can localize to the membrane regardless of its GTP/GDP status, so it cannot be assumed that all Arf6 localized to membranes is GTP bound.

A useful pharmacological tool for examining Arf function in cells is the fungal metabolite BFA. BFA is an uncompetitive inhibitor of certain Arf GEFs, stabilizing a complex of the GEF with GDP-bound Arf. In this way, it inhibits activation of Arfs by that GEF. BFA inhibits Arf activation catalyzed by GBF and BIG family GEFs that contain the residues necessary to form this complex whereas other Arf GEFs, such as the cytohesin/ARNO and EFA6 families, lack these residues. An Arf-dependent process that is BFA sensitive would point to activation of the Arf through GBF1 or BIG family exchange factors. An Arf-dependent process that is not BFA-sensitive would suggest activation of Arf through other GEFs. Treating cells with BFA results in a rapid release of Arf1 and Golgi-associated coat proteins from the Golgi, reflecting a block in activation of Arf at the Golgi. At later times of BFA treatment, Golgi membranes and content fuse with the ER, and in some cells an alteration of endosomal and lysosomal membrane morphology is also observed.

Another useful approach to examining Arf function in cells is expression of mutant Arf proteins. Threonine to asparagine mutations in the nucleotide binding pocket (T31N in Arfs1–5 and T27N in Arf6) act as dominant negative proteins, used to inhibit function of an endogenous Arf. These mutants are inactive and may sequester endogenous Arf GEFs by mimicking the inactive, GDP-bound or nucleotide-free form of the Arf, preventing activation of the endogenous Arf. The first Arf exchange factor was identified as a supressor of an Arf1T31N mutant in a genetic screen in yeast. Both Arf1T31N-HA and Arf1T31N-GFP function effectively as dominant negatives when expressed in cells. Arf1T31N itself is more cytosolic, as it is in a GDP-bound state and its expression results in cytosolic distribution of Golgi coat proteins and loss of Golgi structure, similar to what is observed with acute BFA treatment (see Fig. 14.12.1).

Mutation of a glutamine residue to leucine in the guanine nucleotide binding pocket (Q71L in Arfs1–5 or Q67L in Arf6) creates GTP-hydrolysis-defective mutants of Arf proteins, which are constitutively GTP bound, and can be used to mimic a persistently activated state. Although activated Arfs can presumably function, Arfs must cycle between the GTP-bound, active and GDP-bound, inactive states for biological activity. Thus, expression of these mutants often inhibits Arf-specific processes. For instance,

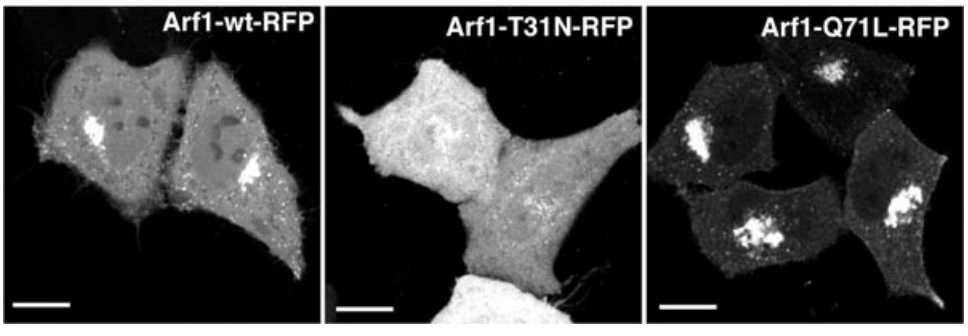

Figure 14.12.1 Expression of Arf1-RFP and its mutants in HeLa cells. Wild-type Arf1-RFP has both a prominent localization at the Golgi complex and a cytosolic pool. In cells expressing Arf1-T31N-RFP, the Arf is largely cytosolic and staining for a Golgi marker would reveal that the Golgi is largely absent (redistributed to the ER). Arf1-Q71L-RFP is almost entirely membrane bound, and causes vesiculation and swelling of the Golgi complex. Bar, 10-μm.

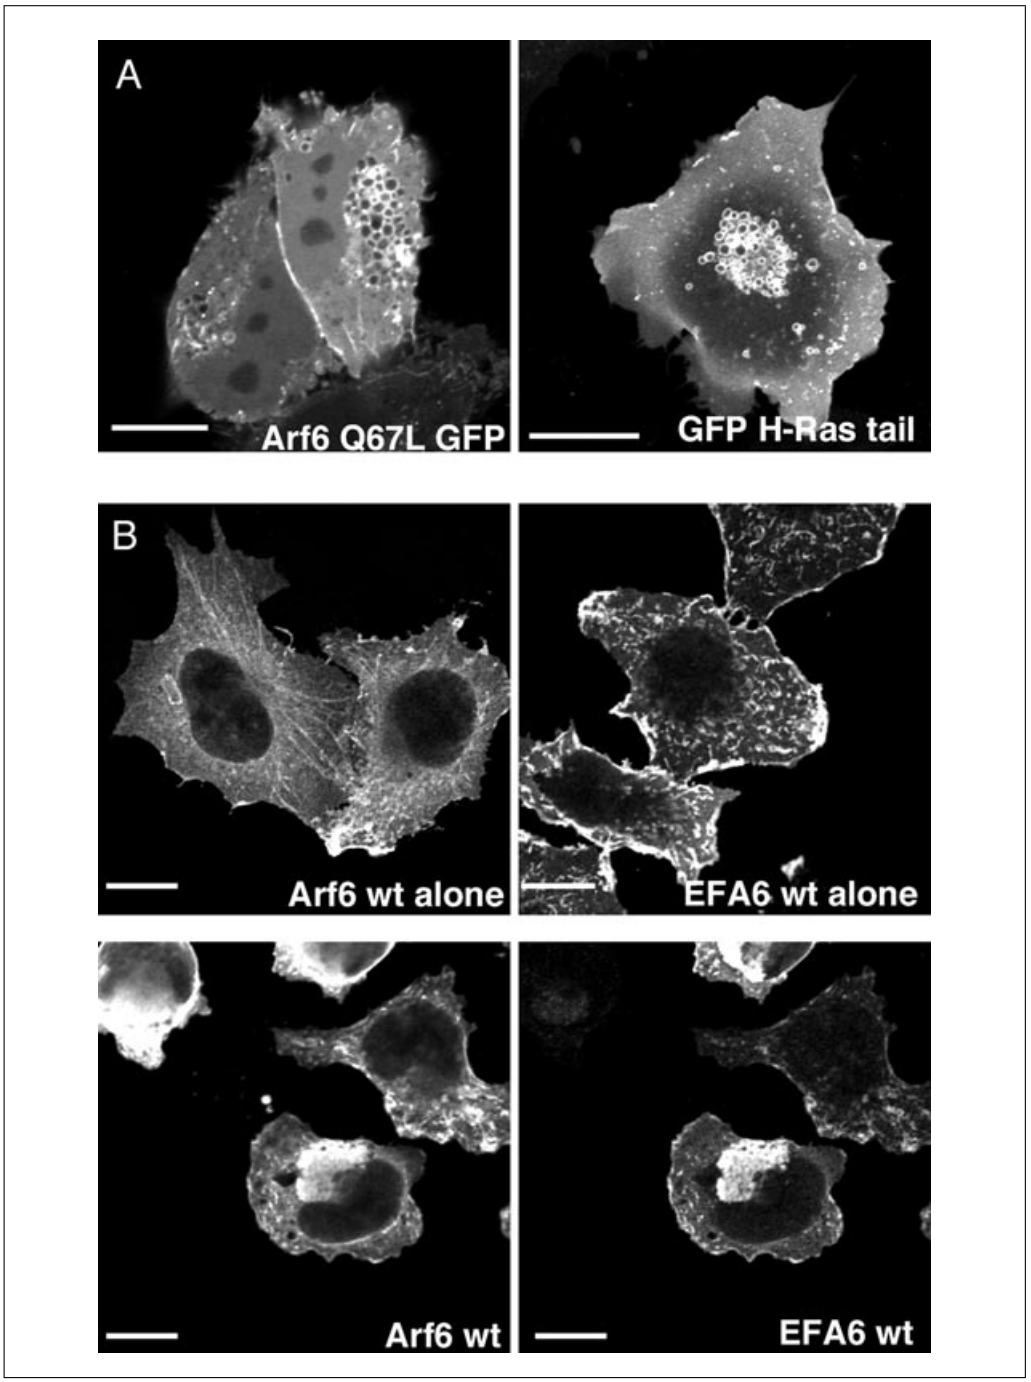

Figure 14.12.2 (**A**) Expression of Arf6-Q67L in cells induces the formation of distinctive vacuoles. The left image shows a HeLa cell expressing Arf6-Q67L-GFP, which causes accumulation of large vacuolar structures. The right image shows a COS-7 cell co-expressing Arf6 Q67L (not shown) and the carboxyl terminal sequence of H-Ras fused to GFP. The H-Ras-tail-GFP highlights the Q67L vacuole clearly. (**B**) Expression of Arf6 and EFA6 in cells promotes a phenotype similar to Arf6 Q67L. Arf6 wild-type localizes on tubular endosomes and at the plasma membrane in HeLa cells. Its GEF, EFA6, is localized mostly at the plasma membrane and causes cell ruffling. Co-expression of Arf6 and EFA6 induces the formation of vacuoles similar to expression of Arf6 Q67L. Bar, 10 μm.

expression of Arf1Q71L leads to the stable association of coat proteins with the Golgi complex causing vesiculation and swelling of Golgi cisternae (see Fig. 14.12.1), which inhibits transport through the secretory pathway. Expression of the Arf6Q67L mutant promotes cellular protrusions and also stimulates endocytosis and leads to the accumulation of endosomal membranes (see Fig. 14.12.2). This is often accompanied by a reduction of the cell footprint, especially with high levels of expression and at longer times after expression. The association of Arf6 Q67L with these membranes is difficult to discern in fixed preparations, and often it is necessary to label the endosomal structures with a marker that retains strong membrane association. The vacuole phenotype is strongest in the non-tagged version of Arf6Q67L, followed by Arf6Q67L-HA, and Arf6Q67L-GFP. Length and level of expression is also an important variable in experiments using Arf6Q67L. Cells tend to round up after long or high-level expression of this mutant.

LOCALIZATION AND FUNCTION OF SPECIFIC Arf PROTEINS IN CELLS

BASIC PROTOCOL 1

This protocol describes how to evaluate Arf function in HeLa cells by exogenous expression of wild-type and mutant Arf proteins in cells. It can easily be adapted to other systems.

Materials

1 M HCl (*APPENDIX 2A*)
70% ethanol
Culture medium: DMEM containing 10% (v/v) FBS and 1% (v/v) penicillin/streptomycin solution (*APPENDIX 2A*)
Cells (e.g., HeLa)
Mammalian expression plasmid containing Arf construct of interest with an epitope tag (e.g., Fugene, Roche)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Drugs, growth factors, etc.
2% (w/v) formaldehyde solution in PBS
PBS/FBS: 10% (v/v) FBS in PBS and 0.02% (w/v) sodium azide
Primary antibody against the epitope tag (e.g., for an HAtag, etc.)
10% (v/v) saponin
Secondary antibody: Alexa Fluor 488 or 594 conjugated against the species of the primary antibody
Fluoromount G
Clear nail polish

12-mm no. 1 round, glass coverslips
65° to 75°C heating block/plate
100-mm and 15-cm tissue culture dishes
Watchmaker forceps
6- and 12-well tissue culture plates
Parafilm
1.2-mm thick glass slides
Small Kimwipes

Prepare cells and coverslips

1. Acid wash coverslips by incubating them in 1 M HCl for 6 to 8 hr at 65° to 75°C. Rinse coverslips four times in distilled water, and three times in 70% ethanol. Store coverslips in 70% ethanol at room temperature.

   CAUTION: *Appropriate care should be taken when heating 1 M HCl as it is corrosive. Coverslips should be acid washed in a glass beaker under a chemical fume hood.*

Acid washing coverslips helps to provide a good surface for cells to adhere to, and helps ensure reproducibility between different batches of coverslips. Coverslips can be treated in large batches in advance and stored in 70% ethanol until needed. Specific cell lines may require different coverslip treatment.

2. In a tissue culture hood, place 10 ml of prewarmed culture medium into a 100-mm tissue culture dish.

3. Remove several coverslips from 70% ethanol with watchmaker forceps, and carefully flame to sterilize and remove ethanol. Place coverslips in tissue culture dish, ensuring that they are carefully separated from one another. Gently push each coverslip down onto the bottom of the culture dish to help prevent them from moving around. Continue until the desired number of coverslips are in the dish (up to 25 coverslips can fit in onedish).

4. Remove medium from coverslips and replace with 10 ml of fresh culture medium to remove any residual ethanol.

Plate cells

5. Plate 0.5–0.75 $\times$ 10^6 cells into the dish with coverslips and incubate in a 37°C, 5% CO_2 incubator.

   Cells should be plated to be 40% to 60% confluent the day after plating. If cells are less crowded, the cells often do not transfect well. If they are more crowded, it is often hard to clearly distinguish subcellular structures by immunofluorescence. This condition could vary with different cell lines. Generally, any adherent cell lines able to be transfected can be plated and used in these experiments.

6. On the following day when cells are 40% to 60% confluent, place 2 ml of culture medium into each well of a 6-well plate. Place one to four coverslips into each well.

7. Transfect cells with 1 μg DNA for all Arf constructs except Arf6 Q67L. Transfect 0.25 μg Arf6 Q67L constructs to avoid toxicity.

   The authors routinely use Fugene from Roche to transfect HeLa cells, and obtain 70% transfection efficiency for most constructs.

8. Incubate cells for 18 hr at 37°C to allow expression of proteins from plasmids.

   Expression of Arf6Q67L causes cells to round up. This is exacerbated by high levels of expression; therefore, often a smaller amount of DNA is used and transfection is carried out for shorter times (12 hr rather than 18 hr) to induce a milder phenotype. Other Arf mutants may also have toxicity issues under different conditions and both level and length of expression may have to be varied similarly.

Fix cells (also see UNIT 4.3)

9. After the transfection period, remove medium and gently rinse cells with 2 ml of PBS, and then replace with 2 ml of culture medium.

10. Treat cells can with drugs, growth factors, etc. as desired and incubate at 37°C.

11. Fix cells by placing one coverslip each into 1 ml of 2% formaldehyde in a 12-well plate. Incubate for 10 min at room temperature.

12. Remove formaldehyde and rinse with 1 ml of PBS and then with 1 ml of PBS/FBS. Incubate for 1 hr at room temperature.

    The PBS/FBS solution is used to inhibit non-specific binding of antibodies to the cells; other blocking solutions can be used containing other proteins, e.g., BSA or gelatin. If the entire immunofluorescence protocol cannot be completed in 1 day, this is an appropriate place to stop. Cells can be stored in PBS/FBS overnight at 4°C.

Stain cells to detect Arf protein

13. Dilute primary antibody to the epitope tag of the Arf used in PBS/FBS with 0.2% saponin.

    Typically, epitope tagged antibodies are diluted to 1 to 2 μg/ml.

14. Place a piece of Parafilm in a 15-cm tissue culture dish. Place a 30-μl drop of the primary antibody onto the Parafilm. Invert coverslip (cells facing down) over the drop. Place twelve coverslips, corresponding to the 12-well plate, into each 15-cm dish. Incubate for 1 hr at room temperature.

    If using GFP-tagged proteins, the fluorescence can be observed directly or the fluorescent signal can be enhanced with an antibody against GFP, followed by Alexa 488-conjugated secondary antibodies. Because Arf1 is discretely localized to the Golgi it is often easily detected by fluorescence alone.

    To help evaluate how expression of Arf proteins affects the system under study, it is often useful to co-stain the cells with antibodies to specific cellular components. The Golgi structure can be monitored by staining with antibodies to Golgi resident proteins (e.g., GM130). Arf6-associated membrane structures can be stained with antibodies directed against endosomal protein markers such as clathrin-independent endosomal cargo proteins (Eyster et al., 2009), transferrin receptor, or co-expression of a GFP-tagged membrane marker like carboxyl terminal sequence of H-Ras (see Fig. 14.12.2).

15. Place coverslips (cells facing up) back into 1 ml PBS/FBS in a 12-well plate. Wash coverslips three times, 5 min each time, with PBS/FBS.

16. Dilute appropriate fluorescently-conjugated secondary antibodies in PBS/FBS with 0.2% saponin. Place a 30-μl drop on a piece of Parafilm in a 15-cm culture dish. Invert coverslip onto drop. Incubate for 30 min at room temperature.

    The authors typically use Alexa dye–conjugated secondary antibodies such as 488, 594, and 633.

17. Place coverslips back into the 12-well plate, cells facing up. Wash two times with 1 ml PBS/FBS and once in PBS, incubating 5 min for each wash.

18. Place a drop of glycerol-based mounting fluid such as Fluoromount G into the middle of a 1.2-mm thick glass slide. Invert coverslip on top of drop (cells facing down). Gently press down on the coverslip using three to four Kimwipes to remove excess mounting solution.

19. Allow coverslips to air-dry for 5 min and then seal coverslips around edges with clear nail polish.

20. Allow nail polish to dry (~10 min) prior to examination of slides.

    Slides can be stored in covered boxes at least 1 month at 4°C.

ASSESSMENT OF GTP-BOUND Arfs

BASIC PROTOCOL 2

In this protocol, a pull-down assay is described using a domain of an Arf-GTP interacting protein to assess the amount of GTP-bound Arf. This is a variation of the protocol first described by Santy (Santy and Casanova, 2001). Gamma-adaptin ear domain homology art binding domain (GGAs) are a family of Golgi-associated coat proteins that bind to GTP-bound Arf. The domain that binds to Arf-GTP is restricted to what is called the GGA and TOM domain (GAT) (Boman et al., 2000; Dell'Angelica et al., 2000). In vitro, this region binds to Arf-GTP with high affinity, with little binding to Arf-GDP. In addition, like many Arf effectors, GGA can bind all Arf isoforms. This protocol uses the purified recombinant VHS-GAT domains of GGA3 fused to GST to probe cellular lysates for GTP-bound Arf. The VHS-GAT domain binds to active Arf, and thus can provide an

estimate of the percentage of Arf in the cell that is active. This protocol describes using this pull-down to look at activation of endogenous Arfs. The Alternate Protocol describes an adaptation of this protocol for assessing the activation of transfected Arf proteins and the effect of co-expression of regulators.

Materials

Frozen bacterial stock for GST-VHS-GAT expression (Dell'Angelica et al., 2000)
LB/Amp (LB plus 100 μg/ml ampicillin; *APPENDIX 2A*) plates and medium
1 M isopropyl-beta-D-thiogalactopyranoside (IPTG)
Phosphate-buffered saline (PBS; *APPENDIX 2A*), ice cold
2 mM EDTA
Lysozyme (lyophilized powder)
Protease inhibitors (e.g., 1 mg/ml pepstatin, 1 mM leupeptin, 5 mg/ml aproptinin, and 1 mM PMSF)
10% (v/v) Triton X-100 stock
10 U/μl DNase I
1 mg/ml RNase stock
1 M dithiothreitol (DTT; *APPENDIX 2A*)
Glutathione Sepharose 4B beads (GE Life Sciences)
Lysis buffer (see recipe)
5× SDS-PAGE sample buffer (*APPENDIX 2A*)
2× sample buffer without reducing agent
12% polyacrylamide gel or 4% to 20% gradient gel
Specific antibodies for detecting Arf proteins in immunoblots

37°C incubator
14-ml round-bottom culture tubes
Spectrophotometer
Refrigerated centrifuge
Tube rotator, 4°C
10-cm tissue culture dish
Cell scraper
1.7-ml microcentrifuge tubes
Refrigerated microcentrifuge
Microcentrifuge spin columns (e.g., Pierce Spin Cups with cellulose acetate filters)
Nitrocellulose paper

Additional reagents and equipment for SDS-PAGE gel (*UNIT 6.1*) and nitrocellulose transfer (*UNIT 6.2*)

Express GST-VHS GAT from GGA3

1. From a frozen bacterial stock, streak out GST-VHS GAT–bearing bacteria on an LB/Amp plate to obtain single colonies after growth overnight at 37°C.
2. Inoculate one colony into a 2-ml culture of LB/Amp in 14-ml tube and grow overnight at 37°C with shaking.
3. On the following morning, inoculate a 100-ml culture of LB/Amp with 100 μl of overnight culture in a 500-ml sterile flask and place in 37°C shaking incubator.
4. When the OD_{600} of the culture reaches 0.8 to 1.0 (about 3 hr), add 500 μM IPTG from a 1 M stock. Grow for 3 hr at 37°C.
5. Transfer culture to centrifuge bottles and centrifuge 10 min at 10,000 × g, 4°C, remove culture medium, and freeze pellet at −80°C.

   Pellet can be kept at −80°C for 2 to 5 days if necessary.

Purify GST-VHS-GAT

6. Thaw bacterial pellet on ice.

   This and subsequent steps are used to purify GST-VHS-GAT. Other protocols for purifying GST fusion proteins will also work.

7. Resuspend in 20 ml ice-cold PBS containing 2 mM EDTA, 1 mg/ml lysozyme, plus protease inhibitors.

8. Incubate for 30 min on ice.

9. Add 0.4 ml of 10% Triton-X 100 stock (for final concentration of 0.2%).

10. Add 30 μl DNase I (10 U/μl stock), and 70 μl of a 1 mg/ml solution of RNase.

11. Incubate 10 min in a cold room with tube rotation.

12. Add DTT to a final concentration of 1 mM (20 μl of 1 M stock).

13. Centrifuge 30 min at × *g* (10,000 rpm in a Sorvall SS-34), 4°C.

    For convenience, the resultant supernatant (lysate) may be aliquoted into single-use aliquots (5-ml) and frozen in liquid N_2 and stored at −80°C. It is best to avoid repeated rounds of freeze/thaw at this point.

14. Wash 250 μl of glutathione Sepharose beads once with 1 ml of 0.2% Triton X-100 in PBS, centrifuge beads ∼15 sec and remove supernatant.

15. Incubate glutathione Sepharose with 5 ml of bacterial lysate for 30 min at 4°C.

16. Wash beads three times with 1 ml of 0.2% Triton X-100 in PBS and then once with 1 ml lysis buffer. After each wash, centrifuge beads for 35 sec at 13,000 × *g* in a microcentrifuge. Resuspend beads at a 1:1 ratio of beads to lysis buffer.

    It can be useful to verify that 30 μl of the 1:1 suspension contains 50 to 100 mg of GST-VHS-GAT. This can be done by running a 30-μl sample on an SDS-PAGE gel with appropriate BSA standards and Coomassie gel staining (UNITS 6.1 & 6.6). The GST-VHS-GAT fusion is ∼40 kDa, and should be the major band. Adjust the amount of beads used in the assay if necessary.

Prepare cell lysates

17. Plate 0.75–1.0 × 10^6 cells in 10 ml culture medium in a 10-cm tissue culture dish, and incubate overnight at 37°C.

    The amount of cells used in this experiment will vary depending on what is being examined, the cell type used, the amount of Arf expressed, and the ability to detect an Arf by immunoblotting (UNIT 6.2). This protocol is based on looking for endogenous Arf1 or Arf6 in one 10-cm tissue culture dish that is 70% to 80% confluent. If having trouble detecting the endogenous Arf by immunoblotting, more cells may be needed or adjustments must be made to the protocol. An alternative approach is to transiently express an epitope-tagged Arf in cells to perform this assay. Specific considerations for this approach are outlined in the Alternate Protocol.

18. Treat cells according to experimental design. For example, treat cells with hepatocyte growth factor, which can activate Arf6 in some cells (D'Souza-Schorey and Chavrier, 2006).

19. Wash cells once in 10 ml ice-cold PBS. Carefully remove all excess liquid.

20. Add 250 μl lysis buffer containing protease inhibitors, and use a cell scraper to collect cells.

The amount of lysis buffer used will vary depending on the level of expression of endogenous Arf in the specific cell line used, but generally it has been found that the lysates should be kept as concentrated as possible so that the protein in the loading control is easily detected. To obtain a reliable result, it is very important that clear detection of the endogenous Arf in the whole cell lysate fraction is seen.

21. Place lysate into a 1.7-ml microcentrifuge tube, and microcentrifuge 5 min at 13,000 × *g*, 4°C.

22. Place 20 µl of lysate in 5 µl of 5× sample buffer with reducing agent and heat sample 10 min at 95°C.

Bind Arf to beads

23. Incubate 200 µl of lysate with 30 µl glutathione Sepharose beads bound with GST-VHS-GAT for 30 min on a rotating rack at 4°C.

24. Microcentrifuge beads 30 sec at 6000 × *g*, 4°C, and remove supernatant.

25. Resuspend beads in 0.75 ml lysis buffer and transfer to a microcentrifuge spin column.

26. Wash beads two times in 0.75 ml of lysis buffer at 4°C. Microcentrifuge columns 30 min at 6000 × *g*, 4°C, removing wash from collection tubes with each spin.

27. Place columns in fresh collection tubes and add 25 µl of 2× sample buffer without reducing agent, vortex briefly to mix buffer and beads, and incubate 10 min at room temperature.

28. Microcentrifuge column 1 min at 13,000 × *g*, room temperature, to collect sample.

29. Add 5 µl of 1 M DTT to sample, and boil sample for 5 min (this is the pull-down sample).

Analyze samples

30. Run the whole-cell lysate sample (from step 22) and pull-down sample (from step 29) on an SDS-PAGE gel (either 13% or a 4% to 20% Tris·Cl gradient mini gel; *UNIT 6.1*) and transfer to nitrocellulose paper (*UNIT 6.2*).

    It is useful to run a pre-stained molecular weight marker along with the samples. To obtain good resolution of Arfs, which are ~20 kDa, it is often necessary to run the dye front off the gel, and run the gel until a marker, ~5 kDa, is close to the bottom of the mini gel.

31. Conduct immunoblot using Arf-specific antibodies.

    Of commercially available antibodies, the authors have experience using the Arf1/3 antibody produced in sheep from Sigma (A4594), which can be used at 1:1000 for immunoblotting, and the Arf6 (3A-1) mouse IgG_{2b} antibody from Santa Cruz Biotechnology that can be used at 1:100.

    It is important to verify the specificity of the antibody that is being used. One convenient way to do this is to transiently express different epitope-tagged Arf isoforms and make individual cell lysates. However, be aware that the tag at the carboxyl terminus sometimes may interfere with recognition of an Arf, particularly if the epitope from the Arf is at the extreme carboxyl terminus.

32. Quantify the intensity of the bands to determine the fraction of total Arf that is GTP bound.

    In this scenario that would be the (intensity of the band from the pull down)/(10× the intensity of the whole cell lysate band).

ASSESSMENT OF Arf GTP LEVELS IN TRANSFECTED CELLS

ALTERNATE PROTOCOL

Reliable and reproducible detection of endogenous Arf proteins can be difficult, making interpretation of the pull-down assay an issue. Transient transfection of low levels of epitope-tagged wild-type Arf proteins is an alternative approach. This approach allows one to directly compare activation of different Arf isoforms using the same antibody. It can also be used to look at the effect of expression of regulatory proteins (such as GEFs and GAPs) on Arf isoforms. This protocol is a modification of Basic Protocol 2.

***Additional Materials** (also see Basic Protocol 2)*

Mammalian expression plasmids containing epitope-tagged wild type (and mutant) Arf proteins (epitope tag on carboxyl terminus)
6-well culture plates

Prepare GST-VHS GAT fusion protein

1. Follow Basic Protocol 2, steps 1 through 16.

Prepare cell lysates

2. Plate 1.0×10^5 HeLa cells into each well of a 6-well plate and incubate in a 37°C, 5% CO_2 incubator.

3. On the following day when the cells are ~50% to 60% confluent, transfect the cells with relevant plasmids.

   It is important to have a control lane in which the wild-type Arf alone is expressed, and one in which Arf and a regulator (GEFs or GAPs) is expressed. Expression of a GEF should increase Arf-GTP and a GAP should decrease Arf-GTP levels. This allows one to see a fold change in GTP-bound Arf upon expression of the regulator.

   Generally, this has worked well when transfecting 0.25 μg of the wild-type Arf, and 1.0 μg of the regulator. It is important that most of the cells transfected with the Arf also contain the regulator. To monitor whether this is happening, include one coverslip in the plate and assess the efficiency of co-transfection by immunofluorescence.

   If comparison of the specificity of a regulator for one or another Arf is desired, express Arfs with the same eptitope tag and use the same antibody to conduct the immunoblot.

4. On the following day, remove medium and add 10 ml ice-cold PBS at 4°C.

5. Carefully aspirate all of the PBS from the dish.

6. Lyse cells directly on the plate in 100 μl of lysis buffer at 4°C. Scrape cells off dish with cell scraper and collect lysate.

7. Place lysate into a 1.7-ml microcentrifuge tube, and microcentrifuge 5 min at 13,000 × *g*, 4°C.

8. Place 25 μl of lysate in microcentrifuge tube containing 5 μl of 4× sample buffer with reducing agent and heat 10 min at 95°C.

Collect Arf

9. Dilute 50 μl of lysate into 0.4 ml lysis buffer, and incubate with 30 μl glutathione beads bound with GST-VHS-GAT for 30 min on a rotating rack at 4°C.

10. Microcentrifuge beads 30 sec at 6000 × *g*, 4°C, and remove supernatant.

11. Resuspend beads in 0.75 ml of lysis buffer and transfer to a microcentrifuge spin column.

12. Wash beads two times in 0.75 ml of lysis buffer at 4°C. Microcentrifuge columns 30 sec at 6000 × *g*, 4°C, removing wash from collection tubes with each spin.

13. Place columns in fresh collection tubes and add 25 µl of 2× sample buffer without reducing agent, vortex briefly to mix buffer and beads, and incubate 10 min at room temperature.

14. Microcentrifuge column 60 sec at 13,000 × *g*, room temperature and collect sample.

15. Add 5 µl of 1 M DTT to sample, and boil sample for 5 min (this is the pull-down sample).

Analyze samples

16. Run whole-cell lysate sample (from step 8) and pull-down sample (from step 15) on an SDS-PAGE gel (either 13% or a 4% to 20% Tris·Cl gradient mini gel; *UNIT 6.1*) and transfer to nitrocellulose paper (*UNIT 6.2*).

17. Quantify the intensity of the Arf bands and calculate the fraction of Arf that is GTP bound.

    In this scenario that would be the (intensity of the band from the pull down)/(2 × the intensity of the whole-cell lysate band).

BASIC PROTOCOL 3

ASSESSMENT OF SPECIFICITY AND FUNCTION OF Arf GEFS AND GAPS

In this section strategies for evaluating the function and specificity of Arf GEFs and GAPs in cells are described. Identifying which isoform of Arf is the target of a particular GEF or GAP in cells is a challenge. While cell-free, biochemical assays often point to a preferred substrate, these assays cannot recreate the cellular environment. Furthermore, since GEFs and GAPs have catalytic activity, the expression of these regulators can reveal distinct cellular phenotypes due to activation or inactivation of particular Arf proteins.

Strategies for GEFs

The localization of endogenous GEFs is generally difficult due to the low abundance of these proteins and the lack of specific antibodies. Thus, it is advantageous to transiently over-express epitope-tagged GEFs in cells, and look at them by immunofluorescence, modifying Basic Protocol 1. The localization of the GEF can give some information about the likely specificity of the GEF. If it is localized to the Golgi, then it probably is not using Arf6 as a substrate. However, if it is localized in the cell periphery, then it cannot be assumed that it is acting on Arf6, as other Arfs may be recruited to extra-Golgi sites.

A second important consideration is whether expression of a GEF affects the localization of an Arf protein. This can be addressed by co-expressing the GEF with wild-type Arf proteins and conducting indirect immunofluorescence similar to what is outlined in Basic Protocol 1. A GEF that uses a particular Arf might co-localize with that Arf, but sometimes might change the normal distribution of the Arf. For example, co-expression of Arf1 with the Arf exchange factor ARNO can recruit Arf1 to the plasma membrane where it co-localizes with ARNO. Furthermore, a GEF would be expected to bind to and co-localize with the dominant negative mutant of the Arf it activates.

Unlike over-expression of the wild-type Arf, over-expression of the wild-type GEF sometimes creates an obvious phenotype. For instance, over-expression of the Arf6 exchange factor, EFA6A, induces plasma membrane ruffling and macropinocytosis (Brown et al., 2001), not observed in cells expressing Arf6 alone (see Fig. 14.12.2). All Arf GEFs contain a conserved glutamic acid residue within their sec7 domain that is critical to their activity as exchange factors. When this residue is mutated to lysine (E156K in ARNO or E794K in GBF1), the exchange factor is unable to activate an Arf. In some cases, these mutants have also been reported to act like dominant negatives, and inhibit a process that Arf is involved in. Over-expression of a BFA-sensitive Arf GEF can sometimes provide

protection against the effects of BFA treatment by shifting the dose-response curve to the drug, and prevent or slow loss of its substrate Arf from Golgi membranes.

Co-expression of an Arf GEF with its substrate Arf often mimics the phenotype observed for the constitutively active mutants of the Arf. For example, co-expression of Arf6 with its GEF, EFA6A, can promote a vacuolar phenotype that is similar to expression of Arf6Q67L (see Fig. 14.12.2). Finally, looking at the effect the GEF has on activation of specific Arf proteins can be assessed by using the VHS-GAT pull-down assay described in Basic Protocol 2. Comparing how different Arf proteins respond to a particular GEF when co-expressed in cells may provide some insight into specificity issues.

Strategies for GAPs

Since GAPs inactivate Arf proteins, their expression often antagonizes Arf function. The localization of an Arf GAP can give information about its specificity. If it is localized to the Golgi, then it is probably using a Golgi Arf (Arf 1–5) as a substrate. However, Arf GAPs that localize outside of the Golgi may still work on Arf 1–5 as a substrate since other Arfs can be recruited to extra-Golgi sites. In some cases, there may be antibodies available to look at the localization of endogenous ArfGAPs; however, exogenous expression of epitope-tagged GAPs can be readily performed using Basic Protocol 1.

Just like Arf GEFs, expression of Arf GAPs sometimes exhibits a distinct cellular phenotype. In this case however, an Arf GAP would be expected to mimic the Arf dominant negative and antagonize Arf function. For example, over-expression of ArfGAP1 leads to loss of the COP I coat from the Golgi and dissolution of the Golgi similar to that induced by expression of Arf1 T31N (Aoe et al., 1997). In some cases, co-expression of a GAP with the Arf substrate can ameliorate the phenotype of expression of the GAP by itself. The Arf GAP would also be expected to co-localize with the constitutively active mutant of its Arf substrate. In the VHS-GAT pull-down, co-expression of the GAP with its substrate should lead to a reduction in the amount of Arf that is GTP bound.

Inactive mutants for Arf GAPs have also been described. If expression of the wild-type GAP causes a phenotype, then expression of the inactive GAP should not cause that phenotype, if Arf activity is important in producing the phenotype. GAPs are often large proteins with many other protein domains that are important to their biological activity. Some GAPs have been reported to have phenotypes that are independent of their ability to activate Arf (Inoue and Randazzo, 2007). For example, over-expression of ASAP1, a peripheral Arf1 GAP, can induce podosome formation, but the ASAP1 mutant that lacks GAP activity (ASAP1-R495K) can also induce podosome formation suggesting that the GAP activity is not critical to this aspect of ASAP1's function (Bharti et al., 2007). For this reason, it is very important to determine whether the GEF or GAP activity of the regulator is important to the biological function being examined.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Lysis buffer

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
100 mM NaCl (*APPENDIX 2A*)
2 mM $MgCl_2$ (*APPENDIX 2A*)
1% (v/v) Triton X-100 (*APPENDIX 2A*)
10% (v/v) glycerol
Store up to 1 year at 4°C

COMMENTARY

Background Information

Cell biologists have gained a great deal of information about the functions of Arf proteins in cells using transient expression of wild-type and mutant forms of the GTPase. The ability to examine phenotypes in cells expressing constitutively active and dominant negative forms of Arfs has been an effective tool for figuring out the function of Arf1 at the Golgi complex and Arf6 at the plasma membrane (Donaldson and Jackson, 2000; D'Souza-Schorey and Chavrier, 2006). This experimental tool has also been used for discovering functions of the numerous Rab proteins, which also affect membrane traffic in cells. Although there are some concerns about indirect effects of expression of some of these mutants in cells (see below), a careful evaluation of observed localization and phenotypes for expression of wild-type and mutant forms of Arfs should ensure that a reasonable understanding of Arf function can be revealed.

Studies of Arf proteins have benefited greatly from the identification of the many Arf GEFs and GAPs in the genome (Casanova, 2007; Inoue and Randazzo, 2007). By contrast, few GEFs and GAPs have been identified for the Rab GTPases. Although analysis of the function of these regulatory molecules can in themselves be complex, their anticipated actions in terms of turning on and off a particular Arf can complement the analysis of the effect of expressing the corresponding Arf-GDP versus Arf-GTP mutant. Results from studies on transfected cells expressing specific Arfs, GEFs, and GAPs should complement cell-free biochemical assays using recombinant proteins where GTP binding and hydrolysis can be measured directly.

The use of the GGA-VHS-GAT pull-down assay to determine the fraction of Arf in the GTP-bound state has been widely used to demonstrate Arf activation and inactivation in response to a physiological signal. For Arf6, EGF treatment results in an increase in Arf6-GTP (Morishige et al., 2008) whereas platelet activation leads to an immediate drop in Arf6-GTP (Choi et al., 2006). These changes in the Arf6 GTP/GDP state can be due to either stimulation or inhibition of actions of the GEFs and GAPs. The Arf investigator thus has many tools with which to investigate these effects.

In addition to the expression of mutant and wild-type Arfs, GEFs, and GAPs, another approach is to deplete cells of these proteins using siRNA protocols. These studies have many challenges and require good immunological reagents to determine the extent of depletion of the protein; however, they offer the possibility of rescuing a given phenotype by expression of an siRNA-resistant, wild-type or mutants of the protein. In addition to the classical dominant negative and constitutively active mutants of Arf proteins, other mutations have been described including effector domain mutants in Arf1 (N52R) and Arf6 (N48R) that are defective in stimulating phospholipase D (PLD), but are normal with respect to other activities (Skippen et al., 2002).

Critical Parameters

In attempting to investigate potential Arf function in a physiological process, it is important to gather reliable reagents to undertake these studies. For expression of Arfs, GEFs, and GAPs, vectors encoding these proteins for expression in mammalian cells can usually be obtained from active investigators in the field. Depending on whether antibodies are available to detect these proteins, epitope tagging of these constructs is often desirable so that commercial, anti-epitope antibodies can be used.

The choice of cell type for these studies is usually dictated by the particular biological process under study. If the process is apparent in all cells, the standard use of HeLa or Cos cells will ensure high efficiency of transfection and ease of analysis. More specialized cell types may, for example, require alternative transfection strategies. The amount of plasmid DNA to use in the transfection and also the time of transfection may also vary with the cell type and type of protein being expressed. Pilot experiments to maximize expression of protein are advisable. It is generally helpful to examine first the localization and cellular phenotype of expression of the Arfs, GEFs, and GAPs in cells by immunofluorescence prior to looking specifically at whether a particular GEF or GAP or physiological stimulus affects Arf-GTP levels in the pull-down assay. Looking at the whole cell can also alert the investigator to toxic or secondary, indirect effects. For example, when examining effects of Arf1T31N on an endosomal compartment, one should examine whether in these cells the Golgi complex is still functional. Since Arf1T31N often disassembles the Golgi complex and blocks the secretory pathway, the effect observed on the endosomal compartment could reflect a requirement for normal secretory pathway traffic. Another consideration when examining

specific Arf function in cells is possible redundancy among Arf proteins in the biological processes under study. From siRNA depletion studies, there is evidence that Arf proteins may act in pairs at particular locations (Volpicelli-Daley et al., 2005).

Troubleshooting

Described here are common problems encountered when conducting these types of experiments.

No immunoflourescence signal for epitope-tagged Arf

Check to see that a protein with the same epitope tag, which previously has been known to express fluorescence under the experimental conditions, is detectable. If no fluorescence signal is detected, it may be a more general problem in the transfection protocol, or a general problem detecting the epitope tag by immunofluorescence. If fluorescence is detected from the test protein, it suggests a specific problem expressing or detecting the Arf protein of interest. Check the quality of the plasmid DNA source, as poor quality plasmid DNA might interfere with expression. Consider using an anti-GFP antibody to boost the fluorescence signal if visualizing a GFP-fusion protein.

Vary the amount of DNA used, and the time of expression, making it either shorter or longer. Arf mutants can have toxic effects on cells, particularly when expressed for a longer period of time, and some cells may be more sensitive to these effects than others. Observing a lot of floating cells after the transfection might indicate a toxicity problem. Shortening the time of expression and decreasing the amount of DNA used may help with toxicity issues.

Low co-transfection efficiency

Sometimes Arfs or their mutants are refractory to being co-expressed with other proteins. Try varying the ratio of the Arf to the other protein of interest, and shorten the length of time of expression. Consider the experimental design when varying the ratio. For example, when using the GAT assay to look at the effect of a protein on Arf's nucleotide status, it is critical that most of the Arf is expressed in cells with the protein of interest. Therefore, the ratio should be biased to favor expression of the protein of interest. Occasionally, this is hard to overcome, but be aware that often the problem is co-transfecting the protein with a specific mutant (constitutively active or dominant negative), so information may be obtained by using the wild-type or a different mutant.

Little or no Arf GTP signal in VHS-GAT pulldown assay

Verify that the GST fusion protein is present by staining nitrocellulose membrane with Ponceau S. A prominent band at ~40 kDa should be apparent. There might also be some degradation products of the GST fusion protein present, but as long as the 40-kDa band in abundant, it should not interfere with the assay. If there is no 40-kDa band present, there is a problem with the purification or expression of the GST-fusion protein.

Verify that the GST-fusion protein can precipitate constitutively active Arf. If it cannot, there is a problem with the fusion protein or the assay. Check to see that the fusion protein is intact. For this assay to work well, it is also important once the cells containing the Arf are lysed that the assay is completed in a timely fashion (2 to 3 hr), and kept cold. If the GST-VHS GAT beads can precipitate constitutively active Arf, it suggests the fusion protein and assay are working correctly. Consider increasing the amount of lysate used in the pull-down.

Reproducibility of the VHS-GAT pull-down assay

Results for the GAT assay need to be verified by repetition of the experiment. If results are variable from one experiment to another, it suggests a problem in the assay. Consider monitoring the ability of the VHS-GAT-GST fusion to distinguish between the constitutively active and dominant negative mutants. If the constitutively active and dominant negative mutants are pulled down in the assay in similar amounts, try loading less lysate for the pull-down, or increasing the number of washing steps.

It is critical to be able to detect the Arf of interest in the whole-cell lysate. A very weak signal could make it difficult to quantify band intensity reliably, and this could add a large amount of error into the final calculation. Optimize the conditions for the immunoblot. Consider increasing the amount of total protein used in the whole-cell lysate sample. One way to do this is to reduce the volume of total lysis buffer used to make the initial sample more concentrated, or to use more cells and the same amount of lysis buffer. Although the ultimate measure in this assay is the percentage of Arf that is GTP bound, and slight differences for the level of Arf expression in the whole-cell lysate will be accounted for in this calculation,

a large difference may artificially bias the results. If protein loading between samples in the whole-cell lysate is uneven, consider quantifying total protein concentration using a Bradford or BCA assay, and correcting for differences. Sometimes when co-expressing an Arf and a regulator, the amount of Arf expressed decreases. Consider using less of the regulator.

Anticipated Results

This unit is meant to help investigators evaluate whether an Arf is involved in a biological process under study by providing basic tools and strategies to investigate Arf protein function. Investigators should be able to examine whether an Arf localizes on cellular structures of interest, or co-localizes with proteins of interest. They can also evaluate whether a particular biological process is affected by expression of dominant negative or constitutively active mutants of Arfs. They can evaluate whether an Arf is activated or inactivated during a particular treatment or process. Finally, they can address how an Arf might be regulated in their system by addressing GEF and GAP function using wild-type and mutant proteins.

Time Considerations

For localization and function of Arf proteins in cells (see Basic Protocol 1), cells are plated on day 1, transfected on day 2, and an experiment performed 12 to 24 hr after the start of transfection. After fixing the cells in formaldehyde and replacing the formaldehyde with a blocking solution, the cells may be placed for up to 24 hr at 4°C. After fixation, the immunofluorescence staining should take ~4 hr to complete.

For assessment of GTP-bound Arfs (see Basic Protocol 2), a bacterial lysate of the GST-VHS-GAT protein can be made in advance, and stored at −80°C. Allow 2 days for growth of the bacteria, and 2 hr for making the bacterial lysate. Purification of the GST-VHS-GAT fusion will take ~1 hr. The purification of the GST-VHS-GAT fusion protein should be done on the same day as the preparation of cell lysates. For preparation of cell lysates, cells are plated on day 1. The experiment is either performed on day 2, or the cells are transfected on day 2, and the experiment is performed 12 to 24 hr after transfection. It will take ~3 hr to prepare cell lyates and the pull-down portion of this experiment. Once boiled, samples can be stored at −20°C. Allow 2 additional days to finish the experiment: to run and transfer SDS-PAGE gels, and conduct the immunoblot.

CHAPTER 15
Protein Trafficking

INTRODUCTION

As discussed in the introduction to Chapter 3, eukaryotic cells are not simply sacs of amorphous protoplasm but are instead organized into an array of membrane-bound structures known as organelles. Subcellular fractionation (Chapter 3) and microscopic analyses (Chapter 4) have revealed a wondrous diversity of subcellular organelles, including the nucleus, endoplasmic reticulum (ER), Golgi complex, lysosomes, endosomes, secretory granules, plasma membrane, mitochondria, peroxisomes, chloroplasts, and a variety of other structures found in specialized cells. Each of these organelles fulfills a distinct function, which is carried out by a specific set of organellar proteins. Genetic information directing the synthesis of most organellar proteins, as well as cytosolic and extracellular proteins, is encoded by DNA contained within the nucleus. Genomic DNA is transcribed into messenger RNA (see *UNIT 11.6*), and this in turn is translated into protein (see *UNIT 11.1*). It is at the time of their translation that proteins begin a journey that will take them to different locations within the cell, or out to the extracellular space. Some proteins are synthesized on ribosomes that exist free in the cytosol. These proteins either remain soluble in the cytosol, become incorporated into supramolecular structures such as the cytoskeleton, or are imported into the nucleus, mitochondria, peroxisomes, chloroplasts, and in some cases the ER. Other proteins are synthesized on ribosomes that are associated with the cytosolic face of the ER membrane. These proteins are translocated across that membrane and subsequently distributed to different compartments of the secretory and endocytic pathways, including the ER proper, the Golgi complex, lysosomes, endosomes, secretory granules, and the plasma membrane; in other cases they are secreted into the extracellular medium. Thus, the interior of the cell is a highly dynamic environment, in which heterogeneous yet precisely controlled protein distributions are achieved via various protein trafficking pathways.

In vitro assays for examining specific protein transport steps and their molecular mechanisms have been described in Chapter 11. However, in vitro assays are valid only if they reflect the transport processes that occur in intact cells. In addition, the itineraries followed by proteins as they traffic through different cellular compartments are often too complex to be reconstituted in vitro and are best studied in intact cells.

Chapter 15 is devoted to biochemical and morphologic assays used to study protein trafficking in vivo. The chapter begins with an overview of protein trafficking in the secretory and endocytic pathways (*UNIT 15.1*), which provides useful background information for some of the succeeding protocol units. Most proteins destined for organelles of the secretory or endocytic pathways, or for secretion into the extracellular milieu, are co-translationally modified by addition of carbohydrate moities. These moieties are progressively remodeled as the proteins traverse the different compartments of the secretory pathway. The type of carbohydrate present on a protein thus serves as a record of its itinerary through the cell. Gross analyses of the carbohydrate moities of glycoproteins can be conveniently carried out by treatment of metabolically labeled, immunoprecipitated proteins (see *UNITS 7.1 & 7.2*) with an assortment of specific glycosidases. *UNIT 15.2* presents a comprehensive description of carbohydrate modifications along the secretory pathway, and provides a series of protocols for analysis of the general structure of carbohydrate moieties of glycoproteins labeled in vivo.

Current Protocols in Cell Biology 15.0.1-15.0.5, September 2010
Published online September 2010 in Wiley Online Library (wileyonlinelibrary.com).
DOI: 10.1002/0471143030.cb1500s48

Even after proteins reach their allotted destinations within the cells, they remain in constant flux. Indeed, most proteins are not fixed at a particular location but attain a particular steady-state distribution as a result of opposing exit and retrieval pathways. This is very neatly exemplified by some plasma membrane proteins, such as endocytic receptors, that are rapidly internalized but return to the cell surface after a sojourn in the endosomal system. *UNIT 15.3* describes a set of biochemical techniques for measuring the steady-state distribution, internalization, and recycling of the transferrin receptor, a typical endocytic receptor, using radioiodinated transferrin as a probe. Protocols are also provided to measure the steady-state distribution, internalization, and recycling of any plasma membrane protein, even those that do not have a physiologic ligand, by using radioiodinated antibodies or Fab fragments. Internalized ligands and antibodies used to tag plasma membrane proteins are often degraded in lysosomes, a process that can be measured using another protocol included in this unit. Finally, the unit also covers methods for measuring fluid-phase uptake from the medium and for inhibiting endocytosis.

Integral membrane proteins expressed at the cell surface are synthesized in the ER and transported to the plasma membrane following the secretory pathway. By the time that these proteins reach the cell surface, almost all post-translational modifications have taken place. For this reason, the carbohydrate analyses described in *UNIT 15.2* cannot be used to determine the kinetics of protein arrival at the cell surface. However, the accessibility of cell surface proteins to externally added reagents has been exploited to develop assays for biosynthetic protein transport to the plasma membrane. *UNIT 15.4* contains several protocols that combine pulse-chase metabolic labeling (see *UNIT 7.1*) with treatments that modify surface-exposed proteins on intact cells: hydrolysis of sialic acid residues with sialidase, biotinylation, protease digestion, and antibody binding. Modified surface-exposed proteins are detected by electrophoretic or immunoprecipitation techniques sensitive to the modifications introduced.

Although one often refers to the plasma membrane as if it were a single compartment, most eukaryotic cells exhibit more than one plasma membrane domain. Polarized epithelial cells are perhaps the best characterized example of cells that have specialized plasma membrane domains. In epithelial cells, these domains are known as apical and basolateral. Protein trafficking to and from these two domains follows distinct pathways, the analysis of which is the focus of *UNIT 15.5*. For analysis of polarized sorting to be possible, these cells need to be grown in special chambers fitted with porous filters. The cells form a tight monolayer in which the apical and basolateral domains are segregated. In the chambers, the apical and basolateral media are separately available for addition of reagents or collection of secreted proteins. The unit contains protocols for metabolic labeling of polarized epithelial cells and collection of proteins secreted from the apical and basolateral surfaces, stable transfection and selection of transfected clones, culture of epithelial cells on filters, determination of leakiness of epithelial monolayers, monitoring the arrival of newly synthesized proteins at both plasma membrane domains, and indirect immunofluorescence microscopy of epithelial cells grown as polarized monolayers.

UNIT 15.6 takes us back to early events in the maturation of newly synthesized proteins in the ER. Upon emergence into the lumen of the ER, nascent polypeptide chains undergo a series of post-translational modifications that lead to the development of a mature protein (see *UNIT 15.1*). Among these modifications are glycosylation (*UNIT 15.2*), folding, and disulfide bond formation. *UNIT 15.6* describes a series of protocols for the analysis of protein folding and disulfide bond formation in the ER. In these protocols, newly synthesized proteins are first labeled with radiolabeled amino acids either in intact cells (also see *UNIT 7.1*) or in cell-free (also see *UNIT 11.4*) or semi-permeabilized cell systems. Protein folding can then be followed by limited proteolytic digestion or immunoprecipitation

with conformation-specific antibodies. Disulfide bond formation can be analyzed by monitoring the disappearance of sulfhydryl groups or the appearance of faster-moving species on nonreducing SDS-PAGE (also see *UNIT 6.5*).

The subject of *UNIT 15.7* is phagocytosis—the process by which specialized cells such as macrophages and monocytes ingest particles such as bacteria, yeast, and apoptotic bodies. Because of the size and complexity of the internalized particles, phagocytosis is distinct from the receptor-mediated or fluid-phase endocytosis described in *UNIT 15.3*. The first step in phagocytosis is the recognition of specific molecules on the surface of the particle by the phagocytic cell. These molecules can be intrinsic to the particle or deposited onto the particle by the host (i.e., "opsonization"). The unit starts with microscope-based protocols to measure phagocytosis of red blood cells or latex beads opsonized with immunoglobulin G (IgG), which are internalized upon binding to Fcγ receptors on the phagocytic cells. These protocols are followed by others designed to measure complement-mediated phagocytosis of red blood cells or latex beads opsonized with complement factor C3bi, a process that is mediated by binding to complement receptors. Phagocytosis can be measured more quantitatively by flow cytometry, for which a protocol is also included in this unit. The next protocols deal with events that follow the uptake of particles, such as the acidification and maturation of the phagosome. The final protocol describes a procedure to inhibit phagocytosis with wortmannin or cytochalasin D.

UNIT 15.8 deals with protein transport to lysosomes, organelles that constitute a major site of degradation for both endogenous and exogenous biomacromolecules. The degenerative function of lysosomes depends on over 50 acidic hydrolases contained within the lumen and a similarly large set of tranmembrane proteins embedded in their limiting membrane. The transport of these resident proteins, or of proteins targeted for lysosomal degradation, can be measured by methods that take advantage of the high density of lysosomes. The best of these methods is centrifugation on self-forming Percoll gradients, in which lysosomes band near the bottom while most other organelles band near the tops of the gradients. When used in combination with metabolic labeling, pulse-chase analyses, Percoll gradient fractionation allows analysis of biosynthetic transport of proteins to lysosomes. It is also possible to combine extrinsic labeling of the plasma membrane or internalization of cargo molecules with Percoll gradient fractionation in order to monitor endocytic delivery to lysosomes. In addition to the basic protocol for Percoll gradient fractionation, *UNIT 15.8* describes a β-hexosaminidase assay to check the efficiency of the fractionation.

Another major system for the degradation of endogenous proteins relies on their covalent modification with ubiquitin followed by their targeting to proteasomes. Conjugation with ubiquitin also regulates many other cellular functions, including endocytosis, lysosomal targeting, signal transduction, transcription, and nuclear-cytoplasmic shuttling. So numerous and varied are the roles of ubiquitylation that it has been likened to another ubiquitous covalent modification, phosphorylation. *UNIT 15.9* prevents a comprehensive set of protocols to analyze protein modification with ubiquitin and other molecules (the latter as exemplified by NEDD8). Among the protocols described in this unit are procedures to produce and characterize the cascade of enzyme (i.e., E1, E2, and E3) that mediate ubiquitylation, examine ubiquitylation of proteins in vivo and in vitro, and inhibit ubiquitylation and proteasomal degradation. Protocols to study modification with NEDD8 are also described.

After internalization from the cell surface into endosomes, membrane-bound proteins can follow different fates: they can recycle back to the cell surface like the transferrin receptor, be delivered to lysosomes like the activated EGF receptor, or undergo transport to the TGN. *UNIT 15.10* deals with this latter pathway, mainly using the B subunit of Shiga

toxin (STxB) as a model cargo protein. STxB binds to cell surface glycosphingolipids and is endocytosed into early endosomes, from where it begins a journey that takes it to the TGN, the cisternae of the Golgi complex, and eventually the ER. The assays for measuring this "retrograde" transport from endosomes to the TGN rely on the addition of a sulfation site peptide to the cargo protein (e.g., STxB, the B subunit of cholera toxin, antibody to a GFP-mannose 6-phosphate receptor fusion protein) by either genetic fusion or chemical coupling, and then monitoring the incorporation of radioactive sulfate into the cargo protein either by trichloroacetic acid precipitation and scintillation counting or by SDS-PAGE and fluorography. These protocols are applicable to both live and permeabilized cells. This unit also includes a protocol for chemical coupling of horseradish peroxidase to STxB, which permits ultrastructural analysis by whole-mount electron microscopy of the intracellular compartments through which STxB transits in its retrograde path. The unit ends with protocols designed to analyze the internalization of biotinylated STxB into cells.

UNIT 15.11 deals with another important function of certain specialized cells, which is the regulated secretion of proteins and other substances into the extracellular space. The protocols in this unit make use of mast cells as a model system. These cells have secretory granules that contain a variety of mediators of inflammation, including serotonin, histamine, proteoglycans, proteases, and lysosomal hydrolases. Allergen-induced aggregation of immunoglobulin E bound to its receptor or engagement of other signaling receptors on the surface of these cells triggers the fusion of the regulated secretory granules with the plasma membrane, resulting in the release of the granule contents into the extracellular milieu. This unit describes protocols to measure regulated secretion of the soluble granule contents, serotonin and β-hexosaminidase, into the medium. In addition, granule exocytosis causes the merging of the membrane of the granules with the plasma membrane. This leads to transient changes in both the protein and lipid composition of the plasma membrane. One of these changes is a transient increase in the levels of phosphatidylserine, which, as described in another protocol, can be detected by binding of Annexin V using flow cytofluorometry. Finally, protocols are presented to indirectly detect the release of histamine in live mice by measuring passive or active anaphylactic reactions.

UNIT 15.12 continues with the topic of regulated secretion, in this case using PC12 cells as a model system. PC12 is a cell line derived from a rat pheochromocytoma, a catecholamine-producing tumor of the adrenal medulla. Like their normal counterparts, PC12 cells have dense-core (chromaffin) granules filled with proteins (e.g., granins, peptide hormones, neuropeptides) and small molecules (e.g., catecholamines, nucleotides, Ca^{2+}), which can be released into the extracellular space upon exposure of the cells to various secretagogues (e.g., cholinergic agonists, depolarizing agents, Ca^{2+} ionophores). This unit includes protocols for measuring exocytic release of a radiolabeled catecholamine, [^{3}H]-L-norepinephrine, the polypeptide human growth hormone, and the reporter protein, CgA-EAP, a chimeric protein comprising chromogranin A fused to embryonic alkaline phosphatase (EAP). Additional protocols in this unit describe how to culture and transfect PC12 cells.

The post-endocytic fate of cell surface proteins can be monitored by extracellular tagging with fluorescent ligands and visualization by fluorescence microscopy. Localization of the fluorescently tagged proteins to organelles along the pathway can be determined by costaining for organellar markers. Although informative, these microscopic analyses generally suffer from limited accuracy and low quantitative power. *UNIT 15.13* presents a set of protocols that overcome these shortcomings by exploiting the ability to measure the pH of endocytic organelles using a pH-sensitive fluorescent tag. Internalized cargo proteins are progressively exposed to increasingly acidic environments as they move from

early endosomes to late endosomes to lysosomes. Each of these organelles possesses a lumenal pH in a characteristic range of values. Thus, measurement of the pH to which the fluorescent tag is exposed over time provides a more precise assessment of the localization and transport of endocytic cargo. The basic technique, named fluorescence ratiometric image analysis (FRIA), involves labeling cell surface proteins with a primary antibody followed by a secondary antibody conjugated with fluoroscein isothiocyanate (FITC). After different times of internalization, single-cell FRIA measurements are made by fluorescence microscopy.

The epidermal growth factor (EGF) receptor (EGFR) is a prototypical example of a transmembrane signaling receptor that is down-regulated from the cell surface upon ligand binding. EGF binding to the EGFR triggers activation of signal transduction pathways that lead to changes in gene expression. Receptor activation is quickly followed by endocytosis and lysosomal delivery of the EGF-EGFR complex via the multivesicular body (MVB) pathway. Analyses of EGFR-EGF traffic and degradation are often used to assess the importance of various components of the endocytic and lysosomal/MVB targeting machinery. *UNIT 15.14* describes several protocols aimed at quantifying EGF and EGFR traffic and turnover within cells. The first two protocols are used to measure the rates of EGFR synthesis and degradation. These are followed by protocols to measure down-regulation of cell surface EGFR and internalization, recycling, and degradation of radioiodinated EGF.

Juan S. Bonifacino

Overview of Protein Trafficking in the Secretory and Endocytic Pathways

COMPARTMENTALIZATION OF EUKARYOTIC CELLS

The interior of eukaryotic cells is organized as an interconnected system of membrane-bounded compartments. The compartments that form part of the secretory and endocytic pathways include the endoplasmic reticulum (ER), the ER-Golgi intermediate compartment (ERGIC), the Golgi complex with its different subcompartments (*cis*, medial, and *trans* cisternae, and the *trans*-Golgi network or TGN), early and late endosomes, lysosomes, regulated secretory granules, the plasma membrane, and various types of intermediary vesicles and tubular-vesicular carriers (Fig. 15.1.1). Each of these compartments contains a characteristic set of resident proteins. Protein localization to these compartments is mediated by specific targeting information present within the proteins (see *APPENDIX 1C*). This unit is intended as a brief overview of the itinerary followed by proteins as they move through the secretory and endocytic pathways, and of the mechanisms that determine protein sorting within these pathways.

TARGETING AND TRANSLOCATION OF PROTEINS INTO THE ER

Most proteins enter the secretory pathway by translocation from the cytosol into the ER. In mammalian cells, protein translocation in the ER occurs co-translationally as the nascent polypeptide chain emerges from the ribosome. In yeast cells, some proteins utilize this cotranslational mechanism and others are translocated posttranslationally. The steps involved in cotranslational transport are shown in Figure 15.1.2. Early experiments established that the signal for translocation of a protein across the ER membrane lies in the nascent polypeptide rather than in the encoding mRNA (reviewed by Rapoport et al., 1996). As the signal sequence emerges from the ribosome, it binds to the signal-recognition particle (SRP; step 1), a complex composed of six proteins and one 7S RNA molecule. SRP arrests further elongation of the polypeptide on the ribosome and then binds the complex to the SRP receptor on the cytosolic side of the ER membrane (step 2). Both SRP and the SRP receptor bind GTP, which allows transfer of the ribosome to the translocon. Hydrolysis of GTP induces dissociation of SRP from the SRP receptor (step 3). The nascent polypeptide then moves through the central channel of the translocon, the main component of which is the multi-spanning membrane protein Sec61α (step 4). The signal peptide is cleaved cotranslationally by signal peptidase. Throughout translocation, the impermeability of the ER membrane is maintained by a complex set of events, involving the ribosome or ER-lumenal proteins such as BiP (binding immunoglobin protein). Translocation is complete either when a stop-transfer sequence in the polypeptide is encountered (step 5), leading to protein integration in the lipid bilayer (step 6), or when a stop codon is reached, in which case the protein is released into the ER lumen.

PROTEIN MODIFICATIONS IN THE ER

Once the nascent polypeptide chains emerge into the ER lumen, they undergo a series of modifications including signal peptide cleavage, glycosylation, folding, and disulfide-bond formation. Amino-terminal signal sequences are cotranslationally cleaved by signal peptidase, an enzyme complex that is closely associated with the translocon (Andrews and Johnson, 1996). In addition to signal peptidase, the oligosaccharyl transferase complex also appears to be in close proximity to the translocon. This complex is responsible for transferring the preassembled core oligosaccharide moieties to the nascent polypeptide chains at Asn-X-Ser/Thr sequences (see *UNIT 15.2*). The nascent polypeptide chain can be glycosylated when as few as fifteen amino acids have emerged from the translocon.

The nascent polypeptide chain associates with a number of chaperone proteins in the ER, including BiP, GRP94, calnexin, calreticulin, protein disulfide isomerase, and peptidyl proline *cis-trans* isomerase. BiP comprises ~5% of the ER lumenal protein content and associates transiently with a number of newly synthesized proteins (Gething and Sambrook, 1992). BiP has been postulated to sequentially bind, release, and rebind newly synthesized proteins in an ATP-dependent manner until the proteins fold correctly and their hydrophobic regions are no longer accessible to BiP. Proteins

Contributed by Caroline Enns
Current Protocols in Cell Biology (1999) 15.1.1-15.1.10

that do not fold correctly remain bound to BiP and are not transported further along the secretory pathway.

Calreticulin and calnexin are carbohydrate-binding chaperones, which are also involved in quality control in the ER (reviewed by Bergeron et al., 1994; Hammond and Helenius, 1995). Calreticulin is a lumenal protein, whereas calnexin is an integral membrane protein. Shortly after addition of the core oligosaccharide complex to the nascent polypeptide, the two terminal glucose residues of the complex are removed by glucosidases I and II (Fig. 15.1.3). This generates a monoglucosylated oligosaccharide to which calnexin or calreticulin binds. Further processing of the oligosaccharide results in the release of the newly synthesized polypeptide from either chaperone. If the protein is not folded correctly, it is re-glucosylated by a UDP-glucosyl transferase, and the

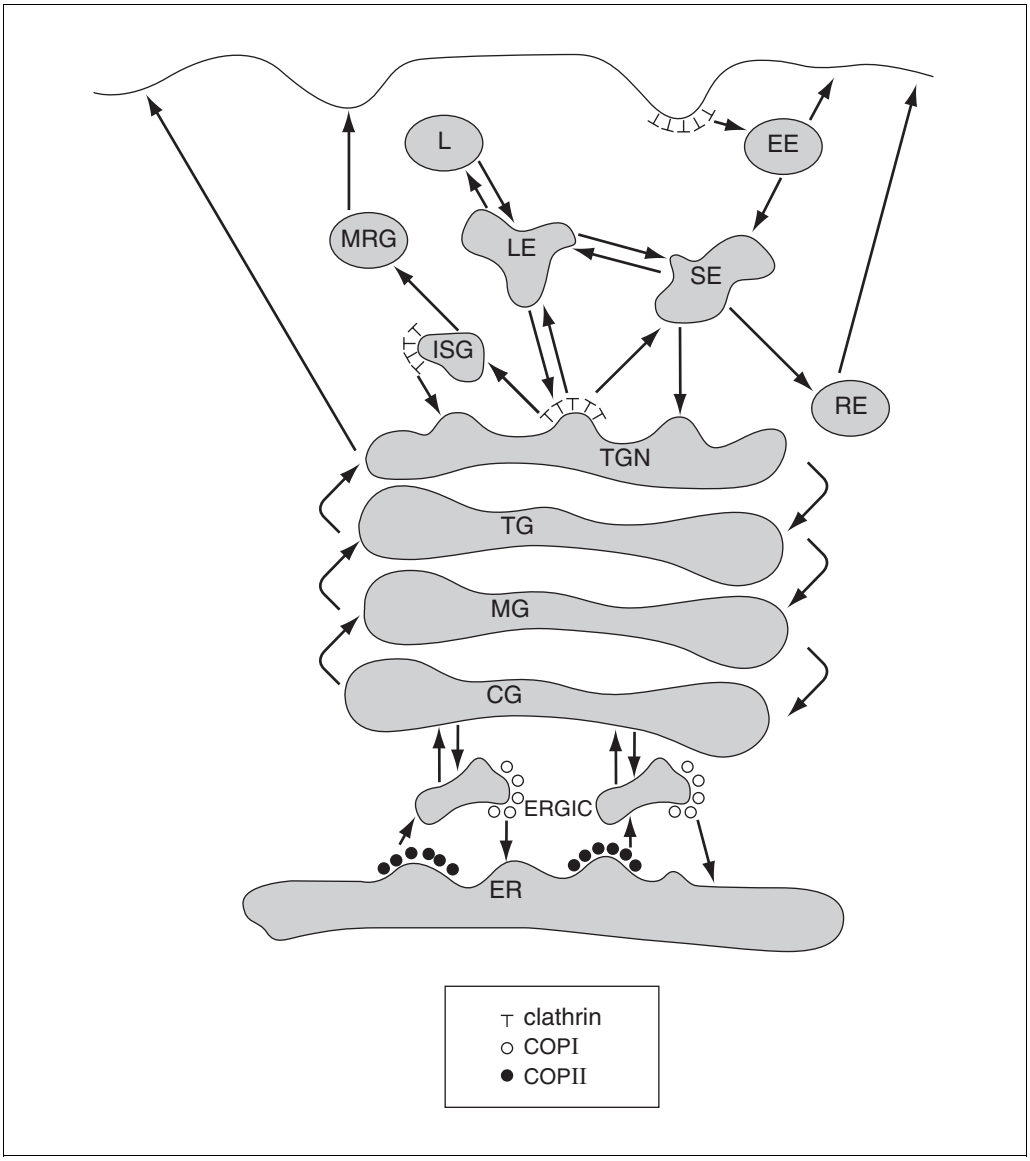

Figure 15.1.1 Compartments of the biosynthetic and endocytic pathways. The known routes in the biosynthetic and endocytic pathways are shown in this schematic diagram. The compartments include: the endoplasmic reticulum (ER), the ER-Golgi intermediate compartment (ERGIC), the *cis*-Golgi (CG), the medial Golgi (MG), the *trans*-Golgi (TG), the *trans*-Golgi network (TGN), the lysosome (L), the late endosome (LE), the sorting endosome (SE), the recycling endosome (RE), the early endosome (EE), the immature secretory granule (ISG), and the mature regulated granule (MRG). The extent to which each of the pathways are utilized is not known. The steps where coat proteins have been identified to be involved in vesicle formation are indicated. See Transit Between the ER and the Golgi Complex for discussion of COPI and COPII.

cycle of calnexin/calreticulin binding is repeated until the protein folds correctly and no longer interacts with the UDP-glucosyl transferase. The lumen of the ER is much more oxidizing than the cytosol, allowing the formation of disulfide bonds in a reaction catalyzed by protein disulfide isomerase.

ER-ASSOCIATED PROTEIN DEGRADATION

Quality control mechanisms of the ER not only prevent misfolded proteins from exiting the ER, but also ensure that abnormal proteins are degraded (Sommer and Wolf, 1997). Recent evidence indicates that misfolded proteins, as well as ER proteins whose levels are subject to

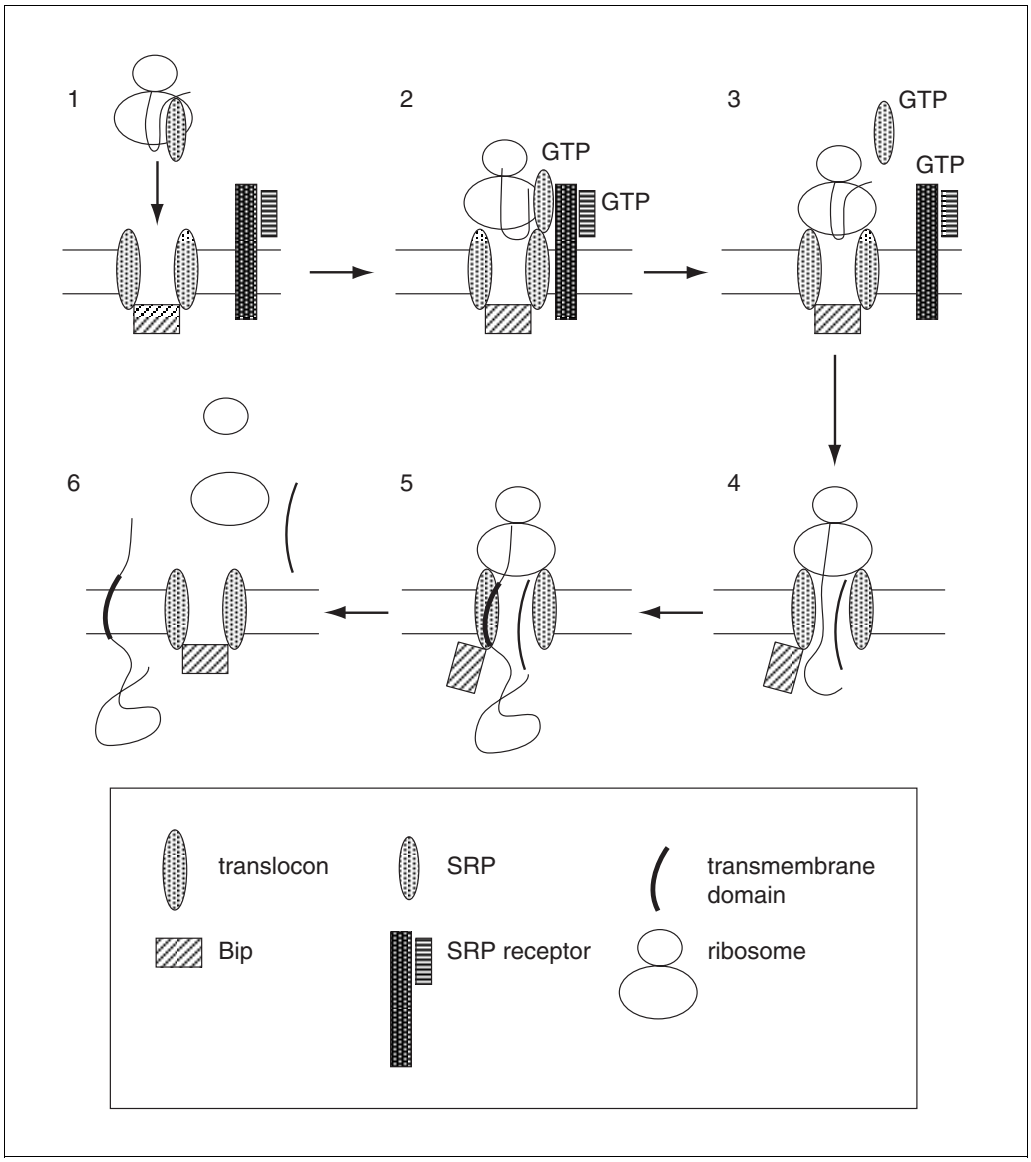

Figure 15.1.2 Cotranslational translocation of a type 1 membrane protein into the ER. (**1**) When the signal sequence emerges from the ribosome, it binds to the signal-recognition particle (SRP) in the GTP-empty form and translocation is arrested. The pore of the translocon is in the closed position, sealed by binding immunoglobulin protein (Bip). (**2**) The SRP/signal peptide/ribosome complex binds to the two subunits of the GTP-bound SRP receptor. The ribosome interacts with the translocon. (**3**) GTP is hydrolyzed, releasing the SRP from the SRP receptor. Translation is continued. (**4**) The ribosome seals the pore and when the nascent chain reaches ~70 residues Bip is released. The protein is extruded into the lumen of the ER, where the signal peptide is cleaved. (**5**) The transmembrane sequence emerges from the ribosome and interacts with different proteins in the translocon. (**6**) The protein is inserted into the bilayer by the completion of translation. The ribosome disassociates and the pore is closed by Bip.

metabolic regulation, are exported from the ER into the cytosol, where they are degraded by the ubiquitin-proteasome pathway (Sommer and Wolf, 1997). A variety of viruses use this degradative pathway to subvert the immune system. For example, viral proteins such as US2 and US11 of human cytomegalovirus appear to promote ejection from the ER and subsequent proteosomal degradation of the heavy chain of MHC class I complexes (Wiertz et al., 1996). This serves to down-regulate molecules that would otherwise stimulate an immune response against the virus.

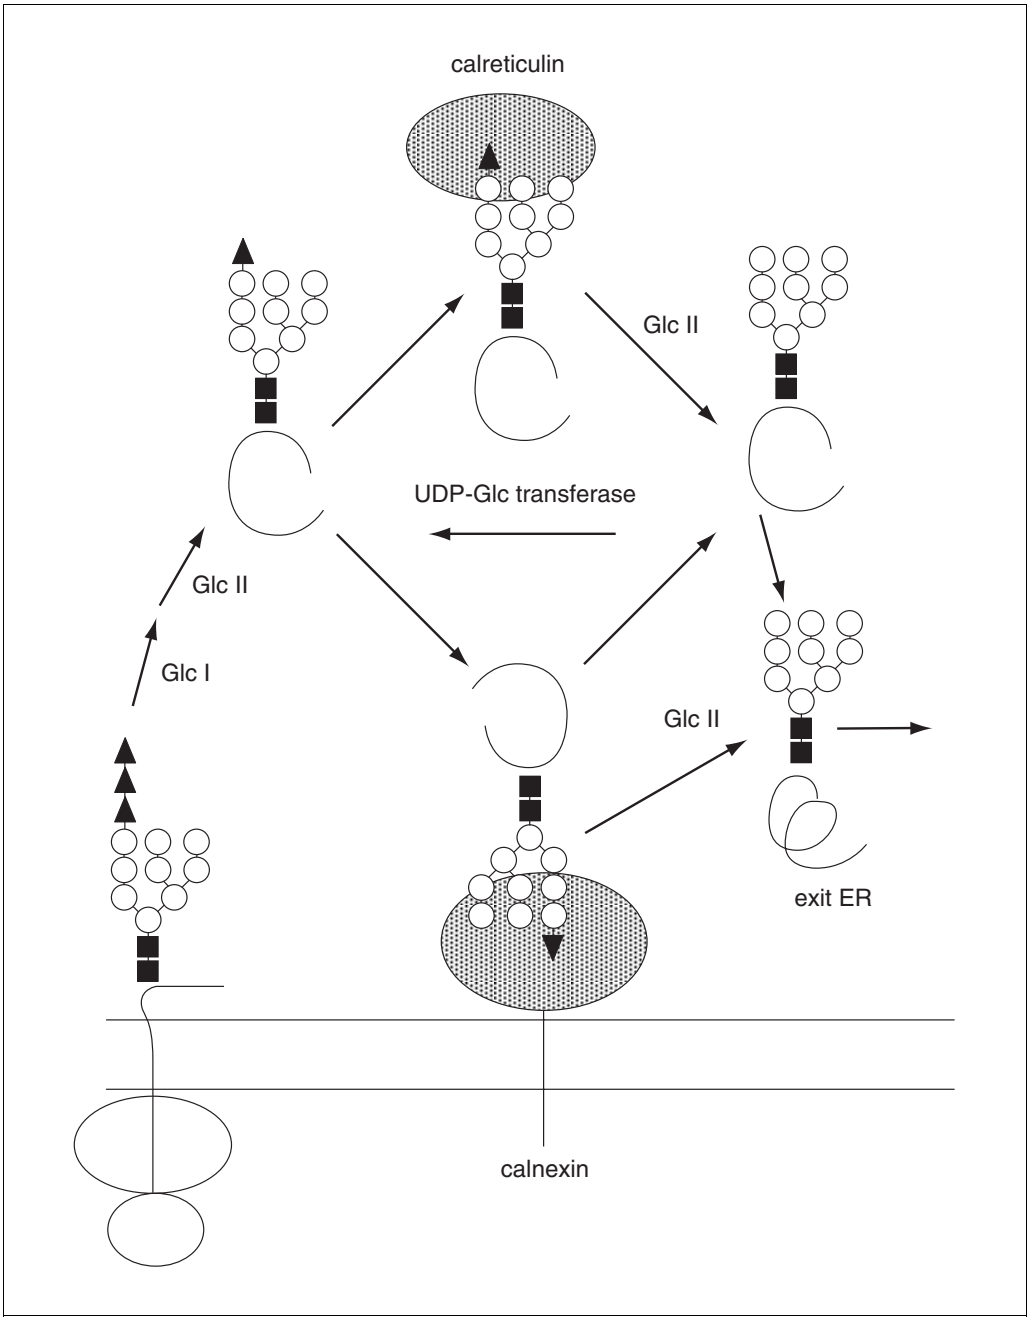

Figure 15.1.3 The calnexin/calreticulin quality control pathway in the ER. Glucosidases I and II (Glc I and Glc II) remove the two outermost glucose residues (black triangles) from the protein and allow interaction of the oligosaccharide with either calnexin or calreticulin. Glucosidase II removes the last glucose residue, and the protein no longer associates with these lectins. If the protein is folded properly, it is free to exit the ER. If it is not folded correctly, it is reglucosylated by the enzyme UDP-glucosyl transferase and rebinds to calnexin or calreticulin. Adapted from Hammond and Helenius (1995). See Figure 15.2.1 for identification of the sugar residues.

TRANSIT BETWEEN THE ER AND THE GOLGI COMPLEX

Vesicle budding in both the secretory and endocytic pathways is mediated by cytosolic proteins that form coated structures on the membranes. Two types of coat proteins—known as COPI and COPII—have been shown to be involved in trafficking of proteins between the ER and the Golgi complex (Cosson and Letourneur, 1997; Kuehn and Schekman, 1997; Fig. 15.1.1). COPII-coated vesicles mediate anterograde ER-to-Golgi transport, whereas COPI-coated vesicles mediate retrograde Golgi-to-ER transport. Controversy still exists as to whether COPI vesicles are also involved in anterograde transport. Vesicles generated from the ER are targeted to and fuse with the ER-Golgi intermediate compartment (ERGIC). ERGIC structures then migrate towards the centrosomal region of the cell and fuse with the Golgi complex.

Newly synthesized proteins were initially proposed to exit the ER via a bulk-flow mechanism that did not involve concentration into transport vesicles. However, recent evidence suggests that newly synthesized proteins destined for transport out of the ER are specifically concentrated at ER exit sites (reviewed by Bannykh et al., 1998). For example, a diacidic (D/EXD/E) sequence close to an internalization signal has been shown to be responsible for the efficient concentration of vesicular stomatitis virus G protein at ER exit sites (Nishimura and Balch, 1997). In yeast, selective packaging of glycosylated pro-α-factor for export from the ER has also been demonstrated (Kuehn and Schekman, 1997). A lectin-like molecule named ERGIC-53 (Emp47p in yeast) is thought to be involved in the transport of some soluble glycoproteins out of the ER after the glucose residues have been trimmed (reviewed by Hammond and Helenius, 1995).

RETENTION IN THE ER AND RETRIEVAL FROM THE GOLGI COMPLEX

Most soluble ER-resident proteins contain a carboxy-terminal tetrapeptide sequence, KDEL (HDEL in *S. cerevisiae*). Addition of this sequence to the carboxy terminus of soluble secreted proteins results in their accumulation in the ER, implying that this motif is sufficient for ER localization. The KDEL sequence is thought to retrieve proteins from the ERGIC or the Golgi complex to the ER. This retrieval is mediated by the membrane-bound receptor protein Erd2p.

Other signals are used to retrieve integral membrane proteins to the ER. Type I ER-resident membrane proteins have cytosolic KKXX or KXKXX (dilysine) motifs at their carboxy termini. Some type II ER-resident membrane proteins have a cytosolic ER localization signal consisting of two arginine residues (RR) located within the first five amino-terminal residues of the protein. Direct binding of COPI to the dilysine motif of ER integral membrane proteins has been implicated in the retrograde transport of these proteins to the ER (reviewed by Cosson and Letourneur, 1997).

Thus, a picture emerges in which anterograde transport of secretory cargo allows newly synthesized proteins to exit the ER selectively, and retrograde transport mediates the retrieval of ER-resident proteins, as well as transport factors necessary for a subsequent round of anterograde transport. The balance of the two transport pathways determines the steady-state distribution of proteins in each compartment.

CARBOHYDRATE MODIFICATIONS IN THE GOLGI COMPLEX

The Golgi complex is a major site of N-linked oligosaccharide modification within the secretory pathway. A highly organized set of glycosyl transferases, glycosidases, and nucleotide- or lipid-linked glycosyl donors and transporters cooperates to produce these modifications. Each component of this protein modification machinery has a characteristic distribution within the Golgi complex. For example, generation of mannose-6-phosphate residues, which serve as a signal for sorting soluble proteins to lysosomes, occurs in the *cis* region of the Golgi complex. In the biosynthesis of complex carbohydrates (*UNIT 15.2*), mannose residues are removed in the *cis*-medial Golgi complex, and *N*-acetylglucosamine residues are added in the medial Golgi complex, whereas galactose and sialic acid addition occurs in the *trans*-Golgi complex and TGN (Fig. 15.1.4). Sulfation of oligosaccharides and tyrosine residues takes place in the TGN. The extent of glycosylation of proteins traveling through the Golgi complex can be deduced by a variety of methods, including the use of glycosidases specific for certain oligosaccharide structures (see *UNIT 15.2*). The oligosaccharide composition of a mature glycoprotein can be quite heterogeneous and can depend on the cell type and metabolic state. Moreover, whether a particular consensus sequence is modified and

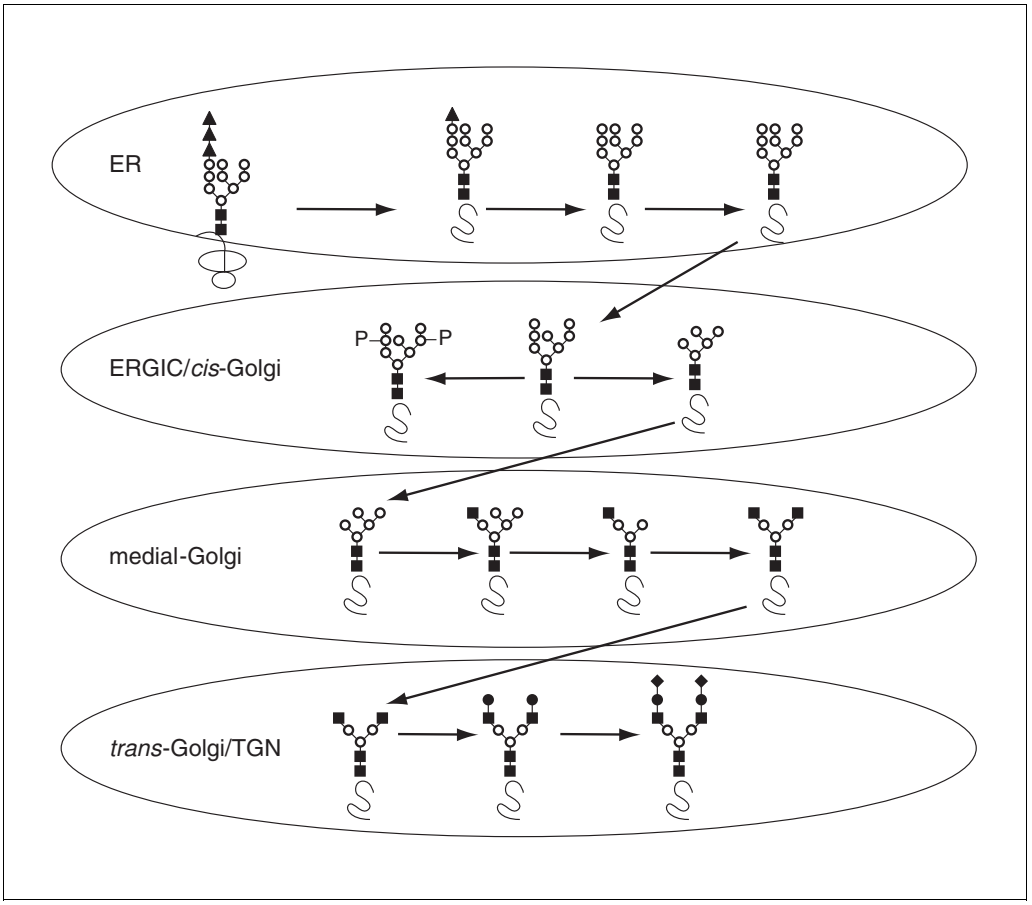

Figure 15.1.4 Processing of oligosaccharides in the Golgi. A schematic diagram of the approximate locations of oligosaccharide modification in the biosynthetic pathway. See Figure 15.2.1 for identification of sugar residues.

to what extent depend on the local conformation of the protein at each glycosylation site (Dwek, 1995).

In contrast to N-linked glycosylation, O-linked glycosylation occurs posttranslationally with the addition of a single *N*-acetylglucosamine residue to a serine/threonine residue. While there is no consensus sequence for O-linked glycosylation, it often occurs in the proximity of proline and close to transmembrane regions (Hounsell et al., 1996; see *UNIT 15.2*).

MODELS OF PROTEIN RETENTION IN AND TRANSPORT THROUGH THE GOLGI COMPLEX

How are secretory proteins transported through the Golgi complex, and how are resident components retained in the Golgi in the face of this continuous transport? At present, no single mechanistic model has been embraced by all cell biologists (Mellman and Simons, 1992; Mironov et al., 1997; Glick and Malhotra, 1998).

A widely accepted model for Golgi protein transport is by vesicular traffic (Rothman, 1994). This model views the Golgi complex as comprised of a series of distinct and stable subcompartments. Secretory cargo moves between subcompartments in a vectorial direction (*cis* to *trans*) by being packaged into transport vesicles that specifically target acceptor membranes. According to this model, membrane association of COPI provides the mechanochemical force for driving vesicle budding from donor membranes. Golgi enzymes are thought to be organized into large, immobile aggregates in Golgi membranes to avoid being packaged into the forward-moving transport vesicles, which deliver secretory cargo by bulk flow. Evidence in favor of this model includes the findings that cisternae exhibit relatively distinct and stable enzymatic composition, that protein transport can be reconstituted in vitro between biochemically isolated donor and acceptor Golgi compartments, and that COPI-coated Golgi vesicles accumulate in cells where pro-

tein transport has been inhibited with GTPγS (a GTP analog that prevents COPI dissociation from membranes; Rothman, 1994).

A second model for Golgi protein transport that is gaining popularity is transport by cisternal maturation (Mironov et al., 1997; Bonfanti et al., 1998; Pelham, 1998). In this model, Golgi cisternae themselves act as carriers through the Golgi stack. The observation that ER-derived vesicles carrying protein into the Golgi complex undergo a process of fusion and maturation into relatively large (200- to 500-nm), pleiomorphic intermediates that translocate into the Golgi region is consistent with this nonvesicular transport model (Presley et al., 1998). According to the maturation hypothesis, as pre-Golgi intermediates arrive at the *cis* face of the Golgi stack, they form a new *cis* cisternae replacing preexisting *cis* cisternae. This replacement of one cisternae for another continues distally through the stack. The size of the stack is kept constant by the continued consumption of *trans* cisternae through the formation of post-Golgi transport intermediates. To account for the observed constancy of cisternal enzyme distribution by this model, the anterograde shift of each cisterna would be coupled with retrograde relocation of its enzymes into the next proximal cisterna. Morphological observations of the transport of supramolecular structures through the Golgi complex—including casein submicelles, apolipoprotein E, and procollagen—are consistent with this possibility (Bonfanti et al., 1998). These structures are detected throughout Golgi cisternae, but are consistently absent from Golgi vesicles. As these secretory products are simply too large to be packaged into transport vesicles, progression of Golgi cisternae seems reasonable. The observation that Golgi enzymes are highly mobile within the Golgi stack (Cole et al., 1996) and undergo continuous recycling (Cole et al., 1998) is also consistent with this model. A problem with this model, however, is that it cannot explain how different cargo passes through the Golgi complex at distinct rates.

A third model for protein transport through the Golgi complex is by directed diffusion within a single compartment that is interconnected by tubules (Mironov et al., 1997). Tubules are a well characterized feature of the Golgi complex, with both the *cis*- and *trans*-most Golgi elements largely tubular in character. Moreover, the central part of the Golgi complex is comprised of stacks of cisternae that are interlinked by tubular-reticular networks. The finding that there is rapid diffusion of enzymes within the intact Golgi complex of living cells (Cole et al., 1996) is consistent with the possibility that protein transport through the Golgi occurs by directed diffusion within an interconnected structure. Different cargo would move through this system at distinct rates based on their rate of diffusion within the extended membrane system. Directional, *cis*-to-*trans* flow would arise because of continuous membrane addition at the proximal end (*cis* face) of this system, and membrane removal at the distal end (*trans* face). One difficulty with this model is that it requires unknown mechanisms for maintaining distinct membrane domains within an interconnected system. It also requires alternative functions for COPI coat proteins, which previously have been thought of only in the context of vesicle formation.

The above models for Golgi protein transport may not be mutually exclusive; instead, a spectrum of interrelated mechanisms may be involved. For example, recycling of Golgi enzymes may occur by directed diffusion within a continuous bilayer or by vesicles. Intermittent tubular connections might allow fast forward traffic of cargo, while large structures progress by the slower cisternal maturation pathway. Future work in this area will undoubtedly involve more systematic study of key aspects of each of the above models. Distinguishing between these models is nevertheless important for characterizing the exact roles of molecular machinery identified in in vitro transport assays and genetic screens (Schekman and Orci, 1996), and for understanding the relationship between protein traffic and Golgi structure/function.

PROTEIN SORTING IN POST-GOLGI COMPARTMENTS

The TGN is the major sorting compartment for newly synthesized proteins destined for endosomes, lysosomes, regulated secretory granules, or different domains of the plasma membrane (Fig. 15.1.1; reviewed by Keller and Simons, 1997; Traub and Kornfeld, 1997). The signals for sorting integral membrane proteins to endosomes, lysosomes, and the basolateral plasma membrane of polarized epithelial cells are found in the cytosolic domain of the proteins (see *APPENDIX 1C*). Two types of signal, referred to as tyrosine-based and dileucine-based signals, have been shown to play multiple roles in sorting to these compartments (Kirchhausen et al., 1997). Both types of signal interact with the heterotetrameric adaptor protein complexes AP-1, AP-2, and AP-3. AP-1 is com-

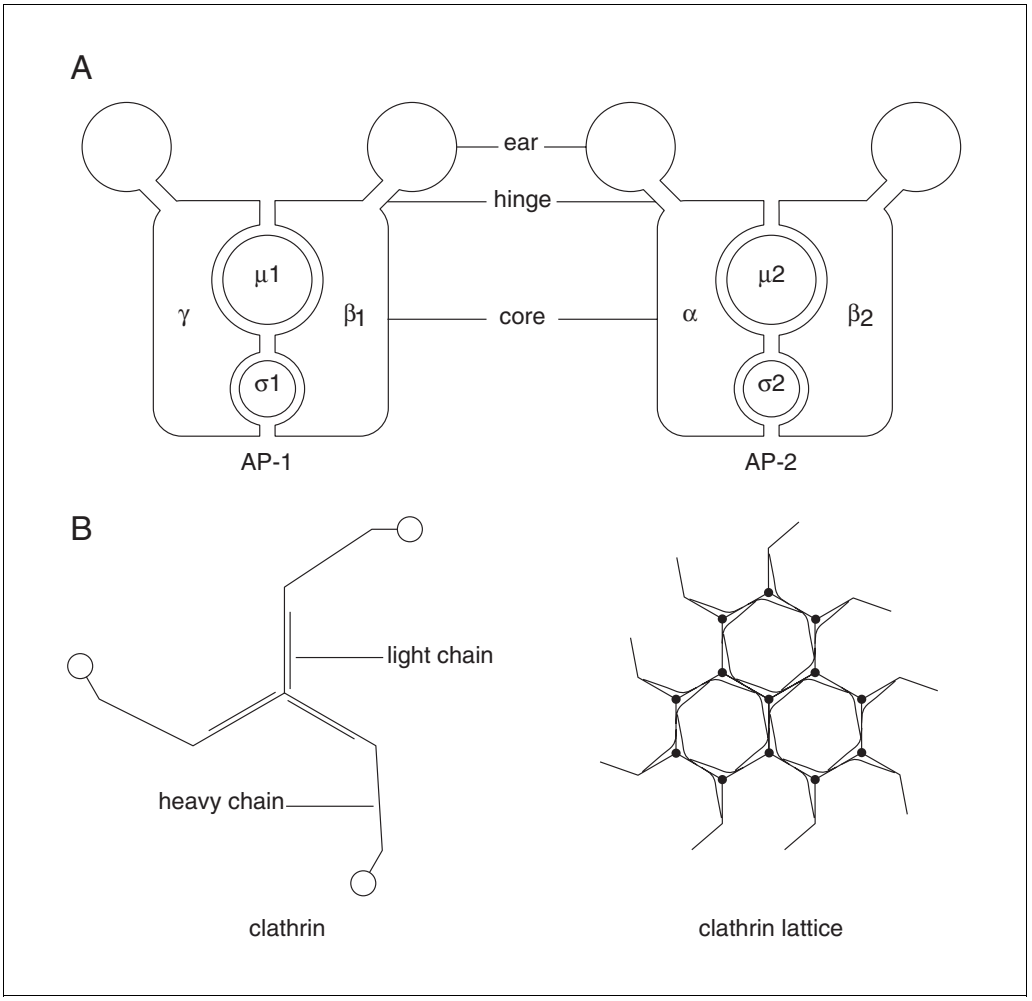

Figure 15.1.5 Clathrin and associated proteins. (**A**) Subunit composition and overall structure of AP-1, which is associated with the TGN, and of AP-2, which is associated with the plasma membrane. (**B**) Clathrin is composed of three heavy chains and three light chains forming a triskelion (left). Clathrin oligomerizes to form two-dimensional lattices (right) or three-dimensional clathrate structures (not pictured).

posed of γ, β1, μ1, and σ1 subunits; AP-2 of α, β2, μ2, and σ2 subunits; and AP-3 of δ, β3, μ3, and σ3 subunits (Fig. 15.1.5A). AP-1 localizes to the TGN and endosomes, whereas AP-2 is found on the plasma membrane. AP-3 has been proposed to exist in association with the TGN and/or endosomes. Both AP-1 and AP-2 associate with clathrin, a protein composed of three heavy chains (~190 kDa) and three light chains (~30 kDa). Electron microscopy of purified clathrin shows a three-legged structure termed a triskelion (Fig. 15.1.5B). The triskelion can self-associate into both planar lattices and three-dimensional clathrate structures. Both AP-1 and AP-2 promote the formation of these structures. AP-3 also interacts with clathrin in vitro, although it is currently unclear whether this interaction is required for AP-3 function in vivo.

Lysosomal integral membrane proteins, as well as lysosomal lumenal proteins bound via mannose-6-phosphate residues to specific receptors, are concentrated into AP-1/clathrin-coated areas of the TGN. The resulting coated vesicles transport these proteins to early or late endosomes, where they are in turn delivered to lysosomes. The cytosolic domain of the proteins targeted to lysosomes by this pathway—e.g., lysosome associated protein 1 (LAMP-1) and the mannose-6-phosphate receptors—appear to interact directly with AP-1. The mannose-6-phosphate receptors are subsequently recycled to the TGN by virtue of sorting information contained within the cytosolic tail. Recent studies suggest that the AP-3 adaptor complex may also play a role in transport of lysosomal membrane proteins to lysosomes.

Transport of proteins to the plasma membrane occurs either by default or by information contained within the cytosolic domains of the proteins. All plasma membrane proteins were originally thought to be targeted directly from the TGN. However, recent evidence suggests that at least a fraction of proteins intersect with the endocytic pathway en route to the cell surface (Fig. 15.1.1). In polarized epithelial cells, proteins can be targeted to either the basolateral or the apical plasma membrane. Basolateral targeting of integral membrane proteins appears to be dominant over apical targeting and depends on information found in the cytosolic domain of the proteins. Truncation of the cytosolic domain results in distribution to both the basolateral and apical membranes or only to the apical membrane. Proteins may be directed to the apical region by concentration into membrane domains rich in sphingolipids and cholesterol, or by interaction of N-linked oligosaccharides with putative sorting lectins in the TGN (Keller and Simons, 1997).

Exocrine, endocrine, and neuronal cells, as well as certain other cell types, have specialized vesicles whose secretion is regulated. Two models have been proposed for the biogenesis of these vesicles. One model proposes that proteins aggregate in the environment of the TGN, and that nonaggregated proteins are sorted from the condensed proteins in the immature vesicles that pinch off from the TGN. A second model proposes that the proteins bind to a putative receptor in a manner similar to the mechanism used by soluble lysosomal proteins (reviewed in Keller and Simons, 1997).

ENDOCYTOSIS

Most plasma membrane proteins are subject to internalization. However, only a subset of plasma membrane proteins are internalized at a very rapid rate. In most cases, rapid internalization occurs at areas of the plasma membrane that are coated with clathrin and the AP-2 adaptor complex (i.e., clathrin-coated pits). Concentration of integral membrane proteins within clathrin-coated pits is mediated by cytosolic tyrosine-based or dileucine-based signals similar to those that mediate sorting at the TGN. These signals interact directly with proteins within the clathrin-coated pits. Rapid internalization of endocytic receptors can occur either constitutively or upon ligand binding. For example, the transferrin receptor and the low-density lipoprotein receptor are internalized by a constitutive mechanism, even in the absence of ligand. In contrast, the rate of endocytosis of the epidermal growth factor receptor increases several fold upon ligand binding (Wiley, 1988).

Clathrin-coated pits become invaginated and eventually pinch off as clathrin-coated vesicles. Various accessory molecules such as dynamin, amphiphysin, and Eps15 participate in the formation of clathrin-coated vesicles (reviewed in Schmid, 1997). The clathrin-coated vesicles are subsequently uncoated by the HSP70 chaperone in an ATP-dependent reaction and fuse with early endosomes. In this compartment, internalized proteins are either sorted to late endosomes and lysosomes (e.g., activated epidermal growth factor receptors) or recycle to the plasma membrane (e.g., transferrin receptors, low-density lipoprotein receptors).

BIOCHEMICAL ANALYSES OF PROTEIN TRAFFICKING

The localization of proteins to different compartments of the secretory and endocytic pathways described above can be determined by immunofluorescence and immunoelectron microscopy (see Chapter 4). In addition, direct visualization of protein movement in these pathways is now possible through the use of chimeras containing green fluorescent protein (GFP). However, quantitative analyses of protein trafficking in cell populations require the use of biochemical assays. These assays rely on the acquisition of posttranslational modifications (e.g., glycosylation, disulfide-bond formation, proteolytic cleavage), accessibility to externally added reagents (e.g., biotinylating agents, glycosidases), or detection by specific probes (e.g., labeled ligands or antibodies). The following units in this chapter describe a series of protocols based on these principles.

Use Of Glycosidases To Study Protein Trafficking

Carbohydrate chain modifications are often used to monitor glycoprotein movement through the secretory pathway (*UNIT 15.1*). This is because stepwise sugar-chain processing is unidirectional and generally corresponds to the forward or anterograde movement of proteins. This unit offers a group of techniques that will help analyze the general structure of carbohydrate chains on a protein and, therefore, oligosaccharide processing mileposts. The minimum requirements are that the protein can be labeled metabolically (*UNIT 7.1*) and immunoprecipitated (*UNIT 7.2*) and clearly seen on a gel or blot (*UNIT 6.2*). The sugar chains themselves are not analyzed, but their presence and structure are inferred from gel mobility differences after one or more enzymatic digestions. This approach is most often used in combination with [^{35}S]Met pulse-chase metabolic labeling protocols, but they can be applied to any suitably labeled protein (e.g., biotinylated or ^{125}I-labeled). As the oligosaccharide chains mature, they become either sensitive or resistant to highly specific glycosidases. Some of these enzymes cleave intact oligosaccharide chains from the protein—e.g., endo H, endo F_2, endo F_3, peptide:N-glycosidase F (PNGase F), endo D, and O-glycosidase. Others strip only terminal sugars (e.g., sialidase) or degrade a selected portion of the chain (e.g., endo-β-galactosidase). The techniques can be adapted to count the number of N-linked oligosaccharide chains on a protein. One unusual protease (O-sialoglycoprotease) degrades only proteins containing tight clusters of O-linked sialylated sugar chains. These techniques work best on average size proteins (<100 kDa) that contain a few percent carbohydrate by weight, where a gel shift of 1 kDa can be seen. A summary of the enzymes and their applications is shown in Table 15.2.1.

The ever-changing view of the organization and structure of the secretory pathway, and of protein trafficking through it, presents formidable conceptual challenges, but these will not be covered here. Instead, this unit provides information on how to measure changes in carbohydrate structure and how these changes relate to protein trafficking. Fortunately,

Table 15.2.1 Enzymes Described in This Unit

Enzyme	Indications and uses	Monitors[a]
Endo D	Transient appearance of highly processed, sensitive forms prior to addition of GlcNAc by GlcNAc transferase I	*Cis* to medial Golgi
Endo F_2	Presence of biantennary chains ± core fucose	Medial Golgi
Endo F_3	Presence of core fucosylated biantennary α chains and/or triantennary chains ± core fucosylation	Medial Golgi
Endo-β-galactosidase	Presence of polylactosamines	*Trans*-Golgi and TGN
Endo H	Conversion of high mannose to complex type N-linked chains	*Cis*- to medial Golgi
O-Glycosidase	Presence of Galβ1,3GalNAc-α-Thr/Ser O-linked chains	*Cis*/medial Golgi
PNGase F	Presence of N-linked chains cleaves; nearly all N-linked chains; only enzyme that cleaves tetrantennary chains	Medial Golgi
Sialidase	Acquisition of sialic acids	*Trans*-Golgi and TGN
O-Sialoglycoprotease	Presence of mucin-like proteins with cluster of sialylated oligosaccharides	*Trans*-Golgi and TGN

[a]Abbreviation: TGN, *trans*-Golgi network.

Current Protocols in Cell Biology (1999) 15.2.1-15.2.26

the techniques are independent of mechanistic views, although it should be borne in mind that the organization and distribution of many of these indicator enzymes are cell type dependent.

The starting material for these protocols is assumed to be [^{35}S]Met-labeled, immunoprecipitated protein bound to ~20 µl of protein A–Sepharose beads (as described in *UNIT 7.2*). The trace amount of protein is eluted by heating in a small volume of 0.1% SDS, diluted in the appropriate buffer and then digested with one or more enzymes in a small volume. The digest is analyzed on an appropriate SDS-PAGE system that can detect a 1- to 2-kDa size change. A change in the mobility of the protein after digestion is evidence that the carbohydrate chain was sensitive to the enzyme and therefore, that the protein had encountered a certain enzyme in the processing pathway. Alternatively, the analysis can be done by two-dimensional isoelectric focusing (IEF)/SDS-PAGE or two-dimensional nonequilibrium pH gradient electrophoresis (NEPHGE)/SDS-PAGE (*APPENDIX 3*) to see the loss of charged sugar residues or of anionic oligosaccharide chains. The same digestions and SDS-PAGE analysis also apply to proteins that are radioiodinated or biotinylated, or to immunoprecipitates derived from subcellular fractions separated on sucrose or Percoll gradients.

It is important to present the glycosylation pathways, as a detailed description of the pathways is needed to appreciate how they will be used in this unit. A single protein can have more than one kind of oligosaccharide (N-linked and O-linked), and each individual N-linked chain can mature into a different final form. The same is true for O-linked chains. Each is described below.

THE N-LINKED PATHWAY

The N-linked oligosaccharide maturation pathway is most frequently used for tracking protein movement through the Golgi complex. A common feature of all N-linked chains is the core region pentasaccharide shown in Figure 15.2.1, which consists of three mannose units and two *N*-acetylglucosamine units. The mannose units comprise the trimannosyl core, and two of these residues are α-linked to the only β-linked mannose in the molecule. The β-linked mannose is bound to one of the two *N*-acetylglucosamines. Because they are β1-4 linked to each other, resembling the polysaccharide chitin, this is called a chitobiose disaccharide. Initially, all *N*-glycosylated proteins begin life when a preformed, lipid-associated oligosaccharide is transferred within the lumen of the endoplasmic reticulum (ER) to Asn of proteins having an Asn-X-Thr/Ser sequence. This precursor oligosaccharide contains three glucose (Glc), nine mannose (Man), and two *N*-acetylglucosamine (GlcNAc) sugar residues, and has the structure shown in Figure 15.2.1. There are several ways to depict this structure. The short-hand symbol method used in Figure 15.2.1 is the most convenient, but be sure to note the linkages of the individual sugars, as they are important. The α and β symbols denote the anomeric configuration of the sugar, and the number indicates which hydoxyl group of the next sugar is involved in the glycosidic linkage. In all cases, the anomeric position is 1, except in sialic acid where it is 2.

The details of the pathway are presented in Figures 15.2.2 and 15.2.3, along with the sensitivity to each endoglycosidase or glycoamidase. The figures show the steps between high-mannose and hybrid types (Fig. 15.2.2) and complex types (Fig. 15.2.3). The three Glc residues (filled triangles) are removed from properly folded proteins within the ER by two different oligosaccharide-processing α-glucosidases. The first α1-2Glc is cleaved by α-glucosidase I, and the next two α1-3Glc residues by α-glucosidase II (Fig. 15.2.2, step 1). An ER-associated α-mannosidase removes one Man residue (open circle; Fig.

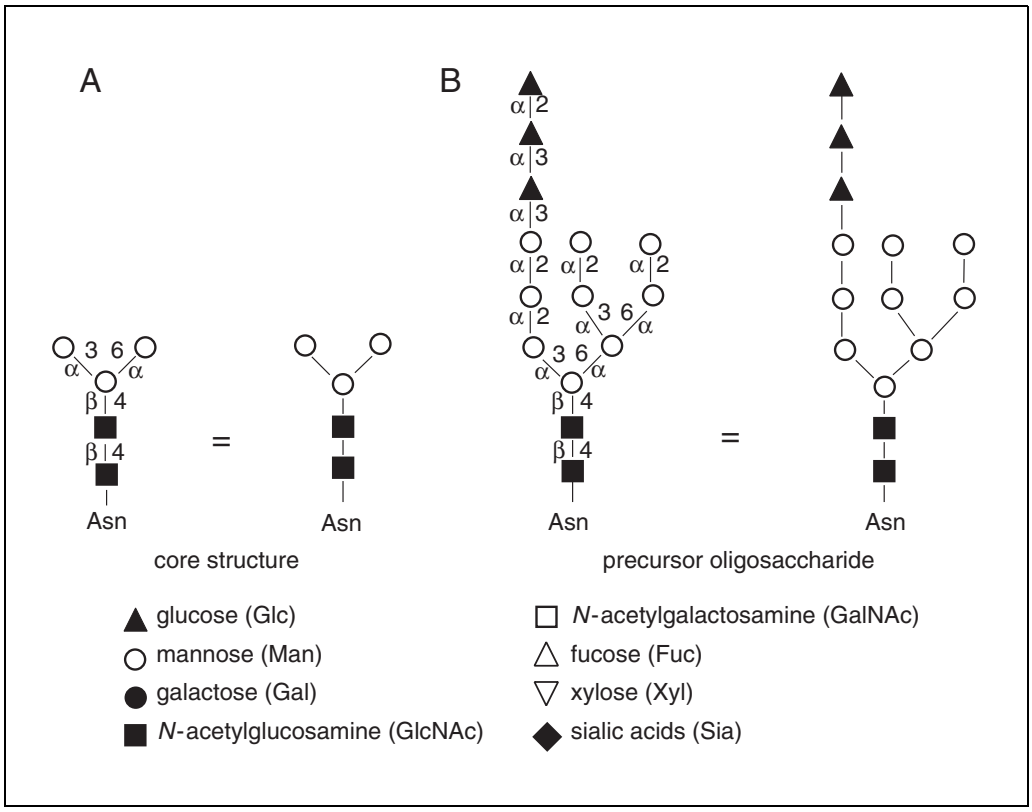

Figure 15.2.1 Symbol structures for the core region and precursor of N-linked sugar chains. Each sugar is given a symbol and abbreviation at the bottom of the figure. Each one except sialic acid uses its anomeric carbon (C-1) for linking to other sugars. Sialic acid uses C-2 for glycosidic linkage to other sugars. Glycosidases and glycosyltransferases are anomeric specific and distinguish α or β configurations of each sugar. The core structure (**A**) is common to all N-linked chains and is composed of three Man and two GlcNAc residues. The α or β configuration of each sugar is indicated, and the OH group to which that sugar is linked is shown on the bar linking the two symbols. Thus, GlcNAcβ1-4GlcNAcβ is represented by two filled squares with β and 4 between them. When a structure is first presented, it will have full display such as that on the left side; if it is repeated, only the symbols will be used as shown immediately to the right. The precursor oligosaccharide (**B**) for all N-linked chains is synthesized in the ER and transferred cotranslationally to the peptide containing an available Asn-X-Thr/Ser sequon.

15.2.2, step 2). The protein then moves on to the first step in Golgi-localized processing—the removal of the three remaining α1-2 Man units by Golgi α-mannosidase I to produce $Man_5GlcNAc_2$ (Fig. 15.2.2, steps 3 and 4). Many proteins have only high-mannose-type oligosaccharides with five to nine Man residues, and no further processing occurs. Alternatively, one to five GlcNAc residues (filled squares) can be added to the trimannosyl core, and these are usually extended with galactose (Gal; filled circles) and sialic acid (Sia; filled diamonds) residues. These extensions, called antennae, are the hallmarks of complex-type oligosaccharides. The transformation of the precursor sugar chain into various high-mannose or complex types is called oligosaccharide processing (Kornfeld and Kornfeld, 1985).

$Man_5GlcNAc_2$ is an important intermediate because it can have several fates. The first is the well-established addition of one GlcNAc residue by GlcNAc transferase I (Fig. 15.2.2, step 6). This is the first step toward the formation of complex chains. However, simply adding Gal and Sia to the terminal GlcNAc of this oligosaccharide forms a hybrid structure (Fig. 15.2.2, steps 12 and 13), where the left side of the molecule looks like a complex chain having one antenna, and the right side still resembles a high-mannose chain. The

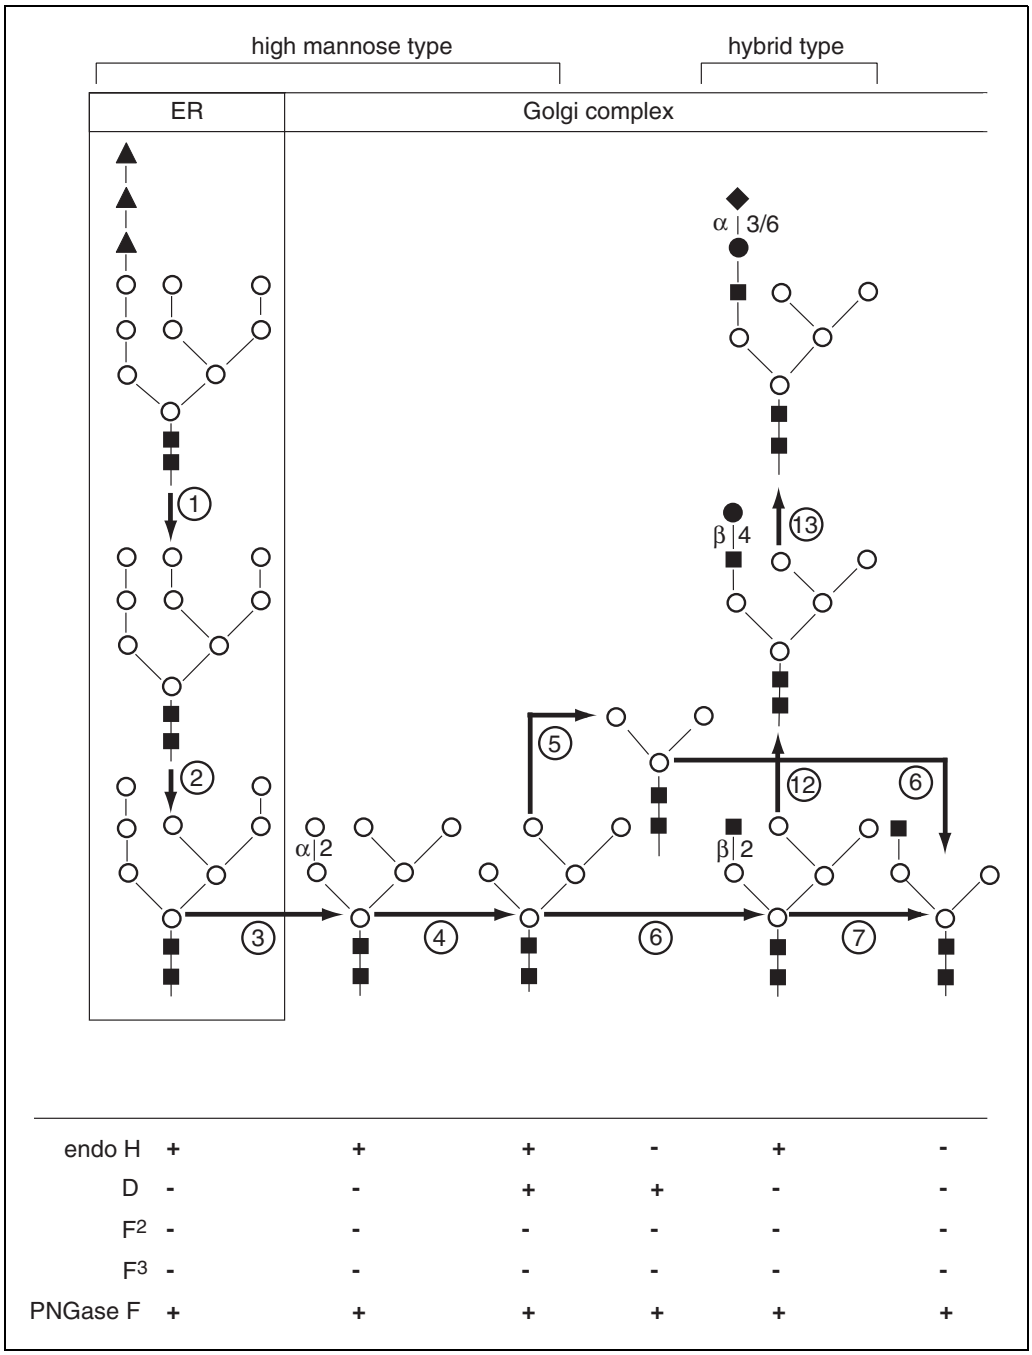

Figure 15.2.2 N-linked oligosaccharide maturation pathway for high-mannose and hybrid types, and sensitivities to various enzymes (see Fig. 15.2.1 for key). Brackets (top) show the structures designated as high-mannose and hybrid chains. The boxes indicate ER or Golgi localization.The pathway begins with the precursor oligosaccharide (see Figure 15.2.1). Each successive numbered step in circles represents a glycosidase or glycosyl transferase that generates a new sugar chain with different sensitivities to the various endoglycosidases or PNGase F. (**1**) precursor oligosaccharide is trimmed by α-glucosidases I and II, removing three Glc. (**2**) ER mannosidase removes one Man. (**3**) α-Mannosidase I in Golgi complex removes two Man to make $Man_6GlcNAc_2$, with a single remaining α1-2Man. (**4**) The final α1-2Man is removed by a Golgi complex α-mannosidase I. (**5**) α-Mannosidase III removes the α1-3 and α1-6Man units to make $Man_3GlcNAc_2$. (**6**) GlcNAc transferase I adds GlcNAc to either $Man_5GlcNAc_2$ or $Man_3GlcNAc_2$. (**7**) α-Mannosidase II removes the α1-3 and α1-6Man units to make $GlcNAc_1Man_3GlcNAc_2$. Sensitivity to various enzymes (bottom) changes when moving from left to right, but remains the same within vertical columns. *NOTE:* This continued maturation to form complex chains is shown in Figure 15.2.3. Additionally, these figures are not comprehensive; many glycosylation steps have not been included, but they do not affect the sensitivities to the enzymes listed.

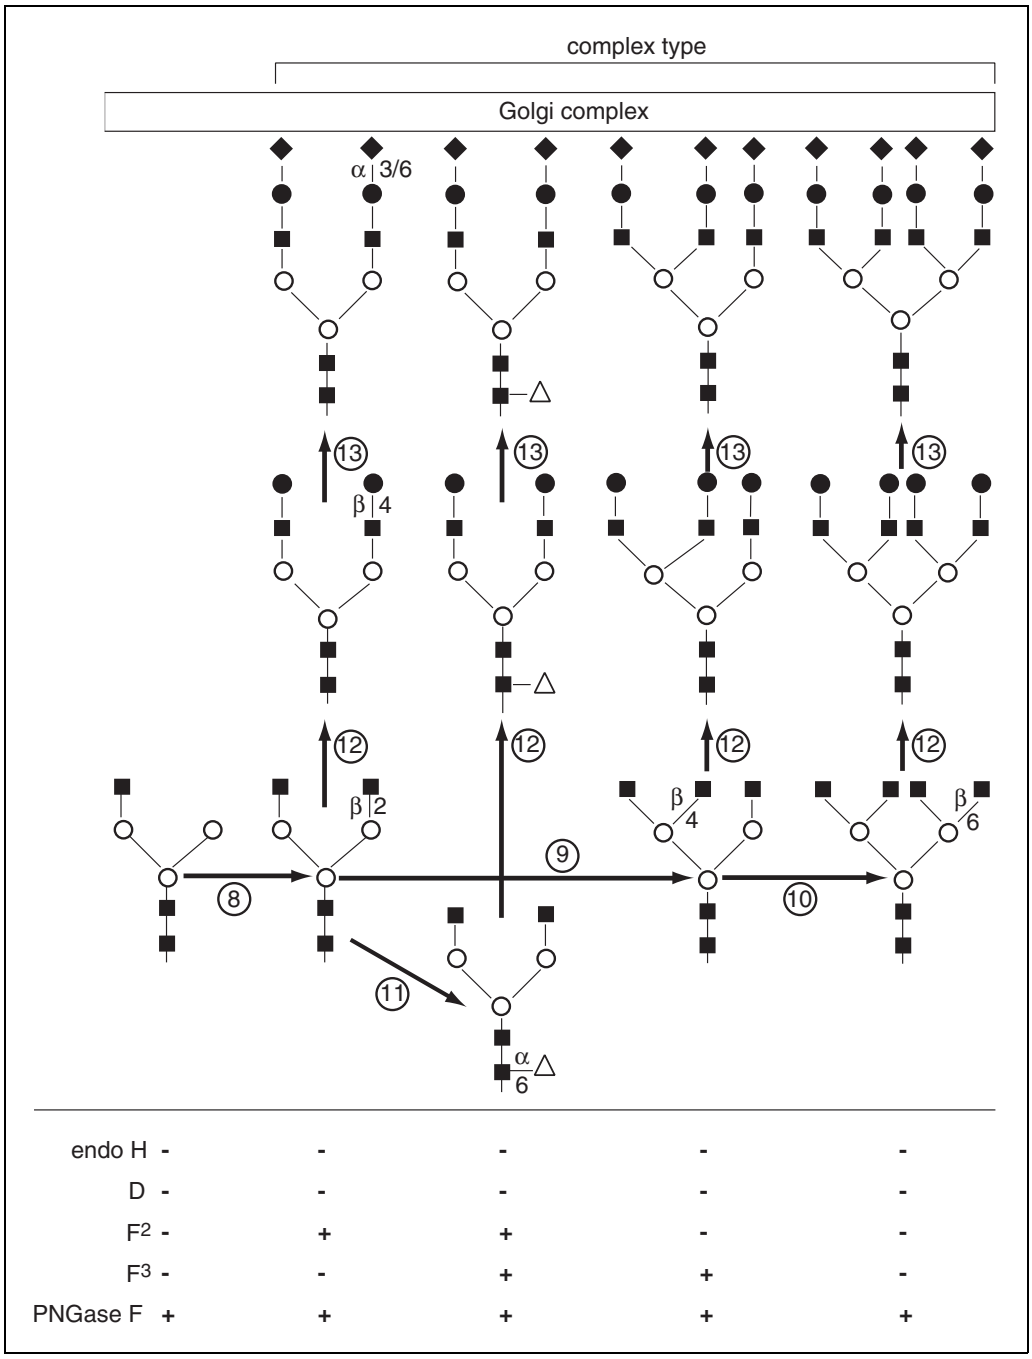

Figure 15.2.3 N-linked oligosaccharide maturation pathway for complex types, and sensitivities to various enzymes (see Fig. 15.2.1 for key; see Fig. 15.2.2 for additional details). (**8**) GlcNAc transferase II adds a second GlcNAc to initiate a biantennary chain. (**9**) GlcNAc transferase IV adds a third GlcNAc to initiate a triantennary chain. (**10**) GlcNAc transferase V adds a fourth GlcNAc to initiate a tetraantennary chain. (**11**) Fucosyltransferase adds α1-6Fuc to the core region of complex chains. (**12**) β1-4Gal is added to available GlcNAc residues of hybrid and complex chains. (**13**) α2-3 or α2-6Sia is added to Gal residues of hybrid and complex chains.

$GlcNAc_1Man_5GlcNAc_2$ structure is the *required* substrate for α-mannosidase II, which removes the two terminal Man units from the upper branch of the chain (i.e., the α1-3Man and α1-6 Man units; Fig. 15.2.2, step 7). This enzyme only works after the addition of the first GlcNAc.

The other fate for the $Man_5GlcNAc_2$ chain is to act as a substrate for the newly identified α-mannosidase III (Chui et al., 1997), which removes the same two Man units as α-mannosidase II, but does not require the prior addition of the first GlcNAc (Fig. 15.2.2, step 5). α-Mannosidases II and III show partial overlap in the Golgi complex, but α-mannosidase III may occur preferentially in an earlier compartment. The $Man_3GlcNAc_2$ product of α-mannosidase III is also a substrate for GlcNAc transferase I. Thus, the same product, $GlcNAc_1Man_3GlcNAc_2$ can be formed in two ways: first, by the sequential action of α-mannosidase III and GlcNAc transferase I (Fig. 15.2.2, steps 5 and 6) or, second, by GlcNAc transferase I and α-mannosidase II (Fig. 15.2.2, steps 6 and 7). Sensitivity to specific enzyme digestions (endo H and endo D) can distinguish which route was taken (Fig. 15.2.2).

GlcNAc transferase II now adds a second GlcNAc to the α1-6-linked Man (Fig. 15.2.3, step 8). This molecule can also have several fates. First, fucose (Fuc) can be added to GlcNAc residue linked to the Asn of the protein (Fig. 15.2.3, step 11). Second, one to three more GlcNAc residues can be added to the core mannose residues to initiate tri- and tetraantennary chains (Fig. 15.2.3, steps 9 and 10), and even pentaantennary chains (not shown). GlcNAc additions are considered to occur in the medial Golgi regions. Each GlcNAc-based branch can be individually modified, but they are usually extended by one Gal (Fig. 15.2.3, step 12) and terminated by a Sia (Fig. 15.2.3, step 13). Both of these sugars are usually thought to be added in *trans*-Golgi cisternae or in the *trans*-Golgi network (TGN). Sometimes selected antennae are also fucosylated in the TGN. One or more terminal Gal residues can be extended by variable-length polylactosamines (Galβ4-GlcNAc repeats) capped by a Sia. GlcNAc and Gal can be sulfated as a late, perhaps even final, step of processing. These extensions/modifications are thought to occur in the late Golgi complex and TGN, but their order and compartmental segregation are not well understood. Other modifications of N-linked sugar chains are known, but there are fewer tools available to analyze their biosynthetic localization.

THE O-LINKED PATHWAY

For practical purposes, only a portion of the O-linked pathway—i.e., the addition of the first few sugars—will be presented. However, it is very important to remember that some of the same outer chain structures such as Sia, polylactosamines, and Fuc residues are common to both N- and O-linked oligosaccharides.

α-*N*-acetylgalactosamine (α-GalNAc; open square) is the lead-off sugar for the O-linked pathway (Fig. 15.2.4; also see Fig. 15.2.1 for symbols). It is added to Ser/Thr residues that occur in the proper configuration, generating a broad variety of acceptor sequences. These sequences often cluster as repeats within mucin-like domains. GalNAc is added in the earliest parts of the Golgi complex, not cotranslationally. GalNAc can be further extended by at least six different sugars. The most common is the addition of a β1-3Gal (Fig. 15.2.4, step 1), forming a disaccharide that is one of the few O-linked chains that can be diagnosed by enzymatic digestions. This disaccharide is often capped by a Sia (Fig. 15.2.4, step 2). Additional sugars such as Sia (Fig. 15.2.4, step 3) or GlcNAc followed by Gal (Fig. 15.2.4, steps 4 and 5) can be added. Structural analysis can be done by sequential exoglycosidase digestion, but given the complexity and heterogeneity of the sugar chains, such analysis is not a very useful indicator for tracking protein movement through the Golgi complex. Many O-linked chains have terminal Sia residues and, when

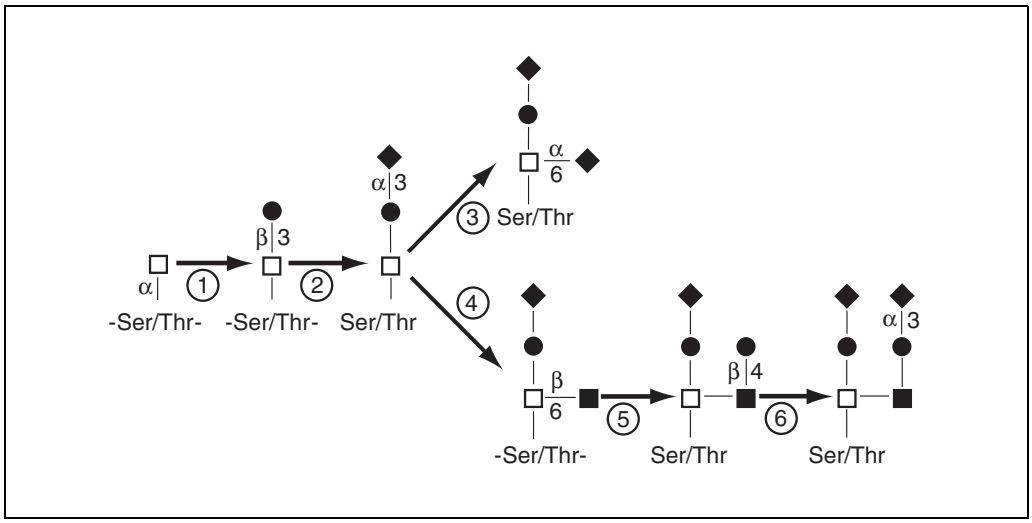

Figure 15.2.4 A small portion of the O-GalNAc pathway (see Fig. 15.2.1 for key). The first step of the O-linked pathway occurs in the early Golgi complex with the addition of α-GalNAc. There are at least six other sugars that can be added at this point in this complex pathway. Often β1-3Gal is added (**1**), quickly followed by α2-3Sia (**2**). The presence of these structures can be detected with a combination of O-glycosidase and sialidase. Additional sugars can be added as shown. α2-6Sia (**3**) or β1-6GlcNAc (**4**) followed by β1-4Gal (**5**) and α2-3Sia (**6**) on Gal. Each of these sugars must be removed before O-glycosidase can cleave the disaccharide.

tightly clustered on Ser/Thr residues, these chains promote proteolysis by O-sialoglycoprotease regardless of the structure of the underlying sugar chain.

Another type of O-linked glycosylation is the addition of glycosaminoglycan (GAG) chains to form proteoglycans. This occurs by a different pathway than the α-GalNAc linkage. Instead, the chains begin by addition of a β-Xylose (Xyl; open inverted triangle) residue to Ser and are then elongated by two Gal residues and a glucuronic acid (GlcA; half-filled diamond) residue. This core structure can be further elongated by the addition of GlcAβ1-3GalNAcβ disaccharides to form the backbone of chondroitin/dermatan sulfate chains, or by GlcAβ1-3GlcNAcα to form the backbone of heparan sulfate chains. Biosynthesis and movement of these proteins have also been followed through the Golgi complex. Initiation begins in late ER/early Golgi complex, and the core tetrasaccharide is probably finished within the medial Golgi, but the addition of chondroitin chains appears to be confined to the TGN. In addition to the well-known O-linked GAG chains, there is clear evidence for the existence of a class of N-linked GAG chains.

ENDOGLYCOSIDASE H DIGESTION

BASIC PROTOCOL 1

Endoglycosidase H (endo H) cleaves N-linked oligosaccharides between the two *N*-acetylglucosamine (GlcNAc) residues (Fig. 15.2.5) in the core region of the oligosaccharide chain (Fig. 15.2.1) on high-mannose and hybrid, but not complex, oligosaccharides. In this protocol, a fully denatured protein is digested with endo H to obtain complete release of sensitive oligosaccharides.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M sodium citrate, pH 5.5
1% (w/v) phenylmethylsulfonyl fluoride (PMSF) in isopropanol

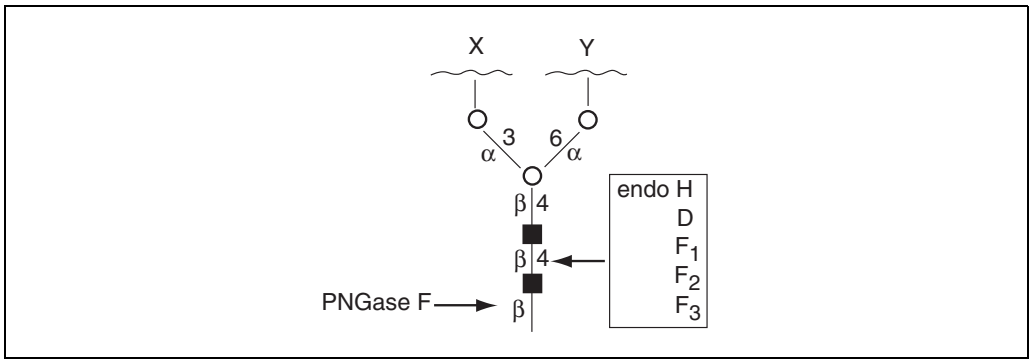

Figure 15.2.5 PNGase F and endoglycosidase-sensitive bonds in the core of N-linked oligosaccharides (see Fig. 15.2.1 for key). PNGase F is a glycoamidase that severs the bond between GlcNAc and Asn, liberating the entire sugar chain and converting Asn into Asp. The endoglycosidases (H, D, and Fs) cleave the bond between the two GlcNAc residues in the core region, leaving one GlcNAc still bound to the protein. The differential specificity of the endoglyosidases is based on the structure of the sugar chain in a fully denatured protein. Incomplete denaturation may not expose all sensitive linkages. X and Y are unspecified sugar residues.

0.5 U/ml endoglycosidase H (endo H; natural or recombinant; Sigma, Glyko, or Boehringer Mannheim)
10× SDS-PAGE sample buffer (*APPENDIX 2A*)
Water baths, 30° to 37°C and 90°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Add 20 to 30 µl of 0.1 M 2-ME/0.1% SDS to immunoprecipitate in a microcentrifuge tube, mix well, and heat denature 3 to 5 min at 90°C.

   Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

   Protein solubilization in nonionic detergents such as Triton X-100 or Nonidet P-40 is not always sufficient to completely expose all susceptible cleavage sites. Only strong denaturation with SDS exposes all sites for maximum cleavage.

2. Cool and microcentrifuge for 1 sec at 1000 × *g* to collect condensed droplets in the bottom of the tube.

3. Place 10-µl aliquots of solubilized, denatured protein (supernatant) in each of two clean microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).

4. Add in the following order, mixing after each addition:

   6 µl 0.5 M sodium citrate, pH 5.5
   20 µl H_2O
   2 µl 1% PMSF (in isopropanol)
   1 µl 0.5 U/ml endo H (enzyme digest only; substitute with water in control).

   The PMSF prevents proteolysis. Nonionic detergent is not required to prevent inactivation of endo H as long as high-purity SDS is used.

   The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate overnight at 30°C to 37°C.

6. Immediately prior to electrophoresis, inactivate endo H by adding 4 µl of 10× SDS-PAGE sample buffer and heating 5 min at 90°C.

7. Analyze protein by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

   The presence of high mannose and/or hybrid N-linked oligsaccharide chains will be evidenced by increased mobility of the digested proteins on SDS-PAGE.

ENDOGLYCOSIDASE D DIGESTION

BASIC PROTOCOL 2

Like endo H, endo D also cleaves between the two GlcNAc residues in the core of the N-linked sugar chains (Fig. 15.2.5). However, its narrow substrate specificity makes it useful for detecting the transient appearance of just a few early processing intermediates. It requires that the 2 position of the α1-3-linked core Man be unsubstituted. This intermediate arises after processing by either α-mannosidase I or III, but prior to addition of the first GlcNAc or action of α-mannosidase II (see Fig. 15.2.2, steps 3 to 5). Cells with a defect in GlcNAc I transferase (e.g., Lec 1 CHO cells) do not add the first GlcNAc residue (Fig. 15.2.2, step 6), and N-linked oligosaccharides will remain sensitive to endo D because they cannot modify the α1-3Man residue.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M NaH_2PO_4, pH 6.5
10% (w/v) Triton X-100 (*APPENDIX 2A*) or Nonidet P-40 (NP-40)
0.5 U/ml endoglycosidase D (endo D; Boehringer Mannheim)
10× SDS-PAGE sample buffer (*APPENDIX 2A*)
Water baths, 37° and 90°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating for 3 to 5 min at 90°C.

   Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge at 1000 × *g* for 1 sec to collect condensed droplets in the bottom of the tube.

3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).

4. Add in the following order, mixing after each addition:

   2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
   2 µl 0.5 M NaH_2PO_4, pH 6.5
   5 µl H_2O
   1 µl 1 IU/ml endo D (enzyme digest only; substitute with water in control).

   The 20-fold excess of nonionic detergent is essential to prevent inactivation of endo D by SDS.

   The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because

they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 2 µl of 10× SDS-PAGE sample buffer and heating for 5 min at 90°C to 95°C.
7. Analyze protein by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

Endo D sensitivity is detected by increased electrophoretic mobility of the digested proteins on SDS-PAGE.

BASIC PROTOCOL 3

ENDOGLYCOSIDASE F_2 DIGESTION

Endo F_2, like endo H and endo D, cleaves between the two GlcNAc residues in the chitobiose core (Fig. 15.2.5). It preferentially releases biantennary complex-type oligosaccharide chains from glycoproteins, but does not cleave tri- or tetraantennary chains.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M sodium acetate, pH 4.5
10% (w/v) Triton X-100 (*APPENDIX 2A*) or Nonidet P-40 (NP-40)
0.1 M 1,10-phenanthroline in methanol
200 mU/ml endoglycosidase F_2 (endo F_2; Glyko)
4× SDS-PAGE sample buffer (*APPENDIX 2A*)
Water baths, 30° to 37°C and 90°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating for 3 to 5 min at 90°C.

Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge at 1000 × *g* for 1 sec to collect condensed droplets in the bottom of the tube.
3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

   15 µl 0.5 M sodium acetate, pH 4.5
   3 µl 0.1 M 1,10-phenanthroline in methanol
   2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
   1 µl 200 mU/ml endo F_2 (enzyme digest only; substitute 0.5 M sodium acetate in control).

A 10- to 20-fold excess of nonionic detergent is required to stabilize the enzyme.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate the mixture at 30°C to 37°C overnight.

   Some inactivation of the enzyme occurs at 37°C, even with nonionic detergent present; however, if the enzyme is present in sufficient excess, incubation can generally be carried out successfully at 37°C.

6. Immediately before electrophoresis, inactivate by adding 8 µl of 4× SDS-PAGE sample buffer and heating for 5 min at 90°C to 95°C.

7. Analyze the protein by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

   Sensitivity to endo F_2 is detected by increased electrophoretic mobility on SDS-PAGE.

ENDOGLYCOSIDASE F_3 DIGESTION

BASIC PROTOCOL 4

Endoglycosidase F_3 (endo F_3) is another endoglycosidase with a narrow substrate range and, therefore, high specificity: it cleaves triantennary chains, but not high-mannose, hybrid, nonfucosylated biantennary or tetraantennary chains. A core-fucosylated biantennary chain is the only other demonstrated substrate. When both endo F_3 and endo F_2 digestions are done in parallel on a sample, it can provide evidence for chain branching and core fucosylation. The approach is essentially the same as for the other endoglycosidases.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M sodium acetate, pH 4.5
10% (w/v) Triton X-100 (*APPENDIX 2A*) or NP-40
0.1 U/ml endoglycosidase F_3 (endo F_3; Glyko)
10× SDS-PAGE sample buffer (*APPENDIX 2A*)
Water baths, 37° and 90°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS and heat denature 3 to 5 min at 90°C.

   Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge for 1 sec at 1000 × *g* to collect condensed droplets at the bottom of the tube.

3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).

4. Add in the following order, mixing after each addition:

   2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
   4 µl 0.5 M sodium acetate, pH 4.5
   5 µl H_2O
   1 µl 0.1 U/ml endo F_3 (enzyme digest only; substitute with water in control).

   The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 2 µl of 10× SDS-PAGE sample buffer and heating for 5 min at 90°C to 95°C.
7. Analyze by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

Sensitivity to endo F_3 is detected by increased mobility on SDS-PAGE.

BASIC PROTOCOL 5

PEPTIDE: N-GLYCOSIDASE F DIGESTION

PNGase F is a glycoamidase that cleaves the bond between the Asp residue of the protein and the GlcNAc residue that joins the carbohydrate to the protein (Fig. 15.2.5). Because it liberates nearly all known N-linked oligosaccharides from glycoproteins, it is the preferred enzyme for complete removal of N-linked chains. It is the only enzyme that releases tetra- and pentaantennary chains. The glycoprotein sample must be denatured and digested with PNGase F to remove N-linked oligosaccharides completely.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M Tris·Cl, pH 8.6 determined at 37°C (*APPENDIX 2A*)
10% (w/v) Triton X-100 (*APPENDIX 2A*) or Nonidet P-40 (NP-40)
200 to 250 mU/ml peptide:N-glycosidase F (PNGase F; Sigma or Glyko)
10× SDS sample buffer (*APPENDIX 2A*)
Water baths, 30° to 37°C and 90°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 90°C.

   Use the larger amount of reagent ≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge for 1 sec at 1000 × *g* to collect condensed droplets in the bottom of the tube.
3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

   3 µl 0.5 M Tris·Cl, pH 8.6
   5 µl H_2O
   2 µl 10% NP-40 or Triton X-100
   5 µl 200 to 250 mU/ml PNGase F (enzyme digest only; substitute with 0.5 M Tris·Cl in control).

   Sodium phosphate or HEPES buffer, pH 7.0, can be used instead of Tris·Cl. Avoid potassium buffers because these may cause precipitation of a potassium SDS salt. Use of a nonionic detergent is essential, because SDS inactivates PNGase F. A 10-fold weight excess of any of the above nonionic detergents over the amount of SDS will stabilize the enzyme.

   The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate overnight at 30°C to 37°C.

6. Immediately prior to electrophoresis, inactivate the enzyme by adding 2.5 µl of 10× SDS-PAGE sample buffer and heating 3 to 5 min at 90°C.

7. Analyze the protein by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

   The presence of N-linked oligosaccharide chains will be evidenced by increased electrophoretic mobility on SDS-PAGE.

ESTIMATING THE NUMBER OF N-LINKED OLIGOSACCHARIDE CHAINS ON A GLYCOPROTEIN

SUPPORT PROTOCOL

One widely used application of endo H or PNGase F digestion is estimation of the number of N-linked oligosaccharide chains on a given glycoprotein. This is done by creating a ladder of partially digested molecules that each differ by only one N-linked sugar chain. The number of separate bands in a one-dimensional polyacrylamide gel (less one for the totally deglycosylated protein) provides an estimate of the number of N-linked chains. The conditions used to generate partially deglycosylated protein must be determined for each protein studied, because the sensitivity of each chain may be different, even when all of them are completely exposed by denaturation. For this protocol, either the incubation time or the amount of enzyme can be varied to determine the best conditions to produce a ladder of partial digests. Usually five or six points are enough to provide a reasonable estimate (Fig. 15.2.6). Of course, it is important to use enough enzyme to obtain complete deglycosylation. This is best done by monitoring the effects of endo H or PNGase F on newly synthesized [^{35}S]Met pulse-labeled protein just after synthesis, but before any N-linked oligosaccharide processing has occurred. Pulse labeling of protein for 10 min with [^{35}S]Met followed by digestion is the best way to be sure that all chains are removed.

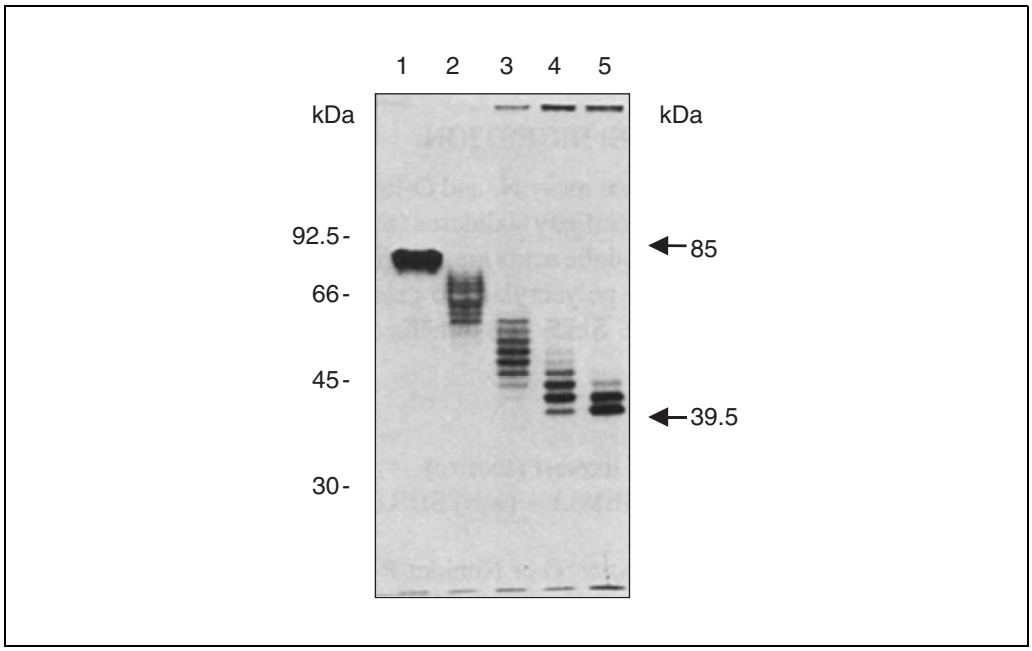

Figure 15.2.6 Data from the estimation of the number of glycosylation sites on lysosome-associated membrane protein 1 (LAMP-1; Viitala et al., 1988). LAMP-1 contains eighteen potential N-linked sites. Graded digestion with increasing amounts of PNGase F was used to generate this ladder of glycoforms. Each band contains at least one less N-linked chain than the band above it. An average N-linked carbohydrate chain has an apparent mass of ~1.5 to 3 kDa. Lysosomal membrane glycoprotein was immunoprecipitated from [^{35}S]Met-labeled cells and the sample was digested with PNGase F for 0 min (lane 1), 5 min (lane 2), 20 min (lane 3), 45 min (lane 4), and 24 hr (lane 5). Figure courtesy of Dr. Minoru Fukuda.

1. Add 0.1 M 2-ME/0.1% SDS solution to the total volume of immunoprecipitated protein required and heat denature by incubating 3 to 5 min at 90°C.

   Each digestion reaction requires 20 µl of immunoprecipitate. Thus, 120 to 140 µl is sufficient for one control plus five or six digests.

2. Cool and centrifuge for 1 sec at 1000 × *g* to collect condensed droplets at the bottom of the tube.

3. Aliquot 10 µl supernatant to the number of microcentrifuge tubes required to cover the concentration range (e.g., 0.01 to 1 mU/ml PNGase F) or incubation times (e.g., 5 to 60 min) plus one for an undigested control.

4. Add remaining reagents as specified for endo H (see Basic Protocol 1, step 4) or PNGase F (see Basic Protocol 5, step 4), adjusting the enzyme concentration as desired.

5. Incubate at 30°C for the desired length of time.

   High enzyme concentration (10 mU/ml) and prolonged incubation (16 hr) must be among the conditions included, in order to ensure that there is a data point for maximum deglycosylation.

   For varying enzyme concentrations, incubate for the same amount of time, but the duration of incubation should be shorter than what would give complete digestion because the goal is to obtain increasing extent of incomplete cleavage.

6. After the desired incubation time, inactivate enzyme by adding 0.1 volume of µl of 10× SDS-PAGE sample buffer and heating 5 min at 90° to 95°C.

7. Analyze the sample from each concentration/time point, including undigested sample, by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

   Most newly formed N-linked chains will have a molecular weight in the range of 1500 to 2200, and loss of one chain is sufficient to change the migration of a protein. This procedure has been used to count up to eighteen N-linked sites on one molecule. A sample result is shown in Figure 15.2.6.

BASIC PROTOCOL 6

SIALIDASE (NEURAMINIDASE) DIGESTION

Sialic acids are the terminal sugars on many N- and O-linked oligosaccharides. The great majority are released with broad-specificity sialidases (neuraminidases) such as that from *Arthrobacter ureafaciens*. Because sialic acids are charged, their loss usually changes the mobility on one-dimensional SDS polyacrylamide gels, but it will always change the mobility on a two-dimensional gel. Since one-dimensional analysis is easier, it can be tried first.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
10% (w/v) Triton X-100 (*APPENDIX 2A*) or Nonidet P-40 (NP-40)
0.5 M sodium acetate, pH 5.0(*APPENDIX 2A*)
1 IU/ml neuraminidase from *Arthrobacter ureafaciens* (Sigma or Glyko)
10× SDS sample buffer (*APPENDIX 2A*)
Water baths, 37° and 90°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), IEF/SDS-PAGE, or NEPHGE/SDS-PAGE (*APPENDIX 3*), and for autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 90°C.

   Denaturation is less important here, because the sialic acids are exposed at the ends of the sugar chains. In most instances, the denaturation step can probably be omitted and the digestion done while the protein is still bound to the beads.

2. Cool and microcentrifuge for 1 sec at 1000 × *g* to collect condensed droplets in the bottom of the tube.

3. Transfer 10-µl aliquots of supernatant to two clean microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).

4. Add in the following order, mixing after each addition:

   2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
   4 µl 0.5 M sodium acetate, pH 5.0
   5 µl H_2O
   1 µl 1 IU/ml neuraminidase (enzyme digest only; substitute with water for control).

   This amount of neuraminidase should be in great excess. Addition of nonionic detergent is not needed if the digestion is done while the protein was still bound to the beads.

   The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.

   This time can be shortened to 2 hr, if necessary, but longer incubations are better.

6. Immediately prior to electrophoresis, inactivate the enzyme by adding 2 µl of 10× SDS sample buffer and heating 3 to 5 min at 90°C.

   If the protein will be analyzed by IEF or NEPHGE, addition of sample buffer is replaced by lysis buffer used for these techniques.

7. Analyze the protein on the appropriate one-dimentional SDS-PAGE system (*UNIT 6.1*) or by a two-dimentional IEF/SDS-PAGE or NEPHGE/SDS-PAGE system (*APPENDIX 3*), and detect by autoradiography (*UNIT 6.3*).

   Removal of sialic acids usually results in a decrease in apparent molecular weight on one-dimentional gel analysis, or an increase in the isoelectric point of the protein analyzed by two-dimentional gel analysis.

ENDO-β-GALACTOSIDASE DIGESTION

BASIC PROTOCOL 7

The endo-β-galactosidase from *Bacillus fragilis* degrades polylactosamine chains $(Gal\beta1\text{-}4GlcNAc\beta1\text{-}3)_n$ found on both N- and O-linked oligosaccharides. The variable length of these repeating units usually causes the protein to run as a broad band or a smear on the gel. Although not all linkages are equally cleaved by this enzyme (see Fig. 15.2.7), sensitive proteins that often run as broad bands or smears on gels—e.g., lysosome-associated membrane protein 1 (LAMP-1)—produce both sharper bands and lower molecular weight species after digestion.

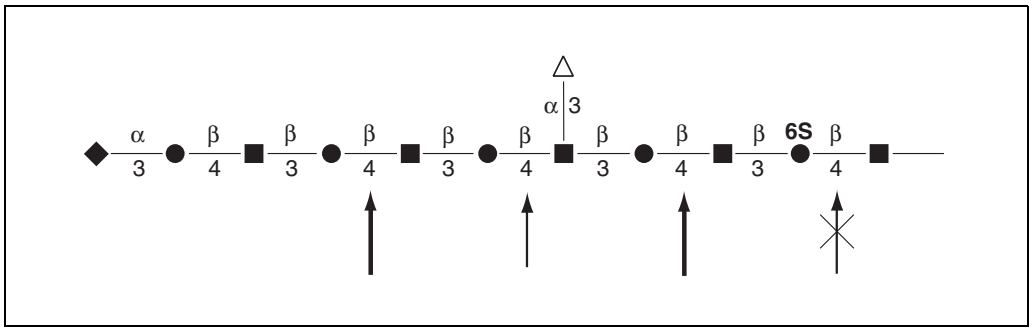

Figure 15.2.7 Endo-β-galactosidase-sensitive linkages in polylactosamines (see Fig. 15.2.1 for key). Linear, unsubstituted polylactosamine units (GlcNAcβ1-3Galβ1-4) are sensitive to digestion with endo-β-galactosidase, while substitutions—such as sulfate esters (S) or branches starting with GlcNAc (not shown)—completely block digestion. Substitution of neighboring GlcNAc with Fuc or sulfate esters slows the rate, but does not block cleavage. Sensitive sites are shown with bold arrows, slowly hydrolyzed sites with a lighter arrow, and resistant bonds are struck out. Various substitutions are possible, leading to broad bands on gels. This will create variable sensitivities, but even partial sensitivity should give a sharper, more defined band.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M sodium acetate buffer, pH 5.8
10% (w/v) Triton X-100 (*APPENDIX 2A*) or Nonidet P-40 (NP-40)
100 mU/ml endo-β-galactosidase (Boehringer Mannheim, Oxford GlycoSystems, Sigma)
10× SDS-PAGE sample buffer (*APPENDIX 2A*)
Water baths, 37° and 95°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 95°C.

   Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge 1 sec at 1000 × *g* to collect condensed droplets in the bottom of the tube.

3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).

4. Add in the following order, mixing after each addition:

   2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
   4 µl 0.5 M sodium acetate, pH 5.8
   5 µl H_2O
   1 µl 100 mU/ml endo-β-galactosidase (enzyme digest only; substitute with water in control).

   The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 3 µl of 10× SDS-PAGE sample buffer and heating for 5 min at 90°C.
7. Analyze protein by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

If the protein has polylactosamine chains, its mobility should increase after digestion.

ENDO-α-*N*-ACETYLGALACTOSAMINIDASE DIGESTION

BASIC PROTOCOL 8

This enzyme (also known as O-glycosidase or O-glycanase) has limited utility because it is highly specific for cleaving only one O-linked disaccharide, Galβ1-3GalNAcα-Ser/Thr. Adding any more sugars, including sialic acid, renders the molecule resistant to cleavage and requires removal of each residue before the enzyme will work. Prior sialidase digestion is sometimes used (see Basic Protocol 6), and this can be done while the protein is still bound to the immunoprecipitation beads.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.5 M sodium citrate phosphate buffer, pH 6.0, containing 500 µg/ml BSA (complete buffer supplied with enzyme)
10% (w/v) Triton X-100 (*APPENDIX 2A*) or Nonidet P-40 (NP-40)
300 mU/ml endo-α-*N*-acetylgalactosaminidase (5× concentrate from Glyko; use according to directions)
10× SDS-PAGE sample buffer (*APPENDIX 2A*)
Water bath, 37° and 95°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 95°C.

   Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge 1 sec at 1000 × *g* to collect condensed droplets in the bottom of the tube.
3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

   2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
   4 µl 0.5 M sodium citrate phosphate buffer, pH 6.0, with 500 µg/ml BSA
   3 µl H_2O
   1 µl 300 mU/ml endo-α-*N*-acetylgalactosidase (enzyme digest only; substitute with water in control).

   The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 2 µl of 10× SDS-PAGE sample buffer and heating for 5 min at 90°C.
7. Analyze protein by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

If the protein contains the disaccharide unit, the mobility of the protein should increase. Presence of only a single unit (mol. wt. ~400 Da) may be difficult to detect unless a high-resolution gel is used.

BASIC PROTOCOL 9

O-SIALOGLYCOPROTEASE DIGESTION

Digestion with O-sialoglycoprotease requires that the substrate have a tight cluster of sialylated O-linked oligosaccharides. Proteins with a single O-linked chain or a few widely spaced chains will not be cleaved. This property makes the enzyme a valuable diagnostic tool.

Materials

Immunoprecipitated protein of interest (*UNIT 7.2*)
0.1 M 2-mercaptoethanol (2-ME)/0.1% (w/v) SDS (ultrapure electrophoresis grade; prepare fresh)
0.4 M HEPES buffer, pH 7.4
10% (w/v) Triton X-100 (*APPENDIX 2A*) or Nonidet P-40 (NP-40)
2.4 mg/ml O-sialoglycoprotease (O-sialoglycoprotein endoglycoprotease; Accurate Chemical & Scientific; reconstituted according to directions)
10× SDS-PAGE sample buffer (*APPENDIX 2A*)
Water baths, 37° and 95°C

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Denature immunoprecipitated protein in 20 to 30 µl of 0.1 M 2-ME/0.1% SDS by heating 3 to 5 min at 95°C.

Use the larger amount of reagent (≥30 µl) for more complete recovery. This treatment may also release some (unlabeled) antibody molecules.

2. Cool and microcentrifuge 1 sec at 1000 × *g* to collect condensed droplets in the bottom of the tube.
3. Transfer 10-µl aliquots of supernatant into two microcentrifuge tubes, one for a control (no enzyme) and the other to digest (plus enzyme).
4. Add in the following order, mixing after each addition:

2 µl 10% Triton X-100 or NP-40 (20-fold excess over SDS)
4 µl 0.4 M HEPES buffer, pH 7.4
5 µl H_2O
2 µl 2.4 mg/ml O-*s*ialoglycoprotease (enzyme digest only; substitute with water in control).

O-Sialoglycoprotein endopeptidase is a partially purified enzyme, and the specific activity is relatively low. A quantity of 1.0 µg of this enzyme preparation will cleave 5 µg of sensitive substrate per hour at 37°C. Human glycophorin A can serve as a positive control.

The amount of water can be varied. Other solutions (or an increased amount of sample) may be substituted for water if needed, but potassium buffers should be avoided because they precipitate SDS as a potassium salt. The reaction volume can be scaled up proportionally if required, but in nearly all cases the enzyme will be in vast excess.

5. Incubate at 37°C overnight.
6. Immediately prior to electrophoresis, inactivate by adding 2.5 µl of 10× SDS-PAGE sample buffer and heating for 5 min at 90°C.
7. Analyze protein by one-dimensional SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

If the digestion was successful, the target protein will be undetectable or may be cleaved into small fragments.

COMMENTARY

Background Information

The results of digestion of a hypothetical protein with two N-linked carbohydrate chains as it moves through the ER and Golgi complex with various enzymes are shown in Figure 15.2.8. At 0 min, both *N*-linked chains are high-mannose type. They have lost their Glc residues and one Man residue in the ER. Both are sensitive to endo H and PNGase F digestion, yielding a protein with only two remaining GlcNAc residues in the case of endo H digestion, and no carbohydrate at all in the case of PNGase F digestion. These sugar chains are resistant to the other enzyme digestions.

At 45 min, the protein is in the medial Golgi complex and both sugar chains have been processed by Golgi α-mannosidase I. However, one of the chains (left) has been partially processed

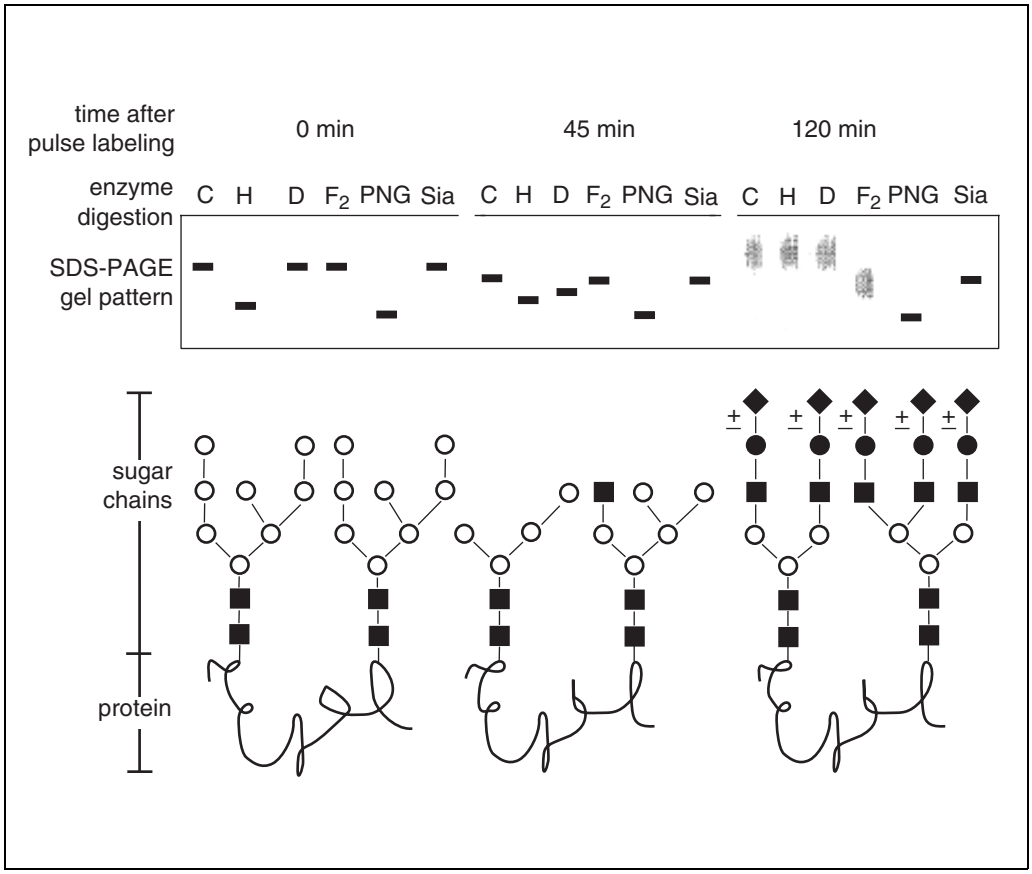

Figure 15.2.8 Schematic diagram showing results that could be obtained for a hypothetical protein with two N-linked glycosylation sites as it moves through the Golgi complex. Assume that the protein has been biosynthetically labeled with an amino acid precursor (such as [^{35}S]Met) for 10 min and chased in the absence of label for 45 min and 120 min. The protein is then precipitated with a specific antibody. At each time point, equal amounts of the sample are analyzed by flourography after one-dimensional SDS-PAGE, either without any digestion (control; C) or following digestion with endo H (H), endo D (D), endo F_2 (F_2), PNGase F (PNG), or sialidase (Sia). Oligosaccharide structures consistent with the banding patterns are shown below the schematic gel pattern.

by Golgi α-mannosidase III to an endo H–resistant/endo D–sensitive chain. The other chain (right) has received a GlcNAc residue from GlcNAc transferase I, but has not encountered Golgi α-mannosidase II. This chain is still endo H sensitive and endo D resistant. Both chains are sensitive to PNGase F, but neither is sensitive to endo F_2 or sialidase digestion.

At 120 min, both chains have fully matured to complex-type chains. One is a sialylated biantennary chain and the other is a sialylated triantennary chain. Note that each sialic acid is marked ±, indicating that not all molecules are fully sialylated, accounting for the broader bands. Neither sugar chain is sensitive to endo H or endo D digestion. The biantennary chain (left) is sensitive to endo F_2 cleavage, leaving one GlcNAc residue on the protein, but the triantennary chain (right) is not sensitive to this enzyme. Both chains are cleaved by PNGase F. All sialic acids are removed by sialidase to produce a sharp band, but the underlying sugar chains remain.

Endoglycosidase H

Endo H from *Streptomyces plicatus* cleaves the bond between the two GlcNAc residues in the core of N-linked oligosaccharides. One GlcNAc residue remains attached to the protein or peptide and the remainder of the chain is released as an intact unit (Tarentino et al., 1989). The oligosaccharide structures cleaved by endo H are shown schematically in Figure 15.2.5. Substrates for endo H include all high-mannose oligosaccharides and certain hybrid types, but not bi-, tri-, tetra- or pentaantennary (complex) chains. Endo H also cleaves oligosaccharides that have a1-6 fucose residues bound to the reducing (protein to carbohydrate linkage) GlcNAc residue (Tarentino et al., 1989).

Endo H sensitivity is the most common way to trace the movement of newly synthesized glycoproteins from the endoplasmic reticulum (ER) into the Golgi complex. Proteins remain sensitive to endo H while they are in the ER and in early regions of the Golgi complex; they become endo H–resistant after they are processed by enzymes located in the medial Golgi complex. Endo H cleaves the N-linked oligosaccharides from proteins as long as they have not lost the α1-3Man residue cleaved by Golgi mannosidase II or mannosidase III (Fig. 15.2.2). After removal of that mannose, the oligosaccharide becomes endo H resistant. Endo H is the best enzyme for identifying high-mannose and hybrid chains and their general transition toward complex chains.

Using endo H alone gives an incomplete map of subcellular trafficking. The resolution of this picture can be enhanced by combining it with endo D digestions. In general, N-linked chains become endo H resistant at about the same time they become transiently sensitive to endo D. However, the discovery of the alternative pathway for complex *N*-glycan processing using α-mannosidase III now gives a different perspective. Both α-mannosidase II and III are expressed in most mouse tissues except for hematopoietic cells, which seem to have only α-mannosidase II. So it is conceivable that some proteins, and even different N-linked chains on a single protein, can be processed by α-mannosidase II and others by α-mannosidase III, yielding complex digestion patterns and kinetics of endo H and endo D sensitivity.

Endoglycosidase D

The narrow substrate specificity of endo D makes it useful for detecting a very restricted set of processing intermediates, particularly for distinguishing α-mannosidase II from α-mannosidase III processing. When the results of endo D digestion are combined with the results of an endo H digestion of the same sample, it can help determine which of the two alternate processing pathways is being used. The key requirement for endo D cleavage is an unsubstituted 2 position on the α1-3Man that forms the trimannosyl core (Fig. 15.2.1). This window of endo D sensitivity occurs only *after* removal of the α1-2Man residue by α-mannosidase I and *before* the addition of a GlcNAc residue to this same position by GlcNAc transferase I (Beckers et al., 1987; Davidson and Balch, 1993). The immediate precursor of both pathways is $Man_6GlcNAc_2$, which is endo D resistant/endo H sensitive. The better-known α-mannosidase II pathway involves the removal of the last α1-2Man residue by α-mannosidase I (making the oligosaccharide endo D sensitive/endo H sensitive), and then the addition of GlcNAc via GlcNAc transferase I (making it endo D resistant/endo H sensitive). This product, and only this one, is the substrate for α-mannosidase II, which removes two of the remaining five Man residues, specifically the α1-3Man and α1-6Man that form the upper branch. Once this occurs, this endo D–resistant molecule also becomes endo H resistant. This structure is also a substrate for GlcNAc transferase II on the way to forming a biantennary chain.

The second pathway involves α-mannosidase III, which was identified as a functionally

important enzyme in nearly all tissues when the α-mannosidase II pathway was ablated in mice (Chui et al., 1997). After α-mannosidase I removes the final α1-2Man from $Man_6GlcNAc_2$ to generate $Man_5GlcNAc_2$, α-mannosidase III cleaves the same two Man residues as α-mannosidase II; however, α-mannosidase III cleavage does not require addition of the first GlcNAc that α-mannosidase II requires. α-Mannosidase III creates the endo D–sensitive/endo H–resistant trimannosyl core. This sugar chain serves as an acceptor for GlcNAc transferase I to form an endo D–resistant/endo H–resistant molecule that can be modified by GlcNAc transferase II, and then on to biantennary chains. As summarized in Figure 15.2.2, using the two endoglycosidases together will distinguish whether the oligosaccharide was processed by α-mannosidase II or α-mannosidase III. This may be important since there is evidence that distribution of the two enzymes in the Golgi complex is different with α-mannosidase III in an earlier compartment. It is important to point out that all chains of even a single protein are not necessarily processed using all the same enzymes.

Mutant cell line CHO Lec1 lacks GlcNAc transferase I activity and cannot synthesize either complex or hybrid chains. These cells can be used to measure the kinetics of acquiring endo D sensitivity (Beckers et al., 1987). This cell line can be obtained through ATCC (CRL-1735) . The chains become permanently endo D sensitive, because they lack GlcNAc transferase I and cannot be converted back to an endo D–resistant form. These chains will also remain endo H sensitive, because α-mannosidase II requires GlcNAc transferase I. However, if any chains are processed by α-mannosidase III, they would be become endo H resistant. Again, the combination of endo D and endo H digestions can reveal which pathway was used.

CHO Lec1 cells are also useful for tracking the movement of a protein from the ER into the earliest Golgi compartment where α-mannosidase I is located. Acquisition of endo D sensitivity requires the action of this enzyme. The advantage of using Lec1 cells is that the proteins remain permanently endo D sensitive and there is no risk of kinetically missing that small window of sensitivity before the sugar chain might become endo D resistant once again. Even if α-mannosidase III acts on the protein, it would still remain endo D sensitive, and no further processing would occur.

Endoglycosidase F and peptide N-glycosidase F

Elder and Alexander (1982; Alexander and Elder, 1989) made a landmark discovery when they identified an enzyme in culture filtrates of the bacterium *Flavobacterium meningosepticum* that cleaved N-linked oligosaccharides from glycoproteins. This preparation had a broad substrate specificity. The endoglycosidase activity in this preparation (endo F) was actually due to a set of enzymes, each with a more restricted substrate range. Like endo H, the endo F enzymes cleave the sugar chains between the two core GlcNAc residues (Fig. 15.2.5). Endo F was originally thought to be a single enzyme, but it is now known that each of the three enzymes has a distinct specificity (Plummer and Tarentino, 1991). The specificity of endo F_1 is very similar to that of endo H, while endo F_2 prefers biantennary chains, and endo F_3 will cleave core fucosylated biantennary and triantennary, but not tetraantennary, chains (Fig. 15.2.2 and Fig. 15.2.3). All are commercially available from Glyko.

Plummer et al. (1984) carefully analyzed *Flavobacterium* filtrates and found that the very broad substrate range was actually due to a glycoamidase activity rather than an endoglycosidase activity. The glycoamidase releases the entire carbohydrate chain from the protein by cleaving the Asp-GlcNAc bond (Fig. 15.2.5). The enzyme is called by various names, including peptide:N-glycosidase F (PNGase F), glycopeptidase F, and N-glycanase (previously available from Genzyme), but the proper name is peptide *N*-4(*N*-acetyl-β-glucosaminyl)asparagine amidase F. PNGase F has the broadest specificity, and it releases most of the N-linked oligosaccharide chains from proteins.

Endo F_2 and Endo F_3

Endo F_2 prefers biantennary chains over high-mannose chains by ~20 fold. Thus, endo H and PNGase F are better choices for broadly distinguishing high-mannose from complex chains as described above in the endo H protocol (Tarentino and Plummer, 1994).

Many proteins have core-fucosylated N-linked glycans, and the addition of fucose can be used as an additional trafficking marker. Endo F_3 will hydrolyze triantennary chains, but endo F_2 will not. Endo F_2 hydrolyzes biantennary chains; however, endo F_3 will also hydrolyze core-fucosylated biantennary chains only a bit more slowly than it does triantennary chains. Thus, if all the chains on a protein are

sensitive to endo F_2 (biantennary) and to endo F_3, this is evidence for the presence of a core fucose on those chains.

The enhancement of endo F_3 activity on biantennary chains with a core α1-6Fuc points out that some specificities are really a matter of relative rates of cleavage. If both endo F_2 (biantennary) and endo F_3 (triantennary and biantennary with core fucose) cleave the protein, they may be acting on different chains on the same molecule. If there is only a single chain, repeat the experiment under the same conditions using 10- to 20-fold dilutions of each enzyme. If both still cleave the chain about equally, it is evidence for core fucosylation of a biantennary chain.

PNGase F

PNGase F has the broadest specificity of all the enzymes that cleave N-linked oligosaccharides. It is indifferent to all extended structures on the chains, such as sulfate, phosphate, polylactosamines, polysialic acids, and even the occasional glycosaminoglycan chain. Most of the modifications in the $Man_3GlcNAc_2$ core region also make no difference in chain cleavage. The only oligosaccharide structural feature that confers PNGase F resistance is the presence of an α1-3Fuc on the GlcNAc bound to Asn (Tretter et al., 1991). This modification is commonly found in plants and in some insect glycoproteins, but it is rare in most mammalian cell lines. However, caution is warranted, as there is evidence that some mammalian cells do have the critical α1-3Fuc transferase, and some studies show that a majority of N-linked chains of bovine lung are actually PNGase F resistant! It is not known how common this resistance may be. It is thus important to document N-glycosylation with proteins still in the ER (see Support Protocol) before they might be processed to a PNGase F–resistant form.

Sialidase

Sialidases are also called neuraminidases because the most common form of sialic acid is *N*-acetyl neuraminic acid. The sialic acids are a family with over forty different members, but fortunately the very great majority of them can be removed from the oligosaccharides by the broad-spectrum sialidase from *Arthrobacter ureafaciens* (AUS). It can even digest polysialic acids, a rare modification found on only a few proteins such as neuronal cell adhesion molecule (NCAM). Sialidases with selected specificities from other sources are available but would not usually be needed. AUS has an optimum pH of 5.0, with ~30% of maximum activity at pH 7.

Because sialic acids are charged, they affect gel mobility of proteins more than would be expected from their nominal molecular weight. The magnitude of the gel shift depends on the number of residues. It is difficult to estimate their number by sialidase digestion, but the mobility change is usually sufficient if there are several sialic acid residues. On the other hand, if a protein has only one sialic acid, its presence could be missed using standard one-dimensional SDS-PAGE. To be certain of the effects of sialidase, the sample can be analyzed by a two-dimensional system, using IEF or NEPHGE in the first dimension. The loss of even a single sialic acid will be evident because it changes the isoelectric point.

AUS will remove sialic acids from both N- and O-linked chains, so the type of chain carrying them must be determined independently using PNGase F or possibly O-glycosidase in combination with sialidase. A protein will generally be partially or completely resistant to O-glycosidase because the required disaccharide, Galβ1-3GalNAc, is usually extended and often sialylated. Until the sialic acid is removed, it will be resistant.

The presence of sialic acid (sialidase sensitivity) is often used as an indication of the transport of a protein into the *trans*-Golgi network (TGN). This may be true in general, but it is important to remember that the distribution of Golgi enzymes is cell type dependent. For instance, α-mannosidases I and II, which are typically considered *cis*/medial Golgi enzymes, are strongly expressed on the brush border of enterocytes—hardly a Golgi compartment. There are other similar examples of various distributions of sialyl transferase. Moreover, there are different sialyl transferases and each may have its own unique distribution. Although one should be cautious, it is probably safe to place sialyl transferase in the late Golgi compartment rather than an early one.

Endo-α-N-acetylgalactosaminidase

This enzyme from *Dipplococcus pneumoniae* also goes by various names, including O-glycosidase and O-Glycanase. The last name is a trade name from Genzyme, which no longer sells enzymes; the enzyme is now available from Glyko. This enzyme has a narrow substrate range and cleaves only Galβ1-3GalNAcα-Ser/Thr. These are only the first two sugars added in the diverse O-linked pathway that can produce glycans with a dozen or more

sugar units. A portion of the pathway is shown in Figure 15.2.4. Fortunately, many, but far from all, O-linked chains have the simple trisaccharide structure and would be sensitive to cleavage after removing the Sia. Thus, sequential individual digestions or mixed digestions can be used. As both Gal and GalNAc (and probably Sia) are added in the early Golgi complex, sensitivity to the enzyme shows that the protein carries O-linked chains, but matching enzyme sensitivity and a Golgi compartment to further chain extension is difficult. Combining a battery of exoglycosidases (sialidase, α-fucosidase, α-*N*-acetylgalactosaminidase, and β-hexosaminidase) with endo-α-*N*-acetylgalactosaminidase will probably remove most O-linked sugar chains, except sulfated ones. The bottom line is that it is easy to use the enzyme in combination with sialidase to show that a protein has simple O-linked chains, but it is difficult to conclude much more concerning either the structure of the sugar chain or intracellular trafficking.

Endo-β-galactosidase

Bacterioides fragilis endo-β-galactosidase is one of several enzymes that specifically degrade polylactosamines by cleaving linear chains of GlcNAcβ1-3Galβ1-4 repeats at the Galβ1-4 linkage. Any substitution on the galactose itself blocks cleavage; however, modifications of the neighboring sugars can slow hydrolysis (Fig. 15.2.7). For instance, fucosylation and/or sulfation of nearby GlcNAc slows cleavage, but chain branching or sulfation at Gal block it. Even with these potential complexities, digestion with endo-β-galactosidase will sharpen a broad band even if it does not cleave every linkage. The repeating GlcNAcβ1-3Galβ1-4 units can be found on both N- and O-linked chains, so sensitivity to PNGase F digestion can potentially distinguish the location. Lysosome-associated membrane protein 1 (LAMP-1) has polylactosamine repeats on N-linked chains. Remember that glycosylation is not template driven, so oligosaccharides often exist as a continuum of different structures on individual proteins. For example, heavily sulfated polylactosamine repeats are also known as keratan sulfate and are degraded by keratanases.

O-Sialoglycoprotease

O-Sialoglycoprotease (also called O-glycoprotease or O-sialoglycoprotein endopeptidase; Mellors and Lo, 1995) is a neutral metalloprotease produced by *Pasteurella haemolytica*. This enzyme requires clusters of sialylated oligosaccharides on Ser or Thr residues (Norgard et al., 1993). Having a single sialylated O-linked sugar chain on a protein will not lead to degradation, nor will having a nonsialylated sugar chain. Therefore, this enzyme can be used in a typical pulse-chase experiment to indicate whether there are tightly grouped O-linked chains and when they are sialylated. Adding the initial α-GalNAc in the early Golgi complex is insufficient to cause proteolysis; sialylation is specifically required, and this may occur in a later Golgi compartment. Proteolysis can generate smaller fragments of a target protein that are still visible on gels, or the fragments may be so small that they are not even seen on the gels. It depends on the protein. Many leukocyte antigens such as the P-selectin ligand, or others such as CD43, CD44, CD45, and CD34 found on hematopoietic stem cells, are all substrates. As sialic acids are found on both N- and O-linked chains (in clusters and not), sequential digestions using PNGase F, sialidase, and O-sialoglycoprotease endopeptidase in different orders can reveal different kinds of sialylated glycans. If used as part of a pulse-chase protocol, they can reveal different kinetic subcompartments. Not all sialyl transferases are necessarily within the same Golgi compartment.

Critical Parameters

For nearly all of the digestions, complete denaturation of the protein can be important, as maximum deglycosylation occurs only when the sugar chains of glycoproteins are completely exposed. This is not important for sialidase digestions since sialic acids are exposed. Usually endo H digestions will work without full denaturation, but the unprocessed high-mannose chains remain unprocessed because they are often less exposed to the processing enzymes. This may or may not be true of the target protein, but it is better to be safe and denature it completely before digestion. Heating the immunoprecipitate with 0.1 M 2-mercaptoethanol/0.1% SDS is the best way to release the protein in a denatured state. Assuming that the immunoprecipitate contains <10 μg of protein, 30 μl of 0.1% SDS still provides a three-fold excess over the protein. Adding SDS presents another problem: free SDS may denature the digesting enzyme before it has a chance to finish its job. For most enzymes, be sure that the free SDS concentration is <0.01%. The best way to do this is to add a 10- to 20-fold weight excess of nonionic detergent with a low critical

micellar concentration (e.g., Triton X-100 or NP-40). These detergents will form mixed micelles with the free SDS and keep it from denaturing the added enzymes.

The amount of enzyme and the incubation time recommended in the protocols are in excess and should be sufficient to cleave any of the sensitive linkages. The incubation times can be shortened, if necessary, but it is better to keep the enzyme concentration as indicated.

Many of the digestions (e.g., sialidase, O-sialoglycoprotease) can be adapted for use on membrane preparations or on live cell surfaces by simply omitting the ionic and nonionic detergents and decreasing the incubation time. The problem is that some linkages may not be exposed and/or sensitive to the digestion. Thus, the usefulness of this approach needs to be determined on a case-by-case basis.

Endo H

Endo H has a broad pH optimum between 5.5 and 6.5, and phosphate or citrate/phosphate buffers can be used in place of citrate. Endo H is very stable to proteases, freezing and thawing, and prolonged incubations. No additives are required for storage of the enzyme. At concentrations below 5 to 10 µg/ml (200 to 400 mU/ml), endo H will bind to glass, so it should be stored in plastic vials (e.g., screw-cap microcentrifuge tubes).

Endo D

Endo D has a broad pH optimum of 4 to 6.5. One unit of enzyme activity will cleave 1 µmole of a $Man_5GlcNAc_3$ glycopeptide per min at 37°C. It is supplied from Boehringer Mannheim as a powder containing 0.1 U of activity. Adding 0.1 ml of water gives a 20 mM phosphate buffer, pH 7, 0.05% sodium azide, and 5 mg/ml BSA. It is stable for 3 months at 4°C or at −20°C, but freezing and thawing should be avoided. There may be a slight contamination (<0.2%) with β-*N*-acetylglucosaminidase activity.

Endo F

Commercial endo F preparations are mixtures of endo F_1, F_2, and F_3. Endo F preparations should not be used for routine deglycosylation or to draw conclusions about the structure of the released oligosaccharides unless the specificity is clearly defined.

Endo F_2

Endo F_2 has a broad pH optimum of 4 to 6 and retains >50% of its activity at pH 7. The enzyme is sensitive to SDS, but adding nonionic detergents prevents denaturation of the enzyme by SDS. Although the enzyme is stable at 4°C for months, it can be frozen in aliquots at −70°C as long as repeated freeze/thaw cycles are avoided. The 1,10-phenanthroline can be used to inhibit a trace of a zinc metalloprotease that may be present.

PNGase F

The pH optimum for PNGase F is 8.6, but 80% of full activity occurs between 7.5 to 9.5 with a range of buffers including phosphate, ammonium bicarbonate, Tris·Cl, and HEPES. Borate buffers inhibit the enzyme. Commercial PNGase F is endo F free and is stable for 6 months at 4°C, or indefinitely at −70°C. However, it should be stored in small aliquots and repeated freeze/thaw cycles should be avoided. PNGase F will bind to glass and plastic surfaces and should not be stored in dilute solutions (<0.1 mU/ml). All of the unit activities of commercial preparations are based on cleavage of dansylated glycopeptides; they are expressed in nmoles/min, which are actually mU, not true International Units (1 International Unit = 1 µmole/min). SDS inactivates PNGase F, but adding a ten-fold weight excess of nonionic detergents protects the enzyme (Tarentino et al., 1989; Tarentino and Plummer, 1994).

Sialidase

AUS is available as a lyophilyzed powder from typical commercial sources such as Sigma, Boehringer Mannheim, and Glyko. It should be reconstituted in water at 1 to 10 mU/µl according to manufacturer's directions. It is stable for 6 months at 4°C. Treatment with sialidase is also used in assays of protein transport to the cell surface.

Endo-α-N-acetylgalactosaminidase (O-glycosidase)

Endo-α-*N*-acetylgalactosaminidase has a pH optimum of 6.0 and has 50% activity at 5.5 to 7.0. The thiol inhibitor parachloromercuric benzoate (PCMB; 1 mM) inactivates the enzyme, and 1 mM EDTA inhibits it (63%), as do Mn^{2+} and Zn^{2+} (50%). Chloride also inhibits the enzyme, so HCl-containing buffers should be avoided. The enzyme will have full access to the sugar chains only after denaturating the protein with SDS, but the excess SDS needs to be removed by forming mixed micelles with nonionic detergents. The enzyme is stable at 4°C and at −20°C, but freeze/thaw cycles should be avoided.

Endo-ß-galactosidase

The enzyme is supplied by several commercial sources, including Glyko and Sigma. The enzyme is free of contaminating endo- and exoglycosidases. It has a pH optimum of 5.8 and should be stored at −20°C, but is stable for ≥2 months at 4°C. Glyko supplies the enzyme as a lyophilyzed powder with BSA for stability. EDTA, Ca^{2+}, Mn^{2+}, and Mg^{2+} do not affect stability or activity, but PCMB inactivates it.

O-Sialoglycoprotease

The partially purified enzyme is supplied by Accurate Chemical and Scientific as a lyophilyzed powder containing nonsubstrate bovine serum proteins and HEPES buffer. The enzyme should be reconstituted according to the manufacturer's instructions, divided into aliquots appropriate for a single use, and stored at −20°C. Freeze/thaw cycles inactivate the enzyme, and it is inhibited by EDTA or 1,10-phenanthroline. It is possible to check the activity with a positive control of glycophorin A, which is available through Sigma.

Troubleshooting

Most of the procedures should work as described, but there is a chance that the enzyme is inactive because of a variety of factors such as age, poor storage, or excess SDS. To check activity, it is worthwhile to run a positive control digestion using the same solutions including SDS and nonionic detergents as for the samples. Since the positive controls are simply glycoproteins that are visualized by Coomassie or silver staining, this requires running a separate gel for staining. This should not be required on a routine basis if the enzymes are used and stored as directed. The most likely culprit in failed digestions is using SDS solutions that are too old or too impure.

Anticipated Results

If the digestions are effective, the labeled band will usually show increased mobility on the gel. In rare instances, digestions can actually decrease mobility. The amount of change will depend on the contribution of that component to the overall mass of the protein. As mentioned before, a gel system that allows visualization of a 1-kDa change should be used. Proteins that are >100 kDa may cause problems for fine resolution. Here are a few numbers to keep in mind.

1. The smallest N-linked chain ($Man_3GlcNAc_2$) will have a mass of ~0.9 kDa.

2. Two sialic acids on a single N-linked biantennary chain will have a mass of ~0.6 kDa, but their loss may appear larger. If they occur on clustered O-linked chains (sialoglycoprotease sensitive), the apparent size difference will be even larger.

3. Most polylactosamines are three or more repeats, and therefore their mass would be ~1 kDa. The protein will probably run as a heterogeneous smear or broad band before digestion.

4. A single O-glycosidase-sensitive disaccharide (0.4 kDa) may be below detection limits.

Time Considerations

All digestions can be done overnight for convenience, but the amount of enzymes should be sufficient for complete digestion in less time. The gels are run the next day, but the time needed for the development of autoradiograms will depend on the strength of the signal. A low-abundance protein labeled for 10 to 30 min with [^{35}S]Met may give a weak signal and require long exposures (e.g., 2 weeks). Trafficking of abundant glycoproteins such as viral coat proteins require only short exposure times (e.g., a few hours).

Endocytosis: Biochemical Analyses

Cells internalize a large variety of macromolecules from the extracellular milieu (e.g., growth hormones, nutrients, viruses) by the process of endocytosis (Mellman, 1996; Mukherjee et al., 1997). In addition, endocytic membrane trafficking plays an important role in the constitutive and regulated targeting of proteins among cellular membrane compartments such as the plasma membrane, endosomes, and the *trans*-Golgi network (TGN). Thus, endosomal trafficking includes the internalization of membrane from the cell surface, intracellular traffic among membrane compartments, and the recycling of membrane from endosomes back to the cell surface. This unit describes biochemical methods for analyzing the kinetics of endocytic trafficking. One set of assays describes the use of radio-iodinated transferrin to analyze trafficking of the transferrin receptor. The other set describes the use of radio-iodinated antibody to analyze trafficking of any membrane protein that cycles through the plasma membrane.

The transferrin receptor is the most commonly used probe of endocytic trafficking (Dautry-Varsat et al., 1983; Klausner et al., 1983). Extracellular diferric transferrin binds to transferrin receptor on the cell surface (Fig. 15.3.1). This complex is rapidly internalized through clathrin-coated pits into endosomes. Iron is released from transferrin at the acidic lumenal pH of endosomes. The iron-free transferrin remains bound to the receptor because the pH of endocytic recycling compartments is mildly acidic. Iron-free transferrin is recycled back to the plasma membrane with transferrin receptor. At the neutral extracellular pH, iron-free transferrin is released from the receptor. The fact that transferrin remains bound to the receptor for the complete endocytic cycle makes transferrin an ideal ligand for studies of intracellular trafficking and recycling.

Basic Protocol 1 is a method for measuring the steady-state surface-to-internal distribution of the transferrin receptor, and Alternate Protocol 1 is a method for measuring the steady-state surface-to-internal distribution of other proteins that cycle through the plasma membrane. Support Protocol 1 describes how to load transferrin with iron, and Support Protocol 2 is a method for radio-iodinating transferrin. Basic Protocol 2 is a method for measuring the internalization rate of the transferrin receptor, Alternate Protocol 2 measures internalization of other proteins, and Alternate Protocol 3 measures internalization in cells grown in suspension. Basic Protocol 3 is a method for measuring the recycling rate of the transferrin receptor. Basic Protocol 4 is a method for measuring the recycling rate of a membrane protein using an antibody as a probe. Basic Protocol 5 is a method for measuring the proteolysis of internalized proteins. Basic Protocol 6 is a method for measuring fluid-phase uptake. Finally, two methods for inhibiting endocytosis by clathrin-coated pits are described in Support Protocol 3 and Support Protocol 4.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX ID*).

MEASURING THE STEADY-STATE SURFACE-TO-INTERNAL DISTRIBUTION OF THE TRANSFERRIN RECEPTOR

BASIC PROTOCOL 1

The steady-state distribution of a membrane protein between the surface and cell interior is dependent on its rate of internalization and its rate of recycling. This distribution is measured for the transferrin receptor by incubating cells with radio-iodinated transferrin and determining the amounts of transferrin on the cell surface and inside cells at steady state. There are two methods for measuring surface-bound label. In one method, transfer-

Current Protocols in Cell Biology (1999) 15.3.1-15.3.23

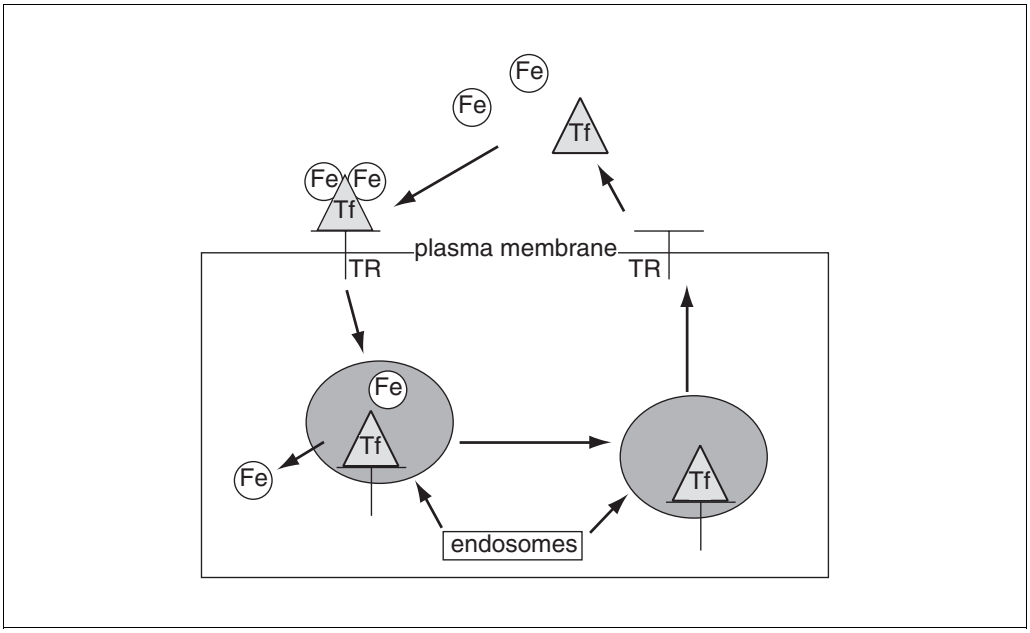

Figure 15.3.1 Transferrin and transferrin receptor cycle. At the near-neutral extracellular pH, diferric transferrin binds to the transferrin receptor with high affinity ($k_d \approx 10^{-9}$), whereas at neutral pH, iron-free transferrin has ~10-fold lower affinity for the receptor. The transferrin receptor–transferrin complex is concentrated in clathrin-coated pits and rapidly internalized into endosomes. At the mildly acidic pH of endosomes, Fe is released from transferrin. However, at this pH iron-free transferrin remains bound to the receptor. Because the endosomal recycling compartments are mildly acidic, the iron-free transferrin remains bound to the receptor until the complex is recycled back to the cell surface. When the iron-free transferrin is exposed to the near-neutral extracellular pH, it is released form the receptor. The unoccupied receptor can bind diferric transferrin and mediate another round of transferrin internalization. The iron-free transferrin binds two atoms of iron, and then binds the transferrin receptor. The transferrin receptor is constitutively cycled regardless of occupancy with ligand. For details see Dautry-Varsat et al. (1983). Tf, transferrin; TR, transferrin receptor.

rin released by an acidic pH wash is measured. In the second method, the amount of transferrin bound to cells at 4°C is measured. Measurement of surface transferrin receptor by incubating cells at 4°C usually gives more consistent results and is the preferred method. Since transferrin does not alter the trafficking of the transferrin receptor, either method can be used. If, however, ligand binding to its receptor changes trafficking of the receptor (e.g., induces internalization), then surface binding should be measured by collecting the acid wash and the two neutral pH washes (step 7).

Materials

Cells of interest
SF medium (see recipe)
^{125}I-labeled human diferric transferrin (~500 cpm/ng; see Support Protocol 2)
Unlabeled (nonradioactive) human diferric transferrin
Neutral pH buffer (see recipe), ice cold
pH 2.0 buffer (see recipe), ice cold
Solubilization solution: 1% (w/v) Triton X-100 in 0.1 N NaOH
10 mg/ml BSA

6-well tissue culture plates
γ counter and tubes

Prepare cells

1. Plate 1×10^5 cells/well in SF medium in two 6-well tissue culture plates 2 days before the experiment. Allow the cells to reach ~80% confluency ($\sim 5 \times 10^5$/well) on the day of the experiment.

   Bicarbonate-buffered medium is used if the experiment is performed in a CO_2 incubator. HEPES-buffered medium is used if the experiment is performed in air.

Measure intracellular transferrin

2. Wash one 6-well plate of cells with 2 ml/well SF medium.
3. Add 1 ml SF medium containing a saturating concentration (3 μg/ml) of ^{125}I-labeled transferrin to four wells (total radioactivity wells). Add 1 ml SF medium containing 3 μg/ml ^{125}I-labeled transferrin and a 200-fold excess of unlabeled diferric transferrin to the other two wells (nonspecific radioactivity wells).
4. Incubate at 37°C for a sufficient time for all transferrin receptors to be occupied with ^{125}I-labeled transferrin.

   This time is determined empirically (see Basic Protocol 4). For most cell lines, a 120-min incubation is sufficient.

5. Place plate on ice and wash six times with 2 ml/wash prechilled neutral pH buffer.

   Endocytosis is inhibited at 4°C. The neutral pH washes will not remove transferrin bound to the transferrin receptor.

   CAUTION: *Dispose of radioactive waste appropriately.*

6. Incubate cells with 1 ml prechilled pH 2.0 buffer for 5 min at 4°C.

   This incubation removes transferrin bound to the cell surface. Internal transferrin is not released from the cells.

7. Remove and discard the pH 2.0 buffer. Wash the cells twice with prechilled neutral pH buffer.
8. Add 1 ml solubilization solution to each well and transfer the solubilized cells to tubes suitable for γ counting. Rinse wells once with 1 ml water, and pool with the solubilization solution.
9. Determine the amount of ^{125}I-labeled transferrin per tube using a γ counter.

   These values are the amount of intracellular transferrin.

Measure cell-surface transferrin

10. Wash the second 6-well plate with SF medium. Discard wash and incubate in fresh SF medium at 37°C for the same time as in step 4.

    This incubation can be performed concurrently with the incubation in step 4.

11. Place cells on ice and wash three times with 2 ml/wash prechilled neutral pH buffer.
12. Add 1 ml of prechilled (4°C) neutral pH buffer containing a saturating concentration (3 μg/ml) of ^{125}I-labeled transferrin (3 μg/ml) and 1 mg/ml BSA to four wells (total radioactivity wells). Add 1 ml of the same solution containing a 200-fold excess of unlabeled transferrin to the other two wells (nonspecific radioactivity wells).
13. Incubate the cells at 4°C for 2 hr.

    Endocytosis is blocked at 4°C; therefore, the amount of transferrin bound at 4°C is a measure of the amount of receptor on the cell surface.

14. Place plate on ice and wash the cells six times with 2 ml/wash prechilled neutral pH buffer.

    CAUTION: *Dispose of radioactive waste appropriately.*

15. Solubilize cells and determine the amount of ^{125}I-labeled transferrin per tube as described in steps 8 and 9.

    These values are a measure of the amount of transferrin receptor on the cell surface at steady state.

Analyze data

16. Calculate the specific radioactivity of both intracellular and surface transferrin by subtracting the average of the two nonspecific radioactivity wells from the average of the four total radioactivity wells.

17. Present data as the surface-to-internal ratio or as the amount of transferrin on the surface as percent of the total.

    In CHO cells, the steady-state surface-to-internal ratio for the transferrin receptor is ~0.5 (~35% on the surface; Johnson et al., 1994).

    Another method for determining the surface-to-internal distribution of the transferrin receptor is to collect and count the pH 2.0 buffer and neutral buffer washes of steps 6 and 7. In this method, the surface-to-internal ratio for each well is determined after correcting for nonspecific radioactivity. However, the authors find that the procedure outlined in Basic Protocol 1 yields more reproducible results.

ALTERNATE PROTOCOL 1

MEASURING THE STEADY-STATE SURFACE-TO-INTERNAL DISTRIBUTION OF OTHER MEMBRANE PROTEINS

The surface-to-internal ratio of any membrane protein that constitutively cycles between intracellular compartments and the plasma membrane can be measured using Basic Protocol 1 and a radio-iodinated antibody to the extracellular domain of the protein. Iodinated Fab fragments should be used, because bivalent antibodies cause cross-linking and therefore may modify the protein's trafficking (Weissman et al., 1986). Fab fragments can be prepared using the ImmunoPure Fab preparation kit (Pierce) and iodinated using Support Protocol 2. An excess of unlabeled antibody is used to determine nonspecific binding.

The procedures are the same as described in Basic Protocol 1, except that ^{125}I-labeled Fab fragments (2 to 10 μCi/μg) are used in place of ^{125}I-labeled transferrin. Some antibodies are not efficiently stripped from the surface with a single incubation in pH 2.0 buffer. If this is the case, several rounds of alternating acid/neutral washes can be used to increase the stripping efficiency. Some antibodies are resistant to the acid stripping. In these cases, incubation with 1 mg/ml proteinase K or pronase at 4°C for 30 min (or more) can be used to release surface-bound antibody.

BASIC PROTOCOL 2

MEASURING THE KINETICS OF TRANSFERRIN INTERNALIZATION

Internalization of the transferrin receptor is measured by monitoring the internalization of ^{125}I-labeled transferrin. Cells are washed with an acidic pH buffer to distinguish internalized transferrin from transferrin bound to receptors on the cell surface. The initial transferrin receptor internalization rate constant is the slope of a plot of the ratio of internalized transferrin to surface transferrin versus time.

Materials

Cells of interest
SF medium (see recipe)
^{125}I-labeled human diferric transferrin (~500 cpm/ng; see Support Protocol 2)
Unlabeled (nonradioactive) human diferric transferrin
Neutral pH buffer (see recipe), ice cold
pH 2.0 buffer (see recipe), ice cold
Solubilization buffer: 1% (w/v) Triton X-100 in 0.1 N NaOH
10 mg/ml BSA

6-well tissue culture plates
γ counter and tubes

Prepare cells

1. Plate 1×10^5 cells/well in SF medium in 6-well tissue culture plates 2 days before the experiment. Allow the cells to reach ~80% confluency (~5×10^5/well) on the day of the experiment.

   Bicarbonate-buffered medium is used if the experiment is to be performed in a CO_2 incubator; HEPES-buffered medium is used if the experiment is to be performed in air.

   One 6-well plate is required for each time point and an additional plate is required to measure steady-state surface transferrin binding. Typically four time points are used, in which case a total of five 6-well plates are required.

Measure internalized transferrin

2. On the day of the experiment, wash the cells from plates for specific time points once with 2 ml SF medium and incubate in SF medium for 1 hr at 37°C.

   During this incubation, any cell-associated transferrin from the growth medium will be recycled and dissociated from the cells, ensuring that the receptors will be unoccupied at the beginning of the experiment.

3. Starting with a single 6-well plate, add 1 ml SF medium containing a saturating concentration (3 μg/ml) of ^{125}I-labeled transferrin to four wells (total radioactivity wells) and add 1 ml SF medium containing ^{125}I-labeled transferrin and a 200-fold excess of unlabeled transferrin to the other two wells (nonspecific radioactivity wells).

4. Incubate the plate for the desired time at 37°C.

   Incubation time points of <10 min are typically used (e.g., 2, 4, 6, and 8 min). Internalized transferrin is eventually returned to the cell surface; therefore, it is important to use incubations times in which little of the transferrin is recycled.

5. Remove the plate from the incubator, place on ice, and wash six times with 2 ml/wash prechilled neutral pH buffer.

   Endocytosis is inhibited at 4°C. The neutral pH washes will remove transferrin not specifically bound to the transferrin receptor.

   CAUTION: *Dispose of radioactive waste appropriately.*

6. Incubate the cells with 1 ml/well prechilled pH 2.0 buffer for 5 min at 4°C.

   This incubation removes transferrin bound to the cell surface. Internal transferrin is not released from the cells.

7. Remove and discard the pH 2.0 buffer. Wash the wells twice with prechilled (4°) neutral pH buffer.

8. Repeat steps 3 to 7 with the plates for the remaining time points (but not with the plate for steady-state surface binding). Treat each time point individually.

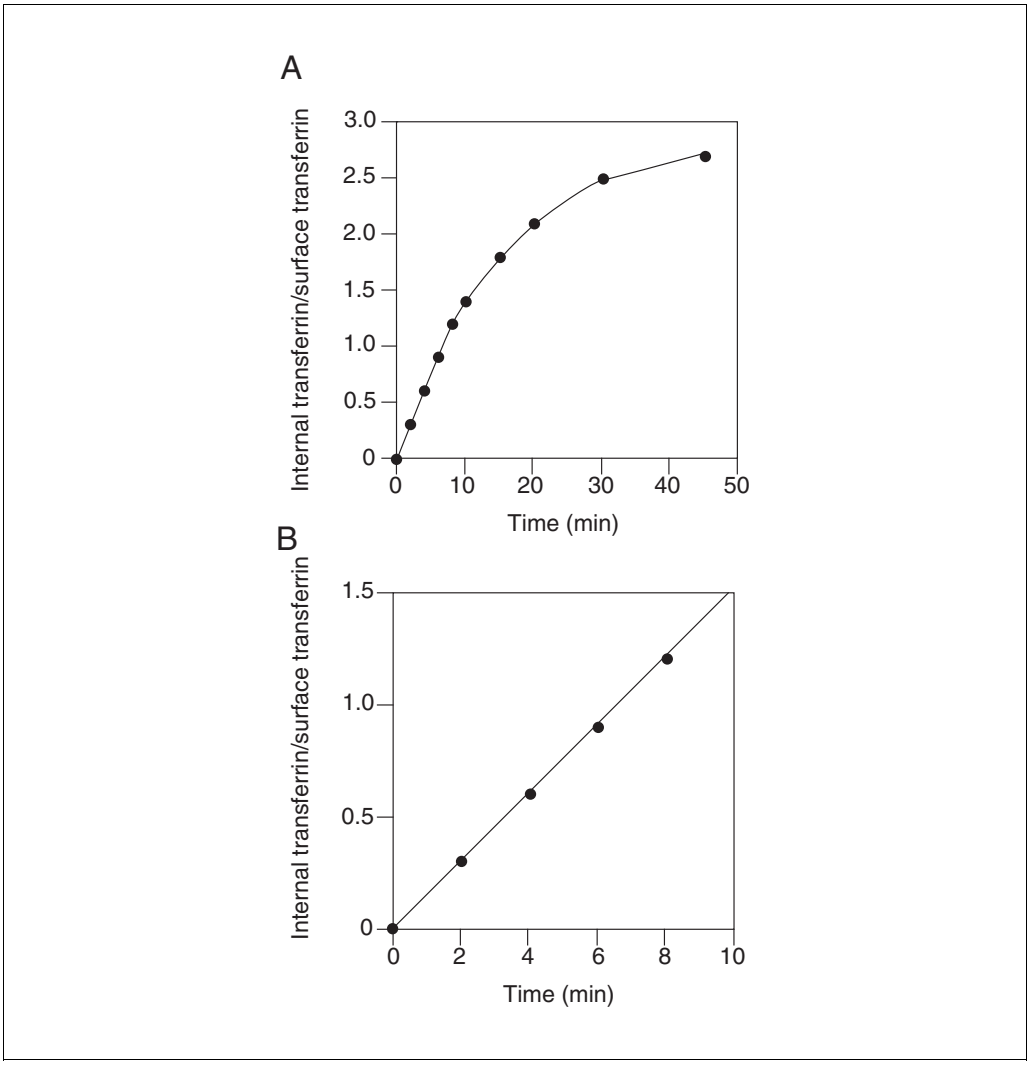

Figure 15.3.2 Data from an idealized transferrin internalization assay are shown. (**A**) Data are shown for an assay carried out for a time sufficient to reach steady state. Data from the early time points are replotted on an expanded time scale in (**B**). In both graphs the ratios of internal transferrin to steady-state surface transferrin are plotted as a function of time.

9. Add 1 ml of solubilization solution to each well. Remove the solubilized cells by trituration and transfer to tubes suitable for γ counting. Rinse wells once with 1 ml water, and pool with the solubilization solution.
10. Determine the amount of ^{125}I-labeled transferrin per tube using a γ counter.

These values are the amount of transferrin internalized during the incubation at 37°C.

Measure steady-state surface transferrin

11. Wash the steady-state plate with 2 ml SF medium. Discard wash and incubate in fresh SF medium for 1 hr at 37°C.

This incubation can be performed concurrently with the incubations of step 4.

12. Place cells on ice and wash three times with 2 ml/wash prechilled neutral pH buffer.
13. Add 1 ml prechilled neutral pH buffer containing a saturating concentration of ^{125}I-labeled transferrin (3 μg/ml) and 1 mg/ml BSA to four wells (total radioactivity wells). Add 1 ml of the same solution containing a 200-fold excess of unlabeled transferrin to the other two wells (nonspecific radioactivity wells).

14. Incubate the cells at 4°C for 2 hr.

    Endocytosis is blocked at 4°C; therefore, the amount of transferrin bound at 4°C is a measure of the receptors on the cell surface.

15. Place the plate on ice and wash the cells six times with 2 ml/well neutral pH buffer.

    CAUTION: *Dispose of radioactive waste appropriately.*

16. Solubilize the cells and quantify the amount of ^{125}I-labeled transferrin as in steps 9 and 10.

    This value is the amount of transferrin receptor on the cell surface at steady state.

Analyze data

17. Calculate the specific radioactivity of intracellular and surface transferrin by subtracting the average of the two nonspecific radioactivity wells from the average of the four total radioactivity wells.

18. Calculate the internal-to-surface transferrin ratio and plot versus time (see Fig. 15.3.2).

    The data should yield a straight line extrapolating through zero. The slope of this line is the internalization rate constant (Wiley and Cunningham, 1982). In CHO cells, the internalization rate constant of the transferrin receptor is ~0.15 min^{-1} (Johnson et al., 1994). If the slope decreases at the later time points (i.e., if the line flattens), then shorter time points must be used. The internal-to-surface plot will begin to flatten as internalized transferrin is recycled back to the cell surface.

    Another method for determining the amount of transferrin bound to the surface is to collect and count the pH 2.0 buffer and neutral buffer washes of steps 7 and 8. For each time point, the total radioactivity removed by the acid wash and the total cell-associated radioactivity are individually corrected for nonspecific radioactivity, and the internal-to-surface ratio is determined for each well. The average of these values for each time point is plotted as a function of time. However, the authors find that the procedure described in Basic Protocol 2 yields more reproducible results.

MEASURING THE KINETICS OF MEMBRANE PROTEIN INTERNALIZATION USING ^{125}I-LABELED ANTIBODIES

ALTERNATE PROTOCOL 2

For membrane proteins with no known ligand, antibodies against the extracellular domain can be used to measure internalization. For these experiments an ^{125}I-labeled antibody against the extracellular domain is used. Fab fragments should be used, because bivalent antibodies cause cross-linking and therefore may modify the protein's trafficking (Weissman et al., 1986). Fab fragments can be prepared using the ImmunoPure Fab preparation kit (Pierce) and labeled using Support Protocol 2. An excess of unlabeled antibody is used to determine nonspecific binding.

The procedures are the same as that described in Basic Protocol 2, except that iodinated Fab antibody fragments are used instead of ^{125}I-labeled transferrin. Some antibodies are not efficiently stripped from the surface with a single incubation in pH 2.0 buffer. If this is the case, several rounds of alternating acid/neutral wash can be used to increase the stripping efficiency. Some antibodies are resistant to the acid stripping. In these cases, incubation with 1 mg/ml proteinase K or pronase at 4°C for 30 min (or more) can be used to release surface-bound antibody.

ALTERNATE PROTOCOL 3

MEASURING THE KINETICS OF TRANSFERRIN INTERNALIZATION IN CELLS GROWN IN SUSPENSION

For cells grown in suspension (e.g., K562 human erythroleukemia cells), the procedure is basically the same, but the washes are more tedious because they require centrifugation. To avoid handling too many tubes, each time point is a single determination. Nonspecific labeling is determined on two of the time points, and the results are averaged and subtracted from every time point.

Additional Materials *(also see Basic Protocol 2)*

Suspension culture of interest
HEPES-buffered SF medium (see recipe)
pH 2.0 medium, ice cold: medium formulation used to grow cells (e.g., RPMI, DMEM) with 25 mM sodium acetate, adjusted to pH 2.0 with HCl
pH 11.0 medium, ice cold: medium formulation used to grow cells (e.g., RPMI, DMEM) with 25 mM Tris base, adjusted to pH 11.0 with NaOH

Prepare cells

1. For this assay, ~1×10^5 cells are used per time point. Transfer the number of cells sufficient for all time points to a 15-ml conical centrifuge tube. Pellet the cells by centrifuging 5 min at 500 × *g*, room temperature.

   Typically five time points are used, so a total of 5×10^5 cells would be sufficient.

2. Aspirate medium, wash cells once with 10 ml HEPES-buffered SF medium, and centrifuge 5 min at 500 × *g*, room temperature.

3. Incubate in 10 ml SF medium for 30 min at 37°C.

   During this incubation, any cell-associated transferrin from the growth medium will be recycled and released from the cells, ensuring that the receptors will be unoccupied at the beginning of the experiment.

4. Centrifuge cells (5 min at 500 × *g*, room temperature). Resuspend in 0.8 ml SF medium and place at 37°C.

Perform timed internalization

5. Transfer 0.2 ml cell suspension to a microcentrifuge tube and add 0.6 mg/ml unlabeled transferrin to the 0.2-ml aliquot. Place tube in a 37°C water bath.

   These cells are for nonspecific labeling (see step 8).

6. For $t = 0$, add 3 µg/ml ^{125}I-labeled transferrin to the 15-ml conical tube containing 0.6 ml cell suspension. Place tube at 37°C.

7. At the appropriate time points (e.g., 1, 2, 3, 4, and 5 min), resuspend the cells in the 15-ml tube (containing labeled transferrin only) by gently inverting the tube. Transfer 100 µl of cell suspension into a new 1.5-ml tube containing 1 ml prechilled neutral pH buffer on ice. Repeat for each time point.

   Diluting the cells in a large volume of cold neutral buffer ensures that endocytosis is stopped at once. Internalized transferrin is eventually returned to the cell surface, therefore it is important to use incubations times in which little of the transferrin is recycled. In K562 cells, incubation times <5 min are commonly used.

8. Add 3 µg/ml of ^{125}I-labeled transferrin to the tube containing 0.2 ml cell suspension and 0.6 mg/ml transferrin (step 5). Place the tube at 37°C. At the appropriate time points (e.g., 2 and 5 min), invert the tube to resuspend the cells and transfer 100 µl of the suspension to a new 1.5-ml conical tube containing 1 ml prechilled neutral buffer on ice. Repeat the procedure for the second time point.

   These are the nonspecific uptake samples.

9. Wash the time point three times with 1 ml/wash prechilled neutral pH buffer. Centrifuge each wash for 5 min at 500 × *g*, 4°C.

   The authors have also successfully used shorter centrifugations at higher speed (e.g., 15,000 × g for 20 sec).

   CAUTION: *Dispose of radioactive waste appropriately.*

10. Incubate cells with 0.2 ml prechilled pH 2.0 medium for 2 min at 4°C.

    This incubation removes transferrin bound to the cell surface.

11. Add 0.2 ml prechilled pH 11.0 medium to bring the cell to a neutral pH, and repeat centrifugation.

12. Transfer supernatant to a tube suitable for γ counting (surface radioactivity). Resuspend cell pellet in 200 µl water and transfer to another tube suitable for counting (intracellular radioactivity).

13. Determine the amount of ^{125}I-labeled transferrin in each tube.

Analyze data

14. Calculate the average surface radioactivity of the two tubes containing nonradioactive transferrin (nonspecific surface radioactivity). Subtract this value from the surface radioactivity of each of the sample time points to give the specific surface radioactivity.

15. Similarly, calculate the average nonspecific intracellular radioactivity and subtract this from the intracellular radioactivity of each of the sample time points.

16. Express the results as the ratio of internal to surface label versus time.

MEASURING THE KINETICS OF TRANSFERRIN RECEPTOR RECYCLING

BASIC PROTOCOL 3

The recycling of the transferrin receptor from endosomes back to the cell surface is examined by measuring the release of transferrin into the medium. For these studies, cells are incubated with ^{125}I-labeled transferrin to achieve steady-state occupancy of the transferrin receptor with transferrin. Transferrin bound to the cell surface is removed, and the release of internal transferrin from cells is then monitored as a function of time. Because transferrin remains bound to the transferrin receptor in intracellular endosomal compartments, the release of previously endocytosed transferrin into the medium reflects the return of transferrin receptors from endosomes to the plasma membrane. The iron-free transferrin returned to the plasma membrane with the recycled transferrin receptor is released from the receptor at the extracellular pH.

Materials

Cells of interest
SF medium (see recipe)
^{125}I-labeled human transferrin (see Support Protocol 2)
Unlabeled (nonradioactive) human diferric transferrin
pH 5.0 buffer (see recipe), prewarmed to 37°C
Efflux medium (see recipe), prewarmed to 37°C
Solubilization solution: 1% (w/v) Triton X-100 in 0.1 N NaOH

6-well tissue culture plates
γ counter and tubes

Prepare cells

1. Plate 1.5×10^5 cells/well in SF medium in 6-well tissue culture plates 2 days before the experiment. Prepare one plate for each time point. Allow the cells to reach ~80% confluency on the day of the experiment.

   Six time points are typically used. The time points used depend on the rate of recycling of the cell line being studied. In CHO cells, which have a half-time for transferrin receptor recycling of ~2 min, time points of 2.5, 5, 10, 15, 20, and 30 min are used.

   Bicarbonate-buffered medium is used if the experiment is to be performed in a CO_2 incubator; HEPES-buffered medium is used if the experiment is to be performed in air.

2. Wash cells with 2 ml SF medium.

Remove surface transferrin

3. Add 1 ml SF medium containing a saturating concentration (3 μg/ml) of ^{125}I-labeled transferrin to four wells (total radioactivity wells). Add 1 ml of SF medium containing a saturating concentration of ^{125}I-labeled transferrin and a 200-fold excess of unlabeled transferrin to the other two wells (nonspecific wells).
4. Incubate at 37°C for a time sufficient to reach steady-state occupancy of the transferrin receptor with transferrin (~20 min for most cell types).
5. Remove the first plate from the incubator, wash the cells with 2 ml SF medium, and incubate for 2 min at room temperature with 1 ml prewarmed (37°C) pH 5.0 buffer.

   Either the citrate- or the MES-based pH 5.0 buffer can be used.

   CAUTION: *Dispose of radioactive waste appropriately.*

6. Discard the pH 5.0 buffer and wash the wells three times over the course of 1 min at room temperature with prewarmed (37°C) efflux medium.

   Incubation in pH 5.0 buffer followed by washes with efflux medium promotes the release of transferrin bound to receptors on the cell surface.

Measure recycled transferrin

7. Add 1 ml prewarmed efflux medium to each well and incubate at 37°C for the desired amount of time (see time points in step 1).

   The unlabeled transferrin and the iron chelator desferrioxamine in the efflux medium ensure that the released radioactive iron-free transferrin is not reloaded with iron, and therefore cannot rebind the transferrin receptor.

8. Repeat steps 5 through 7 on each six-well plate (i.e., time point).
9. At the appropriate time, remove the plate from the incubator and transfer the efflux medium to a suitable tube for γ counting. Wash the cells (rapidly) with 1 ml efflux medium and add this wash to efflux medium in the tube.
10. Add 1 ml solubilization solution to each well. Remove the solubilized cells by trituration and transfer to tube suitable for γ counting. Rinse the wells once with 1 ml water, and pool with the solubilization solution.
11. Determine the amount of ^{125}I-labeled transferrin in each tube of efflux medium and solubilized cells.

Analyze data

12. At each time point, correct the radioactivity of ^{125}I-labeled transferrin in each individual vial of efflux medium and solubilization solution for nonspecific binding by subtracting the average of the radioactivity in the two nonspecific radioactivity wells.

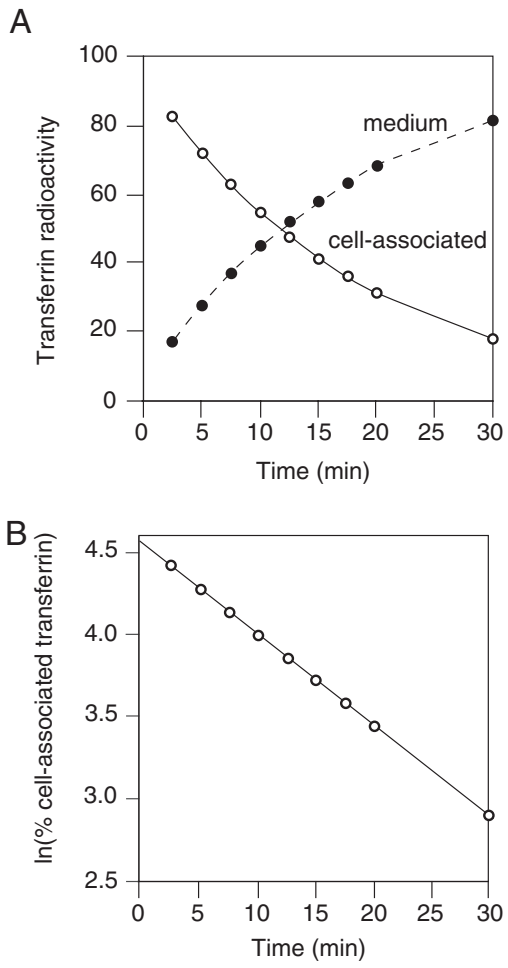

Figure 15.3.3 Transferrin recycling assay. (**A**) Data from an idealized transferrin recycling assay are shown. Over time, the amount of transferrin in the medium increases, while the cell-associated transferrin decreases as iron-free transferrin is released from cells. (**B**) The recycling rate constant is the slope of a graph of the natural logarithm of the percent-cell-associated transferrin versus time.

13. Calculate the percent cell-associated transferrin for each well, and average the four values per time point.

14. Plot percent cell-associated transferrin as a function of time (see Fig. 15.3.3).

In most cell types, transferrin is recycled by an apparent first-order process; therefore, the decrease in cell-associated transferrin should fit an exponential decay. The externalization rate constant can be calculated by determining the slope of a plot of the natural logarithm of the percent cell-associated versus time. In CHO cells, transferrin receptor is recycled at a rate of ~0.06 min^{-1} (Johnson et al., 1994).

IRON-LOADING TRANSFERRIN

SUPPORT PROTOCOL 1

This protocol describes the method for preparing diferric transferrin for use in transferrin recycling experiments (Basic Protocols 1 to 3). Its subsequent radiolabeling is described in Support Protocol 2.

Materials

Apo-transferrin (iron-free transferrin; available from a number of commercial sources)
PBS (see recipe)
1 mg/ml ferric ammonium citrate solution in 10 mM $NaHCO_3$/20 mM HEPES acid, pH 7.7
PD-10 columns (pre-packed Sephadex G-25 columns; Pharmacia Biotech) or any other desalting column
0.2-µm sterile syringe filter

1. Dissolve 200 mg apo-transferrin (iron-free) in 6 ml PBS.
2. Add 4 ml ferric ammonium citrate solution.

   The solution will be an ochre color.
3. Incubate at 37°C for 10 min.

   The solution will turn a dark rust color.
4. During this incubation, equilibrate five prepacked PD-10 columns with PBS.

   Any desalting column can be used.
5. Run 2 ml iron-loaded transferrin over each column.
6. Collect the orange product (iron-loaded transferrin). Pool the orange fractions from each column.
7. Measure the OD of the sample at 280 and 465 nm.

   The OD_{280}/OD_{465} ratio should be 0.0496 if 100% of the transferrin is loaded with iron.
8. Filter sterilize the iron-loaded transferrin with a 0.2-µm filter and store at 4°C.

   The transferrin is stable for at least 6 months at 4°C.

SUPPORT PROTOCOL 2

RADIO-IODINATION OF DIFERRIC TRANSFERRIN

There are a number of methods for radio-iodinating transferrin. The chloramine T method is described below. This method is suitable for use with any protein that contains tyrosine residues. In addition, it is important to test that the radio-iodination procedure has not grossly altered the affinity of transferrin for the transferrin receptor. This is done by measuring the ability of unlabeled transferrin to compete for the binding of ^{125}I-labeled transferrin to cells.

CAUTION: This procedure must be performed in a hood certified for radio-iodination. All personnel performing iodinations or using radioactive materials must be properly trained.

Additional Materials *(also see Basic Protocol 1)*

PBS (see recipe)
Human diferric transferrin (see Support Protocol 1)
37 MBq/ml $Na^{125}I$ (100 mCi/ml; NEN Life Science Products)
4 mg/ml chloramine T in PBS (prepare fresh)
8 mg/ml sodium bisulfite in PBS (prepare fresh)
1 mg/ml BSA
100% (w/v) trichloroacetic acid (TCA)
5×10^5 cells/well plated in 6-well tissue culture plates (see Basic Protocol 1, step 1)
PD-10 column (pre-packed Sephadex G-25 column; Pharmacia Biotech) or any other desalting column

Radiolabel transferrin

1. Equilibrate a PD-10 column with three bed volumes of PBS.
2. Add 2 mg human diferric transferrin in 0.2 ml PBS to a vial containing 1 mCi $Na^{125}I$. Mix by pipetting up and down.
3. Add 25 µl freshly prepared 4 mg/ml chloramine T in PBS. Mix by pipetting up and down. Incubate in the hood for 2 min.
4. To stop the reaction, add 25 µl freshly prepared 8 mg/ml sodium bisulfite in PBS. Mix by pipetting up and down.
5. Transfer solution to the equilibrated PD-10 column and collect 1-ml fractions.

   With a PD-10 column, the protein will be in fractions 3 and 4. It is not necessary to collect more than six fractions.

Analyze labeling

6. Quantify radioactivity in 10-µl aliquots of each fraction.
7. To confirm that the counts in the excluded fractions are ^{125}I-labeled protein, dilute a 10-µl aliquot of each fraction with 100 µl of 1 mg/ml BSA solution. Add 15 µl of 100% TCA, mix, and incubate at 4°C for 30 min.
8. Microcentrifuge samples at maximum speed for 10 min at room temperature. Quantify radioactivity in the supernatant and pellet separately.

   Radioactivity in the pellet is ^{125}I-labeled protein, and radioactivity in the supernatant is free ^{125}I.

9. Determine the specific activity (radioactivity per ng of protein).

   The procedure yields transferrin with a specific activity of 300 to 500 cpm/ng.

   CAUTION: *Dispose of radioactive waste appropriately.*

Test affinity of radiolabeled transferrin

10. Chill 6-well plate of cells (5×10^5 cells/well) to 4°C and wash each well with 2 ml prechilled neutral pH buffer.
11. Add 3 µg/ml ^{125}I-labeled transferrin and various amounts of unlabeled transferrin to each sample and incubate for 2 hr at 4°C in SF medium.
12. Wash cells with 2 ml neutral pH buffer (4°C).
13. Solubilize the cells and measure cell-associated radioactivity (see Basic Protocol 1, steps 8 and 9, for details).

    A 200-fold excess of unlabeled transferrin reduces ^{125}I-labeled transferrin binding to less than 10%.

14. Store radio-iodinated transferrin for up to 1 month at 4°C in a lead container.

TIME COURSE FOR STEADY-STATE OCCUPANCY OF MEMBRANE PROTEIN WITH ANTIBODY

BASIC PROTOCOL 4

It is not possible to use a modification of Basic Protocol 3 to measure the recycling of a membrane protein using a ^{125}I-labeled antibody, because the antibody remains bound to the membrane protein when it is returned to the cell surface, and the methods used to strip antibodies are not compatible with studies in living cells. One method for determining the recycling rate of a membrane protein using an antibody is to incubate cells at 37°C with ^{125}I-labeled antibody and monitor the amount of cell-associated antibody as a function of incubation time. The protein on the surface at the start of the experiment will be rapidly bound by the antibody, and will remain bound throughout the course of the

experiment (i.e., is it recycles between the cell surface and endosomes). Cell-associated label, however, will increase over time as the pool of protein that was inside the cell at the beginning of the experiment (and therefore unoccupied) is recycled back to the cell surface. Cell-associated label will plateau (reach a steady-state value) when all the cycling protein has bound antibody (i.e., is trafficked to the cell surface). Thus, the rate of approach to the steady-state value is the rate at which the intracellular pool is cycled to the surface. Note that this method for measuring recycling of a membrane protein requires that the antibody remain associated with the protein during its cycle, that the antibody does not modify the trafficking of the protein, and that the amount of protein synthesized over the course of the experiment is negligible compared to the amount of recycled protein.

Materials

Cells of interest
SF medium (see recipe)
^{125}I-labeled antibody (Fab fragments; 2 to 10 μCi/μg)
Unlabeled (nonradioactive) antibody
Neutral pH buffer (see recipe), room temperature
Solubilization solution: 1% (w/v) Triton X-100 in 0.1 N NaOH

6-well tissue culture plates
γ counter and tubes

1. Plate 1×10^5 cells/well in SF medium in 6-well tissue culture plates 2 days before the experiment. Use one plate for each time point. Allow cells to reach ~80% confluency on the day of the experiment.

   Eight time points are typically sufficient.

   Bicarbonate-buffered medium is used if the experiment is to be performed in a CO_2 incubator. HEPES-buffered medium is used if the experiment is to be performed in air.

2. Wash cells with 2 ml SF medium.
3. Add 1 ml SF medium containing 1 to 5 nM ^{125}I-labeled antibody to four wells (total radioactivity wells). Add 1 ml SF medium containing the same concentration of ^{125}I-labeled antibody and a 200-fold excess of unlabeled antibody (nonspecific radioactivity wells) to the other two wells.
4. Incubate the plates for variable times at 37°C (e.g., 2.5, 5, 10, 15 min).

   The time points used are empirically determined.

5. At the appropriate times, remove the plates from the incubator and wash three times with 2 ml neutral pH buffer.

   CAUTION: *Dispose of radioactive waste appropriately.*

6. Add 1 ml solubilization solution to each well. Remove the solubilized cells by trituration and transfer to tubes suitable for γ counting. Rinse the wells once with 1 ml water, and pool with the solubilization solution.
7. Determine the amount of ^{125}I-labeled antibody per tube.
8. Repeat steps 5 to 7 are for each plate after the appropriate incubation time.
9. For each plate (time point), average the values of the four total radioactivity wells and subtract the average of the two nonspecific radioactivity wells.
10. Plot the amount of cell-associated antibody (specific radioactivity) as a function of incubation time.

    This curve should asymptotically approach a plateau level. The increase in cell-associated antibody over time reflects the recycling of unoccupied membrane protein receptors from

endosomes to the surface. The recycling rate constant is calculated from this curve (Johnson et al., 1993).

DETECTING DEGRADATION OF INTERNALIZED LIGANDS

BASIC PROTOCOL 5

Most ligands internalized by endocytosis are delivered to late endosomal or lysosomal compartments where they are degraded into peptides. The degradation of ^{125}I-labeled ligand is examined by measuring the release of these peptides into the medium. The medium is collected and proteins are precipitated with trichloroacetic acid (TCA). The radioactivity in the pellet is intact protein, and the radioactivity in the supernatant is degraded ligand. This protocol describes the detection of degraded peptide in the extracellular medium after various times of endocytosis.

Materials

Cells of interest
SF medium (see recipe)
Neutral pH buffer (see recipe), ice cold
^{125}I-labeled ligand of interest (Support Protocol 2)
Unlabeled (nonradioactive) ligand
10 mg/ml BSA
100% (w/v) trichloroacetic acid (TCA) solution

6-well tissue culture plate
γ counter and tubes

Prepare cells

1. Plate 1×10^5 cells/ml in SF medium in three wells of a 6-well tissue culture plate 2 days before the experiment. Prepare one plate (three wells) per time point. Allow cells to reach ~80% confluency on the day of the experiment.

   Bicarbonate-buffered medium is used if the experiment is to be performed in a CO_2 incubator. HEPES-buffered medium is used if the experiment is to be performed in air.

2. On the day of the experiment, wash the cells once with 2 ml SF medium and incubate in SF medium for 1 hr at 37°C.

   During this incubation, most of the cell-associated ligand from the growth medium will be released from the cells, ensuring that the receptors will be unoccupied at the beginning of the experiment.

3. At the end of this incubation, place the cells on ice and wash two times with 2 ml/well prechilled neutral pH buffer.

Internalize ligand

4. Add 1 ml prechilled (4°C) neutral pH buffer containing a saturating concentration of ^{125}I-labeled ligand and 1 mg/ml BSA to two wells (total radioactivity wells). Add 1 ml of the same solution containing a 200-fold excess of unlabeled ligand to the other well (nonspecific radioactivity well).

   The concentration of ligand depends on the ligand used; refer to appropriate literature.

5. Incubate the cells at 4°C for 2 hr.

6. Wash cells four times with 2 ml neutral pH buffer at 4°C.

   CAUTION: *Dispose of radioactive waste appropriately.*

   The neutral pH wash removes unbound ligand from the cells.

7. Add 1 ml SF medium to each well and incubate the plate at 37°C.

   At 37°C, receptor-bound ligands are internalized.

Collect/precipitate degraded and intact ligand

8. At various time points (e.g., 10, 20, 30, 60, 90, and 120 min) transfer the incubation medium from the three walls into separate microcentrifuge tubes on ice.
9. Solubilize the cells and determine the radioactivity (see Basic Protocol, steps 8 and 9).

   This is the cell-associated radioactivity.

10. Add 10 mg/ml BSA to the incubation medium at a final concentration of 2 mg/ml.

    Adding BSA will increase the efficiency of precipitation of the intact ligand.

11. Add 100% (w/v) TCA at a final concentration of 15%.
12. Incubate 30 min at 4°C.
13. Centrifuge at 15,000 × *g*, 4°C, for 20 min.
14. Collect the supernatant and count the radioactivity in each separately.
15. At the same time, test the efficiency of the precipitation procedure by precipitating a 5-µl aliquot of labeled ligand diluted to 1 ml in SF medium as described in steps 9 to 13.

    Typically, more than 90% of the ligand should be precipitable.

Analyze data

16. Correct all the data for nonspecific radioactivity by subtracting the radioactivity in the nonspecific sample from the average of the radioactivity in the other two samples. Determine the radioactivity in the 15% TCA supernatant (ligand released into the medium in degraded form) and in the 15% TCA pellet (ligand released in the undegraded or intact form). Plot the three values—cell-associated radioactivity (step 9), the released degraded ligand, and the released intact ligand—as per cent of the total (the sum of the three values at that time point) versus time.

    An alternative protocol is to incubate the cells at 37°C in the presence of ^{125}I-labeled ligand (pulse), wash the cells, and measure the appearance of degraded ligand in the medium after various chase times (Brown and Goldstein, 1976), which is more sensitive because it does not rely on a single round of internalization.

BASIC PROTOCOL 6

MEASURING FLUID-PHASE UPTAKE

Any molecule in the extracellular medium can be internalized by bulk fluid uptake inside newly endocytosed vesicles. To measure this non-concentrated uptake, cells are incubated with a protein that does not have a specific membrane receptor and accumulation of this protein inside cells over time is determined.

Materials

Cells of interest
SF medium (see recipe)
5 mg/ml horseradish peroxidase (HRP) in SF medium
Neutral pH buffer (see recipe), ice cold
0.01% (w/v) Triton X-100
6-well tissue culture plates

Additional reagents and equipment for colorimetric assay (see Steinman et al., 1976) and protein assay (*APPENDIX 3*)

1. Plate 1×10^5 cells/well in SF medium in 6-well tissue culture plates 2 days before the experiment. Use three wells for each time point. Allow the cells to reach ~80% confluency on the day of the experiment.

   The time points used are determined empirically.

   Bicarbonate-buffered medium is used if the experiment is to be performed in a CO_2 incubator. HEPES-buffered medium is used if the experiment is to be performed in air.

2. Wash the cells once with 2 ml SF medium, and incubate the cells in 5 mg/ml HRP in SF medium at 37°C for various times (e.g., 5, 10, 15, 20, 30, 60 min).

   ^{125}I-labeled BSA or other detectable protein can be used instead of HRP.

3. At the appropriate times, remove the plate from the incubator, place on ice, and wash six times with 2 ml/wash prechilled neutral pH buffer.

   Endocytosis is inhibited at 4°C. More than six washes may be needed to remove HRP adsorbed to the cell surface. To test this, incubate 6 wells with 5 mg/ml HRP at 4°C for 2 hr. Measure the number of washes necessary to remove essentially all cell-associated HRP activity as determined in step 4. The surface HRP can also be removed by incubation in 0.1% pronase in PBS. This procedure also removes the cells from the plate; the cells are collected by centrifugation 3 min at 15,000 × g.

4. Lyse cells in 1 ml of 0.01% Triton X-100. Take a 100-µl aliquot to measure HRP activity in the lysate using a colorimetric assay (see Steinman et al., 1976). Measure HRP activity of a 5 mg/ml HRP solution as a standard for normalization.

5. Measure protein content in the lysate (*APPENDIX 3)*.

   A number of kits are also available to measure protein content.

6. Express the results as the amount of HRP with respect to the total protein content for each well (i.e., ng HRP/mg cell protein). Calculate the average of these values for each time point, and plot as a function of time.

INHIBITION OF CLATHRIN-MEDIATED ENDOCYTOSIS BY POTASSIUM DEPLETION

SUPPORT PROTOCOL 3

All endocytic mechanisms are energy and temperature dependent, and are blocked at 4°C. Clathrin-mediated endocytosis (e.g., transferrin endocytosis) is also inhibited by two other methods: intracellular potassium depletion (Larkin et al., 1983) and cytosol acidification (Sandvig et al., 1987; see Support Protocol 4). The potassium depletion assay is easy to perform, but inhibits clathrin-dependent endocytosis only in certain cell types (e.g., human and chick embryo fibroblasts, Hep 2 cells; Moya et al., 1985). These assays are used to establish that internalization is by clathrin-mediated endocytosis.

Materials

Cells of interest
SF medium (see recipe)
Hypotonic medium: 1:1 (v/v) SF medium/water
K^+-depleted buffer: 100 mM NaCl, 50 mM HEPES acid, pH 7.4
6-well tissue culture plates

Additional reagents and equipment for measuring internalization (see Basic Protocol 2 or Alternate Protocol 2)

1. Plate 1×10^5 cells/well in SF medium in 6-well tissue culture plates 2 days before the experiment. Allow the cells to reach ~80% confluency (~5×10^5/well) on the day of the experiment. Prepare one plate for each time point and one plate for surface labeling.

Bicarbonate-buffered medium is used if the experiment is to be performed in a CO_2 incubator; HEPES-buffered medium is used if the experiment is to be performed in air.

2. On the day of the experiment, wash the cells once with 2 ml SF medium.
3. Incubate cells for 5 min at 37°C in 2 ml hypotonic medium.
4. Wash cells with 2 ml K^+-depleted buffer.
5. Incubate cells for 30 min at 37°C in K^+-depleted buffer.
6. Measure internalization as described (see Basic Protocol 2, steps 3 to 17, or see Alternate Protocol 2), but perform internalization incubations (step 3) in K^+-depleted buffer.

The inhibition is fully reversible within 15 min of adding back 10 mM KCl in the K^+-depleted buffer. Incubating cells in hypertonic media (e.g., 0.45 M sucrose) also inhibits clathrin-dependent endocytosis, but may affect other types of endocytosis as well (Sandvig et al., 1989).

SUPPORT PROTOCOL 4

INHIBITION OF CLATHRIN-MEDIATED ENDOCYTOSIS BY CYTOSOL ACIDIFICATION

Only one of a number of methods for acidifying the cytosol are discussed below (Sandvig et al., 1987). Excessive acidification of the cytosol may also inhibit clathrin-independent endocytosis, as measured following fluid-phase endocytosis.

Materials

Cells of interest
SF medium (see recipe)
SF medium supplemented with 25 mM NH_4Cl
140 mM KCl/1 mM amiloride/40 mM HEPES acid, pH 7.0
6-well tissue culture plates

Additional reagents and equipment for measuring internalization (see Basic Protocol 2 or Alternate Protocol 2)

1. Plate 1×10^5 cells/well in SF medium in 6-well tissue culture plates 2 days before the experiment. Allow the cells to reach ~80% confluency (~5×10^5/well) on the day of the experiment. Prepare one plate for each time point and one for surface labeling.

Bicarbonate-buffered medium is used if the experiment is to be performed in a CO_2 incubator; HEPES-buffered medium is used if the experiment is to be performed in air.

2. On the day of the experiment, wash the cells once with 2 ml SF medium.
3. Incubate for 30 min at 37°C in SF medium supplemented with 25 mM NH_4Cl.

The optimal NH_4Cl concentration that inhibits clathrin-mediated entry without affecting other cellular processes may vary with the cell line, and different concentrations (e.g., 10 to 50 mM) should be tested.

4. Incubate cells for 2 min at 37°C in 140 mM KCl/1 mM amiloride/40 mM HEPES acid, pH 7.0.
5. Measure internalization (see Basic Protocol 2, steps 3 to 17, or see Alternate Protocol 2), but perform internalization incubations (step 4) in the amiloride-containing buffer.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Either concentrated HCl or concentrated NaOH is used to pH all buffers.

Efflux medium

SF medium (see recipe) containing:
0.1 mM desferrioxamine (Sigma; from 10 mM stock in H_2O)
3 µg/ml human diferric transferrin
Prepare fresh

Neutral pH buffer

8.8 g NaCl (final 150 mM)
0.37 g KCl (5 mM)
0.11 g $CaCl_2$ (1 mM)
0.20 g $MgCl_2$ (1 mM)
4.77 g HEPES acid (20 mM)
Adjust to 1 liter with distilled water
Adjust pH to 7.4
Store up to 6 months at 4°C

pH 2.0 buffer

29.22 g NaCl (final 500 mM)
28.57 ml glacial acetic acid (0.2 N)
Adjust to 1 liter with distilled water
Adjust pH to 2.0
Store up to 6 months at 4°C

pH 5.0 buffer

8.76 g NaCl (final 150 mM)
9.74 g 2-(*N*-morpholino)ethanesulfonic acid (MES; 50 mM) *or* 5.88 g sodium citrate (20 mM)
Adjust to 1 liter with distilled water
Adjust pH to 5.0
Store up to 6 months at 4°C

Phosphate-buffered saline (PBS)

8 g NaCl (final 137 mM)
0.2 g KCl (2.6 mM)
2.2 g Na_2HPO_4 heptahydrate (8 mM)
0.2 g KH_2PO_4 (1.5 mM)
Adjust to 1 liter with distilled water
Adjust pH to 7.4
Store up to 6 months at room temperature

Serum-free (SF) medium

If the experimental incubations are to be performed in a CO_2 incubator, the SF medium is the medium formulation used to grow cells (e.g., Ham's F12, DMEM, RPMI) supplemented with the amount of sodium bicarbonate recommended for that particular medium formulation, and 10 mM HEPES acid (pH 7.2). A number of manipulations using this medium are performed at room temperature, and the HEPES is included to ensure that the pH of the bicarbonate-buffered medium does not alkalinize during these manipulations. If the experiment is to be performed in an air incubator, omit the sodium bicarbonate from the SF medium.

COMMENTARY

Background Information

The term endocytic trafficking is used to describe the processes of internalization from the cell surface into endosomes, trafficking among various intracellular compartments, and recycling back to the surface. Endocytosis through clathrin-coated pits is the major mechanism for receptor-mediated internalization of extracellular macromolecules. Ligands internalized by endocytosis include peptide hormones (e.g., insulin, epidermal growth factor), nutrient-carrying proteins (e.g., transferrin, low-density lipoprotein), viruses, and both plant and animal toxins. The distribution of receptors between intracellular compartments and the cell surface is determined by the rates of internalization and recycling. Endocytic trafficking also plays a fundamental role in the maintenance of intracellular organelle identity because, in many instances, the localization of membrane proteins to specific compartments involves retrieval and retargeting through the endosomal system. In addition, a number of specialized and regulated trafficking processes overlap, at least in part, with the general endosomal system (e.g., insulin-regulated trafficking of the glucose transporter GLUT4). For reviews of constitutive and regulated endocytic trafficking, see Watts and Marsh (1992), Sorkin and Waters (1993), Holman et al. (1994), Gruenberg and Maxfield (1995), and Mukherjee et al. (1997).

Transferrin receptor trafficking has been extensively studied in many different cell types. The are a number of advantages in using the transferrin receptor to monitor endocytic trafficking. First, transferrin remains bound to its receptor until it is recycled back to the cell surface. Therefore, recycling of the receptor can be followed directly using labeled transferrin. Second, transferrin receptors are expressed in most cell types. Third, transferrin is commercially available and readily labeled for use in biochemistry and microscopy experiments. Fourth, human transferrin has a high affinity for transferrin receptors from other species, making human transferrin a versatile reagent.

Using transferrin as a probe, the kinetics of clathrin-coated-pit-mediated internalization (see Basic Protocol 2) and the kinetics of constitutive recycling (see Basic Protocol 3) can be measured. Since transferrin receptor is constitutively cycled between endosomes and the plasma membrane, the rates of internalization and recycling determine the steady-state surface-to-internal distribution of transferrin receptor (see Basic Protocol 1; Johnson et al., 1994). Thus, when characterizing the behavior of the transferrin receptor, the ratio of the recycling to internalization rate constants should be equal to the measured surface-to-internal ratio. The transferrin receptor assays described in this unit (and slight modifications of these assays) have been used successfully in conjunction with molecular genetic approaches (e.g., expression of dominant negative mutants; Bucci et al., 1992; van der Sluijs et al., 1992) and chemical inhibitors (Schonhorn and Wessling-Resnick, 1994; Martys et al., 1996) to further understand the molecular mechanisms of endocytosis.

The antibody-based trafficking assays described in this unit can be used to monitor the behavior of any membrane protein for which an antibody to the extracellular domain is available (see Alternate Protocols 1 and 2, and Basic Protocol 4). Although many proteins are internalized through clathrin-coated pits, there are other non-clathrin mechanisms for internalization. Methods for inhibiting endocytosis—via potassium depletion (see Support Protocol 3) or cytosol acidification (see Support Protocol 4)—have proven useful in determining the internalization pathways of membrane proteins (e.g., Moya et al., 1985; Sandvig et al., 1987; Subtil et al., 1994). However, conclusions must be drawn cautiously, as these treatments are not specific and the extent of inhibition varies greatly between cell types (Moya et al., 1985).

When characterizing the trafficking of a membrane protein, one can determine whether the protein is recycled or if it trafficks to lysosomes and is degraded (see Basic Protocol 5). If the protein is recycled, then the approach to steady-state occupancy (Basic Protocol 4) can be used to measure the recycling rate. As is the case for the transferrin receptor, if a membrane protein is constitutively recycled, then the ratio of the rate of internalization to the rate of recycling should be equal to the steady-state surface-to-internal distribution. In the case of antibody-based trafficking studies, the internalization rate and the surface-to-internal ratio can be directly measured, and a value for the recycling rate can be determined by multiplying the internalization rate by the surface-to-internal ratio.

In addition to the biochemical assays described in this unit, similar quantitative fluorescence microscopy assays have been used to

characterize endocytic trafficking (e.g., Mayor et al., 1993; Presley et al., 1993). A description of these powerful approaches is beyond the scope of this unit. Quantitative studies can also be performed by flow cytometry using fluorescent ligands or antibodies (Marks et al., 1996).

Critical Parameters

The sensitivity of the biochemical assays depends on the number of receptors (or molecules of membrane protein being studied) per cell and the specific activity of the probe. If a protein expressed by transfection is being studied, highly expressing clones can be used. However, it is imperative to demonstrate that the behavior of the protein is not dependent on the level of expression, as would be the case if a critical trafficking step is saturated at high levels of expression (Marks et al., 1996). Increasing the specific activity of the ^{125}I-labeled probe can compensate for a low number of receptors, but too high incorporation of ^{125}I may result in a loss of specificity (see Troubleshooting).

Another critical parameter is the efficient release of ligand from the cell surface, because this is used to discriminate between surface and internal ligand. The efficiency of the acid stripping is assessed by stripping ligand bound to the surface of cells at 4°C. When it works, acid stripping is the method of choice (see Basic Protocol 1). Several rounds of alternating acid/neutral washes can be performed to increase the stripping efficiency. Some antibodies are resistant to release by incubation in acidic buffers. In those cases, incubation with 1 mg/ml proteinase K or pronase at 4°C for 30 min (or more) can be tried to release surface-associated radioactivity.

To minimize experiment-to-experiment variation, it is important to use cells at the same degree of confluency.

Troubleshooting

The quality of the ^{125}I-labeled ligand (transferrin, other ligand, or antibody) is critical. If the ligand is over-derivatized (too high specific activity), specific binding to receptor/antigen can be compromised, which will result in a reduced signal-to-noise ratio (i.e., the nonspecific radioactivity will be a large percentage of the total radioactivity). In addition, the trafficking of an over-derivatized ligand can be altered. For example, over-derivatized transferrin often aggregates, and these aggregates are trafficked to lysosomes and degraded rather than recycled. On the other hand, if the specific activity is too low, there may not be enough signal. The optimal specific activity must be determined empirically for each ligand and each cell type. There are a number of different methods for iodinating proteins. If problems are encountered with the degree of derivatization using one method, one of the other methods should be tried.

If the nonspecific radioactivity is a large fraction of the total, the amount of unlabeled ligand used for competition can be increased, and the number of washes can also be increased. Adding 1 mg/ml BSA during the incubation with the radio-iodinated probe can help lower background.

When using an antibody as a probe, verify (if possible) that the antibody does not modify trafficking of the protein (Subtil et al., 1994). Fab fragments should be used because bivalent antibodies cause cross-linking and therefore may modify the protein's trafficking (Weissman et al., 1986). Also, antibodies should be aliquoted and frozen immediately after radiolabeling to avoid freeze/thaw cycles. Aliquots may be kept at 4°C for several days.

Anticipated Results

The methods discussed in this unit (and variations of these methods) have been widely used. Examples of results obtained using these methods can be found in Weissman et al. (1986), Backer et al. (1991), Pelchen-Matthews et al. (1991), Herbst et al. (1994), Johnson et al. (1994), Schonhorn and Wessling-Resnick (1994), and Subtil et al. (1997).

The values for transferrin receptor trafficking in cultured fibroblast cells lines are:

Internalization rate constant: 0.15 to 0.2 min^{-1}
Recycling rate constant: 0.05 to 0.07 min^{-1}
Percent on surface at steady state: 30% to 40%.

Data from an idealized transferrin internalization assay are shown Figure 15.3.2. In panel A, data are shown for an assay carried out for a time sufficient to reach steady-state. During short incubation times, the ratio of the internal transferrin to surface transferrin increases linearly (panel B). The slope of this line is the internalization rate constant. After longer incubations, the rate of increase in ratio of internal-to-surface transferrin slows down as transferrin is recycled. To accurately measure the internalization rate constant it is important to use time points in the linear (early) portion of the curve. Ideally, the line should extrapolate through zero.

Data from an idealized transferrin recycling assay are shown in Figure 15.3.3. At the start

of the experiment, the great majority of transferrin is inside the cells because the pH 5 wash followed by neutral pH washes removes transferrin from the surface of cells. Over time the amount of transferrin in the medium increases and the amount of transferrin inside cells decreases as iron-free transferrin is recycled back to the cell surface. The recycling rate constant is the slope of a plot of the natural logarithm of the percent cell-associated transferrin versus time.

Time Considerations

Each individual experiment is readily performed within a single day.

Determining Protein Transport to the Plasma Membrane

Many integral membrane proteins, synthesized in the endoplasmic reticulum (ER), ultimately arrive at the cell surface to contact the cell's environment. During export from the ER, and transport through the Golgi subcompartments and *trans*-Golgi network (TGN), proteins may undergo a number of posttranslational modifications that affect the molecular weight and/or charge. These post-translational modifications include N-linked glycan modifications, O-linked glycan modifications, sulfation, phosphorylation, lipid modifications, and proteolytic trimming/cleavage (*UNITS 15.1 & 15.2*).

Since localization of the enzymes involved in these alterations is well known, posttranslational modifications are the most convenient tool to monitor intracellular transport processes. However, these modifications have gone to completion when the proteins arrive at the plasma membrane. The appearance of a particular protein at the cell surface can then be visualized by pulse-labeling the protein and removing the posttranslational modifications in intact cells using various enzymes (see Basic Protocol 1). Alternatively, cell-surface appearance can be assayed by selectively labeling the cell-surface pool of pulse-labeled proteins using biotin (see Alternate Protocol 1) or antibodies (see Alternate Protocol 3), or by removing the surface-protein pool with proteases (see Alternate Protocol 2). Various techniques for measuring cell-surface appearance based on these principles are also described. Changes in molecular charge can be assessed by one-dimensional isoelectric focusing (IEF; see Support Protocol 2). Fab fragments of antibodies can be biotinylated (see Support Protocol 1) and used to detect surface proteins. It is also possible to measure transport to endosomes before appearance at the plasma membrane (see Basic Protocol 2).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1D*).

MEASURING ARRIVAL AT THE CELL SURFACE BY DIGESTION WITH SIALIDASE

BASIC PROTOCOL 1

This assay is based on the fact that, in the TGN, glycoproteins acquire one or more sialic-acid residues at the end of their N- and O-linked carbohydrate chains. This sialylation alters not only the total molecular weight (although this will only be observed by SDS-PAGE when many sialic acids are added; see Fig. 15.2.6), but also the charge or isoelectric point of the glycoprotein (*UNIT 15.2*). Addition of sialic acids can be most readily observed when isolated proteins are separated by isoelectric point, i.e., using one-dimensional IEF (see Support Protocol 2) or two-dimensional IEF/SDS-PAGE (*UNIT 6.4*). The sialic acids can be easily and quantitatively removed from intact cells by incubation with sialidase, resulting in a more basic isoelectric point and a shift of the glycoprotein to the position on IEF corresponding to that of the glycoprotein prior to sialylation. Cell-surface appearance of glycoproteins can thus be determined by combining a pulse-chase experiment (*UNIT 7.1*) with incubations of the intact cells in the presence or absence of sialidase (*UNIT 15.2*). Cell-surface appearance is then determined by comparing the sialic-acid content of a glycoprotein prior to and after sialidase treatment. A glycoprotein has arrived at the plasma membrane when it becomes a substrate for the sialidase treatment of intact cells at low temperature.

Contributed by Jacques Neefjes
Current Protocols in Cell Biology (2000) 15.4.1-15.4.14

Materials

Cells
Amino acid–free medium containing 8% to 10% (v/v) FBS
Radiolabeled amino acid
PBS (*APPENDIX 2A*), ice cold
PBS containing 1 mM $CaCl_2$
Sialidase Type V from *Clostridium perfringens* (Sigma) dissolved in PBS and stored in 10-µl 1 to 10 U/ml aliquots up to several years at −20°C
PBS containing 10% (v/v) fetal bovine serum (FBS)
Lysis mixture (see recipe)
Fetuin

Additional reagents and equipment for pulse-labeling (*UNIT 7.1*), TCA precipitation (*UNIT 7.1*), immunoprecipitation (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*) or one-dimensional IEF (see Support Protocol 2), and autoradiography (*UNIT 6.3*)

1. Culture cells in amino acid-free medium containing 8% to 10% FBS. Pulse label ~5 × 10^6 cells per sample with a ~50 µCi radiolabeled amino acid and chase for various times. Chase times can be 0, 1, 2, 3, 5, 10, and 30 min for early events, and 0, 15, 30, 60, 120, and 240 min for following most stages in intracellular transport. Label two sets of cells for each chase time point: one for sialidase treatment and one as a control sample.

   Usually cells are labeled with 10 to 50 µCi radioactive amino acids (UNIT 7.1), but they can also be labeled with radioactive sugars (Warmerdam et al., 1996).

2a. Collect nonadherent cells at each chase point by low-speed centrifugation (3 min at 1500 × g, 4°C).

2b. Collect adherent cells at each chase point by detaching from the plate with 10 mM EDTA in PBS at <15°C (to stop intracellular transport).

   Alternatively, the sialidase digestion can be performed with the cells attached to the plate.

3. Wash cells two times with 1 ml PBS at 4°C. Collect nonadherent or detached cells between washes by centrifuging 3 min at 1500 × *g*, 4°C. Resuspend the pellet by gently tapping the bottom of the tube before adding PBS.

4. Suspend the final pellet from the control sample in 100 µl PBS containing 1 mM $CaCl_2$ and the other sample in 100 µl PBS containing 1 mM $CaCl_2$ and 0.1 IU sialidase. Incubate cells on ice for 1 hr.

   Both the time of sialidase treatment and the concentration of sialidase may be varied to ensure full desialylation.

   Sialidase from other sources, e.g., Arthrobacter ureafaciens, can also be used.

5. Remove sialidase by washing the cells three times with 1 ml PBS containing 10% FBS.

6. Lyse cells in 1 ml lysis mixture containing 1 to 10 mg fetuin to inhibit postlysis desialylation.

   It is advisable to confirm the conditions for complete sialic acid removal that may result in postlysis desialylation. This can be done by mixing cells containing radiolabeled surface proteins with unlabeled cells incubated with sialidase prior to lysis.

7. To ensure the isolation of proteins from equal numbers of radioactively labeled cells, determine the amount of incorporated radioactivity per lysate by TCA precipitation of 10 µl of each cell lysate (see *UNIT 7.1*).

8. Isolate the proteins from equal amounts of radioactivity by immunoprecipitation (*UNIT 7.2*).

9. Analyze immunoprecipitates by SDS-PAGE (*UNIT 6.1*) or one-dimensional IEF (see Support Protocol 2) followed by autoradiography (*UNIT 6.3*).

   Sialic acid addition/removal may sometimes result in an altered apparent molecular weight on SDS-PAGE (UNIT 6.1; Fig. 15.2.6). This can be most easily visualized by loading the control sample next to the sialidase-treated sample. If this does not give proper resolution, however, proteins have to be separated on the basis of isoelectric point, either by one-dimensional IEF (see Support Protocol 2) or two-dimensional IEF/SDS-PAGE (UNIT 6.4). SDS-PAGE as well as one-dimensional IEF allows separation of many samples in a single run and direct side-by-side comparison.

MEASURING ARRIVAL AT THE CELL SURFACE BY BIOTINYLATION OF CELL-SURFACE MOLECULES

ALTERNATE PROTOCOL 1

Biotinylation of surface proteins employs monovalent, water-soluble cross-linkers with an additional biotin group to allow isolation by avidin or streptavidin coupled to Sepharose. Only proteins at the plasma membrane are substrates for this reaction, provided that the reaction is performed at temperatures <15°C. Arrival of newly synthesized proteins at the cell surface can be analyzed by performing biotinylation of cells after a pulse-chase protocol (see *UNIT 7.1*). The experimental design is simple but not quantitative. Generally, between 0% and 25% of the surface-protein pool is biotinylated. As most cross-linkers react with amine groups, including those from serum components, cells should be extensively washed with PBS before biotinylation.

Materials

Cells
Wash buffer: PBS (*APPENDIX 2A*) containing 1 mM $MgCl_2$ and 0.1 mM $CaCl_2$
15 mg/ml sulfo-*N*-hydroxysuccinimde-biotin (sulfo-NHS-biotin; Pierce) in PBS, prepared fresh prior to use
Wash buffer containing 25 mM lysine monohydrochloride
Lysis buffer containing 50 mM glycine
0.5% (w/v) SDS
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Antibody specific for protein of interest
Avidin- or streptavidin-Sepharose beads

Additional reagents and equipment for pulse labeling (*UNIT 7.1*), immunoprecipitation (*UNIT 7.2*), and SDS-PAGE (*UNIT 6.1*)

1. Perform a pulse-chase experiment (see *UNIT 7.1*).

   The number of cells required depends on the experiment and expression level of the protein. The cells can be either suspension or adherent cells.

2. At the respective chase times, wash a sample/dish of cells carefully with wash buffer three times.

3. Incubate cells 30 min at 4°C in a small volume of wash buffer (enough to cover the cells) containing sulfo-NHS-biotin to a final concentration of 1 mg/ml.

   Other water-soluble, biotin-coupled cross-linkers can be used as well. Since the reagent reacts with amine groups, use of Tris-based buffers should be avoided.

   If the biotinylation is inefficient, the concentration of the reagent can be increased up to 10 mg/ml.

4. Wash cells twice with wash buffer containing 25 mM lysine monohydrochloride.

   Lysine contains two reactive amino groups for inactivation of the NHS group.

5. Lyse cells in an appropriate lysis buffer containing 50 mM glycine.

   Lysis buffer also usually contains Triton X-100; however, when unstable interactions occur use octylglucoside, digitonin, or CHAPS (e.g., see recipe for lysis mixture).

6. Determine the radioactivity, as above (see Basic Protocol 1, step 7). Immunoprecipitate (*UNIT 7.2*) the protein of interest from equal amounts of TCA-precipitable radioactivity.

7. Split the immunoprecipitate in two equal portions. Analyze one portion by SDS-PAGE (*UNIT 6.1*) directly after immunoprecipitation.

8. Denature the other portion by boiling 5 min in 100 µl of 0.5% SDS. Dilute the SDS by adding 900 µl of 50 mM Tris·Cl, pH 7.5. Centrifuge 5 min at 10,000 × *g*, 4°C. Transfer the supernatant to a new microcentrifuge tube. Take the supernatant and reprecipitate the biotinylated pool of immunoisolated proteins with ~10 µl packed avidin- or streptavidin-Sepharose beads. Analyze by SDS-PAGE (*UNIT 6.1*).

   Comparison of the total and biotinylated protein pool (run on the same gel) will show the kinetics of plasma membrane appearance.

ALTERNATE PROTOCOL 2

MEASURING ARRIVAL AT THE CELL SURFACE USING PROTEASE SENSITIVITY

Proteases can also be used to selectively degrade plasma-membrane proteins and thus to measure their arrival at the cell surface. Various proteases can be used depending on the susceptibility of the protein of interest. The optimal concentration of the protease for complete digestion has to be determined first. It should be below protease concentrations that break up cells.

Materials

Cells
PBS (*APPENDIX 2A*)
Protease: fresh 10 mg/ml stock solutions of either trypsin, chymotrypsin, or pronase in PBS
PBS containing 5% (v/v) fetal bovine serum (FBS)
Protease inhibitors, freshly prepared stocks:
  for trypsin: 100 mM (1000×) phenylmethylsulfonyl fluoride (PMSF) in methanol and 1 mg/ml (100×) trypsin inhibitor in PBS
  for chymotrypsin: 100 mM PMSF and 2 mg/ml (1000×) aprotinin in PBS
  for pronase: 100 mM PMSF and 10 mM (1000×) *N*-tosyl-lysine chloromethyl ketone (TLCK) in PBS
Lysis mixture (see recipe)
Antibody specific for protein of interest

Additional reagents and equipment for biotinylation of cell-surface proteins (Alternate Protocol 1), immunoprecipitation (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), pulse labeling (*UNIT 7.1*), and autoradiogarphy (*UNIT 6.3*)

Determine appropriate protease concentration

1. Label the protein pool at the plasma membrane by biotinylation (see Alternate Protocol 1).
2. Incubate labeled cells (usually one dish per condition or ~1 to 5×10^6 cells per condition) 30 min on ice in ~5 ml PBS with varying concentrations of proteases (0 to 10 mg/ml).

   Note that adherent cells will become detached by the protease treatment.
3. Remove soluble proteases by washing cells at least three times with 1 ml PBS containing 5% FBS each. Collect cells after each wash by centrifuging 3 min at 1500 × *g*, 4°C.

   Centrifugation is necessary because the cells will be detached by the protease treatment.
4. After the final wash, resuspend cells in a small volume of FBS (5×10^6 cells in 250 µl) and inactivate the proteases by adding the respective protease inhibitors at the correct 1× concentrations. Incubate the cells 10 min on ice. Centrifuge cells 5 min at 1500 × *g*, 4°C. Remove supernatant.

   Pronase should be removed by extensive washing.

   Adding protease inhibitors directly from stock solutions involves very small volumes (~0.25 µl); it is best if they are serially diluted to allow for more accurate pipetting.
5. Lyse cells with 1 ml lysis mixture containing the appropriate protease inhibitors at indicated 1× concentrations.
6. Isolate the desired protein by immunoprecipitation from equal numbers of cells (*UNIT 7.2*).
7. Analyze samples by SDS-PAGE (*UNITS 6.1*) followed by immunoblotting (*UNIT 6.2*) and incubation of the filters with avidin or streptavidin-coupled to peroxidase.
8. Detect the proteins with peroxidase-catalyzed reactions, preferably by chemiluminescence (e.g., enhanced chemiluminescence; ECL).

   This assay will determine the optimal concentration and the appropriate protease that will allow quantitative removal of surface protein without substantial cell destruction.

Measure protein arrival

9. Perform a pulse-chase experiment (*UNIT 7.1*).
10. Incubate cells from every chase time in the presence or absence of proteases under conditions determined above (steps 2 to 4).
11. Lyse cells (step 5), then immunoprecipitate proteins from equal numbers of cells (*UNIT 7.2*).
12. Analyze samples by SDS-PAGE (*UNIT 6.1*).
13. Fix gel and detect surface appearance by autoradiography (*UNIT 6.3*).

    Newly arrived protein will be trimmed (migrate faster by SDS-PAGE) or disappear due to protease activity.

ALTERNATE PROTOCOL 3

MEASURING ARRIVAL AT THE CELL SURFACE USING ANTIBODIES

Cell-surface appearance of proteins can also be analyzed by combining a pulse-chase experiment (*UNIT 7.1*) with incubation of antibodies with intact cells (Burke et al., 1984). After removal of unbound antibodies, the surface-protein population can be isolated and analyzed. Postlysis binding of intracellular proteins to the antibodies (which have two or more antigen-combining sites) should be prevented, and a control for this should be included in the analysis. To avoid this problem, it is preferable to use biotinylated Fab fragments instead of complete antibodies.

Materials

Cells
PBS (*APPENDIX 2A*), ice cold
Biotinylated Fab fragments of antibody specific for protein of interest (see Support Protocol 1) or complete antibody
PBS containing 5% (v/v) fetal bovine serum (FBS)
Unlabeled cells or antigen
Protein A–Sepharose *or* avidin- or streptavidin-coupled beads

Additional reagents and equipment for pulse labeling (*UNIT 7.1*), immunoprecipitation (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*), and autoradiography (*UNIT 6.3*)

1. Perform a pulse-chase experiment (*UNIT 7.1*); include at least one early chase-point at which the protein has not yet reached the plasma membrane (e.g., 10 min).

2. At each chase time, wash cells once with 1 ml ice-cold PBS, suspend cells in a small volume (sufficient to cover the cells) of PBS or culture medium with antibodies or biotinylated Fab fragments, and incubate 30 min on ice.

   Antibody or Fab should be added at a saturation concentration as determined by preliminary experiments.

   Biotinylated Fab fragments are preferred because they have only one binding site, but complete antibodies can be used. In the latter case, controls for postlysis binding should be performed (see step 4).

3. Remove unbound antibodies/Fab fragments by washing at least three times at 4°C with 1 ml PBS containing 5% FBS.

   If using biotinylated Fab fragments, proceed directly to step 5.

4. *If using intact antibodies:* Add a 10-fold excess of unlabeled cells or a 10- to 100-fold excess of antigen before lysis to prevent postlysis binding of intracellular radiolabeled proteins to the antibody.

   Most intact antibodies have two antigen-binding sites (up to ten for IgM), of which only one may be occupied by the surface protein. The others may thus capture antigen postlysis. Competition with nonradioactive antigen added exogenously is not necessary when Fab fragments are used.

   Control (and exclude) postlysis binding of antigen through the analysis of at least one early chase point (see step 1) that should not give precipitation of radiolabeled surface proteins.

5. Lyse (see Basic Protocol 1, step 6), clear by centrifuging 10 min at 10,000 × *g*, 4°C, and add 20 µl protein A–Sepharose (when using antibodies) or streptavidin- or avidin-coupled beads (when using biotinylated Fab fragments) to the lysate. Follow a normal immunoprecipitation protocol (*UNIT 7.2*).

6. Analyze immunoprecipitates by SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*).

PREPARATION OF BIOTINYLATED FAB FRAGMENTS

The production of biotinylated Fab antibody fragments requires some time investment. However, the investment is easily rewarded because they can be used for multiple surface-appearance studies (see Alternate Protocol 3) and internalization experiments. Papain appears to be an ideal protease, cleaving between the Fc and Fab portions of the antibody. Since papain is a cysteine protease, it first has to be activated (by reducing the active-site cysteine) and then titrated to establish the optimal conditions for Ig digestion (also see *UNIT 16.4*).

Materials

23 mg/ml papain in 70% ethanol
25 and 40 mM sodium acetate buffer, pH 4.5 (*APPENDIX 2A*)
2-Mercaptoethanol
100 mM sodium acetate buffer, pH 5.5 (*APPENDIX 2A*)
Protein A– or G–purified antibody (*UNIT 16.3*)
150 mM NaCl/5 mM EDTA/100 mM Tris·Cl, pH 8.0
Dithiothreitol (DTT)
Iodoacetamide (store protected from light and moisture)
50 mM $NaHCO_3$ buffer, pH 8.5
Sulfo-*N*-hydroxysuccinimidyl-6-biotinamido-hexanoate (sulfo-NHS-SS-biotin; Pierce)
10 mM Na_3PO_4, pH 7.4/150 mM NaCl buffer

Sephadex G-25 column
Centricon-30 (Amicon)

Additional reagents and equipment for dialysis (*APPENDIX 3C*), SDS-PAGE (*UNIT 6.1*), and standard anion or cation exchange chromatography (*UNIT 16.4*)

Activate papain

1. Dilute 23 mg/ml papain stock with 25 mM sodium acetate buffer, pH 4.5, to a final papain concentration of 8 mg/ml.

   Ready-to-use kits for activation of papain are available from Pierce.

2. Add 6 µl of 2-mercaptoethanol to 200 µl diluted papain and 400 µl of 40 mM sodium acetate buffer, pH 4.5. Incubate 20 to 30 min at 4°C.

   2-ME is added to activate the papain.

3. Equilibrate and elute a 10-ml Sephadex G-25 column with 20 ml of 100 mM sodium acetate buffer, pH 5.5.

4. Run the activated papain solution over the column to remove various impurities from papain. Pool fractions with the highest protein concentration by measuring the absorbance at 280 nm.

Digest antibody

5. Dialyze protein A– or G–purified antibody against three changes of 200 ml of 150 mM NaCl/5 mM EDTA/100 mM Tris·Cl, pH 8.0.

6. Add 1 to 2 mM DTT prior to digestion.

7. Mix antibody and activated papain. Incubate at 4°C or room temperature.

   The efficiency of cleavage depends on the antibody isotype. It is thus best to vary the digestion period, the temperature, and the concentration of papain to determine optimal conditions for digesting the antibody of interest.

   The ratio of papain to antibody is usually between 1:50 and 1:200 for time points between 1 and 24 hr.

8. Stop reaction by adding iodoacetamide to a final concentration of 2 mM.
9. Check the digestion by analyzing an aliquot 12% SDS-PAGE (*UNIT 6.1*).

Isolate Fab fragments

10. Separate the Fab fragment from the Fc fragment by standard anion or cation exchange chromatography (*UNIT 16.4*).

    The Fc fragment will be selectively retained by an anion-exchange column, whereas the Fab fragment will be retained by a cation-exchange column and will only elute with high salt.

11. Check separation by SDS-PAGE under reducing and nonreducing conditions (*UNIT 6.1*).

    The Fc fragment contains an intrachain disulfide bridge and contaminations can best be visualized under nonreducing conditions.

Biotinylate Fab fragments

12. Dialyze the Fab fragments with three changes of 200 ml of 50 mM $NaHCO_3$ buffer, pH 8.5.
13. Add a ten-fold molar excess of sulfo-NHS-SS-biotin and incubate 2 hr at 4°C.
14. Remove unreacted biotin by centrifugation through a Centricon-30 concentrator according to manufacturers' instructions.
15. Dilute the sample in 10 ml of 10 mM Na_3PO_4, pH 7.4/150 mM NaCl buffer and centrifuge two successive times through the Centricon-30 concentrator to remove unreacted biotin.
16. Store labeled Fab at a concentration of 10 mg/ml in 50- to 100-µl aliquots at −80°C.

BASIC PROTOCOL 2

MEASURING TRANSPORT TO ENDOSOMES BEFORE PLASMA MEMBRANE APPEARANCE

Some proteins, like class II molecules of the major histocompatibility complex, first enter the endocytic pathway before they appear at the plasma membrane (Neefjes et al., 1990). A variation on the sialidase protection assay, described in Basic Protocol 1, has been used to visualize this on intact cells. Plasma membrane, but not endosomal, glycoproteins can be desialylated by sialidase treatment at 4°C on intact cells, whereas both protein pools are digested by sialidase that has entered the endocytic pathway by fluid-phase endocytosis at 37°C. A comparison of the number of sialic acids on glycoproteins from cells incubated under these conditions will allow determination of the localization of proteins in the ER/Golgi (not sialylated in the control situation), the TGN (sialylated under all conditions), endosomes (desialylated by endocytosed sialidase only), and the plasma membrane (desialylated by sialidase at 4°C and in the medium). Combined with a pulse-chase experiment, this will allow the positioning of the protein in the respective compartments at any time during the chase period. Entry in endosomes *before* arrival at the plasma membrane is indicative of direct transport from TGN to endosomes (see Neefjes et al., 1990). However, very rapid transit of the protein over the plasma membrane is still possible, and chase points should be selected carefully for validating the direct transport (without intersection with the plasma membrane) from TGN to endosomes.

Materials

Cells
Sialidase Type V from *Clostridium perfringens* (Sigma), dissolved in PBS and stored in aliquots at −20°C
Normal culture medium with 0.1% (w/v) BSA and no FBS
PBS (*APPENDIX 2A*) containing 10% (v/v) fetal bovine serum (FBS), ice-cold
Lysis mixture (see recipe)
Fetuin

Additional reagents and equipment for pulse labeling and TCA precipitation (*UNIT 7.1*), immunoprecipitation (*UNIT 7.2*), one-dimensional IEF (see Support Protocol 2), SDS-PAGE (*UNIT 6.1*), and autoradiography (*UNIT 6.3*)

1. Perform a pulse-chase experiment (*UNIT 7.1*); follow a 10- to 15-min labeling period with chases of 0, 15, 30, 60, 120, and 240 min.

   In this experiment, three conditions are tested at each chase point: (1) cells will be cultured after the radioactive labeling and analyzed at each chase point without further treatment to determine entry in the TGN; (2) cells will be treated with sialidase at 4°C to show appearance at the plasma membrane; (3) and cells will be cultured after the pulse in the presence of sialidase that will enter the endocytic pathway and thus desialylate endosomal and plasma-membrane proteins.

   For adherent cells, label three plates per chase point. Use ~5×10^6 cells per chase point per condition.

2. Split the cell culture at the beginning of the chase into two aliquots or use different dishes for the various conditions. Culture one set of cells at 37°C in culture medium containing 0.1% BSA and sialidase at a final concentration of 1 IU/ml to allow entry of sialidase in the endocytic route. Culture the other half of the cells in culture medium with 0.1% BSA alone.

   The culture medium should not contain fetal bovine serum (which has many sialylated proteins), but should contain 0.1% (w/v) BSA (which is not glycosylated).

   Cells like B lymphocytes that endocytose only small volumes may require higher concentrations of sialidase.

3. At every chase point divide the sample of the cells cultured in the medium/BSA alone (step 2) into two equal portions and incubate 1 hr at 4°C (or use two dishes), wash the cells, add PBS/$CaCl_2$ with or without 1 IU/ml sialidase. Also incubate the sample that was cultured in the presence of sialidase (step 2) for an additional 1 hr at 4°C.

   Include in the assay one sample that is not radiolabeled but is cultured in the presence of sialidase. These cells will be mixed with control radiolabeled cells before washing and lysis to verify complete removal of sialidase activity (because the sialidase should not act postlysis).

4. Remove sialidase by washing the cells three times with 1 ml ice-cold PBS containing 10% FBS.

5. Lyse cells in 1 ml lysis mixture containing 1 to 10 mg/ml fetuin.

   Fetuin is highly sialylated (for further inhibition of sialidase) and has a neutral pH. Thus, unlike free sialic acids, it will not increase the background during the immunoprecipitation procedure.

6. Determine the amount of radioactivity incorporated by TCA precipitation of 10 µl of each lysate (*UNIT 7.1*). Isolate proteins by immunoprecipitation (*UNIT 7.2*) from lysates containing equal amounts of TCA-precipitable radioactivity.

7. Analyze immunoprecipitates by one-dimensional IEF (see Support Protocol 2) or SDS-PAGE (*UNIT 6.1*).

   For best comparison, analyze the three conditions (control, sialidase 4°C, and sialidase 37°C) side by side on the gel. The protein has entered the TGN when the carbohydrate acquires terminal sialic acids that are not removed by the different sialidase treatments. The protein has entered endosomes when desialylated by the sialidase added to the chase medium, but not by the sialidase treatment at 4°C. Finally, the protein has reached the plasma membrane when it is a substrate for sialidase both in the culture medium and at 4°C.

SUPPORT PROTOCOL 2

SEPARATION OF PROTEINS BY CHARGE USING DENATURING ONE-DIMENSIONAL ISOELECTRIC FOCUSING

For one-dimensional IEF a 4% polyacrylamide gel is used to avoid separation by size (Neefjes et al., 1986). This requires careful handling of the gels during the preparation, run, and fixation. This protocol is for gels of ~55 ml.

Materials

0.8% (w/v) agarose in water
Urea
10% (v/v) Triton X-100 or Igepal CA-630 (Sigma)
30% (w/v) acrylamide/1.6% (w/v) bisacrylamide solution
Ampholytes (Pharmacia Biotech)
10% (w/v) ammonium persulfate
N,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED)
Isoelectric focusing sample buffer (see recipe)
Immunoprecipitates (see Basic Protocol 1 or see Basic Protocol 2)
20 mM H_3PO_4
Bromphenol blue
50 mM NaOH

30 × 19–cm glass plates
1-mm spacers
20-well Teflon comb
Vertical gel chamber

Additional reagents and equipment for gel electrophoresis (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

Prepare IEF gel

1. Assemble electrophoresis apparatus using 30 × 19–cm glass plates with 1-mm spacers. To prevent the gel from slipping between the glass plates, place spacers slightly tilted towards each other with the narrow side toward the bottom. Apply 0.8% (w/v) agarose outside spacers, between the glass plates, to prevent leakage.

2. Prepare 55 ml gel solution by mixing the following reagents. Dissolve urea by gently shaking the solution under hot tap water.

   30.25 g urea
   11 ml 10% Triton X-100 or Igepal CA-630
   8.25 ml 30% acrylamide/1.6% bisacrylamide solution
   12.1 ml H_2O.

   Do not dissolve urea in a microwave or by boiling as this can result in evaporation and crystalization of the urea after polymerization of the gel.

3. Add ampholytes after solubilization of the urea.

   The mixture of ampholytes determines the pH gradient over the gel. The author generally uses 2.2 ml of pH 5.7 ampholytes, 550 µl of pH 3.5 to 10 ampholytes, and 220 µl of pH 7 to 9 ampholytes.

4. Polymerize the gel by adding 200 µl of 10% ammonium persulfate and 100 µl TEMED.

5. Pour gel mixture between the preassembled plates and insert a 20-well Teflon comb. Allow to solidify.

   The gel usually takes ~30 min to solidify.

6. Place gel in a vertical gel chamber. Fill lower chamber with 20 mM H_3PO_4.

Prepare samples and run gel

7. Incubate immunoprecipitates ≥5 min at room temperature with isoelectric focusing sample buffer and load samples.

8. Before addition of the upper buffer, load a small layer of 3-fold diluted isoelectric focusing sample buffer with ~1 (% or mg/ml) bromphenol blue.

   This is to prevent hydrolysis of asparagine and glutamine side chains by the NaOH in the upper gel chamber.

   The bromphenol blue will indicate the extent of the run but is not strictly necessary.

9. Carefully fill the upper chamber with 50 mM NaOH.

10. Run the gel overnight at 1000 V. Limit power such that the run starts at ~300 to 400 V and increases to a maximum of 1000 V.

    This will prevent heating and melting of the gel. The voltage will swiftly rise due to increased resistance. Smaller gels should be run at a lower limiting voltage; e.g., a gel 15 cm wide should be run at ~600 V with the power set such that the run starts at ~200 V.

11. Fix gel and expose for autoradiography (*UNIT 6.3*).

    The gel is very sloppy. Do not take the gel off the glass plates, but rather turn the glass plates around over the fixative. The gel will then fall into the fixative. Perform a similar procedure for transfer of the gel to Whatman 3MM paper prior to drying the gel.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Isoelectric focusing sample buffer

9.5 M urea
2% (w/v) Triton X-100 or Igepal CA-630 (Sigma)
2% (v/v) ampholytes (Pharmacia Biotech), pH 3.5 to 10
5% (v/v) 2-mercaptoethanol
Store 1-ml aliquots at −20°C

Lysis mixture

50 mM Tris·Cl, pH 7.5AS (*APPENDIX 2A*)
150 mM NaCl
5 mM $MgCl_2$
0.5% (w/v) detergent
Store at 4°C

The choice of detergent depends on the experiment. For stable protein complexes the author routinely uses 0.5% Igepal CA-630 (Sigma) or Triton X-100. For more unstable protein complexes, 0.5% digitonin or 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS) should be used.

COMMENTARY

Background Information

Plasma-membrane proteins are synthesized in the ER. Here they have to fold properly and assemble before they are allowed to pass the "quality control system" of the ER and enter the Golgi complex. The folding and assembly steps are rate limiting and can vary considerably between different proteins, although some variability in transport rates through the Golgi complex occurs as well. Consequently, the rate of surface appearance can vary from 10 to 15 min up to many hours, even for proteins belonging to the same family such as MHC class I alleles (Neefjes and Ploegh, 1988). These differences cannot be predicted and can only be experimentally determined.

Many endosomal and lysosomal proteins are transported to their final destination by transient trafficking through the plasma membrane. Because proteins are only briefly at the plasma membrane before endocytosis, it is very hard to distinguish between direct sorting at the TGN for the endocytic pathway and an indirect route involving transport over the plasma membrane. In addition, the two routes are not mutually exclusive. For example, the process of sorting at the TGN appears to be saturable (Marks et al., 1996) and overexpression of endosomal proteins may easily result in transient cell-surface appearance. Transient transport over the plasma membrane can best be visualized by slowing or inhibiting endocytosis in combination with the techniques described in this unit for detection of cell-surface appearance. However, easy and reproducible techniques for selectively inhibiting endocytosis have not been developed yet.

Several different techniques to selectively tag the surface population of glycoproteins have been described in this unit. All of these techniques consist of combinations of pulse-chase experiments and chemical or enzymatic modification on intact cells. These techniques require that the modifications are quantitative and readily inhibitable. In addition, optimal conditions for the modifications should be determined prior to the experiment. Internal controls excluding postlysis modifications should always be included in the experiments. The different experimental protocols all have advantages and disadvantages as discussed below.

Biotinylation of intact cells to tag the cell-surface protein pool is an efficient way to visualize cell-surface arrival (see Alternate Protocol 1). Postlysis biotinylation does not occur. Since the modification is not quantitative, the unmodified pool of proteins contains intracellular as well as cell-surface proteins. The assay employing sialidase to remove the sialic acids at the plasma membrane (see Basic Protocol 1) is quantitative and thus makes it possible to distinguish the intracellular from the cell-surface pool. However, the sialidase treatment protocol is more laborious. Furthermore, the effect of desialylation is not always obvious upon analysis by SDS-PAGE and often requires analysis by one-dimensional IEF or two-dimensional IEF/SDS-PAGE, techniques that are more time consuming.

Protease removal of cell-surface proteins (Alternate Protocol 2) is another alternative, but the usefulness of this technique depends on the sensitivity of the target protein. The optimal concentration and type of protease have to be defined first. If proteolysis requires high concentrations of protease, cell death and DNA release may be observed, which may complicate the interpretation of the experiment. In addition, some remnants of proteolytic activity in the lysate may obscure the results. Unless the protein is sensitive and accessible to a particular protease, this assay will not easily result in quantitative removal of cell-surface proteins.

Finally, biotinylated Fab fragments are an easy tool to follow specifically the surface appearance of proteins by combining a pulse-chase protocol with surface binding (Alternate Protocol 3). However, the generation and biotinylation of Fab fragments is laborious. Complete (bivalent) antibodies may be a more convenient alternative for immunoprecipitation of proteins expressed at the cell surface, but postlysis binding of antigen should be excluded.

Critical Parameters and Troubleshooting

All the protocols presented in this unit require a pulse-chase experiment in combination

with detection of cell-surface appearance. When early events (folding or assembly) are followed, label for 5 min and chase 0, 5, 10, 20, 30, and 60 min. Early folding events may be traced by labeling for 1 min and chasing for 0, 1, 2, 4, 7, and 10 min. For transport processes to the plasma membrane, the author usually labels cells for 15 min followed by chases of 0, 15, 30, 60, 120, and 240 min. Proteins should be sufficiently labeled so as to effectively visualize them after each incubation step. If they are not, use more cells for the pulse labeling, increase the pulse time, and/or add more radioactive amino acid. The concentration of radioactive amino acids during the pulse may be increased by simply performing the pulse in a smaller volume. Starve the cells for 30 to 45 min prior to the pulse in culture medium devoid of the amino acid used for radioactive labeling of the cells. Include 10% fetal bovine serum in this starvation medium; the cells will then be more viable and will incorporate higher amounts of radioactivity. [^{35}S]Methionine and/or cysteine are usually employed for biosynthetic labeling. If proteins are poor in these amino acids, consider pulse labeling the cells with other amino acids (see *UNIT 7.1*).

It is essential to keep the cells viable and intact during the different incubation and washing steps. Gentle centrifugation (e.g., $400 \times g$) during the washing procedures improves the intactness and recovery of the cells. Cells can best be resuspended after removal of the supernatant by simply tapping against the microcentrifuge tube. Addition of 0.1% (w/v) bovine serum albumin or 5% to 10% (v/v) fetal bovine serum to the washing buffer may also increase viability and recovery of the cells.

Biotinylation of intact cells (Alternate Protocol 1) to label surface proteins is a convenient assay although it is not quantitative. However, this protocol is useful for establishing when and at what rate proteins appear at the plasma membrane, provided that identical conditions are used to treat the samples. The decrease in intracellular protein pool cannot be easily determined when, for example, 20% of the surface proteins are biotinylated. Higher concentrations of the biotinylation reagent increase the efficiency of labeling, but such experiments require relatively large amounts of reagent and are very expensive. When biotin labeling is poor, wash cells more carefully to remove competing proteins from the medium.

The sialidase treatment of intact cells (Basic Protocol 1) to detect surface appearance requires establishing the conditions for full desialylation. The conditions for inactivation/removal of sialidase should be internally controlled. The conditions described usually result in quantitative removal of sialic acids on nonadherent cells. Adherent cells can be detached from the culture plates before the sialidase treatment to ensure complete desialylation. Although this is usually not necessary, it ensures complete desialylation. Free sialic acids should not be included in the lysis buffers for inactivation of sialidase because this acidifies the buffer and thus increases the background of the immunoprecipitation. Fetuin (which is a highly sialylated glycoprotein) inhibits sialidase without changing the pH of the lysis buffer.

One-dimensional IEF to separate different sialylated forms of a protein (Support Protocol 2) is a powerful but difficult technique. Always place the spacers on the sides slightly tilted towards each other to prevent the gel from slipping into the lower chamber. Also be careful not to allow direct contact between the lower and upper gel chambers, e.g., along the spacers. If this happens, the gel will become very hot and the glass plates may break. The author often adds a small drop of agarose to the corners of the gel contacting the spacers to prevent leakage and direct contact between the upper and lower buffer. One-dimensional IEF gels are very fragile and can easily break. Handle gels carefully and never pick them up with your hands. Most fixatives will not make the gel stronger. One clear exception is fixation in dimethyl sulfoxide/2,5-diphenyloxazole (DMSO/PPO), but this is no longer regularly used.

The use of proteases (Alternate Protocol 2) also requires titration to determine the optimal conditions. Often, cell destruction is observed and the resulting released DNA interferes with the experiments. This protocol is not suitable for all proteins, as many proteins are very resistant to proteases or are only degraded under conditions that also destroy the intact cell. If so, try to use other proteases that more selectively degrade the surface protein without resulting in significant cell damage. Most commercial proteases have selective and efficient inhibitors. However, this may be a problem for protease cocktails like pronase, which should not be used for cell-surface appearance experiments.

The production of the biotinylated Fab fragments (Support Protocol 1) is somewhat time consuming and requires isolation of reasonably large quantities of antibodies before the papain digestion can be performed. Ready-to-use kits

are available for this. Biotinylated Fab fragments may result in easy isolation of the surface pool of proteins. The unbound fraction may not necessarily be the intracellular fraction unless it is shown that *all* surface proteins were captured by the Fab fragment. To test this, take a late chase point (e.g., 6 hr) and show experimentally that the radioactive protein is quantitatively recovered. It is preferable to not use intact multivalent antibodies because they may induce internalization by cross-linking two or more antigens, and they may easily bind antigens postlysis.

Anticipated Results

Sialidase treatment is the most sensitive and quantitative of the assays described and allows analysis of surface appearance when the chase times are correctly chosen. SDS-PAGE may show a shift in apparent molecular weight. Otherwise, one-dimensional IEF or two-dimensional IEF/SDS-PAGE should be used. Combining a pulse-chase experiment with treatment of cells at 4°C and 37°C (see Basic Protocol 2) allows biochemical detection of the localization of the glycoprotein in pre-Golgi, TGN, endosomes, and plasma membrane.

The biotinylation protocol does not quantitatively modify all proteins at the plasma membrane, but it is still a very practical way to determine cell-surface appearance. Quantitative biotinylation is not required. The isolates can be analyzed by normal SDS-PAGE and surface appearance can be efficiently seen.

Protease treatment of intact cells to remove the plasma-membrane protein pool is possible for protease-sensitive proteins, but it is difficult to verify that the digested protein is obtained from equal numbers of cells/proteins.

Cell-surface immunoisolation by Fab fragments is an efficient way to show cell-surface appearance. The pulse-chase can be analyzed by SDS-PAGE prior to and after Fab isolation and the rate of cell-surface appearance of the protein of interest can be easily determined.

Time Considerations

Most assays described in this unit are relatively laborious. Pulse-chase experiments combined with protease/sialidase/biotin treatment, TCA precipitation for quantitation and immunoprecipitation, followed by SDS-PAGE or one-dimensional IEF take ≥3 days before the result can be seen. The preparation of the biotinylated Fab fragments is time consuming (~2 to 3 days) but clearly worth the effort when used for multiple experiments.

Analysis of Membrane Traffic in Polarized Epithelial Cells

Spatial asymmetry is fundamental to the structure and function of most eukaryotic cells (Drubin and Nelson, 1996). A basic aspect of this polarity is that the cell's plasma membrane is divided into discrete domains. The best studied and simplest example of this occurs in epithelial cells, which line exposed body surfaces (Matter and Mellman, 1994; Mostov et al., 1999, 2000). Epithelial cells have an apical surface facing the outside world and a basolateral surface contacting adjacent cells and the underlying connective tissue. These surfaces have completely different compositions and are separated by tight junctions, which block movement of plasma membrane proteins between the apical and basolateral surfaces and also prevent diffusion of extracellular material between cells. Epithelial cells use two pathways to send proteins to the cell surface. Newly made proteins can travel directly from the trans-Golgi network (TGN) to either the apical or basolateral surface. Alternatively, proteins can be sent to the basolateral surface and then endocytosed and transcytosed to the apical surface. A schematic view of a simple polarized epithelial cell is given in Figure 15.5.1.

Studies on membrane traffic in polarized epithelial cells have been greatly facilitated by the use of cell lines grown as a well-polarized monolayer. The most widely utilized of these is the Madin-Darby canine kidney (MDCK) cell line. Other cell lines that have been used for studying polarized membrane traffic include Caco-2 (human intestinal cancer) and FRTL (Fischer rat thyroid; Weimbs et al., 1997). Table 15.5.1 summarizes the cell lines most commonly used in studies of membrane traffic in polarized epithelial cells. Generally these cell lines are maintained by growing adherent cells in standard cell culture plastic dishes or flasks; however, for the actual experiments in which polarized traffic is assessed, the cells are usually grown on porous filters. Such filters are available mounted in holders sold by several manufacturers, including Corning, Falcon, and Nunc. These devices come in several sizes and are available with pores of different diameters. Most of the work done by the authors has been with 12-mm Corning Transwells with filters containing pores of 0.4-μm diameter. Table 15.5.2 lists the main types of units that are commercially available.

The usual type of study is to examine the biosynthetic delivery of a membrane or secreted protein to the apical or basolateral surface (see Basic Protocol 2). This sort of experiment is quite similar to studying the delivery of proteins to the surface of nonpolarized cells, as described in *UNIT 15.4*, with the principal difference being that delivery to either the apical or basolateral surface is measured, as opposed to the plasma membrane as a whole. Although MDCK cells contain numerous endogenous apical and basolateral plasma membrane proteins, these are usually expressed at very low levels, making it difficult to study the trafficking of any individual protein. Additionally, one often wishes to examine the polarized localization or trafficking of a protein that may not be expressed endogenously in MDCK cells; therefore, one typically begins a project by transfecting cDNA for the protein of interest into MDCK cells in order to overexpress the protein for study (see Basic Protocol 1). Most of the authors' experience is with the calcium phosphate-based transfection system (see Basic Protocol 1; Breitfeld et al., 1989). Cells can be transfected by other methods, including various commercially available lipid-based transfection reagents (e.g., Lipofectamine 2000) or by electroporation. Although transient transfection and expression systems can be used, in many cases the fraction of cells expressing the protein of interest is very low, and the cells that express the transfected protein tend to be less well polarized in part because the process of polarization takes 4

Current Protocols in Cell Biology (2001) 15.5.1-15.5.18

to 7 days, whereas transient protein expression generally peaks at 48 hr and is often gone by 72 hr; therefore, in most cases it is advisable to generate stable clones (see Support Protocol 1). These clones are then expanded for further use by growing on standard tissue culture dishes. For studies of membrane traffic the cells must be cultured on filter units (see Support Protocol 2). It is important to check that the cells form a tight, well-polarized monolayer on the filter. Several methods are available to do this, and a particularly easy method is presented in this unit (see Support Protocol 3). A cell surface biotinylation assay to measure delivery of proteins is presented (Basic Protocol 3; Luton and Mostov, 1999). As the study of polarized membrane traffic is fundamentally the study of the localization of proteins, it is extremely useful to visualize the location of proteins in the epithelial cell. In addition, a fixation method to use for laser scanning confocal immunofluorescence

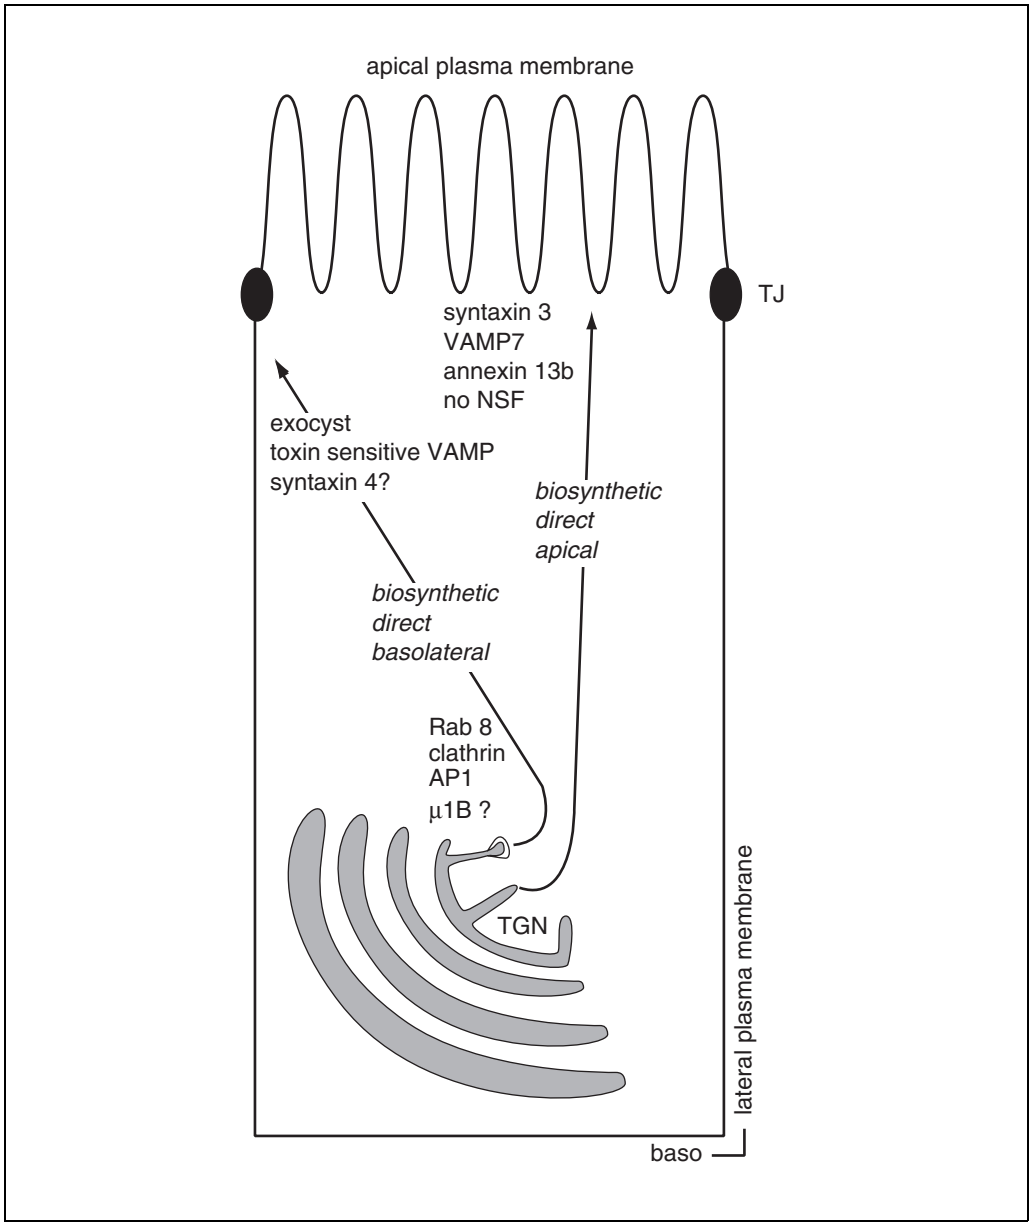

Figure 15.5.1 Schematic diagram of a polarized epithelial cell. Only the major biosynthetic pathways leading directly from the TGN to the apical and basolateral surfaces are shown. Components of the membrane traffic machinery that are likely to be involved in each of these two pathways are also indicated. For further details, see Mostov et al. (2000). Abbreviations: TGN, trans-Golgi network; TJ, tight junction.

Table 15.5.1 Cell Lines Commonly Used to Study Epithelial Membrane Traffic in Polarized Epithelial Cells

Cell line	Origin	Comments	ATCC#[a]
MDCK	Canine kidney	Most widely used. Two major categories, types I and II, though many clones with specific phenotypes.	CCL-34
Caco-2	Human intestine	Although derived from human colon cancer, more closely resembles small intestine. Slow growing.	HTB-37
FRTL	Rat thyroid	Some glycolipids and GPI-anchored proteins are found at the basolateral surface, unlike other epithelial cells.	CRL-1468

[a]The ATCC home page can be reached at *http://www.atcc.org.*

Table 15.5.2 Commercially Available Filters for Growth of Epithelial Cells

Material	Manufacturer	Comments
Polycarbonate	Corning Millipore BD Biosciences Labware Nalge Nunc International	Most widely used
PTFE/FP	Millipore Corning BD Biosciences Labware	Good optics. Coating with extracellular matrix (ECM) is usually required; can be purchased precoated
PET	BD Biosciences Labware	Available in different pore densities, with low density having better optical properties, but lower porosity. Available precoated with several types of ECM
Anopore	Nalge Nunc International	Very low intrinsic fluorescence, well-suited for immunofluorescence microscopy
Cellulose esters	Millipore	High protein binding
Polyester	Corning	Good optics

microscopy of proteins in polarized epithelial cells is also presented (see Basic Protocol 4; Luton and Mostov, 1999).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly (e.g., use of a sterile hood).

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) require altered levels of CO_2 to maintain pH.

BASIC PROTOCOL 1

TRANSFECTION OF POLARIZED EPITHELIAL CELLS IN SUSPENSION AND SELECTION OF RESISTANT CLONES

The goal of this protocol is to transfect a plasmid containing the gene of interest into mammalian epithelial cells under a suitable promoter (i.e., a CMV promoter). This protocol provides the basis for the other experimental protocols described.

Materials

Confluent cells grown on 10-cm tissue culture dish
HEPES buffered saline (HeBS), pH 7.05 (see recipe; also see *APPENDIX 2A*)
20 µg plasmid DNA in 1 to 20 µl H_2O
2 M $CaCl_2$: filter sterilize and store up to 6 months at 4°C
CMF-DPBS (*APPENDIX 2A*)
Trypsin/EDTA solution—e.g., 0.25% (w/v) trypsin/0.2% (w/v) EDTA (*UNIT 1.1*)
MEM medium (*APPENDIX 2B*) with and without 5% (v/v) FBS (*APPENDIX 2A*)
20 mM chloroquine in water: filter sterilize and store up to 6 months at 4°C
15% (w/v) glycerol in HeBS: filter sterilize and store up to 6 months at 4°C
Selection medium: MEM/5% FBS containing eukaryotic antibiotic (e.g., G418; see recipe)
Nontransfected cells
10-cm dishes

Additional reagents and equipment for picking clones (see Support Protocol 1)

Transfect cells

1. Split cells grown on a 10-cm dish 1:10 on the day prior to transfection in order to yield ~30% confluency on the day of transfection.
2. To 0.5 ml HEPES buffered saline (HeBS), pH 7.05, add 20 µg plasmid DNA in 1 to 20 µl water, and 31 µl of 2.0 M $CaCl_2$. Flick the tube for 20 sec.

   The pH of the HeBS has to be exact for a good precipitate to form.

   This step should be done in a sterile hood.
3. Incubate the plasmid at room temperature for 30 min, avoiding any unnecessary shaking of the sample.
4. Trypsinize one subconfluent (i.e., ~30% confluent or ~1×10^7 cells) 10-cm dish of cells by adding 1 to 2 ml of trypsin/EDTA solution after washing with CMF-DPBS.

   For trypsinization of MDCK cells, use 0.25% (w/v) trypsin/0.2% (w/v) EDTA. The desired concentration of cells is ~0.5 to 1 × 10^6 cells/ml.
5. Centrifuge cells for 3 min at 300 × *g*, room temperature. Resuspend in 5 ml MEM medium with 5% FBS.
6. Transfer 1 ml of the cell suspension into a 10-cm dish.
7. Slowly add 500 µl DNA-Ca^{2+} coprecipitate (step 3) while simultaneously agitating the 10-cm dish. Incubate at room temperature for 15 to 20 min.
8. Add 50 µl of 20 mM chloroquine (200 µM final) to 3.5 ml MEM/5% FBS. Add the MEM/FBS/chloroquine mixture to the dish and agitate to spread cells.
9. Incubate 6 to 18 hr (e.g., overnight) at 37°C in order to allow the cells to attach to the dish.

Plate transfected cells

10. Remove the medium. Wash once with chloroquine-containing medium (see step 8).
11. Add 2 ml of 15% glycerol in HeBS gently. Incubate exactly 1 min at 37°C.
12. Remove glycerol by washing gently twice with MEM without FBS, and then adding 10 ml MEM/5% FBS.
13. Allow cells to grow 2 to 3 days at 37°C, until dish is confluent.

    Don't allow the cells to grow >3 days, even if the dish is not yet confluent as this will result in an overgrowth of nontransfected cells. The important thing is to allow the cells to divide several times.

14. Trypsinize the cells (step 4), and resuspend in 10 ml selection medium. As a control, use nontransfected cells.

Clone cells

15. Split the cells into 7 different dilutions in 10-cm dishes:

Cell suspension (ml)	0.025	0.05	0.1	0.2	0.4	0.8
Selection medium (ml)	9.975	9.95	9.9	9.8	9.6	9.2

    Shake to distribute cells evenly.

Select stably transfected cells

16. Incubate cells at 37°C for 16 to 21 days (i.e., until the colonies are big enough to pick), adding fresh selection medium every 4 to 6 days.

    Depending on the stability of the selection agent, it may not be necessary to change the medium.

    Cells will start to die after 3 to 5 days and colonies should be seen within 10 to 14 days, but will not be big enough to pick until after 16 to 21 days.

17. Clones should generally be picked from the dishes with the highest dilution possible (see Support Protocol 1).

    Dilutions in which 0.4 or 0.8 ml cells were used can usually serve as the pooled clones.

PICKING STABLY TRANSFECTED CLONES

SUPPORT PROTOCOL 1

The goal in this protocol is to identify and stably propagate epithelial cell clones that express the gene of interest.

Additional Materials *(also see Basic Protocol 1)*

~16-day-old 10-cm dishes containing diluted transfected and nontransfected cells in selection medium (see Basic Protocol 1)
Calcium- and magnesium-free DPBS (CMF-DPBS; *APPENDIX 2A*)
Medium-sized glass cloning ring, sterile (Bellco Glass)
0.5% (w/v) SDS lysis buffer
12% (w/v) slurry of CL-2B beads
12-well tissue culture plates

1. Examine ~16-day-old 10-cm dishes containing diluted transfected and nontransfected cells in selection medium, looking for single colonies. With a marker, draw a circle around the single colonies on the outside bottom of the dishes.

If the original 10-cm dishes (i.e., the one which was split into seven different dilutions; see Basic Protocol 1, step 15) was ~30% confluent, single colonies are generally found in the dilutions in which 0.025 to 0.2 ml cells were used.

2. Wash dishes with 10 ml CMF-DPBS.
3. Use a Pasteur pipet attached to a vacuum device to aspirate a "dry" ring (i.e., devoid of liquid) around a single colony.

   The "dry" ring will prevent trypsin from leaking under the cloning ring in step 4. Do this procedure for each colony individually, as the cells will dry out if more than one colony is harvested at a time.

4. Place a medium-sized sterile glass cloning ring around the colony. Add trypsin/EDTA solution until the cloning ring is filled. Repeat steps 3 and 4 for all colonies to be picked.

   For epithelial cells (e.g., MDCK), use 0.25% trypsin and 0.2% EDTA.

   At least 15 clones should be picked, though more is preferable (i.e., 50 if possible).

5. After all the cloning rings have been placed, incubate for ~20 min at room temperature in a sterile hood.
6. Remove the trypsin containing the loose cells and add to the well (i.e., 1 colony per well) of a 12-well tissue culture plate containing 2 ml selection medium. Repeat for all colonies.
7. Resuspend cells by pipetting up and down several times. Transfer 1 ml from each well to the corresponding well of a new 12-well plate (one plate will be for protein collection and the other for colony expansion).
8. Incubate to confluency (i.e., ~5 to 7 days) at 37°C.

   It is generally not necessary to change the medium if the cells are harvested as soon as they are confluent.

   The length of time to confluency depends on how many loose cells are transferred in good condition to the wells. This can vary significantly from well to well.

9. Add 500 µl 0.5% SDS lysis buffer, boil the samples 5 min at 100°C. Vortex samples 10 min. Preclear the samples by adding 20 µl of a 12% slurry of CL-2B beads. Mix several times. Microcentrifuge briefly at maximum speed. Collect supernatant and use an aliquot for immunoblotting (*UNIT 6.2*).
10. For the colonies that show expression, use the second identical well to expand the cells.

    The authors recommend keeping the cells under selection while expanding the colony size.

SUPPORT PROTOCOL 2

CULTURE OF EPITHELIAL CELLS ON FILTERS

The goal in this protocol is to allow epithelial cells to become fully polarized. This is accomplished by culturing epithelial cells on porous filters that allow the cells to access medium both apically and basolaterally.

Additional Materials *(also see Basic Protocol 1 and Support Protocol 1)*

10-cm dish of confluent epithelial cells (Table 15.5.1)
12-mm Transwell filters and appropriate dishes
IEC clinical centrifuge with 12 × 15 rotor

Additional reagents and equipment for determining the tightness of epithelial monolayers (see Support Protocol 3)

1. Wash a 10-cm dish of confluent epithelial cells with 10 ml CMF-PBS.
2. Add 3 ml trypsin/EDTA solution (e.g., 0.25% trypsin/0.2% EDTA for MDCK cells) and incubate at 37°C for 15 min.
3. Tap dish to agitate cells. When all cells are detached, add 8 ml MEM/5% FBS.

   This step is done in order to neutralize the trypsin.
4. Transfer to an appropriate tube and centrifuge cells 3 min at 300 × *g* (e.g., 1000 rpm in an IEC 12 × 15 rotor), room temperature. Discard the supernatant.
5. Resuspend cells in 10 ml MEM/5% FBS and mix thoroughly by pipetting up and down ~10 times. Add 0.5 ml of this solution to the apical chamber (i.e., inside) of a 12-mm Transwell filter. Then add an additional 0.4 ml MEM/5% FBS to the apical chamber for a total of 0.9 ml.

   This corresponds to ~2.5×10^5 cells/well.
6. Add 1 ml MEM/FBS to the basal chamber (i.e., area surrounding the Transwell filter).
7. Incubate at 37°C, replacing 1 ml apical and 1 ml basolateral medium every day for 3 to 5 days until cells form a tight monolayer (see Support Protocol 3).

   IMPORTANT NOTE: *It is important to first remove the basal medium and then remove the apical medium, and to replace in the opposite order. If the basal medium is present and the apical medium is absent then the cells can be pushed off the filter.*

   The cells are fully polarized and ready to examine after 4 to 7 days of growth on the filter.

DETERMINING THE LEAKINESS OF A MONOLAYER OF CELLS GROWN ON A FILTER

SUPPORT PROTOCOL 3

When grown on a Transwell or similar filter support, epithelial cells should form a confluent monolayer; however, with most types of filter materials, it is difficult or impossible to clearly visualize the cells themselves. Hence, it is not easy to determine if they have formed a confluent tight monolayer. Several methods have been devised to measure how intact the monolayer is. Classically, electrical resistance across the monolayer is measured; however, type II MDCK cells typically have a rather low electrical resistance, on the order of 100 ohms/cm^2, and so electrical resistance is rather insensitive to defects in the monolayer. Thus, the authors devised an extremely simple method to monitor the integrity of the monolayer. Although it is qualitative, it has been found to be a very reliable predictor of the integrity of the monolayer and the success of the experiment in the authors' laboratory.

Additional Materials *(also see Support Protocol 2)*

Pasteur pipet connected to a vacuum system

1. Culture cells on filters, as described (see Support Protocol 2).
2. The day before the experiment (i.e., typically after 3 to 6 days of growth on the filter), add normal cell culture medium to the apical well to fill it to overflowing.

   This support protocol is usually performed as part of the daily replacement of apical and basolateral media.

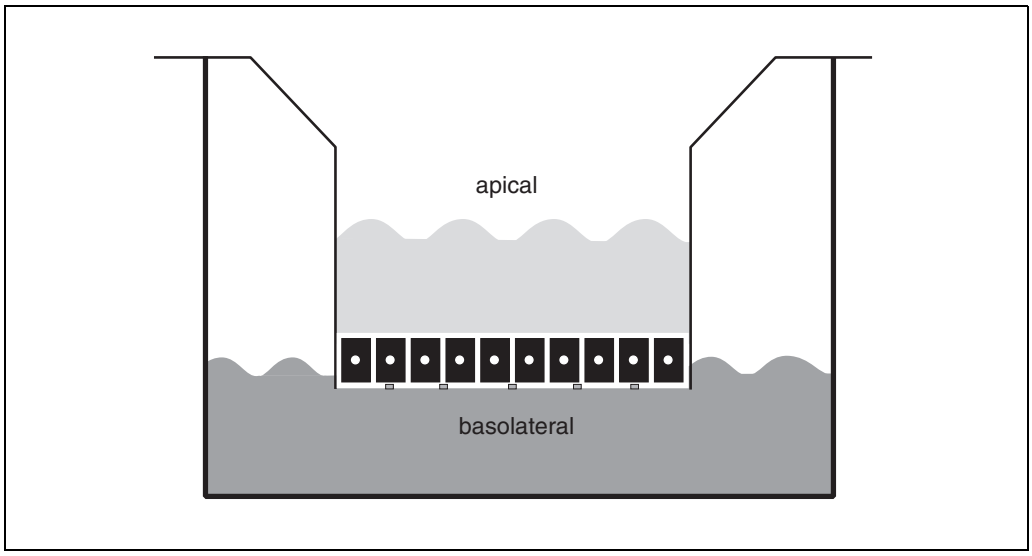

Figure 15.5.2 Schematic diagram of polarized epithelial cells growing in a Transwell. Cells are black rectangles with small white circles indicating nuclei. The apical and basolateral medium are gray. The fluid level of the apical medium is higher than the basolateral medium, as occurs during Support Protocol 3.

3. Use a sterile Pasteur pipet connected to a vacuum system to aspirate most of the medium from the basolateral chamber, leaving just enough medium to contact the entire basal surface of the filter.
4. Incubate the Transwell filter, still in the multiwell plate, at 37°C overnight (i.e., typically 8 to 16 hr).
5. Determine the tightness of the monolayer by assessing the fluid level of the apical chamber.

   If the cell monolayer is intact, the fluid level inside the apical chamber will not go down overnight—i.e., the apical chamber will remain filled to the brim (Figure 15.5.2). If, on the other hand, the fluid level leaks, the monolayer is not tight and the cells should be discarded.

BASIC PROTOCOL 2

PULSE-CHASE EXPERIMENTS IN POLARIZED EPITHELIAL CELLS

The goal of this protocol is to study the trafficking of apical and basolateral secreted proteins in transfected polarized mammalian epithelial cells. This is accomplished utilizing a radioactive amino acid as a tracer molecule (Lipshutz et al., 2000).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimentor and surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1D*).

Materials

4- to 7-day-old epithelial cell cultures growing on 12-mm Transwell filters (see Support Protocol 2)
Dulbecco's phosphate-buffered saline (DPBS; *APPENDIX 2A*)
Starvation medium: MEM medium (*APPENDIX 2B*) lacking the radioactive tracer amino acid
Radioactive amino acid (e.g., 1175 Ci/mmol [^{35}S]methionine)
MEM medium
0.5% (w/v) SDS lysis buffer (see recipe)

Parafilm
Humid box: plastic box with 2 charcoal bags and a piece of wet Whatman filter paper
12-well Transwell tissue culture plate (Table 15.5.2)
Phosphorimager
Scalpel

Additional reagents and equipment for gel electrophoresis (Chapter 6)

Label cells

1. Obtain 4- to 7-day-old epithelial cell cultures growing on 12-mm Transwell filters.
2. Wash cells three times with 37°C Dulbecco's phosphate-buffered saline (DPBS).
3. Add 500 µl starvation medium apically and basolaterally. Incubate at 37°C, 5% CO_2 for 15 min.

   For example, if [^{35}S]methionine is to be used as the radioactive amino acid, then the starvation medium is medium lacking methionine.

4. Place 25-µl spots containing radioactive amino acid (e.g., 4 µl of 1175 Ci/mmol [^{35}S]methionine and 21 µl starvation medium) on a Parafilm sheet inside a humid box.

   The humid box is a plastic box to which two bags containing charcoal are attached to the top inside surface of the box in order to trap the aerosolized [^{35}S]methionine. A piece of Whatman filter paper is placed on the bottom of the plastic box and soaked with water in order to prevent the cells from drying out. Finally, a piece of Parafilm is placed on top of the damp Whatman filter paper.

5. Remove the basal medium while leaving the apical medium in place. Carefully, set one filter on top of each spot for basolateral exposure of cells to the radioactive amino acid.
6. Incubate (i.e., allow labeling to occur) for 15 to 20 min at 37°C. Analyze labeled protein.

   If one is interested in analyzing the synthesis of secretory proteins, carry out steps 11 and 12 at this point.

7. Prepare a new 12-well plate containing fresh MEM medium. Transfer transwells to the new plate and wash cells three times apically and basolaterally with 37°C DPBS.
8. Add 300 µl MEM medium apically and 500 µl basolaterally. Incubate for the desired amount of time (e.g., 1 hr) at 37°C.

   In the case of incubation in an environment without CO_2, 20 mM HEPES is added to the medium as a buffer.

9. Collect apical medium. Transfer transwells to a new 12-well plate, and collect the basolateral medium.
10. Analyze aliquots of the secreted apical and basolateral medium on an appropriate gel by electrophoresis (Chapter 6), and determine amounts of radioactivity using a phosphorimager.

    Immunoprecipitation (UNIT 7.2) of specific secretory proteins can be done before gel electrophoresis.

11. Cut out the filters with a scalpel and collect the cells. Lyse cells by placing the filters in 500 µl of 0.5% SDS-lysis buffer.
12. Determine the amounts of intracellular protein radioactivity by analyzing aliquots on an appropriate gel (*UNIT 6.1*) followed by phospoimaging (*UNIT 6.3*).

    Again, immunoprecipitation (UNIT 7.2) can be performed before gel electrophoresis.

BASIC PROTOCOL 3

BIOTINYLATION OF NEWLY SYNTHESIZED EPITHELIAL CELL SURFACE PROTEINS

The goal in this protocol is to study the trafficking of newly synthesized apical and basolateral epithelial cell surface proteins using a combination of a radioactive amino acid tracer molecule and sulfo-NHS-biotin, an exogenous cell surface marker. Sulfo-NHS-biotin is used to label all cell surface proteins. Individual surface proteins are then isolated by immunoprecipitation (*UNIT 7.2*). This method is adapted from one developed by E. Rodriguez-Boulan and colleagues (LeBivic et al., 1989).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimentor and surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by your local radiation safety officer (also see *APPENDIX 1D*).

Materials

Radioactively labeled amino acid
4-day-old epithelial cultures growing on 12-mm Transwell filters (see Support Protocol 2)
Hanks' balanced salt solution (HBSS; *APPENDIX 2A*), 4°C
20 mg/ml sulfo-NHS-biotin (Pierce) in anhydrous DMSO: prepare just before use
10 mM Tris buffered saline, pH 7.4 (TBS; *APPENDIX 2A*)
0.5% (v/v) SDS lysis buffer (see recipe)
2.5% (v/v) Triton dilution buffer (see recipe)
Protein A–Sepharose beads without and with rabbit antimouse and the monoclonal antibody of choice, or rabbit polyclonal antibodies
Streptavidin beads (e.g., Pierce)
Mixed micelle wash buffer (see recipe)
Final wash buffer (see recipe)
5% (w/v) SDS
2× loading buffer (see recipe)

Platform rocker
Orbital shaker (e.g., Bellco)
Phosphorimager

Additional equipment and reagents for radioactively labeling epithelial cultures (see Basic Protocol 2, steps 1 to 6) and denaturing (SDS) gel electrophoresis (*UNIT 6.1*)

Label cells

1. Add radioactively labeled amino acid to 4-day-old epithelial cultures growing on 12-mm Transwell filters as described for pulse-chase experiments (see Basic Protocol 2, steps 1 to 6), labeling for 15 min.
2. Remove medium and wash cells three times with cold HBSS.
3. Just before using prepare 20 mg/ml sulfo-NHS-biotin in anhydrous DMSO and then dilute it 1:100 with HBSS to a final concentration of 200 µg/ml. Add either 400 µl apically or 800 µl basolaterally to cells.

   Sulfo-NHS-biotin binds tightly to primary amines on cell surface proteins via the NHS ester.

4. Incubate 30 min at 4°C on a platform rocker.
5. Remove biotin solution and wash five times with 10 mM Tris buffered saline.

Prepare lysate

6. Cut out filters and place in 500 µl of 0.5% SDS lysis buffer in a microcentrifuge tube. Boil 5 min, vortex 15 min, and microcentrifuge 5 min at 13,000 rpm. Transfer supernatant to new microcentrifuge tube.

   The filters are most easily cut out of the plastic ring with a surgical scalpel (i.e., Bard-Parker no. 11 blade).

7. Add an equal volume of 2.5% Triton dilution buffer to give final concentrations of 0.25% SDS lysis buffer/1.25% Triton dilution buffer.

Immunoprecipitate target protein

8. Preclear the lysate by incubating with 4 µl protein A–Sepharose beads free of antibody on an orbital shaker for 30 min at 4°C. Microcentrifuge 20 min at 13,000 rpm, 4°C. Transfer supernatant to a new microcentrifuge tube.

9. Add protein A–Sepharose precoated with rabbit antimouse and the monoclonal antibody of choice, or rabbit polyclonal antibodies, to 10 mg/ml. Incubate 12 hr at 4°C.

10. Block streptavidin beads by incubating in equal amounts of 0.5% SDS and 2.5% Triton dilution buffer for 1 to 12 hr.

    This mixture of SDS and Triton buffers is also called lysis buffer.

11. Wash protein A–Sepharose-antibody complexes three times with mixed micelle wash buffer and one time with final wash buffer by diluting with buffer and then microcentrifuging.

12. To recover immunoprecipitated biotinylated antigens, boil the beads in 40 µl of 5% (w/v) SDS for 5 min.

    Boiling in 5% (w/v) SDS will separate the biotinylated antigens from the antibody-protein A complex. The biotin, however, will remain attached to the antigen (surface protein of interest).

13. Dilute with 460 µl of 0.5% SDS/2.5% Triton dilution buffer and microcentrifuge 1 min at 13,000 rpm. Transfer the supernatant to a fresh microcentrifuge tube.

14. Add 13 µl streptavidin beads (i.e., 13 µl per filter) and immunoprecipitate overnight on an orbital shaker at 4°C.

15. Wash streptavidin-bead-antibody complex three times with mixed micelle wash buffer and one time with final wash buffer as described above (step 11).

16. Add 8 µl of 2× loading buffer, boil 5 min, and analyze by denaturing SDS gel electrophoresis (*UNIT 6.1*).

    The DTT (dithiothreitol; present in the loading buffer) is a reducing agent that will disrupt the S-S bond in the sulfo-NHS-biotin allowing for recovery of the protein.

17. Determine phosphorimager counts according to the manufacturer's instructions.

    This procedure identifies newly synthesized proteins of interest that reach the apical or basolateral surface, depending on which was exposed to biotin.

BASIC PROTOCOL 4

INDIRECT IMMUNOFLUORESCENCE OF PROTEINS IN POLARIZED EPITHELIAL CELLS

The goal of this protocol is to identify the location of proteins in polarized epithelial cells. This is accomplished using a primary antibody directed against the protein of interest and a secondary antibody containing an immunofluorescent marker directed against the species in which the primary antibody was made.

Materials

5- to 7-day-old cells growing on 12-mm Transwell filters (see Support Protocol 2)
DPBS (*APPENDIX 2A*), ice cold
16% or 40% (v/v) paraformaldehyde
Quenching solution, fresh (see recipe)
Permeabilizing solution, fresh (see recipe)
Primary antibody
Secondary antibody coupled to fluorophore
DPBS/0.1% (v/v) Triton: add 250 µl of 20% (v/v) Triton X-100 to 49.75 ml DPBS (*APPENDIX 2A*), store up to 6 months at 4°C
Antifade mounting solution

Metal board
Orbital shaker (e.g., Bellco)
Humid box: plastic box with a piece of damp Whatman filter paper
Aluminum foil
Scalpel
Inverted fluorescent microscope with appropriate glass slide and cover slip

1. Cool 5- to 7-day-old cells growing on 12-mm Transwell filters to 4°C by placing on a metal board on ice.
2. Prepare 4% (v/v) paraformaldehyde in ice-cold DPBS from either a 16% or 40% paraformaldehyde stock.
3. Wash Transwell filters twice with 1 ml ice-cold DPBS, both apically and basally.
4. Fix cells with 4% paraformaldehyde in DPBS by adding 0.5 ml to the basal and apical surfaces. Allow cells to fix by incubating 20 min on a slowly rotating orbital shaker (e.g., setting 3 on a Bellco Glass orbital shaker) in a container on ice.
5. Wash Transwell filters three times with 1 ml DPBS to remove paraformaldehyde.
6. Add 1 ml fresh quenching solution both apically and basally, and rotate slowly for 10 min at room temperature.

   The glycine in the quenching solution will bind to the remaining paraformaldehyde.
7. Wash once with 1 ml DPBS.
8. Add 1 ml fresh permeabilizing solution both apically and basally. Incubate 15 min in a 37°C water bath.
9. Dilute primary antibody in permeabilizing solution as appropriate (i.e., 1:100) in 150 µl. Place 40 µl as a drop on a square of Parafilm inside a humid box and place the Transwell filter on the drop (i.e., add basally) and add 110 µl to the apical surface of the Transwell filter.

   The concentration of primary antibody depends on the properties of each individual antibody. A rough rule is that this technique will require five to ten times the amount required for immunoblotting.

10. Incubate 1 hr at 37°C on an orbital shaker.
11. Transfer Transwell filter back to the plate. Wash four times with 1 ml permeabilizing solution, incubating on an orbital shaker for 5 min each time.
12. Dilute secondary antibody coupled to fluorophore 1:100 (generally) with permeabilizing solution. Add to the filter as described for the primary antibody solution (see step 9). Wrap the humid box in aluminum foil and incubate on a platform rocker 30 min at 37°C.

    The samples in the following steps should be protected from light as much as possible.

13. Wash four times with 1 ml permeabilizing solution for 5 min each on an orbital shaker.
14. Rinse once with 1 ml DPBS.
15. Wash twice for 3 min each with 1 ml DPBS/0.1% Triton.
16. Rinse once with 1 ml DPBS.
17. Post-fix with 4% paraformaldehyde in DPBS for 15 min at room temperature (see step 4).
18. Rinse once with 1 ml DPBS.
19. Cut out filter with a scalpel and place on slide containing a drop of antifade mounting solution. Add a coverslip and dry overnight at room temperature in the dark.

    Mount the filter cell-side-up so that the coverslip can be placed directly on an inverted fluorescent microscope.

20. Analyze on an inverted fluorescent or confocal microscope to detemine the location of the protein of interest, or store in the dark at −20°C to prevent fading of the fluorophore.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Final wash buffer

37.5 ml 4 M NaCl (150 mM final; *APPENDIX 2A*)
20 ml 1 M triethanolamine chloride (TEA·Cl), pH 8.6 (20 mM final)
10 ml 0.5 M EDTA, pH 8.0 (5 mM final; *APPENDIX 2A*)
1.0 ml Trasylol (0.001% v/v final)
2.0 ml 10% NaN_3 (0.02% w/v final)
Adjust volume to 1 liter with H_2O
Store up to 6 months at 4°C

Geneticin (G418)

Prepare G418 as a 100 mg/ml stock in 200 mM HEPES (sodium salt), pH 7.9. Filter sterilize and store at −20°or −80°C. For every new batch (new lot number of G418 powder), determine the effective G418 concentration which kills cells by performing killing curves (i.e., expose the cells to different G418 concentrations and determine the minimal drug concentration needed to kill the entire cell population in the dish in a 14-day test).

For more information concerning geneticin, see APPENDIX 1B.

HEPES buffered saline (HeBS), pH 7.05

For 500 ml HeBS, add 2.5 g HEPES (final concentration 20 mM) to DPBS and adjust the pH to 7.05 with 5 M NaOH (*APPENDIX 2A*).

Loading buffer, 2×

0.3 ml 1 M Tris·Cl, pH 6.8 (15 mM; *APPENDIX 2A*)
2.0 ml 10% SDS (1% w/v; *APPENDIX 2A*)
0.05 ml 100 mM EDTA, pH 7.0 (25 mM; *APPENDIX 2A*)
0.2 g DTT (65 mM)
0.5 ml 1% bromophenol blue dye (0.025% w/v)
1.2 ml 100% glycerol or sucrose (6% w/v)
5.75 ml H_2O
10 ml total volume
Store up to 6 months at 4°C

Concentrations in parentheses are for a 1× solution.

Mixed micelle wash buffer

37.5 ml 4 M NaCl (150 mM final; *APPENDIX 2A*)
20 ml 1 M TEA·Cl, pH 8.6 (20 mM final)
10 ml 0.5 M EDTA, pH 8.0 (5 mM final; *APPENDIX 2A*)
1.0 ml Trasylol (0.001% v/v final)
2.0 ml 10% NaN_3 (0.02% w/v final)
60 ml 65% (w/w), 85% (w/v), or 39 g sucrose
942 ml H_2O
50 ml 20% Triton X-100 (1% v/v final)
20 ml 10% SDS (0.2% v/v final; *APPENDIX 2A*)
Total volume 1 liter
Store up to 6 months at 4°C

Permeabilizing solution

3.5 g of cold-water fish skin gelatin (0.7% w/v final; Sigma-Aldrich)
0.8 ml 10% (w/v) saponin in H_2O (0.016% final)
Bring to 500 ml with PBS (*APPENDIX 2A*)
Prepare fresh on the day of the experiment; do not store

This is a sufficient amount of solution for the preparation of twelve 12-mm Transwell filters.

Quenching solution

1.5 ml 1 M NH_4Cl (75 mM final)
0.4 ml 1 M glycine (20 mM final)
18.1 ml PBS (*APPENDIX 2A*)
20 ml total volume
Prepare fresh on the day of the experiment; do not store

SDS lysis buffer, 0.5% (w/v)

12.5 ml 4 M NaCl (100 mM final; *APPENDIX 2A*)
25 ml 1 M TEA·Cl, pH 8.1 (50 mM final; *APPENDIX 2A*)
5 ml 0.5 M EDTA, pH 8.0 (5 mM final; *APPENDIX 2A*)
1.0 ml Trasylol (0.2% v/v final)
1.0 ml 10% NaN_3 (0.02% w/v final)
25 ml 10% SDS (0.5% w/v final; *APPENDIX 2A*)
475 ml H_2O
500 ml total volume
Store up to 6 months at room temperature

Triton dilution buffer, 2.5% (v/v)

12.5 ml 4 M NaCl (100 mM final; *APPENDIX 2A*)
50 ml 1 M TEA·Cl, pH 8.6 (100 mM final; *APPENDIX 2A*)
5 ml 0.5 M EDTA, pH 8.0 (5 mM final; *APPENDIX 2A*)
5.0 ml Trasylol (1% v/v final)
1.0 ml 10% NaN_3 (0.02% w/v final)
Add H_2O to 436 ml
Add 62.5 ml of 20% Triton X-100 (2.5% v/v final)
Total volume 500 ml
Store up to 6 months at 4°C

COMMENTARY

Background Information

Growing cells on porous (i.e., Transwell) filters has two major advantages. First, polarized epithelial cells usually obtain most of their nutrients from their basolateral surface, which in vivo is exposed to the blood. When grown on a typical impermeable plastic culture dish, the cells cannot obtain nutrients from the overlying culture medium in contact with the apical surface because the tight junctions prevent nutrients from reaching the basolateral surface. This forces the cells to become partially depolarized in order to survive. In contrast, when grown on permeable filters, the cells can obtain nutrients from the culture medium that underlies the filter, which is in contact with the basolateral surface via the pores in the filter.

Second, the cells form a continuous monolayer covering the filter, and the tight junctions between cells largely prevent diffusion between them. Thus, the culture medium in contact with the apical surface of the cells cannot exchange with medium in contact with the basolateral surface. In the Transwell or similar device, the filter is mounted at the end of a short plastic tube, which is suspended in the well of a multiwell tissue culture plate. This effectively provides two chambers holding two potentially different pools of culture medium: an apical chamber overlying the apical surface of the cells on top of the monolayer, and a basolateral chamber underlying the filter and in contact with the basolateral surface of the cells.

Many early studies on biosynthetic protein sorting utilized viral membrane proteins. Typically in these studies, cells were infected with a virus and the transport of the envelope glycoproteins to the surface was studied. This provided a large amount of one or two viral glycoproteins, which could easily be followed. The most widely used examples were the hemagglutinin (HA) protein of influenza, which goes apical and the G protein of vesicular stomatitis virus (VSG-G) which goes basolateral (Brewer and Roth, 1991); however, infection with these and other viruses has significant toxic repercussions to the cell. Thus, expression of these proteins from the actual virus has largely been supplanted by expression from transfected vectors (e.g., Brewer and Roth, 1991). VSV-G has the added advantage that a temperature sensitive form (i.e., ts-045) accumulates in the rough endoplasmic reticulum (RER) at 40°C, but is transported through the biosynthetic pathway at ≤30°C. Additionally, green fluorescent protein (GFP)–fusions with this and other proteins are being used to follow transport in live cells.

This unit focuses on biosynthetic pathways leading to the cell surface. One can also study endocytosis from either the apical or basolateral surface. The approaches used are similar to those presented in *UNIT 15.4*. Additionally, one can study the fate of material endocytosed from either surface (*UNIT 15.3*). This can include recycling to the original surface from which the material was endocytosed, transcytosis to the opposite surface, or degradation. One difficulty is that there are relatively few endogenous receptors in Madin-Darby canine kidney (MDCK) cells that can be conveniently utilized to follow receptor-mediated endocytosis. When confluent and well polarized, MDCK cells express relatively few receptors for many nutrients (e.g., transferrin or low-density lipoprotein). The endogenous transferrin receptors work very poorly with human transferrin, although they do work considerably better with canine transferrin, which is available commercially from Sigma-Aldrich. Most endogenous endocytotic receptors are located on the basolateral surface, so finding a receptor system for studying apical endocytosis is more difficult. Most studies on endocytosis and post-endocytic sorting in epithelial cells have utilized transfected exogenous receptors, expressed at a high level. For instance, the authors' labora-

tory has primarily utilized the transfected polymeric immunoglobulin receptor.

Critical Parameters and Troubleshooting

Clonal variation of MDCK cells

The original MDCK cell line, available from the American Type Culture collection (*http://www.atcc.org*; ATCC #CCL-34), is quite heterogeneous. Several investigators have isolated individual clonal lines from this heterogeneous population. Clones of MDCK cells can be broadly divided into two categories, type I and type II. Generally, type I have a high electrical resistance (i.e., >1000 ohms/cm^2), whereas type II have a low electrical resistance (~100 ohms/cm^2). In reality, MDCK clones can be thought of as forming a nearly continuous spectrum in terms of their electrical resistance as well as other properties. Almost all of the work done by the authors has utilized a nominally type II clonal line originally isolated by Daniel Louvard at the European Molecular Biology Laboratory (EMBL) in Heidelberg, which is sometimes referred to as Heidelberg MDCK (Louvard, 1980).

When transfected cDNA is expressed in MDCK cells, and a stable expressing clone is isolated, the cell line is effectively subcloned. The authors have found that each subclone of MDCK can have unique and quite distinct properties; therefore, it is important to characterize each one. For example, an easy test for the ability of a subclone to form a tight monolayer is described (see Support Protocol 3). Moreover, the authors have found that the polarized trafficking of any particular protein can vary considerably among subclones. For this reason, when studying the trafficking of a newly transfected protein, the authors generally examine at least three independent subclones (Aroeti et al., 1993). If clones show different trafficking properties it is likely due to clonal variation and not a direct result of the exogenous protein being expressed. Only if three separate clones give the same result can one assume that the effect is due to the truncated gene/protein.

In addition to MDCK cells, several other epithelial cell lines have often been used for studies of polarized membrane traffic, including the major ones listed in Table 15.5.1.

Instability and heterogeneity of expression of exogenous proteins

In many cases, expression of an exogenous protein in MDCK cells appears to be detrimental to the long-term growth of the cell. In severe cases, the protein can be so toxic that it is difficult or impossible to recover clones that express a detectable level of the exogenous protein. In less severe cases, expression of the protein is lost during successive passages of the clonal cell line (Barth et al., 1997). Presumably, this is due to a growth advantage of spontaneously arising cell variants, which do not express the protein. Moreover, when the expression of the exogenous protein is observed in a population of MDCK cells by immunofluorescence microscopy, the level of expression can appear to vary from cell to cell. One strategy to deal with these problems is to freeze numerous vials of early passage cells, which are then thawed at frequent intervals and used for only a limited period before the cells are discarded. In some cases, the newly thawed cells are used for only one experiment. This helps to ensure that the cells used in every experiment are consistent.

Another approach is to repeatedly subclone the cells. In principle this should yield a clone with uniform expression of the exogenous protein; however, it is often observed that despite repeated subcloning, expression of exogenous proteins is not uniform. This suggests that variation in expression is an inherent feature of MDCK cells.

Type of filter material and support unit

Most of the authors' experience is with polycarbonate filters containing 0.4-μm nominal size pores, as part of Transwell units from Corning. Filters are available in a number of materials and support units, from several manufacturers (Table 15.5.2). Some filters are available in pore sizes >1 μm; however, these are not recommended for growth of polarized epithelial monolayers as the cells can migrate into and through the pores. Indeed, filters with pores of 3 μm or larger are used for cell migration studies. In general, filters that have more pores and/or larger pores will have optical transmission properties which are more poor, though it is not necessary to be able to visualize live cells on the filter for most experiments.

Anticipated Results

Ideally, one will find that the protein of interest is delivered directly to one surface of the cell or the other and resides at that surface. In this case, there will be a clear-cut agreement between the steady-state localization determined by immunofluorescence microscopy, and the site of delivery, as measured by the pulse-chase and biotinylation protocols. An ex-

ample of results from immunofluorescence microscopy is presented in Figure 15.5.3; however, it should be kept in mind that no protein is ever delivered 100% to only one surface. Even in the best cases, typically only ~90% of a protein is delivered to one surface, with the balance reaching the other surface. Furthermore, proteins can differ in the stability at the surface. Some, such as Na-K-ATPase, can reside at the basolateral surface for hours. Others, such as the polymeric immunoglobulin receptor, are delivered to the basolateral surface, but are then endocytosed and transcytosed to the apical surface within minutes.

Time Considerations

It takes ~4 hr to carry out a pulse-chase labeling experiment to assess trafficking. Transfection of the cells requires ~2 hr plus 2 to 3 weeks to select clones. Picking clones takes ~2 hr. It takes 7 to 14 days to expand the clones. Plating cells on Transwell filters requires ~1 hr, but 4 to 7 days are required to grow confluent monolayers of polarized cells. It takes one complete day to assess a culture for leakiness. Biotinylation of newly synthesized proteins and their analysis requires ~8 hr. Immunofluorescence experiments require ~6 hr to complete.

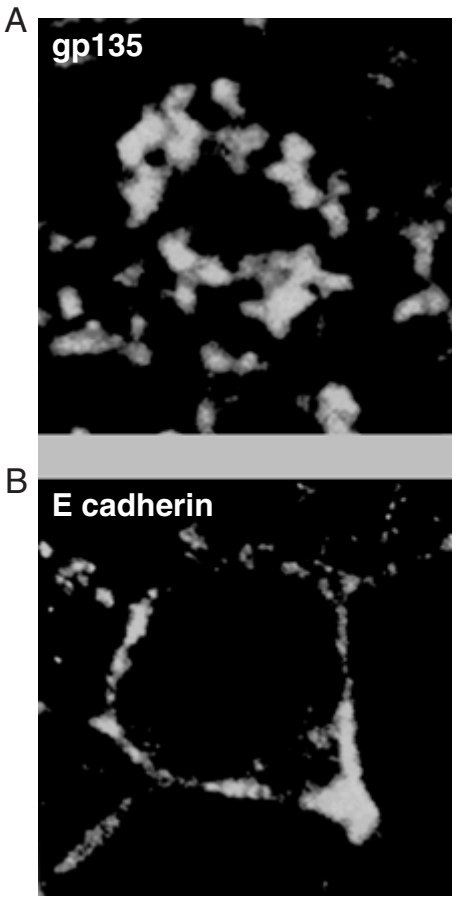

Figure 15.5.3 Immunofluorescence micrographs of polarized epithelial cells grown on a Transwell. Samples were prepared as in Basic Protocol 4, and then viewed with a Bio-Rad 1024 confocal microscope. (**A**) Staining using a monoclonal antibody directed against an apical plasma membrane protein, gp135 (kindly provided by George Ojakian, SUNY Downstate Medical Center, Brooklyn, NY), as a primary antibody. The micrograph was taken at the level of the apical surface. Staining appears irregular, due to microvilli and other irregularities of the apical surface. It is not easy in this view to discern the outline of individual cells. (**B**) A sample prepared using a primary antibody against a basolateral surface marker, E-cadherin (Chapter 9). The micrograph was taken at a level below the apical surface, approximately midway between the apical and basal poles of the cell. The E-cadherin largely outlines the lateral borders of the cell, though some intracellular staining is also seen.

Analysis of Protein Folding and Oxidation in the Endoplasmic Reticulum

Proteins that traverse the eukaryotic secretory pathway are co-translationally inserted through the endoplasmic reticulum (ER) membrane into the lumen. Upon emergence of the protein into the lumen, a series of important maturation steps begin co-translationally and finish post-translationally before the protein exits from the ER. Among these processes are protein folding and the formation of disulfide bonds, which is supported by the oxidizing ER environment. This unit describes protocols for analyzing the folding and oxidation of proteins in the ER.

Protein oxidation can be analyzed either co-translationally (Basic Protocol 1) or post-translationally (Alternate Protocol 1) by monitoring the disappearance of free cysteine thiols or appearance of faster-migrating oxidative forms on nonreducing SDS-polyacrylamide gels. Protein folding can be followed by analyzing a protein's increased resistance to proteolysis during the course of maturation (Basic Protocol 2) or by immunoprecipitation with conformation-specific antibodies (Basic Protocol 4). The transient association of folding or oxidative intermediates with chaperone proteins can also be studied using a co-immunoprecipitation procedure (Basic Protocol 3 and Alternate Protocol 2). These procedures can be applied to study protein maturation in the ER using a variety of experimental systems including: a cell-free system composed of rough ER–derived microsomes and an in vitro translation system (Basic Protocol 1), adherent cell monolayers (Basic Protocol 5), cells in suspension (Alternate Protocol 3), and an in vitro translation system that targets proteins to intact ER from semipermeabilized (SP) cells (Support Protocol). To choose the most effective system(s) for a given study, the inherent advantages and disadvantages of each system must be weighed.

CAUTION: When working with radioactive materials, take appropriate precautions to avoid contamination of the experimenter, instruments, and surroundings. Carry out the experiments and the disposal of the wastes in the appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*). In addition, some extra precautions should be taken when using ^{35}S-labeled amino acids (*UNIT 7.1*).

ANALYSIS OF DISULFIDE BOND FORMATION IN ROUGH ENDOPLASMIC RETICULUM–DERIVED MICROSOMES BY ALKYLATION AND NONREDUCING SDS-PAGE

BASIC PROTOCOL 1

Disulfide bond formation can be followed by translating proteins under oxidizing conditions in the presence of rough ER–derived microsomes. The polypeptide chain is co-translationally translocated across the ER membrane into the lumen where disulfide bond formation occurs. Because free cysteine thiols form disulfide bonds with the aid of an oxidizing agent, the disappearance of these free thiols can be used to monitor disulfide bond formation. The modification of free thiols with an alkylating agent can be used to trap oxidative intermediates and cause a mobility shift proportional to the number of free thiols modified (Fig. 15.6.1). Common alkylating reagents for this technique are *N*-ethylmaleimide (NEM; 125 Da) and 4-acetamido-4′-maleimidylstilbene-2, 2′-disulfonic acid disodium salt (AMS; 536 Da).

As proteins fold and form disulfide bonds, they become more compact. This generally causes the protein to migrate faster by nonreducing SDS-PAGE compared with its fully reduced form (Fig. 15.6.1). Therefore, a mobility comparison of the reduced and oxidized

Contributed by Edwin Francis, Robert Daniels, and Daniel N. Hebert
Current Protocols in Cell Biology (2002) 15.6.1-15.6.29

protein on nonreducing SDS-PAGE can be used to monitor the formation of disulfide bonds. These studies can also be used in some cases to identify oxidative intermediates. In this protocol, a time course for protein oxidation is performed and the immunoprecipitates or lysates are analyzed by nonreducing SDS-PAGE to detect changes in mobility over time due to disulfide bond formation.

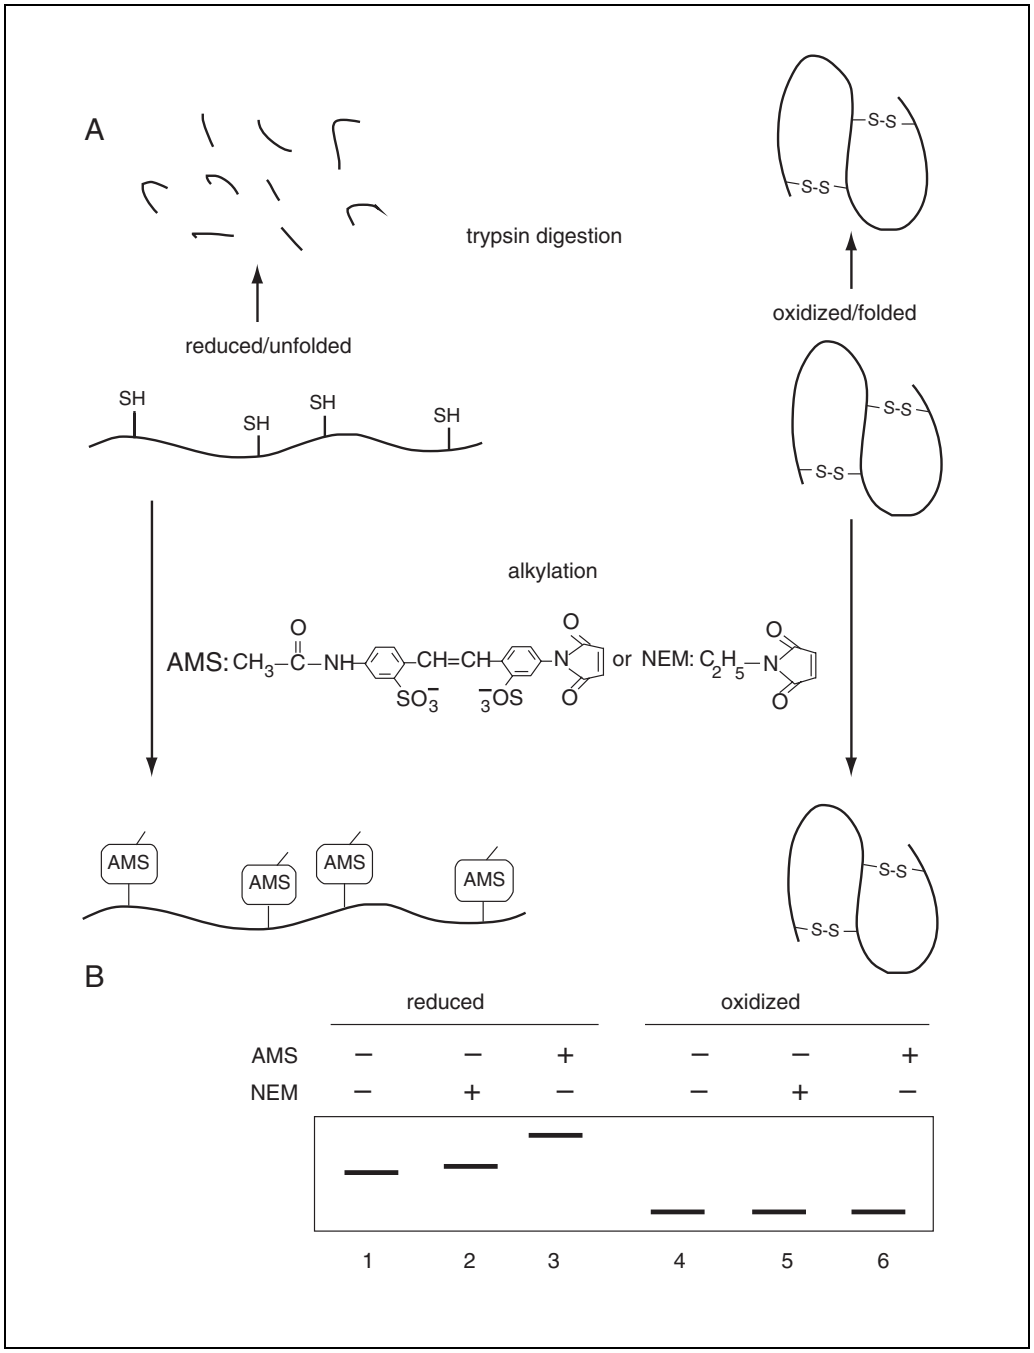

Figure 15.6.1 The effects of disulfide bond formation in proteins. (**A**) Schematic demonstration of the sensitivity of a reduced and oxidized polypeptide chain to protease digestion (top) and alkylation (bottom). (**B**) Resulting mobility changes visualized by SDS-PAGE. When a reduced or unfolded polypeptide containing free thiols is alkylated with 4-acetamido-4′-maleimidylstilbene-2, 2′-disulfonic acid disodium salt (AMS), a bulk alkylating agent, or *N*-ethylmaleimide (NEM), a shift in protein mobility on an SDS-polyacrylamide gel is observed (compare lanes 2 and 3 to lane 1). The oxidized (disulfide bonded) or folded protein is not sensitive to alkylation with either AMS or NEM as fewer or no free cysteines are available (lanes 4 to 6). The reduced or unfolded protein is more accessible to proteolytic digestion with trypsin than the oxidized or folded protein.

This protocol uses ^{35}S-labeled proteins generated by translating an mRNA (*UNIT 11.2*) for the protein of interest with a rabbit reticulocyte lysate translation system along with [^{35}S]methionine and [^{35}S]cysteine in the presence of rough ER–derived microsomes. This system is advantageous for studying protein maturation in the ER as it provides optimum flexibility in the control and manipulation of experimental conditions. One manipulation is the addition of the oxidizing agents oxidized glutathione (GSSG) or flavin adenine dinucleotide (FAD) during translation. Both FAD and GSSG provide conditions that mimic the normal physiological environment under which proteins acquire their native disulfide bonds in the cell. Therefore, these reagents, when present during translation, permit disulfide bond formation to commence co-translationally or vectorially from the N terminus to C terminus of the protein and to be completed post-translationally.

Materials

In vitro translation reagents, including:
- 1 equivalent/µl nuclease-treated canine pancreatic microsomes (*UNIT 11.4*) or 1 × 10^5 cells/µl semipermeabilized (SP) cells (see Support Protocol)
- Rabbit reticulocyte lysate treated with ATP-regenerating system and nucleases (e.g., Promega)
- 1 mM amino acid mixture lacking methionine and cysteine
- 11 mCi/ml [^{35}S]methionine and [^{35}S]cysteine (1175 Ci/mmol; e.g., PE Biosystems)
- 40 U/µl RNase inhibitor (e.g., RNasin; Promega)
- 100 mM GSSG (see recipe) or 2.5 mM FAD (see recipe)
- 100 mM dithiothreitol (DTT; e.g., Promega or *APPENDIX 2A*)
- 2.5 M KCl
- 1 µg/µl mRNA for the protein of interest (e.g., *UNIT 11.2*)
- Nuclease-free H_2O

50 mM cycloheximide (see recipe)
120 mM *N*-ethylmaleimide (NEM) (see recipe)
20 mM AMS, prepared fresh (see recipe)
0.5% and 2% (w/v) 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate) (CHAPS) in HeBS (CHAPS/HeBS, see recipe), ice cold
2× nonreducing sample buffer (see recipe)
10% (w/v) protein A–Sepharose (see recipe)
Antibodies raised against the protein of interest
PBS (*APPENDIX 2A*), optional
2% (w/v) salicylate (see recipe)

27°C water bath
1.5-ml microcentrifuge tubes, RNase free
Tube rotator (capable of end-over-end inversions), 4°C
Microcentrifuge with a fixed-angle rotor (Eppendorf 5415C or equivalent), 4°C and room temperature
Vacuum aspirator
Microcentrifuge tube rack vortex mixer (e.g., Tommy MT-360; Tomy Tech USA Inc.), 4°C
95°C heating block
Whatman 3MM filter paper

Additional reagents and equipment for SDS-polyacrylamide gel electrophoresis (SDS-PAGE) minigel with Laemmli buffers (*UNIT 6.1*), Coomassie blue staining and destaining (*UNIT. 6.6*), and gel autoradiography (*UNIT 6.3*)

NOTE: It is important to avoid contamination by RNases that degrade the mRNA during in vitro translations. Wear gloves throughout the experiment. Treat water and salt solutions with diethylpyrocarbonate (DEPC) to chemically inactivate RNases. Treat all glass and plasticware with DEPC-treated water or otherwise to remove RNase activity.

Carry out in vitro translation

1. Thaw in vitro translation reagents rapidly in a 27°C water bath and then place on ice.

   Canine pancreatic microsomes should be stored in aliquots of working volumes (multiples of 6 µl). Freeze-thawing of rabbit reticulocyte lysate more than twice should be avoided as each freeze-thaw cycle results in a decrease in translation and translocation efficiency. All other reagents should be frozen rapidly in liquid nitrogen after use and stored at −70°C.

2. Assemble reaction mixture in a 1.5-ml RNase-free microcentrifuge tube at room temperature (~92.0 µl total volume) as follows:

   6 µl of 1 equivalent/µl nuclease-treated canine pancreatic microsomes *or* 12 µl of 1×10^5 cells/µl SP cells (1.3×10^4 cells/µl final)
   52 µl treated rabbit reticulocyte lysate
   2 µl of 1 mM amino acid mixture lacking methionine and cysteine
   8 µl of 11 mCi/ml [^{35}S]methionine and [^{35}S]cysteine
   4 µl of 40 U/µl RNase inhibitor
   3.7 µl of 100 mM GSSG (4 mM final) or 2.5 mM FAD (100 µM final concentration)
   3 µl of 100 mM DTT
   3.2 µl of 2.5 M KCl
   4 µl of 1 µg/µl mRNA for the protein of interest
   6.1 µl nuclease-free H_2O.

   This reaction mix is sufficient for nine samples (i.e., three time points) and should be adjusted proportionately as needed.

   One equivalent per microliter of microsomes is equal to 50 A_{280} U/ml. A range of 6 to 12 µl of 1 eq/µl of microsomes or 0.5 to 2.5 × 10^4 cells/µl of SP-cells provides optimum translocation for a 92-µl translation mix.

   The authors have found that ~4.0 µg mRNA per 92-µl reaction is optimal for their transcripts, but this is transcript dependent and should be optimized individually. The KCl and microsome concentrations in the translation also have to be optimized for individual mRNAs. A final KCl concentration range of 30 to 90 mM is a good starting point. In general, increasing the amount of microsomes in the reaction increases the proportion of polypeptides that are processed, but it may also reduce the amount of total polypeptide synthesized.

   For oxidation, usually 4 mM GSSG or 100 µM FAD with 1.1 mM DTT can provide optimal redox conditions, but a titration may be required to provide maximal results. If more than one mRNA is used or conditions are varied, it is advantageous to aliquot the mix and make the adjustments prior to mRNA addition.

3. Mix the lysate gently but thoroughly by pipeting up and down a few times and incubate 1 hr at 27°C.

   To avoid air bubbles during mixing, the pipettor should be set to less than the total volume of the mixture. If necessary, the sample should be centrifuged briefly to bring the mixture to the bottom of the tube.

4. Add 2 µl of 50 mM cycloheximide (1 mM final) and pipet up and down to stop the translation reaction.

   Cycloheximide is a protein synthesis inhibitor.

Alkylate proteins

5. Transfer 10 µl lysate into each of three 1.5-ml microcentrifuge tubes. Return the remaining lysate to the 27°C water bath for further oxidation and maturation.

   These samples represent the first time point. For each time point, three fractions will be generated: control, no alkylation; alkylation with NEM; and alkylation with AMS.

6. Set one of the three tubes aside on ice for the control, nonalkylated sample.

7. To the second tube, add 2.0 µl of 120 mM NEM (20 mM final) to alkylate free thiols. Place on ice for 10 min.

8. To the third tube, add 25 µl of 20 mM AMS (14 mM final) to alkylate free thiols and incubate 1 hr at room temperature in the dark.

   Because AMS is a membrane-impermeable alkylating agent, the membranes have to be lysed. Therefore, the solution containing AMS also contains SDS for membrane solubilization. AMS is sensitive to light; the bottle containing the solution should be wrapped with aluminum foil, and a freshly prepared stock solution should be used.

9. After appropriate incubation times, repeat steps 5 to 8 for remaining time points.

10a. *For immunoprecipitation:* Add 500 µl ice-cold 2% CHAPS/HeBS to each sample and continue with step 11.

10b. *For direct analysis of total proteins translated:* Add 2× nonreducing sample buffer to the three samples as follows and continue with step 19:

   10 µl to nonalkylated sample
   12 µl to NEM-treated sample
   35 µl to AMS-treated sample.

   Adjust the sample volume with 1× nonreducing sample buffer to 70 µl to keep the protein concentration constant for quantification purposes.

Immunoprecipitate proteins

11. Add 100 µl of 10% protein A–Sepharose to each tube to preclear immunoprecipitation samples. Rotate samples end over end on a tube rotator for 1 hr at 4°C.

    Preclearing with protein A–Sepharose should decrease the amount of background associated with the use of protein A. More details on immunoprecipitation can be found in UNIT 7.2.

12. Microcentrifuge samples 5 min at 2900 × *g* (6000 rpm), 4°C, and transfer the supernatant to a new 1.5-ml microcentrifuge tube containing 100 µl of 10% protein A–Sepharose and the appropriate amount of antibodies raised against the protein of interest.

    A titration with antiserum may be required to obtain optimal results. Excess antibodies may give nonspecific binding or saturate the protein A–Sepharose.

13. Rotate samples end over end for 4 to 8 hr or overnight at 4°C.

14. Microcentrifuge samples 5 min at 2900 × *g*, 4°C, to pellet the protein-antibody immune complexes.

15. Place samples on ice, and use a vacuum aspirator to remove supernatant.

16. Add 500 µl of 0.5% CHAPS/HeBS and vortex in a microcentrifuge tube rack vortex mixer at medium speed for 10 min at 4°C, to wash pellet.

For in vitro translated proteins, only a single wash is needed. However, cellular studies (see Basic Protocol 5 and see Alternate Protocol 3) may require multiple washes to reduce background.

17. Microcentrifuge samples 5 min at 2900 × *g*, 4°C, and aspirate supernatant.
18. Resuspend samples in 40 µl of 2× nonreducing sample buffer by vortexing for 5 min.

Electrophorese proteins

19. Heat samples 5 min in a 95°C heating block.

    A boiling water bath may be used instead of the heating block.

20. Microcentrifuge samples 5 min at 16,000 × *g* (14,000 rpm), room temperature, to pellet the Sepharose beads prior to loading on the gel.

    Take care not to clog the pipet tip by pipetting beads.

21. For reduced samples, place 13.5 µl nonreduced sample into a fresh 1.5-ml microcentrifuge tube. Add 1.5 µl of 1 M DTT (100 mM final) and heat 5 min at 95°C. Centrifuge briefly to concentrate sample at the bottom of the tube.

    Reducing and nonreducing conditions are used to identify the disulfide bonded forms of the protein that migrate faster in the nonreducing gel compared to the reducing gel.

22. Prepare a 1- or 0.75-mm-thick SDS-polyacrylamide separating and stacking minigel with a 10- or 15-well comb (*UNIT 6.1*).

    Separating-gel acrylamide concentration depends on the molecular weight of the proteins to be resolved.

23. Load 10 µl nonreduced sample or 11.1 µl reduced sample into each well and bring all lanes, including the empty ones, up to 11.1 µl with 1× sample buffer.

    Each well must be intact and straight. If nonreduced and reduced samples are to be placed on the same gel, care must be taken to ensure that the DTT from the reduced samples does not reduce the nonreduced samples in the gel. This can be avoided by leaving two empty lanes between nonreduced and reduced samples and filling these lanes with nonreducing sample buffer. If nonreduced and reduced samples need to be loaded next to each other, samples should be cooled, and NEM added to a final concentration of 100 mM to both sets of samples to alkylate excess DTT. Samples should be loaded carefully using a gel loading pipet tip.

24. Run the gel for ~2 hr at 20 to 25 mA until the dye front is at the bottom of the gel.
25. Stain and destain the gel, including stacking gel, with Coomassie blue stain and destain (*UNIT 6.6*)

    Stacking gels often contain aggregated proteins.

26. Wash gel with distilled water or PBS by rocking gently. Repeat two or three times. Check that the pH has reached neutrality with pH paper.

    Salicylate (step 27) is inactivated by acidic pH.

27. Incubate gel 10 min with gentle agitation in 2% salicylate.

    Salicylate is used to enhance the radioactive signal 3- to 5-fold (UNIT 6.3).

28. Dry gel onto Whatman 3MM filter paper and expose gel to radiographic film for autoradiography (*UNIT 6.3*).

    An exposure of 6 to 12 hr is generally sufficient for total protein lysate samples. Immunoprecipitated samples may require longer exposure time.

ANALYSIS OF POST-TRANSLATIONAL DISULFIDE BOND FORMATION IN ROUGH ENDOPLASMIC RETICULUM–DERIVED MICROSOMES

ALTERNATE PROTOCOL 1

The formation of disulfide bonds can be inhibited by the addition of a powerful reducing agent such as dithiothreitol (DTT) while protein synthesis, translocation, signal sequence cleavage, and glycosylation continue. Here, disulfide bond formation is initiated post-translationally by the removal of the reducing agent or the addition of oxidizing agents. This post-translational method allows for synchronous initiation of disulfide bond formation. In addition, the isolation of the oxidation and folding steps in the post-translational procedure permits the characterization of factors required in this process independent of other processes involved in protein maturation such as translocation and glycosylation (Braakman et al., 1992).

This protocol is similar to Basic Protocol 1 (and uses the same list of materials) with the exception that the radiolabeled protein is synthesized under reducing conditions to inhibit disulfide bond formation (Fig. 15.6.2). Synthesis is then terminated and oxidizing conditions are restored by adding oxidizing agents such as oxidized glutathione (GSSG) or flavin adenine dinucleotide (FAD) to initiate disulfide bond formation. An intact endoplasmic reticulum (ER) source can also be used here by substituting semipermeabilized (SP) cells (see Support Protocol) for the microsomes. For cellular studies, the reducing agent (5 mM DTT final concentration) is added during the radioactive pulse and removed to initiate oxidation because intralumenal oxidizing conditions will be rapidly restored upon returning the cells to medium lacking reducing agents (Braakman et al., 1992).

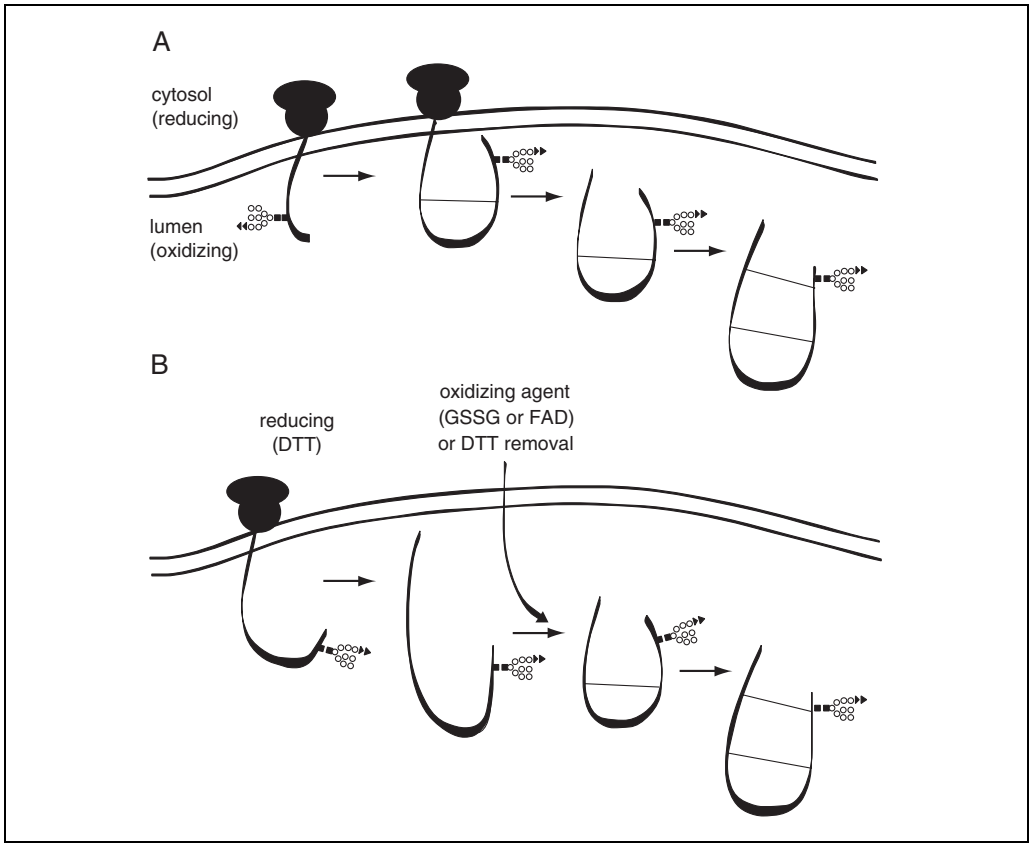

Figure 15.6.2 Formation of disulfide bonds. (**A**) Co-translational bond formation. (**B**) Post-translational bond formation. Under normal cellular redox conditions, the cytosol is reducing and the endoplasmic reticulum (ER) lumen is oxidizing. Disulfide bond formation and glycan addition can take place co-translationally (A) as the C terminus of the protein is being completed by the ribosome. Synchronous oxidation of the completed glycosylated and reduced chain can be initiated post-translationally (B) by synthesizing the protein under reducing conditions (e.g., DTT), inhibiting protein synthesis, and then adding oxidizing agents, such as oxidized glutathione (GSSG) or flavin adenine dinucleotide (FAD), post-translationally.

NOTE: It is important to avoid contamination by RNases that degrade the mRNA during in vitro translations. Wear gloves throughout the experiment. Treat water and salt solutions with diethylpyrocarbonate (DEPC) to chemically inactivate RNases. Treat all glass and plasticware with DEPC-treated water or otherwise to remove RNase activity.

1. Carry out in vitro translation using either canine pancreatic microsomes or SP cells as described (see Basic Protocol 1, steps 1 to 4) with the omission of the oxidizing agent GSSG or FAD in step 2. Adjust the reaction volume with nuclease-free water accordingly.
2. Add 3.7 µl of 100 mM GSSG (4 mM final) or 3.7 µl of 2.5 mM FAD (100 µM final) to initiate oxidation. Mix and incubate for an appropriate length of time at 27°C.

   The incubation time(s) will depend on the experimental design.
3. Alkylate the remaining free cysteines with NEM and/or AMS to arrest further oxidation, and analyze proteins as described (see Basic Protocol 1, steps 5 to 28).

BASIC PROTOCOL 2

ANALYSIS OF PROTEIN FOLDING BY PROTEOLYTIC SENSITIVITY

The folded state and stability of proteins synthesized in vitro and in vivo can be analyzed by proteolysis. Limited proteolysis is a powerful tool for probing the globular structure of folded proteins. While a variety of promiscuous proteases can be employed for these studies, the most commonly used is trypsin. Trypsin cleaves the peptide bonds C-terminal to the basic amino acids lysine and arginine. Peptide regions buried in the protein core and in the secondary structural elements are less accessible to the enzyme (usually in the folded conformation), therefore they are not cleaved as quickly (Fig. 15.6.1). Here, in vitro translated, ^{35}S-labeled protein is allowed to fold under oxidizing conditions in the presence of canine pancreatic microsomes (see Basic Protocol 1). Microsomal membranes containing the ^{35}S-labeled protein are isolated from the lysate and solubilized in a digestion buffer. The folded state of the protein is analyzed by trypsin digestion. Early oxidation or folding forms will be easily digested by the protease while mature forms will be more protease resistant. The digested samples are analyzed directly by reducing SDS-PAGE and autoradiography. This technique can also be used with semipermeabilized (SP) cells (see Support Protocol), or it can easily be adapted for intact cell studies (see Basic Protocol 5 and see Alternate Protocol 3).

Materials

1× sucrose cushion (see recipe)
1% and 10% digestion buffer: 1% and 10% (w/v) 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate) (CHAPS) in HeBS (see recipe for HeBS)
50 µg/ml trypsin (prepared from 1 mg/ml stock; stored at 4°C up to 6 months)
50 µg/ml soybean trypsin inhibitor (prepared from 1 mg/ml stock; stored at 4°C up to 6 months)
150 mM PMSF (see recipe)
2× reducing sample buffer: 10% (v/v) 1 M DTT (*APPENDIX 2A*; 100 mM final) in 2× nonreducing sample buffer (see recipe)
Beckman Airfuge, 4°C, and 5 × 20–mm ultraclear centrifuge tubes (Beckman)
Additional reagents and equipment for in vitro translation using either canine pancreatic microsomes or SP cells, analyzing proteins by SDS-polyacrylamide gel electrophoresis (SDS-PAGE), and gel autoradiography (see Basic Protocol 1)

NOTE: It is important to avoid contamination by RNases that degrade the mRNA during in vitro translations. Wear gloves throughout the experiment. Treat water and salt solutions

with diethylpyrocarbonate (DEPC) to chemically inactivate RNases. Treat all glass and plasticware with DEPC-treated water or otherwise to remove RNase activity.

Carry out in vitro translation

1. In vitro translate the protein of interest as described (see Basic Protocol 1, steps 1 to 3) in the presence of GSSG or FAD.

   The number of samples should be determined and the translation reaction scaled up accordingly.

2. Add 50 mM cycloheximide to a final concentration of 1 mM to stop the translation reaction.

   For a 92-µl reaction, 2 µl of 50 mM cycloheximide is added.

Alkylate proteins

3. Transfer 10 µl lysate to a new 1.5-ml microcentrifuge tube containing 2 µl of 120 mM NEM (20 mM final) to alkylate free cysteines, and place on ice for 10 min.

4. Return remaining lysate to the 27°C water bath for further oxidation and maturation.

5. After appropriate incubation times, repeat steps 3 and 4 for remaining time points.

Isolate membranes

6. Add 50 µl of 1× sucrose cushion to the bottom of a 5 × 20–mm ultraclear centrifuge tube. Overlay 12 µl NEM-alkylated lysate on the top of the sucrose cushion and centrifuge 10 min in a Beckman Airfuge at 20 psi, 4°C.

7. Discard supernatant and resuspend pellet containing the ^{35}S-labeled protein in 20 µl of 1% digestion buffer.

   Adherent cells or cells in suspension can be applied to this assay after this step. For adherent cells perform steps 1 to 10, Basic Protocol 5, or for cells in suspension perform steps 1 to 11, Alternate Protocol 3. Then immunoprecipitate the protein (UNIT 7.2) and resuspend the pellet in 20 µl of 1% digestion buffer and continue with step 8.

   Care must be taken not to create air bubbles while resuspending the pellet. Make sure that no pellet clumps are left undissolved.

8. Transfer 1 µl sample to pH paper to check the pH. If necessary, add 2 to 3 µl of 10% digestion buffer to increase the buffer strength and recheck the pH.

   The optimal pH range for trypsin is 7.5 to 8.0.

Digest with trypsin

9. Add 0.4 to 0.8 µl of 50 µg/ml trypsin (1 to 2 µg/ml final) to the sample (step 7) and incubate 30 min at 27°C.

   Control samples without added enzyme should be set aside for all time points. Set aside half of the sample (~10 µl) from step 8 for a control.Trypsin concentration may need to be titrated for optimal digestion. The incubation time and temperature can also be varied for optimal digestion.

10. Add 2 µl of 50 µg/ml trypsin inhibitor and 1 µl of 150 mM PMSF to stop the digestion. Mix thoroughly by pipetting up and down. Leave the sample at room temperature for 2 min.

Electrophorese proteins

11. Add 25 µl of 2× reducing sample buffer and mix thoroughly. Immediately heat 5 min at 95°C and microcentrifuge 5 min at 16,000 × *g* (14,000 rpm), room temperature.

12. Prepare and run an SDS-polyacrylamide gel and analyze proteins by gel autoradiography as described (see Basic Protocol 1, steps 22 to 28), but load 10 µl sample in step 23.

The remaining sample can be stored up to 2 months at −20°C.

SUPPORT PROTOCOL

ISOLATION OF SEMIPERMEABILIZED CELLS FOR ANALYSIS OF PROTEIN FOLDING

To study the oxidation of a protein in an intact cellular ER while maintaining the manipulative advantage of the in vitro translation system, proteins translated in vitro can be translocated into the ER of semipermeabilized cells (SP cells). Here, essentially any eukaryotic cell type can be used as the ER source. The plasma membrane is permeabilized with the detergent digitonin while the endomembranes remain intact. The SP-cell membranes can then be substituted for the microsomal membranes as discussed in Basic Protocol 1.

Materials

Cells in 75-cm^2 tissue culture flask in appropriate medium
PBS (*APPENDIX 2A*)
Trypsin/EDTA solution (see recipe), room temperature
KHM-STI buffer (see recipe), ice cold
0.4% (w/v) trypan blue solution (Sigma-Aldrich)
KHM buffer (see recipe), ice cold
20 mg/ml digitonin in dimethyl sulfoxide (DMSO), stored in 1-ml aliquots up to 2 years at −20°C
HEPES/potassium acetate buffer (see recipe), ice cold
100 mM $CaCl_2$ (*APPENDIX 2A*)
15,000 U/ml micrococcal nuclease, from *Staphylococcal aureus* (Boehringer Mannheim), stored in working-volume aliquots (e.g., 5 µl or multiples of 5 µl) at −80°C
250 mM ethylene glycol bis(β-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA), adjusted to pH 7.4 with NaOH (stored up to 2 years at −20°C)

Vacuum aspirator
15-ml sterile polystyrene centrifuge tubes, prechilled on ice
Beckman GPR centrifuge (or equivalent), 4°C
Microcentrifuge, 4°C

Additional reagents and equipment for counting cells (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Isolate cells

1. Grow cells in 75-cm^2 tissue culture flask in appropriate medium to ~80% confluency.

Chinese Hamster Ovary (CHO) cells commonly yield 0.6 to 2 × 10^6 SP-cells from a single 75-cm^2 flask. For the 12 µl of SP-cells used in the 92 µl translation mix, two flasks are sufficient, scale up the number of flasks with respect to the size of the experiment.

2. Remove medium from flask, rinse twice with ~10 ml PBS, and use a vacuum aspirator to remove the PBS.
3. Add 4 ml trypsin/EDTA solution, prewarmed at room temperature. Quickly tilt flask back and forth so that the whole flask is covered. Remove trypsin solution immediately and incubate flask 5 min at room temperature.
4. Slap the bottom of the flask to loosen cells, add 6 ml ice-cold KHM-STI buffer, and suspend cells by pipetting up and down until there are no visible cell clumps. Place flask on ice.

   NOTE: *Cells should be kept on ice for all remaining steps except where indicated.*

5. Rinse flask with an additional 2 ml KHM-STI buffer for a total volume of 8 ml.
6. Transfer 10 µl suspended cells to a 1.5-ml microcentrifuge tube and add 10 µl of 0.4% trypan blue solution. Mix thoroughly and count cells. Note percent of dyed cells at this stage (*UNIT 1.1*).
7. Transfer cell suspension (step 5) to a prechilled 15-ml sterile polystyrene centrifuge tube ($\leq 5 \times 10^7$ cells/tube) and place on ice.

   The cell suspension should be divided among multiple tubes as needed.

8. Centrifuge 5 min at 250 × *g* (1200 rpm), 4°C, in a Beckman GPR centrifuge, to pellet cells.

Permeabilize cells

9. Remove supernatant and add 100 µl ice-cold KHM buffer at the bottom of the tube and tap the bottom of the tube to resuspend cells. Add 5.9 ml ice-cold KHM buffer and invert tube two to three times.
10. Add 6 µl of 20 mg/ml digitonin in DMSO (20 µg/ml final) to each tube and mix immediately. Incubate 5 min on ice.
11. Add 8 ml ice-cold KHM buffer and mix by inverting two or three times. Centrifuge 5 min at 250 × *g*, 4°C. Discard supernatant.
12. Resuspend cells in 14 ml ice-cold HEPES/potassium acetate buffer and incubate 10 min on ice. Centrifuge 5 min at 250 × *g*, 4°C. Discard supernatant.
13. Resuspend cells in 1 ml ice-cold KHM buffer and transfer cells into a 1.5-ml microcentrifuge tube.

    All cell pellets from different tubes ($\leq 4 \times 10^7$ cells) should be pooled in 1 ml KHM buffer.

14. Transfer 10 µl cell suspension to a 1.5-ml microcentrifuge tube and dilute 1:5 in ice-cold KHM buffer. Transfer 10 µl of this dilution to a new 1.5-ml tube and count cells and test for permeabilization efficiency with trypan blue (step 6).

    At this step, there are usually about half of the total number of cells that were present in step 6.

15. Microcentrifuge cells (step 13) 2 min at 5,200 × *g* (8,000 rpm), 4°C. Aspirate supernatant and resuspend cells in 100 µl ice-cold KHM buffer (for $2–4 \times 10^6$ cells).

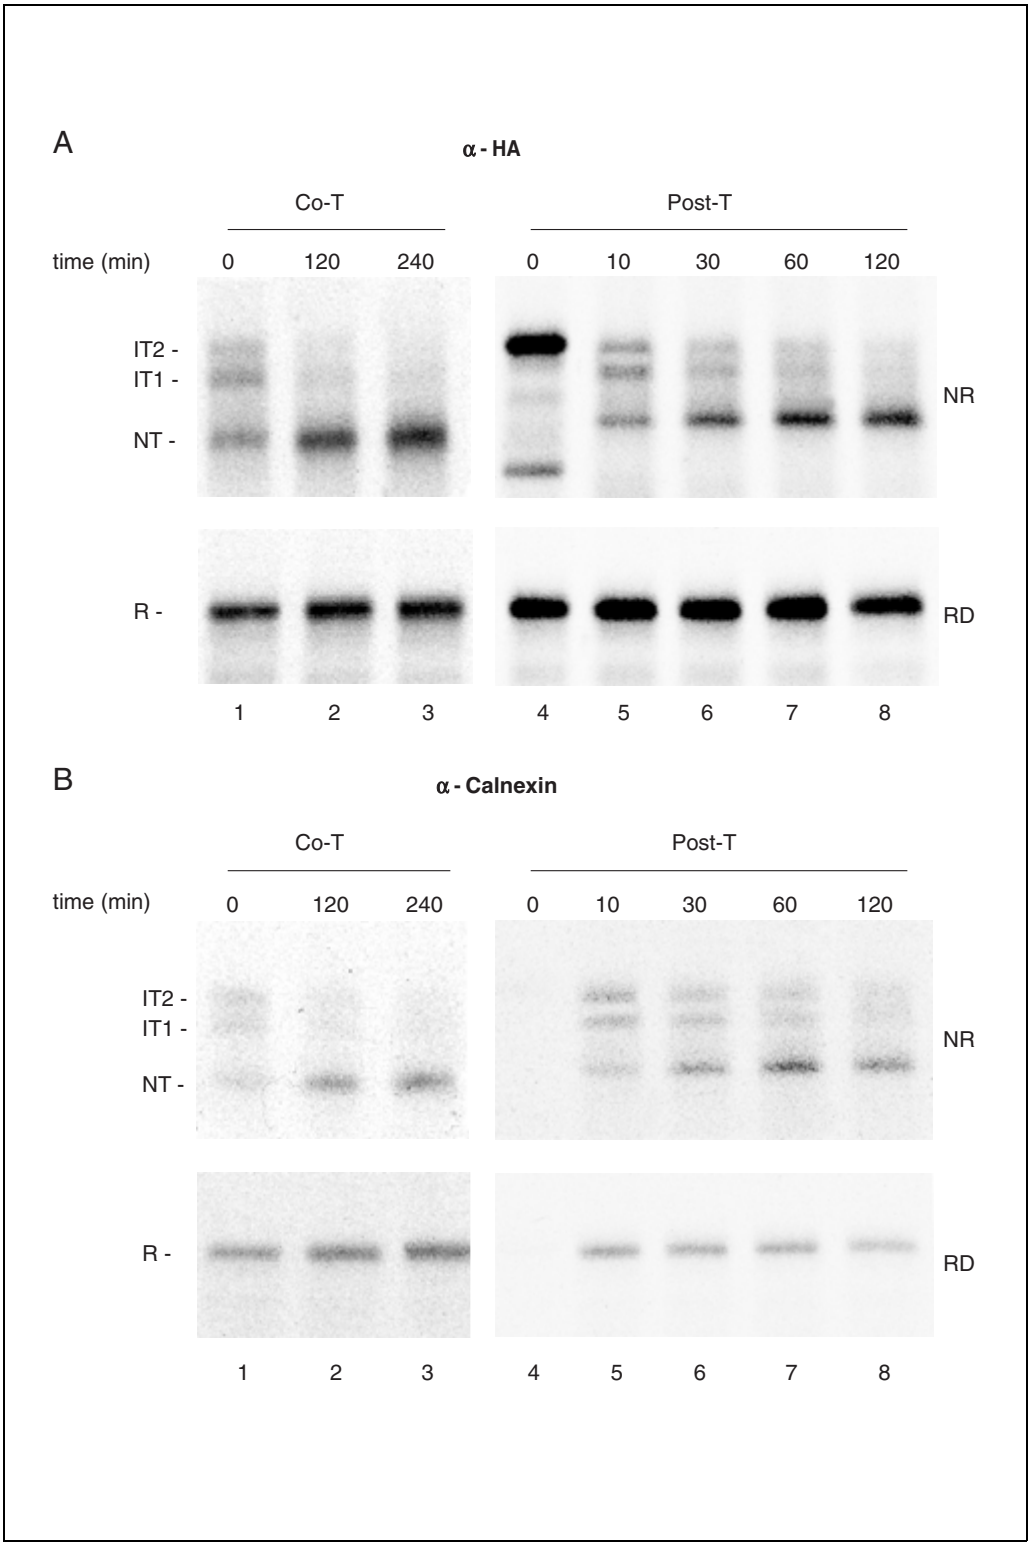

Figure 15.6.3 Disulfide bond formation and folding of hemagglutinin (HA). (A) Co-translational and post-translational formation of disulfide bonds. (B) Calnexin binding. ^{35}S-labeled HA was in vitro translated with rabbit reticulocyte lysate at 27°C for 1 hr in the presence of canine pancreatic endoplasmic reticulum (ER)–derived microsomes under oxidizing (co-translational; Co-T) or reducing (post-translational; Post-T) conditions. Cycloheximide was added to inhibit protein synthesis and protein samples were removed after the indicated chase times and subjected to immunoprecipitation with antisera raised against the whole influenza virus (A) and resolved by nonreducing (NR) and reducing (RD) SDS-PAGE. For post-translational analysis, oxidation was initiated at time zero and followed. The same samples were used to identify interactions with calnexin by the co-immunoprecipitation of ^{35}S-labeled HA with anti-calnexin antiserum (B). Protein forms are as follows: IT1, intermediate 1; IT2, intermediate 2; NT, native; R, reduced.

Treat with nuclease

16. Add 1 µl of 100 mM $CaCl_2$ (1 mM final) and 2 µl of 15,000 U/ml (300 U/ml final) micrococcal nuclease. Mix and incubate 12 min at room temperature.

    Micrococcal nuclease is a calcium-dependent nuclease that will digest endogenous mRNA.

17. Add 1.6 µl of 250 mM EGTA (4 mM final) to chelate calcium and inactivate the nuclease.

18. Microcentrifuge cells 2 min at 5,200 × *g*, 4°C. Aspirate supernatant and resuspend SP-cell pellet with ice-cold KHM buffer to a final concentration of 1×10^5 cells/µl.

    SP cells should be used as soon as they are prepared.

ANALYSIS OF FOLDING-INTERMEDIATE BINDING TO MOLECULAR CHAPERONES IN ROUGH ENDOPLASMIC RETICULUM–DERIVED MICROSOMES

BASIC PROTOCOL 3

Protein folding in the cell is a highly assisted process. Molecular chaperones and foldases play important roles in aiding the folding or stabilization of nascent proteins. In the endoplasmic reticulum (ER), proteins that help in the folding process include BiP (GRP78; an hsp70 family member), GRP94 (an hsp90 family member), the lectin chaperones calnexin and calreticulin, and the protein disulfide isomerase family members PDI, ERp57, and ERp72. The transient binding of these folding factors to the nascent chain can be studied through a co-immunoprecipitation procedure if the interactions persist during the solubilization and immunoprecipitation protocol.

In this protocol, a co-immunoprecipitation procedure is described that permits the characterization of transient interactions of folding factors. Co-immunoprecipitations (Fig. 15.6.3) require modifications to the general immunoprecipitation protocol described previously (see Basic Protocol 1). First, the detergent used in cell or microsomal lysis must enable the persistence of the native interaction of the chaperones with the substrate. Common nondenaturing detergents used for this purpose include Triton X-100, digitonin, and CHAPS (*UNIT 7.2*). In addition, antibodies against the chaperones or folding factors are required. Finally, if folding-factor binding is regulated by ATP binding (as found with BiP), it may be necessary to deplete ATP during the solubilization step to trap the interaction with the nascent chain. Chemical cross-linking can also be performed to provide a covalent bond to trap interactions between the chaperone and its substrate prior to lysis (see Alternate Protocol 2).

Materials

Antiserum raised against protein of interest
Antiserum raised against chaperone of interest

Additional reagents and equipment for in vitro translation using canine pancreatic microsomes or SP cells, immunoprecipitation, SDS-polyacrylamide gel electrophoresis (SDS-PAGE), and gel autoradiography (see Basic Protocol 1)

NOTE: It is important to avoid contamination by RNases that degrade the mRNA during in vitro translations. Wear gloves throughout the experiment. Treat water and salt solutions with diethylpyrocarbonate (DEPC) to chemically inactivate RNases. Treat all glass and plasticware with DEPC-treated water or otherwise to remove RNase activity.

1. In vitro translate the protein of interest as described (see Basic Protocol 1, steps 1 to 3, when using microsomes or Support Protocol, steps 1 to 18 for SP-cells), adjusting the volume of any control reactions with nuclease-free water.

The number of time points should be determined and the translation reaction scaled up accordingly. For each time point, three samples will be needed: lysate (for total protein analysis), immunoprecipitation with antibodies directed against the maturing protein, and immunoprecipitation with antibodies directed against the chaperone(s). A reaction mixture of 30 µl is appropriate for each time point when only one chaperone immunoprecipitation is performed. For each additional chaperone immunoprecipitation increase the reaction mixture by 10 µl. Keeping the DTT concentration constant (1.1 mM) for these reactions, titrate GSSG from 2 to 6 mM or FAD from 50 to 200 µM to determine optimum oxidation conditions.

A control reaction without microsomes or SP-cells should be performed to eliminate the possibility that non-specific binding is occurring int he chaperone binding assays.

2. Transfer 30 µl lysate into a 1.5-ml microcentrifuge tube. Return the remaining lysate to the 27°C water bath for further oxidation and maturation.
3. Add 6 µl of 120 mM NEM to 30-µl sample to arrest oxidation and incubate 10 min on ice to stop the translation.

   Cycloheximide at a final concentration of 1 mM can also be included to stop the translation if further maturation is to be followed in the absence of protein synthesis.

4. Divide the sample into three 12-µl aliquots.
5. To the first, add 12 µl of 2× nonreducing sample buffer and 16 µl of 1× nonreducing sample buffer, store samples at −20°C until all samples are prepared. To prepare the samples heat 5 min at 920°C and analyze total proteins (see Basic Protocol 1, steps 22 to 28).
6. To the remaining two aliquots, add 500 µl ice-cold 2% CHAPS/HeBS to lyse the samples.
7. Immunoprecipitate both samples as described (see Basic Protocol 1, steps 11 to 18), using an antibody raised against the protein of interest in one sample to measure total protein level and an antibody raised against the interacting molecular chaperone in the other.
8. Electrophorese and analyze proteins by SDS-PAGE and gel autoradiography as described (see Basic Protocol 1, steps 19 to 28).

   Table 15.6.1 is a list of chaperones and their molecular weights; this can be used to calculate the molecular weight change in complexes.

Table 15.6.1 Approximate Molecular Weights of Endoplasmic Reticulum Chaperones

Chaperone[a]	Molecular weight (kDa)
BiP (GRP78)	75
CNX	57[b]; 90[c]
CRT	48[b]; 60[c]
ERp57	57
ERp72	72
GRP94	94
PDI	55

[a]Abbreviations: CNX, calnexin; CRT, calreticulin; ER, endoplasmic reticulum; GRP, glucose-regulated protein; PDI, protein disulfide isomerase.
[b]Calculated molecular weight.

MONITORING TRANSIENT CHAPERONE INTERACTIONS USING CROSS-LINKING AND DENATURING IMMUNOPRECIPITATIONS

In some cases, the interactions between maturing proteins and molecular chaperones may be weak, therefore disruption can occur during the immunoprecipitation procedure. These types of interactions may require the additional stability offered through chemical cross-linking. Several types of membrane-permeable chemical cross-linkers are commercially available with reactivity towards free sulfhydryls, amines, carboxyls, or other functional groups, while others are UV excitable and can trap a broader range of functional groups (Table 15.6.2).

Once a cross-link is recognized by a molecular weight shift following SDS-PAGE, it can be identified using denaturing immunoprecipitation with antiserum raised against the molecular chaperone adduct. To minimize background cross-linking, the microsomes are isolated from the translation system by centrifugation and resuspended in an isotonic resuspension buffer prior to cross-linking.

Additional Materials *(also see Basic Protocol 3)*

Isotonic sucrose cushion (see recipe)
Isotonic resuspension buffer (see recipe)
10 mM BMH (see recipe) or alternative cross-linker
Quenching solution: 100 mM 2-mercaptoethanol (stored up to 1 month at 4°C)
20% (w/v) SDS (*APPENDIX 2A*)
Denaturing immunoprecipitation buffer (see recipe)
Beckman Optima TLX ultracentrifuge and TLA 120.2 rotor, 4°C, and 7 × 20–mm ultracentrifuge tubes *or* Beckman Airfuge, 4°C, and 5 × 20–mm ultraclear centrifuge tubes

NOTE: It is important to avoid contamination by RNases that degrade the mRNA during in vitro translations. Wear gloves throughout the experiment. Treat water and salt solutions with diethylpyrocarbonate (DEPC) to chemically inactivate RNases. Treat all glass and plasticware with DEPC-treated water or otherwise to remove RNase activity.

1. In vitro translate the protein of interest as described (see Basic Protocol 3 steps 1 to 3), but when using a thiol-reactive cross-linker, such as BMH (step 4), do not add NEM. Adjust samples to 1 mM cycloheximide and incubate 10 min on ice to terminate translation.

   NEM will block reactive groups on thiol-reactive cross-linkers (e.g., BMH).

Table 15.6.2 Commonly Used Cross-Linkers for Monitoring Chaperone Interactions

Cross-linker[a]	Reactivity
BASED	Nonselective, photoreactive
BMH	Sulfhydryls
DSP	Amines
EDC	Amines and carboxyls
SMCC	Amines and sulfhydryls

[a]Available from Pierce Chemical. Abbreviations: BASED, bis[β-(4-azidosalicylamido)ethyl] disulfide; BMH, bismaleimidohexane; DSP, dithiobis(succinimidyl propionate); EDC, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride; SMCC, succinimidyl 4-[*N*-maleimidomethyl]cyclohexane-1-carboxylate.

For interactions with some folding factors, it is essential that the translation be performed under oxidizing conditions, as this will enable the chaperones to remain in their native oxidized state. Nonnative reducing conditions may reduce a critical disulfide bond in the chaperone thereby destroying its ability to interact with other substrates (for example, calnexin and calreticulin's lectin-binding properties are diminished under reducing conditions; Fig. 15.6.3B, lane 4).

2. Carefully layer a 10-µl sample on a 30-µl isotonic sucrose cushion (1:3 sample/cushion ratio) within a 7 × 20–mm ultracentrifuge tube or a 5 × 20–mm ultraclear centrifuge tube, and centrifuge 10 min either at 157,000 × *g* (60,000 rpm), 4°C, using a Beckman Optima TLX ultracentrifuge with a TLA 120.2 rotor or at 20 psi, 4°C, using a Beckman Airfuge, respectively.
3. Keeping samples on ice, aspirate the supernatant. Resuspend pellet by pipetting up and down in 10 µl isotonic resuspension buffer, and transfer to a new 1.5-ml microcentrifuge tube.

   It is important that the microsomal pellet is fully resuspended and the samples are kept on ice.

   Removal of the reticulocyte lysate by centrifugation ensures that cross-links will not occur with reticulocyte lysate proteins.
4. Add 1.1 µl of 10 mM BMH (1 mM final) and incubate 10 min at 27°C.

   It may be necessary to increase or decrease the cross-linker concentration to obtain the optimal results.
5. Add 1.2 µl quenching solution and place samples on ice for 10 min.

   While the authors describe a protocol for BMH, a thiol-reactive cross-linker that is quenched with alkylating agents, a variety of cross-linkers (Table 15.6.2) should be tested for optimal cross-linking. The quenching agent employed will depend on the cross-linker chemistry.
6. Add 0.65 µl of 20% SDS to a 12.2 µl sample (1% final) and heat 5 min at 95°C.

   This will denature all noncovalent interactions and ensure that only cross-linked adducts are visualized,
7. Add 500 µl denaturing immunoprecipitation buffer to quench SDS.
8. Complete immunoprecipitation as described (see Basic Protocol 3, steps 7 to 8), but use 500 µl denaturing immunoprecipitation buffer in place of 500 µl of 0.5% CHAPS/HeBS for the wash step (see Basic Protocol 1, step 16).

   Antibodies to predicted adducts can be used here (Table 15.6.2; Affinity BioReagents, Stressgen). Once adducts are observed, their molecular weights can be estimated by reducing SDS-PAGE. Antibodies to molecular chaperones with similar molecular weights (Table 15.6.1) can then be used to identify protein adducts. StressGen Biotechnologies and Affinity BioReagents are excellent sources for antibodies against ER folding factors.

BASIC PROTOCOL 4

MONITORING PROTEIN FOLDING USING CONFORMATION-SPECIFIC ANTIBODIES

The recognition of protein determinants (epitopes) by antibodies can be conformation dependent. This enables the use of conformation-specific antibodies as a powerful tool for the characterization of the folding process (Goldberg, 1991). The acquisition or disappearance of specific epitopes can be used as a probe to monitor the folding reaction. On occasion, monospecific antibodies that recognize a single epitope can be obtained from polyclonal sources by generating antipeptide antibodies or by antibody purification. However, more commonly, monoclonal antibodies (mAbs) have been found to be the most effective for these studies.

This protocol describes the use of conformation-specific antibodies to characterize the folding process in rough endoplasmic reticulum (ER)–derived microsomes. It is similar to Basic Protocol 3, which explains the analysis of chaperone binding with the use of co-immunoprecipitation studies. Here, it is also important to lyse the microsomes and perform the antibody binding and washing under gentle nondenaturing conditions to ensure that the protein conformation is not disrupted. The antibodies employed are mAbs raised against the folding substrate that recognize individual epitopes. In short, the folding reaction is initiated with the radiolabeled protein as in Basic Protocol 1 (co-translationally) or Alternate Protocol 1 (post-translationally), with samples being removed at various times and analyzed by immunoprecipitation with the mAbs, and then the radiolabeled precipitate is resolved by SDS-PAGE and autoradiography.

Materials

50% (w/v) protein G–Sepharose or protein A–Sepharose bead (Sigma-Aldrich) slurry in PBS/0.1% (w/v) BSA/0.01% (w/v) sodium azide

Conformation-specific monoclonal antibody (mAb) against protein of interest

Control antibodies (preimmune control and antibody control that recognizes all conformations of the protein of interest)

Additional reagents and equipment for in vitro translation using canine pancreatic microsomes, immunoprecipitation, SDS-polyacrylamide gel electrophoresis (SDS-PAGE), and gel autoradiography (see Basic Protocol 1)

CAUTION: Sodium azide is poisonous; follow appropriate precautions for handling, storage, and disposal.

NOTE: It is important to avoid contamination by RNases that degrade the mRNA during in vitro translations. Wear gloves throughout the experiment. Treat water and salt solutions with diethylpyrocarbonate (DEPC) to chemically inactivate RNases. Treat all glass and plasticware with DEPC-treated water or otherwise to remove RNase activity.

NOTE: All solutions should be ice cold and procedures should be carried out at 4°C or on ice unless otherwise indicated.

1. In vitro translate the protein of interest as described (for cotranslational analysis see Basic Protocol 1, steps 1 to 3; for post-translational analysis see Alternate Protocol 1, steps 1 to 3).

   The number of time points should be determined and the translation reaction scaled up accordingly. For each time point three 12-µl samples will be needed: lysate (for total protein analysis), immunoprecipitate with antibody that is not conformation dependent, and immunoprecipitate with antibody that is conformation dependent.

2. Transfer 30 µl lysate into a 1.5-ml microcentrifuge tube. Return the remaining lysate to the 27°C water bath for further oxidation and maturation.

3. Add 6 µl of 120 mM NEM to 30-µl sample and incubate on ice 10 min to alkylate proteins and arrest disulfide bond formation.

4. Add 500 µl ice-cold 2% CHAPS/HeBS and vortex in a microcentrifuge tube rack vortex mixer at medium speed for 10 min at 4°C to lyse ER microsomes.

5. Add 100 µl of 50% protein G (or A)–Sepharose bead slurry and rotate end over end on a tube rotator for 1 hr at 4°C, to preclear sample.

   For a discussion and chart on the use of protein A versus protein G, see UNIT 7.2 (Table 7.2.1).

6. Centrifuge sample 5 min at 2900 × *g*, 4°C, and divide sample among three 1.5-ml microcentrifuge tubes containing 100 µl of 50% protein G (or A)–Sepharose and 2 to 10 µl of either a conformation-specific mAb against the protein of interest, a preimmune control antibody, or a control antibody that recognizes all conformations of the protein of interest.

   A titration with antiserum may be required to obtain optimal results. Excess antibodies may give nonspecific binding or saturate the protein G (or A)–Sepharose.

7. Immunoprecipitate and analyze the proteins using nonreducing and reducing SDS-PAGE and gel autoradiography as described (see Basic Protocol 1, steps 13 to 28).

BASIC PROTOCOL 5

ANALYSIS OF PROTEIN FOLDING AND DISULFIDE BOND FORMATION IN CELLS GROWN IN INTACT MONOLAYERS (ADHERENT CELLS)

Co-translational and post-translational folding of a protein can be followed in cells grown in monolayers in tissue culture dishes (Braakman et al., 1991). This procedure allows multiple rapid wash steps, facilitating experiments that require short pulse-chase times. Adherent-cell studies are also ideal for experiments requiring frequent changes of medium. The disadvantage of these studies is that large volumes of medium can be required. When low total volume of medium is desired (e.g., when expensive reagents are needed for the experiment), the analysis can be performed with cells in suspension (see Alternate Protocol 3).

For a detailed explanation of metabolic labeling procedures, see *UNIT 7.1*. In brief, cellular proteins are metabolically labeled in tissue culture dishes with [^{35}S]methionine and [^{35}S]cysteine (the pulse). The labeling medium is removed by aspiration and replaced by medium containing cold (i.e., unlabeled) amino acids, and the cells are incubated (the chase). Samples are removed at various times and oxidative intermediates trapped with chilled buffer containing alkylating agents. Because all cellular proteins are labeled by this procedure, analysis of a specific protein requires isolation by immunoprecipitation (*UNIT 7.2* or see Basic Protocol 1). The isolated protein can then be analyzed for disulfide bond formation (Basic Protocol 1), protease sensitivity (Basic Protocol 2), chaperone binding (Basic Protocol 3), or folding with conformation-specific antibodies (Basic Protocol 4).

Materials

Adherent cells grown to 80% to 90% confluency in a 60-mm tissue culture dish
Depletion medium: cysteine- and methionine-free tissue culture medium, 37°C
Labeling medium: depletion medium containing 0.125 to 0.75 mCi/ml [^{35}S]methionine and [^{35}S]cysteine (prepared fresh), 37°C
Chase medium (see recipe), 37°C
Stop buffer: 20 mM NEM (see recipe for 1 M stock) in PBS, prepared just before use and kept on ice
Lysis buffer (see recipe), ice cold

Aspirator
Cell scraper

Additional reagents and equipment for immunoprecipitation (*UNIT 7.2* or see Basic Protocol 1) and analysis of disulfide bond formation (see Basic Protocol 1), protein folding by proteolytic sensitivity (see Basic Protocol 2), chaperone binding (see Basic Protocol 3), *or* protein folding with conformation-specific antibodies (see Basic Protocol 4)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

NOTE: For the analysis of co-translational protein folding no reducing agents are added to either the pulse or chase medium. Chase medium should contain 1 mM cycloheximide in order to stop protein synthesis. In the case of post-translational protein folding and disulfide bond formation, reducing agent (5 mM DTT final) is added to the pulse medium. When the reducing agent is removed after pulse labeling, redox conditions are restored that support the formation of disulfide bonds.

NOTE: Separate cell culture dishes will be required for each condition and time point.

Perform metabolic labeling

1. Use an aspirator to remove culture medium from adherent cells grown to 80% to 90% confluency in a 60-mm tissue culture dish, and wash dish twice by gently swirling with 10 ml prewarmed depletion medium, aspirating medium after each wash.

   Prior to the experiment, the number of chase time points should be determined. Depending on the cell type, a confluent 60-mm dish will contain 1.8–7 × 10^6 cells, or enough for approximately one time point. Other dish sizes can be used. The volumes should be adjusted accordingly based on the surface area of the dish.

2. Add 5 ml prewarmed depletion medium and incubate 15 min in a humidified 37°C, 5% CO_2 incubator to deplete intracellular pools of methionine and cysteine.

3. Remove medium from cells, add 450 µl labeling medium, and incubate 10 to 60 min in a CO_2 incubator.

   It is critical that the plates sit on a perfectly horizontal surface during incubation to avoid drying of the cell monolayer.

   Mammalian translation rates are on the order of five amino acids per second. Labeling time will depend on the length and the expression level of the protein of interest, as well as the number of methionine and cysteine residues in the protein.

4. Remove and discard labeling medium.

Perform chase

5a. *For 0-min chase:* Add 2 ml chase medium and gently rock solution over cells. Rapidly aspirate chase medium, immediately add 2.5 ml ice-cold stop buffer, and place dish on ice.

   The chase medium contains the protein synthesis inhibitor cycloheximide (1 mM final).

5b. *For other chase times:* Add 2 ml chase medium and gently rock solution over cells. Aspirate medium, replace with 2 ml fresh chase medium, and incubate for desired times in the CO_2 incubator. Rapidly aspirate chase medium, immediately add 2.5 ml ice-cold stop buffer, and place dish on ice.

   Chase times are dependent upon the time it takes the protein of interest to oxidize, fold, and exit the endoplasmic reticulum (ER).

Prepare lysate

6. Remove stop buffer and add 2.5 ml fresh stop buffer. Aspirate dish dry.

7. Add 600 µl ice-cold lysis buffer.

8. Scrape off cells using a cell scraper and collect in a 1.5-ml microcentrifuge tube.
9. Microcentrifuge 5 min at 11,800 × *g* (12,000 rpm), 4°C, to pellet nuclei.
10. Transfer post-nuclear supernatant to a new 1.5-ml microcentrifuge tube.
11. Analyze disulfide bond formation (see Basic Protocol 1, steps 5 to 28), protein folding by proteolytic sensitivity (see Basic Protocol 2, steps 7 to 12), chaperone binding (see Basic Protocol 3, steps 7 to 8), or protein folding with conformation-specific antibodies (see Basic Protocol 4, steps 5 to 7). Immunoprecipitate the protein of interest (*UNIT 7.2*) if needed.

To analyze the disulfide bond formation (Basic Protocol 1) use ice-cold PBS without NEM for the stop buffer (steps 5b and 6 above). Divide the sample appropriately after step 10 and alkylate with either NEM or AMS. Keep one sample that is not alkylated on ice as a control.

When analyzing for proteolytic sensitivity immunoprecipitate (UNIT 7.2) the 600 µl of post nuclear lysate from step 10 prior to performing steps 7 to 12 of Basic Protocol 2.

ALTERNATE PROTOCOL 3

ANALYSIS OF PROTEIN FOLDING AND DISULFIDE BOND FORMATION IN SUSPENDED (NONADHERENT) CELLS

When cells do not adhere adequately or when it is desirable to use small volumes of reagents for analysis (i.e., when expensive drugs are used), cells in suspension may be used to analyze protein folding and disulfide bond formation. The advantage with this approach is that samples at different chase intervals can be divided from the same population of ^{35}S-labeled cells. Cells are collected in 15- or 50-ml polystyrene conical centrifuge tubes and the pulse-chase is performed in the tube. However, the exchange of media and buffers requires centrifugation of cells. Each chase time point should have ~1 × 10^6 cells. Co-translational and post-translational folding can be followed using appropriate reducing and oxidizing conditions in the pulse and chase medium (see Alternate Protocol 1) and analyzed for disulfide bond formation (Basic Protocol 1), protease sensitivity (Basic Protocol 2), chaperone binding (Basic Protocol 3), or protein folding with conformation-specific antibodies (Basic Protocol 4).

Additional Materials (also see Basic Protocol 5)

Cell suspension
Suspension labeling medium: depletion medium containing 25 to 50 µCi/ml [^{35}S]methionine and [^{35}S]cysteine (prepared fresh), 37°C
15-ml sterile polystyrene conical centrifuge tubes
Beckman GPR centrifuge or equivalent
37°C water bath
Additional reagents and equipment for immunoprecipitation (*UNIT 7.2* or see Basic Protocol 1) and for analysis of disulfide bond formation (see Basic Protocol 1), protein folding by proteolytic sensitivity (see Basic Protocol 2), chaperone binding (see Basic Protocol 3), *or* protein folding with conformation-specific antibodies (see Basic Protocol 4)

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

NOTE: Keep cells in suspension by periodically swirling the tube during incubations.

Collect cells

1. Collect cell suspension in a 15-ml sterile polystyrene conical centrifuge tube.

   Prior to the experiment, the minimum volume in which the cells are to be suspended, the number of chase time points, and the desired sample volume should be determined. Approximately 1×10^6 cells should be used per time point. The volumes should be scaled up accordingly; a 50-ml conical centrifuge tube should be used for larger volumes.

   The cells can also be collected by treating adherent cells with sterile 0.25% (w/v) trypsin/0.2% (w/v) EDTA at room temperature and resuspending in regular culture medium. (Some cell types require EDTA for detachment while others do not. This must be determined in each case.) Cells are resuspended in normal growth medium by pipetting up and down two to three times.

2. Centrifuge cell suspension 5 min at $250 \times g$ (1200 rpm), room temperature, in a Beckman GPR centrifuge and discard the medium.

   The pelleting efficiency may vary with different cell types.

3. Resuspend cells in 0.5 ml per time point depletion medium and centrifuge 5 min at $250 \times g$, room temperature.

   For resuspending cells, a minimal volume of depletion medium should be used.

4. Discard supernatant and resuspend cells in 0.5 ml per time point depletion medium and incubate 30 to 60 min in a 37°C water bath to deplete intracellular methionine and cysteine. Resuspend the cells periodically by gently swirling the tube.

5. Centrifuge cells 5 min at $250 \times g$, room temperature, and aspirate supernatant.

Perform pulse-chase labeling

6. Resuspend cells in 2 ml suspension labeling medium. Cap tube tightly and incubate for the desired pulse time at 37°C. Resuspend the cells periodically by swirling the tube.

   A 15- to 30-min pulse is usually sufficient. However, labeling time will depend on the length and expression level of the protein of interest, as well as the number of methionine and cysteine residues in the protein.

7. Centrifuge cells 5 min at $250 \times g$, room temperature, and aspirate supernatant. Resuspend cells in 0.5 ml per time point chase medium and centrifuge again. Aspirate supernatant and resuspend cells in 0.5 ml per time point chase medium.

   Chase medium contains a protein synthesis inhibitor (1 mM cycloheximide).

   For experiments with multiple time points, a single population of cells is labeled, and then aliquots (each containing ~1×10^6 cells) are removed at appropriate chase time points. Because the cells settle to the bottom of the tube during the pulse and chase intervals, the tube should be swirled gently at regular intervals and the cells mixed thoroughly by pipeting up and down several times before dividing.

8a. *For 0-min chase:* Immediately take an aliquot of cells (~10^6 cells) and add an equal volume of ice-cold lysis buffer to the aliquot, mix well, and place on ice.

   Alternatively, 14 mM 4-acetamido-4′-maleimidylstilbene-2,2′-disulfonic acid disodium salt (AMS) can be used instead of NEM in the lysis buffer. When analyzing disulfide bond formation AMS provides a larger molecular weight shift than NEM.

8b. *For other chase times:* Incubate cell suspension for the desired chase time at 37°C. At the end of each of the appropriate chase times, take an aliquot of ~10^6 cells and add an equal volume ice-cold lysis buffer, mix well, and place on ice.

   Alternatively, 14 mM 4-acetamido-4′-maleimidylstilbene-2,2′-disulfonic acid disodium salt (AMS) can be used instead of NEM in the lysis buffer.

Prepare lysate

9. Transfer sample to a 1.5-ml microcentrifuge tube, and vortex sample 10 min in a microcentrifuge tube rack vortex mixer at full speed, 4°C, to ensure complete cell lysis.
10. Microcentrifuge 10 min at 11,800 × *g*, 4°C.
11. Discard nuclear pellet. Transfer postnuclear supernatant to a new 1.5-ml microcentrifuge tube.
12. Analyze disulfide bond formation (see Basic Protocol 1, steps 5 to 28), protein folding by proteolytic sensitivity (see Basic Protocol 2, steps 7 to 12), chaperone binding (see Basic Protocol 3, steps 7 to 8), or protein folding with conformation-specific antibodies (see Basic Protocol 4, steps 5 to 7). Immunoprecipitate the protein of interest (see *UNIT 7.2*) if needed.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

4-Acetamido-4′-maleimidylstilbene-2,2′-disulfonic acid disodium salt (AMS), 20 mM

5.36 mg AMS (Molecular Probes; 20 mM final)
40 µl 1 M Tris·Cl, pH 6.8 (*APPENDIX 2A*; 80 mM final)
25 µl 20% (w/v) SDS (*APPENDIX 2A*; 1% final)
H_2O to 0.5 ml
Prepare fresh daily, keep on ice, and avoid exposure to light

AMS is sensitive to light and hydrolysis.

Bismaleimidohexane (BMH), 100 mM

2.76 mg bis-maleimidohexane (BMH; Pierce Chemical)
100 µl 50% (v/v) dimethyl sulfoxide (DMSO)
Store up to 6 months at −20°C
Dilute as needed in 50% (v/v) DMSO

Chase medium

2 ml 1 M HEPES buffer (see recipe), pH 7.3 (20 mM final)
0.5 ml 1 M methionine (see recipe; 5 mM final)
0.5 ml 1 M cysteine (see recipe; 5 mM final)
2 ml 50 mM cycloheximide (see recipe; 1 mM final)
Tissue culture medium to 100 ml
Prepare fresh daily

The tissue culture medium should be appropriate for the cells of interest.

Cycloheximide, 50 mM

0.28 g cycloheximide
H_2O to 10 ml
Store 1-ml aliquots up to 2 years at −20°C

Cysteine, 1 M

1.212 g L-cysteine
H_2O to 10 ml
Store 1-ml aliquots up to 2 years at −20°C

Denaturing immunoprecipitation buffer

5 ml 1 M Tris·Cl, pH 7.6 (*APPENDIX 2A*; 10 mM final)
70 ml 1 M NaCl (140 mM final)
2 ml 250 mM EDTA, pH 8.0 (*APPENDIX 2A*; 1 mM final)
5 ml Triton X-100 (1% final)
H_2O to 500 ml
Store up to 6 months at 4°C

Flavin adenine dinucleotide (FAD), 25 mM

0.207 g FAD
H_2O to 10 ml
Store in 1-ml aliquots up to 2 years at −20°C

Glutathione (GSSG), 100 mM, pH 7.0

0.656 g oxidized GSSG
9 ml H_2O
Adjust pH to 7.0 with 1 N NaOH
H_2O to 10 ml
Store 1-ml aliquots up to 2 years at −20°C

NaOH is used here because K^+ concentrations are more critical in maintaining the fidelity of the translation system.

HEPES buffer

260.3 g *N*-2-hydroxyethylpiperazine-(*N*′2)-2-ethanesulfonic acid (HEPES), sodium salt
H_2O to 800 ml
Adjust pH to 7.2, 7.3, or 7.5 with 10 N KOH
H_2O to 1 liter
Store up to 6 months at 4°C

HEPES-buffered saline (HeBS)

50 ml 1 M HEPES buffer (see recipe), pH 7.5 (50 mM final)
11.69 g NaCl (200 mM final)
H_2O to 1 liter
Store up to 6 months at 4°C

HEPES/potassium acetate buffer

18 ml 1 M HEPES buffer (see recipe), pH 7.2 (90 mM final)
10 ml 1 M potassium acetate, pH 7.2 (50 mM final)
H_2O to 200 ml
Store up to 6 months at 4°C

Isotonic resuspension buffer

2.5 ml 1 M sucrose (250 mM final)
1 ml 1 M potassium acetate (100 mM final)
50 µl 1 M magnesium acetate (5 mM final)
0.5 ml 1 M HEPES buffer (see recipe), pH 7.5 (50 mM final)
H_2O to 10 ml
Store up to 6 months at 4°C

Isotonic sucrose cushion

2.5 ml 1 M sucrose (250 mM final)
0.5 ml 1 M potassium acetate (500 mM final)
50 µl 1 M magnesium acetate (5 mM final)
0.5 ml 1 M HEPES buffer (see recipe), pH 7.5 (50 mM final)
H_2O to 10 ml
Store up to 6 months at 4°C

KHM buffer

55 ml 1 M potassium acetate (110 mM final)
1 ml 1 M magnesium acetate (2 mM final)
10 ml 1 M HEPES buffer, pH 7.2 (see recipe; 20 mM final)
H_2O to 500 ml
Store up to 6 months at 4°C

KHM-STI buffer

100 ml KHM buffer (see recipe)
200 µl 50 mg/ml soybean trypsin inhibitor
Prepare fresh daily and store at 4°C

Lysis buffer

0.2 ml 10% (w/v) 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate) (CHAPS) in HeBS (see recipe; 2% final)
26.7 µl 150 mM PMSF (see recipe; 0.4 mM final)
10 µl 10 mg/ml leupeptin (10 µg/ml final)
80 µl 1.25 mg/ml aprotinin (10 µg/ml final)
0.2 ml 1 M NEM (see recipe; 20 mM final)
PBS or similar buffer to 10 ml
Add PMSF, leupeptin, aprotinin, and NEM from concentrated stocks just before use

Methionine, 1 M

1.49 g L-methionine
H_2O to 10 ml
Store 1-ml aliquots up to 2 years at −20°C

N-ethylmaleimide (NEM), 1 M

1.25 g NEM
10 ml 100% (v/v) ethanol
Store in 1-ml aliquots up to 2 years at −20°C protected from light
Dilute as needed with 100% (v/v) ethanol

NEM is sensitive to hydrolysis in water and light. The number of freeze thaws should be limited as the NEM will precipitate out and the solution will turn yellow.

Nonreducing sample buffer, 2×

4.5 g SDS (9% final)
7.5 ml glycerol (15% final)
1.5 ml 1 M Tris·Cl, pH 7.8 (*APPENDIX 2A*; 30 mM final)
25 mg bromphenol blue (0.05% final)
H_2O to 50 ml
Store up to 1 year at room temperature

Phenylmethylsulfonyl fluoride (PMSF), 150 mM

2.613 g PMSF
10 ml DMSO
Store in 500-µl aliquots up to 2 years at −20°C

PMSF is highly unstable in water: the half life is ~30 min at 37°C and a few hours on ice.

Protein A–Sepharose, 10%

0.5 g protein A–Sepharose
20 ml 0.5% (w/v) 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate) (CHAPS) in HeBS (see recipe for HeBS)
Store up to 6 months at 4°C

Salicylate, 2%

2 g sodium salicylate
30 ml methanol
H_2O to 100 ml
Cover the bottle with aluminum foil and store up to 6 to 12 months at room temperature

CAUTION: Gloves should be worn at all times; sodium salicylate can elicit allergic reactions and is readily absorbed through the skin.

Sucrose cushion, 1×

5 ml 1 M sucrose (0.5 M final)
76.1 µl 98% (w/v) triethanolamine (50 mM final)
H_2O to 10 ml
Store up to 6 months at 4°C

Trypsin/EDTA solution

90 ml 1× S-MEM (from 10× S-MEM; Life Technologies) containing 0.23% (w/v) $NaCO_3$ mix and adjust to pH 4.1 to 4.2
10 ml 2.5% trypsin/2% EDTA (Life Technologies; 0.25% final trypsin and 0.2% final EDTA)
Prepare fresh daily

COMMENTARY

Background Information

The early maturation events for a protein in the secretory pathway involve protein folding and oxidation in the endoplasmic reticulum (ER). The folding process commences co-translationally as the protein is vectorially inserted into the ER lumen and is generally completed post-translationally once the protein is released from the ribosome (Braakman et al., 1991; Chen et al., 1995; Fig. 15.6.2). Protein folding can be monitored by using antibodies for immunoprecipitation that recognize specific epitopes that appear or disappear during the folding process (see Basic Protocol 4). In addition, as a protein folds and stabilizes, it becomes more resistant to protease digestion. Domains that are cleaved by the protease in the unfolded state become concealed within the protein core making them inaccessible to proteases (see Basic Protocol 2).

The ER lumen provides an intracellular compartment that is topologically equivalent to the extracellular space. This allows the preparation of proteins that will be secreted and will reside outside the cell. The ER lumen is an oxidizing environment that supports the formation of disulfide bonds. Disulfide bonds can form within a protein (intramolecular) or between two different polypeptide chains (intermolecular). Intramolecular disulfide bond formation can begin co-translationally and is often completed post-translationally. Usually, disulfide bond formation results in a more compact structure that can be resolved following nonreducing SDS-PAGE as an increase in protein mobility (see Basic Protocol 1). As a general rule, intermolecular disulfides form after the folding and oxidation of individual polypeptides. Once this occurs, the two subunits can come together to form an intermolecular covalent bond causing a decrease in protein mobility on nonreducing SDS-polyacrylamide gels.

Besides providing an environment for disulfide bond formation, the ER also contains a variety of resident proteins that assist in the protein maturation process. These proteins include covalent modifiers that add glycans, remove carbohydrates or signal sequences, and catalyze the formation of disulfide bonds as well as molecular chaperones that assist in translocation, protect vulnerable nascent chains from aggregation, and retain misfolded proteins. These proteins play a central role in defining the ER, retaining misfolded or misassembled proteins so they do not travel through the secretory pathway and ensuring the high success rates of nascent protein maturation observed in the cell.

Pulse-chase experiments in live cells permit the biogenesis of a protein to be followed after sufficient radiolabel has been incorporated for visualization (see Critical Parameters, discussion of protein radiolabeling). Currently this methodology provides the most sensitive meth-

Table 15.6.3 Troubleshooting Guide for Protein Folding Analyses[a]

Problem	Possible causes	Solutions
Little or no protein translation	Ionic strength not optimized for transcript	Perform a K^+ titration, or purify mRNA to remove residual buffer salts and then perform K^+ titration
	Oxidation conditions are inhibitory	Perform a titration with GSSG or FAD to determine best oxidation and translation conditions
	Microsome or SP-cell concentrations are inhibitory (i.e., too high)	Perform a microsomal or SP-cell titration to optimize translation and translocation
	mRNA degradation	Check mRNA on agarose gel for degradation; monitor working environment and supplies more carefully to prevent RNase degradation while performing a new transcription
	Transcript too large	Translate individual domains of the protein
Little or no translocation	Microsome or SP-cell concentrations not optimized	Perform a microsomal or SP-cell titration
	SP cells not permeabilized	Make sure cells are not overconfluent. Use an appropriate amount of digitonin after counting cells for optimum permeabilization
	Poor signal sequence	Replace old signal sequence with a powerful ER-targeting signal sequence
	SRP degraded or absent	If using wheat germ, switch to reticulocyte lysate or add purified SRP
No post-translational oxidation	Too much oxidizing agent	Check nonreducing gel for aggregates at the top and within the stacker; if there are a lot, decrease oxidizing agent concentration
	Insufficient oxidizing agent	Perform titration with GSSG or FAD
Inability to co-immunoprecipitate protein	Detergent is denaturing	Use less or change detergent in the lysis buffer to a more native condition (e.g., digitonin, Triton X-100)
	Not enough antibody	Perform antibody titration
	Binding too transient	Cross-link prior to immunoprecipitation
		Deplete ATP with apyrase before adding antibody
Trypsin overdigestion	Too much trypsin	Perform a trypsin titration
	Incubation too long	Incubate at 4°C for shorter time
		Pick the best concentration and perform a time course for digestion

continued

Table 15.6.3 Troubleshooting Guide for Protein Folding Analyses[a], *continued*

Problem	Possible causes	Solutions
No trypsin digestion	Incubation temperature too high or low	Pick the best digestion time and perform a digestion at various temperatures
	Microsomes or SP cells not lysed	Use a higher concentration of lysis buffer
	Incubation time too short	Pick the best concentration and perform a time course for digestion
	Trypsin not the appropriate protease for the protein	Try proteinase K, chymotrypsin, or another protease
Inability to cross-link	No reactive groups available in the protein	Check protein sequence, or structure if available, to determine the best cross-linker
		Try a nonspecific broad-range UV cross-linker
	Too much cross-linking	Check stacker and top of gel for aggregates; if present, try decreasing the amount of cross-linker
Nonreducing gel is blurry	pH of resolving buffer incorrect	Test pH of the resolving buffer to make sure it is 8.8
	Stacking gel too small	Increase size of the stacker and decrease current when running sample through the stacker
	Gel too thick	Decrease thickness of the gel

[a]Abbreviations: ER, endoplasmic reticulum; FAD, flavin adenine dinucleotide; GSSG, oxidized glutathione; SP, semipermeabilized.

ods to monitor the synchronous maturation of nascent proteins in the complexity of the live cell. The pulse-chase approach can also be used with an in vitro translation system coupled with canine pancreatic microsomes to study the maturation of proteins that can be controlled and manipulated to a higher degree than intact cells. Originally, this system was used to study the translocation of secretory-pathway proteins across the ER membrane (Blobel and Dobberstein, 1975). More recently, it has been shown to support the maturation of proteins from their earliest folding intermediate to the mature oligomer through careful control of the redox conditions (Hebert et al., 1996). The in vitro translation system can also be coupled with semipermeabilized (SP) cells to combine the facilitated production of radiolabeled proteins with the maturation in an intact ER (Wilson et al., 1995). Together, these various biological systems can be combined with the protocols described to dissect the protein folding and oxidation pathway in the ER.

Critical Parameters

Protein radiolabeling

All the methods described in this unit involve the generation of a radiolabeled protein, which permits the monitoring of its maturation. In choosing a labeling reagent, the amino acid composition of the protein should be considered so that an adequate number of radiolabeled sites will be incorporated. Most commonly, a mixture of ^{35}S-labeled methionine and cysteine is used, but other radiolabeled amino acids are also available for use with proteins lacking an adequate number of cysteines or methionines. The number of radiolabeled sites, the length of the protein, and the level of protein expression will all be important for determining the length of the radioactive pulse. Generally with cells, a 15- to 30-min radioactive pulse is sufficient for visualization of a moderately expressed protein by autoradiography. In vitro translation studies require a longer pulse period because the translation rate is three to five times slower and the optimal temperature for translation is lower at ~27°C. A pulse time of 1 hr is sufficient for most transcripts. Chase times are highly

protein dependent, and a variety of durations (1 to 5 hr) should be explored.

In vitro translation systems

Success with the in vitro translation systems used in Basic Protocols 1 to 4, and Alternate Protocols 1 and 2 is dependent on optimizing the protein translation, translocation, and maturation processes. For specific details for the optimization of each step, see Table 15.6.3. In short, translation levels rely on the integrity of the transcript used, as well as salt concentrations. It is also common for different reticulocyte lysate or wheat germ preparations (*UNIT 11.2*) to translate a given transcript with varying levels of success. The efficiency of protein targeting to and translocation into the ER membrane source (ER-derived microsomes or SP cells) is highly dependent on the membrane concentration. Care must also be taken to ensure that a lumenal redox environment that supports disulfide bond formation is maintained using the oxidizing agents GSSG or FAD. However, the extralumenal environment cannot be overly oxidizing as this will inhibit translation. Therefore, a thorough titration with the oxidizing agent is needed, and in many cases this has to be repeated for every batch of reticulocyte lysate or wheat germ or membrane preparation employed. When SP cells are used as membranes, the cell concentration may be varied for efficient translation and translocation.

Cell studies

Because pulse-chase experiments in cells involve the production of a lysate containing thousands of radiolabeled proteins, an immunoprecipitation procedure is essential to monitor a single individual protein. This often results in a high background. To optimize the signal-to-background ratio, a number of wash buffers at various temperatures and different numbers of wash steps should be tested (*UNIT 7.2*).

Care must also be taken to ensure that the adherent cells remain attached to the cell dish during the many wash steps performed with medium changes (see Basic Protocol 5). The presence of Ca^{2+} and Mg^{2+} in the wash buffer aids in cell adherence.

Monitoring protein maturation

To characterize the protein folding and oxidation process, the maturation process has to be stopped and the protein conformation maintained during the extraction and analysis procedures. An alkylating agent such as NEM, AMS, iodoacetamide, or iodoacetic acid can be used to prevent further formation of disulfide bonds. To preserve the protein's conformation during the extraction procedure, nondenaturing detergents such as CHAPS, Triton X-100, digitonin, Nonidet P-40, or octyl glucoside should be used for membrane and protein solubilization (*UNIT 5.1*). In some cases, these gentle detergents may also preserve the interactions with ER resident molecular chaperones and therefore can be used to monitor these interactions.

Anticipated Results

Regardless of the system used for the studies (adherent, suspended, or SP cells or ER-derived microsomes), a similar maturation pathway should be identified for a given protein. However, because the rate of translation with the in vitro translation system is 3- to 5-fold slower than in live cells, the time frame for maturation may vary. As a protein is oxidized, it will generally migrate faster on nonreducing SDS-polyacrylamide gels (Fig. 15.6.1). For the influenza glycoprotein hemagglutinin (HA), two folding intermediates have been identified that are designated intermediate 1 and 2 (IT1 and IT2; Fig. 15.6.3). The native (NT) protein, with all its disulfides in place, migrates at an even faster rate. Overall, a shift that corresponds to ~15 kDa is observed between the reduced (R) and completely oxidized (NT) protein on nonreducing SDS-polyacrylamide gels. On a reducing gel, all oxidative forms migrate with a similar mobility, indicating that the molecular mass of the oxidative form is the same and that the differences in mobility are due solely to disulfide bond formation. Oxidation can be followed under normal physiological conditions (co-translationally; Figs. 15.6.2 and 15.6.3), or synchronous oxidation can be monitored by accumulating the protein under reducing conditions and initiating oxidation post-translationally (Figs. 15.6.2 and 15.6.3).

The alkylation of free thiols with alkylating agents can also be used to accentuate mobility shifts observed for oxidative forms of a protein by SDS-PAGE. The larger the number of free thiols, the more alkylating groups should attach to the polypeptide, producing an enhanced shift on reducing SDS-polyacrylamide gels (Fig. 15.6.1).

Chaperone binding to the oxidative intermediates can be probed by co-immunoprecipitation studies. Interactions between the lectin chaperone calnexin and HA were analyzed by immunoprecipitating with anti-calnexin antibodies (Fig. 15.6.3B). Calnexin binds to proteins possessing monoglucosylated glycans

(*UNIT 15.1*; Fig. 15.1.3). Calnexin bound to all oxidative forms of HA under oxidizing conditions. However, under reducing conditions, the lectin-binding properties of calnexin were inhibited by the reduction of a calnexin intramolecular disulfide bond (Fig. 15.6.3B, compare lanes 4 and 5; Hebert et al., 1995). In the microsomal system at 27°C (Fig. 15.6.3), binding to calnexin persists even after 120 min of post-translational oxidation. Release from the chaperone and oligomerization can be observed if the chase temperature is increased to 32°C (Hebert et al., 1996).

Under reducing conditions, one protein band should be observed with cell studies; however, with systems that use in vitro translations, two bands should be generated for glycosylated substrates. Because protein targeting and translocation are not 100% efficient with the in vitro translation systems, a common artifact is the production of an untranslocated product. This protein retains its signal sequence and does not receive glycosylations. Therefore it migrates faster than the glycosylated and translocated form (Fig. 15.6.3).

Time Considerations

In vitro translation experiments require 1 hr for translation with chase times varying depending on the protein. For cell studies, the cells are starved for 2 hr prior to the pulse-chase experiment, which can take an additional 1 to 8 hr depending upon the chase times. SP-cell preparation requires 2 to 3 hrs. Processing of samples using both systems requires 90 min followed by an overnight (or 4 to 6 hr) incubation with antibodies for immunoprecipitations. Sample preparation, including cross-linking and protease sensitivity studies, requires ≥90 min after the antibody binding step. Immunoprecipitates can then be analyzed immediately by SDS-PAGE or frozen for future analysis.

Measurements of Phagocytosis and Phagosomal Maturation

Invading microorganisms and other foreign particles, as well as apoptotic bodies, are eliminated in the organism by a process known as phagocytosis (Aderem and Underhill, 1999; Greenberg and Grinstein, 2002). The elimination process can be conceptually divided into two stages: an initial uptake phase that involves ingestion of the target particle into a plasma membrane–derived vacuole, known as the phagosome, and a secondary phase in which the particle is degraded and the debris are cleared. The nascent phagosome, which is generated by invagination of the plasmalemma, lacks the machinery required for particle degradation and clearance. These capabilities are acquired subsequently by an exquisitely coordinated sequence of membrane fusion and fission events collectively termed phagosomal maturation (Vieira et al., 2002). The objective of this unit is to briefly overview the processes of phagosome formation and maturation, and to provide protocols to assess and quantify their occurrence.

Phagocytosis is initiated by the interaction of receptors on the plasma membrane of the effector cell, or phagocyte, with their cognate ligands on the surface of the target particle. The ligands can be endogenous components of the target particle, such as lipopolysaccharides of the bacterial wall, or the phosphatidylserine that becomes exposed on the outer monolayer of apoptotic cells. However, particles lacking intrinsic ligands can also be targeted for phagocytosis by a process called opsonization, which entails coating of their surface with host-derived proteins that are themselves recognized by phagocytic receptors. Such coating host proteins, termed opsonins, include immunoglobulins, components of the complement cascade, and other serum proteins such as thrombospondin. Different receptors are responsible for the recognition of these opsonins, and they, in turn, differ from the receptors that mediate nonopsonic phagocytosis. The responses triggered by these different receptors are not identical, and one must therefore appreciate that phagocytosis is not a single phenomenon, but a term of convenience used to encompass a collection of different, yet related, processes.

At the molecular level, the sequence of events that result in particle engulfment has only been studied in some detail for a couple of receptor types. Briefly, engagement by their ligands on the particle surface induces the clustering and activation of the receptors. Though none of the phagocytic receptors studied to date possess intrinsic kinase activity, phosphorylation has been identified as the most proximal response to receptor clustering. Tyrosine kinases of the Src family are an integral part of these early events, which are rapidly followed by extensive remodeling of phospholipids in the immediate vicinity of the phagocytic cup. Kinases and lipases that target phosphoinositides are activated during the early stages of phagocytosis, as are phospholipases D and A2. Jointly, the products of tyrosine phosphorylation and lipid metabolism recruit and activate other effectors that direct two principal responses: the extensive remodelling of the actin cytoskeleton and the focal fusion of endomembranes with the membrane of nascent and early phagosomes. The cytoskeletal reorganization is complex and incompletely understood, but early activation of Rho-family GTPases is believed to be essential. In contrast, little is known about the determinants of membrane fusion and fission that initiate phagosomal maturation.

Phagosomal maturation resembles, yet is not identical to, the progression of internalized fluid or solutes along the endocytic pathway. Both processes involve sequential fusion with components of the early and late endosomal compartments and culminate in coalescence with lysosomes. It is thought that the lysosomal hydrolases play a central

Contributed by Chung-Wai Chow, Gregory P. Downey, and Sergio Grinstein
Current Protocols in Cell Biology (2004) 15.7.1-15.7.33

role in microbial killing and in the degradation and disposal of foreign particles in general. The lumen of the hybrid organelles, formed as the phagosome merges with components of the endocytic pathway, undergoes a gradual acidification that is similarly important for the microbicidal and degradative functions of the phagosome.

Simple protocols are included for the assessment of FcγR-mediated phagocytosis (see Basic Protocol 1, Alternate Protocol 1, and Support Protocol 1), for the assessment of complement-mediated phagocytosis (see Basic Protocol 2, Alternate Protocol 2, and Alternate Protocol 3), and for flow cytometric analysis of phagocytosis (see Basic Protocol 3). These protocols include steps for opsonization of target particles and for the assessment of the efficiency of phagocytosis. Additional protocols are provided for assessment of phagosomal acidification (see Basic Protocol 4 and Alternate Protocol 4) and maturation (see Basic Protocol 5, Alternate Protocol 5, and Alternate Protocol 6). Finally, a protocol is provided for assessment of inhibition of phagocytosis (see Basic Protocol 6). Phagocytosis assays are illustrated schematically in Figure 15.7.1.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

ASSESSMENT OF Fcγ RECEPTOR-MEDIATED PHAGOCYTOSIS

Particles opsonized by immunoglobulins are recognized by Fcγ receptors (FcγR), that specifically interact with the Fc portion of IgG (McKenzie and Schreiber, 1998; Heyman, 2000). Focal clustering of FcγR upon binding to IgG-opsonized materials results in receptor activation and initiation of phagocytosis. There are three general classes of FcγR (FcγRI, II, and III) that vary in their molecular structure, affinity for different IgG isotypes, and signaling ability. It is noteworthy that not all FcγR are equally capable of eliciting phagocytosis. A subgroup of Fc receptors, typified by FcγRIIB, are unable to support phagocytosis and in fact generate inhibitory signals.

The protocols below detail several different methods to opsonize particles with IgG and to estimate FcγR-mediated phagocytosis. Two types of model particles, namely latex beads and red blood cells (RBC), have been extensively used to assess phagocytosis. The advantages and limitations of these systems are described below. Labeling of the particles with fluorescent probes is recommended in some of the protocols listed below to locate the particles and to quantify their uptake. A wide range of fluorophores is available for these purposes; consult the manufacturers' handbooks to select the probes with the appropriate spectral features that will best suit the particular microscopic setup and experimental design (also see *APPENDIX 1E*).

BASIC PROTOCOL 1

Assessment of FcγR-Mediated Phagocytosis Using IgG-Opsonized Red Blood Cells (RBCs)

This section describes a method to coat RBCs with IgG and to assess phagocytosis of the resulting opsonized particles. A procedure for labeling such IgG-coated RBCs by conjugation with an amine-reactive fluorescent dye to facilitate detection is included. The protocol is written for assessment of phagocytosis of the opsonized particles by adherent cells, but it can easily be adapted for use with suspended phagocytic cells.

RBCs are very well suited for the study of phagocytosis, for several reasons: (1) their size is remarkably homogeneous; (2) normal, unopsonized RBCs are rarely internalized by

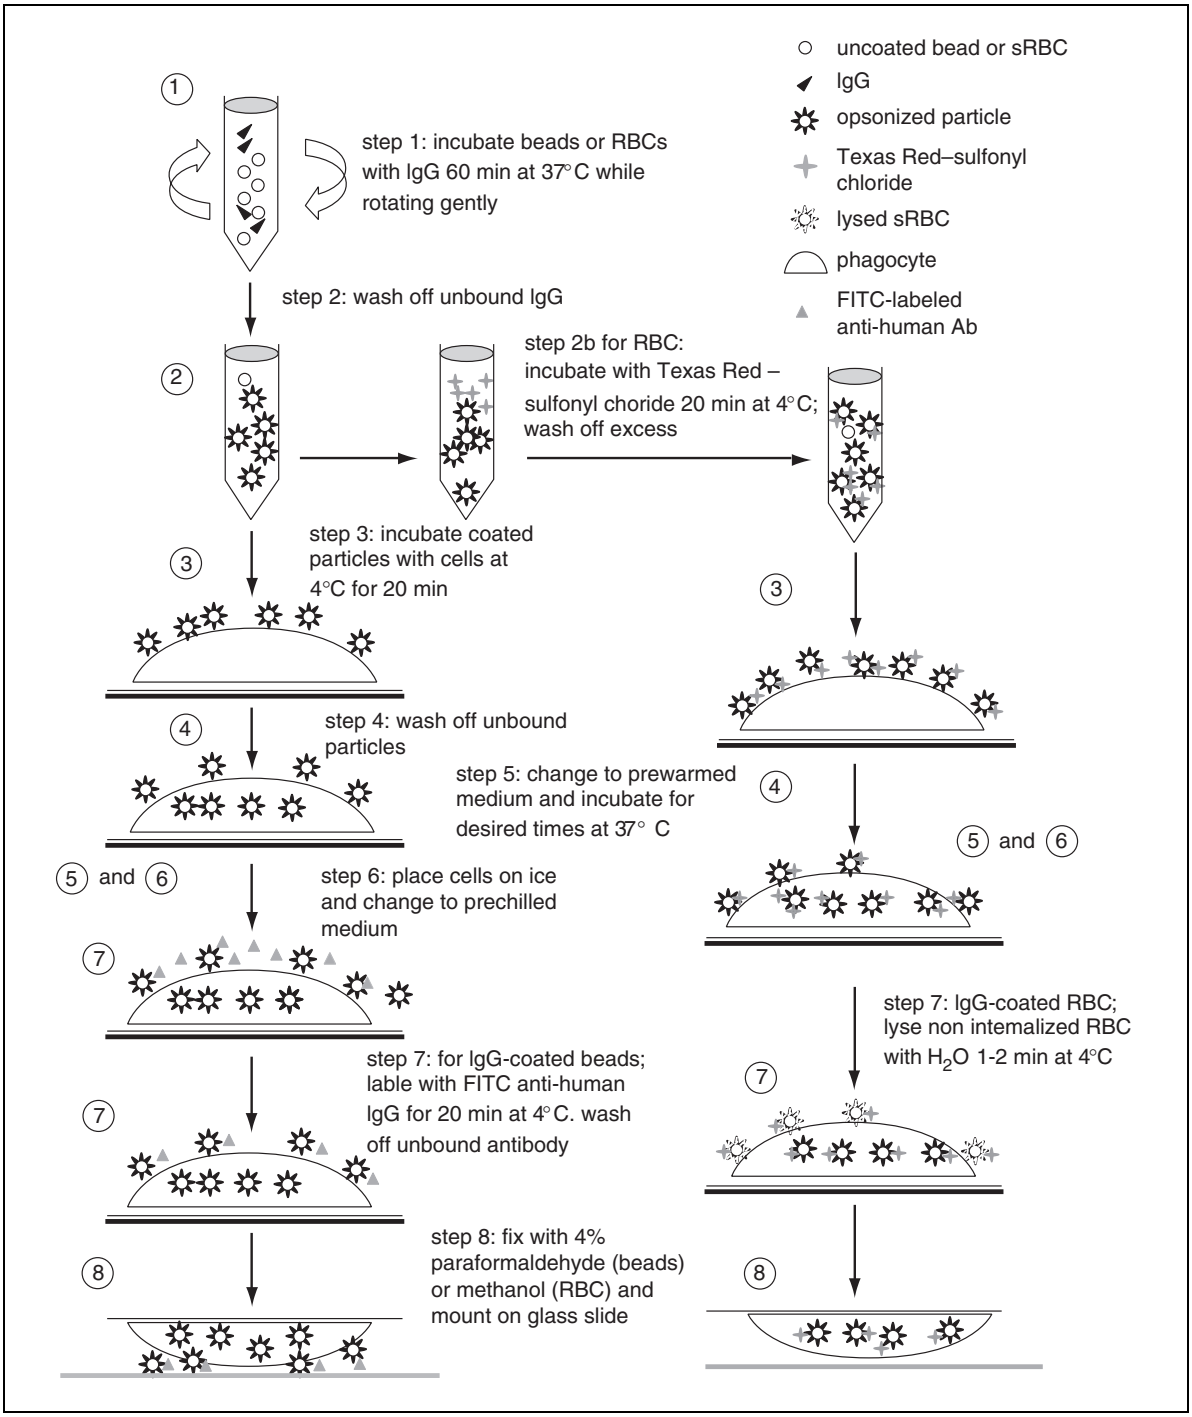

Figure 15.7.1 Schematic representation of the protocol for phagocytosis of IgG-opsonized particles. The procedure outlines the steps involved in the preparation of IgG-coated red cells or latex beads, for the identification of intracellular versus extracellular particles or for elimination of the latter prior to analysis. Note that Texas-Red labeled red cell ghosts that remain adherent (extracellular) after hypotonic lysis will be observable by fluorescence microscopy but not by bright field because they have lost hemoglobin.

phagocytosis, contributing a very low background; (3) the light absorbance of hemoglobin facilitates their detection by light microscopy; and (4) adherent, noninternalized RBCs are susceptible to osmotic lysis, while those protected within phagosomes are not. This provides a simple means of identifying internalized particles. On the other hand, RBCs are malleable and can undergo constriction and fragmentation during phagocytosis, which may lead to an underestimation of the number of phagocytic events.

Materials

Primary monocytes or macrophages (*UNIT 2.2*), or monocytic cell lines (e.g., RAW 264.7 cells ATCC #TIB-71 or J774 cells, ATCC #HB-197).

Culture medium: e.g., DMEM with or without 10% FBS (*APPENDIX 2B*); nominally bicarbonate-free, HEPES-buffered media can be used to obviate the need for a CO_2 atmosphere

Sheep red blood cells (sRBCs; 10% v/v suspension, ICN Biomedicals)

Phosphate-buffered saline (PBS; without Ca^{2+} or Mg^{2+}; see recipe)

4% (v/v) paraformaldehyde in PBS (optional)

PBS (see recipe) containing 100 mM glycine

Rabbit IgG stock: reconstitute rabbit antibody (IgG fraction) to sRBC (ICN Biomedicals) with Milli-Q water to 5 mg/ml (store in aliquots at –20°C; store thawed aliquots up to 1 month at 4°C)

HEPES-buffered RPMI 1640 (e.g., Life Technologies)

Texas Red–sulfonyl chloride (Molecular Probes, 1 mg per ampule)

Methanol, prechilled to –20°C

Fluorescence mounting medium (Dako)

6-well tissue culture plates containing sterile glass coverslips (see recipe)

End-over-end rotator

Glass microscope slides

Epifluorescence microscope with bright-field capabilities and appropriate filters (see *UNITS 4.1 & 4.2* and *APPENDIX 1E*)

Additional reagents and equipment for cell culture and counting cells (*UNIT 1.1*) and microscopy (*UNITS 4.1 & 4.2*)

Plate phagocytes (day 1)

1. Grow cells of choice in DMEM with 10% FBS (*UNIT 1.1*). At a point 24 to 48 hr prior to the experiment, passage cells onto sterile glass coverslips contained in 6-well plates (prepared as described in Reagents and Solutions) so that they will to reach ~75% confluence at the time of the experiment.

   The phagocytic index and rate are easier to quantitate when cells are subconfluent.

Opsonize sRBCs with IgG (day 2)

2. Prewarm the end-over-end rotator within an incubator to 37°C. Keep all reagents on ice until step 8.
3. Place a 200-µl aliquot of 10% sRBC suspension into a 1.5-ml microcentrifuge tube.
4. Sediment the sRBCs by microcentrifuging 5 to 30 sec at maximum speed.
5. Aspirate supernatant and resuspend cells in 1 ml ice-cold PBS.
6. Wash two more times with ice-cold PBS as in steps 4 to 5.
7. *Optional:* Fix sRBCs with 4% paraformaldehyde prior to opsonization.

   This has been found empirically to enhance phagocytosis, most likely by exposing ligands to receptors other than FcγR.

   a. Resuspend the sRBCs in 1 ml of 4% paraformaldehyde in PBS.
   b. Incubate overnight at 4°C in end-over-end rotor.
   c. Sediment and wash fixed cells as in steps 4 to 5. Repeat two additional times.
   d. Resuspend the fixed sRBCs in 1 ml PBS containing 100 mM glycine and incubate 20 to 30 min at 4°C to quench free aldehyde groups.
   e. Sediment fixed cells using the microcentrifuge. Aspirate supernatant. Wash twice with 1 ml PBS as in steps 4 to 5.

8. Resuspend the washed sRBCs in 200 µl PBS.

9. Dilute 1 µl of rabbit IgG stock into 50 µl of PBS. Add 4 µl of the diluted rabbit IgG to the washed sRBCs.

   The protocol has been optimized for the sRBCs and rabbit IgG from ICN Biomedicals. However, for other suppliers of sRBCs or IgG it may be necessary to optimize the opsonization ratio by varying the dilution of IgG.

10. Incubate sRBC-rabbit IgG mixture at 37°C for 1 to 1.5 hr in the prewarmed end-over-end rotator (see step 2).

To perform phagocytosis assay using unlabeled opsonized sRBCs

11a. Wash opsonized sRBCs from step 10 three times with ice-cold PBS as in steps 4 to 5, and resuspend in 500 µl ice-cold PBS. Keep on ice until use.

12a. Count the opsonized sRBCs using a Coulter counter or hemocytometer (*UNIT 1.1*) and resuspend in cold HEPES-buffered DMEM at 5–7 × 10^8 cells/ml.

13a. Proceed to phagocytosis assay (step 14).

To perform phagocytosis assay using opsonized sRBCs labeled with Texas Red–sulfonyl chloride

11b. Take one ampule of Texas Red–sulfonyl chloride and dissolve in 0.5 ml ice-cold PBS in a 1.5-ml microcentrifuge tube.

   Covered with aluminum foil and stored at 4°C, this stock solution will keep for a several days.

12b. Add 100 µl of the diluted Texas Red–sulfonyl chloride to 0.5 ml of opsonized sRBCs (from step 10). Incubate on ice for 20 min. Mix by inverting the tube every 5 min.

   Texas Red–sulfonyl chloride is an amine-reactive dye that labels proteins covalently. As an alternative, IgG prelabeled with the fluorescent dye of choice can be used for opsonization.

13b. Wash the IgG-sRBC-dye mixture three times with 1 ml cold PBS, or until the supernatant is clear, using the technique described in step 4 to 5. Resuspend in 0.6 ml cold HEPES-buffered DMEM as in step 12a. Proceed to phagocytosis assay (step 14).

Perform phagocytosis assay (day 2)

14. Place the tissue culture plates with the prepared cells (from step 1) on ice.

   Optionally, replace the culture medium with 1 ml fresh, prechilled medium to accelerate the cooling process.

15. For each well to be assayed, prewarm 2 ml of HEPES-buffered RPMI 1640 medium to 37°C.

16. Add 50 to 100 µl of prepared IgG-sRBCs (from step 13a or b) to each well and incubate on ice for 10 to 20 min.

   Ideally, the ratio of IgG-sRBC to phagocytic cells should be between 5:1 and 10:1.

   Phagocytosis does not proceed at 4°C. This step will therefore standardize and synchronize the binding of IgG-sRBC to the cells and allow for comparison of different treatment conditions or at different time points.

17. Wash cells gently once with cold medium to remove unbound IgG-sRBC.

18. To initiate phagocytosis, remove cells from ice, aspirate the cold medium, and add 2 ml prewarmed (37°C) DMEM medium per well. Place in 37°C incubator.

    The duration of incubation at 37°C will depend on the stage of phagocytosis and phagosomal maturation of interest. For assessment of phagocytic efficiency, 30 min is a convenient point for evaluation.

19. Stop phagocytosis by placing the cells back on ice. Wash with ice-cold PBS.

20. *Optional:* To remove the IgG-sRBCs that have not been internalized, lyse the sRBCs by incubating with 1 ml of water for 2 min at 4°C.

    Depending on the cell type being assessed, incubation with water may affect cell morphology and/or integrity. When evaluating different phagocytes, a preliminary time course experiment may be necessary to optimize the duration of hypotonic lysis of sRBC.

21. Wash again with cold PBS. Keep on ice.

    Wet mounts of the preparation can be analyzed directly or the cells can be fixed for subsequent analysis. For direct analysis proceed to step 23. For fixation see step 22.

Fix cells (days 2 to 3)

22. Aspirate PBS and add 1 ml per well of prechilled methanol. Incubate on ice 20 min. Wash twice with PBS.

    It is important to aspirate gently and add the methanol slowly to the side of the well to avoid dislodging any cells. The authors recommend prechilling the methanol to –20°C. An alternative to fixation with methanol is to fix with 1% to 2% glutaraldehyde. When using sRBCs, do not use paraformaldehyde for fixation because retention of hemoglobin is poor.

Mount coverslips and score phagocytosis

23. Mount coverslips containing cells onto slides with Dako fluorescence mounting medium. Allow to dry at room temperature for several hours prior to visualization.

    It is preferable to dry the slides overnight before analysis.

    Dab the coverslip on tissue wipe to remove excess fluid before mounting. This will decrease the time required for the slide to dry. To minimize air bubbles in the mounted slide, place a drop of the mounting medium on the glass slide first, then slowly ease the coverslip onto the slide. Slides can be stored for months at –20°C with little loss of fluorescence.

24. Score phagocytosis under microscope.

    Only the internalized sRBC remain intact and can be readily identified by bright-field (phase or differential interference contrast) microscopy. Typically, phagocytic efficiency is scored as the number of sRBC internalized per 100 phagocytic cells counted.

    Fluorescence microscopy and automated image analysis can be used if the SRBC are coupled to Texas-Red.

ALTERNATE PROTOCOL 1

Assessment of FcγR-Mediated Phagocytosis Using IgG-Opsonized Latex Particles

A second approach to evaluating FcγR-mediated phagocytosis utilizes inert latex beads opsonized with IgG. The advantages of beads over sRBC include their uniform (spherical) shape, which allows for ready identification of phagosomes on visual inspection or when using automated image analysis programs, and the availability of varying bead sizes. However, uniform-size latex beads that are appropriate for phagocytosis experiments are considerably more expensive than RBCs. Furthermore, unlike sRBCs, extracellular beads are not amenable to hypotonic lysis for elimination. Therefore, if it is necessary to distinguish internalized versus noninternalized adherent beads by alternative means, the experiment will consume additional time and reagents. Lastly, plain, unopsonized latex beads can be recognized and engulfed by phagocytes at significant rates, complicating the analysis of the contribution of FcγR.

Additional Materials *(also see Basic Protocol 1)*

10% slurry of latex beads, ~3-μm diameter (Bangs Laboratories cat no. PS05N or equivalent from other manufacturers)

Human IgG stock solution: reconstitute IgG from human serum (Sigma) to 50 mg/ml in PBS (see recipe) or Milli-Q purified H_2O (store in aliquots at –20°C; store thawed aliquots up to 1 month at 4°C)

Fluorescently labeled anti-human IgG secondary antibody (e.g., Cy3- or FITC-labeled anti-human IgG $F(ab)_2$, Jackson Laboratories), diluted 1/500 in PBS (see recipe) containing 1% (w/v) BSA and 5% (v/v) goat serum

15-ml polystyrene tubes, sterile

End-over-end rotator

Tabletop centrifuge

Prepare cells (day 1)

1. Grow cells of choice in DMEM with 10% FBS (*UNIT 1.1*). At a point 24 to 48 hr prior to the experiment, passage cells onto sterile glass coverslips contained in 6-well plates (prepared as described in Reagents and Solutions) so that they will to reach ~75% confluence at the time of the experiment.

Opsonize beads with IgG (day 2)

2. Place the following in a sterile 15-ml polystyrene tube:

   3 ml PBS
   60 μl bead suspension
   60 μl human IgG stock solution.

   The volumes given are sufficient for an experiment using one 6-well plate. They can be scaled up or down depending on the number of wells being assessed.

3. Incubate 60 min at 37°C, rotating gently in an end-over-end rotator.

4. Sediment beads by centrifuging 10 min at 750 × *g* (2500 rpm), 4°C, in a tabletop centrifuge. Aspirate supernatant, being careful not to aspirate the beads.

5. Resuspend beads in 5 ml cold PBS, centrifuge again as in step 4, and aspirate supernatant. Repeat this washing procedure a second time.

6. Resuspend beads in 3 ml cold HEPES-buffered DMEM. Keep on ice until ready to use.

Perform phagocytosis assay (day 2)

7. Prewarm culture medium at 37°C (to be used in step 12).

8. Put prepared plate of cells (from step 1) on ice.

   One may wish to exchange the culture medium with prechilled medium just prior to this step.

9. Add 0.5 ml of the IgG-opsonized bead suspension (from step 6) per well.

10. Incubate on ice for 20 min to allow beads to bind.

11. Wash off excess beads with cold PBS.

    The excess beads can be washed three times with PBS and reused. When stored at 4°C with 0.01% sodium azide, the beads can be used for 2 to 3 months.

12. Remove the plate from ice. Aspirate medium and add 2 ml of 37°C prewarmed culture medium per well.

13. Incubate at 37°C for the desired time periods.

14. Stop phagocytosis by placing plates on ice and changing to ice-cold medium or PBS.

Label extracellular opsonized beads

15. To label beads that are adherent to the cells but not internalized, incubate 20 min on ice with a fluorescently labeled anti-human IgG secondary antibody.

    Cover the plate with foil to minimize bleaching of the fluorophore during the incubation procedure.

    The authors typically use Cy3- or FITC-labeled anti-human IgG $F(ab)_2$ (Jackson Laboratories). Dilute antibody 1:500 in PBS (see recipe) containing 1% (w/v) BSA and 5% (v/v) goat serum.

Fix cells (days 2 to 3)

16. Wash three times with PBS.

17. Fix the cells by covering them with 4% paraformaldehyde in PBS. Incubate 20 min at room temperature. Wash three times with PBS.

18. *Optional:* Quench free aldehyde groups with PBS containing 100 mM glycine in PBS for 20 min. Wash three times with PBS.

19. Mount coverslips containing cells onto slides with Dako fluorescence mounting reagent. Allow to dry at room temperature for several hours prior to visualization.

    Slides can be stored at –20°C in the dark for months with little loss of fluorescence intensity.

20. Score phagocytosis under microscope.

    The phagocytic index is generally defined as the number of particles internalized per 100 cells located.

SUPPORT PROTOCOL 1

Assessment of Surface Expression and Binding Capacity of Fcγ

The surface expression and the binding affinity of the FcγR for their ligands will determine the efficiency and rate of phagocytosis. For many experiments (e.g., comparison of phagocytic rates under different treatment conditions or in phagocytes with different genotypes), it is important to determine the surface expression and binding capacity of the FcγR in order to draw valid conclusions. Receptor density and phagocytic efficiency can then be directly compared.

Additional Materials *(also see Basic Protocol 1 and Alternate Protocol 1)*

FcγR-specific antibody: e.g., rat anti-mouse CD 16/CD32 (BD Bioscience)
Fluorescently labeled secondary antibody (Jackson Immunoresearch Labs)

To assess Fcγ receptor expression and binding using IgG-opsonized sRBC

1a. Follow steps 1 to 16 of Basic Protocol 1.

2a. After the 20-min incubation on ice, wash wells twice with ice-cold PBS.

3a. Fix with methanol and mount as in Basic Protocol 1, step 22-24.

4a. Score the number of bound sRBCs per phagocytic cell.

To assess Fcγ receptor expression and binding using IgG-opsonized beads

1b. Follow steps 1 to 12 of Alternate Protocol 1.

2b. Fix with 4% paraformaldehyde as in Alternate Protocol 1, steps 17 to 19.

3b. Score the number of bound beads per cell.

To assess Fcγ receptor expression and binding using FcγR-specific antibodies

1c. Label surface receptors by incubating 60 min at 4°C with 0.5 ml of FcγR-specific antibody diluted 1:10 PBS containing 1% BSA.

Antibodies directed against several classes of human as well as murine FcγR are commercially available and can be used to assess surface expression of the these receptors. If using these antibodies to label surface receptors, perform the incubations at 4°C to prevent internalization of the receptors by endocytosis.

2c. Wash twice with PBS.

3c. Mount using Dako fluorescent mounting medium and evaluate expression by counting the traction of fluorescently labeled cells using microscopy or flow cytometry.

ASSESSMENT OF COMPLEMENT-MEDIATED PHAGOCYTOSIS

Activation of the complement cascade leads to cleavage of the normally inactive complement proteins into several functional fragments. Some of these complement fragments function as opsonins which attach to microorganisms or particles, promoting their internalization via complement receptor (CR)–mediated phagocytosis. Complement-dependent phagocytosis is mediated primarily by the complement receptor CR3 (also known as CD11b/CD18 or Mac1). Unlike FcγR-mediated phagocytosis, where binding of the ligand to its cognate receptor is sufficient to initiate phagocytosis, CR3-mediated phagocytosis requires an additional stimulus to render the CR competent for phagocytosis (Newman et al., 1985; Aderem and Underhill, 1999). Success of experiments involving complement-opsonized particles depends on the optimal deposition of the C3bi component of complement onto the particles and on suitable priming of the phagocytic cells to capacitate the CR.

Assessment of Complement-Mediated Phagocytosis Using C3bi-Opsonized Erythrocytes

BASIC PROTOCOL 2

The protocol below describes a method to attach C3bi to RBCs. This method relies on binding of IgM to activate the complement cascade on the particle surface by the classical pathway. Under the conditions described, C3b fragments are rapidly deposited onto RBCs and are almost completely converted to C3bi (Newman and Mikus, 1985).

Materials

Primary monocytes or macrophages (*UNIT 2.2*) or monocytic cell lines (e.g., RAW 264.7 cells ATCC #TIB-71 or J774 cells, ATCC #HB-197)

Culture medium: e.g., DMEM with or without 10% FBS (*APPENDIX 2B*); nominally bicarbonate-free, HEPES-buffered media can be used to obviate the need for a CO_2 atmosphere

Sheep red blood cells (sRBCs; 10% v/v suspension, ICN Biomedicals)

Phosphate-buffered saline (without Ca^{2+} or Mg^{2+}; see recipe)

Gelatin veronal buffer (GVB; Sigma)

Rabbit anti-sheep erythrocyte IgM (Cedarlane or Accurate Chemical): reconstitute lyophilized antibody in 1 ml H_2O (final concentration 1 mg/ml) and store aliquots at –20°C (avoid repeated freeze-thaw cycles)

C5-deficient human serum (Sigma)

GVB (Sigma) supplemented with 1% (w/v) BSA and 7.5% (v/v) goat serum (optional)

Goat anti-C3bi antibody (optional; Sigma)

GVB (Sigma) supplemented with 5% (w/v) BSA and 7.5% (v/v) donkey serum (optional)

FITC-conjugated donkey anti-goat IgG (Jackson ImmunoResearch Labs; optional)
HEPES-buffered DMEM (e.g., Life Technologies)
20 mM phorbol 12-myristate 13-acetate (PMA) in DMSO
Methanol, prechilled to –20°C
Fluorescence mounting medium (Dako)

6-well tissue culture plates containing sterile glass coverslips (see recipe)
End-over-end rotator
Glass microscope slides
Epifluorescence microscope with bright-field capabilities and appropriate filters to visualize FITC fluorescence (see *UNITS 4.1 & 4.2* and *APPENDIX 1E*)

Additional reagents and equipment for cell culture and counting cells (*UNIT 1.1*) and microscopy (*UNITS 4.1 & 4.2*)

Plate phagocytes (day 1)

1. Grow cells of choice in DMEM with 10% FBS (*UNIT 1.1*). At a point 24 to 48 hr prior to the experiment, passage cells onto sterile glass coverslips contained in 6-well plates (prepared as described in Reagents and Solutions) so that they will to reach ~75% confluence at the time of the experiment.

Opsonize sRBCs with IgG (day 2)

2. Prewarm the end-over-end rotator within an incubator to 37°C. Keep all reagents on ice until step 8.
3. Place a 200-µl aliquot of 10% sRBC suspension into a 1.5-ml microcentrifuge tube.
4. Sediment the sRBCs by microcentrifuging 5 to 30 sec at maximum speed.
5. Aspirate supernatant and resuspend cells in 1 ml ice-cold PBS.

   It is best to use freshly opsonized sRBC for the phagocytosis assay. Keep all reagents on ice until step 8.

6. Wash two more times, first with ice-cold PBS and then with 1 ml of cold GVB, using the technique described in steps 4 to 5. After the last wash, resuspend the sRBCs in 200 µl GVB. Count cells using a hemocytometer (*UNIT 1.1*).

   Use of GVB minimizes aggregation and spontaneous lysis of the cells.

7. Dilute 1 µl of rabbit anti-sheep IgM stock in 50 µl of GVB. Add 2 µl of the diluted IgM to the sRBC suspension.

   It may be necessary to determine the optimal sub-agglutinating dilution for individual lots of IgM.

8. Incubate sRBC-rabbit IgM at 37°C for 1 hr in the prewarmed end-over-end rotator (see step 2).
9. Wash sRBCs three times with ice-cold GVB using the technique described in steps 4 to 5, then resuspend in 225 µl cold GVB. Keep on ice.
10. Add 25 µl of C5-deficient human serum (for a final concentration of 10% v/v) and incubate at 37°C for 20 min. Wash three times in GVB using the technique described in steps 4 to 5.

    Under these conditions, the Fc region of the IgM pentamer activates the classical pathway of the complement cascade and deposits C3b to the IgM-coated sRBCs, where it is rapidly converted to C3bi (Newman and Mikus, 1985). While IgG-coated RBCs can also be used to opsonize particles with C3bi under comparable conditions, IgG is not an efficient activator of the complement cascade because two adjacent Fc regions are required to initiate the first step of the cascade. Furthermore, the presence of IgG could confound subsequent interpretation of phagocytosis data due to concomitant engagement of the Fcγ receptors. Use of C5-deficient serum prevents lysis of the red blood cells.

11. *Optional:* Assess opsonization efficiency using immunofluorescence.

    This step is recommended for each lot of sRBC and IgM used.

    a. Take a small aliquot of the opsonized sRBC and resuspend in 200 µl of GVB supplemented with 1% BSA and 7.5% donkey serum.

    b. Add goat anti-C3bi antibody to a final dilution of 1:100. Incubate for 20 min on end-over-end rotator at 4°C. Wash three times with GVB.

    c. Counterstain with a 1:100 dilution of FITC-conjugated donkey anti-goat IgG in GVB containing 5% bovine serum albumin and 7.5% donkey serum for 20 min.

    d. Observe under a fluorescence microscope using the appropriate filters for the fluorochrome (*APPENDIX 1E*).

    A positive reaction will yield obvious, bright fluorescence.

12. Resuspend the opsonized sRBC in HEPES-buffered DMEM to yield 5–7 × 10^8 cells/ml

Perform phagocytosis assay (day 2)

13. Add 50 to 100 µl of C3bi-opsonized sRBC to each well of the tissue culture plates with the cells (step 1) and allow binding to proceed for 20 min at 37°C. Use 5 to 10 C3bi-coated sRBCs per phagocytic cell for optimal assessment of phagocytosis.

    C3bi binds to CR3 poorly at 4°C. At 37°C, resting cells will bind C3bi but will not initiate CR3-mediated phagocytosis.

14. To activate CR3 and initiate phagocytosis, add PMA (as 20 mM stock) to each well for a final concentration of 150 ng/ml and incubate at 37°C for the desired time period.

    In resting leukocytes, CR3 is inactive, although capable of binding C3bi, and requires an additional signal for activation and initiation of phagocytosis. A number of different stimuli can activate CR3. Phorbol esters such as PMA activate CR3 by stimulation of protein kinase C (Wright et al., 1983). Other stimuli that lead to activation of CR3 include certain cytokines and chemokines, attachment to extracellular matrix proteins, and glucan binding.

15. Stop phagocytosis by placing the cells on ice. Wash with ice-cold PBS.

    The duration of incubation at 37°C will depend on the stage of phagocytosis and phagosomal maturation that are of interest.

16. *Optional:* To remove the C3bi-sRBCs that have not been internalized, lyse the sRBC by incubating with 1 ml of water for 2 min.

17. Wash again with cold PBS. Keep on ice.

Fix cells

18. Aspirate PBS and add 1 ml per well of prechilled methanol. Incubate on ice for 20 min. Wash twice with PBS.

19. Mount coverslips containing cells onto slides with Dako fluorescence mounting medium. Allow to dry at room temperature for several hours prior to visualization.

    It is preferable to dry the slides overnight before analysis.

    Dab the coverslip on tissue wipe to remove excess fluid before mounting. This will decrease the time required for the slide to dry. To minimize air bubbles in the mounted slides, place a drop of the mounting medium on the glass slide first, then slowly ease the coverslip onto the slide. Slides can be stored for months at –20°C with little loss of fluorescence.

20. Score phagocytosis under microscope.

    Only the internalized sRBC remain intact and can be readily identified by bright-field (phase or differential interference contrast) microscopy. Typically, phagocytic efficiency is scored as the number of sRBC internalized per 100 phagocytic cells counted.

ALTERNATE PROTOCOL 2

Assessment of Complement-Mediated Phagocytosis Using C3bi-Opsonized Latex Beads

CR-mediated phagocytosis can also be assessed using complement-opsonized latex beads. This protocol and Alternate Protocol 3 below describe the opsonization and fluorescent labeling of beads for assessment of phagocytosis.

Coating of latex beads with C3bi is less complicated than the similar procedure using erythrocytes (see Basic Protocol 2). Furthermore, the uniform sizes of the beads allows for easy identification of phagosomes and, because lysis is not a concern, C5-deficient serum is not required. However, latex beads are significantly more expensive than sRBCs.

Additional Materials *(also see Basic Protocol 2)*

10% slurry of latex beads, ~3-μm diameter (Bangs Laboratories cat no. PS05N or equivalent from other manufacturers)
1 mg/ml human IgM stock (Sigma; store in aliquots at –20°C)
Human or mouse serum, freshly isolated, diluted 1:1 in PBS (see recipe for PBS)
Hanks' balanced salt solution (HBSS; see recipe)
20 mM phorbol 12-myristate 13-acetate (PMA) in DMSO
Goat anti-human C3bi antibody (Sigma)
PBS (see recipe) supplemented with 1% (w/v) BSA and 7.5% (v/v) goat serum (optional)
FITC-conjugated donkey anti-goat IgG (optional)
4% (v/v) paraformaldehyde in PBS (optional)
PBS (see recipe) supplemented with 1% (w/v) BSA and 7.5% (v/v) donkey serum (optional)
PBS (see recipe) containing 100 mM glycine (optional)
15-ml polystyrene tubes, sterile

Plate phagocytes (day 1)

1. Grow cells of choice in DMEM with 10% FBS (*UNIT 1.1*). At a point 24 to 48 hr prior to the experiment, passage cells onto sterile glass coverslips contained in 6-well plates (prepared as described in Reagents and Solutions) so that they will to reach ~75% confluence at the time of the experiment.

Opsonize beads (day 2)

2. Place the following in a sterile 15-ml polystyrene tube:

   3 ml PBS
   60 μl bead suspension
   60 μl IgM stock solution.

3. Incubate 60 min at 37°C, rotating gently in an end-over-end rotator.
4. Sediment beads by centrifuging 10 min at 750 × *g* (2500 rpm), 4°C, in a tabletop centrifuge. Aspirate supernatant, being careful not to remove the beads.
5. Resuspend beads in 5 ml cold PBS, centrifuge again as in step 4, and aspirate supernatant. Repeat this washing procedure a second time.
6. Resuspend beads in freshly isolated human or mouse serum diluted 1:1 in PBS. Incubate at 37° for another 20 min.

   During this step, the Fc region of IgM will initiate the classical pathway of complement cascade and fix C3b to the beads where it is quickly and completely converted to C3bi (Newman and Mikus, 1985).

7. At the end of the incubation period, collect beads by microcentrifugation and wash with HBSS using the technique described in steps 4 and 5. Resuspend in 3 ml HEPES-buffered DMEM.

Perform phagocytosis assay (day 2)

8. Add 500 µl of the C3bi-beads from step 7 to each well of the tissue culture plates with the cells (see step 1) and allow binding to proceed for 20 min at 37°C.
9. To activate CR3 and initiate phagocytosis, add PMA (as 20 mM stock) to each well for a final concentration of 150 ng/ml and incubate at 37°C for the desired time period.
10. Stop phagocytosis by placing the cells on ice. Wash with ice-cold PBS.
11. *Optional:* To identify C3bi-beads that are bound but not internalized, label the external beads with anti-C3bi antibodies on ice as follows:
    a. Incubate each well with a 1:100 dilution of goat anti-C3bi antibody in 200 µl PBS supplemented with1% BSA and 7.5% donkey serum for 20 min.
    b. Wash three times with ice-cold PBS.
    c. Incubate with a 1:100 dilution of FITC-conjugated donkey anti-goat IgG in 200 µl PBS with 1% BSA and 7.5% donkey serum for 20 min
    d. Wash three times with ice-cold PBS.

Fix cells and score phagocytosis (day 2)

12. Aspirate PBS and add 1 ml of 4% paraformaldehyde in PBS per well. Incubate on ice for 20 min. Wash twice with PBS.
13. *Optional:* Add 1 ml of PBS containing 100 mM glycine to each well and incubate 15 to 30 min at 4°C to quench the free aldehyde groups. Wash three times with PBS.
14. Mount cells using fluorescent mounting medium and score phagocytosis efficiency by counting the fraction of fluorescently labeled cells using microscopy or flow cytometry.

C3bi Opsonization of Beads

ALTERNATE PROTOCOL 3

It is possible to skip the IgM adsorption step and deposit C3bi onto the beads by incubating directly with fresh human or mouse serum. This requires a longer incubation period in serum to allow for the complement cascade and fixation of C3bi to the beads to proceed. It is recommended that efficiency of C3bi deposition be verified by immunofluorescence before proceeding with the phagocytosis assay.

Additional Materials *(also see Alternate Protocol 2)*

Human or mouse serum, freshly isolated

At step 2 of Alternate Protocol 2, place the following in a sterile 15-ml polystyrene tube instead of the items indicated in that protocol:

1.5 ml PBS
1.5 ml human or murine serum
60 µl bead suspension.

Incubate 60 min at 37°C with rotation. At the end of the incubation period in step 3, continue with Alternate Protocol 2, starting from step 7.

BASIC PROTOCOL 3

ASSESSMENT OF PHAGOCYTOSIS USING FLOW CYTOMETRY

In addition to the conventional microscope-based techniques described above, phagocytosis of microorganisms and particles can be measured using flow cytometry (Bassoe and Solberg, 1984; Santos et al., 1995; Oben and Foreman, 1988; Lehmann et al., 2000). The principle of the flow cytometric technique for assessment of phagocytosis is relatively straightforward. After allowing phagocytic cells to ingest fluorescent particles (e.g., labeled microorganisms or particles), cell-associated fluorescence is quantified using flow cytometry. If the fluorescent phagocytic "prey" is evenly labeled, the amount of cell-associated fluorescence is directly proportional to the number of ingested particles, thus allowing a calculation of the phagocytic index. This technique has several advantages over the conventional techniques (Harvath and Terle, 1999), but also some limitations that are discussed below, along with several strategic considerations.

Distinguishing Particle Attachment to the Cell Surface From Internalization ("In" From "On")

A key technical issue is the necessity to quantify only internalized particles, while excluding extracellular adherent ones. This is generally accomplished by minimizing extracellular fluorescence using impermeant quenching agents. Many fluorophores can be quenched by compounds such as trypan blue, ethidium bromide, or iodoacetate that, under optimal conditions, are able to dampen surface fluorescence by up to 95% without penetrating the plasma membrane (Steinkamp et al., 1982; Bassoe and Solberg, 1984). In addition, many fluorophores including FITC, Alexa Fluor 488, BODIPY FL, Oregon Green, tetramethylrhodamine, Texas Red, and Cascade Blue dyes can be quenched by specific antibodies. It should be emphasized that quenching is not an all-or-none phenomenon and that proper controls must be carried out to ensure that there is satisfactory separation of the internalized and adherent particle populations. It is also important to note that not all fluorophores can be quenched in this manner, and it is essential to ascertain that untested dyes can be quenched efficiently. In addition, the florescence of synthetic beads that are synthesized with the fluorophore incorporated within the polymer cannot be quenched in this manner.

Sensitivity To pH

It is important to consider that many fluorophores are sensitive to environmental factors—notably intracellular pH—that can affect the signal of the fluorescent probe. In the case of phagocytosis, this is particularly important because, as the phagosome matures, the luminal pH decreases, thus quenching the fluorescence of dyes such as FITC. This can result in artifactual underestimation of the phagocytic efficiency. Fluorophores such as those of the Alexa and BODIPY series, tetramethylrhodamine, and Texas Red exhibit much less quenching over a wide pH range (from pH 4 to 9), and they are much less susceptible to artifactual quenching.

On the other hand, one can take advantage of the pH sensitivity of some probes to discriminate between internalized and externally adherent particles. As described in more detail elsewhere, it is also possible to tag phagocytic targets with pH-sensitive dyes such as FITC, SNARF, SNAFL, or Oregon Green (Molecular Probes) that undergo spectral shifts or intensity changes at the acidic pH found within phagosomes. If the appropriate pH-sensitive wavelength is selected for detection, the fluorescence intensity will be proportional to phagocytosis and can be used to quantify internalized particles by flow cytometry.

Selection of Phagocytic Targets

Phagocytic targets suitable for flow cytometry include bacteria (*E. coli* and *Staphylococcus aureus*), zymosan (*Saccharomyces cerevisiae*), fungi (*Aspergillus*), and latex beads. These targets are usually opsonized with IgG or complement fragments (see Basic Protocols 1 and 2 and Alternate Protocols 1 and 2), but many present endogenous ligands such as β-glucan and other complex carbohydrates that can initiate or at least influence phagocytosis. These factors must be taken into consideration when selecting the most appropriate target and when comparing the efficiency of phagocytosis between different targets.

The protocol below delineates several different methods to assess phagocytosis by flow cytometry using bacteria, yeast, or synthetic beads.

Materials

Zymosan A (from *S. cerevisiae*; Sigma)
Phosphate-buffered saline (PBS; see recipe), pH 7.4
0.1 M sodium carbonate, pH 9.3
1 mg/ml solution of reactive fluorophore, e.g., fluorescein isothiocyanate (FITC) *or* Oregon Green 514 succinimidyl ester, in 0.1 M sodium carbonate, pH 9.3
Bacteria of interest as phagocytic target (e.g., *E. coli* K-12 strain)
1 mg/ml fluorescein isothiocyanate (FITC) in PBS (see recipe), pH 8.0
1% (v/v) glutaraldehyde in PBS (see recipe for PBS)
PBS (see recipe) containing 100 mM glycine
Phagocytic cells of interest: cultured cell lines or primary isolates of peripheral blood neutrophils or monocytes (e.g., *UNIT 2.2*)
PBS (see recipe) containing 0.02% EDTA
PBS (see recipe) containing 1.25 mg/ml trypan blue
0.25% trypsin/EDTA *or* nonenzymatic cell dissociation solution (both available from Sigma)
Quenching antibody to fluorophore (*e.g.,* anti-FITC/Oregon Green Cat# A-889; anti-Alexa Fluor 488 Cat # A-11094 Molecular Probes)

Bath sonicator (e.g., Bransonic 1200 Ultracleaner, Branson)
Rotating shaker
Polypropylene tubes for use with flow cytometer
24- or 96-well tissue culture plates (Polypropylene Cluster, Costar)
Flow cytometer

Additional reagents and equipment for flow cytometry (e.g., Robinson et al., 2003)

Prepare fluorophore-coupled phagocytic particles

For zymosan A

1a. Suspend 10 to 20 mg of dried zymosan A in 10 ml PBS. Vortex vigorously and boil for 10 min.

2a. Wash three times in 1 ml PBS by resuspension followed by centrifugation 1 min at 3000 × *g* and resuspend in PBS. Sonicate in bath sonicator to disperse aggregates.

3a. Sediment zymosan A by centrifuging 1 min at 3000 × *g*, 4°C, remove supernatant, and resuspend pellet in 0.1 M sodium carbonate, pH 9.3, at a final concentration of 50 mg/ml.

4a. Initiate labeling reaction by adding 0.1 mg of fluorophore (as 1 mg/ml solution) to 1 mg of suspended zymosan particles. Allow reaction to proceed 4 hr at room temperature with constant mixing.

Reactive fluorophores (e.g., fluorescein isothiocyanate and the succinimidyl ester of Oregon Green 514) are dissolved in 0.1 M sodium carbonate at 1 mg/ml.

5a. Remove unbound probe by centrifugation for 1 min at 3000 × *g*, 4°C, discard the supernatant, and resuspend product in 0.5 ml of dimethylsulfoxide with 3 drops of PBS, pH 7.4. Sonicate to disperse the zymosan. Repeat centrifugation, resuspension, and sonication 2 to 3 more times while adding progressively more PBS until the supernatant is completely clear.

6a. Dissolve the final pellet in 1 ml PBS.

This can be frozen in aliquots or stored at 4°C in 2 mM sodium azide for several weeks (make certain to wash off the azide before using for phagocytosis assays, as azide inhibits phagocytosis).

For bacteria

1b. Transfer 5.0×10^8 bacteria from overnight culture to a microcentrifuge tube.

2b. Sediment by microcentrifuging 1 min at maximum speed and wash once by resuspension in PBS and resedimentation.

3b. Resuspend cells in 1 ml of 1 mg/ml FITC in PBS, pH 8.0. Incubate at room temperature on an end-over-end rotator for 25 min.

4b. Wash in PBS as in 2b and fix in 1 ml of 1% glutaraldehyde in PBS for 20 min.

5b. Quench free aldehyde groups by incubating in 0.5 ml of PBS containing 100 mM glycine for 10 min at room temperature.

6b. Wash as in 2b and resuspend in 500 µl sterile PBS. Keep on ice until use the same day.

Initiate phagocytosis

Using the labeled zymosan A particles or bacteria from step 6a or 6b, respectively, proceed with steps 7a to 11a if studying phagocytosis by cells in suspension (e.g., neutrophils or monocytes) or proceed with steps 7b to 1b if studying phagocytosis by adherent cells.

Phagocytosis assays for cells in suspension

7a. To a 1.5-ml microcentrifuge tube, add 100 µl of a suspension of 5×10^6 phagocytic cells/ml, prewarmed to 37°C. Next, mix with 100 µl of a suspension of 5×10^7 particles/ml of the labeled phagocytic target from step 6a or b.

It is crucial to ensure good contact between the phagocytes and their prey, bearing in mind that while adherent phagocytes can crawl, suspended cells cannot swim.

8a. To bring phagocytic cells and target particles into close proximity, cosediment the cells and beads by a rapid microcentrifugion (15 sec at 70% maximum speed or ~8000 rpm).

The cell-to-particle ratio should be optimized for the specific cell type, but it is usually ~1:10 (range 1:5 to 1:100).

9a. Incubate the cells at 37°C for the appropriate length of time. Terminate phagocytosis by adding 1 ml ice-cold PBS containing 0.02% EDTA. Keep samples on ice.

The incubation time for maximum phagocytosis should be optimized for the individual cell type and can vary from 10 to 15 min for human neutrophils to 30 to 40 min for monocytes.

10a. Dilute samples 1:5 with PBS containing 1.25 mg/ml trypan blue. Incubate at 4°C for at least 2 min to allow efficient quenching of fluorophore. Maintain the samples at 4°C in trypan blue–containing solution until analysis.

11a. Harvest cells using a micropipettor and transfer to a polypropylene tube suitable for use in the flow cytometer.

If there will be a delay before analysis, fix cells with 2% paraformaldehyde. Fluorescence will be stable for at least 24 to 48 hr in fixed cells.

For adherent cells

7b. Add labeled particles (from step 6 a or b; 5 to 10 per cell) to adherent phagocytes growing in wells of a 24-well tissue culture plate. Incubate for 10 to 60 min at 37°C.

8b. Terminate phagocytosis by adding 200 µl per well of ice-cold PBS containing 0.02% EDTA.

9b. Remove the cells from the surface using 0.25% trypsin/EDTA or nonenzymatic cell dissociation solution. Pipet repeatedly yet gently to ensure dispersal into a single-cell suspension.

10b. If needed, filter through a mesh filter to remove clumps of cells

One risks the wrath of the flow cytometry facility if one clogs up the aspiration port of the cytometer.

11b. Keep samples on ice and dilute 1:5 with PBS containing 1.25 mg/ml trypan blue. Transfer to a polypropylene tube suitable for use with the flow cytometer and analyze immediately.

If there will be a delay, fix cells with 2% paraformaldehyde. Fluorescence will be stable for at least 24 to 48 hr in fixed cells.

Analyze by flow cytometry

12. Aspirate cells into the chamber of the flow cytometer and collect a minimum of 10,000 cells in the viable cell gate (also see Robinson et al., 2003).

Flow cytometers with one or several lasers are available from several commercial sources. the authors use either a BD Biosciences FACSCalibur or a Beckman-Coulter Elite.

The fluorescence measurements collected in the individual fluorescence channels are displayed on log scales. The proportion of cells that performed phagocytosis is estimated as the percentage of viable cells that have target fluorescence exceeding the background values (van Eeden et al., 1999).

When using evenly labeled fluorescent beads, the mean number of beads per phagocytic cell can be calculated by dividing the mean target fluorescence in the appropriate gate by the fluorescence of a single extracellular bead. The latter value is estimated separately using pure beads.

DETERMINATION OF PHAGOSOMAL pH

Acidification of the phagosomal lumen is apparent shortly after sealing of the phagosomal cup. As in the case of endosomes, accumulation of H^+ is thought to result from vectorial pumping by vacuolar-type (V) ATPases (Demaurex, 2002), which are delivered to the membrane of the maturing phagosome via fusion with acidic endomembrane compartments (i.e., endosomes and lysosomes). What determines the progressive acidification is unclear, but increased density of pumps, reduced leakage of H^+ (equivalents), and/or increasing counterion conductance have all been contemplated. All V-type ATPases are exquisitely sensitive to inhibition by macrolide antibiotics such as bafilomycin and

concanamycin (folimycin), and these drugs are routinely used to prevent or dissipate the phagosomal acidification and to validate the measurements of luminal pH. Two general approaches have been used to detect and quantify phagosomal pH, as described in Basic Protocol 4 and Alternate Protocol 4, below.

BASIC PROTOCOL 4

Measuring Phagosomal pH with Permeant Reagent

The simplest method for determining phagosomal pH involves the use of absorbing or fluorescent weak bases that can permeate biological membranes in their unprotonated state. Such compounds readily traverse the surface and phagosomal membranes to reach the phagosomal lumen where they become protonated because of the prevailing low pH. Because the resulting protonated species is much less permeant than its unprotonated precursor, the total concentration of the molecule in the phagosome increases beyond that of the medium and cytosol, in direct proportion to $[H^+]$. This accumulation, an indirect measure of pH, can then be detected spectroscopically either by the increased absorbance or fluorescence of the probe, or by spectral shifts that are a consequence of the formation of excimers at high fluorophore concentrations. Acridine orange, quinacrine, and LysoTracker are fluorescent weak bases that can be used to detect phagosomal acidification.

Materials

Cells of interest (e.g., RAW264.7 macrophages; ATCC #TIB-71)
Na^+-rich medium (see recipe), 37°C
Fluorophore-coupled phagocytic particles (see other protocols in this unit)
1 mM stock of LysoTracker Red DND 99 (Molecular Probes) in DMSO

6-well tissue culture plates containing sterile glass coverslips (see recipe)
Leiden chambers and thermostatted holder for microscope stage
Fluorescence imaging microscope system with rhodamine filter set
Light microscope with differential interference contrast (DIC) capability (*UNIT 4.1*)

Additional reagents and equipment for light and fluorescence microscopy (*UNIT 4.1*)

Prepare cells

1. Seed cells onto sterile glass coverslips contained in 6-well plates (prepared as in Reagents and Solutions) and grow to desired level of confluence.
2. Remove coverslip from well, place in Leiden chamber and immediately cover with prewarmed (37°C) Na^+-rich medium.

Allow cells to carry out phagocytosis and accumulate LysoTracker

3. Initiate phagocytosis by incubation with desired particles (see other protocols in this unit).
4. Wash off excess particles and allow maturation to proceed for desired time.
5. Add to the medium 50 to 100 nM LysoTracker Red DND 99 (as 1 mM stock) and allow a minimum of 10 min for complete equilibration.
6. Visualize fluorescence using a fluorescence microscope with a conventional rhodamine filter set.
7. Confirm the identity of phagosomes by visualizing the same field by differential interference contrast (DIC) microscopy.

Quantitative pH Determinations by Fluorescence Ratio Microscopy

More quantitative measurements can be made by ratio fluorimetry. This approach is based on the use of pH-sensitive fluorophores that are trapped in the phagosome along with the particle. It is best to attach the probe covalently to the particle, since the rapid remodeling of the luminal contents during maturation results in rapid clearance of soluble material that is trapped during phagosome formation. Very accurate determinations can be obtained by calculating the ratio of fluorescence at two different wavelengths that behave differentially when pH is altered. This normalization procedure corrects for overall changes in emission due to photobleaching or to alterations in focal plane, a common occurrence in the case of phagosomes, which are comparatively mobile organelles. Derivatives of fluorescein have been used extensively for this purpose.

Additional Materials *(also see Basic Protocol 4)*

Fluorophore-coupled zymosan particles (see Basic Protocol 3, steps 1a to 6a)
K^+-rich medium, pH 7.5 and lower pHs for calibration (see recipe)
1 mg/ml nigericin stock in ethanol
Ratio imaging setup (see Support Protocol 2)

Prepare cells

1. Grow cells, load in a Leiden chamber, and overlay with Na^+-rich medium (see Basic Protocol 4, steps 1 and 2).
2. Place chamber on thermostatted holder on stage of imaging microscope.

Allow cells to phagocytose particles

3. Allow the cells to ingest fluorophore-coupled zymosan particles (see Basic Protocol 3).

   Particles can be opsonized if desired by incubation with anti-zymosan antibodies (Molecular Probes), as described for red cells in Basic Protocol 1. Use a ratio of 5 to 10 particles per cell for effective phagocytosis

4. Wash off excess particles and allow maturation to proceed for desired time.
5. Acquire images, alternating the excitation between 440 nm and 490 nm and directing the light to the samples with a 510 nm dichroic mirror. Record emitted light using a 535BP25 nm filter.

Calibrate the pH

6. For calibration, replace Na^+-rich medium with K^+-rich medium, pH 7.5. Add 5 µg/ml nigericin (from 1 mM stock) and allow 3 to 5 min for equilibration.
7. Repeat image acquisition as in step 5.
8. Replace K^+-rich medium, pH 7.5, with similar medium of lower pH, and nigericin as in step 6.
9. Allow equilibration and repeat image acquisition cycle
10. Repeat steps 8 to 9 for all calibration solutions.

    At least four calibration points in the range of pH 5 to 7.5 are recommended.

11. Construct a calibration curve plotting fluorescence ratio versus pH. Interpolate experimental values obtained in step 5 to calculate the absolute pH from the calibration curve.

If using the Metamorph software, these steps can be expedited by using the QUICK TITRATION feature.

Calibration can be done, alternatively, by gently permeabilizing the plasma and phagosomal membranes using 0.1% Triton X-100, while ensuring that the phagocytic particle(s) of interest remain in the field of view. The K^+-rich media of varying pH can then be introduced sequentially as above, but nigericin can be omitted. Ensure that the particle being calibrated is not displaced during solution changes.

SUPPORT PROTOCOL 2

Ratio Imaging Setup

A complete imaging system appropriate for use in quantitative pH determination via ratio imaging (see Alternate Protocol 4) consists of an excitation source, microscope with appropriate filter sets and filter-positioning devices, camera, computer, and software (Demaurex et al., 1998). Several "turn-key" complete systems are available for fluorescence imaging. On the other hand, a large variety of setups can be assembled using individual components from different manufacturers. The system that the authors have assembled in their laboratory consists of a Leica DMR IB fluorescence microscope equipped with a PL Fluotar 100×/1.3 N.A. oil-immersion objective. A Sutter wheel and controller position the excitation filters in front of a mercury lamp. Neutral-density filters are often used to minimize dye bleaching and photodynamic damage to the cells. Emitted fluorescence is captured by an Orca ER cooled charge-coupled device camera. Image acquisition is controlled by the Metafluor software (Universal Imaging Corp.) operating on a Dell computer.

The authors' system includes a modification that makes it possible to continuously monitor the cells by bright-field (differential interference contrast) microscopy (also see *UNIT 4.1*). To this end, the sample is continuously illuminated at >620 nm by placing a red filter in front of the transmitted incandescent source. By placing an additional 660-nm dichroic mirror in the light path, the red light can be directed to a separate video camera (Dage MTI).

ASSESSMENT OF PHAGOSOMAL MATURATION

The composition of the nascent phagosome is very similar to that of the plasma membrane. However, both the limiting membrane and luminal contents of the phagosome undergo graded changes that result from progressive and finely coordinated rounds of fusion with endomembranes. These fusion events, together with the concomitant membrane budding and vesiculation steps that maintain the phagosomal area nearly constant, are collectively termed phagosomal maturation. Maturation confers upon the phagosome its microbicidal and lytic capabilities. Table 15.7.1 summarizes some of the characteristics of phagosomes at different stages of maturation.

The following protocols, outline methods to assess the occurrence of phagosomal maturation and to identify some of the intermediate stages of the process, using reagents that are readily available. It should be noted, however, that the rate and extent of maturation, and consequently the fate of the internalized particles, most likely depend on the number and type of receptors engaged. Therefore, the design and interpretation of individual experiments need to be tailored to the particular phagocytic stimulus under investigation.

Assessment of the Presence of Transferrin Receptors in Early Phagosomes

Transferrin (Tfn) receptors, which are abundant in early/recycling endosomes, are present on the phagosomal membrane at the earliest stages of maturation. The following are steps assess transferrin distribution in cells.

Materials

Primary monocytes or macrophages (*UNIT 2.2*), or monocytic cell lines (e.g., RAW 264.7 cells, ATCC #TIB-71 or J774 cells, ATCC #HB-197)
DMEM with 10% FBS (*APPENDIX 2B*)
Phosphate-buffered saline (PBS; see recipe)
Serum-free DMEM (e.g., Life Technologies)
Fluorophore-conjugated transferrin (Tfn; Molecular Probes; store in small aliquots at −20°C)
HEPES-buffered DMEM (e.g., Life Technologies)

6-well tissue culture plates containing sterile glass coverslips (see recipe)
Fluorescence microscope with appropriate filters (*UNIT 4.2* and *APPENDIX 1E*)

Additional reagents and equipment for phagocytosis assay using sRBCs (see Basic Protocol 1 or Alternate Protocol 1) or latex beads (see Alternate Protocol 1 or 2) and fluorescence microscopy (*UNIT 4.2*)

1. Grow cells of choice in DMEM with 10% FBS (*UNIT 1.1*). At a point 24 to 48 hr prior to the experiment, passage cells onto sterile glass coverslips contained in 6-well plates (prepared as described in Reagents and Solutions) so that they will to reach ~75% confluence at the time of the experiment.
2. Wash cells with PBS, then incubate in serum-free DMEM for 1 hr in a CO_2 incubator at 37°C.

   This step will deplete the cells of endogenous transferrin.
3. While the cells are incubating, proceed with opsonization of sRBC or latex beads (see Basic Protocol 1 or Alternate Protocol 1) in preparation for the phagocytosis assay (step 6 below).

Table 15.7.1 Markers of Phagosomal Maturation

Stage	Time	pH	Interacting organelle	Markers[a]
Early phagosome	~5 min	6.0	Sorting endosomes, endoplasmic reticulum (?)	Transferrin receptor[b], EEA1[b], Rab5[b], PI(3)P, syntaxin 13
Late phagosome	~20 min	5.0–6.0	Late endosomes, multivesicular bodies	Mannose-6-phosphate receptor[b], LAMP1/2[b], Rab7[b], Rab9[b], syntaxin 7, lyso(bis)phosphatidic acid
Phagolysosome	~40 min	4.5–5.0	Lysosomes	LAMP1/2[b], mature cathepsin D[b], fluid-phase markers chased for = 2 hr

[a]Abbreviation: PI(3)P, phosphatidylinositol 3-phosphate.
[b]Antibodies directed against these antigens are commercially available.

4. Prepare a solution of 50 µg/ml fluorophore-conjugated Tfn in HEPES-buffered DMEM. Overlay cells with this solution and incubate for 1 hr at 37°C to label the endosomes.

   Molecular Probes sells human transferrin conjugated to a number of different fluorophores. One should choose the most appropriate fluorophore for one's application. Reconstitute according to manufacturer's directions and store in the dark in small aliquots at –20°C.

5. Wash off excess unbound Tfn with PBS.

6. Proceed with phagocytosis assay (see Basic Protocol 1 or Alternate Protocol 1).

7. Assess the presence of fluorescently labeled Tfn on the phagosomal membrane using fluorescence microscopy.

   Tfn should be present in phagosomes at early times (5 to 15 min), but not thereafter.

   Confocal microscopy is optimal for evaluation, particularly when latex beads are employed, since such beads are prone to birefringence of fluorescent light emitted outside the focal plane.

ALTERNATE PROTOCOL 5

Assessment of the Delivery of Fluid-Phase Markers to the Phagosome

The protocol detailed below takes advantage of the uptake and accumulation in lysosomes of biologically inert fluorophore-conjugated dextrans to identify phagolysosomes. For these experiments, the authors recommend the use of latex particles to avoid the conflicting fixative requirements of sRBC and the lysine-fixable dextran.

Materials

Primary monocytes or macrophages (*UNIT 2.2*), or monocytic cell lines (e.g., RAW 264.7 cells, ATCC #TIB-71 or J774 cells, ATCC #HB-197)
DMEM with 10% FBS (*APPENDIX 2B*)
Fluorophore-conjugated dextran, MW 3000, lysine fixable (Molecular Probes; store in dark in small aliquots at –20°C)

6-well tissue culture plates containing sterile glass coverslips (see recipe)
Fluorescence microscope with appropriate filters (*UNIT 4.2* and *APPENDIX 1E*)

Additional reagents and equipment for phagocytosis assay using sRBCs (see Basic Protocol 1 or Alternate Protocol 1) or latex beads (see Alternate Protocol 1 or 2) and fluorescence microscopy (*UNIT 4.2*)

1. Grow cells of choice in DMEM with 10% FBS (*UNIT 1.1*). At a point 24 to 48 hr prior to the experiment, passage cells onto sterile glass coverslips contained in 6-well plates (prepared as described in Reagents and Solutions) so that they will to reach ~75% confluence at the time of the experiment.

2. Add the fluorophore-conjugated dextran at 250 µg/ml. Incubate 30 to 45 min at 37°C.

   Molecular Probes sells dextran (mol. wt. 3000, lysine fixable) conjugated to a number of different fluorophores. One should choose the most appropriate fluorophore for one's application. Reconstitute according to manufacturer's directions and store in the dark in small aliquots at –20°C. The "fixable" probes have lysine residues incorporated into the dextran which allow them to be fixed by paraformaldehyde and other aldehyde fixatives.

3. Wash off excess dextran with two changes of medium.

4. Incubate for an additional 3 to 4 hr at 37°C in DMEM with 10% FBS.

5. While the cells are incubating, proceed with opsonization of sRBC or latex beads (see Basic Protocol 1 or Alternate Protocol 1) in preparation for the phagocytosis assay (step 6).
6. Proceed with phagocytosis assay (see Basic Protocol 1 or Alternate Protocol 1).
7. Assess the colocalization of fluorescently labeled dextran with the internalized latex beads by microscopy.

   Dextran will be found in phagosomes only at advanced stages of maturation (>30 min).

   Fresh mounts or samples fixed with 4% paraformaldehyde can be used. Confocal microscopy (UNIT 4.5) is optimal for evaluation, particularly when latex beads are employed.

Assessment of Phagosomal Maturation by Immunostaining of Endogenous Organellar Markers

ALTERNATE PROTOCOL 6

As it matures, the phagosome acquires and sheds a number of different membrane and soluble proteins, characteristic of the compartments it interacts with. Antibodies directed against many of these proteins are commercially available and can be used to assess their presence in phagosomes by immunofluorescence.

It should be noted, however, that these markers are not always discretely localized to one single compartment (e.g., LAMP1 and LAMP2 are abundant in both late endosomes and lysosomes and can be present at lower density in the plasma membrane and early endosomes). Therefore, the authors recommend the use of multiple markers to validate the stage of phagosomal maturation

The following is a generic protocol that describes the immunofluorescence staining procedure following a phagocytosis assay. The species and concentrations of the primary and secondary antibodies will depend on the specific antigen under investigation. Some of the antibodies, such as those directed against some types of LAMP, are only effective in cells fixed with methanol. Please consult the specifications provided by the manufacturer for the appropriate antibody dilutions, blocking and permeabilizing conditions, and fixative to be used.

Materials

Permeabilization buffer: e.g., 0.1% (v/v) Triton X-100 in PBS or 2% (w/v) saponin in PBS (see recipe for PBS)
Blocking buffer: PBS (see recipe) containing 1% (w/v) BSA and 7.5% (v/v) of serum in which primary antibody was raised)
Primary antibody directed against the protein marker of interest (Table 15.7.1)
Fluorophore-conjugated secondary antibody
Fluorescence mounting medium (Dako)
Additional reagents and equipment for phagocytosis assay (see Basic Protocol 1 or Alternate Protocol 1) and fluorescence microscopy (*UNIT 4.2*)

1. Perform phagocytosis assay (see Basic Protocol 1, steps 1 to 21, or Alternate Protocol 1, steps 1 to 15).
2. Fix with methanol (see Basic Protocol 1, step 21) or paraformaldehyde (see Alternate Protocol 1, step 17). Quench with 100 mM glycine in PBS (see Alternate Protocol 1, step 17) if paraformaldehyde is used.
3. Wash fixed cells three times with PBS.

4. Permeabilize fixed cells for 20 min with the appropriate permeabilization buffer at 4°C.

   Detergent-containing permeabilization buffers are required if paraformaldehyde is used to fix the cells but not if methanol is used.

5. Block for 1 hr at room temperature in blocking buffer.
6. Incubate with primary antibody diluted in blocking buffer for 1 hr at room temperature.
7. Wash three times with PBS.
8. Incubate with fluorophore-conjugated secondary antibody diluted in blocking buffer for1 hr at room temperature.
9. Wash three times with PBS.
10. Mount in Dako fluorescence mounting medium and analyze by fluorescence microscopy.

BASIC PROTOCOL 6

INHIBITION OF PHAGOCYTOSIS

Because phagocytosis is a complex phenomenon, it can be arrested at a number of steps, all of which are essential for completion of particle engulfment (Aderem and Underhill, 1999). A variety of conditions and agents have been reported to impair phagocytosis, but their detailed mode of action is not known in every instance. The simplest, most readily reversible means of preventing phagocytosis is to cool the cells. For mammalian phagocytes, temperatures below 15°C virtually eliminate particle ingestion. The precise critical step(s) affected by reducing the temperature has not been identified, and it is likely that multiple events of the phagocytic reaction are impaired simultaneously. Because it is harmless and reversible, cooling is used extensively to synchronize phagocytosis. This approach is based on the notion that binding of phagocytic receptors to their ligands is much less temperature sensitive than the consequent signaling and effector functions that lead to particle internalization.

The requirement for extensive rearrangement of the actin cytoskeleton during the uptake of large particles is universally acknowledged. For this reason, many laboratories have used cytochalasins or other antagonists of actin remodelling, such as latrunculin, to inhibit phagocytosis (also see *APPENDIX 1B*). Under these conditions, the phagocytes still associate with the target particles, but fail to extend pseudopods and do not engulf their prey. It is important to note that the effectiveness of antagonists of actin remodeling as inhibitors of phagocytosis is proportional to the size of the particle. Uptake of particles of ≤1 μm is only modestly affected, if at all, whereas engulfment of large targets such as apoptotic bodies is fully arrested. This divergence highlights the notion, introduced earlier, that phagocytosis is not a single phenomenon but rather a collection of phenotypically related events.

Inhibitors of phosphatidylinositol 3 kinase, such as wortmannin and compound LY294002 (*APPENDIX 1B*), also effectively impair the uptake of large particles. These drugs inactivate both class I and class III phosphatidylinositol 3 kinases at similar concentrations, and their use alone cannot distinguish the contribution of these enzyme types. However, experiments using inhibitory antibodies as well as studies of targeted gene disruption indicate that the class I, but not class III kinases are required for phagocytosis. Conversely, class III phosphatidylinositol 3 kinase is essential for normal maturation of the phagosome. Cells pretreated with wortmannin bind the target particles and initiate pseudopod extension, but the process is arrested before the particle becomes entirely trapped, resulting in the sustained formation of phagosomal cups, rich in F-actin. The critical step impaired by phosphatidylinositol 3 kinase inhibitors may be the detachment of actin from the base of the phagocytic cup, limiting the availability of actin and

associated proteins for the continued extension of the pseudopods. This may result, for instance, from sustained stimulation of Rho-family GTPases that are unable to inactivate in a timely manner. Alternatively (or additionally), phosphatidylinositol 3 kinase blockers may prevent the targeted delivery of endomembranes to the site of phagocytosis, which may be required for extension of the pseudopodia. As in the case of actin antagonists, inhibition by wortmannin and related compounds is particle size dependent. Phagocytosis of particles smaller than 2 to 3 μm can proceed to varying degrees despite inhibition of the kinase, while the uptake of larger particles is virtually eliminated.

Materials

20 to 50 μM wortmannin stock solution in DMSO *or* 1 to 2 mM cytochalasin D stock solution in ethanol (see *APPENDIX 1B* for more information on these reagents)

Additional reagents and equipment for phagocytosis assay (see Basic Protocol 1 or Alternate Protocol 1)

1. Prepare cells for phagocytosis assay (see Basic Protocol 1 or Alternate Protocol 1).
2. Prior to addition of phagocytic target particles, incubate cells in medium of choice containing either 50 to 100 nM wortmannin or 5 to 10 μM cytochalasin D. Incubate ≥10 min.
3. Add phagocytic particles.

   Note that cytochalasin needs to be maintained in the medium during phagocytosis, as it is a reversible agent. In contrast, wortmannin is thought to alkylate and irreversibly modify phosphatidylinositol 3 kinase and, in principle, need not be present after the preincubation period is completed.
4. Mount cells and score phagocytosis (see Basic Protocol 1 or Alternate Protocol 1).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Hanks balanced salt solution (HBSS)

5.4 mM KCl
0.3 mM Na_2HPO_4
0.4 mM KH_2HPO_4
4.2 mM $NaHCO_3$
1.3 mM $CaCl_2$
0.5 mM $MgCl_2$
0.5 mM $MgSO_4$
137 mM NaCl
5.6 mM D-glucose
Adjust pH to 7.4.
Store up to 1 month at 4°C

K^+-rich media

143 mM KCl
1 mM $MgCl_2$
1 mM $CaCl_2$
5 mM glucose
Store up to 1 month at 4°C.

Titrate to desired pH between 5.0 and 7.5 using PIPES, MES, or HEPES, as appropriate.

Na^+-rich medium

140 mM NaCl
3 mM KCl
1 mM $MgCl_2$
1 mM $CaCl_2$
5 mM glucose
20 mM HEPES, titrated to pH 7.3 at 37°C
Store up to 1 month at 4°C.

Phosphate-buffered saline (PBS)

140 mM NaCl
10 mM KCl
8 mM monobasic sodium phosphate
2 mM dibasic potassium phosphate
Check that pH is 7.4
Store up to 6 months at 4°C

Tissue culture plates, 6-well, containing sterile glass coverslips

Hold glass 25-mm round glass coverslips with 5-in. stainless steel tissue forceps and dip in a beaker containing 70% ethanol to sterilize. Gently shake off the excess ethanol and place coverslip on an angle in the well of the 6-well plate. When all six wells have been fitted with sterile coverslips, loosely place the lid over the plate and allow it to air dry in a culture hood for 10 to 15 min. Lower the lid securely onto the plate and gently tap the plate to allow the coverslips to settle to the bottom of the well. Seed cells as usual (*UNIT 1.1*).

COMMENTARY

Background Information

FcγR-mediated phagocytosis (Basic Protocol 1, Alternate Protocol 1, and Support Protocol 1)

The principal immunoglobulin (Ig) that functions as an opsonin is IgG. The constant (Fc) region of IgG binds to its cognate Fcγ receptor (FcγR). Binding of other classes of immunoglobulins, such as IgA and IgE, to their cognate Fcα and Fcε receptors can also support particle engulfment. However, phagocytosis is not the primary function of these receptors and is not discussed in this unit.

Internalization of IgG-opsonized materials is mediated by some but not all Fcγ receptors, including FcγRI, FcγRIIA, and FcγRIIIA. The cell expression and binding specificities of individual FcγR are listed in Table 15.7.2. FcγRI and FcγRIIIA are heterotrimeric proteins composed of a single α chain (which contains the Fc binding region) and two associated γ chains that contain the immunoreceptor tyrosine activation motif (ITAM). FcγRII is a monomeric transmembrane protein containing both the Fc-binding and the signal transduction motifs. FcγRIIA, expressed exclusively on human leukocytes, contains an ITAM motif in the cytosolic region of the protein and is able to support phagocytosis.

FcγRIIB, on the other hand, has an inhibitory ITIM (immunoreceptor tyrosine inhibitory motif) in place of the ITAM motif and is a negative (inhibitory) receptor. FcγRIIIB is a GPI-linked protein expressed in granulocytes. It can initiate calcium signaling and actin polymerization but it was omitted from Table 15.7.2 because its role in phagocytosis is ill defined.

Complement-mediated phagocytosis (Basic Protocol 2, Alternate Protocol 2, and Alternate Protocol 3)

Complement (C) comprises a group of proteins that are constitutively produced and secreted as inactive precursors by macrophages and hepatocytes. Complement is an important component of the innate immune response. It is not antigen-specific and can be activated

rapidly in the presence of microorganisms or foreign bodies to induce phagocytosis and cell lysis.

Activation of the complement cascade results in the cleavage of the inactive complement precursor proteins, some of which, in turn, become proteases that cleave other complement components. There are two complement cascades. The classical cascade is activated by the Fc (constant) region of antigen-bound IgG and IgM, and it is the pathway utilized in the above protocols to deposit C3bi onto erythrocytes and latex beads. The alternative complement cascade is activated by cell-surface molecules of bacteria, including the lipopolysaccharide (LPS) of gram-negative organisms, teichoic acid from gram-positive bacteria, and components from fungal and yeast cell walls.

As indicated, some fragments such as C3bi are opsonins that target coated materials for degradation. Particles that have been opsonized by complement fragments can be internalized by several complement receptors. Table 15.7.3 summarizes the different complement receptors (CR) that support phagocytosis, the receptor-binding specificities of each receptor, and the cell types where they are found. CR1 is a large monomeric glycoprotein that binds primarily C3b fragments and promotes phagocytosis and clearance of antigen-antibody complexes in conjunction with Fc receptors. CR3 and CR4 are integrin heterodimers which bind specifically to C3bi. CR3, also known as Mac1, $\alpha_M\beta2$, or CD11b/CD18, binds to C3bi with the highest affinity and is commonly considered to be the primary receptor involved in complement-mediated phagocytosis. The binding specificities of the receptors for C3bi are as follows: CR3>CR1>CR4. Ligation of C3bi-coated material is insufficient to initiate phagocytosis via CR3 and CR4, which, like other integrins, require a second activation (priming) stimulus such as phorbol esters (e.g., PMA), glucan binding, or adhesion of the cells to extracellular matrix proteins. For professional phagocytes such as neutrophils, cell adhesion may provide a sufficient stimulus to initiate CR3-mediated phagocytosis.

As discussed in the introduction to this unit, cell model systems using heterologous transfection of receptors have been used extensively to study phagocytosis. If using such model systems to study complement receptor–mediated phagocytosis, bear in mind that, when expressed exogenously, most integrins are in the active state. Therefore, a priming stimulus may not be necessary to elicit phagocytosis.

Flow cytometry of phagocytosis (Basic Protocol 3)

Flow cytometric analysis offers many potential advantages over microscopic assays of phagocytosis. These include: (1) the ability to assess large numbers of cells (tens of thousands), thus facilitating statistical analysis; (2) the availability of new fluorophores and multiparametric analysis that enable simultaneous measurements of structural (e.g., change in cell size or shape) and/or functional (e.g., calcium flux, oxidant production, surface adhesion molecule expression) properties of suspended cells rapidly and quantitatively (Trinkle et al, 1987); and (3) the capacity to use small volumes of whole blood. This method is particularly well suited for analysis of human samples from individuals suspected of having defects in the innate immune system, or for analysis of rodent (murine or rat) blood samples for which

Table 15.7.2 Main Types of FcγR

Receptor	Cell type	Binding affinity	Ligands	Function
FcγRI	Neutrophil, macrophage	High	IgG2a	Phagocytosis
FcγRIIA	Human neutrophil, macrophage	Low	IgG1, IgG2a, and IgG2b	Phagocytosis
FcγRIIB	Murine neutrophil, macrophage, B cell, mast cell	ND[a]	IgG1, IgG2a, and IgG2b	Inhibitory receptor
FcγRIIIA	Macrophage	High	IgG1, IgG2a, and IgG2b	Phagocytosis

[a]Abbreviation: ND, not determined

Table 15.7.3 Complement Receptor (CR)-Mediated Phagocytosis

Receptor	Cell type	Ligands
CRI (CD35)	Monocytes, neutrophils, dendritic cells	C3b, C3bi, C4b, C4bi
CR3 (Mac1, $\alpha_M\beta_2$ CD11b/CD18)	Monocytes, neutrophils, natural killer cells, dendritic cells	C3bi
CR4 (p150.95, $\alpha_V\ \beta_2$ integrin,CD11c/CD18)	Macrophages, neutrophils, natural killer cells, dendritic cells	C3bi
CR5aR	Macrophages, neutrophils	C5a

only small volumes are available. The method is compatible with the use of whole blood, which reduces the possibility of artifactual changes (e.g., priming or activation) caused by even the most gentle of cell purification procedures, and may be more reflective of the behavior of leukocytes in vivo.

Assessment of phagosomal pH (Basic Protocol 4 and Alternate Protocol 4)

The addition of labeled weak bases to assess the pH of acidic organelles is convenient and has therefore been used extensively. While rapid and convenient, this method is not exactly quantitative, because factors other than the transmembrane proton gradient contribute to the accumulation and retention of the bases. Binding of the probes to the contents of the probe can skew the determinations and limit their reversibility.

The more quantitative measurements using covalently labeled particles are far superior, though technically more demanding. The fact that fluorescence ratios are determined greatly reduces the risk of misinterpretation or miscalculation due to bleaching or defocusing. Nevertheless, the experimenter must be cautious to ensure that the appropriate background is subtracted separately from each one of the signals acquired at different wavelengths and that any changes, such as oxidation of the dye that can occur in phagosomes, affects both wavelengths to a comparable extent.

Assessment of phagosomal maturation (Basic Protocol 5, Alternate Protocol 5, and Alternate Protocol 6)

The primary purpose of internalization of opsonized particles is their ultimate destruction by a combination of low pH, degradative enzymes, and cytotoxic mediators. To achieve this goal, the phagosome acquires proteases and other hydrolases, high concentrations of H^+ ions, a variety of bactericidal peptides, and other factors as it matures. A detailed review of phagosome maturation has recently been published (Vieira et al, 2002).

In the maturation protocols, advantage is taken of the progressive acquisition of specific markers as the phagosome interacts with defined intracellular compartments to identify the stage of phagosomal maturation. Assessments of maturation can be complemented with measurement of phagosomal pH.

Inhibition of phagocytosis (Basic Protocol 6)

Pharmacological tools have been the source of a great deal of knowledge in the field of phagocytosis. While they are deservedly criticized for their imperfect specificity, they can be most useful when used under optimal conditions (i.e., the concentration range where their effect is most specific) and while bearing in mind their potential limitations. Molecular approaches, such as transfection of dominant negative constructs, gene ablation, or silencing using interference RNA technology are in principle more specific. However, these normally take many hours or days to develop within the cell or animal, and they can therefore generate a plethora of secondary, even developmental defects that are only distantly related to phagocytosis. Thus, pharmacology and molecular approaches are complementary. Continued improvement of the selectivity of pharmacological agonists and antagonists will surely be an

ongoing source of information about phagosome formation and maturation.

Critical Parameters and Troubleshooting

FcγR-mediated phagocytosis (Basic Protocol 1, Alternate Protocol 1, and Support Protocol 1)

Optimal adsorption of IgG onto sRBC and latex beads is critical for the success of the phagocytosis assays. The authors highly recommend that pilot experiments be performed with serial dilutions of IgG to find the concentrations required for optimal opsonization of individual lots of reagents.

Complement-mediated phagocytosis (Basic Protocol 2, Alternate Protocol 2, and Alternate Protocol 3)

For both Basic Protocol 2 and Alternate Protocol 2, the most critical parameter is the coating of the erythrocytes or latex beads with C3bi. The authors have indicated their preferred sources for some of the critical reagents in the respective protocols. It is recommended that initial experiments with serial dilutions of IgM be performed to find the optimal sub-agglutinating titers of individual lots of antibody, as well as for sRBC and latex beads from different sources.

The incubation period in C5-deficient medium is also critical. In studies of IgG- and IgM-coated erythrocytes, it has been shown that excessively long incubation periods (>20 min) lead to loss of surface-bound C3bi (Newman and Mikus, 1985).

Flow cytometry of phagocytosis (Basic Protocol 3)

The success of these experiments will depend on several factors: optimal condition of the phagocytes to be assessed, proper opsonization of phagocytic targets, and a signal-to-noise ratio that will allow clear discrimination of particles that are internalized from those that are adherent to the cell surface ("in" from "on"). For flow cytometry, this means efficient quenching of extracellular fluorescence of surface-bound particles. In studies using trypan blue to quench extracellular fluorescence, it is important not to wash the trypan blue away, or else the quenching of fluorescence will be lost.

Because of the automated nature of the procedure and the fact that the cells are never directly visualized during the course of flow cytometry, there are several potential artifacts that need to be avoided. These include false positive scoring of particles that are adherent to the cell surface rather than internalized and enclosed within a phagosome. This may result when quenching of the fluorescence of extracellular particles is incomplete. In addition, because the technique involves the analysis of cells in suspension, it is limited to cells that are naturally suspended or to adherent cells that can be detached easily from their substrate to form single-cell suspensions. Lifting adherent neutrophils or macrophages without incurring damage is not simple, especially after the cells have performed phagocytosis. Finally, because clumps of cells are either removed by filters designed to collect debris or excluded from analysis by gating, phagocytosis by cell types that are prone to aggregate after stimulation, such as neutrophils, might be underestimated if the most responsive and likely most avidly phagocytic cells are excluded from analysis.

There are several key parameters that require attention during flow cytometric analysis:

1. *Gating.* Cells are gated on a forward versus side scatter plot to exclude debris and broken cells. Forward scatter is proportional to the size of cells and side scatter is proportional to their granularity and shape. If there is a mixed cell population (e.g., when using whole blood or buffy coat preparations), it is critical that relatively pure populations of the cells of interest be included in the gate. It is usually possible to separate neutrophils, monocytes, and lymphocytes into distinct populations based on their light scattering. However, there is some overlap between small monocytes and neutrophils, and complete separation of these two cell types requires the use of a fluorescently labeled antibody that binds to a unique surface epitope on one cell type (e.g., CD15a for neutrophils and CD14 for monocytes). A minimum of 10,000 cells are counted in the viable cell gate

2. *Coincidence.* This term refers to the simultaneous appearance through the laser beam of the cytometer of more than one cell or free target particle, and it can lead to inaccuracies in the assessment of phagocytosis. Several parameters impact on coincidence, including the flow rate of the sheath fluid, the concentration of phagocytic cells and targets in the sample, and the ratio of targets per cell (Lehmann et al., 2000).

3. *Fluorescence channels.* Each channel is designed to collect emitted light within a defined range of wavelengths. However, each fluorochrome emits light with wider emission spectra than the limits of the single channel. This gives rise to the possibility of spectral overlap, an issue that is of critical importance when two or more fluorochromes are used (e.g., FITC-labeled phagocytic particles and a phycoerythrin-labeled anti-CD15 antibody to allow identification of human neutrophils). This potential problem can be overcome by choosing fluorochromes that have minimal spectral overlap and by electronic color compensation (a discussion of this issue is beyond the scope of this unit).

Assessment of phagosomal pH (Basic Protocol 4 and Alternate Protocol 4)

In the case of partitioning probes, such as weak bases, a range of different compounds are available with varying spectral properties. For experiments where multiple fluorophores need to be used, pH-sensitive probes that absorb light in the ultraviolet, blue, or green parts of the spectrum are commercially available.

It is essential to select probes that are most pH-sensitive in the range of interest. The pK_a of the probe chosen for analysis must ideally be in the mid-range of the measurements to be performed to provide optimal linearity. In the case of macrophage phagosomes, the pH generally becomes more acidic than in neutrophils, where the oxygen radicals generated by the NADPH oxidase can scavenge protons and thereby make the lumen more alkaline.

These oxygen radicals can greatly complicate the measurements by inducing acute chemical transformation of the fluorescent probes. When the contribution of the oxidase is not important to the measurements, it is convenient, indeed advisable to inhibit the flavoprotein component of the enzyme using diphenylene iodonium. Alternatively, the contribution of peroxidases can be minimized by addition of azide, bearing in mind that this compound will block mitochondrial ATP generation.

Assessment of phagosomal maturation (Basic Protocol 5, Alternate Protocol 5, and Alternate Protocol 6)

None of the procedures outlined will, by itself, identify the stage of phagosome maturation unambiguously. Therefore, the authors suggest that two or more different markers or methods be used to confirm the precise stage of maturation. Acquisition of defined isoforms of Rab (e.g., Rab5 versus Rab7), and differentiation between the mature and immature forms of lysosomal enzymes, such as cathepsins, can be most informative.

The second critical parameter is the choice of fluorophores used for the colocalization experiments. Care must be taken to avoid cross-talk between fluorophores when multiple determinations are performed simultaneously.

Inhibition of phagocytosis (Basic Protocol 6)

The duration of the (pre)treatment with inhibitors should be kept to the minimum required to achieve the inactivation of the desired target. Longer than necessary treatments should be avoided as they can result in secondary, indirect effects that can complicate the interpretation of the data. Extended pretreatment with wortmannin will impair vesicular traffic along the endocytic and secretory pathways and may impact negatively on the composition of the plasma membrane or on the ability of endosomes to be delivered to the surface upon activation. Similarly, prolonged exposure to cytochalasins will grossly distort cell morphology and function and can ultimately lead to detachment of the cells from the substratum. For non-adherent cells like blood neutrophils, cytochalasins have been reported to have a "priming" effect that potentiates some responses like granule secretion. The possible consequences of such priming must be borne in mind.

Anticipated Results

FcγR-mediated phagocytosis (Basic Protocol 1, Alternate Protocol 1, and Support Protocol 1)

Particles coated with IgG are expected to be ingested avidly by both macrophages and neutrophils and by monocytic cell lines like J774 and RAW264.7. The vast majority of the cells in any one culture will prove to be competent to internalize one or more particles over the course of 5 to 10 min.

The simplest and least ambiguous way to differentiate between extracellular adherent particles and those that have been internalized is to lyse hypotonically those on the outside. Visualization by bright-field microscopy will only detect the engulfed, intact red cells that retained their hemoglobin. Bear in mind that while fluorescently labeled red cell ghosts that remain adherent (extracellular) after hypotonic

lysis will be observable by fluorescence microscopy they will not be observable by bright-field microscopy because they have lost hemoglobin.

Complement-mediated phagocytosis (Basic Protocol 2, Alternate Protocol 2, and Alternate Protocol 3)

The efficiency of complement-mediated phagocytosis is, in the authors' experience, considerably lower that that of Fc-mediated phagocytosis. Therefore, expect only a fraction of the cells (typically 30% to 50%) to ingest one or a couple of the particles. Moreover, the kinetics of ingestion appears to be slower, perhaps because it is mediated by Rho, unlike Fc-dependent phagocytosis that involves Rac and Cdc42. The morphology of the phagocytic site also differs: complement-coated particles appear to "sink" into the cells and do not reveal the florid pseudopods seen in Fc-dependent internalization.

Flow cytometry of phagocytosis (Basic Protocol 3)

If the protocols outlined above are followed and if the phagocytic cells are healthy, the use of flow cytometry to assess phagocytosis is straightforward. For professional phagocytes such as neutrophils, phagocytosis should be very efficient, with over 70% of cells ingesting one or more phagocytic particles. By comparison, in cell lines such as COS or Chinese hamster ovary cells transfected with phagocytic receptors, phagocytosis may be much less efficient, with only 20% to 30% of cells ingesting particles.

Assessment of phagosomal pH (Basic Protocol 4 and Alternate Protocol 4)

Phagosomes formed by macrophages are expected to become acidic very rapidly, reaching steady state after 10 to 15 min at pH as low as 5.0. In human neutrophils the pH change is smaller and has been reported to be biphasic, with some authors reporting a transient alkalinization due to proton consumption by superoxide. The latter can be obviated and the acidification accentuated by inhibition of the NADPH oxidase with diphenylene iodonium.

Assessment of phagosomal maturation (Basic Protocol 5, Alternate Protocol 5, and Alternate Protocol 6)

Under normal circumstances, phagosomes formed by macrophages acquire early endosomal markers almost immediately. In fact, delivery of endosomal components to the nascent (unsealed) phagosome has been detected, accounting for the increased membrane area measured by electrophysiological capacitance determinations. Late endosomal markers appear as early as 10 min after ingestion and bona-fide lysosomal contents are detects after 45 to 60 min of phagocytosis.

Neutrophils contain unique secretory organelles that are delivered to phagosomes with different kinetics. Secretory vesicles, primary, secondary, and tertiary granules are all thought to deliver their constituents to the phagosome, although the signals that mediate fusion and the kinetics of delivery vary. Bear in mind that some granulocytic cell lines, such as HL-60 cells, fail to generate and/or accumulate some of the secretory compartments, which will therefore not contribute to phagosomal maturation.

Inhibition of phagocytosis (Basic Protocol 6)

As intimated in the introductory section of this unit, phagocytosis is a generic term that describes multiple, related but not identical processes. Even in the case of a single type of receptor and ligand, the properties of the phagocytic event may vary. Thus, phagocytosis of large particles is much more sensitive to wortmannin than is the ingestion of smaller ones (≤3 μm). Similarly, cytochalasin effectively inhibits the uptake of particles larger than 1–2 μm, but it is not nearly as effective in preventing the uptake of smaller particles. Much less is known for phagocytosis mediated by other receptors, so the reader should be prepared to find variations in the effectiveness of drugs when testing new systems.

Time Considerations

FcγR-mediated phagocytosis (Basic Protocol 1, Alternate Protocol 1, and Support Protocol 1)

Growth, expansion, and plating of the cells on the appropriate substratum is the most time-consuming part of the procedure. The phagocytosis protocol proper can be performed within 1 day. Therefore, in cases where primary cells can be isolated the same day, the entire experiment can be completed in a regular working day. It is not advisable to store opsonized red cells for extended periods.

Complement-mediated phagocytosis (Basic Protocol 2, Alternate Protocol 2, and Alternate Protocol 3)

The preparation of complement-opsonized particles is more laborious than that of IgG-coated particles. Nevertheless, it can and should be performed the day of the experiment. As in the case of Fc-mediated phagocytosis experiments, the most time-consuming part of the procedure is the growth, expansion, and plating of the cells on the appropriate substratum. Bear in mind that priming with phorbol esters is required for optimal complement-mediated phagocytosis, and this increases the duration of the experiments.

Flow cytometry of phagocytosis (Basic Protocol 3)

When studying primary cells, the entire experiment will take 5 to 6 hr if the phagocytic targets are prepared ahead of time. When working with cultured cells, the entire experiment will take 2 to 3 days, with the majority of the bench work on day 2.

Assessment of phagosomal pH (Basic Protocol 4 and Alternate Protocol 4)

Qualitative assessment of phagosomal pH using fluorescent weak bases can be accomplished in under 1 hr, if the reagents are prepared in advance and the microscope is available. In contrast, the ratiometric determinations are more laborious, requiring several hours from start to finish, even when the labeled particles are prepared in advance. A sizable fraction of the time is invested in the calibrations, which last longer than the pH determinations themselves. Nevertheless, if the cells are available at the beginning of the day, multiple measurements can be accommodated in a single working day.

Assessment of phagosomal maturation (Basic Protocol 5, Alternate Protocol 5, and Alternate Protocol 6)

The delivery of fluid-phase markers to phagosomes can be assessed within hours, provided the cells and opsonized particles are prepared in advance. The marker solutions are generally stable for considerable periods and can be prepared in advance.

Assessment of maturation by immunostaining is more time-consuming, requiring long fixation, blocking, staining, and mounting steps. From start to finish, an immunolabeling experiments can be completed within 2 days.

Inhibition of phagocytosis (Basic Protocol 6)

Pretreatment with most inhibitors is generally short (under 1 hr). Therefore, assessment of their effects on phagocytosis should not take much longer than the measurements of phagocytosis themselves (see above).

Analysis of Protein Transport to Lysosomes

Lysosomes are membrane-bound degradative organelles that are found in all higher eukaryotic cells. The limiting membranes of lysosomes contain a characteristic set of transmembrane glycoproteins that are transported to lysosomes by virtue of lysosomal targeting motifs found in the proteins' cytoplasmic tails (Bonifacino and Dell'angelica, 1999) The lumens of lysosomes contain an assortment of acidic hydrolases. These enzymes are synthesized in the endoplasmic reticulum (ER), where they become core-glycosylated. They are then transported into the Golgi complex, where they acquire a mannose-6-phosphate recognition tag in a two-step enzymatic process mediated by a phosphotransferase and an uncovering enzyme. The tag is then recognized by cation-dependent and cation-independent mannose-6-phoshate receptors in the *trans*-Golgi network (TGN). The resulting enzyme-receptor complexes are transported onward to endosomes, where the acidic pH induces dissociation of the enzymes from the receptors. The enzymes are then transported to lysosomes, while the receptors recycle back to the TGN to facilitate further rounds of transport. Failure of the receptors to recycle results in their misrouting to (and subsequent degradation in) lysosomes. The return of these receptors from endosomes to the TGN depends on specific amino acid residues (including specific cysteine residues that undergo reversible palmitoylation) in the cytoplasmic tails of receptor molecules. The final delivery of lysosomal enzymes to lysosomes has been proposed to occur by a fusion-fission process, referred to as "kiss and run," involving late endosomes and lysosomes (Luzio et al., 2003).

In this unit, the authors describe a method for analyzing the transport of proteins to lysosomes using subcellular fractionation on Percoll gradients. As an example, the authors have used this method to analyze how mutations in known signal sequences in the cytoplasmic tail of the cation-dependent mannose-6-phosphate receptor affect the routing of this protein to lysosomes (Nair et al., 2003). In brief, a mutation in which the residues in a diaromatic motif in the cytoplasmic tail of the receptor are replaced by other amino acid residues leads to varying degrees of receptor mislocalization to lysosomes. Using Percoll density gradients, it is possible to determine the amount of receptor mislocalized to lysosomes within a given period of time, and this allows validation of the strict requirement for the critical diaromatic motif to be present to ensure proper intracellular sorting of the receptor. The homogeneity of the fractions obtained following density gradient centrifugation can be tested using enzymatic activity assays and immunoblotting (*UNIT 6.2*) for marker proteins.

The Basic Protocol described in this unit is aimed at determining the amount of a protein of interest in lysosomes. Additionally, a comparison of two different homogenization methods and a description of the conditions to be optimized for the cell line being used are provided later in the unit. Furthermore, methods of fraction analysis are described in detail in the Support Protocol.

FRACTIONATION OF CELLS USING A SELF-FORMING PERCOLL DENSITY GRADIENT

BASIC PROTOCOL

Sedimentation on self-forming Percoll gradients can be used to separate dense lysosomes from lower-density organelles such as endosomes, Golgi apparatus, plasma membrane, and ER. Separation is based on the sedimentation of particles to their isopycnic position—i.e., the position where the gradient density is equal to the density of the particle. The organelles are thus separated solely on the basis of differences in density, irrespective of their size. The gradient described in this protocol is a continuous gradient that forms

Current Protocols in Cell Biology (2005) 15.8.1-15.8.12

upon centrifugation of a homogeneous Percoll suspension. This is in contrast to preformed gradients, which can be generated using various types of gradient makers (*UNIT 5.3*).

The method described here can be used for the analysis of transport of proteins to lysosomes. As an example, the authors study the misrouting of the cation-dependent mannose-6-phosphate receptor (CD-MPR) in a mouse L fibroblast cell line that lacks the cation-independent mannose-6-phosphate receptor (CI-MPR). The cell line used is transfected either with wild-type bovine CD-MPR or with a mutant form lacking the diaromatic endosomal sorting motif in its cytoplasmic tail. The effect of this mutation on the localization of the construct is analyzed by assessing levels of the construct in each fraction obtained upon gradient centrifugation. In order to detect receptor that has been mislocalized to lysosomes, the transfected cells are incubated with lysosomal protease inhibitors prior to homogenization.

In brief, cells are prepared, harvested, homogenized, and then fractionated on the Percoll gradient. A cushion and nine subsequent fractions are collected from the bottom of the gradient tube and pooled as follows: fractions 1 to 3 are combined to give pool I (containing 70% to 80% of lysosomal enzyme activity); fractions 4 to 6 are combined to give pool II (containing intermediate-density membranes); and fractions 7 to 9 are combined to give pool III (containing low-density membranes, including endosomes, Golgi apparatus, plasma membrane, and ER). Fraction analysis is described in the Support Protocol.

Materials

Mouse D9 L (Rec$^-$) fibroblast cell line (CRL-2648 mouse L cells available from ATCC; for mutant strain, contact Dr. Stuart Kornfeld at *skornfel@im.wustl.edu*) or other cell line of choice (e.g., HeLa)
Growth medium: e.g., Invitrogen α-minimal essential medium supplemented with 10% v/v fetal bovine serum, with or without 500 μg/ml geneticin
Growth medium containing 100 μM pepstatin A (from 30 mM stock in dimethyl sulfoxide; Sigma) and 100 μM leupeptin (from 30 mM stock in H_2O; Sigma)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
10× and 1× homogenization buffer (see recipe)
1× homogenization buffer/17.5% (v/v) Percoll solution (see recipe)
10% (v/v) Triton X-100
500× protease inhibitor cocktail (see recipe)
3× protein gel sample buffer (see recipe)
10-cm-diameter Falcon tissue culture dishes (BD Biosciences)
Rubber or plastic cell scraper
Refrigerated centrifuge with swinging-bucket rotor suitable for 15-ml tubes (e.g., Heraeus Cryofuge M7000)
Ball-bearing homogenizer (clearance, 16 μm; Isobiotec) or 25-G needle attached to 1-ml syringe
16 × 76–mm Ultra-Clear centrifuge tubes with metal screw caps (Beckman Coulter)
Refrigerated ultracentrifuge with Beckman Ti50 rotor (or equivalent) and Beckman TLA 100.3 rotor (or equivalent)
20-G needles
3-ml thick-walled polycarbonate ultracentrifuge tubes (Beckman Coulter)
1.5-ml polyallomer microcentrifuge tubes (Beckman Coulter) with suitable adaptors
Adaptors for centrifuging 1.5-ml microcentrifuge tubes in Beckman TLA 100.3 rotor (or equivalent)

NOTE: After cell culturing, perform all steps on ice, and cool all centrifuge parts to 4°C before use.

Prepare cells

1. Several days before fractionation is to be performed, plate the cells of interest on 10-cm-diameter tissue culture dishes (one dish of cells per sample to be analyzed). Grow the cells (*UNIT 1.1*) so that they reach 100% confluence 2 to 3 days before the start of the fractionation process. If the protein of interest is expected to undergo degradation in the lysosomes, add 10 ml growth medium supplemented with 100 μM pepstatin A and 100 μM leupeptin to the confluent cells 24 hr before performing step 2.

Homogenize cells

2. Aspirate growth medium from culture dish. Wash cells twice, each time by adding 10 ml ice-cold PBS and then aspirating.

   Process each culture dish separately throughout the steps that follow.

3. Add 2 ml ice-cold 1× homogenization buffer (HB) to the culture dish.

4. Scrape cells off of the dish using a rubber or plastic scraper, and then transfer the contents to a separate 15-ml centrifuge tube.

   It may be useful to hold the dish up to the light to check for parts of the cell lawn that might still be stuck to the surface following scraping.

5. To ensure that cell harvesting is complete, rinse the dish with 2 ml of 1× HB, scrape the surface of the dish with a rubber or plastic scraper, and then pool the contents of the dish with the material in the 15-ml tube from step 4.

6. Centrifuge the harvested cell suspension 5 min at ∼260 × *g*, 4°C, in a swinging-bucket rotor.

7. Aspirate the supernatant. Add 850 μl of 1× HB to the pellet, resuspend by trituration, and transfer the resulting suspension to a 1.5-ml microcentrifuge tube.

8. Homogenize the suspension using twelve strokes in a ball-bearing homogenizer with a clearance of 16 μm (optimal clearance for L, HeLa and HepG2 cells). Transfer the homogenized suspension to a 15-ml centrifuge tube.

   Alternatively, the cell suspension can be homogenized using twelve passes through a 1-ml syringe attached to a 25-G needle.

   The appropriate homogenizer clearance (and thus the diameter of choice for the ball bearing in the homogenizer) depends on the cell line being fractionated. Therefore, homogenizer clearance needs to be optimized empirically for the cell line of interest. In this optimization process, homogenization efficiency can be assessed by using special dyes (e.g., Evans blue) to stain intact nuclei and comparing the number of free nuclei after homogenization with the number of cells present before homogenization.

   Special care of the homogenizer is crucial to the success of every fractionation. Rust on the ball bearing and particles adhering to the tunnel walls can result in clearance aberrations, thereby creating suboptimal homogenization conditions. Rust and particle adherence can be prevented by cleaning the homogenizer with an appropriate brush, making sure not to use any detergent.

   It is important not to introduce air bubbles into the suspension during homogenization, as the presence of air bubbles can make passage through the homogenizer difficult and result in improper homogenization.

Fractionate cells

9. Add 850 μl of 1× HB to the homogenized suspension, and then centrifuge 10 min at ∼370 × *g*, 4°C, in a swinging-bucket rotor. Collect the supernatant (i.e., the

upper liquid phase) and transfer it to a separate 1.5-ml microcentrifuge tube kept on ice.

Following centrifugation, two liquid phases will be visible. The upper phase (referred to as the postnuclear supernatant, or PNS), which contains the cell membranes, will have a turbid appearance; this is the phase that should be collected. The lower phase, which contains cell nuclei, should be discarded.

10. Prepare a Percoll gradient on which to fractionate the postnuclear supernatant (PNS) collected in step 9.

    a. Add 1.2 ml of 10× HB to a 16 × 76–mm Beckman Ultra-Clear centrifuge tube.

       This 10× HB will serve as a sucrose cushion, ensuring that organelles are not pelleted by centrifugation.

    b. Using a pipet filler and pipet, carefully layer 8.5 ml of 1× HB/17.5% Percoll on top of the 10× HB sucrose cushion in the tube.

11. Using a pipet filler and pipet, carefully layer the PNS on top of the Percoll gradient. When PNS layering is complete, cap the Percoll gradient tube and centrifuge 30 min at ∼26,500 × *g*, 4°C, in an ultracentrifuge equipped with a Beckman Ti50 rotor or equivalent.

    If more than one gradient is being centrifuged, add 1× HB as necessary to ensure that all tubes are carrying the same weight.

12. After centrifugation, collect fractions in the following way.

    a. Uncap the tube, and then punch a hole in its bottom using a 20-G needle attached to a syringe.

       Uncapping of the centrifuge tube is critical, as this will prevent the subsequent introduction of air bubbles into the liquid in the tube.

    b. Draw 1 ml of liquid (i.e., the sucrose cushion) into the syringe from the bottom of the tube. Discard this liquid, and then use the syringe to collect nine more 1.2-ml fractions from the bottom of the tube. Transfer each collected fraction to a separate microcentrifuge tube.

       Beckman Ultra-Clear centrifuge tubes are soft and should therefore not be squeezed during fraction collection, as doing so can lead to turbulence and mixing of fractions.

13. Pool fractions 1 to 3 (pool I), fractions 4 to 6 (pool II), and fractions 7 to 9 (pool III). Use each of these fraction pools to fill a separate thick-walled 3-ml centrifuge tube, and save the remainder of each pool for use in step 15. Add PBS as necessary to ensure that all tubes are carrying the same weight.

    Alternatively, the collected fractions can be kept separate and analyzed individually.

    Sample tubes are adjusted to equal weight with the aid of a sensitive balance (±10 mg). Such a balance should also be used to equalize tube weights in steps 15 and 17.

    If larger tubes are available, each fraction pool can be transferred in its entirety to a separate tube and centrifuged in a single step (i.e., steps 14 and 15 can be skipped).

14. Centrifuge the pooled fractions 20 min at 300,000 × *g*, 4°C, in an ultracentrifuge equipped with a Beckman TLA 100.3 rotor or equivalent.

15. Remove and discard 0.5 to 1 ml of the supernatant from each centrifuge tube, add the rest of each fraction pool (i.e., what was saved in step 13) to the appropriate tube, and then add PBS as necessary to ensure that all tubes are carrying the same weight.

16. Centrifuge the pooled fractions once more, this time for 30 min at 300,000 × *g*, 4°C, in an ultracentrifuge equipped with a Beckman TLA 100.3 rotor or equivalent.

    After this centrifugation step, each tube will contain a white cell membrane band settled on top of a clear Percoll layer. Of the three fraction pools, pool III will have the highest membrane content; after centrifugation, membranes should be visible as a tight clump in this pool.

17. Using a micropipettor with a trimmed pipet tip, collect the entire white membrane band from each centrifuge tube, taking care to obtain as little excess liquid as possible. Carefully transfer each collected band to a separate 1.5-ml polyallomer microcentrifuge tube. Add PBS as necessary to ensure that all of the microcentrifuge tubes are carrying the same weight.

    It is advisable to cut the pipet tip before collecting the membranes. This prevents loss of membrane material during collection.

18. Centrifuge the collected membrane layers 30 min at 200,000 × *g*, 4°C, in an ultracentrifuge equipped with a TLA 100.3 rotor (or equivalent) fitted with suitable adaptors.

    This additional centrifugation step removes residual Percoll from the collected membranes. Although Percoll is inert and does not penetrate organelles, it can hamper the smooth running of polyacrylamide gels during fraction analysis.

19. Using a micropipettor with a trimmed pipet tip, collect the membrane layer from each tube (leaving the clear Percoll layer behind) and transfer it to a clean 1.5-ml microcentrifuge tube. Add PBS as necessary to adjust the amount of liquid in each tube, using a sensitive balance to ensure that all tubes are carrying the same weight.

20. Add 1/20 volume of 10% Triton X-100 and 1 μl of 500× protease inhibitor cocktail (PIC) to each tube and vortex.

    Triton X-100 solubilizes membranes, thereby releasing hydrolytic enzymes. Among the hydrolytic enzymes released are proteases, which are inhibited by the subsequent addition of protease inhibitors.

    Some antibody-antigen interactions are affected by Triton X-100, and therefore, it may be necessary to use a different detergent, depending on the protein being analyzed.

    If membranes do not dissolve after the addition of Triton X-100, it will be necessary to sonicate the membrane samples.

Analyze fractions

21. Use the contents of the tubes from step 20 to perform the β-hexosaminidase assay (Support Protocol).

22. If the results of the β-hexosaminidase assay are satisfactory, prepare samples for further analysis by combining material from step 20 with an appropriate volume of 3× protein gel loading buffer and then boiling 3 min. Use these samples to perform SDS-PAGE (*UNIT 6.1*) followed by immunoblotting with the antibody of choice (*UNIT 6.2*).

β-HEXOSAMINIDASE ASSAY TO CHECK THE EFFICIENCY OF FRACTIONATION

SUPPORT PROTOCOL

This assay is used to determine how the activity of the lysosomal marker enzyme β-hexosaminidase activity is distributed among the different pools obtained at the end of fractionation in the Basic Protocol. Therefore, the results of the assay indicate, to a certain extent, the purity or homogeneity of the lysosomal fractions obtained using Percoll gradient fractionation. Ideally, pool I should show >70% of all β-hexosaminidase activity; such a finding would indicate that the lysosomal fraction is acceptably pure and

that the other fractions are mostly free of lysosomes. It is worth mentioning that certain lysosomal enzymes are partially activated in late endosomes (Hunziker and Geuze, 1996). The assay presented here has been used successfully in several studies for the assessment of fraction purity (Rohrer et al., 1995; Nair et al., 2003).

Materials

Percoll gradient fractions/pools (see Basic Protocol)
β-Hexosaminidase substrate mix (see recipe)
0.2 M Na_2CO_3
Spectrophotometer capable of reading at 400 nm

1. Transfer 5 μl of each fraction/pool to a separate 1.5-ml microcentrifuge tube. To each tube, add distilled water to a total volume of 80 μl. Prepare a blank sample by adding 80 μl distilled water to another 1.5-ml tube.
2. Add 200 μl β-hexosaminidase substrate mix to each tube (including the blank) and incubate for 15 to 30 min at 37°C.

   To maximize the likelihood of staying within the linear range of the assay, do not incubate samples longer than 30 min.

   Samples turn turbid in this step, because their pH is lowered by the addition of substrate mix.
3. Stop the β-hexosaminidase-catalyzed reaction by adding 1 ml of 0.2 M Na_2CO_3 to each tube (including the blank).

   Samples (aside from the blank) should begin turning yellow upon the addition of 0.2 M Na_2CO_3.
4. Set the spectrophotometer wavelength to 400 nm, zero the spectrophotometer using the blank sample, and then obtain an optical density (OD) reading for each experimental sample.

   If the OD for a given sample is not within the linear range (0.1 to ~1.5 OD units), prepare a new sample (step 1) using a smaller or larger aliquot of the fraction/pool used to prepare the original sample, and then repeat steps 2 to 4 using this new sample. The OD reading yielded by the new sample must be normalized before it can be directly compared with other OD readings. This is done by multiplying the new OD reading by 5/v, where v is the volume (in μl) of the fraction/pool aliquot used to prepare the new sample.
5. For each Percoll gradient used in the Basic Protocol, calculate the percentage of β-hexosaminidase activity attributable to each of the fractions/pools obtained from that gradient.

   The calculations in this step are made under the following assumptions: (1) each OD reading is proportional to the amount of β-hexosaminidase activity in the corresponding fraction/pool; and (2) the amount of activity in pool I, the amount of activity in pool II, and the amount of activity in pool III (or, equivalently, the activity values observed in fractions 1 to 9) add up to 100%.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

β-Hexosaminidase substrate mix

For one sample:
50 μl of 0.01 M *p*-nitrophenyl-*N*-acetyl-β-D-glucosaminide (Sigma)
15 μl of 10 M sodium citrate, pH 4

continued

3 μl of 10% (v/v) Triton X-100
132 μl H_2O
Prepare fresh before each use, and scale recipe up according to the number of samples to be tested

Homogenization buffer (10× stock)

2.5 M sucrose
10 mM EDTA
Store for several months at 4°C

Percoll solution, 17.5% (v/v)

To make enough material for four gradients, add 7 ml of 90% (v/v) Percoll solution (see recipe) to 29 ml of 1× homogenization buffer (see recipe for 10× stock). Store for several months at 4°C.

Percoll solution, 90% (v/v)

90 ml Percoll
10 ml of 10× homogenization buffer (see recipe)
Store for several months at 4°C

Protease inhibitor cocktail (500× stock)

To a 3:2 (v/v) mixture of ethanol and dimethyl sulfoxide, add:
5 mg/ml benzamidine
1 mg/ml pepstatin A
1 mg/ml leupeptin
1 mg/ml antipain
1 mg/ml chymostatin
Store for several months at −20°C

Protein gel sample buffer (3× stock)

1.135 g Tris base (0.1875 M final)
3 g SDS (6% w/v final)
15 g glycerol (30% w/v final)
5 mg bromphenol blue (0.003% w/v final)
2.31 g dithiothreitol (0.3 M final; where required)
Add H_2O to 40 ml and then adjust pH to 6.8 with 1 M HCl
Add H_2O to 50 ml
Store for several months at −20°C

COMMENTARY

Background Information

Lysosomes are degradative organelles that contain numerous acid hydrolases capable of catabolizing proteins, lipids, nucleic acids, and carbohydrates. Among the plethora of lysosomal functions are turnover of cellular constituents, breakdown of damaged macromolecules, autophagy, and antigen processing. Proper synthesis and delivery of the acid hydrolases are crucial to the physiological functioning of this organelle. Defects in lysosomal enzyme synthesis, functioning, or targeting can lead to one of the many known lysosomal storage disorders (Varki et al., 1982; Wilcox, 2004; Vellodi, 2005). The limiting membrane of the lysosome has several important functions, such as acidification and sequestration of lysosomal contents, maintenance of lysosomal stability and integrity, and export of the degradation products resulting from catabolic activity (Peters and von Figura, 1994). The proper transport of lysosomal membrane glycoproteins is thus equally crucial. The membrane is composed of several transient and resident glycoproteins (Williams and Fukuda, 1990; Peters and von Figura, 1994), including LAP (lysosomal acid phosphatase), LAMP-1 (lysosome-associated membrane protein 1), LAMP-2 (lysosome-associated membrane protein 2),

and LIMP-2 (lysosomal integral membrane protein 2).

The biogenesis of lysosomes results from the convergence of the endocytic and biosynthetic pathways. The soluble lysosomal hydrolases are transported initially by the biosynthetic pathway to the *trans*-Golgi network (TGN), by the cation-dependent mannose-6-phosphate receptor (CD-MPR) and the cation-independent mannose-6-phosphate receptor (CI-MPR) from the TGN to endosomes, and subsequently by the endocytic pathway to lysosomes. Lysosomes are thought to mature by a process of fusion and fission with the penultimate organelle in the biosynthetic pathway, referred to as the late endosome, thereby acquiring the lysosomal hydrolases (Storrie and Desjardins, 1996). However, lysosomes are devoid of mannose-6-phosphate receptors, which get retrieved by the *trans*-Golgi network because they possess signals for escaping lysosomal delivery.

The lysosomal membrane proteins are transported in much the same way, with their inclusion in the lysosome being attributable to signals that direct lysosomal delivery. The cytoplasmic tails of LAMP-1, LAMP-2, and LAP all contain tyrosine-based signals for endocytosis and delivery to the lysosome (Peters et al., 1990; Williams and Fukuda, 1990; Lehmann et al., 1992). Kinetic analysis of the delivery of lysosomal membrane proteins has revealed that the median time ($t_{1/2}$) for delivery of LAMP-1, LAMP-2, and LIMP-2 to lysosomes is ~30 to 45 min, while LIMP-1 is delivered to lysosomes with a $t_{1/2}$ of ~90 min (Barriocanal et al., 1986; D'Souza and August, 1986; Gottschalk et al., 1989). However, other lysosomal membrane proteins, such as the precursor of LAP, are delivered rather slowly to dense lysosomes. LAP undergoes, on average, 20 to 50 cycles of transport between endosomes and the plasma membrane before being delivered to lysosomes (Braun et al., 1989). This indicates that the sorting signal directing the transport of LAP from endosomes to lysosomes is not very efficient.

Density gradient centrifugation has long been the method of choice for the separation of intracellular organelles. The position of an organelle in a density gradient depends on the lipid-to-protein ratio in the organelle's membranes, the organelle's contents, and the density of the particles potentially attached to the organelle. Percoll is a modified form of colloidal silica that was introduced by Amersham Pharmacia Biotech in 1977 as a medium for density gradient centrifugation. It provides a useful density range for separation of organelles, is nontoxic, possesses physiological ionic strength and pH, does not penetrate into the organelles, is osmotically inactive, and is easily removed from purified organelles. Furthermore, self-forming Percoll gradients can be generated by a single centrifugation step.

Percoll density gradients have long been used as a reliable method for studying transport of proteins to lysosomes. The combination of Percoll gradient fractionation with pulse–chase methods greatly increases the potential of this technique for studying the kinetics of lysosomal protein transport. The transport of newly synthesized LAMP-1 from Golgi to lysosomes, for example, was studied by isolating lysosomes using isosmotic Percoll gradient fractionation followed by immunoprecipitation of LAMP-1 from lysosomal fractions (Green et al., 1987). Furthermore, lysosomal structures containing LAMP-1 and the lysosomal enzyme β-glucuronidase were analyzed by electron microscopic examination of frozen sections of lysosomal fractions purified using a Percoll gradient (Green et al., 1987). Percoll density gradient fractionation has also been used to show that the targeting of LAMP-1 to lysosomes is dependent on the spacing of LAMP-1's tyrosine-based sorting motif with respect to the membrane (Rohrer et al., 1996). Likewise, this technique has been used to demonstrate that the correct localization of the CD-MPR and its function in lysosomal enzyme sorting are dependent on the reversible palmitoylation of cysteine-34, which resides in the cytoplasmic tail of the CD-MPR (Schweizer et al., 1996). Furthermore, Percoll gradient fractionation has been used to show that correct endosomal sorting of the human mannose receptor depends on a diaromatic motif in the receptor's cytoplasmic tail, with this motif ensuring that the receptor escapes from lysosomal delivery (Schweizer et al., 2000).

Critical Parameters

The success of every fractionation experiment depends on the optimization of specific experimental steps (see Basic Protocol) for the cell line being used. Key among these are the culturing and homogenization of the cells. The cell lines used in the protocol described here were kept confluent for 2 days before homogenization. In the authors' experience, lysosomes appear to be denser in confluent cells, thus facilitating their separation.

Table 15.8.1 Troubleshooting Guide for Percoll Gradient Fractionation

Problem	Possible cause	Solution
Less than 70% of β-hexosaminidase activity found in pool I, or nonlysosomal markers found in pool I	Improper separation	Verify confluence of cells, adjust centrifugation conditions, and check density of Percoll solution using density marker beads (Amersham)
No membranes pelleted by gradient centrifugation, or too little reporter protein detected in immunoblot	Inadequate homogenization	Optimize homogenization process using guidelines listed in Critical Parameters; measure amount of protein in postnuclear supernatant before loading gradient

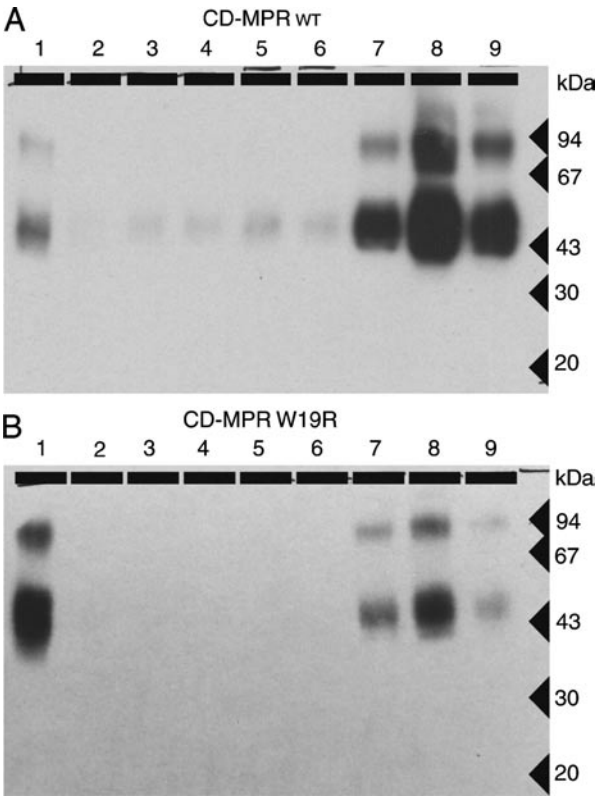

Figure 15.8.1 Immunoblots showing the distribution of wild-type (wt) and mutant cation-dependent mannose-6-phosphate receptor (CD-MPR) among the individual fractions obtained following Percoll density gradient centrifugation. (**A**) Most of the wild-type CD-MPR is recovered in fractions 7, 8, and 9, which contain low-density membranes such as the endoplasmic reticulum (ER), the Golgi membrane, and the plasma membrane. Very little wild-type CD-MPR is detected in fractions 1, 2, and 3, which contain the dense lysosomes and late endosomes. (**B**) A significant amount of CD-MPR mutant W19R is misrouted to lysosomes and subsequently detected in fraction 1. Anti-CD-MPR monoclonal antibody 22D4 was a kind gift from Don Messner.

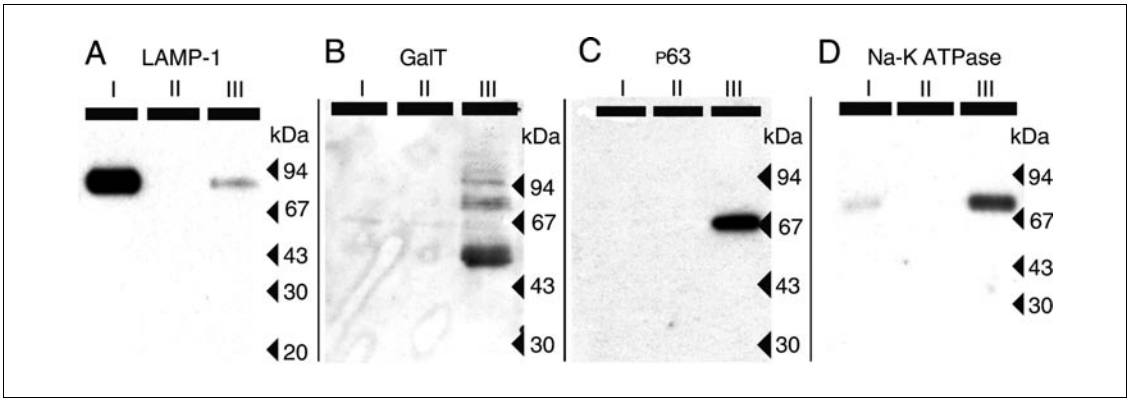

Figure 15.8.2 Immunoblots showing the distributions of four marker proteins from different cell compartments separated by Percoll density gradient centrifugation. (**A**) LAMP-1 is found primarily in pool I (fractions 1 to 3), which contains the dense lysosomes. (**B**) Galactosyltransferase (GalT), a Golgi marker, is found exclusively in pool III (fractions 7 to 9), which contains low-density membranes. (**C**) p63, a marker protein for the endoplasmic reticulum (ER), is also found exclusively in pool III. (**D**) The sodium-potassium (Na-K) ATPase, a marker of the plasma membrane, is found in pool III as well. Antibodies to LAMP-1 and sodium-potassium ATPase were generously provided by Hans-Peter Hauri, and the antibody to GalT was a kind gift from Eric G. Berger.

Excessive homogenization can result in disruption of organelles, while incomplete homogenization leads to poor recovery. It is important to treat all of the samples in each experiment identically during homogenization, in order to reduce experimental variability. Thus, the number of strokes applied with a ball-bearing homogenizer or syringe should be kept constant within an experiment in order to generate reproducible results.

Gradient formation is a function of the percentage of Percoll used. A self-forming Percoll gradient containing 17.5% (v/v) Percoll is used in the Basic Protocol. However, the optimal Percoll concentration depends on the cell line used and the organelle being isolated. The conditions for centrifugation also affect the linearity of gradient formation. For instance, rotor geometry has been shown to affect gradient shape (*UNIT 3.1*). Specifically, as the angle of the tube in the rotor approaches vertical, the path length for gradient formation becomes shorter and the gradient forms more rapidly. The speed and time of centrifugation also affect the shape of the gradient and thus have to be optimized for each experimental setup.

Harvesting the gradient is the final crucial step to be considered. Care should be taken not to introduce air bubbles into the gradient, as this leads to gradient mixing and hampers separation. The flow rate of fraction collection is another critical factor; if the gradient is fractionated too rapidly, mixing could occur.

Troubleshooting

See Table 15.8.1 for a guide to solving problems encountered in Percoll gradient fractionation.

Anticipated Results

The gradient centrifugation method described in this unit has been published previously (Rohrer et al., 1996; Schweizer et al., 1996; 1997; 2000). An example of an analysis of the amount of wild-type versus mutant cation-dependent mannose-6-phosphate receptor in lysosomes is shown in Figure 15.8.1. In their experiments, the authors observed that the lysosomal marker LAMP-1 is found primarily in the fraction containing lysosomes and late endosomes (Fig. 15.8.2). The presence of LAMP-1 on the membranes of late endosomes had been documented previously, confirming the homogeneity of the fraction obtained (Griffiths et al., 1988). Galactosyltransferase, a Golgi marker, was detected exclusively in pool III, where Golgi membranes are expected to band. The same was also true for p63, a marker protein for the rough endoplasmic reticulum (ER). The cation-dependent mannose-6-phosphate receptor, a protein found in late endosomes, early endosomes, the plasma membrane, and the Golgi, also was detected primarily in pool III, as was expected. The sodium-potassium ATPase, a plasma membrane marker, was also found predominantly in pool III (Fig. 15.8.2).

Table 15.8.2 Comparison of Various Experimental Conditions and Their Effects on the Distribution of β-Hexosaminidase Activity

Experimental parameter	% β-hexosaminidase activity in pool I
Cell confluence[a]	
Dense cells	71.1–76.3
Subconfluent cells	38.9–46.8
Homogenization instrument[b]	
Ball-bearing homogenizer	75.3–81.3
Syringe	47.7–68.9
Protease inhibitor treatment of cells[c]	
No	67.7–82.3
Yes	72.8–85.9

[a]Cells were either kept confluent for 2 to 3 days (*dense cells*) or harvested at subconfluent levels (*subconfluent cells).*
[b]Cells were homogenized using either a ball-bearing homogenizer or a 1-ml syringe equipped with a 25-G needle.
[c]Cells were cultured with or without being treated with 100 μM pepstatin A and 100 μM leupeptin for 24 hr.

Comparison of dense versus subconfluent cultures of HeLa cells showed that the denser cultures resulted in better Percoll gradient separation of lysosomes from the other fractions (Table 15.8.2). Furthermore, denser cultures made membrane collection following gradient centrifugation easier. A comparison of the two homogenization methods revealed that homogenization tends to be more variable when using a syringe as opposed to a ball-bearing homogenizer. In addition, the separation obtained after using a ball-bearing homogenizer was found to be superior as revealed by the β-hexosaminidase assay (Table 15.8.2). A comparison of two different cell lines, HeLa and murine D9 fibroblast cells, showed that while a 17% (v/v) Percoll gradient resulted in optimal separation of fractions from HeLa cells, a 17.5% (v/v) Percoll gradient provided better separation of fractions from D9 cells.

Time Considerations

Each individual experiment (assuming a total of four gradients per experiment) takes ~11 hr, according to the following breakdown: preparation of extract for loading onto the gradient, 2 hr; gradient formation, separation, and collection, 1.5 hr; Percoll removal, 3 hr; and fraction analysis, 4 to 5 hr. However, the exact time required needs to be determined empirically for each experimental setup and will depend on the number of gradients to be run and the number of centrifuges available, among other factors.

Studies of the Ubiquitin Proteasome System

The ubiquitin conjugating system, initially described in the late 1970's and early 1980's, was first associated with the targeting of proteins for degradation in proteasomes. While this is clearly the best-studied role for ubiquitylation, it is now appreciated that modification of proteins with ubiquitin has a large number of other functions unrelated to proteasomal targeting (Fig. 15.9.1). These include roles in endocytosis and targeting to lysosomes/vacuoles, in activation of kinase signaling pathways, and in regulating transcription and nuclear-cytoplasmic shuttling. It is no exaggeration that ubiquitylation is now implicated, in one way or another, in essentially all cellular processes in eukaryotes.

There are also a number of ubiquitin-like molecules that are linked to proteins through enzymatic cascades similar to ubiquitylation. Like ubiquitin, these are attached to other proteins by isopeptide linkages between glycines at their carboxyl termini and primary amines on target proteins. Well characterized ubiquitin-like molecules include SUMO1-3, NEDD8, ISG15, and APG12. Among these, NEDD8 is associated primarily with activation of cullin-containing ubiquitin protein ligases; therefore, aspects of the neddylation system are included in this unit (Basic Protocols 14, 15, 16, and Support Protocols 1 and 2).

In general, modification of proteins with ubiquitin (Ub) involves a multienzyme process that utilizes enzymes known as ubiquitin activating enzyme (E1), ubiquitin conjugating enzymes (E2), and ubiquitin protein ligases (E3). There is a single E1, eleven E2s in yeast and over 35 in mammals, and well over 500 different substrate-specific ubiquitin ligases.

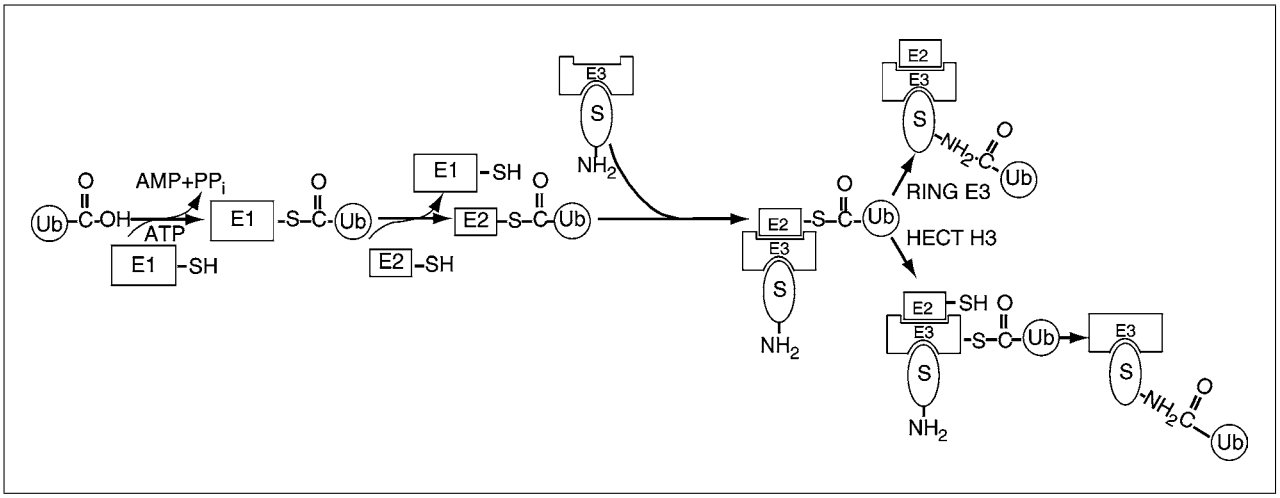

Figure 15.9.1 The ubiquitylation pathway. Free ubiquitin (Ub) is activated in an ATP-dependent manner with the formation of a thiol-ester linkage between E1 and the carboxyl terminus of ubiquitin. Ubiquitin is transferred to one of a number of different E2s. E2s associate with E3s, which might or might not have substrate already bound. For HECT domain E3s, ubiquitin is next transferred to the active-site cysteine of the HECT domain followed by transfer to substrate (S) (as shown) or to a substrate-bound multi-ubiquitin chain. For RING E3s, current evidence indicates that ubiquitin might be transferred directly from the E2 to the substrate. Reproduced with permission from *Nature Reviews Molecular Cell Biology* (A.M. Weissman. 2001. 2:169-178.) copyright 2001 Mcmillan Magazines Ltd (*http://www.nature.com/reviews*).

Current Protocols in Cell Biology (2006) 15.9.1-15.9.85

The details of ubiquitylation are discussed in depth elsewhere (Weissman, 2001; Fang and Weissman, 2004); however, the essentials include invariant steps beginning with the ATP-dependent activation of ubiquitin by E1 where a thiolester linkage between the active-site cysteine of E1 and the C-terminus of ubiquitin is formed. Next the transesterification of ubiquitin to the active-site cysteine of an E2 occurs, followed by the association of E2 with members of the various families of E3s.

While there are exceptions, E3s can be divided into two classes. The first of these is the HECT-domain E3s which have large, highly conserved 350-amino acid catalytic domains and, like E1 and E2, form thiolester intermediates with ubiquitin through conserved cysteine residues as part of the process leading to substrate modification. The second class of E3s is the RING-finger and related E3s. In addition to the RING-finger E3s, this family includes the PHD-finger E3s, which like the RING-finger E3s, coordinate two zinc ions. The U-box E3 conforms to a cross-brace structure in a manner similar to the RING and PHD fingers, but without apparent metal coordination. RING-finger E3s include proteins in which the RING finger and the substrate-recognition element exist on the same polypeptide as well as more complex E3s in which the RING finger is but one subunit of a multi-subunit assembly with a RING finger–containing core associating with various substrate-recognition elements. Most notable among these are the cullin-containing E3s, all of which include a small RING-finger protein.

An important aspect of ubiquitylation is the propensity to form multi-ubiquitin chains on proteins, involving linkages between one of the seven lysines on one ubiquitin and the C terminal of the next ubiquitin in the chain. Chains of four or more ubiquitins linked through K48 represent potent proteasomal targeting signals for modified proteins, while other linkages, or the presence of a single ubiquitin, are associated with other functions. The 26S proteasome is a highly developed and regulated molecular machine that includes a multicatalytic cylindrical 20S proteolytic core. This is capped at either end by a highly complex 19S cap that includes, among other things, multiple ATPases, subunits that recognize ubiquitin and proteins having ubiquitin-like domains, and several distinct deubiquitylating activities (Glickman and Ciechanover, 2002). Akin to the dynamic nature of phosphorylation and dephosphorylation, ubiquitylation is actively opposed by deubiquitylation (Wilkinson, 1997). There are a large number of different deubiquitylating enzymes (DUbs) of at least three distinct classes. These are ubiquitously present and highly active. A major challenge to researchers is detecting ubiquitylation with the ongoing and competing processes of deubiquitylation and proteasomal degradation. Accordingly, in the protocols below, ways to overcome these issues are repeatedly emphasized.

The number of techniques and reagents in common use that are related to ubiquitylation is rapidly growing; thus, the methods described below are by no means inclusive. However, they provide basic techniques to generate tools for determining if a particular protein is modified by ubiquitin or plays a role in the ubiquitylation process and to evaluate the nature of ubiquitin linkages. Further they provide important initial approaches for assessing the fate of ubiquitylated proteins. See Table 15.9.1 for a guide to the protocols included in this unit.

Table 15.9.1 Summary of Protocols Described in this Unit

Assay	Protocol	Authors
E1 and E2 activity		Jensen, Yang, Lorick, Iwai, and Weissman
E1-ubiquitin thiolester formation	Basic Protocol 1	
E2-ubiquitin thiolester formation	Basic Protocol 2	
Binding of ubiquitin-proteasome proteins		Lorick, Jensen, Yang, and Weissman
E2 binding to E3	Basic Protocol 3	
Ubiquitin substrate binding to E3	Alternate Protocol 1	
Ubiquitylation (E3) assays		Lorick, Jensen, Yang, and Weissman
E3 auto-ubiquitylation	Basic Protocol 4	
Auto-ubiquitylation vs. pseudo-substrate ubiquitylation	Basic Protocol 5	
Ubiquitylation of E3 enzymes in in vitro translation	Basic Protocol 6	
Determination of ubiquitin chain variant phenotype	Alternate Protocol 2	
Chelation of zinc from RING- and PHD-finger E3s	Basic Protocol 7	
Inhibition of HECT-domain E3s	Alternate Protocol 3	
Substrate ubiquitylation in vitro		Lorick, Yang, Jensen, Iwai, and Weissman
Substrate ubiquitylation in solution	Basic Protocol 8	
Substrate ubiquitylation after E3 binding	Alternate Protocol 4	
Substrate ubiquitylation by multiple subunit E3s	Basic Protocol 9	
Detection of E3 activity in immunoprecipitates	Basic Protocol 10	
Ubiquitin modification of substrate after GST pull-down	Alternate Protocol 5	
Detection of ubiquitylation in vivo		Yang, Lorick, Jensen, and Weissman
Lysis and immunoprecipitation	Basic Protocol 11	
Detection with tagged ubiquitin	Alternate Protocol 6	
Inhibition of ubiquitylation and degradation		Yang, Lorick, Jensen, and Weissman
Use of dominant negative ubiquitin protein	Basic Protocol 12	
Use of small interfering RNAs	Alternate Protocol 7	
Localizing degration to the proteasome	Basic Protocol 13

Column purification of multimeric E3s	Support Protocol 6	

ASSAYS OF E1 AND E2 ACTIVITY

For large amounts of E1 and E2, consider producing them in house (see Table 15.9.1). Purchasing these reagents is a viable alternative when performing only a few assays. No matter the source, reagents should be tested before using them extensively for assays involving E3s and substrates. Assays for E1 and E2 activity are simple, and consist of detecting thiolester bonds between Ub and the active-site cysteine of the ubiquitin enzyme. The importance of validating reagents in this way cannot be overstated. In the authors' experience, different preparations of E1 can have vastly different activities, due either to amount of time in the freezer or to variations in reducing agent concentrations. In addition, because a particular E3 will show activity only in the presence of a subset of E2 enzymes, the researcher has to be aware of the relative activity of the E2 before concluding that a particular E2/E3 pair has no activity or that an E3 functions preferentially with a particular E2. The protocols provided make use of radiolabeled ubiquitin or cold ubiquitin with anti-ubiquitin antibody immunodetection.

Strategic Planning

Before beginning, be aware of the E1 that is being used. The authors have found E1-thiolesters that are more easily detectable with commercial rabbit E1 antibodies than mouse or wheat E1 generated in the laboratory. This may be a function of some combination of activity and concentration. Where E1 does not exhibit discernable thiolester formation on its own, an E1/E2 combination should be tested as in Basic Protocol 2.

For Basic Protocol 2, make sure that a suitable positive control is used. Wheat E1 works well with mammalian type I E2s, those with only a catalytic core domain. It should not be assumed that it functions well with all mammalian type II, III, and IV E2s, where there are N-terminal, C-terminal, or N-and C-terminal extensions beyond the core domain. On the other hand, mammalian E1s appear to work well with all E2s. The authors find that bacterially expressed UbcH5B is a good positive control that functions with E1s of all sources.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

Thiolester Formation Between Rabbit E1 and Ubiquitin

This protocol is used generally to test the activity of E1 before doing more complex assays. It can be the primary assay used in screens of compounds to be used as E1 inhibitors.

Materials

E1: rabbit E1 (Calbiochem, Boston Biochem, Affiniti), bacterially expressed wheat E1 (Basic Protocol 20), or mouse E1 (Basic Protocol 21)
100 mM HEPES, pH 7.5
10× thiolester buffer (see recipe)
[^{32}P]ubiquitin (Basic Protocol 17) *or* 10 μg/μl "cold" (unlabeled) ubiquitin (Sigma) for immunoblot detection
4× nonreducing SDS-PAGE sample buffer (see recipe)
4× reducing SDS-PAGE sample buffer (see recipe)
6% to 8% SDS-PAGE minigels (*UNIT 6.1*)
Anti-ubiquitin antibody (Basic Protocol 19; for immunoblot detection)
Boiling water bath
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*) *or* immunoblotting (Basic Protocol 18)

1. Dilute commercial E1 to 100 ng/μl in 100 mM HEPES, pH 7.5, or use undiluted recombinant mouse or wheat E1s prepared in house.
2. Set up two identical thiolester reactions in 1.5-ml tubes as follows:

   1.2 μl E1 prepared as in step 1
   1.2 μl 10× thiolester buffer
   1 μl [^{32}P]ubiquitin *or* 1 μl of 10 μg/μl "cold" ubiquitin if immunodetection is used
   H_2O to 12 μl.

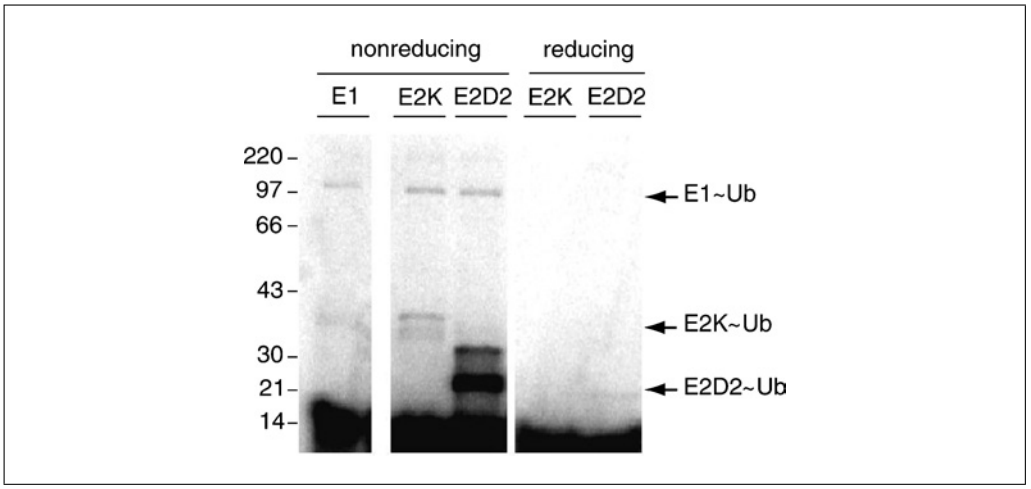

Figure 15.9.2 Thiolester formation between E1 and ubiquitin (E1∼Ub) or one of two E2s and ubiqutin (E2K∼Ub or E2D2∼Ub). 100 ng of mouse E1 alone and with 100 ng of E2K (E2-25K, HIP2) or ∼100 ng E2D2 (UbcH5B) were incubated 5 min at room temperature in the presence of ATP and ^{32}P-labeled ubiquitin (see Basic Protocol 17). The samples were then separated on 4% to 20% gradient SDS-PAGE gels in the absence (nonreducing) or presence (reducing) of 2-mercaptoethanol. Upon reduction, the higher-molecular-weight bands corresponding to ubiquitin-thiolester-modified proteins disappear (see Basic Protocols 1 and 2). Here, mouse E1 was expressed in a baculovirus system (Basic Protocol 21) and purified on nickel affinity resin. E2D2 was expressed in bacteria and used without further purification (see Basic Protocol 22). E2K was expressed as a GST-fusion in bacteria and purified on glutathione Sepharose column with thrombin cleavage (see Alternate Protocol 12; K.L. Lorick, unpub. observ.).

Incubate at room temperature for 5 min.

3. Add 4 μl of 4× nonreducing sample buffer to one tube and add 4 μl of 4× reducing sample buffer to the second tube.
4. Heat samples 5 min in a boiling water bath.
5. Resolve the entire sample on 6% to 8% SDS-PAGE minigels (*UNIT 6.1*).

   Make sure when running the gel that the reduced and nonreduced samples are separated by several lanes or run on separate gels. Gels should be run rapidly to preclude spontaneous reduction of thiolester linkages. See Figure 15.9.2 for results.

6a. *If radiolabeled ubiquitin is used:* Dry the gel and expose for autoradiography (*UNIT 6.3*).

6b. *If unlabeled ubiquitin is used:* Perform anti-ubiquitin immunoblotting (see Basic Protocol 18).

Thiolester Formation Between E2 and Ubiquitin

BASIC PROTOCOL 2

This protocol is used generally to test the activity of E2 before doing more complex assays. It can, however, be the primary assay used in drug screens for E2 inhibitors.

Materials

E1: rabbit E1 (Calbiochem, Boston Biochem, Affiniti,), bacterially expressed wheat E1 (Basic Protocol 20), or mouse E1 (Basic Protocol 21)
100 mM HEPES, pH 7.5
E2: crude (Basic Protocol 22 or 23) or purified (Alternate Protocol 12 or 13) *or* commercially available
10× thiolester buffer (see recipe)
[^{32}P]ubiquitin (Basic Protocol 17)
4× nonreducing SDS-PAGE sample buffer (see recipe)
4× reducing SDS-PAGE sample buffer (see recipe)
18% to 20% SDS-PAGE minigels (*UNIT 6.1*)
Anti-ubiquitin antibody (Basic Protocol 19; optional)
Boiling water bath
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*) *or* immunoblotting (Basic Protocol 18)

1. Dilute commercial E1 to 100 ng/μl in 100 mM HEPES, pH 7.5, or use undiluted recombinant mouse or wheat E1s prepared in house.
2. Dilute commercial E2 to 50 ng/ml in 100 mM HEPES, pH 7.5, or use undiluted crude or purified E2 prepared in house.
3. Set up two identical thiolester reactions for each E2 in 1.5-ml tubes as follows:

   1.2 μl E1 prepared as in step 1
   1.2 μl E2 (prepared as in step 2) or 100 mM HEPES, pH 7.5 as negative control
   1.2 μl 10× thiolester buffer
   1 μl [^{32}P]ubiquitin *or* 1 μl "cold" ubiquitin if immunodetection is used
   H_2O to 12 μl.

   Incubate at room temperature for 5 min.

   If using a crude bacterial preparation of E2, an "empty" bacterial lysate (Support Protocol 4) should be used as the negative control.

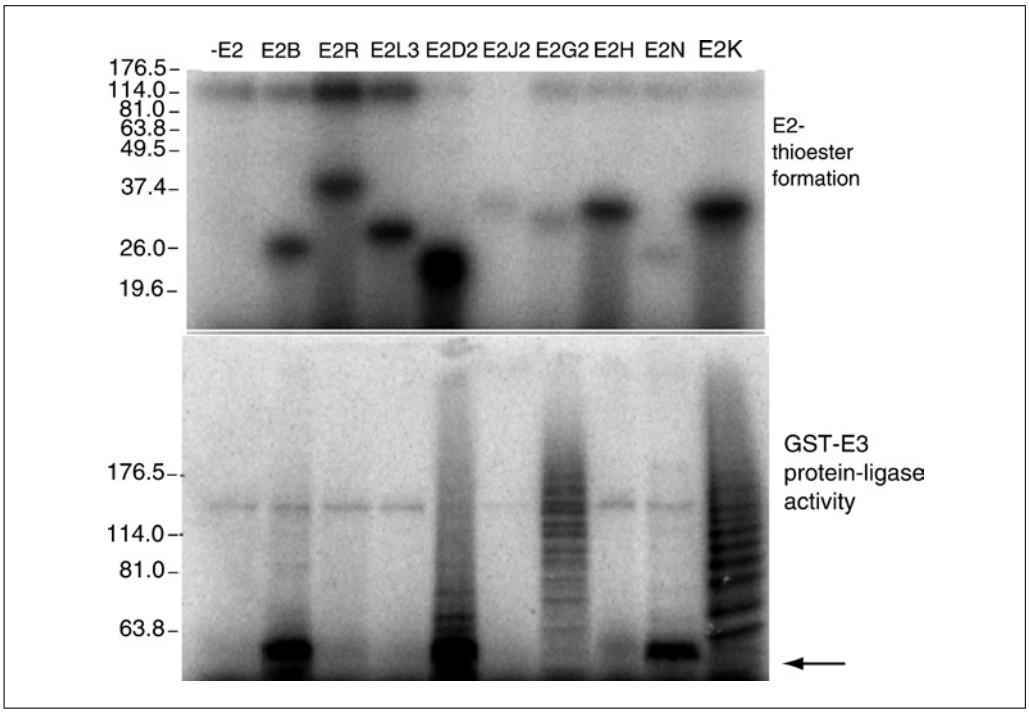

Figure 15.9.3 [^{32}P] Ubiquitin-thioester formation with various E2 enzymes and corresponding ubiquitin ligase activity (See Basic Protocol 4) with GST-SNURF protein. The arrow indicates mono-ubiquitylated protein (From Häkli et al., 2004).

4. Add 4 μl of 4× nonreducing sample buffer to one tube and add 4 μl 4× reducing sample buffer to the second.
5. Heat tubes 5 min in a boiling water bath.
6. Resolve the entire sample on high-percentage (18% to 20%) SDS-PAGE minigels (*UNIT 6.1*).

   Make sure when running the gel that the reduced and nonreduced samples are separated by several lanes or run on separate gels. Gels should be run rapidly to preclude spontaneous reduction of thiolester linkages.

7a. *If radiolabeled ubiquitin is used:* Dry the gel and expose for autoradiography (*UNIT 6.1*).

7b. *If unlabeled ubiquitin is used:* Perform anti-ubiquitin immunoblotting (see Basic Protocol 18).

   Active E2 enzymes will produce a band 8 kDa above their own molecular weight under nonreducing conditions when using radiolabeled ubiquitin or blotting for anti-ubiquitin (see Figure 15.9.3 for example results). Under reducing conditions, the labeled band should disappear and run with the free ubiquitin. If blotting for anti-E2, two bands appear under nonreducing conditions, one 8 kDa above the other; upon reduction the higher band should disappear.

BINDING OF UBIQUITIN-PROTEASOME PROTEINS

This section describes assays to determine binding of a soluble E2 (Basic Protocol 3) or ubiquitylation substrate (Alternate Protocol 1) to glutathione-Sepharose-immobilized GST-E3 or other E2 binding sites. E2s and E3s that work together to ubiquitylate a substrate by definition must interact. However, detection of stable E2-E3 interactions varies considerably when assessed using a standard coimmunoprecipitation or GST pull-down assay (*UNIT 17.5*). In the authors' experience, the easiest E2-E3 interaction to

detect is that between UbcH5B (Ube2d2) and AO7 (Lorick et al., 1999). Other physical interactions, such as that between BRCA1 and UbcH5C (Ube2d3), have only been detected by NMR (Brzovic et al., 2003). The binding assays described here are amenable to detecting E3 substrate interactions and are employed for later substrate ubiquitylation assays (Alternate Protocol 4).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

Binding of E2s to E3s

BASIC PROTOCOL 3

The experiment described here is presented with a number of alternatives for testing binding in a single protocol. The experiments can also be done in a reciprocal manner if the E3 is easily translated using in vitro systems or purified. The E2 can be bound to either glutathione-Sepharose (GS) beads or Ni-NTA agarose.

Materials

E3 or other putative E2 binding site of interest expressed as a GST fusion protein (see Basic Protocol 24 and Alternate Protocols 14 and 15)
Glutathione-Sepharose 4B beads (50% slurry; GE Healthcare)
Phosphate-buffered saline (PBS; see recipe), 4°C
Binding buffer (see recipe), 4°C
Purified native E2 (see Alternate Protocols 12 and 13; for detection by Coomassie blue staining or immunoblotting), E2 fusion with GST, His or other tag (Wu et al., 2003; for detection by Coomassie blue staining or immunoblotting), *or* ^{35}S-labeled E2 (see Basic Protocol 23; for detection by autoradiography)
4× nonreducing SDS-PAGE sample buffer (see recipe)
4× reducing SDS-PAGE sample buffer (see recipe)
18% to 20% SDS-PAGE minigels (*UNIT 6.1*)
10% (v/v) acetic acid/25% methanol
Anti-E2 or anti-tag antibody (Calbiochem, Boston Biochem, Affinity; for immunoblotting)
End-over-end rotator
Boiling water bath
Gel densitometer
Additional reagents and equipment for Coomassie blue staining (*UNIT 6.6*), autoradiography and phospher imaging (*UNIT 6.3*), *or* immunoblotting (*UNIT 6.2*)

Prepare glutathione-Sepharose-immobilized E3

1. On the day that the binding experiment is to be set up, prepare E3 beads by combining 25 µl packed beads and a volume of E3 crude extract containing 100 pmol GST-E3 in a 1.5-ml tube and incubating 1 to 2 hr at 4°C on an end-over-end rotator.

2. Microcentrifuge 30 sec at 14,000× *g*, 4°C, and aspirate the supernatant. Wash four times, each time by adding 1 ml cold PBS, microcentrifuging again as before, and aspirating the supernatant.

Perform binding assay

Include negative controls with glutathione-Sepharose beads only, and glutathione-Sepharose beads plus GST.

3a. *For detection by Coomassie blue staining:* Add 200 µl binding buffer and 1.2 µg (100 pmol) E2 to each tube of E3-GS beads. Incubate overnight at 4°C on an end-over-end rotator.

3b. *For detection by ^{35}S autoradiography:* Add 200 µl binding buffer and 100,000 cpm of in vitro translated [^{35}S]E2. Incubate overnight at 4°C on an end-over-end rotator.

3c. *For detection by immunoblotting:* Add 200 µl binding buffer and 150 to 200 ng E2. Incubate overnight at 4°C on an end-over-end rotator.

4. Wash four times, each time by microcentrifuging 30 sec at 14,000 × *g*, 4°C, removing the supernatant, adding 1 ml cold binding buffer (with gentle mixing after first two washes), centrifuging again as before, and removing the supernatant.

5. Add 30 µl of 4× reducing SDS-PAGE buffer to the final pellet of washed beads, heat 5 min in a boiling water bath, then microcentrifuge briefly at maximum speed to collect the sample (supernatant).

6. Resolve the supernatant on high-percentage (16% to 18%) minigels. Also include one sample that contains ~10% of the amount of the E2 input into each sample, without any additional protein.

Analyze gels

7a. *For staining:* Stain the gel with Coomassie Brilliant Blue R-250 as described in *UNIT 6.6*.

7b. *For autoradiography:* Wash the gel 10 min in 10% (v/v) acetic acid/25% methanol, dry the gel and detect bound protein by autoradiography (*UNIT 6.3*).

7c. *For immunoblotting:* Transfer to Immobilon P (Millipore) or nitrocellulose membrane and carry out immunoblotting (Basic Protocol 18) using anti-E2 or anti-tag antibody.

8. Compare the input band (10%) to the amount of bound material using phosphor imaging or densitometry to determine percentage of input material bound to the protein of interest.

The success of the experiment depends upon what results are expected. For some protein-protein interactions, 1% of the input material bound may be considered positive, 1% to 10% bound is a moderate interaction, and >10% bound is a strong interaction. The interaction of AO7 with Ube2D2 is strong enough that 20% to 40% of the E2 will bind to the E3. The interaction of E2g2 with the tail of gp78 is even stronger. However, in all cases, one has to make sure that the amount of binding observed is not the result of nonspecific interactions of the E2 to either beads alone or to the GST moiety of the E3 protein. Many if not most E2-E3 interactions, while real and significant, can only be detected via much more sensitive methods such as NMR or surface plasmon resonance (UNIT 17.6).

ALTERNATE PROTOCOL 1

Binding of Ubiquitin Substrates to E3s

This protocol is an adaptation of Basic Protocol 3 for determining binding to any substrate that can be expressed in a mammalian translation system. Because of the possibility that the substrate can be degraded by components of the ubiquitin-proteasome system, it may be necessary to add MG132 or other proteasome inhibitor during translation. Here, only the binding of ^{35}S-labeled substrate is described; however, any protein may be detected with appropriate adaptation.

Additional Materials *(also see Basic Protocol 3)*

In vitro–translated ^{35}S-labeled substrate protein (Basic Protocol 25)
50 mM MG132 (Calbiochem, Boston Biochem, or Biomol) in DMSO
10% (v/v) acetic acid/25% (v/v) methanol

1. Bind 20 pmol E3 to 25 μl beads as described in Basic Protocol 3, steps 1 to 2.
2. To each 1.5-ml tube of E3-GS beads, add:

   200 μl binding buffer
   Up to 2.0 μl of 50 mM MG132
   100,000 cpm of in vitro–translated ^{35}S substrate.

   Include negative controls with beads only, and beads plus GST.

3. Incubate overnight at 4°C on an end-over-end rotator.
4. Microcentrifuge 30 sec at 14,000× *g*, 4°C, and aspirate the supernatant. Wash four times, each time by adding 1 ml cold binding buffer, microcentrifuging again as before, and aspirating the supernatant.
5. To washed, pelleted beads, add 30 μl of 4× reducing buffer and heat 5 min in a boiling water bath.
6. Resolve on SDS-PAGE minigels (*UNIT 6.1*) appropriate to the substrate being studied.

   One sample on the gel must include 5% to 10% of the input radiolabeled material in order to determine the percentage of input material bound.

7. Wash the gel 10 min in 10% acetic acid/25% methanol, dry the gel, and detect bound protein by autoradiography (*UNIT 6.3*).

   A detectable amount of binding is usually ~1% of the total input, moderate binding is 1% to 10%, and strong binding will show 10% to 100% of the input. The final determination of the amount bound requires subtracting any background binding found in the GST alone or GS beads samples.

IN VITRO UBIQUITYLATION (E3) ASSAYS

The first protocols in this section test E3s for activity. These protocols lay the groundwork for additional protocols in which an active E3 is used to modify a substrate with ubiquitin. With few exceptions, E3s can ubiquitylate themselves in vitro in the presence of E1 and an appropriate E2. Therefore auto-ubiquitylation is a good indicator of activity. Basic Protocol 4 describes testing bacterially expressed GST fusions of E3 bound to glutathione-Sepharose. In Basic Protocol 5, the GST moiety is cleaved, allowing for an assessment of the specificity of auto-ubiquitylation sites. Basic Protocol 6 describes ubiquitylation in solution of E3s expressed in in vitro translation systems. Alternate Protocol 2 covers the use of ubiquitin variants to assess the nature of the ubiquitin chain formed. Basic Protocol 7 describes chemical inhibition of E3 activity of Zn-binding proteins such as PHD- or RING-finger proteins by the chelation of zinc. Alternate Protocol 3 describes the chemical inhibition of HECT-domain E3s using alkylating agents.

Strategic Planning

When working with proteins for which E3 activity is yet to be established, the use of several E2 enzymes is important to determine which is optimal for ubiquitylation. The authors recommend inclusion of UbcH5 (Ube2d) family members in such evaluations, because, generally, at least one member of this family is functional with almost all E3s, the exception being the TRAF family. A literature search for previous studies on

the E3 being used or those that bear amino acid similarity in the ubiquitin ligase and surrounding region can help make informed choices regarding E2s to test. Once activity has been established, the E3 can be used to ubiquitylate suspected substrate proteins (Basic Protocols 8, 9, and 10), or investigated in vivo (Basic Protocols 11, 12, and 13).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

BASIC PROTOCOL 4

E3 Auto-Ubiquitylation

This simple protocol has several advantages. First, all of the components are expressed in bacteria, which lack the ubiquitin-proteasome system (UPS). Thus, there is no interference from endogenous UPS components. Second, GST oligomerizes. This allows dimerization, which may facilitate detection of E3 activity. Third, immobilization on GS beads allows free ubiquitin to be removed before electrophoresis. The protocol utilizes radiolabeled ubiquitin (Basic Protocol 17) but can easily be adapted to using unlabeled ubiquitin and anti-ubiquitin immunoblotting (Basic Protocol 18).

Materials

Glutathione-Sepharose (GS) beads (GE Healthcare)
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Putative E3 expressed as a GST fusion in bacteria (GST-E3; Basic Protocol 25)
Empty bacterial lysate (Support Protocol 4)
Wheat E1 (Basic Protocol 20), mouse E1 (Basic Protocol 21), or rabbit E1 (Calbiochem)
E2 (Basic Protocol 22)
10× PCK (see recipe)
10× ubiquitylation buffer 1 (see recipe)
[^{32}P]ubiquitin (Basic Protocol 17)
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
4× reducing SDS-PAGE sample buffer (see recipe)
10% (v/v) acetic acid/25% methanol

30°C Thermomixer (Eppendorf), or other heated shaker
Boiling water bath

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

Bind GST protein to GS beads

1. For each E3 sample to be tested, add 50 µl of a 50% slurry of GS beads to two 1.5-ml tubes.
2. Microcentrifuge the beads 30 sec at 8000 × *g*, room temperature, and remove the supernatant. Wash beads three times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, microcentrifuging again as before, and removing the supernatant.
3. Add 20 pmol GST-E3 protein to the beads.

   The E3 does not have to be purified at this point, as the binding to glutathione-Sepharose and subsequent washing will serve as the purification step.

4. Adjust sample volumes to at least 200 µl with 50 mM Tris·Cl, pH 7.5.
5. Allow protein to bind at least 20 min at room temperature on an end-over-end rotator.

6. Rinse the bound material three times, each time with 1 ml of 50 mM Tris·Cl, pH 7.5, using the technique described in step 2.

7. Remove residual fluid using a syringe or gel loading pipet tip.

Set up the in vitro ubiquitylation

8. Make two reaction mixtures for each E3 to be tested as follows:

   2 μl (100 ng) wheat E1
   2 μl (100 ng) E2 *or* empty bacterial lysate as control
   3 μl 10× PCK
   3 μl 10× ubiquitylation buffer 1
   1 μl [^{32}P]Ub
   19 μl H_2O.

9. Add 30 μl of reaction mix either with or without E2 to each E3 sample. Incubate samples 1.5 hr at 30°C, with shaking.

Wash samples (optional)

10. Microcentrifuge beads 30 sec at 14,000 × *g*, 4°C, and remove supernatant (dispose of radioactive material properly).

    Removal of the supernatant allows for a cleaner gel. The supernatant may be run separately to determine the amount of ubiquitylated material that is in that fraction.

11. Wash beads five times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, centrifuging 30 sec at 14,000 × *g*, 4°C, and removing the supernatant.

12. Remove residual fluid. Add 30 μl 50 mM Tris·Cl, pH 7.5.

Carry out electrophoresis

13. Add 8 μl of 4× reducing SDS-PAGE sample buffer to each tube. Heat samples 5 min in a boiling water bath.

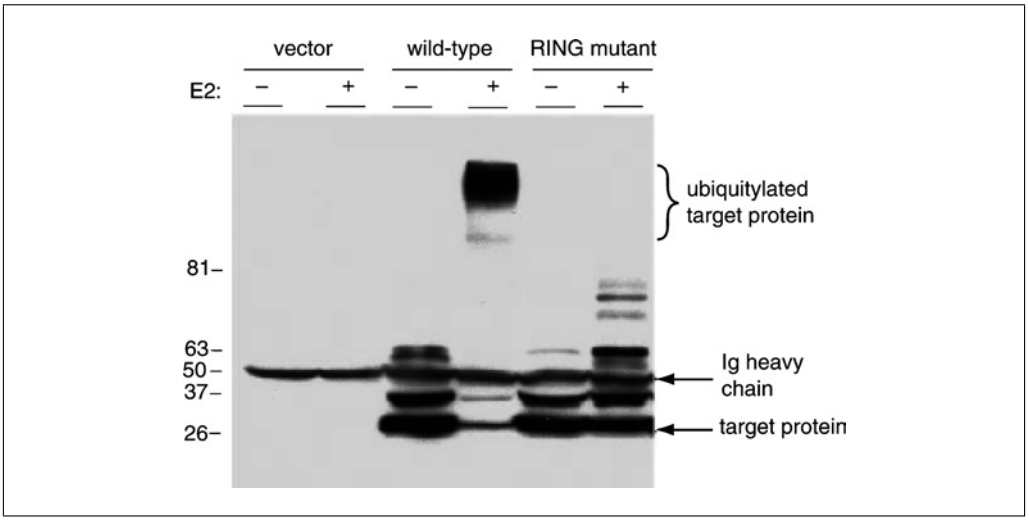

Figure 15.9.4 In vivo ubiquitylation of a typical RING-finger protein in U20S cells. Cells in 6-well plates were transfected with 2 μg Flag-tagged RING-finger protein, a mutant version of the RING-finger protein, or vector alone. In addition, 1 μg of Ube2D2 was transfected in the indicated lanes to enhance the amount of ubiquitylated species. After 24 hr, the cells were lysed in RIPA buffer. 150 μl of lysate was immunoprecipitated with mouse-anti-FLAG antibody and immunoprecipitates were resolved on 4% to 20% SDS-PAGE gels. The protein was transferred to PVDF membrane and immunoblotted with anti-FLAG antibody (Y. Yang, unpub. observ.).

14. Resolve samples on appropriate percentage SDS-PAGE to allow for resolution of species migrating above the unmodified form of the putative E3.

E3s vary in molecular weight from 12,000 to >300,000 kDa. The percentage gel will therefore be very specific to the individual experiment. One needs to resolve one to four bands separated by 8 kDa above the molecular weight of the particular E3 protein. For example, MDM2 migrates at 90 kDa, MDM2 plus Ub migrates at 98 kDa, MDM2 plus 2 Ub migrates at 106 kDa, and MDM2 plus 3 Ub migrates at 114 kDa; this would be separated on an 8% gel.

15. Wash the gel 10 min in 10% acetic acid/25% methanol, dry the gel and detect bound protein by autoradiography (*UNIT 6.3*).

A single ubiquitin modification will increase the weight of the protein of interest by 8 kDa. A protein can be modified with monoubiquitin or polyubiquitin chains or by multiple events on different lysines. Therefore, the autoradiogram may appear as a single band 8 kDa larger than the GST-E3, as a series of bands each 8 kDa above the previous one, or as a smear of radioactive signal that may run to the top of the gel (see Fig. 15.9.4).

BASIC PROTOCOL 5

Determination of Auto-Ubiquitylation versus Pseudo-Substrate Ubiquitylation

This protocol is designed to give a preliminary determination of how much auto-ubiquitylation of a GST-E3 fusion is on the E3 itself and how much is on GST. The procedure is the same Basic Protocol 4, with an added thrombin-cleavage step. The bound material (glutathione-*S*-transferase, GST) is separated from the cleaved material (E3 protein) and both fractions are electrophoresed. This protocol requires that the E3 be expressed in a GST vector that has a cleavage site. Thrombin is the most commonly used cleavage enzyme.

Materials

Putative E3 expressed as a GST fusion in bacteria (Basic Protocol 25)
Glutathione-Sepharose (GS) beads (GE Healthcare)
Empty bacterial lysate (Support Protocol 4)
Wheat E1 (Basic Protocol 20), mouse E1 (Basic Protocol 21), *or* rabbit E1 (Calbiochem)
E2 (Basic Protocol 22)
10× PCK (see recipe)
10× ubiquitylation buffer 1 (see recipe)
[^{32}P]ubiquitin (Basic Protocol 17)
50 mM Tris·Cl, pH 7.5
20× thrombin stock solution (see recipe)
Phosphate-buffered saline (PBS; see recipe)
Ubiquitylation buffer 2 for E3 assays (see recipe; optional)
Thermomixer, or other heated shaker
Additional reagents and equipment for in vitro ubiquitylation (Basic Protocol 5), SDS-PAGE (*UNIT 6.1*), and autoradiography (*UNIT 6.3*).

Carry out ubiquitylation and wash beads

1. Perform in vitro ubiquitylation (see Basic Protocol 4, steps 1 to 9).

2. Wash the ubiquitylated GST-E3 fusion protein on GS beads four to five times, each time by centrifuging 30 sec at 14,000 × *g*, 4°C, removing the supernatant (dispose of radioactive material properly), adding 1 ml of 50 mM Tris·Cl, pH 7.5, centrifuging again as before, and removing the supernatant. Remove residual fluid from final pellet.

Removal of the supernatant allows for a cleaner gel. The supernatant may be run separately to determine the amount of ubiquitylated material that is in that fraction.

Cleave the E3 away from the GST moiety

3. Prepare 1× thrombin by diluting 20× thrombin in PBS. Add 30 µl of 1× thrombin to bead pellet. Incubate at room temperature 30 min.
4. Microcentrifuge 30 sec at 14,000 × *g*, 4°C. Retain supernatant and transfer to a new tube. Repeat thrombin cleavage as described in the previous step and microcentrifuge again as before.
5. Combine supernatants and add 16 µl of 4× reducing SDS-PAGE sample buffer.
6. Wash beads three times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, microcentrifuging 30 sec at 14,000 × *g*, 4°C, and removing the supernatant. Carefully remove residual fluid from the final bead pellet.
7. Add 60 µl 50 mM Tris·Cl and 16 µl of 4× reducing sample buffer to each GS bead pellet.
8. Heat both the supernatants and the pellets (which now contain 1× reducing SDS-PAGE sample buffer) 5 min in a boiling water bath.

Perform electrophoresis and autoradiography

9. Resolve one-half of each sample by SDS-PAGE (*UNIT 6.1*) on gels of a percentage such that species migrating above the molecular weight of the protein of interest can be discerned (see Basic Protocol 4, step 14 annotation).

   Unmodified GST migrates at 28 kDa.

   No more than half of the sample will fit in the wells of the average gel.

10. Wash the gel 10 min in 10% acetic acid/25% methanol, dry the gel, and detect evaluate for ^{32}P signal by autoradiography (*UNIT 6.3*).

    If the E3 under study is modifying itself with ubiquitin, then the supernatant portion of the sample should contain a significant amount of the radioactive signal beginning at the molecular weight of the cleaved protein plus ubiquitin. That is, if the GST-E3 fusion is 68 kDa, following cleavage the GST will run at 28 kDa, and signal from the radiolabeled ubiquitin plus GST will start at 36 kDa and migrate higher from there. All of this would be seen in the bead-bound fraction. The E3 after cleavage would migrate at 40 kDa, and signal from radiolabeled ubiquitin plus E3 would start at 48 kDa and migrate higher from there. All of this would be found in the supernatant fraction. While not definitive, the experiment speaks to the ability of the E3 to modify heterologous substrates with ubiquitin.

Ubiquitylation of E3 Enzymes Expressed in In Vitro Translation Systems

BASIC PROTOCOL 6

The protocol for auto-ubiquitylation of in vitro–translated proteins is similar to Basic Protocol 4; however, eukaryotic in vitro translation systems contain proteasomes. Therefore, unless degradation is desired, inhibitors may need to be included in the reaction. In addition, ubiquitin aldehyde may be added to inhibit deubiquitylation. The protocol described here takes advantage of the fact that the E3 is selectively radiolabeled with ^{35}S-labeled methionine, and evidence of ubiquitylation is manifest as higher-molecular-weight forms of the putative E3 when appropriate controls are included.

Materials

50 mM MG132 (Calbiochem, Boston Biochem, or BioMol) in DMSO
30 µM ubiquitin aldehyde (Calbiochem, Boston Biochem, or BioMol) in 1 M HEPES, pH 8.0
50 ng/µl E1 (Basic Protocols 21 and 22)

50 ng/μl E2 (e.g., Ube2d2/UbcH5B; Basic Protocol 22)
10× PCK (see recipe)
10× ubiquitylation buffer 1 (see recipe) *or* 20× ubiquitylation buffer 2 for E3 assays (see recipe)
10 mg/ml ubiquitin (Sigma)
Suspected E3 protein, expressed with ^{35}S label in reticulocyte or wheat germ lysates (25,000 to 100,000 cpm; Basic Protocol 23)
4× reducing SDS sample buffer (see recipe)
10% (v/v) acetic acid/25% methanol
30°C Thermomixer (Eppendorf), or other heated shaker
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

1. Prepare in vitro ubiquitylation reaction as follows:

   0.5 μl 50 mM MG132
   0.5 μl 30 μM ubiquitin aldehyde
   2.0 μl E1
   2.0 μl E2
   3.0 μl 10× PCK
   3.0 μl 10× ubiquitylation buffer 1 *or* 20× ubiquitylation buffer 2 for E3 assays
   1.0 μl 10 mg/ml ubiquitin
   25,000 to 100,000 cpm ^{35}S-labeled E3
   H_2O to 30 μl.

   Incubate the mixture 90 min at 30°C with shaking.

   Control reactions lacking E1, E2, or ubiquitin add to the clarity and specificity of the experiment.

   See Critical Parameters and Troubleshooting for discussion of the choice between 10× ubiquitylation buffer 1 and 20× ubiquitylation buffer 2 for E3 assays.

2. Add 10 μl 4× reducing SDS-PAGE sample buffer and heat samples 5 min in a boiling water bath. Resolve entire sample on SDS-PAGE minigels (*UNIT 6.1*), using a gel percentage appropriate to the E3.

   The high concentration of protein in plant and rabbit in vitro translation systems can result in formation of aggregates upon heating which can both trap the protein of interest and cloud the final gel. There are a number of ways to prevent this. These include pelleting of material after translation, heating to 65° to 70°C rather than in a boiling water bath before electrophoresis, or heating to lower temperature for longer times, for example 37°C for 30 min.

3. Wash the gel 10 min in 10% acetic acid/25% methanol, dry the gel and detect bound protein by autoradiography (*UNIT 6.3*).

   Unlike experiments using labeled ubiquitin, when E3 is labeled there should be a band corresponding to the unmodified form of the protein, and one band for every ubiquitin molecule added.

   Fixing gels in 10% acetic acid 25% methanol for 10 min before drying also helps to remove free label that may migrate above the dye front; this will therefore provide cleaner results.

Determination of Ubiquitin Chain Variant Phenotype

Ubiquitin has seven lysine residues (K6, K11, K27, K29, K33, K48, and K63). Thus, there is the potential for substantial heterogeneity in ubiquitin chain formation. Additionally, some ubiquitin modifications may consist of a single molecule (mono-ubiquitylation). This protocol utilizes recombinant ubiquitins in which lysines have been mutated to evaluate chain formation with different E2-E3 combinations. While there are a number of mutants to assess, for initial experiments lysine-to-arginine mutations of either lysine 48 or lysine 63 (K48R and K63R) represent a good starting point. For controls, wild-type ubiquitin and a ubiquitin with no lysines (ubiquitin K0) should be included. This experiment may be done with labeled or unlabeled ubiquitin. However, using radiolabeled ubiquitin in these types of experiments can be messy due to the large number of radiolabeling reactions required.

The following is a protocol using unlabeled lysine mutants; detection of modified proteins is accomplished by anti-ubiquitin immunoblotting. The experiment will help determine if a particular type of ubiquitin chain can be formed using a particular E2-E3 combination. It does not address whether the chains are formed under physiological conditions. Such information may be determined using gas chromatography and mass spectrometry (GC-MS) following protease digestion of ubiquitin-modified proteins isolated form cells.

Additional Materials *(also see Basic Protocol 4)*

20× ubiquitylation buffer 2 for E3 assays (see recipe)
Mutant ubiquitins: lysine-less (K0), K48R, K63R, K48 only, K63 only (BioMol, Boston Biochem, or made in house)
Wild-type ubiquitin as reference
Additional reagents and equipment for anti-ubiquitin immunoblotting (Basic Protocol 18)

1. For each type of ubiquitin used, set up and incubate an auto-ubiquitylation reaction, then wash the beads and treat with reducing SDS-PAGE buffer (Basic Protocol 4, steps 8 to 13) with the following variations:

   a. Omit the 10× ubiquitylation buffer 1 and the 10× PCK from the reaction mixture in step 8 of Basic Protocol 4.

   b. Add 1.5 μl of 20× ubiquitylation buffer 2 to that reaction mix in place of the two abovementioned reagents.

   c. Add 1 μg of the ubiquitin to be tested to each reaction.

   d. Bring the final volume of each reaction to 30 μl with water.

2. Perform electrophoresis on all samples (Basic Protocol 4, steps 14 to 15). Perform anti-ubiquitin immunoblotting on the resulting gels (Basic Protocol 18).

3. Determine type of ubiquitin chain formed by comparing ubiquitin patterns of mutants compared to those obtained with the wild type ubiquitin.

   Wild-type ubiquitin is used as a reference for the complete ubiquitin pattern that may be obtained. K(0) ubiquitin should indicate how many lysines are modified (each ubiquitin band above the unmodified protein represents a lysine that may be modified. When multi-ubiquitinylation above the K(0) pattern is detected with K48R or K63R, this indicates that lysines at these positions are not required to form Ub chains. When multi-ubiquitinylation above the K(0) pattern is detected with K48-Ub or K63-Ub only, this indicates that the lysines are used for multi-Ub chain formation when using the E2 and E3 pair employed in the experiment.

BASIC PROTOCOL 7

Chelation of Zinc from RING- and PHD-Finger E3s

When dealing with RING- and PHD-finger proteins in vitro, E3 activity can be eliminated by chelation of zinc from the E3 before binding of substrate or the addition of the ubiquitylation mix. The requirement for zinc can be confirmed by adding it back to restore activity. The following protocol should be employed for any RING- or PHD-finger protein that will be used extensively. The protocol helps provide what can be essential biochemical data about such proteins. For example, the authors have observed E3s that, despite losing activity due to mutation of zinc coordination sites, cannot lose zinc through chelation because the binding is so strong. At the other extreme, some proteins with zinc removed cannot refold in the presence of added zinc.

Materials

Putative E3 expressed as a GST fusion in bacteria (Basic Protocol 24).
Glutathione-Sepharose (GS) beads (GE Healthcare)
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Zinc chelating agents (Sigma): 5 to 10 mM EDTA, 5 to 10 mM EGTA, 5 to 10 mM DTPA, 1 to 5 mM TPEN, *or* 1 to 5 mM *o*-phenanthroline in 50 mM Tris·Cl, pH 7.5
5 mM $ZnCl_2$
Wheat E1 (Basic Protocol 20), mouse E1 (Basic Protocol 21), *or* rabbit E1 (Calbiochem)
E2 (Basic Protocol 22)
Empty bacterial lysate (Support Protocol 4)
10× PCK (see recipe)
10× ubiquitylation buffer 1 (see recipe)
[^{32}P]ubiquitin (Basic Protocol 17)
4× reducing SDS-PAGE sample buffer (see recipe)
End-over-end rotator
Gel-loading pipet tips
30°C Thermomixer (Eppendorf), or other heated shaker
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

Bind E3 to GS beads

1. For each sample, prepare two 1.5-ml microcentrifuge tubes containing the following (combine ingredients in the indicated order):

   20 pmol bacterially produced GST-E3
   50 µl 50% GS bead slurry
   50 mM Tris·Cl, pH 7.5, to 200 µl.

   Incubate 20 min at room temperature on an end-over-end rotator.

2. Microcentrifuge 30 sec at 14,000 × *g*, 4°C, and remove supernatant. Wash three times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, microcentrifuging again as before, and removing the supernatant.

3. Incubate the bead-bound E3 three times, each time for 1 hr at room temperature on an end-over-end rotator with 5 to 10 mM EDTA, 5 to 10 mM EGTA, 5 to 10 mM DTPA, 1 to 5 mM TPEN, or 1 to 5 mM *o*-phenanthroline in 50 mM Tris·Cl, pH 7.5, microcentrifuging 30 sec at 14,000× *g*, 4°C, removing the supernatant and replacing with fresh solution between incubations. Also include one sample incubated in buffer alone as a control.

4. Microcentrifuge beads 30 sec at 14,000 × *g*, room temperature. Wash three times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, microcentrifuging again as before, and removing the supernatant.

Perform zinc add-back (optional)

5. Add 1 ml 5 mM $ZnCl_2$ and incubate for 1 hr at room temperature with rotation.
6. Wash twice 50 mM Tris·Cl, pH 7.5, using the technique described in step 4. Remove any residual fluid with a gel-loading pipet tip.

Perform E3 reaction

7. Add 30 µl ubiquitylating mix to each tube:

   2 µl (100 ng) wheat E1
   2 µl (100 ng) E2 *or* empty bacterial lysate as control
   3 µl 10× PCK
   3 µl 10× ubiquitylation buffer 1
   1 µl [^{32}P]Ub
   19 µl H_2O.

   Incubate 1.5 hr at 30°C.

8. Stop the reaction by adding 8 µl of 4× reducing SDS-PAGE sample buffer. Heat each sample 5 min in a boiling water bath.
9. Using a gel appropriate to the E3, analyze the entire sample on SDS-PAGE minigels (*UNIT 6.1*) followed by autoradiography (*UNIT 6.3*) or immunoblotting (Basic Protocol 18).

   If zinc binding is critical to E3 activity, incubation with TPEN should abrogate E3 activity as seen with buffer alone. The other chelating agents have weaker ability to chelate zinc; however, if they too are able to abrogate E3 activity, this indicates that the E3 requires zinc but does not bind it tightly. Cases where zinc add-back can restore E3 activity provide positive proof of the zinc requirement. Where zinc cannot reconstitute activity, two possibilities arise. The first is that the protein is irreversibly denatured when zinc is removed. The second is that the protein actually binds a divalent cation other than zinc. The second possibility is easier to rule out when TPEN alone destroys E3 activity, as this has a high specificity for zinc, while EDTA has high affinity for most divalent cations.

Inhibition of HECT Domain E3s by Alkylation of Active-Site Cysteines

ALTERNATE PROTOCOL 3

While Zn^{2+} chelation is required for RING-finger activity and is often reversible, inhibition of HECT domain proteins requires irreversible modification of the active-site cysteine. This protocol deals briefly with such inhibition.

Additional Materials *(see Basic Protocol 4)*

Alkylating agents: 10 mM iodoacetamide (IAA) *or* 5 mM N-ethylmaleamide (NEM) in Tris·Cl, pH 7.5 (see *APPENDIX 2A* for buffer)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*) *or* immunoblotting (*UNIT 6.2*)

Bind GST-E3 to beads and perform alkylation reaction

1. Bind GST-E3 to GS beads as described in Basic Protocol 4, steps 1 to 5.
2. Microcentrifuge 30 sec at 14,000 × *g*, room temperature. Wash beads three times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, microcentrifuging again as before, and removing the supernatant.

3. Incubate the bead-bound E3 1 hr in 1 ml of 50 mM Tris·Cl containing 5 mM NEM or 10 mM IAA.

4. Wash three times with 50 mM Tris·Cl, pH 7.5, using the technique described in step 2.

Perform ubiquitylation reaction

5. Add 30 μl ubiquitylating mix to each sample:

   2 μl (100 ng) wheat E1
   2 μl (100 ng) E2 *or* empty bacterial lysate as control
   3 μl 10× PCK
   3 μl 10× ubiquitylation buffer 1
   1 μl [^{32}P]Ub
   18 μl H_2O.

   Incubate 1.5 hr at 30°C

6. Using a gel appropriate to the E3, analyze the entire sample on SDS-PAGE minigels (*UNIT 6.1*) followed by autoradiography (*UNIT 6.3*) or immunoblotting (*UNIT 6.2*).

   If the E3 under study contains an active-site cysteine, increasing amounts of alkylating agents should completely abrogate the ability of the protein to facilitate the formation of ubiquitin modifications. In contrast to RING-finger proteins, the inhibition should be irreversible.

SUBSTRATE UBIQUITYLATION IN VITRO

Once activity has been established for an E3, potential substrates can be evaluated. In Basic Protocol 8, bacterially expressed E3 and radiolabeled in vitro–translated substrate are assessed. In Alternate Protocol 4, the E3 and substrate are bound and unbound material is removed before the ubiquitylation mixture is added.

Strategic Planning

Basic Protocol 8 is useful when interactions between substrate and E3 are not of sufficient affinity to withstand washing. Where interactions are more stable, Alternate Protocol 4 is preferable. As with other protocols in this unit, these experiments can be done either using radiolabeled material for autoradiography or appropriate antibodies for immunoblotting. Until one has a sense of the stability of the expressed substrate, it is best that the in vitro translation reaction and binding of substrate to E3 be carried out before freezing the translated product (preferentially the same day).

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

BASIC PROTOCOL 8

Substrate Ubiquitylation in Solution

This protocol is used when there is no information concerning the affinity of substrate for E3 or when this affinity is too low to withstand washing. This protocol is, in most cases, more indicative of the physiological conditions under which E3 and substrate normally interact.

Materials

50 μM MG132 (Calbiochem, Boston Biochem, or Biomol) in DMSO
30 μM ubiquitin aldehyde (Calbiochem, Boston Biochem, or BioMol) in 1 M HEPES, pH 8.0
50 ng/μl E1 (Basic Protocol 20 or 21)
50 ng/μl E2 (Basic Protocol 22 or 23)
10× PCK (see recipe)
10× ubiquitylation buffer 1 (see recipe)
10 mg/ml ubiquitin
Substrate, expressed with ^{35}S-label in reticulocyte or wheat germ lysates (25,000 to 100,000 cpm; see Basic Protocol 23)
E3, expressed as a GST fusion in bacteria (Basic Protocol 24)
4× reducing SDS-PAGE sample buffer (see recipe)
20× ubiquitylation buffer 2 for E3 assays (see recipe; optional)
30°C Thermomixer (Eppendorf), or other heated shaker
Boiling water bath
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

Set up in vitro ubiquitylation

1. For each E3 to be tested mix the following components in a microcentrifuge tube on ice:

   0.5 μl 50 mM MG132
   0.5 μl 30 μM ubiquitin aldehyde
   2 μl (100 ng) E1
   2 μl (100 ng) E2
   3 μl 10× PCK
   3 μl 10× ubiquitylation buffer 1
   1.0 μl 10 mg/ml ubiquitin
   25,000 to 100,000 cpm ^{35}S-labeled substrate
   H_2O to 30 μl.

2. Add 30 μl of substrate-containing reaction mix to each E3 sample and adjust volume to 30 μl.

   The E3 does not have to be purified at this point, provided that the volume of the E3 and substrate together is less than 18 μl. The reaction may also be carried out with E3 immobilized on glutathione-Sepharose beads, in which case the E3 contributes no volume to the 30-μl reaction.

   Be sure to include one sample of the input material that has been incubated with the ubiquitylation mixture in the absence of any E3 as well as input material that has had no ubiquitylation mixture added as controls.

3. Incubate samples 1.5 hr at 30°C with shaking.

Carry out electrophoresis

4. Terminate reaction by adding 8 μl of 4× reducing SDS-PAGE sample buffer. Heat 5 min in a boiling water bath.

5. Resolve samples on appropriate percentage SDS-PAGE gel so as to allow for resolution of high-molecular-weight forms of substrate (*UNIT 6.1*).

6. Perform autoradiography (*UNIT 6.3*).

If the reaction is successful, there will be a significant shift in the migration of ^{35}S-labeled substrate on the gel. Its migration should shift from that of the unreacted material to a minimum of 8 kDa higher. The pattern will vary from a single band shift to a ladder to a smear, depending upon whether the substrate is mono-ubiquitylated, poly-ubiquitylated, or ubiquitylated on various lysine residues.

ALTERNATE PROTOCOL 4

Substrate Ubiquitylation After E3 Binding

This protocol allows for cleaner results than Basic Protocol 8. However, good results depend upon a detectable binding of the substrate to the E3 (see Alternate Protocol 1). The cleaner results are obtained by removal of material not bound to the GST-E3 fusion protein. For this protocol the E3 should be immobilized before substrate binding.

Additional Materials *(also see Basic Protocol 8)*

Glutathione-Sepharose (GS) beads (GE Healthcare)
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Binding buffer (see recipe)
1× SDS-PAGE sample buffer: 4× sample buffer (see recipe) diluted to 1× with binding buffer (see recipe)
End-over-end rotator
30°C Thermomixer (Eppendorf), or other heated shaker

Bind GST protein to GS beads

1. For each sample, add 50 µl of a 50% GS bead slurry to two 1.5-ml tubes.
2. Microcentrifuge 30 sec at 8000 × *g*, room temperature. Wash beads three times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, centrifuging again as before, and removing the supernatant.
3. Add 20 pmol GST-E3 protein to the beads.

   The E3 does not have to be purified at this point, as the binding to GS and subsequent washing will serve as the purification step.

4. Adjust the volume of the sample to at least 200 µl with 50 mM Tris·Cl, pH 7.5.
5. Allow protein to bind at least 20 min on an end-over-end rotator at room temperature.
6. Wash the bead-bound material three times with 50 mM Tris·Cl, pH 7.5, using the technique described in step 2. Remove residual fluid using a syringe or gel loading pipet tip.

Bind substrate to washed E3 beads

7. Wash the beads once by adding 1 ml binding buffer, microcentrifuging 30 sec at 14,000 × *g*, room temperature, and removing the supernatant.
8. Add 200 µl binding buffer and 1 µl of 50 µM MG132 to each tube.
9. Add 25,000 to 100,000 cpm of substrate protein and allow binding at 4°C overnight on an end-over-end rotator.
10. Wash the beads three times with binding buffer using the technique described in step 7.
11. For each E3 to be tested mix the following components. Keep on ice:

    0.5 µl 50 mM MG132
    0.5 µl 30 µM ubiquitin aldehyde
    2 µl (100 ng) E1

2 μl (100 ng) E2
3 μl 10× PCK
3 μl 10× ubiquitylation buffer 1
1.0 μl ubiquitin
25,000 to 100,000 cpm ^{35}S-labeled substrate
H_2O to 30 μl.

12. Add 30 μl of substrate-containing reaction mix to each bead-bound E3 sample. Incubate 90 min at 30°C with shaking.

Analyze samples

13. Remove residual fluid and add 25 μl of 1× sample buffer to each tube. Heat samples 5 min in a boiling water bath.

14. Resolve samples on appropriate percentage SDS-PAGE to allow for resolution of high-molecular-weight forms of substrate (*UNIT 6.1*).

    Include a sample containing 10% of the input radiolabeled material.

15. Process gel for autoradiography (*UNIT 6.3*).

    If the reaction is successful, there will be a significant shift in the migration of ^{35}S-labeled substrate on the gel. Its migration should shift from that of the unreacted material to a minimum of 8 kDa higher. The pattern will vary from a single band shift, to a ladder to a smear, depending upon whether the substrate is mono-ubiquitylated, poly-ubiquitylated, or ubiquitylated on various lysine residues.

Substrate Ubiquitylation by Multisubunit E3s

BASIC PROTOCOL 9

The authors have established several in vitro ubiquitylation systems mediated by multisubunit E3s. α subunits of hypoxia-inducible factors (HIF-α) are known to be ubiquitylated by a cullin-containing E3 known as VBC-Cul2. As suggested by its designation, this complex consists of von Hippel–Lindau tumor suppressor protein (pVHL), elongin B, elongin C, Rbx1, and Cul2. Ubiquitylation of HIF-α is provoked by hydroxylation of specific prolines in the 22-kDa oxygen-dependent degradation (ODD) domain. Proline hydroxylation is mediated by egg laying defective nine (EGLN) hydroxylases in response to normal oxygen conditions. The following is a protocol for ubiquitylation of the (ODD) domain of HIF-2α (the substrate) by VBC-Cul2 (the E3). The NEDD8 modification system (Basic Protocols 14, 15, 16, and 26) is added because neddylation of cullins enhances the ubiquitin ligase activity of cullin-containing E3 complexes (Kawakami et al., 2001; Amir et al., 2002).

Materials

VBC-Cul2 E3 protein complex expressed and purified using baculoviral expression system (Basic Protocol 26)
Mouse E1 (Basic Protocol 21)
E2-UbcH5B (Basic Protocol 22)
GST-ubiquitin (Alternate Protocol 10)
Human APP-BP1/Uba3 (NEDD8 E1; Basic Protocol 14)
Ubc12 (E2 for NEDD8), expressed and purified by using bacterial expression system (Basic Protocol 15)
NEDD8, expressed and purified by using bacterial expression system (Basic Protocol 15)
MBP-HIF2α-ODD (Megumi et al., 2005) expressed and purified by using bacterial expression system

His_6-EGLN3 (proline hydroxylases of HIF-α; Megumi et al., 2005), expressed and purified by using bacterial expression system (note that this is necessary for proline hydroxylation of MBP-ODD)
10× ATP and ATP-regenerating system (see recipe)
10× ubiquitylation buffer 2 for multisubunit E3s and neddylation (see recipe)
40 mM sodium 2-oxoglutarate (α-ketoglutarate, sodium salt; Sigma)
40 mM ascorbic acid (Sigma)
Anti-MBP antibody (Santa Cruz Biotechnology)

Boiling water bath
Thermomixer, or other heated shaker

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

Set up in vitro ubiquitylation

1. Mix reagents as follows (20 μl per reaction):

   800 ng VBC-Cul2
   100 ng E1
   200 ng E2 (UbcH5c)
   5 μg GST-ubiquitin
   50 ng APP-BP1/Uba3
   160 ng Ubc12
   1 μg NEDD8
   200 ng MBP-ODD
   1 μg EGLN3
   2 μl ATP and ATP-regenerating system
   2 μl 10× ubiquitylation buffer 2 for E3s and neddylation
   1 μl 40 mM sodium 2-oxoglutarate
   1 μl 40 mM ascorbic acid

   As a control omit the E2.

   Note that EGLNs require both 2-oxoglutarate and ascorbic acid.

2. Incubate experimental and control samples 120 min at 37°C.

3. Terminate reactions by addition of 7 μl of 4× reducing SDS-PAGE sample buffer to each tube.

Carry out electrophoresis

4. Heat samples 5 min in a boiling water bath.

5. Run the entire sample on appropriate percentage SDS-PAGE gel so that the MBP-ODD (67 kDa) fusion band runs to the bottom of the gel.

6. Transfer and immunoblot with anti-MBP antibody at 1 μg/ml (*UNIT 6.2*).

   As with all ubiquitylation reactions, results depend upon the nature of the substrate's ubiquitin modification. However, a successful reaction will always have bands that migrate at least 8 kDa above the molecular weight of the unmodified substrate. There may be a single band, a ladder of bands separated by 8 kDa, or a smear of bands indicating multiple ubiquitylation events on different lysines. Under physiological conditions, ODD is degraded by the ubiquitin proteasome system, so there should be at least one band corresponding to a tetra-ubiquitin chain (32 kDa) + the ODD (67 kDa) = 99 kDa. There may be additional bands representing mono-, di-, and tri-ubiquitin modifications.

Detection of E3 Activity in Immunoprecipitated Protein

This protocol combines in vivo protein modification and complex formation with the in vitro ubiquitylation assay described in Basic Protocol 8. The obvious advantage is that ubiquitylation can be carried out using both E3 and substrate proteins that are translated, modified, and folded in the exact system of interest. The protocol can be used to find substrates for a particular E3 or to compare the activity of different E3s on a single substrate. However the reactions rely on the presence of strong binding between the E3 and substrate. Because this experiment is designed to look for E3 activity from cell lysates, those lysates must be generated under nondenaturing conditions. In addition, while the proteasome must be inhibited, there is no need to inhibit deubiquitylating enzymes until the ubiquitylation reaction is set up. The authors have employed a similar technique for the ubiquitin modification of p53 by Hdm2 (Fang et al., 2000). In Alternate Protocol 5, the substrate is pulled out of solution by an excess of bead-bound GST-E3 (Fang et al., 2000).

Materials

Adherent cells expressing the substrate protein and E3 of interest (e.g., U2OS cells for p53 and MDM2), growing in 100-mm dishes
50 mM MG132 (Calbiochem, Boston Biochem, or Biomol) in DMSO *or* other proteasome inhibitor (e.g., lactacystin; Calbiochem or Biomol)
Phosphate-buffered saline (PBS; see recipe)
Nondenaturing Triton X-100 lysis buffer (see recipe) containing 1× phosphatase inhibitors and 50 μM MG132 (or lactacystin)
Anti-E3 or anti-substrate antibody
Nondenaturing Triton X-100 wash buffer (see recipe)
Tris-buffered saline (TBS; *APPENDIX 2A*; optional)
30 μM ubiquitin aldehyde (Calbiochem, Boston Biochem, or BioMol) in 1 M HEPES, pH 8.0
E1: rabbit (Calbiochem, Boston Biochem, Affiniti,), bacterially expressed wheat E1 (Basic Protocol 20), *or* mouse E1 (Basic Protocol 21)
E2: crude (Basic Protocol 22 or 23) or purified (Alternate Protocol 12 or 13)
20× ubiquitin buffer 2 for E3 assays (see recipe)
10 mg/ml ubiquitin
4× reducing sample buffer
30°C Thermomixer (Eppendorf), or other heated shaker
Boiling water bath
Additional reagents and equipment for cell culture (*UNIT 1.1*), immunoprecipitation (*UNIT 7.2*), SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Grow adherent cells expressing the substrate protein and E3 of interest to confluency in 100-mm dishes (*UNIT 1.1*).

   The cells used may be selected because they have high endogenous levels of the proteins of interest or cDNAs for these proteins may be transfected into cells where they are expressed well.

2. Expose the cells to proteasome inhibitor (e.g., 5 to 50 μM MG132 or 5 to 20 μM lactacystin) in order to build up high levels of the substrate.

   The amount of inhibitor will depend upon the half-life of the protein and the sensitivity of the cells to the inhibitor used. These must be determined empirically.

3. Aspirate supernatant. Wash cells by adding 5 ml PBS, then aspirating the PBS. Lyse cells on the plate by adding 250 μl of nondenaturing Triton X-100 lysis buffer containing 1× phosphatase inhibitors and 50 μM MG132 or lactacystin.

4. Immunoprecipitate the protein of interest (*UNIT 7.2*) with 1 μg per sample of anti-E3 or anti-substrate antibody.

   The antibody used must be carefully chosen so that it does not interfere with the protein-protein interaction, the active site of the E3, or the target lysine of the substrate. Often, using a FLAG, HA, or similar epitope tag on the E3 will eliminate this problem by allowing the corresponding anti-tag antibody to be used.

5. Wash the protein precipitate three times, each time by adding 1 ml nondenaturing Triton X-100 wash buffer, centrifuging 30 sec at 3000 × *g*, 4°C, and aspirating the supernatant. Perform a final wash in PBS or TBS using the same technique, to remove wash buffer components. Remove any residual fluid with a gel-loading pipet.

6. Set up a 30-μl ubiquitylation reaction mixture for each immunoprecipitate by combining the following:

   0.5 μl 30 μM ubiquitin aldehyde
   0.5 μl 50 mM MG132 or lactacystin
   2.0 μl E1 (100 ng)
   2.0 μl E2 (100 ng)
   1.5 μl 20× ubiquitin buffer 2
   1.0 μl 10 mg/ml ubiquitin
   22.5 μl H_2O.

   Add the 30-μl reaction mixture to the immunoprecipitate and incubate 1.5 hr at 30°C.

7. Add 4× reducing sample buffer to the incubated reaction mixture for a final concentration of 1× and heat 5 min in a boiling water bath. Analyze the reaction mixture by SDS-PAGE (*UNIT 6.1*) and anti-substrate immunoblotting (*UNIT 6.2*).

   It should be possible to detect higher-molecular-weight bands above the predicted molecular weight of the substrate protein. In order to ensure that the higher-molecular-weight bands are indeed due to added ubiquitin, the immunoblot may be stripped of antibody and reblotted with anti-ubiquitin antibody (Basic Protocol 18).

ALTERNATE PROTOCOL 5

Detection of Ubiquitin Modification of Substrates After GST Pull-Down

This protocol combines Basic Protocols 8 and 10. The benefit of this protocol is that the substrate is generated in cells in what should be the natural state. Here the E3 is generated in bacteria as a GST fusion protein in order to guarantee high levels of the E3. This should be used when expression of the substrate in in vitro translation systems is difficult and when antibodies to the E3 are unavailable or interfere with E3-substrate interaction.

Additional Materials *(also see Basic Protocols 8 and 10)*

Glutathione-Sepharose (GS) beads (GE Healthcare)
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
End-over-end rotator

Bind GST protein to GS beads

1. For each sample, add 50 μl of a 50% slurry of GS beads to two 1.5-ml tubes.

2. Microcentrifuge 30 sec at 8000 × *g*, room temperature, and remove the supernatant. Wash three times, each time by adding 1 ml of 50 mM Tris·Cl, pH 7.5, microcentrifuging again as before, and removing the supernatant.

3. Add 20 pmol (in a volume of up to 1 ml) of GST-E3 protein to the beads.
4. Adjust the volume of the sample to at least 200 μl with 50 mM Tris·Cl, pH 7.5.
5. Allow protein to bind at least 20 min at room temperature on an end-over-end rotator.
6. Wash the bead-bound material three times as in step 2. Remove any residual fluid using a syringe or gel loading pipet tip.

Pull down substrate from cell lysate

7. Grow cells expressing the substrate protein and E3 of interest to confluency in 100-mm dishes (*UNIT 1.1*).

   The cells used may be selected because they have high endogenous levels of the proteins of interest or cDNAs for these proteins may be transfected into cells where they are expressed well. For example, U2OS cells express wild-type p53, a substrate for MDM2 E3 activity.

8. Expose the cells to proteasome inhibitor (e.g., 5 to 50 μM MG132) in order to build up high levels of the substrate.
9. Lyse cells in 250 μl of nondenaturing Triton X-100 lysis buffer containing 1× phosphatase inhibitors and 50 μM MG132 or lactacystin.
10. Combine the lysate with the GS-bound E3 and incubate at 4°C overnight on an end-over-end rotator.
11. Microcentrifuge 30 sec at 14,000 × *g*, 4°C. Wash beads once by adding 1 ml nondenaturing Triton X-100 wash buffer to the bead pellet, microcentrifuging again as before, and removing the supernatant. Perform a second wash in PBS or TBS using the same technique, to remove wash buffer components. Remove any residual fluid with a gel loading pipet.

Set up the E3 reaction

12. Set up a 30-μl ubiquitylation reaction mixture for each sample of the bead-bound lysate:

    0.5 μl 30 μM ubiquitin aldehyde
    0.5 μl 50 mM MG132 or lactacystin
    2.0 μl E1 (100 ng)
    2.0 μl E2 (100 ng)
    1.5 μl 20× ubiquitin buffer 2
    1.0 μl 10 mg/ml ubiquitin
    22.5 μl H_2O.

    Add the 30-μl reaction mixture to the pellet of bead-bound lysate and incubate 1.5 hr at 30°C.

13. Analyze the reaction mixture by SDS-PAGE (*UNIT 6.1*) and anti-substrate immunoblotting (*UNIT 6.2*).

    It should be possible to detect higher-molecular-weight bands above the predicted molecular weight of the substrate protein. In order to ensure that the higher-molecular-weight bands are indeed due to ubiquitin, the immunoblot may be stripped of antibody and reblotted with anti-ubiquitin antibody (Basic Protocol 18).

DETECTION OF UBIQUITYLATION IN VIVO

This section provides an introduction to detecting and evaluating the ubiquitylation system through analysis of proteins produced in mammalian cells. There are a number of permutations of each of the protocols described below. Variables to consider depend on the system and on the question being asked. These variables include the type of lysis buffer, the need for addition of proteasome or lysosome inhibitors to cells, and the need to inactivate DUbs upon cell lysis. Furthermore, inhibition of DUbs may involve using alkylating agents that will also inactivate E1s, E2s, and some E3s. Additionally, there are an increasing number of tools that can be used to enhance detection of ubiquitylated species. These include various anti-ubiquitin antibodies and tagged ubiquitins, which come with the added benefit of enhancing the prevalence of ubiquitylated species. One particularly important point common to almost all approaches is that cells, once harvested, and particularly upon lysis, should be kept cold.

BASIC PROTOCOL 11

Lysis and Immunoprecipitation of Ubiquitylated Protein

The fundamental issues in lysis and immunoprecipitation of potentially ubiquitylated proteins are similar to those for any other proteins. There are myriad of different lysis conditions used by investigators. Some methods include using detergents with a wide range of characteristics; other methods involve mechanical disruption of cell membranes. The protocol presented below uses detergent solubilization. When deciding on a detergent-containing lysis buffer, considerations include the cellular compartments to be examined, the importance of either disrupting or maintaining protein-protein interactions, the need to inhibit deubiquitylating enzymes or ubiquitylating enzymes, whether immunoprecipitation will be carried out, and, if so, the effect of the lysis buffer on the ability of antibody to recognize the target protein. For example if one is interested in looking at ubiquitylated proteins in a multi-protein complex, detergent (and salt) conditions should be chosen that maintain the interactions. Generally, one should start with a relatively mild nonionic detergent such as Triton X-100 or NP-40. On the other hand, if the complex to be examined is nuclear or otherwise not easily solubilized, such buffers may not be optimal. At the other extreme, one might consider direct lysis in SDS-PAGE sample buffer. This is the case if protein-protein interactions are not a concern and the plan is to directly lyse and analyze a protein for evidence of higher-molecular-weight forms by immunoblotting. SDS-PAGE sample buffer also aids in maximum inhibition of deubiquitylating enzyme activity during cell lysis. However, lysis into buffers containing high concentrations of SDS is not generally amenable to immunoprecipitation and will require dilution with nonionic detergents prior to immunoprecipitation. Also, because of release of DNA from chromatin, depending on the cell type and number it may be necessary to treat these samples with DNase.

Another major consideration is which inhibitors to add to the lysis buffer. A cocktail of protease inhibitors is strongly advised. Among these are alkylating agents that serve as cysteine protease inhibitors and also prevent spurious disulfide bond formation during cell lysis. Alkylating agents also inhibit most deubiquitylating enzymes. The authors generally include 10 mM iodoacetamide in the lysis buffer unless the experiment involves functional evaluation of components of the ubiquitin system. However, while E1, E2s, and HECT E3s are inactivated by iodoacetamide, this is not necessarily the case for all E3s. N-ethylmaleamide (NEM) is also commonly used for alkylation, and there may be cases where use of both is desirable. Additionally, it may be helpful to add ubiquitin aldehyde to the lysis buffer to further inhibit deubiquitylation; this reagent is more costly than the alkylating agents, so before committing to routine use it might be worth assessing whether it adds to the value of alkylating agents.

Materials

Protein A–Sepharose CL-4B beads (50% slurry; GE Healthcare)
Tris-buffered saline (TBS; *APPENDIX 2A*), 4°C
Specific antibody for the protein of interest and isotype-matched control antibody, e.g., irrelevant or preimmune serum, purified
Tris-buffered saline/Tween 20 (TBST; see recipe), 4°C
Cells growing in culture (*UNIT 1.1*)
Phosphate-buffered saline (PBS; see recipe), ice cold
Nondenaturing Triton X-100 lysis buffer (see recipe), ice cold
2× reducing SDS-PAGE sample buffer (see recipe for 4×)
Anti–specific antigen antibody
Anti-ubiquitin antibody

End-over-end rotator
Boiling water bath

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (Basic Protocol 18 and *UNIT 6.2*)

Coat beads with antibodies

1. Add 40 µl of 50% suspension of protein A–Sepharose CL-4B beads to a 1.5 ml microcentrifuge tube.
2. Wash once by adding 1 ml 4°C TBS, microcentrifuging 30 sec at 3000 × *g*, 4°C, and removing the supernatant. Resuspend beads in 200 µl TBS.
3. Add 0.5 to 1.0 µg of purified specific antibody or control antibody to the beads.
4. Incubate the tubes 2 hr at 4°C on an end-over-end rotator.
5. Microcentrifuge 5 sec at 3000 × *g*, 4°C, and aspirate supernatant.
6. Wash the beads three times, each time by adding 1 ml 4°C TBST, microcentrifuging 30 sec at 3000 × *g*, 4°C, and aspirating the supernatant.

Prepare cell lysate

7. Collect cells and wash once in 1 ml cold PBS using methods appropriate for the cell type.

   This protocol will work for adherent or suspension cells. Usually start with 10^6 cells, such as U2OS and 293T, for each immunoprecipitation.

8. Add 0.5 to 1.0 ml cold nondenaturing Triton X-100 lysis buffer to cells. Incubate at least 10 min at 4°C or on ice.

   If the cells are already pelleted in a microcentrifuge tube, resuspend them in lysis buffer by vortexing. If lysis was carried out on tissue culture plates, quantitatively transfer the lysates to microcentrifuge tubes.

9. Centrifuge 15 min at 14,000 × *g*, 4°C. Either transfer lysate to a fresh tube and keep on ice or immediately transfer to antibody-coated beads as in step 10.

Perform immunoprecipitation, SDS-PAGE, and immunoblotting

10. Transfer 500 µl cell lysate to each sample of antibody-coated beads. Incubate 1 hr to overnight at 4°C depending on the antibody.
11. Microcentrifuge 30 sec at 4000 × *g*, 4°C. Remove supernatant. Resuspend beads in 1 ml nondenaturing Triton X-100 wash buffer. Wash beads three times, each time by adding 1 ml nondenaturing Triton X-100 wash buffer, microcentrifuging again as before, and removing the supernatant.

12. Add 40 µl of 2× reducing SDS-PAGE sample buffer, mix thoroughly, and heat for 3 min in a boiling water bath.
13. Centrifuge the beads 2 min at 14,000 × *g*, room temperature
14. Divide the supernatant into two equal parts and resolve by SDS-PAGE (*UNIT 6.1*) on separate gels.

    The gel percentage will depend upon protein of interest; however, the band representing unmodified protein should run toward the bottom of the gel. In this way it is possible to resolve multiple ubiquitin modifications more easily.

15. Carry out immunoblotting (Basic Protocol 18) using anti–specific antigen with one membrane and anti-ubiquitin antibody with the other membrane.

    If the target protein is ubiquitylated, high-molecular-weight species are expected on the blot. These may appear as a single band 8 kDa above the unmodified protein, or as multiple discrete bands separated from the unmodified protein by 8 kilodaltons (the pattern looks like a ladder or a raccoon's tail). If multiple lysines are modified with ubiquitin chains, the higher-molecular-weight species appear as a smear running to the top of the gel.

ALTERNATE PROTOCOL 6

Detection of Protein Ubiquitylation Using Tagged Ubiquitin

This alternate protocol uses epitope-tagged ubiquitin expressed by transient transfection (see Alternate Protocol 10 for generation of the plasmid) to detect ubiquitylation of proteins of interest. The ubiquitylated proteins are isolated from the cell lysates using anti-tag antibodies and immunoblotted using a specific antibody against the protein of interest. The experiment can also be done in the reciprocal manner with immunoprecipitation of the substrate and blotting with anti-tag antibody to detect ubiquitylated species. The protocol is easily modified to look for differences in ubiquitin patterns when different E2 proteins are cotransfected (see Basic Protocol 2). It employs the calcium phosphate precipitation method of transfection (also see *UNIT 20.3*), which works well for most adherent cell types and is inexpensive. Lipid-based (*UNIT 20.6*) or other proprietary fusion-based transfection methods may work better for particular DNAs or cells. Electroporation (*UNIT 20.5*) or viral infection is generally the method of choice for most nonadherent cells.

Additional Materials *(also see Basic Protocol 11)*

Cells to be transfected
1 M $CaCl_2$
Mammalian expression plasmid for ubiquitin fused to FLAG, HA, His_6, myc-tag, GFP, or GST tag (Alternate Protocol 10, or obtained by request from other investigators)
Transfection efficiency control plasmid, e.g., GFP, RFP, β-galactosidase
2× HEPES-buffered saline (HeBS; see recipe)
Anti– tag epitope antibody *or* anti-substrate antibody (e.g., Sigma for anti-FLAG; Santa Cruz- Biotechnology for other antibodies)
6-well tissue culture plates
Boiling water bath
Additional reagents and equipment for cell culture (*UNIT 1.1*)

Plate cells for transfection

1. Plate cells the day before use at 40% to 50% confluency in a 6-well plate.

   Typically use 4 × 10^5 cells per well for large cells such as HeLa, 3T3, COS or CHO or 6 × 10^5 cells per well for smaller cells such as HEK293.

2. At a time point 4 hr before transfection, replace the medium on the cells with 1.0 ml fresh medium.

Transfect cells with tagged-ubiquitin expression plasmid

3. For each well of the 6-well plate to be transfected, make up a transfection mix in two parts in two separate microcentrifuge tubes:

   Tube 1:
   18 μl 1 M $CaCl_2$
   5 μg total DNA consisting of 4.5 to 4.9 μg ubiquitin expression plasmid and 0.1 to 0.5 μg transfection efficiency control (e.g., GFP)
   H_2O to 150 μl.
   Tube 2: 150 μl 2× HeBS.

4. Attach a hose with an inline filter to the compressed air line inside the sterile hood and attach a sterile plastic tissue culture pipet to the end. Set the valve to a very low pressure. Place the end of the pipet into tube 2 and gently bubble the solution.

   There should be a gentle bubbling of the solution. The bubbling can be achieved with a Pasteur pipet, but this becomes awkward in the next step.

5. Using a Pasteur pipet, add the solution in tube 1 dropwise to tube 2 while continuing the bubbling. Allow one drop to mix before adding the next.

   This should take ~2 min. The mixture should become cloudy.

6. Remove the bubbler, incubate the mixture 30 min at room temperature, then add the DNA/$CaPO_4$ solution dropwise to the cells (without removing the medium).

Prepare for ubiquitin detection

7. If using anti-tag or anti-substrate antibody for the initial protein precipitation, coat protein A–Sepharose beads with the appropriate antibody (Basic Protocol 11, steps 1 to 6).

8. Precipitate the protein using the antibody-coated beads as described in Basic Protocol 11, steps 10 to 11.

Perform immunoblotting

9. Add 40 μl of 2× reducing SDS-PAGE sample buffer, mix thoroughly, and heat for 3 min in a boiling water bath. Analyze the ubiquitylated proteins by SDS-PAGE (*UNIT 6.1*) and immunoblotting with appropriate antibody (*UNIT 6.2*).

   If the target protein is ubiquitylated, high-molecular-weight species are expected in the blot.

INHIBITION OF UBIQUITYLATION AND PROTEIN DEGRADATION IN VIVO

It is often useful to be able to inhibit the ubiquitylation/degradation process at several steps. A cell line with a temperature-sensitive mutation in the E1 gene (TS85) can inhibit the whole system. Mutation of a specific E2, where several E2s may activate an E3, can help to discern pathways. Mutating an E3 or suspected E3 can confirm localized E3 activity to a particular part of the molecule. Inhibiting proteasomes can preserve a substrate or demonstrate that a different degradation system is required.

Basic Protocol 12 describes mutation of E2s and E3s. Alternate Protocol 7 describes inhibition of ubiquitylation via the use of small interfering RNAs (siRNAs). Finally, Basic Protocol 13 addresses a method for determining if the protein degradation observed is indeed taking place in the proteasome.

BASIC PROTOCOL 12

Use of Dominant Negative Ubiquitin Proteins in Cells

For E2s and HECT-domain E3s, abrogation of ubiquitylating activity is achieved by mutation of single active-site cysteine residues. For RING-finger and PHD-finger proteins, mutation of one or two of eight zinc-binding residues eliminates nearly all activity. When overexpressed in cells, these mutants may act as dominant negative proteins against endogenous wild-type proteins. The mutation of E3s may result in both reduced auto-ubiquitylation and reduction of substrate ubiquitylation and degradation.

Materials

Expression plasmids for mutant and wild-type E2 or E3
Cultured cells to be transfected (e.g., U2OS or 293T)
Nondenaturing Triton X-100 lysis buffer (see recipe), ice cold
Specific antibody to the protein of interest and matched control antibody, e.g., irrelevant antibody or serum from unimmunized rabbits
Antibodies to mutated/wild-type protein *or* substrate *or* ubiquitin
Additional reagents and equipment for transfection (Alternate Protocol 6), SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and immunoprecipitation (Basic Protocol 11)

Transfect and harvest cells

1. Use the transfection protocol in Alternate Protocol 6 with the appropriate plasmids to express the mutant and wild-type E2 or E3 proteins.
2. Lyse 10^6 transfected cells per immunoprecipitation reaction with ice-cold nondenaturing Triton X-100 lysis buffer by incubating 10 min at 4°C.
3. Perform SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*) or immunoprecipitate with appropriate antibody attached to protein A–Sepharose beads and perform immunoblotting, as described in Basic Protocol 11.
4. Analyze total E2, E3, or substrate levels as appropriate by immunoblotting (Basic Protocol 18) with antibodies specific to the protein of interest.

   Pay attention to higher-molecular-weight bands that correspond to ubiquitylated species. A single ubiquitin will add 8 kDa to the mass of the protein that it is modifying. Most proteins will be modified by more than one ubiquitin, resulting in the presence of an 8-kDa ladder or a smear of higher-molecular-weight bands beginning 8 kDa above the molecular weight of the protein of interest and extending sometimes to the top of the gel. Expect less ubiquitin modification of substrate and E3 as well as higher absolute levels of these proteins due to lack of degradation. Be aware that inhibition may not be detected if the protein of interest may be ubiquitin modified by any of several E2-E3 combinations.

ALTERNATE PROTOCOL 7

Use of Small Interfering RNAs (siRNAs) to Reduce Expression of Ubiquitin-Proteasome System Proteins in Cells

The use of small interfering RNAs (siRNA) against E2 or E3 proteins complements the use of active-site mutant forms of these same proteins. While active-site mutants may prevent the degradation of a substrate, they can still influence the overall degradation process by binding to substrates, proteasomes, or other components of the ubiquitin proteasome system. siRNAs, on the other hand, when effective, can remove all influence of a particular E2 or E3. This allows researchers to determine if other E2s or E3s may compensate for, or overcome, the effects of the ablated protein. Two standard approaches have been employed for knocking down protein expression through siRNA. The original approach is to generate complementary oligonucleotides specific to a 19-bp segment of the gene of interest. The oligos are annealed to one another or cotranscribed in the same

tube, forming a double-stranded RNA. The RNA is then transfected into cells using lipid-based reagents, such as Invitrogen's Oligofectamine. The second approach is to place an oligonucleotide with a hairpin loop and self-complementary region into a plasmid vector. This is more correctly referred to as shRNA for short hairpin RNA. The plasmid is transfected into cells and expressed. The RNA transcribed forms a self-complementary hairpin loop structure. The hairpin is processed in the cell to give a double-stranded RNA similar to that introduced in the original method. While the oligonucleotide method (siRNA) is often more effective and has the advantage of rapid knockdown of RNA, the plasmid method (shRNA) is less expensive and more versatile, as it can be stably introduced or placed under an inducible promoter. The investigator should study the benefits of each for a particular system to see which is best. Kits for the design and production of siRNA oligos are available from several companies including Ambion, Qiagen, and Invitrogen. Plasmid-based shRNA kits and protocols are available from Ambion or Oligo Engine.

Once a plasmid or oligo pair has been chosen, transfect cells with shRNA plasmid as described in Alternate Protocol 6 or introduce siRNA oligo pairs by using Oligofectamine (Invitrogen) according to the manufacturer's instructions. Analyze cell lysates for levels of the ablated protein as well as ubiquitin modification of the protein of interest by immunoblotting as in Basic Protocol 18.

If a particular E2 or E3 is absolutely required for a ubiquitin modification to occur, use of siRNAs targeting these proteins should eliminate 80% or more of the modification seen when these enzymes have not been ablated. Where the siRNA is effective in reducing the levels of protein, if no loss of ubiquitin modification or degradation is observed, this should be an indication that the protein of interest is targeted for ubiquitin modification by multiple E3s.

Localizing Degradation to the Proteasome

BASIC PROTOCOL 13

Degradation of proteins can occur through several different systems. When a target protein that is degraded in response to a particular stimulus is identified, the following protocol will help to determine if the proteasome is responsible. The protocol utilizes selective inhibitors of various protein degradation pathways. Inhibiting the system responsible for degrading the protein of interest should increase the overall levels of that protein. The inhibition of other pathways should have no effect. The authors use ALLN (calpain inhibitor I), a peptide aldehyde inhibitor of both calpains and proteasomes, ALLM (calpain inhibitor II), a specific inhibitor of calpains only, MG132, a more potent version of ALLN, lactacystin, a specific inhibitor of proteasomes, and ammonium chloride, which inhibits lysosomal proteases. There are other available inhibitors for these processes, including epoxomicin, clasto-lactacystin, and MG101 for the proteasome and calpain inhibitors III and IV for calpains, so do not feel bound to those mentioned here.

Materials

Cultured cells to be transfected (e.g., U2OS or 293T)
Inhibitors (Calbiochem, Boston Biochem, Biomol):
  Calpain inhibitor I (CPI, also known as LlnL or ALLN), soluble in DMSO
  Calpain inhibitor II (CPII, also known as ALLM), soluble in DMSO
  MG132, soluble in DMSO
  Lactacystin, soluble in DMSO or water, but unstable in H_2O
  NH_4Cl in H_2O
Nondenaturing Triton X-100 lysis buffer (see recipe)
4× reducing SDS-PAGE sample buffer (see recipe)
Specific antibody against protein of interest
6-well tissue culture dishes

Additional reagents and equipment for cell culture (*UNIT 1.1*), SDS-PAGE (*UNIT 6.1*), and immunoblotting (*UNIT 6.2*)

1. Plate adherent cells in 6-well dishes at 50% to 80% confluency (typically 0.8–1.5 $\times$ 10^6 cells/well).
2. Expose different wells to appropriate concentration(s) of the various inhibitors for 4 to 24 hr:

   50 μM CPI
   5 to 50 μM CPII
   5 to 50 μM MG132
   5 to 20 μM lactacystin
   10 to 20 mM NH_4Cl.

   All of the drugs above are listed at their final concentrations in cell culture. A range of concentrations is specified for some because some cell lines are more sensitive to the effects of these inhibitors. The time of exposure and concentration will have to be determined empirically. The inhibitors are available from several manufacturers including Calbiochem, Boston Biochem, and Biomol.

   The length of exposure depends upon the half- life of the protein of interest. Be sure that at least one protein half-life has passed.

3. Harvest and lyse cells as follows:

   a. Remove medium and rinse cells with 1 ml PBS. Aspirate PBS.
   b. Add 250 μl nondenaturing Triton X-100 lysis buffer. Incubate 10 min on ice.
   c. Transfer lysate to 1.5-ml microcentrifuge tubes and microcentrifuge 10 min at 14,000 $\times$ *g*, 4°C. Transfer supernatant to a new microcentrifuge tube.
   d. Prepare samples for SDS-PAGE by adding 10 μl of 4× reducing SDS-PAGE sample buffer to 30 μl lysate.
   e. Freeze remaining lysate at –80°C for future studies.

4. Analyze lysates by SDS-PAGE (*UNIT 6.1*) and immunoblot for the target protein using the appropriate antibody (*UNIT 6.2*).

   Proteins that are degraded exclusively in the proteasome will be stabilized significantly in cells exposed to CPI, MG132, and lactacystin, but not NH_4Cl or CPII. If proteins are degraded in the lysosome, NH_4Cl will cause stabilization. If calpains are responsible for the degradation, CPI and CPII, but not lactacystin or MG132, will stabilize the proteins. Some proteins, such as EGFR, require both the lysosome and the proteasome for degradation, and stabilization may be significant with both types of inhibitor.

THE NEDD8 CONJUGATION SYSTEM

There exist ubiquitin-like protein modifiers that conjugate and regulate function of conjugated proteins. One example is the NEDD8 conjugation system.

NEDD8, like ubiquitin, is a 76–amino acid modifier. It modifies cullins in cullin-based ubiquitin ligase complexes and regulates their E3 activity. NEDD8 conjugation, termed neddylation, is catalyzed by several enzymes that are similar, though not identical to, those involved in ubiquitylation. NEDD8 is activated by a heterodimeric E1-like enzyme, the APP-BP1 and Uba3 complex, and is then transferred to an E2-like enzyme, Ubc12. Here, methods are described to express and purify APP-BP1/Uba3 complex by using a baculovirus expression system (Basic Protocol 14) and Ubc12 and NEDD8 by bacterial expression (Basic Protocol 15). The techniques employed for expressing and testing NEDD8 conjugating system proteins are similar to those used for the ubiquitin system

described in the previous sections. The similarities and differences between this system and the ubiquitin system may help later on when working with other ubiquitin-like modifiers, such as SUMO family members or ISG15. The main differences in these systems appear to be the use of a single subunit E1 for ubiquitin and ISG15 and heterodimeric E1 complexes for NEDD8 or SUMO (Tanaka et al., 1998). In addition, the ubiquitin system appears to require an E3. An absolute requirement for E3 has not been shown for the ubiquitin-like molecules, though the PIAS proteins appear to enhance SUMO1 transfer (Johnson and Gupta, 2001).

Purification of APP-BP1/Uba3 Complex (E1 for NEDD8) Expressed Using the Baculovirus Expression System

BASIC PROTOCOL 14

The baculovirus expression system is well suited to the production of the heterodimeric NEDD8 E1. This is because of the large size of the dimer, along with its requirement for multimeric assembly. In addition, the eukaryotic insect cells provide post-translational modifications that are not detected in bacteria and that may be necessary for proper folding or function of the enzyme.

Materials

*Sf*9 cells or *Sf*21 cells (Invitrogen)
Complete Grace's insect medium (see recipe)
cDNAs encoding APP-BP1 and Uba3
Baculovirus transfer vectors (see Murphy et al., 2004)
Hypotonic lysis buffer (see recipe)
1 M imidazole, pH 7.5 (adjusted with HCl)
Ni-NTA beads (50% slurry; Qiagen)
25-cm^2 culture flasks (Nunc) or 100-mm tissue culture dishes
27°C incubator without enhanced CO_2
175-cm^2 tissue culture flasks
15-ml centrifuge tubes
Refrigerated centrifuge
15-ml Dounce homogenizer with tight-fitting pestle
15-ml and 50-ml centrifuge tubes
Additional reagents and equipment for maintenance of insect cell cultures and generation of recombinant baculovirus (Murphy et al., 2004) and batch (Support Protocol 1) or column (Support Protocol 2) purification of APP-BP1 and Uba3

Culture insect cells

1. Plate 2×10^6 *Sf*9 as adherent cells in 25-cm^2 flasks or 3×10^6 cells in 100-mm dishes in complete Grace's insect medium. Grow in a 27°C incubator without enhanced CO_2.

   Murphy et al. (2004) contains general protocols for working with baculovirus. See Table 15.9.2 for recommendations for other culture configurations. Both Sf9 and Sf21 cells, derived from Spodoptera frugiperda (army moth) ovarian cells, are commonly used to isolate and propagate recombinant AcMNPV (baculovirus) stocks and produce the recombinant protein of interest. Sf9 was isolated as a clone of Sf21. It was reported that Sf21 cells might express more protein than Sf9 cells with some constructs (Heitz et al., 1997; Wang et al., 1997). The cells are grown as adherent cells in culture flasks or dishes.

2. When cells have just reached confluence, split 1:3, dislodging the cells either by streaming medium over the monolayer or by hitting the flask against the palm of the hand. Continue incubation at 27°C.

Table 15.9.2 Plating Recommendations for *Sf*9 Cells

Dish/flask size	Volume medium	Plating density
60-mm	3	2×10^6
100-mm	10	4×10^6
25-cm^2	5	3×10^6
75-cm^2	12	9×10^6
175-cm^2	24	21×10^6

Construct recombinant baculovirus

3. Subclone cDNAs encoding APP-BP1 and Uba3 into baculovirus transfer vectors.

   The authors use His_6-tagged APP-BP1 and T7-tagged Uba3 viral vectors. Any kits and general protocols (e.g., Murphy et al., 2004) for making baculovirus constructs should work well for APP-BP1 and Uba3. However, baculovirus transfer vectors must be suitable to the kits chosen.

Infect the cells

4. Seed 21×10^6 log-phase *Sf*9 cells in 24 ml complete Grace's medium in a 175-cm^2 flask. Allow to adhere at room temperature for >1 hr, then remove medium from cells.

   The baculovirus expression system is suitable for production of heterodimeric proteins because simple coinfection of the two viruses results in the production of heterodimeric protein complexes.

5. Infect His_6-APP-BP1 and T7-Uba3 recombinant baculoviruses at an MOI of 1 to 5 (i.e., 2.1–10.5 $\times$ 10^7 pfu in 5 ml medium from recently titered (see Basic Protocol 21 and Murphy et al., 2004) baculovirus stock. Include at least one flask with a "mock" infection (5 ml medium containing no recombinant baculovirus) as a negative control. Prepare flasks in triplicate.

   The amount of His_6-APP-BP1 baculovirus should be less than Uba3 baculovirus, to avoid contamination of APP-BP1 monomer.

6. Incubate the infected cells 1 hr at 27°C, rocking gently every 15 min to make sure cells are covered with virus supernatant.

7. Remove virus solution and add 24 ml complete Grace's insect medium.

8. Incubate 60 to 72 hr at 27°C (no CO_2).

Purify protein

9. From the triplicate 175-cm^2 flasks, harvest cells by pipetting medium up and down over the monolayer and transfer to 50-ml centrifuge tubes. Centrifuge 5 min at 300 $\times$ *g*, 4°C, and remove the supernatant.

10. Wash twice, each time by adding 10 ml ice-cold PBS, centrifuging 5 min at 300 $\times$ *g*, 4°C, and removing the supernatant.

11. Swell cells by adding 3 to 10 pellet volumes of hypotonic lysis buffer and leaving on ice for 10 min.

12. Lyse cells by 30 to 60 strokes of a 15-ml Dounce homogenizer with a tight-fitting pestle on ice. Transfer lysate to a 15-ml centrifuge tube.

13. Centrifuge 15 min at 20,000 × *g*, 4°C. Transfer supernatant to 15-ml tube.
14. Add 1 M imidazole for a final concentration of 0.2 mM imidazole.
15. Add 0.2 to 0.5 ml Ni-NTA beads as 0.4 to 1.0 ml of the 50% bead slurry supplied by the manufacturer.
16. Incubate at 4°C for 60 min on an end-over-end rotator.
17. Proceed with batch (Support Protocol 1) or column (Support Protocol 2) purification.

Batch Purification of APP-BP1 and Uba3

SUPPORT PROTOCOL 1

Following lysis and binding of the NEDD8 E1 components to Ni-NTA agarose, two common methods are employed to purify the protein. The first is a batch purification employing a centrifuge and the second is a column purification (Support Protocol 2). Normally, the batch purification is best suited to small amounts of protein. For larger quantities of NEDD8 E1, column purification may be easier and give better results.

Materials

NEDD8 E1 on Ni-NTA agarose beads (Basic Protocol 14)
Wash buffer 1 for His_6-tagged proteins (see recipe)
Wash buffer 2 for His_6-tagged proteins (see recipe)
Elution buffer for His_6-tagged proteins (see recipe)
Dialysis buffer (see recipe; include DTT)
Glycerol

Refrigerated centrifuge
1.5-ml screw-cap microcentrifuge tubes
End-over-end rotator
8000-MWCO dialysis membrane

Additional reagents and equipment for dialysis (*APPENDIX 3C*)

NOTE: Perform all steps at 4°C.

Wash the beads

1. Centrifuge the 15-ml tube containing the supernatant and Ni-NTA-agarose 5 min at 300 × *g*, 4°C. Remove supernatant.
2. Wash the Ni-NTA-agarose six times, each time by adding 12 ml wash buffer 1 for His_6-tagged proteins, centrifuging again as in step 1, and removing the supernatant.
3. *Optional:* Wash two times, each time with 12 ml wash buffer 2 for His_6-tagged proteins using the technique described in the previous step.
4. Transfer Ni-NTA-agarose to a 1.5-ml screw-cap microcentrifuge tube.

Elute the protein

5. Elute protein by adding 0.6 ml of elution buffer for His_6-tagged proteins and rotating 10 min at 4°C on an end-over-end rotator.
6. Microcentrifuge 2 min at 800 × *g*, 4°C. Transfer supernatant to a new 1.5-ml screw-cap tube.
7. Repeat steps 5 and 6 and combine the supernatants.

Dialyze and store the purified protein

8. Dialyze the eluate against 1 liter dialysis buffer at 4°C overnight using a 8000-MWCO dialysis membrane, changing the buffer twice at intervals at least 4 hr apart (*APPENDIX 3C*).
9. Remove the dialysate and divide into aliquots in 1.5-ml tubes. Add an equal volume of glycerol to each tube and mix thoroughly.
10. Rapidly freeze samples in liquid nitrogen, then store at −80°C.

SUPPORT PROTOCOL 2

Column Purification of APP-BP1 and Uba3

Loss of Ni-NTA agarose may occur during centrifugation because these beads do not pack down completely and may be aspirated along with the wash buffer. Using a column method, all of the beads are retained on a membrane or filter support, ensuring no loss of protein.

Materials

NEDD8 E1 on Ni-NTA agarose beads (Basic Protocol 14)
Wash buffer 1 for His_6-tagged proteins (see recipe)
Wash buffer 2 for His_6-tagged proteins (see recipe)
Elution buffer for His_6-tagged proteins (see recipe)
Dialysis buffer for ubiquitylating and neddylating enzymes (see recipe; include DTT)
Glycerol
2-ml Poly-Prep disposable chromatography column (Bio-Rad)
8000-MWCO dialysis membrane
Additional reagents and equipment for dialysis (*APPENDIX 3C*)

NOTE: Perform all steps at 4°C.

Elute complex from the beads

1. Transfer Ni-NTA beads to a 2-ml Poly-Prep column.
2. Wash the beads in the column with 10 bed volumes of wash buffer 1 for His_6-tagged proteins.
3. *Optional*: Wash beads with 2 to 3 bed volumes of wash buffer 2 for His_6-tagged proteins.
4. Elute protein with 1 bed volume of elution buffer for His_6-tagged proteins and collect the eluate.
5. Repeat elution step again and combine the eluates.

Dialyze and store the purified protein

6. Dialyze the eluate against 1 liter of dialysis buffer at 4°C overnight using an 8000-MWCO dialysis membrane, changing the buffer twice at intervals at least 4 hr apart.
7. Remove the dialysate and divide into aliquots in 1.5-ml tubes. Add an equal volume of glycerol to each tube and mix thoroughly.
8. Rapidly freeze samples in liquid nitrogen, then store at −80°C.

Production of Ubc12 and NEDD8 in Bacterial Expression Systems

The authors usually use N-terminally His_6-tagged constructs for Ubc12 and NEDD8. This is because purified Ubc12 and NEDD8 are solely used for in vitro assays. The small His_6 tag has little effect on the function of these molecules in such assays. N-terminally His_6-tagged human Ubc12 cDNA or NEDD8 cDNA lacking C-terminal extension (NEDD8-GG) is subcloned into the pT7-7 bacterial expression vector (Studier et. al., 1990; pT7 plasmids are derivatives of pET vectors), or pET vector, respectively. In many cases, E2 can be used without purification, but that requires changing the sonication buffer.

Materials

Ubc12 or NEDD8 plasmids (Kawakami et al., 2001)
E. coli strain BL21(DE3) (Invitrogen)
2×YT + G medium (see recipe) with 50 μg/ml ampicillin
1 M IPTG (dissolve 1 g IPTG in 4.2 ml H_2O; store at −20°C)
Sonication buffer (see recipe) *or* Ni-NTA purification buffer (see recipe)
Liquid N_2
1 M imidazole, pH 7.5 (adjusted with HCl)
Ni-NTA beads (Qiagen)
Wash buffer 1 for His_6-tagged proteins (see recipe)
Wash buffer 2 for His_6-tagged proteins (see recipe)
Elution buffer for His_6-tagged proteins (see recipe)
Dialysis buffer for ubiquitylating and neddylating enzymes (see recipe; include DTT)
Glycerol
37°C shaking incubator or water bath
Refrigerated centrifuge
Probe sonicator
15-ml centrifuge tubes
End-over-end rotator
Screw-cap 1.5-ml microcentrifuge tubes
8000-MWCO dialysis membrane
Additional reagents and equipment for transforming bacteria with plasmids (Seidman et al., 1997) and dialysis (*APPENDIX 3C*)

Prepare transformed cultures

1. Transform Ubc12 or NEDD8 plasmids into *E. coli* strain BL21(DE3) (Seidman et al., 1997).
2. Grow BL21(DE3) cells carrying appropriate plasmids in 2.5 ml of 2×YT + G medium containing 50 μg/ml of ampicillin at 37°C overnight with shaking.
3. Inoculate 2 ml of overnight culture into 1 liter of 2×YT + G with 50 μg/ml of ampicillin. Grow at 37°C with shaking for ~4 to 5 hr (until OD_{600} is 0.7 to 0.8).

Induce expression

4. Add 400 μl of 1 M IPTG to the 1-liter culture (for a final IPTG concentration of 0.4 mM).
5. Culture at 37°C with shaking for 2 to 5 hr.

6. Transfer cells to centrifuge bottles and harvest by centrifuging 10 min at 4000 × *g*, 4°C, and removing the supernatant.

7a. *For further purification on nickel:* Resuspend cells in 25 ml of 20 mM Tris·Cl (pH 7.5)/10 mM 2-ME and protease inhibitors.

In general, the authors recommend this additional purification step.

7b. *If no further purification on nickel is required:* Resuspend cells in 25 to 40 ml of sonication buffer.

Further purification is not necessary in pilot studies where the objective is to determine if a particular protein is neddlyated.

Lyse cells

8. Lyse cells on ice by sonication using a probe sonicator at setting 7, 60% duty cycle, for 90 sec.

9. Centrifuge lysate 20 min at 27,000 × *g*, 4°C. Transfer supernatant to new 15-ml tube and further purify (steps 10 to 21), or divide into 0.1- to 1-ml aliquots, freeze rapidly in liquid nitrogen, and store at −80°C.

Bind protein to Ni-NTA beads

10. Add 1 M imidazole solution to the supernatant to make final imidazole concentration of 2 mM.

11. Add 0.7 ml Ni-NTA beads. Incubate at 4°C for 60 min on an end-over-end rotator.

12. Centrifuge 15-ml tube containing the supernatant and Ni-NTA beads 5 min at 300 × *g*, 4°C. Remove supernatant.

13. Wash the Ni-NTA beads six times, each time by adding 12 ml wash buffer 1, centrifuging again as in the previous step, and removing the supernatant.

14. Wash the Ni-NTA beads twice, each time by adding 12 ml wash buffer 2, centrifuging again as before, and removing the supernatant.

Elute protein

15. Transfer the Ni-NTA beads to a screw-cap 1.5-ml tube

16. Elute protein by adding 1.0 ml of elution buffer and incubating 10 min at 4°C on an end-over-end rotator.

17. Centrifuge 2 min at 800 × *g*, 4°C. Transfer supernatant to a new tube.

18. Repeat steps 15 to 17 once and combine the supernatants.

Dialyze and store the purified protein

19. Dialyze the eluate against dialysis buffer with DTT at 4°C overnight using an 8000-MWCO dialysis membrane, changing the buffer twice at intervals at least 4 hr apart (*APPENDIX 3C*).

20. Remove the dialysate and divide into aliquots into 1.5-ml tubes. Add an equal volume of glycerol to each tube and mix thoroughly.

21. Freeze aliquots rapidly in liquid nitrogen, then store at −80°C.

In Vitro Neddylation

So far, the reported targets of neddylation are the cullins found in cullin-based multimeric E3s. NEDD8 modification of cullin enhances the E3 activity of these complexes. This protocol describes an in vitro neddylation assay for Cul2 in VBC-Cul2 E3 complexes.

Materials

VBC-Cul2 E3 protein complex expressed and purified by using baculoviral expression system (Basic Protocol 14)
Human APP-BP1/Uba3 (NEDD8 E1), expressed and purified by using baculoviral expression system (Basic Protocol 14)
Ubc12 (E2 for NEDD8; Basic Protocol 15)
NEDD8 (Basic Protocol 15)
10× ATP and ATP-regenerating system (see recipe)
10× ubiquitylation buffer 2 for E3s and neddylation (see recipe)
4× nonreducing SDS-PAGE sample buffer (see recipe)
Antibody to detect Cul2 (e.g., anti-myc antibody; Covance)
37°C Thermomixer (Eppendorf), or other heated shaker
Boiling water bath
Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

1. Mix the following in a total volume of 20 µl per reaction:

   800 ng VBC-Cul2
   50 ng APP-BP1/Uba3
   160 ng Ubc12
   1 µg NEDD8
   2 µl ATP and ATP-regenerating system
   2 µl 10× ubiquitylation buffer 2 for E3s and neddlyation.

   As a control, omit the E2 for NEDD8.

2. Incubate experimental and control reaction mixtures 60 min at 37°C.
3. Terminate reactions by adding 7 µl of 4× nonreducing SDS-PAGE sample buffer to each tube. Heat samples 5 min in a boiling water bath.
4. Run samples on 5% SDS-PAGE gel so that the band of Cul2 runs to the bottom of the gel (*UNIT 6.1*).
5. Immunoblot (*UNIT 6.2*) with antibody suitable for detecting Cul2.

   The authors use anti-myc antibody because their baculoviral-expressed Cul2 has an N-terminal myc tag.

6. Evaluate the immunoblot for a slowly migrating signal that reacts with antibody detecting Cul2.

   The slowly migrating signal will be ~8 to 9 kDa above the cul2 signal, which is at ~76 kDa.

LABELING AND DETECTION OF UBIQUITIN

In this section, protocols are provided for labeling ubiquitin to be used in in vitro biochemical assays. The methods of detection vary, and may involve radiolabeling with ^{32}P or ^{125}I followed by autoradiographic detection, labeling with nonradioactive labels such as biotin or fluorescein, or immunoblotting using anti-ubiquitin antibodies.

Strategic Planning

There are several basic considerations in deciding on an approach for detecting ubiquitin in in vitro experiments. Anti-ubiquitin antibodies vary in quality and may differ in their capacity to recognize ubiquitin depending on whether or not it is in chains; antibody binding may also be dependent on the nature of the linkage between ubiquitin molecules. Radiolabeling, while providing a strong signal, is not practical for some laboratories. Nonradioactive methods can be safer and more versatile, but reagents may be less available, more expensive, or otherwise impractical.

In some cases, plasmid constructs that are not commercially available are used in the protocols described; therefore, advance planning is required. However, people in the ubiquitin field are generally responsive to requests for plasmids.

BASIC PROTOCOL 17

Radiolabeling Ubiquitin with ^{32}P

This protocol utilizes a plasmid construct encoding a glutathione-*S*-transferase (GST) tag followed by a thrombin cleavage site and a cAMP-dependent protein kinase phosphorylation site N-terminal to ubiquitin. Radiolabeling is carried out using [γ-^{32}P]ATP and the catalytic subunit of protein kinase A. The protein can be used as a labeled GST fusion or can be cleaved resulting in ubiquitin having a small N-terminal extension modified with ^{32}P.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

Materials

E. coli BL21(DE3) or other protease-deficient bacterial strain (Novagen or Invitrogen)
pGEX-2TK-ubiquitin plasmid (purchase from GE Healthcare or prepare in house as in Alternate Protocol 10)
1 M IPTG (dissolve 1 g IPTG in 4.2 ml H_2O, store at −20°C)
Sonication buffer (see recipe)
Glutathione-Sepharose beads (GE Healthcare)
Phosphate-buffered saline (PBS; see recipe)
4× reducing SDS-PAGE sample buffer (see recipe)
12% SDS-PAGE gel (*UNIT 6.1*)
10× kinase buffer (see recipe)
Protein kinase A catalytic subunit from bovine heart (259 U; Sigma), resuspend lyophilized powder in 25 μl of 40 mM DTT on ice, allow to solubilize 15 min; prepare fresh
[γ-^{32}P]ATP (GE Healthcare) 6000 Ci/mmol
20× thrombin stock solution (see recipe)
Benzamidine-Sepharose (GE Healthcare)
Eco-Scint A (National Diagnostics)
Elution buffer for GST proteins (see recipe)

Refrigerated centrifuge and centrifuge bottles
Probe sonicator (e.g., Misonix Sonicator 3000)
Refrigerated centrifuge
Platform shaker
End-over-end rotator
Nitrocellulose filter circles
4-ml scintillation vials
β scintillation counter

Additional reagents and equipment for transforming bacteria with plasmids (Seidman et al., 1997), SDS-PAGE (*UNIT 6.1*), and staining of gels with Coomassie blue (*UNIT 6.6*)

Generate recombinant GST-thrombin-kinase site-ubiquitin

1. Transform BL21(DE3) with the pGEX-2TK-Ub plasmid (Seidman et al., 1997) and grow in a 1-liter culture with shaking at 37°C to an OD_{600} of 0.6 to 1.0.
2. Induce cultures by adding 1 M IPTG to a final concentration of 0.2 mM IPTG and incubating 1 to 2 hr at 37°C. When incubation is completed, place on ice.
3. Transfer culture to centrifuge bottle and centrifuge 20 min at 3000 × *g*, 4°C. Discard supernatant.
4. Add 40 ml cold sonication buffer to the pellet and resuspend completely by pipetting up and down.

Harvest the protein

5. Sonicate using probe sonicator for a total of 30 sec, either in a cold room or on ice, using three 10-sec pulses at 60% to 70% of the microtip limit setting (3.5 on Misonix Sonicator 3000).

   For smaller volumes (down to 10 ml lysate for a 250-ml culture) linearly reduce sonication time. When volumes of less than l0 ml are used, the sonicator will change pitch when lysis is complete. This can be used to find an optimal stopping point for sonication.

6. Centrifuge the sonicate 20 min at 15,000 × *g*, 4°C, and collect clarified sonicate.

Analyze the sonicate

7. Wash 66 μl of a well mixed glutathione-Sepharose slurry twice to remove the ethanol preservative, each time by microcentrifuging 30 sec at 14,000 × *g*, 4°C, removing the supernatant, adding 10 vol PBS, microcentrifuging again as before, and removing the supernatant.
8. Bind 50 to 500 μl of the sonicate to 50 μl of washed glutathione-Sepharose beads 15 min at room temperature either on an end-over-end rotator or a platform shaker.
9. Wash beads four times, each time by microcentrifuging 15 sec at 14,000 × *g*, 4°C, removing the supernatant, adding 10 vol PBS, microcentrifuging again as before, and removing the supernatant.
10. Add 40 μl of 4× SDS-PAGE reducing buffer to the bead pellet. Heat 3 min in a boiling water bath.
11. Resolve 40 μl of sample on a 12% SDS-PAGE gel (*UNIT 6.1*) that also includes lanes with known amounts of BSA ranging from 0.5 to 20 μg to serve as standards for quantification. Stain gel with Coomassie blue and quantify bands (*UNIT 6.6*). Divide sonicate (generated in step 6) into 1-ml aliquots and store in −80°C freezer.

Purify GST-Ub away from bacterial proteins

12. Add 150 μl of well mixed glutathione-Sepharose slurry to a 1.5-ml microcentrifuge tube.

    This will yield a final packed volume of 100 μl.

13. Wash the beads three times, each time by microcentrifuging briefly at 14,000 × *g*, 4°C, pouring off the supernatant, adding 1 ml PBS, microcentrifuging again as before and removing the supernatant. Remove final wash with a syringe or gel loading pipet.

14. Add 1 ml post-sonication supernatant from step 6. Allow to bind by incubating 30 to 60 min at room temperature on and end-over-end rotator.

15. Wash three times, each time with 1 ml 1× PBS using the technique described in step 13, then wash twice, each time with 0.5 ml 1× kinase buffer, using that same technique. Remove final wash with a syringe or gel loading pipet.

Label GST-ubiquitin

16. Add the following to the GST-Ub-bound beads from the previous step:

    5 µl 10× kinase buffer
    2 µl protein kinase A catalytic subunit
    2 µl [γ-^{32}P]ATP, 6000 Ci/mmol
    41 µl distilled H_2O.

17. Incubate on ice for 30 min, occasionally resuspending beads.

18. To remove unincorporated label, wash beads four to five times, each time by microcentrifuging 30 sec at 14,000 × *g*, 4°C, removing the supernatant, adding enough PBS to fill the tube, and removing the supernatant. Remove final wash with a syringe or gel loading pipet.

19. Proceed with thrombin cleavage (steps 20a to 26a) or skip to step 20b to produce purified labeled GST-ubiquitin.

For purified, labeled ubiquitin

20a. Prepare 800 µl of 1× thrombin by mixing 760 µl PBS with 40 µl of 20× thrombin stock, for a final concentration of 0.05 U/µl. Add to the labeled ubiquitin bound to the beads.

21a. Incubate 2 to 3 hr at room temperature (or overnight at 4°C) on an end-over-end rotator.

22a. Microcentrifuge 1 min at 14,000 × *g*, 4°C. Transfer the labeled Ub (supernatant) to a fresh tube.

23a. Wash benzamidine-Sepharose beads with PBS using the technique described in step 7. Add 100 µl PBS-washed benzamidine-Sepharose beads to the supernatant containing the labeled Ub. Incubate 30 to 60 min at room temperature on an end-over-end rotator.

24a. Microcentrifuge the beads 1 min at 14,000 × *g*, room temperature, and transfer the thrombin-depleted [^{32}P]Ub (supernatant) to a fresh tube.

25a. Spot 1 to 2 µl of the supernatant onto a nitrocellulose filter circle. Submerge the nitrocellulose in EcoScint A in a 4-ml scintillation vial. Count in a β scintillation counter.

Expect 10,000 to 30,000 cpm/µl.

26a. Store supernatant with the labeled Ub at 4°C for up to 4 weeks.

As the [^{32}P]Ub ages, aggregates may form which may obscure smaller protein+Ub conjugates resolved on gels. These aggregates may be removed by centrifuging the preparation for 30 to 60 min at 25,000 × g, 4°C.

For purified, labeled GST-ubiquitin fusion protein

20b. Elute the labeled protein from step 19 with 150 µl PBS elution buffer for GST proteins by incubating 10 min at 4°C.

21b. Microcentrifuge briefly at 14,000 × *g*. Transfer the eluate (supernatant) to a new tube.

22b. Repeat steps 20b and 21b twice. Combine the eluates (supernatants).

23b. Microcentrifuge briefly at 14,000 × *g*, and transfer supernatant to a new tube to remove any remaining beads.

24b. Spot 1 to 2 μl of the supernatant onto a nitrocellulose filter circle. Submerge the nitrocellulose in EcoScint A in a 4-ml scintillation vial. Count in a β scintillation counter.

Expect 10,000 to 40,000 cpm /μl.

25b. Store supernatant at 4°C until needed, up to 4 weeks.

Radiolabeling Ubiquitin with ^{125}Iodine

ALTERNATE PROTOCOL 8

^{125}I[ubiquitin] is available from GE Healthcare. With the availability of commercially available iodinated ubiquitin, the authors do not recommend labeling in-house unless the laboratory is set up with safety hoods, exhaust systems, and scientists trained to deal with non-bound ^{125}I.

Labeling Ubiquitin with Nonradioactive Tag (Biotin)

ALTERNATE PROTOCOL 9

Nonradioactive labeling techniques include biotinylation, labeling with fluorochromes, or labeling with chemiluminescence reagents. All of these require chemical cross-linking to ubiquitin. The authors recommend kits such as Pierce's EZ-Link. Again, the issue of modification of the ubiquitin itself should be considered. Here, the authors specifically present the labeling of ubiquitin with biotin. With this label, modified proteins in subsequent ubiquitylation assays may be detected with avidin–horseradish peroxidase (avidin-HRP).

Materials

20 mg/ml bovine ubiquitin (Sigma-Aldrich) in coupling buffer
Coupling buffer: 50 mM sodium borate, pH 8.5
10 mg/ml Sulfo-NHS-LC-Biotin (Pierce) in coupling buffer (prepare immediately prior to use)
1 M Tris Cl, pH 8.5 (*APPENDIX 2A*)
20 mM Tris Cl, pH 7.4 (*APPENDIX 2A*)
PD-10 column prepacked with Sephadex G-25 medium (GE Healthcare)
2000-MWCO dialysis membrane

1. Dissolve 25 mg bovine ubiquitin in 1.25 ml coupling buffer.
2. Combine the ubiquitin solution with 1 ml of freshly prepared 10 mg/ml Sulfo-NHS-LC-Biotin in coupling buffer. Incubate 30 min at room temperature.
3. Add 0.25 ml of 1 M Tris·Cl, pH 8.5. Incubate 30 min at room temperature.
4. Apply the entire 2.5 ml of reaction mixture to a prepacked PD-10 Sephadex G-25 column. Do not collect flowthrough. After the mixture has entered the column bed, add 3.5 ml of 20 mM Tris·Cl, pH 7.4/150 mM NaCl, and collect the eluate for dialysis.
5. Dialyze (*APPENDIX 3C*), using a 2000-MWCO dialysis membrane, against 1 liter of 20 mM Tris·Cl, pH 7.4, overnight at 4°C. Over the course of the next day, change buffer twice at intervals of several hours.
6. Divide dialysate into 200 μl to 1 ml aliquots and store at −80°C.

ALTERNATE PROTOCOL 10

Generation of Tagged Ubiquitin Expression Plasmids

If ubiquitin plasmids are not available, or if a specific tag is required, it is possible to generate reagents in house using basic molecular biology techniques. Ubiquitin is encoded in several genes, including a polyubiquitin gene that is cleaved by deubiquitylating enzymes (DUbs) to form ubiquitin monomers, and as fusions with certain ribosomal proteins that are later cleaved. In all cases, mature, active ubiquitin includes a C-terminal diglycine that is important for activation by E1. Sources of ubiquitin DNA are plentiful. Ubiquitin only varies in two amino acids between yeast and human, and ubiquitin from any source works well in all organisms. When adding tags to ubiquitin, it is crucial that the C-terminus not be modified, so as to allow activation by E1. Also, large tags, e.g., GST, GFP, or MBP, are more likely to hinder ubiquitin function than are small ones, e.g., His_6, FLAG, HA, or myc. Be aware that the FLAG epitope contains lysines that may themselves be ubiquitylated. The protocol described here uses PCR to generate a plasmid containing ubiquitin fused to GST, which may be used in the labeling protocol above. It may be modified as appropriate for plasmids that are available and to suit specific needs.

Materials

Whole RNA from any eukaryote, or total yeast DNA

Primer for reverse transcription (if starting with whole eukaryotic RNA): RT 3′ reverse: ATATAGAATTCCTATCCTCCTCTCAGGCGAAGGACCAGGT 3′ (synthesized at 100 nM scale, and desalted, by IDT, *http://www.idtdna.com*, Invitrogen, or similar oligonucleotide synthesis facility)

Kit for first-stand cDNA synthesis (e.g., RT-PCR kit; Fermentas)

Kit for PCR amplification of DNA (e.g., RT-PCR kit, Fermentas, or Ready-To-Go PCR beads, GE Healthcare)

Primers for PCR :
5′ forward: ATATAGGATCCCAGATCTTCGTGAAGACCCT
3′ reverse: ATATAGAATTCCTATCCTCCTCTCAGGCGAAGGACCAGGT

QIAquick PCR Purification Kit (Qiagen)

*Bam*HI and *Eco*R1 restriction endonucleases and 10× *Eco*RI buffer

pGEX-2TK vector (GE Healthcare)

1% agarose gels with and without ethidium bromide (Voytas, 2000)

Molecular weight markers

Calf intestinal alkaline phosphatase (CIAP; Roche)

QIAquick Gel Extraction Kit (Qiagen)

T4 DNA ligase kit (Takara)

TOP10 chemically competent *E. coli* strain DH5α (Invitrogen) or other suitable host bacterial strain

SOC medium (Digene)

LB medium (*APPENDIX 2A*) with ampicillin

100-mm LB agar plates containing 100 μg/ml ampicillin (*APPENDIX 2A*)

Ready-To-Go PCR kit (containing PCR tubes premixed PCR reagents; GE Healthcare)

DNA size markers

14°, 42°C. 56° and 65°C water baths

96-well microtiter plate

15-ml snap-cap culture tubes (e.g., Falcon 2059)

Additional reagents and equipment for agarose gel electrophoresis (Voytas, 2000), transformation of bacteria (Seidman et al., 1997), DNA minipreps (Engebrecht et al., 1991), and DNA sequencing (Chapter 7 in Ausubel et al., 2006)

Generate cDNA for ubiquitin

1a. *If using whole RNA:* Perform first-strand synthesis using the RT 3′ primer and the protocol in the Fermentas RT-PCR kit.

1b. *If using yeast DNA:* Proceed directly to step 2.

This procedure is appropriate for yeast DNA, which does not contain introns, but not for other eukaryotic DNA which does contain introns.

2. Use 1 to 3 μg of the first-strand cDNA or yeast DNA template with 25 pmol forward and reverse PCR primers in a total volume of 25 μl to perform PCR for the generation of ubiquitin double-stranded cDNA containing restriction sites that are compatible and in frame for ligation into pGEX-2TK.

The 5′ primer has a BamHI site, the 3′ primer an EcoRI site. Use either the RT-PCR kit or the GE Healthcare Ready-To-Go PCR Beads with the appropriate protocols and reaction conditions for either kit. Also see APPENDIX 3F *for general PCR protocols.*

3. Clean up the PCR reaction using a Qiagen QIAquick PCR Purification Kit, eluting the PCR product in 50 μl.

4. Digest 10 μl of the purified PCR product with 20 U each of *Bam*HI and *Eco*RI in 1× *Eco*RI buffer at 37°C for 2 hr in a total volume of 50 μl.

5. Run 5 μl of the restriction digest on a small 1% agarose gel (Voytas, 2000) with molecular weight markers to quantify the PCR product.

The PCR fragment will be 219 nucleotides plus restriction sites and other exogenous primer sequence. Larger fragments most likely contain polyubiquitin.

Create the ubiquitin fusion protein plasmid

6. Digest 5 μg pGEX-2TK with 50 U each of *Bam*HI and *Eco*RI in 1× *Eco*RI buffer.

Cloning sites may be viewed at http://www.amersham.com.

7. Dephosphorylate the vector DNA by adding 1 U CIAP, incubating 15 min at 37°C, and then incubating 15 min at 56°C. Add another 1 U CIAP and repeat the successive incubations at the two different temperatures. Heat inactivate the phosphatase by incubating at 65°C for 10 min.

8. Purify the digested vector by running on a 1% agarose gel containing ethidium bromide (Voytas, 2000), cut out the band at ∼5 kb, and purify using a Qiagen QIAquick Gel Extraction Kit.

9. Run 5 μl on a small 1% agarose gel (Voytas, 2000) with molecular weight markers to quantify.

10. Combine three molar equivalents of digested PCR fragment with 1 equivalent of vector DNA (30 to 100 ng total) in a 20-μl reaction with T4 ligase and buffer from the Takara T4 DNA ligase kit, according to the kit protocol.

11. Incubate 2 to 14 hr at 14°C or 15 to 30 min at room temperature.

Expand plasmid

12. Use all 20 μl of the ligated DNA to transform 100 μl TOP10 competent bacteria (Seidman et al., 1997) by heat-shock as follows. Incubate 15 min on ice, then 30 sec at 42°C, then 2 min back on ice, then add 400 μl SOC medium. Incubate with shaking at 37°C for 1 hr, microcentrifuge briefly at maximum speed to pellet bacteria, bring up in 100 μl with LB medium, and plate the entire mixture onto 100-mm LB ampicillin plates containing 100 μg/ml ampicillin. Incubate overnight at 37°C.

13. Select eight to twelve large, well isolated colonies to screen by PCR and to prepare a DNA miniprep for further verification by DNA sequencing by touching each colony with a toothpick, then transferring first into 50 μl LB medium with ampicillin in a well on a 96-well plate, and then into 2 ml LB medium with ampicillin in a 15-ml snap-cap culture tube.

14. Grow the bacteria in the 96-well plate, which has been sealed with tape, at 37°C for 1 hr while shaking. Grow the bacteria in the 15-ml tube by shaking at 225 rpm at 37°C until an OD_{600} of 0.6 to 1.0 is reached.

15. Prepare sufficient PCR cocktail for each colony picked plus one (22 μl per sample plus an additional 22 μl):

    0.1 μl 5′ primer at 100 pmol/μl
    0.1 μl 3′ primer at 100 pmol/μl
    H_2O to 22 μl.

    Multiply the above by the number of colonies picked plus 1.

16. Using one Ready-To-Go PCR tube per culture, add 22 μl of the above cocktail to each tube. Add 3 μl of each 1-hr culture from the 96-well plate to an individual PCR tube.

17. Carry out PCR reaction according to the protocol enclosed in the Ready-To-Go PCR kit.

18. Run 5 μl of each PCR reaction on an agarose gel (Voytas, 2000) with size markers to evaluate.

    Correct bands should be ~220 bp plus a little extra for added nucleotides.

19. Prepare minipreps from the appropriate 2-ml cultures (Engebrecht et al., 1991) and verify clones by sequencing miniprep DNA.

    Positive clones may be used to produce larger amounts of DNA. Cultures containing these clones may be stored as glycerol stocks, or the isolated DNA may be stored at –20°C.

BASIC PROTOCOL 18

Immunoblotting with Anti-Ubiquitin

An immunoblot probed with anti-ubiquitin will reveal both native ubiquitin and any protein to which ubiquitin has been conjugated, either as a monomer, or as multiple couplings. This can be used to study both in vivo interactions and to evaluate in vitro ubiquitination.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

Materials

Protein samples to be analyzed
0.5% (v/v) glutaraldehyde (Sigma) in 0.1 M sodium phosphate, pH 7.0 (*APPENDIX 2A*)
Phosphate-buffered saline (PBS; see recipe)
TBST/BSA (see recipe for TBST)
1.5 μg/ml polyclonal rabbit anti-ubiquitin (commercially available or prepared as in Basic Protocol 19) or monoclonal anti-ubiquitin in TBST/BSA

TBST buffer (see recipe)

[^{125}I]protein A (MP Biomedicals Life Science Division, or see recipe) *or* HRP-conjugated anti–rabbit Ig and chemiluminescent detection reagents (SuperSignal West Pico, Pierce, or ECL Plus, GE Healthcare)

Biomax MR film (Kodak)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), blotting from gels to PDVF or nitrocellulose membranes (*UNIT 6.2*), and autoradiography (*UNIT 6.3*)

Analyze and transfer protein

1. Resolve samples generated with unlabeled ubiquitin on SDS-PAGE gel (*UNIT 6.1*) and transfer to Immobilon (PVDF) or nitrocellulose membrane using established protocols (*UNIT 6.2*).

2a. *For PVDF membrane:* Fix the membrane by incubating in a solution of 0.5% glutaraldehyde for 20 min at room temperature. Wash three times, each time with 20 ml PBS.

2b. *For nitrocellulose membrane:* Fix by autoclaving the membrane on a wet cycle.

Expose membrane

3. Block nonspecific binding by incubating membrane with TBST/BSA for at least 1 hr at room temperature or overnight at 4°C.

4. Incubate with rabbit polyclonal anti-Ub (1.5 μg/ml in TBST/BSA) for at least 1 hr at room temperature with shaking, or overnight at 4°C.

5. Wash extensively with TBST at room temperature.

Detect bound antibody

To detect with ^{125}I

6a. Expose membrane to 0.5 to 1 μCi/ml [^{125}I]protein A in TBST/BSA for 1 hr at room temperature. Wash extensively with TBST buffer.

7a. Evaluate by autoradiography (*UNIT 6.3*).

To detect with enhanced chemiluminescence (ECL)

6b. Expose membrane to a 1/20,000 dilution of HRP-conjugated rabbit IgG secondary antibody in TBST/BSA for 1 hr.

Use HRP anti-mouse IgG at 1/10,000 when primary antibody is mouse monoclonal.

7b. Wash extensively with TBST buffer.

8b. Mix equal parts of SuperSignal West Pico Stable Peroxide Solution and Luminol/Enhancer Solution, or follow the directions for the ECL Plus kit.

About 2 ml total is sufficient for a membrane of 48 cm^2.

9b. Place the membrane on a piece of plastic wrap and cover with the SuperSignal mixture. After a few minutes drain the membrane onto the plastic wrap and place the opposite side of the membrane on top of the pool.

10b. Drain onto a paper towel, wrap in plastic wrap, and expose to Kodak Biomax MR film in a darkroom for varying times, usually 5 sec to a few minutes.

A band of ~8 kDa is native, unbound ubiquitin. A known protein that is even multiples of 8 kDa higher than expected is either mono-ubiquitylated or multi-ubiquitylated. An upward smear represents various multiples of ubiquitinations, either as multiple mono-ubiquitins, or various combinations of multi-ubiquitin chains.

GENERATION AND PURIFICATION OF RABBIT ANTI-UBIQUITIN ANTIBODIES

Often, the use of tagged or radiolabeled ubiquitin is undesirable. This is either because the epitope tags may interfere with ubiquitin modification or because the availability of radiolabeled ubiquitin or the licenses required for this type of work are problematic. In this case, it is desirable to use anti-ubiquitin antibodies to detect the modification of proteins.

There are an increasing number of anti-ubiquitin reagents commercially available, including monoclonal antibodies that will differentially recognize multi-ubiquitin chains. A problem in the field has been the quality of commercially available reagents. This is in part due to quality-control issues, but it is made more difficult by the conservation of ubiquitin between species and its consequent poor immunogenicity. The authors have had success in producing high-quality polyclonal antibodies useful for immunoblotting using commercial ubiquitin as a source. However, because of low yield and high background, affinity purification is necessary. In general, yields after purification are on the order of 0.2 to 1.2 mg antibody from 25 ml of serum. Other potential sources of antigen include recombinant ubiquitins, such as GST-ubiquitin and synthetic ubiquitin peptides. Each of these has potential advantages and disadvantages. The protocol described here uses commercial ubiquitin linked to a carrier to generate rabbit polyclonal antibodies.

Even though affinity purification will eventually be carried out, the authors recommend that investigators obtain a number of preimmune sera from rabbits that can potentially be immunized and select those that have relatively little background when used to probe a cell lysate.

BASIC PROTOCOL 19

Generation and Purification of Anti-Ubiquitin Antibodies

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Chicken albumin or ovalbumin, KLH, or other suitable hapten
Ubiquitin (from bovine erythrocytes; Sigma)
0.1 M potassium phosphate buffer, pH 7.0 (*APPENDIX 2A*)
3% (v/v) glutaraldehyde in potassium phosphate buffer, pH 7.0
Phosphate buffered saline (PBS; see recipe)
10% (w/v) SDS
Rabbits
Complete Freund's adjuvant (CFA, Sigma)
Incomplete Freund's adjuvant (IFA, Sigma)
Sodium azide
Ubiquitin-agarose affinity column (see Support Protocol 3)
0.2 M glycine, pH 2.7
2 M Tris base
PBS (see recipe) containing 0.02% (w/v) sodium azide
1 M KCl

15-ml tube
10,000-MWCO dialysis membrane
90°C water bath
Tabletop and refrigerated centrifuges

Additional reagents and equipment for preparing antigens with adjuvants (*UNIT 16.1*), immunoblotting (Basic Protocol 18), and dialysis (*APPENDIX 3C*)

Prepare the ubiquitin/hapten antigen

1. Combine the following in a 15-ml tube:

   15 mg chicken albumin or ovalbumin
   3.8 mg bovine erythrocyte ubiquitin
   2.2 ml of 0.1 M potassium phosphate buffer, pH 7.0.

   Vortex at room temperature until homogeneous.

2. To the above mixture, add 80 µl of 3% glutaraldehyde, 20 µl at a time at 10-min intervals. Vortex between additions.

3. Dialyze (*APPENDIX 3C*) overnight against 4 liters PBS using a 3500-MWCO dialysis membrane. Change the buffer at least once after 4 hr.

4. To the dialysate, add sufficient 10% SDS for a final concentration of 2% (w/v). Heat 10 min at 90°C.

5. Dilute 1:10, then divide into aliquots containing ~0.2 mg of Ub each.

Immunize rabbits

6. Obtain an ~20- to 30-ml bleed from the ear vein of unimmunized rabbits for preimmune negative controls. Store at 4°C overnight and remove coagulate by centrifuging 5 min at 750 × *g*, room temperature. Collect the serum.

   This should provide 10 to 15 ml of serum.

   The authors strongly recommend using a reputable commercial laboratory for animal care, immunization, and bleeding.

7. For each rabbit to be immunized, emulsify 0.2 to 0.5 mg of the albumin-conjugated ubiquitin 1:1 with complete Freund's adjuvant (*UNIT 16.1*). Inject the rabbit subcutaneously at multiple sites with 0.2 to 0.5 mg of this mixture.

   Booster injections can be done at single sites but the comfort of the animal should always be considered.

Collect antisera

8. After 1 month, collect a test bleed of 2 ml and prepare serum as for the pre-bleed.

9. Every 2 weeks, collect a test bleed of 2 ml and boost with 0.12 to 0.25 mg conjugated Ub diluted and emulsified at a 1:10 ratio with incomplete Freund's adjuvant.

10. Test the bleeds by immunoblotting (Basic Protocol 18) on 1, 10, and 100 ng of GST-ubiquitin or free ubiquitin and on cell lysate from cells treated with and without proteasome inhibitor (Basic Protocol 13). Use an initial serum dilution of 1:200.

11. After the test bleed indicates that the rabbit has produced a significant amount of antibody, continue boosting and set up regular bleeding schedule of ~ 25 ml serum every 2 weeks.

Affinity purify anti-ubiquitin antibodies

12. Clarify sera by centrifuging 30 min at 15,000 × *g*, 4°C, to remove debris. Add sodium azide to the supernatant for a final concentration of 0.02% (w/v).

    If there is significant lipid in the cleared serum, filter through gauze or cheesecloth. Lipid is readily detected by eye and characterized by the presence of a milky appearing white suspension in serum sample.

13. Wash ubiquitin affinity columns with 20 to 50 ml of PBS.

14. Bind antibodies to the column by passing 50 ml serum through the column twice. Save the flowthrough.

    It generally takes ~1 hr per pass of 50 ml.

14. Wash the column extensively with at least 100 ml PBS, monitoring the OD_{280} of the flowthrough until it is <0.005.

    If OD_{280} is >0.005 after 100 ml, wash with an additional 50 ml PBS and recheck. If the OD is not dropping at all and is <0.010, proceed with elution; if not continue washing.

15. Elute antibody using 0.2 M glycine, pH 2.7, collecting eluate fractions 1 ml at a time into tubes containing 50 µl of 2 M Tris base.

16. After collecting fifteen 1-ml fractions, determine the OD_{280} of each using the a mixture of 1 ml of 0.2 M glycine and 50 µl of Tris base as a blank.

17. Pool the tubes with significant levels of material (OD_{600} > 0.010) and dialyze (*APPENDIX 3C*) against 4 liters PBS with 0.02% sodium azide (0.02%) at 4°C overnight using a 10,000-MWCO dialysis membrane. Perform two additional changes of buffer over the course of the following day.

18. Regenerate column by passing 10 to 15 ml PBS through it, followed by 10 ml of 1 M KCl. Run an additional 50 ml of PBS through the column and store at 4°C in PBS/0.02% NaN_3.

SUPPORT PROTOCOL 3

Preparation of Ubiquitin Affinity Column

Crude serum or protein A–clarified antibodies often give good results in immunoblotting and other applications. However, the use of antibody purified on specific affinity columns avoids detection of nonspecific bands that are often seen with the more crude preparations.

Affinity columns for use in Basic Protocol 19 can be made using kits available from Pierce, Amersham, and other companies. The authors use Affi-gel-10 from Bio-Rad, which couples basic and neutral proteins such as ubiquitin through primary amine groups.

Materials

Affi-Gel-10 slurry (Bio-Rad)
4 mg/ml ubiquitin (Sigma) in 0.1 M $NaHCO_3$/0.5 M NaCl, pH 8.0
1 M ethanolamine, pH 8.0
0.2 M glycine, pH 4.0 (adjusted with HCl)
Phosphate-buffered saline (PBS; see recipe)
1 M KCl
1% (w/v) sodium azide

Fritted-glass filter, coarse
50-ml conical centrifuge tubes

1. Wash 25 ml of Affi-Gel-10 slurry in water over a clean coarse fritted-glass filter.

2. Remove the slurry from filter into a 50-ml conical centrifuge tube. Add 9 to 10 ml of 4 mg/ml ubiquitin in 0.1 M $NaHCO_3$/0.5 M NaCl, pH 8.0.

3. Incubate on an end-over-end rotator overnight at 4°C or for 1 to 2 hr at room temperature. Recover supernatant by centrifuging 5 min at 3750 × *g*, 4°C.

4. Block unreacted sites by incubating at room temperature for 1 hr with an equal bed volume of 1 M ethanolamine, pH 8.0.

5. Wash three times over fritted-glass filter alternately with 0.1 M $NaHCO_3$/0.5 M NaCl, pH 8.0, and 0.2 M glycine, pH 4, using 1 bed volume for each wash.

   Six washes are thus performed, three with the bicarbonate/NaCl solution and three with the glycine solution.

6. Follow up by washing on filter with 10 bed volumes of PBS followed by 10 bed volumes of 1 M KCl two to three times.

7. Finish by washing slurry into 10 vol PBS, add 1 M sodium azide to 0.02% final, and store at 4°C.

GENERATION OF REAGENT-GRADE UBIQUITIN ACTIVATING ENZYME (E1)

When studying the ubiquitin system, it is necessary to have the means to produce partially pure or fully purified components. Many components of the ubiquitin system are available commercially; however, it is often cost effective to produce these proteins in house.

In this section, the authors describe the production of E1 or ubiquitin activating enzyme, the first protein in the multi-step process of ubiquitin chain formation. Subsequent sections address the production of other ubiquitin pathway components.

Any E1 purchased or generated in the laboratory will have to be tested both for its own activity and for its ability to interact with specific ubiquitin conjugating enzymes or E2s (see Basic Protocol 2). Wheat E1 works well with many E2s, but it has been shown to be inactive with HIP2 (E2-25K), for example. If wheat E1 works in the system of interest, producing it is comparatively inexpensive and easy (Basic Protocol 20). For most purposes, mouse and rabbit E1s work very well with any E2. They are, however, more difficult to produce or more expensive, depending on the source. Mouse E1 can be produced in a baculovirus system and will show good activity during long-term storage in glycerol (Basic Protocol 21). If the laboratory does few ubiquitin assays, it may be worth considering purchasing rabbit E1 from a commercial source.

Preparation of Wheat E1 in *E. coli*

BASIC PROTOCOL 20

Wheat E1 is inexpensive and easy to produce because it can successfully be obtained in an active form from *E. coli*. It generally works with most E2s, but in some cases mammalian E2 will require mammalian E1.

The bacterially expressed E1 that the authors use, which is cloned from wheat by Richard Vierstra and colleagues, University of Wisconsin at Madison (Hatfield et al., 1990), is in pET3a. pET vectors are supplied by Novagen. The pET vectors are transformed into BL21 competent cells (Novagen) according to the manufacturer's protocol. Appropriate bacterial strains may also be grown in the laboratory and made competent for transformation.

Materials

pET E1 plasmid (request from R. Vierstra, University of Wisconsin at Madison, or A. Weissman)
E. coli strain BL21 transformation-competent bacteria (Novagen)
SOC medium (Digene)
LB plates (*APPENDIX 2A*) containing the appropriate selection antibiotic
LB medium (*APPENDIX 2A*) containing the appropriate selection antibiotic
1 M IPTG (dissolve 1 g IPTG in 4.2 ml water; store at −20°C)
Sonication buffer (see recipe)
E2 of choice

42°C water bath
Platform shaker
Refrigerated centrifuge
Probe sonicator (e.g., Misonix Sonicator 3000)

Transform BL21 with pET E1 construct

1. Add 1 μl ubiquitin-containing plasmid to 50 μl of transformation-competent cells which have been thawed on ice.
2. Incubate on ice for 30 min, heat shock for 45 sec at 42°C, and return to ice for 2 min.
3. Add 450 μl of room temperature SOC medium. Incubate 1 hr at 37°C with shaking on a platform shaker.
4. Microcentrifuge 15 min at 14,000 × *g*, 4°C. Remove all but 100 μl of medium, resuspend cells in this residual medium, and spread onto an LB plate with appropriate antibiotic. Incubate at 37°C.
5. The following day start a 2-ml culture in LB medium with appropriate antibiotic from a single colony. Incubate 8 hr at 37°C with shaking.
6. Use the 2-ml culture to start a larger culture (100 ml to 1 liter) with antibiotic. Grow the larger culture at 37°C until the OD_{600} is 0.6 to 1.0.

Express protein in bacteria

7. Add 1 M IPTG to the culture for a final concentration of 0.2 mM IPTG and continue incubation 1 to 2 hr at room temperature.
8. Centrifuge cells 15 min at 300 × *g*, 4°C, and remove the supernatant. Freeze pellet at −80°C or sonicate immediately.

Prepare lysate

9. For each 50 ml of culture, add 1 ml sonication buffer to the cell pellet. Sonicate 30 sec on ice at 60% to 70% of the microtip limit (setting 3.5 on Misonix Sonicator 3000).
10. Centrifuge 15 min at 15,000 × *g*, 4°C, to pellet debris.

    The supernatant is the crude lysate, which generally contains 100 to 150 ng recombinant protein/μl crude lysate.

11. Divide supernatant into aliquots sufficient for individual experiments and store at −80°C.
12. Assay for function by thiolester assay with E2 of choice (Basic Protocol 2).

BASIC PROTOCOL 21

Preparation of Mouse E1 in Insect Cells Using a Baculovirus System

Certain E2s require a mammalian E1, and for some E3 ubiquitylation assays the robustness of ubiquitylation is enhanced by using a mammalian E1. For poorly understood reasons, active mouse E1 is not readily expressed in *E. coli*, but it can be successfully expressed in insect cells. *Sf*9 cells, derived from *Spodoptera frugiperda* (army moth) ovarian cells, are commonly used to isolate and propagate recombinant AcMNPV (baculovirus) stocks and produce the recombinant protein of interest. The authors' mouse E1 baculovirus stock was generated in the Iwai laboratory (Iwai et al., 1999). Stratagene and Promega also have kits and protocols for making these baculovirus constructs. The following describes a generic method for working with baculovirus and producing mouse E1 protein in insect cells.

Materials

*Sf*9 cells (Invitrogen)
Complete Grace's insect medium (see recipe)
Baculovirus (AcMNPV) stock encoding His_6-tagged E1, recently titered
Baculovirus lysis buffer 2 (see recipe)
5% (w/v) agarose (SeaKem from FMC or Baculovirus Agarose from Invitrogen) in H_2O
Grace's insect medium (Invitrogen), serum free
1% (w/v) neutral red (Sigma)
175-cm^2 tissue culture flasks and 60-mm tissue culture dishes, plus other appropriate tissue culture vessels (Table 15.9.2)
50-ml conical polypropylene centrifuge tubes
60°C and 47°C water baths
Refrigerated centrifuge
Probe sonicator (e.g., Misonix Sonicator 3000)
Additional reagents and equipment for maintenance of insect cell cultures and generation of recombinant baculovirus (Murphy et al., 2004)

Culture cells

1. Plate *Sf*9 cells as adherent cells in flasks or dishes in complete Grace's insect medium (see Table 15.9.2).
2. Grow cells at 27°C without enhanced CO_2 just to confluence, then split 1:3, dislodging the cells either by streaming medium over the monolayer or by hitting the flask against the palm of the hand. Continue incubation at 27°C.

Produce virus

3. Seed a 175-cm^2 tissue culture flask with 21×10^6 log-phase *Sf*9 cells. Incubate at room temperature for >1 hr, then remove medium.
4. Infect cells at MOI of 0.1, i.e., 21×10^5 pfu in 5 ml medium from recently titered baculovirus stock.
5. Incubate the infected cells 1.25 hr, rocking gently every 15 min.
6. Remove virus solution and add 24 ml complete Grace's medium. Incubate 5 days at 27°C (no CO_2).
7. Transfer the culture to a 50-ml centrifuge tube. Centrifuge 5 min at $500 \times g$, room temperature.
8. Collect the supernatant, which is the high-titer virus stock. Store at 4°C, wrapped in foil to protect from light.
9. Titer by serial dilution to determine the pfu/ml.

Perform plaque assay to purify recombinant virus or titer virus

10. Seed 2×10^6 log-phase *Sf*9 cells in 3 ml complete Grace's medium in 60-mm Nunc dishes. Set up two dishes for each dilution to be used. Include a dish for one uninfected control.

    If cell number is limited, set up only one dish per dilution.

11. Let cells adhere at room temperature at least 1 hr.

12. During the incubation in the previous step, prepare agarose overlay as follows:
    a. Autoclave 0.5 ml of 5% agarose per dish, then cool to 60°C in a water bath.
    b. Heat 4.5 ml complete Grace's medium to 60°C per dish.
    c. Mix the medium with the agarose and cool to 40°C.
13. Prepare serial ten-fold dilutions of virus stock from 10^{-2} to 10^{-10} in complete Grace's medium. For duplicate dishes, make the 1:100 dilution by mixing 30 µl of stock with 3 ml medium, then for the rest take 240 µl of this and add to 2.2 ml Grace's medium.
14. Remove medium from cells and add 1 ml of viral stock dilution to each dish. Incubate at room temperature for 1.25 hr, rocking plates every 15 min.
15. Remove virus inocula from cells and add 4 ml of agarose overlay by slowly streaming down the side of the dish. Let solidify.
16. Incubate, top-side-up, in a 27°C humidified incubator for 5 to 8 days.
17. Count plaques when clearly visible. If plaques are difficult to see, enhance with neutral red as follows:
    a. Add 5 ml 2.5% agarose at 47°C to 24 ml serum-free Grace's insect medium at 47°C. Place in 47°C water bath.
    b. Add 0.8 ml of 1% neutral red (Sigma).
    c. Add 2 ml of this mixture per plate and let stand 3 hr at room temperature.
18. Calculate pfu/ml as follows:

$$\text{Average pfu/dish} \times \text{dilution}^{(-1)} = \text{pfu/ml}.$$

For example, if plates with 10^{-5} dilutions have an average of 200 plaques per dish, pfu/ml = 200×10^5 or 2×10^7/ml.

BD Biosystems is offering a new technology for titering baculovirus stocks, based on an ELISA assay, with results available in a few days rather than almost 2 weeks. It is called BacPAK Baculovirus Rapid Titer Kit.

Infect Sf9 cells with recombinant baculovirus to produce protein

19. Seed 21×10^6 *Sf*9 cells in 24 ml complete Grace's medium in a 175-cm^2 flask. Allow to adhere at room temperature for > 1 hr.
20. Remove medium from cells, add 5 ml virus solution containing 10 to 50 MOI, i.e., 21×10^7 to 1×10^8 pfu per 5 ml. Incubate at room temperature for 1.25 hr, rocking flask every 15 min.
21. Remove virus inoculum from cells and add back 24 ml complete Grace's medium Incubate at 27°C for 2 to 3 days. Include at least one flask with a "mock" infection (medium only) to use as a negative control.
22. Harvest cells by centrifuging 5 min at $750 \times g$, 4°C. Add 1 ml baculovirus lysis buffer 2 to the pellet per 8×10^6 cells (~1.5 ml buffer per 175-cm^2 flask).
23. Sonicate three times, each time for 20 sec using Misonix sonicator at 3.5 setting, on ice. Centrifuge 20 min at $12{,}000 \times g$, 4°C. Collect the supernatant, which is the crude E1 extract.
24. Store in small aliquots at −80°C, or purify by chromatography.

Preparation of Rabbit E1

ALTERNATE PROTOCOL 11

Mammalian E1 from rabbit may be purchased commercially from Calbiochem. The authors dilute the Calbiochem E1 1:5 in 50 mM HEPES, pH 7.6, which yields 100 ng/μl. The diluted E1 is stored up to 6 months at −80°C.

Generation of Empty Bacterial Lysates

SUPPORT PROTOCOL 4

For many of the protocols described, ubiquitin system enzymes are generated in bacteria as crude lysates. As a proper control in many of these reactions, it is necessary to add bacterial proteins that contain none of the ubiquitin-conjugating enzymes, i.e., "empty" lysates. This protocol is essentially identical to Basic Protocol 20. Briefly, pET vectors without a protein sequence are transformed into BL21 competent cells according to the manufacturer's protocol.

Additional Materials *(also see Basic Protocol 20)*

PET3a, pET15b or other vector for expression of proteins in *E. coli* from a T7 promoter but without a protein sequence

Transform BL21 with pET E1 construct

1. Transform BL21 with pET vector that has not had a cDNA cloned into its multiple cloning region and spread onto a plate with appropriate antibiotic. Incubate at 37°C.
2. The following day, start a 2-ml culture in LB medium with appropriate antibiotic from a single colony. Grow 8 hr at 37° with shaking.
3. From the 2-ml start a larger culture (100 ml to 1 liter) in LB medium with antibiotic. Grow at 37°C with shaking until the OD_{600} is 0.6 to 1.0.

Produce protein in bacteria and generate lysate

4. Add 1 M IPTG to the culture for a final concentration of 0.2 mM and continue incubation 1 to 2 hr at 37°C.
5. Pellet cells by centrifuging 15 min at 300 × *g*, 4°C. Discard the supernatant. Freeze pellet at −80°C or sonicate immediately.
6. For each 50 ml of culture, add 1 ml sonication buffer to the cell pellet. Sonicate 30 sec on ice at 60% to 70% of the microtip limit (setting 3.5 on Misonix Sonicator 3000).
7. Centrifuge 15 min at 15,000 × *g*, 4°C, to pellet debris.
8. Divide supernatant into aliquots sufficient for individual experiments and store at −80°C.

GENERATION OF UBIQUITIN-CONJUGATING ENZYMES (E2s)

In this section, protocols are included for the generation of members of the second class of enzymes of the ubiquitylation pathway, ubiquitin-conjugating enzymes, or E2s. While there is only a single mammalian E1, there are approximately 34 different E2s. Protocols are provided for production of both crude and purified forms of E2.

Strategic Planning

A major issue in working with E2s (Ubc's or Ube's) is making sure one is working with the correct enzyme. While some E2s from higher eukaryotes match the names of their yeast counterparts, in many cases they do not. Table 15.9.3 clarifies some of the confusion (Lorick et al., 2005a, b). Accession numbers provided are current GenBank reference sequences where available.

Table 15.9.3 Current E2 Nomenclature

Common name(s) of human E2/E2 variant	Official name	Refseq/Genbank ID	Nearest yeast E2 homolog
E2s for ubiquitin or ubiquitin-like molecules			
Apollon, BRUCE, BIR6	BIRC6	NP_057336	ubc7p/qri8p

Before embarking on expressing E2s, it may be worth checking whether the increasing number of commercially available E2s suits one's needs.

Expression of E2s in *E. coli* Without a Purification Tag

BASIC PROTOCOL 22

For most applications, a crude bacterial lysate containing expressed protein is sufficient for use in ubiquitylation assays. Bacteria do not have a ubiquitylation system, and therefore the only ubiquitin-related protein in the crude lysate will be the mammalian enzyme expressed by the bacteria.

Materials

pET expression vector (Novagen) containing cDNA for E2 of interest

Additional reagents and equipment for transforming bacteria with pET plasmid and preparing crude lysates of bacteria (Basic Protocol 20), purification of E2 (Alternate Protocol 12 or 13), and testing E2 activity (Basic Protocol 2)

1. Transform bacteria with pET plasmid containing cDNA for the E2 of interest and grow the cells (see Basic Protocol 20).
2. Prepare crude lysates of bacterial transformed with E2 plasmid (see Basic Protocol 20).

3. Store E2 in small aliquots (10 μl) or proceed to purification (Alternate Protocols 12 and 13).

4. Test E2 activity before use (Basic Protocol 2).

   E2s have varied requirements for reducing agent. Some will have maximum activity with no DTT added; some may require as much as 10 mM. This will have to be determined empirically. The authors typically start with 5 mM DTT in the lysis buffer.

ALTERNATE PROTOCOL 12

Purification of E2s from *E. coli* Using an Affinity Tag

When purified E2 is required, small tags such as His_6, T7, FLAG, or HA may be added by cloning into commercially available vectors. These tags may often be used for rapid purification without affecting overall function. All tags, especially larger ones, such as GFP or GST, have to be tested in the specific application to make sure they do not alter or eliminate activity of the E2. Most of the tagged E2 constructs used in the authors' laboratory have a His_6 tag and their purification is described below. Purification of other tags may be carried out using an agarose-conjugated anti-tag antibody or other affinity matrices (Alternate Protocol 13). In all cases, a protease cleavage site may be inserted between the tag and the E2 allowing for purification of untagged E2. This type of purification is described in Basic Protocol 17 for GST fusions.

Materials

Affinity matrix (Ni-NTA agarose from Qiagen; Talon from Clontech; or equivalent product from Invitrogen)
50 mM sodium phosphate, pH 8.0 (*APPENDIX 2A*)
Bacterial lysate containing E2 protein (Basic Protocol 22)
1 M imidazole, pH 7.5 (adjusted with HCl)
Wash buffer 1 for His_6-tagged proteins (see recipe)
Elution buffer for His_6-tagged proteins (see recipe)
Dialysis buffer for ubiquitylating and neddylating enzymes (see recipe)
Glycerol
3500-MWCO dialysis membrane

Additional reagents and equipment for dialysis (*APPENDIX 3C*) and testing E2 activity

Prepare affinity matrix

1. Add 50 μl affinity matrix to a 1.5-ml microcentrifuge tube.

2. Rinse the beads twice, each time by adding 1 ml of 50 mM sodium phosphate, microcentrifuging 30 sec at 6000 × *g*, room temperature, and removing the supernatant.

   Agarose conjugates are susceptible to matrix crushing, so higher speeds are not recommended.

Bind and wash the lysate

3. Add 1.0 ml (up to 500 μg of the protein to be purified, depending on the capacity of the matrix) crude lysate to the beads and adjust the concentration of the solution to 8 mM imidazole by adding 8 μl of 1 M imidazole. Remove a 10-μl aliquot for electrophoresis.

4. Bind the protein to the matrix beads by incubating 2 hr at 4°C on an end-over-end rotator.

5. Centrifuge the tube 30 sec at 6000 × *g*, 4°C. Remove the depleted supernatant, reserving a 10-μl aliquot for electrophoresis.

6. Wash the beads three times, each time by adding 1 ml wash buffer 1, centrifuging again as before, and removing the supernatant.
7. Elute the protein from the beads by adding 500 µl elution buffer and incubating 10 min at room temperature.
8. Centrifuge 30 sec at 6000 × *g*. Collect the supernatant into a fresh 1.5-ml microcentrifuge tube on ice.
9. Repeat the elution and pool the supernatants.

Dialyze and store the purified protein

10. Dialyze the eluate against 4 liters dialysis buffer overnight at 4°C using a 3500-MWCO dialysis membrane, changing the buffer twice at intervals at least 4 hr apart.
11. Remove the dialysate and divide into two tubes. Add an equal volume of glycerol to each tube and mix thoroughly. Store at −20°C to −80°C.
12. Test E2 activity before use (Basic Protocol 2).

Purification of E2s from *E. coli* Using Anti–Affinity Tag Antibodies

ALTERNATE PROTOCOL 13

This protocol can be carried out using centrifugation as described here, but it is easily modified for column purification. The latter option should be considered when working with larger volumes or when the matrix needs to be reused. However, success in purifying with antibodies varies greatly with the affinity of the antibody and the quality of the antibody-agarose conjugate, so materials should be reused only when necessary. In addition, the activity of the E2 purified in this way may be questionable. Therefore it may be most useful for producing antigen for antibody production or as a positive control for immunoblotting. Alternatively, protease cleavage may be employed to avoid the harsh acid elution (see Basic Protocol 17 for thrombin cleavage of GST fusions).

Materials

Antibody-agarose conjugates (Santa Cruz Biotechnology; 50% w/v slurry)
50 mM sodium phosphate, pH 7.0
Bacterial lysate containing E2 protein (Basic Protocol 22)
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
200 mM glycine, pH 2.8
1 M Tris base
Dialysis buffer (see recipe)
Glycerol
0.1 M NaOH (optional)
20% ethanol or 50 mM sodium phosphate (pH 7.0)/0.02% (w/v) sodium azide (optional)
3500-MWCO dialysis membrane
Additional reagents and equipment for dialysis (*APPENDIX 3C*) and testing E2 activity (Basic Protocol 2)

Prepare affinity matrix

1. Add 25 µl of a 50% slurry of agarose-conjugated antibody to a 1.5-ml tube.
2. Microcentrifuge 30 sec at 6000 × *g*, 4°C. Wash beads twice, each time by adding 1 ml of 50 mM sodium phosphate, microcentrifuging again as before, and removing the supernatant.

Bind and wash the lysate

3. Add 1.0 ml crude lysate (containing up to 500 μg protein, depending on the capacity of the matrix) to the beads. Remove 10 μl for electrophoresis.
4. Bind the protein to the matrix beads by incubating 2 hr at 4°C on an end-over-end rotator.
5. Pellet beads by centrifuging 30 sec at 6000 × *g*. Remove the depleted supernatant, retaining a 10-μl aliquot for electrophoresis.
6. Wash beads three times, each time by adding 1 ml Tris·Cl, pH 7.4, centrifuging 30 sec at 6000 × *g* to pellet the beads, and removing the supernatant.
7. Elute protein from beads by adding 500 μl 100 mM glycine, pH 2.8, and incubating 10 min at room temperature.
8. Microcentrifuge 30 sec at 6000 × *g*. Collect the supernatant into a fresh tube on ice containing 50 μl 2 M unbuffered Tris base.
9. Repeat the elution (steps 7 and 8) into a second tube containing 50 μl of 2 M Tris base and pool the supernatants. Retain beads for regeneration (steps 13 to 15).

Dialyze and store the purified protein

10. Dialyze the eluate (*APPENDIX 3C*) against 4 liters dialysis buffer at 4°C overnight using a 3500-MWCO dialysis membrane, changing the buffer twice at intervals of at least 4 hr.
11. Remove the dialysate and divide into two tubes. Add an equal volume of glycerol to each tube and mix thoroughly. Store up to 6 months at −20°C or indefinitely at −80°C.
12. Test E2 activity before use (Basic Protocol 2)

Regenerate the antibody matrix (optional)

13. If the matrix needs to be regenerated, after elution, add 500 μl of 0.1 M NaOH, Microcentrifuge 30 sec at 6000 × *g*, and remove the supernatant.
14. Wash beads with 500 μl 50 mM sodium phosphate, pH 7.0, using the technique described in the previous step.
15. Store in 20% ethanol or 50 mM sodium phosphate (pH 7.0)/0.02% sodium azide for later use.

BASIC PROTOCOL 23

Expression of E2s with In Vitro Transcription and Translation Systems

The large amount of protein produced at relatively low cost and lack of endogenous E2s make bacterial expression systems preferable for many studies of E2 activity. However, several factors may make it advantageous to produce a particular E2 in a higher eukaryotic expression system. In particular, the authors have found lower background in E2-E3 binding assays using radiolabeled in vitro–translated E2 material. Other factors include cross-species incompatibility of E2 for an E3, requirements for post-translational modifications, or the need for an unknown co-factor not present in prokaryotic systems. In such cases, in vitro translation (IVT) in wheat germ extracts or rabbit reticulocyte lysates is very convenient (*UNIT 11.2*). In addition, when attempting to detect the interaction of E2s with other proteins, it is often necessary to label the E2. These in vitro systems are particularly well suited for this purpose. For some proteins, researchers may find best results when producing their own RNA and using it in one of these systems. However, because most E2s are very small and easily expressed, the authors recommend using commercially available coupled transcription and translation systems.

Strategic planning

The ubiquitin conjugating system was first discovered in rabbit reticulocyte lysates (Ellison and Hochstrasser, 1991). Components of the ubiquitylation system are enriched in reticulocytes because of the high level of ongoing protein degradation required for transformation into an erythrocyte. This can be an advantage in some cases and a detriment in others. In one case, the protein of interest could be tagged with ubiquitin and prematurely degraded before one has the chance to analyze its function. With E2s, in particular, care must be taken to make sure that effects seen with reticulocyte-expressed proteins are the result of the expressed E2 and not of those proteins endogenous to reticulocytes. Often, a mammalian protein that is degraded in reticulocytes will not be degraded when translated in wheat germ extracts, due to incompatibilities between plant E1s and some mammalian E2s. In many cases, the use of proteasome inhibitors, such as MG132, allows for the production of ubiquitin system components with minimal degradation. This is especially important for producing E3 proteins or substrates for E3s, but may also be an issue in E2 production. Proteins produced using IVT systems may, of course, also be expressed with affinity tags and purified as described in Alternate Protocol 13.

When labeling the IVT product with radioactive amino acids, amino acid mixtures added to the reaction must be complete except for the radioactive component. Nonradioactive labels are also available for amino acids. For unlabeled protein, use a complete amino acid mixture.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by local radiation safety officer (also see *APPENDIX 1D*).

Materials

10× transcription buffer (Promega)
20 to 40 U/μl ribonuclease inhibitor (e.g., RNasin; Promega)
10 mM NTP mix (10 mM each ATP, CTP, GTP, UTP; Promega)
0.5 + 2μg/μl plasmid vector containing cDNA for E2 of interest under the control of a bacteriophage RNA polymerase, e.g., T7, SP6, or T3 (Promega)10 to 20 U/μl RNA polymerase appropriate to vector (SP6, T3, or T7)
0.7% agarose gel in MOPS-formaldehyde (optional; Brown et al., 2004)
10× in vitro translation (IVT) buffer (Promega)
Rabbit reticulocyte lysate or wheat germ extract (Promega)
Amino acid mixture (Promega) lacking methionine (−Met), cysteine (−Cys) or lysine (−Lys) depending on amino acid of choice for radiolabeling
50 mM MG132 (Calbiochem, Boston Biochem, or Biomol) in DMSO
15 μCi/μl [^{35}S]methionine, [^{35}S]cysteine, or [^{15}N]lysine (1000 Ci/mmol, NEN)
10% (w/v) trichloroacetic acid (TCA; Sigma), cold
EcoScint scintillation fluid (National Diagnostics)
30°C water bath
0.45-μM HA filters (Millipore)
Additional reagents and equipment for spectrophotometric determination of RNA concentration (*APPENDIX 3D*) *or* agarose-formaldehyde gel electrophoresis of RNA (Brown et al., 2004) and SDS-PAGE (*UNIT 6.1*) and autoradiography (*UNIT 6.3*)

Generate RNA for E2s

1. In a 1.5-ml tube, mix:

   5 μl 10× transcription buffer
   2 μl 20 to 40 U/μl ribonuclease inhibitor

4 μl 10 mM NTP mix
2 μg plasmid DNA (from 0.5 to 2μg/μl stock)
2 μl of appropriate RNA polymerase for the vector (SP6, T3, or T7; typically at 10 to 20 U/μl)
H_2O to 50 μl.

Incubate at 30°C for 1.5 hr

2. Measure the RNA content in a spectrophotometer (*APPENDIX 3D*) or by agarose gel electrophoresis (typically using a 0.7% agarose gel in MOPS-formaldehyde; Brown et al., 2004).

Use 100 ng to 1 μg RNA for translation; the remainder of the RNA may be frozen in aliquots at −80°C for later use.

Translate RNA to protein

3. To a 1.5-ml tube add:

5 μl 10× IVT buffer
25 μl reticulocyte lysate
4 μl amino acid mixture (lacking the amino acid of choice for radiolabeling)
2 μl 20 to 40 U/μl ribonuclease inhibitor
100 ng to 1 μg RNA for E2 of interest (from step 2)
Up to 1 μl 50 mM MG132 or other proteasome inhibitor (optional).
2 μl 15 μCi/μl [^{35}S]methionine (or radiolabeled amino acid of choice).

4. Microcentrifuge briefly at maximum speed to mix the sample and collect the solution at the bottom of the tube.
5. Incubate 1.5 hr at 30°C.
6. Test the quality of the protein via SDS-PAGE (*UNIT 6.1*), detecting radioactive proteins by autoradiography (*UNIT 6.3*).

Most E2s have molecular weights between 14 and 35 kDa so 16% or 18% gels are generally appropriate.

7. *Optional:* Further check radioactive proteins by precipitating 1 μl of the sample from step 6 in 10% cold TCA and spotting on 0.45-μm filters. Place filter in 5 ml scintillation fluid and measure cpm using a liquid scintillation counter.
8. Store protein up to 1 month at −20°C.

IN VITRO PRODUCTION OF UBIQUITIN-PROTEIN LIGASES (E3s)

Ubiquitin ligases (E3s) are the ultimate arbiters of substrate specificity in ubiquitylation. E3s fall into two broad classes defined by the nature of their ubiquitin ligase domains. The first class is the HECT (Homologous to E6-AP C-Terminus) domain family. These enzymes are characterized by a ∼350 amino acid, highly conserved catalytic domain and by the formation of obligate catalytic intermediates between a C-terminal cysteine in the HECT domain and ubiquitin. The second, and by far larger class, consists of the RING-finger E3s and RING-finger-like E3s. The RING finger is characterized by a three-dimensional structure defined by the presence of two Zn ions coordinated by a total of eight cysteine and histidine residues in a cross-braced type of pattern. This forms a platform for E2-Ub and facilitates the transfer of ubiquitin from E2 to heterologous substrates or to the E3 itself. The PHD finger is a variation on the RING finger that differs in the distribution of coordinating residues. The more distantly related U-box takes on the same general three-dimensional structure as the RING finger, but its stability relies

on salt bridges and charged residues, rather than on Zn binding (Aravind and Koonin, 2000; Hatakeyama et al., 2001).

The RING finger E3s may exist as a multi-subunit complex in which multiple components are necessary for both E3 activity and substrate specificity. These are characterized by a small RING finger, a member of the cullin family of proteins and other linkers, regulatory components, and substrate recognition elements that are required for activity. Such multi-subunit E3s include the SCF complexes, the anaphase-promoting complex, or cyclosome, and the CBC E3s (Iwai et al., 1999; Skowyra et al., 1999; Chan et al., 2001). For most RING-finger proteins, it is currently thought that the RING finger and substrate-recognition element are encoded on a single polypeptide (Lorick et al., 2005b).

Strategic Planning

There are a variety of ways to generate recombinant ubiquitin ligases. For the most part, the authors produce these either as GST or His_6 fusions in *E. coli* or in in vitro translation systems in much the same way as E2s (see above). At other times, the authors express and purify E3s from cells (see Basic Protocol 10, for example). Regardless, negative controls are important in evaluating function. While samples lacking added E1 or E2 serve such a role for in vitro ubiquitylation assays, it is also helpful to generate catalytically inactive versions of the putative E3. These can be particularly useful when trying to determine whether a low level of activity is real or background. With HECT domain proteins, simple mutation of the active-site cysteine is sufficient to abrogate E3 activity. For RING- or PHD-finger proteins, mutation of a single Zn-coordinating Cys or His will eliminate most activity. However, it is the authors' experience that some RING-finger E3s have the potential to show residual activity with mutation of a single residue; thus it is reasonable to consider mutating two residues—one involved in the coordination of each Zn. For U-box proteins, mutation of specific residues required for the structure will destroy E3 activity (see Hatekayama et al., 2001). Alternatively, the authors generate inactive forms through truncations or by treating with alkylating agents to inactive HECT E3s—this will also inactivate some RING-finger proteins.

Nearly all E3s that have been tested by the authors are able to ubiquitylate themselves in vitro to a greater or lesser degree. This is referred to as either auto- or self-ubiquitylation. Consequently, when produced in eukaryotic translation systems, one potentially needs to deal with ubiquitylation and proteasomal degradation during synthesis or when a ubiquitylation reaction is carried out. This is especially true when a reticulocyte lysate is being used, as this material is rich in ubiquitin-proteasome components.

When generating RING-finger proteins, the presence of sufficient Zn is critical to proper folding and E3 activity, so consider addition of Zn either during production or purification. Inhibition of RING-finger E3s by the use of metal-chelating agents to remove zinc is discussed in Basic Protocol 7. For production of most E3s, and particularly HECT proteins, maintaining a reducing environment is desirable. Multi-subunit E3s are a challenge to produce because all necessary components may not be known or be available, or they may need to be simultaneously produced in an insect cell system (see Basic Protocol 26). Expression in IVT systems is essentially identical to that described above for E2 production. Most of the protocols discussed here deal specifically with Zn-containing E3s expressed in bacteria. GST tagging has the advantage of dimerization, which appears to be necessary for the activity of many E3s. As is the case with other enzymes, some E3s are more stable in an unpurified form in a cell lysate than after purification. The authors have found several E3s to be particularly difficult to maintain in an active form after undergoing freeze-thaw cycles, regardless of their purification. Prominent among these is Hdm2/Mdm2. Alternate Protocol 15 provides one way in which this problem may be avoided.

Expression of RING-Finger E3s in Bacterial Lysates

The protocol described here takes advantage of affinity tags for purification of E3. Unlike E2, E3s often require at least partial purification before they can be detected by Coomassie blue staining. In most cases, however, RING-finger E3s expressed in bacteria possess high levels of activity.

Materials

E. coli, transformation-competent strain BL21(DE3) pLysS (Novagen)
E3 plasmid construct (typically pET vectors from Novagen or pGex vectors from GE Healthcare containing E3 cDNA alone or as a tagged fusion protein)
LB agar plates and liquid medium containing appropriate antibiotic (*APPENDIX 2A*)
2×YT medium (see recipe) containing appropriate antibiotic and up to 250 μM $ZnCl_2$
1 M IPTG (dissolve 1 g IPTG in 4.2 ml water; store at −20°C)
Sonication buffer (see recipe)
Glutathione-Sepharose (GS) or Ni-NTA agarose (Ni-NTA) beads
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
2 μg/μl stock solution of bovine serum albumin (BSA; Pierce)
Platform shaker
Spectrophotometer
Probe sonicator (e.g., Misonix Sonicator 300)
Refrigerated centrifuge and round-bottom centrifuge tubes
Additional reagents and equipment for transforming bacteria with plasmids (Seidman et al., 1997), SDS-PAGE (*UNIT 6.1*), and staining of gels (*UNIT 6.6*)

Transform bacteria

1. Transform competent BL21(DE3) pLysS *E. coli* with a prokaryotic plasmid vector expressing the E3 of interest (Seidman et al., 1997).

2. Spread the transformants onto LB agar plates containing appropriate antibiotic.

Start culture for protein production

3. The next morning, select a single colony and use it to inoculate 4 ml of LB liquid medium containing the appropriate antibiotic. Incubate with shaking at 37°C for 8 hr.

4. Transfer 10 μl of this starter culture to 100 ml of 2×YT medium containing appropriate antibiotic and up to 250 μM $ZnCl_2$. Incubate overnight with shaking at 25° to 37°C.

   Larger proteins are often made more efficiently at lower temperatures. The addition of zinc chloride is meant to increase the folding and therefore the activity of the RING finger. Temperature and zinc addition must be determined empirically for each E3 studied.

Induce protein expression in bacteria

5. The next morning, check OD_{600}. If between 0.6 and 1.0, proceed with the induction. If the $0D_{600}$ is below 0.6, allow cultures to grow at 37°C until an $0D_{600}$ of 0.6 has been reached. If the reading is above 1.0, dilute culture below 0.6 and allow to reach 0.6 to 1.0.

6. Induce protein expression by adding 10 μl of 1 M IPTG to the 100-ml culture. Incubate with shaking for the duration and at the temperature determined empirically for each fusion.

Collect lysate

7. Centrifuge bacterial culture 20 min at 3500 × *g*, 4°C. Remove supernatant.
8. Resuspend bacterial pellet in 4 ml cold sonication buffer per 100 ml of original culture.
9. Sonicate with a probe sonicator, either in a cold room or on ice, using three 10-sec pulses at 60% to 70% of the microtip limit setting (3.5 on a Misonix Sonicator 3000).

   For smaller volumes (down to 10 ml lysate for a 250-ml culture), linearly reduce the sonication time. The sonicator will change pitch when lysis of volumes less than 10 ml is complete. This can be used to find an optimal stopping point for sonication.

10. Transfer lysate to a round-bottom centrifuge tube and centrifuge 30 min at 20,000 × *g*, 4°C.
11. Collect the supernatant. Reserve 200 µl for quantitation.

    If the protein of interest does not form inclusion bodies, the supernatant will contain the crude protein lysate and the pellet may be discarded.

12. Divide lysate into aliquots and store at −80°C, reserving 200 µl for quantitation as in the remaining steps of this protocol, or proceed with purification by Basic Protocol 17 for GST-tagged proteins or by Alternate Protocol 12 for His_6-tagged proteins. If using the latter, add $ZnCl_2$ to buffers at 25 µM final to maintain RING-finger structure.

Measure crude protein content

13. Bind 200 µl of lysate to 50 µl GS or Ni-NTA beads by incubating them together for 20 min at room temperature on an end-over end rotator.
14. Microcentrifuge 30 sec at 14,000 × *g*, and remove supernatant. Wash by adding 1 ml of 50 mM Tris·Cl, pH 7.5, centrifuging again.
15. Wash the beads three more times with 50 mM Tris·Cl.
16. Analyze by SDS-PAGE (*UNIT 6.1*). Also load BSA standards ranging from 1 to 10 µg on the gel, and compare to 10 to 500 µl of unbound lysate. Stain gel with Coomassie blue (*UNIT 6.6*).

    If no protein is detected in the supernatant, it may be in inclusion bodies in the pellet. Protein may be extracted from inclusion bodies using SDS-PAGE sample buffer or using commercial kits (Pierce).

Expression of HECT and U-Box E3s in Bacterial Lysates

ALTERNATE PROTOCOL 14

The protocol for expression of E3s that do not coordinate Zn is identical to that for RING- and PHD-finger E3s described in Basic Protocol 24, *except* that addition of Zn to buffers is not necessary. To ensure that the conditions used are suitable to maintain the critical free cysteines for HECT domain proteins and otherwise maintain E3 structure, reducing agents and pH should be optimized for each protein.

Expression of Unstable E3s in Bacterial Lysates

ALTERNATE PROTOCOL 15

Several E3s including Hdm2/Mdm2 do not provide consistently reproducible results from frozen stocks. To circumvent this problem, the authors aliquot induced bacteria in amounts suitable for individual experiments (typically 50 ml of bacterial culture at OD_{600} of 0.6 to 1.0). Again the IPTG concentration, time, and temperature for induction must be determined empirically for each protein prepared. These aliquots are pelleted by

centrifuging 20 min at 3500 × *g*, 4°C, to produce the bacterial pellet, and the supernatant is removed. The pellets are stored at −80°C. When needed, the cells from an individual aliquot are lysed in 400 µl sonication buffer (see recipe), using the technique described in Basic Protocol 24.

BASIC PROTOCOL 25

Expression of E3s in Eukaryotic In Vitro Translation Systems

Expression of E3s in in vitro translation systems follows the same protocol as expression of E2s (Basic Protocol 23) and the same considerations apply. E3s have the potential to utilize E1 and E2 intrinsic to reticulocyte and wheat germ lysates. Therefore, consider the possibility that the E3 may undergo auto-ubiquitylation and proteasomal degradation while synthesis is taking place. If this is an issue, addition of proteasome inhibitor (e.g., 500 µM MG132) may be required. Unlike expression in bacterial systems, adjustment of pH and the presence Zn are generally not required.

BASIC PROTOCOL 26

Expression of Multi-Subunit E3s Using a Baculovirus Expression System

E3s can be divided into single-subunit E3s and E3s in which the substrate recognition element is on a distinct subunit from the ubiquitin-ligase domain. Most of the latter E3s contain a member of the cullin family as a central element. For example, Cul1-based SCF E3s are composed of four subunits. These include elements common to all of the SCF E3s, Cul1, Skp1, and Rbx1/ROC1/Hrt, and one of a number of F-box proteins that serve to recognize substrate. Baculoviral expression systems are well suited to express and purify multi-subunit E3s because coinfection with the multiple viruses that encode the individual E3 subunits results in the assembly of the multimeric protein complex. The authors generally add a His_6 tag to the subunits (i.e., F-box proteins) that are heterogeneous and recognize substrates so as to facilitate purification of E3 complexes. MOI of the viruses should be determined carefully to minimize incomplete protein complexes.

Materials

*Sf*9 cells or *Sf*21 cells (Invitrogen)
Complete Grace's insect medium (see recipe)
Baculovirus lysis buffer 1 (see recipe)
1 M imidazole, pH 7.5 (adjust with HCl)
Ni-NTA beads (Qiagen)
25-cm^2 culture flasks (Nunc) or 100-mm tissue culture dishes
27°C incubator without enhanced CO_2
175-cm^2 tissue culture flasks
15- and 50-ml centrifuge tubes
Additional reagents and equipment for maintenance of insect cell cultures and generation of recombinant baculovirus (Murphy et al., 2004) and batch (Support Protocol 5) or column (Support Protocol 6) purification of multimeric E3s

Culture insect cells

1. Plate 2 × 10^6 *Sf*9 as adherent cells in 25-cm^2 flasks or 3 × 10^6 cells in 100-mm dishes in complete Grace's insect medium.

   Murphy et al. (2004) contains general protocols for working with baculovirus. See Table 15.9.2 for recommendations for other culture configurations. Both Sf9 and Sf21 cells, derived from Spodoptera frugiperda (army moth) ovarian cells, are commonly used to isolate and propagate recombinant AcMNPV (baculovirus) stocks and produce the recombinant protein of interest. Sf9 was isolated as a clone of Sf21. It was reported that Sf21 cells might express more protein than Sf9 cells with some constructs (Heitz et al., 1997; Wang et al., 1997). They are grown as adherent cells in culture flasks or dishes.

2. Grow just to confluence in a 27°C incubator without enhanced CO_2, then split 1:3, dislodging the cells either by streaming medium over the monolayer or by hitting the flask against the palm of the hand.

Construct recombinant baculovirus

3. Subclone cDNAs encoding subunits of the E3s into baculovirus transfer vectors.

   Any kits and general protocols (e.g., Murphy et al., 2004) for making baculovirus constructs should work well for E3s. However, baculovirus transfer vectors must be suitable to the kits chosen.

Infect cells

4. Seed a 175-cm^2 with 21×10^6 log-phase *Sf*9 cells in 24 ml complete Grace's medium. Allow cells to adhere at room temperature for >1 hr, then remove medium from cells.

5. Infect cells with recombinant baculoviruses encoding E3 subunits at MOI of 1 to 5 virus particles per cell (i.e., $2.1–10.5 \times 10^7$ pfu) in 5 ml medium from recently titered (see Basic Protocol 21 and Murphy et al., 2004) baculovirus stock. Include at least one flask with a "mock" infection (medium only) as a negative control.

   The amount of His_6-tagged baculovirus should be at a lower MOI than other baculoviruses to minimize partial complexes.

6. Incubate the infected cells 1 hr at 27°C, rocking gently every 15 min to make sure that cells are covered with virus supernatant.

7. Remove virus solution and add 24 ml complete Grace's insect medium.

8. Incubate 60 to 72 hr at 27°C (no CO_2).

Lyse cells

9. Harvest cells by pipetting medium up and down. Transfer cells to a 50-ml centrifuge tube.

10. Centrifuge 4 min at $350 \times g$, 4°C, to pellet cells. Remove supernatant.

11. Wash twice, each time by adding 30 ml ice-cold PBS, centrifuging 4 min at $350 \times g$, 4°C, and removing the supernatant.

12. Lyse cells by adding 3 to 10 vol baculovirus lysis buffer 1 and incubating on ice for 20 min.

13. Centrifuge 15 min at $20{,}000 \times g$, 4°C. Transfer supernatant to new 15-ml tubes.

Purify the complex

14. Add appropriate amount of 1 M imidazole stock solution for a final concentration of 0.2 mM imidazole.

15. Add 0.2 to 0.4 ml of Ni-NTA beads for every ten 175-cm^2 flasks. Incubate 60 min at 4°C on an end-over-end rotator.

    The authors usually use ten 175-cm^2 flasks for purification of the E3 complex.

16. Purify the multimeric E3s by batch purification (Support Protocol 5) or column purification (Support Protocol 6).

SUPPORT PROTOCOL 5

Batch Purification of Multimeric E3s

Multimeric E3s can be purified either in batch or by column purification. The batch method is usually used by the authors.

Materials

E3 complexes bound to Ni-NTA beads (Basic Protocol 26)
Wash buffer 1 for His_6-tagged proteins (see recipe)
Wash buffer 2 for His_6-tagged proteins (see recipe)
Elution buffer for His_6-tagged proteins (see recipe)
Dialysis buffer 1 for ubiquitylating and neddylating enzymes (see recipe)
Glycerol

Refrigerated centrifuge
1.5-ml screw-cap microcentrifuge tubes
End-over-end rotator
8000-MWCO dialysis membrane

Additional reagents and equipment for dialysis (*APPENDIX 3C*)

Elute complexes

1. Centrifuge 15-ml tube containing the supernatant of Ni-NTA-agarose 5 min at 350 × *g*, 4°C. Remove supernatant.
2. Wash the Ni-NTA-agarose six times, each time by adding 12 ml wash buffer 1 for His_6-tagged proteins, centrifuging again as in step 1, and removing the supernatant.
3. *Optional:* Wash twice, each time with 12 ml wash buffer 2 for His_6-tagged proteins using the technique described in step 1.
4. Transfer Ni-NTA-agarose to a 1.5-ml screw-cap microcentrifuge tube.
5. Elute protein by adding 0.6 ml of elution buffer for His_6-tagged proteins and rotating 10 min at 4°C on an end-over-end rotator.
6. Microcentrifuge 2 min at 800 × *g*, 4°C. Transfer supernatant to a new 1.5-ml screw-cap tube.
7. Repeat steps 5 and 6 and combine the supernatants.

Dialyze and store the purified protein

8. Dialyze the eluate against 1 liter of dialysis buffer overnight at 4°C, using a 8000-MWCO dialysis membrane, changing the buffer twice at intervals at least 4 hr apart (*APPENDIX 3C*).
9. Remove the dialysate and divide into aliquots in 1.5-ml tubes. Add an equal volume of glycerol to each tube and mix thoroughly.
10. Rapidly freeze samples in liquid nitrogen, then store at −80°C.

SUPPORT PROTOCOL 6

Column Purification of Multimeric E3s

Column purification of E3 complexes is an alternative to batch purification.

Materials

E3 complexes bound to Ni-NTA beads
Wash buffer 1 for His_6-tagged proteins (see recipe)
Wash buffer 2 for His_6-tagged proteins (see recipe)
Elution buffer for His_6-tagged proteins (see recipe)

Dialysis buffer for ubiquitylating and neddylating enzymes (see recipe)
Glycerol

2-ml Poly-Prep disposable chromatography column (Bio-Rad)
8000-MWCO dialysis membrane

Additional reagents and equipment for dialysis (*APPENDIX 3C*)

Elute complex from the beads

1. Transfer Ni-NTA beads to a 2-ml Poly-Prep column.
2. Wash the beads in the column with 10 column volumes of wash buffer 1 for His_6-tagged proteins.
3. *Optional:* Wash beads with 2 to 3 column volumes of wash buffer 2 for His_6-tagged proteins.
4. Elute protein with one bed volume of elution buffer for His_6-tagged proteins.
5. Repeat elution step again and combine the eluates. Dialyze and store the purified protein
6. Dialyze the eluate against 1 liter of dialysis buffer overnight at 4°C using a 8000-MWCO dialysis membrane, changing the buffer twice at intervals at least 4 hr apart.
7. Remove the dialysate and divide into aliquots in 1.5-ml tubes. Add an equal volume of glycerol to each tube and mix thoroughly.
8. Rapidly freeze samples in liquid nitrogen, then store at −80°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

[^{125}I]protein A for immunoblotting

Purchase from ICN Biochemicals; dilute 1/1000 (for a final concentration of 0.5 to 1 μCi/ml) in PBS/0.1% (v/v) Tween 20. Prepare fresh.

2×YT medium

16 g Bacto tryptone (Invitrogen)
10 g Bacto yeast extract (Invitrogen)
5 g NaCl
H_2O to 1 liter
Autoclave
Store up to 1 year at room temperature

2×YT + G medium

16 g Bacto tryptone (Invitrogen)
10 g Bacto yeast extract (Invitrogen)
5 g NaCl
20 g glucose
H_2O to 1 liter
Autoclave
Store up to 1 month at room temperature

ATP, and ATP-regenerating system, 10×

5 mM ATP
100 mM creatine phosphate
100 μg/ml creatine phosphokinase
40 mm DTT (for ubiquitinylation only)
Prepare just before use

ATP and creatine phosphate are stored at −20°C.

Baculovirus lysis buffer 1

1% (v/v) Triton X-100
50 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
150 mM NaCl
10 mM 2-mercaptoethanol
1× protease inhibitors (e.g., Complete Protease Inhibitor Cocktail from Roche Diagnostics)
Prepare fresh; keep at 4°C during use

Baculovirus lysis buffer 2

1% (v/v) NP-40
100 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
100 mM NaCl
1 mM dithioerthyritol (DTE; Sigma)
10% (v/v) glycerol
1× protease inhibitors (e.g., Complete Protease Inhibitor Cocktail from Roche Diagnostics)
Prepare fresh; keep at 4°C during use

Binding buffer

5 ml 1 M Tris·Cl, pH 7.4 (*APPENDIX 2A*; 25 mM final)
2 ml 5 M NaCl (50 mM final)
0.154 g DTT (add immediately before use; 5 mM final)
1 ml NP-40 (0.5% v/v final)
H_2O to 200 ml
Store indefinitely at room temperature without DTT

Complete Grace's insect medium

Grace's insect medium (Invitrogen) supplemented with:
10% (v/v) fetal bovine serum
2 mM L-glutamine
100 IU/ml penicillin
100 μg/ml streptomycin
Store up to 1 month at 4°C

Dialysis buffer

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.5 mM DTT

DTT is not required for ubiquitin or NEDD8 production.

Elution buffer for GST proteins

20 mM Tris·Cl pH 7.5 (*APPENDIX 2A*)
20 mM reduced glutathione
Store up to 8 months at −20°C

Elution buffer for His_6-tagged proteins

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
300 mM imidazole
Prepare fresh

HEPES-buffered saline (HBS), 2×

16.4 g NaCl (280 mM final)
11.9 g HEPES acid (50 mM final)
0.21 g anhydrous Na_2HPO_4 (14.8 mM final)
Add H_2O to 800 ml
Adjust pH to 7.05 with NaOH
Add H_2O to 1 liter
Store in 50-ml aliquots up to 1 year at −20°C

The pH of 2× HBS and $CaCl_2$ used in transfections is critical. A narrow range of 7.05 to 7.12 is acceptable. Including glucose up to 15 mM helps maintain health of cell cultures where glucose is normally present. Addition of phenol red provides a pH indictor.

Hypotonic lysis buffer

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM 2-mercaptoethanol
1× protease inhibitors (e.g., Complete Protease Inhibitor Cocktail from Roche Diagnostics)
Prepare fresh

Kinase buffer for ubiquitin labeling, 10×

200 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
1 M NaCl
120 mM $MgCl_2$
10 mM DTT
Store up to 1 year at −20°C

Ni-NTA purification buffer

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM 2-mercaptoethanol
2 mM PMSF
Prepare fresh

Nondenaturing Triton X-100 lysis buffer for detection of ubiquitylation

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
300 mM NaCl
5 mM EDTA (optional)
0.5% (v/v) Triton X-100
Store with above ingredients indefinitely at 4°C
Immediately before use, add:
1 mM PMSF
2 μg/ml aprotinin
5 μg/ml leupeptin
1× phosphatase inhibitors (optional; see recipe for 10×)

Do not substitute PMSF with AEBSF, the nonhydrolyzable analog, as AEBSF may inhibit certain enzymatic reactions.

Nonreducing SDS-PAGE sample buffer, 4×

2.5 ml 1 M Tris·Cl, pH 6.8 (*APPENDIX 2A*; 250 mM final)
0.8 g SDS (8% w/v final)
4 ml glycerol (40% v/v final)
2 mg bromphenol blue (0.2% w/v final)
H_2O to 10 ml
Store in 0.5- to 1-ml aliquots up to 8 months at room temperature

PCK 10×

(Calbiochem, 5000 U), reconstitute in 1 ml 10 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*).

Phosphatase inhibitors, 10×

4 mM sodium orthovanadate
4 mM EDTA
100 mM sodium fluoride
100 mM sodium pyrophosphate
Store stock solutions up to 1 year at 4°C

Phosphate-buffered saline (PBS,) pH 7.4

1.9 mM NaH_2PO_4
8.1 mM Na_2HPO_4
154 mM NaCl
H_2O to 900 ml
Adjust pH to 7.4 with NaOH or HCl as necessary
H_2O to 1 liter
Store indefinitely at room temperature

Reducing SDS-PAGE sample buffer, 4×

2.5 ml 1 M Tris·Cl, pH 6.8 (*APPENDIX 2A*; 250 mM final)
0.4 ml 2-mercaptoethanol (4% v/v final)
0.8 g SDS (8% w/v final)
4 ml glycerol (40% v/v final)
2 mg bromphenol blue (0.2 % w/v final)
H_2O to 10 ml
Store in 0.5- to 1-ml aliquots up to 8 months at room temperature

Sonication buffer

50 mM Tris·Cl, pH 8 (*APPENDIX 2A*)
1 mM EDTA
1 % (v/v) Triton X-100
Store with above components up to 1 year at 4°C
10 mM 2-mercaptoethanol or 5 mM DTT (add just before use)
2 mM PMSF (add just before use)

Thiolester buffer, 10×

200 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
500 mM NaCl
50 mM ATP
50 mM $MgCl_2$
Store up to 1 year at −20°C

Thrombin stock solution, 20×

Dissolve 500 U lyophilized thrombin (GE Healthcare) in 0.5 ml cold PBS (*APPENDIX 2A*). Stored in 100-µl aliquots up to 6 months at −80°C.

Tris-buffered saline containing bovine serum albumin (TBS/BSA)

25 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
150 mM NaCl
0.5% (w/v) bovine serum albumin (BSA)
Store up to 1 month at 4°C

Tris-buffered saline(TBS) containing Tween 20 (TBST)

25 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
150 mM NaCl
0.05% to 0.1% (v/v) Tween 20
Store indefinitely at room temperature

Ubiquitin buffer 2 for E3 assays, 20×

1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
40 mM ATP
100 mM $MgCl_2$
40 mM DTT

The 1× buffer contains 25 mM Tris·Cl, 5 mM ATP, 4 mM $MgCl_2$, and 0.1 mM DTT.

Ubiquitylation buffer 1 for E3, 10×

500 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
2 mM ATP
5 mM $MgCl_2$
1 mM DTT
10 mM creatine phosphate (Sigma; 45 mg/10 ml)
Store up to 1 year at −20°C

Ubiquitylation buffer 2 for multi-subunit E3s and neddylation, 10×

200 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
50 mM $MgCl_2$
20 mM DTT
Prepare fresh

Wash buffer 1 for His_6-tagged proteins

20 mM Tris·Cl pH 7.5 (*APPENDIX 2A*)
5 mM imidazole
Prepare fresh

Wash buffer 2 for His_6-tagged proteins

20 mM Tris·Cl pH 7.5 (*APPENDIX 2A*)
10 mM imidazole
Prepare fresh

COMMENTARY

Background Information

Thiolester assays

Thiolester bonds formed between ubiquitin and E1 or E2 are evaluated in Basic Protocols 1 and 2. Thiolester bonds are relatively stable to heat but sensitive to reducing agents. Formation of a thiolester linkage of E1 or E2 with ubiquitin results is a change in migration of E1 or E2 by 8 kDa under nonreducing conditions. Upon reduction, the E1 or E2 migrates at its unnmodified molecular weight, while the ubiquitin is observed at 8 kDa (assuming the resolving gel distinguishes this from the dye front).

In vitro ubiquitylation (E3) assays

In this unit, protocols are included for determining whether a putative E3 can transfer ubiquitin in an E2-dependent manner. In Basic Protocol 8 a GST-E3 fusion serves as the predominant substrate for ubiquitylation.

Basic Protocol 5 is used to demonstrate that the E3 may modify itself when separated from the GST. Basic Protocol 6 addresses the inherent artificial nature of the system by removing the E3 from beads and eliminating the dimerization that is forced by the GST moiety. A number of E3s have been shown to function as dimers or to form dimers, e.g., as c-Cbl, Brca1-Bard1, and Rad5-Rad23. Alternate Protocol 2 addresses the potential for E2-E3 combination to result in various types of ubiquitin chains or to preferentially stimulate the addition of ubiquitin monomers. Of course it is important to be cognizant that chains preferentially formed in vitro using a substrate that may or may not be a bona fide intracellular substrate may not reflect the situation in a cell.

Substrate ubiquitylation in vitro

The purpose of this set of protocols is to establish, as clearly as possible, the ability of an E3 to modify a particular substrate with ubiquitin. To achieve this, the authors have generally used recombinant proteins to avoid obscuring the results with other ubiquitin-proteasome system proteins (see Basic Protocol 8 and Alternate Protocol 4). However, for multi-subunit E3s, use of eukaryotic systems is necessary (see Basic Protocol 9). These types of assays in which the E3 components are either expressed in bacteria or overexpressed may not, of course, reflect the physiological system. A missing cofactor could be required for substrate modification. In such cases, the use of in vivo protocols is recommended. Alternatively, use of eukaryotic systems such as insect cells may result in the unwitting copurification of a factor necessary for activity. In fact, this was the case for Rbx1 which was not originally appreciated as a component of cullin-containing E3s.

When substrate is expressed using in vitro systems, it is useful to add ubiquitin aldehyde along with proteasome inhibitor to the reaction mixture to inhibit deubiquitylation and proteasome activity, respectively.

An additional theme of this section is the precipitation of proteins. The authors use two general methods to study ubiquitylation of proteins from cell lysates. The first is detection of ubiquitin modification in precipitated proteins (Basic Protocol 11). The second is using precipitated proteins as the source of substrate for in vitro ubiquitylation reactions (Basic Protocol 10, Alternate Protocol 5). The authors precipitate proteins in two ways. The first (Basic Protocol 10) is using a specific antibody to the protein of interest. This can be used to pull down a ubiquitin-modified protein or an E3-substrate complex (coimmunoprecipitation). The second (Alternate Protocol 5) is pull-down of substrate using a GST-fusion of the E3. The second technique is perhaps most useful when subsequent activity assays will be performed.

Detection of ubiquitylation in vivo

The protocols in this section are designed to look at a "snapshot" of ubiquitylated species in living tissue. Under ideal conditions, the substrate will be of high abundance and will be easily detected in unstimulated cells. This is also the case for the ubiquitin-modified form of the protein. However, the activity of proteasomes, proteases, and DUbs may result in the protein being rapidly degraded, of low abundance, or deubiquitylated. The use of chemical inhibitors (Basic Protocol 13) may aid in overcoming these problems. In addition, anti-substrate antibodies may not recognize the ubiquitin-modified forms. Also, commercial anti-ubiquitin antibodies are notoriously variable. However, this may be overcome by the use of tagged ubiquitins (Alternate Protocol 6). These have the advantage that they can be detected by inexpensive, high-quality, well-defined antibodies. In addition, tagged ubiquitin may be less susceptible to the activity of DUbs.

Inhibition of ubiquitylation of protein and degradation

Each of these protocols (Basic Protocol 12, Alternate Protocol 7, Basic Protocol 13) takes a different approach to inhibiting target protein modification or degradation. Before employing a particular protocol, one must consider whether the answer needed will best be obtained by inhibiting the ubiquitin proteasome pathway at the E2, E3, or proteasome level.

NEDD8 conjugation

The protocols for NEDD8 conjugation (neddylation; Basic Protocols 14 to 16 and Support Protocols 1 and 2) are a prototype for conjugation of a ubiquitin-like modifier. NEDD8 modifies cullins in cullin-based ubiquitin ligase complexes and regulates their E3 activity. Although p53 and pVHL have recently been shown to be conjugated by NEDD8, cullins in cullin-based ubiquitin ligase complexes are the major targets of neddylation. Neddylation is catalyzed by several enzymes that are similar, though not identical to those involved in ubiquitylation. NEDD8 is activated by a heterodimeric E1-like enzyme,

the APP-BP1 and Uba3 complex, and is then transferred to an E2-like enzyme, Ubc12. Although the ubiquitin system appears to require an E3, an absolute requirement for E3 has not been shown for the ubiquitin-like molecules. However, Rbx1, a RING-finger protein, which is the catalytic center of ubiquitylation mediated by cullin-based E3s, also appears to function as an E3 for NEDD8 (Kamura et al., 1999).

E2 production

Expression of proteins in bacteria has been carried out for a number of years and has been used to express every kind of protein imaginable. However, this strategy is not well suited to every protein, as issues of solubility, premature transcriptional termination, and post-translational modification have arisen. In nearly all cases, small proteins, such as E2s, have been easy to express in large quantities in bacteria (Basic Protocol 22 and Alternate Protocols 12 and 13). Where bacteria can be used with satisfactory results, proteins are produced quickly, in large quantities, and at low cost. When expressing components of the ubiquitin proteasome system, bacteria have an added advantage–they possess none of these components endogenously. This permits the use of crude bacterial extracts containing the expressed E2 in ubiquitylation reactions with little or no purification (Basic Protocols 2 and 3). This is also true of bacterial extracts containing E1, E3, or ubiquitin (Basic Protocols 17, 20, and 24).

When bacterial expression of E2s is problematic, the use of eukaryotic in vitro transcription and translation systems provides for a more physiological setting (Basic Protocol 23). These systems provide proteins that are more likely to be folded properly and contain post-translational modifications, thereby maximizing the opportunity to obtain active E2. In most cases, the in vitro–translated protein should be used soon after synthesis in order to avoid the many complications caused by ubiquitin conjugation or degradation. This is because the proteasome machinery is also present in these systems. In addition, therefore, experiments employing IVT E2 should include both wild-type and active-site-mutant forms of the E2. This guarantees that the E2 of interest and not an endogenous wheat or rabbit E2 is responsible for observed effects.

E2s, particularly, can be very sensitive to freeze/thaw cycles and to redox conditions. Therefore, when using crude lysates stored at −80°C, aliquotting in the smallest volume convenient for an average experiment (10 to 20 μl) is wise. The authors find that 5 mM DTT works well to regulate the redox condition of most E2s, but they have seen maximum activity vary with DTT concentrations from 0 mM to 10 mM.

E3 production

E3s were originally considered to be substrate-recognition elements that facilitated transfer of ubiquitin from E2. The discovery of HECT-domain proteins, with active-site cysteines, provided evidence that E3s themselves could be catalytic. The subsequent description of RING-finger E3s seemed to indicate that the original concept was correct for these E3s, as RING fingers apparently do not form intermediates with ubiquitin. There is evidence to suggest, however, that they are not merely docking sites for E2s. (Lorick et al., 2005b).

Critical Parameters and Troubleshooting

Thiolester assays

Different E2s prepared under identical conditions may have different activities as assessed by ubiquitin thiolester bonds. This may reflect differing requirements for reducing agents during purification. If there are large differences in activity among E2s, it may be necessary to experiment with varying the DTT (or other reducing agent) level between 0 and 10 mM for production and purification. Redox potential of the E2s or E1 may also be affected by pH so this may similarly need to be varied from ~6.8 to 8.0.

E2s and E1s can lose activity after freeze/thaw cycles from −80°C. This can be avoided either purifying the protein and storing it at −20°C in 50% glycerol or by distributing it in small, single-use aliquots and storing at −80°C.

To guarantee that the amount of thiolester formation is equal when comparing various E2s, test all of them together using Basic Protocol 2. Use the results from this to normalize the thiolester formation potential and run a second assay. One problem that has arisen from this practice is that too much E2 added to the assay will result in decreased activity compared to when less material is used. While the authors are not certain of the biological reasons for this, it may be that inactive E2 molecules have a dominant-negative effect on interactions between E1 and active E2s.

Binding of ubiquitin-proteasome proteins

Generally, washing more than four or five times will not reduce background. If background persists, consider increasing detergent or altering the NaCl concentration. The concentration of NaCl determines the stringency of the binding. A range of 50 to 200 mM is reasonable to evaluate most interactions. Different protein interactions vary in the optimal NaCl for assessing binding.

In vitro ubiquitylation (E3) assays

The protocols described are fairly straightforward. One problem that has arisen in the authors' hands is the decay of radiolabeled ubiquitin. ^{32}P has a 2-week half-life. In addition, the ubiquitin is labeled to high specific activity. This causes loss of signal both due to radioactive decay and radiodegradation of the ubiquitin. Labeling ubiquitin every 3 weeks is usually sufficient to maintain signal (see Basic Protocol 17).

Occasionally the authors find a lack of activity in their bacterial preparations of E3. For RING-finger E3s, this may be obviated under certain circumstance by addition of Zn to the bacterial culture when RING- and PHD-finger proteins are being evaluated (see Basic Protocol 25).

When using Basic Protocol 6, 20× ubiquitin buffer 2 may be used in place of the 10× ubiquitin buffer 1. The former buffer replaces the ATP-regenerating system of the latter with much higher levels of $MgCl_2$ and ATP, and increases the reduction potential as a consequence of increased DTT. A similar buffer has been used by Huibregeste et al. (1993) which also includes NaCl. Occasionally, this has resulted in gels with aberrant migration, and may interfere with the activity of a particular E3 when compared to the buffer without added salt. The lack of salt in the buffers described here may be advantageous when using rabbit reticulocytes in in vitro translation systems. This is because the net salt concentration is above physiological. The 10× buffer is recommended for initial assays, but consider trying the 20× high-ATP system or the Huibregeste buffer to see if it increases ubiquitylation.

When generating mutant ubiquitin, be aware that bacterial codon usage is a particular problem in Alternate Protocol 2. This is regardless of whether radiolabeled or unlabeled ubiquitin is employed. Because bacteria have few of the mammalian codons for arginine, they may incorporate lysines into mutant ubiquitins where a lysine was thought to have been eliminated. Use of codon-optimized bacteria strains such as Stratagene CodonPlus RP or RIL strains may overcome the problem. In addition, gas chromatography–mass spectrometry (GC-MS) techniques should be employed to purify or confirm the proper translation of a mutant ubiquitin if amino acid misincorporation is a potential issue.

Zinc chelation also provides variable results. Some RING-finger E3s never lose activity even when exposed to the strongest zinc chelators (Lorick et al., 1999). Others cannot reconstitute activity when zinc is added back.

As an alternative to chelation of zinc or alkylation of active site cysteines, similar information may be obtained by mutation of critical RING-finger domain or HECT-domain residues.

Substrate ubiquitylation in vitro

The use of proteasome inhibitors increases the chance of detecting the substrate protein. Additionally, substrate generated in mammalian systems will be subject to the activity of DUbs. This activity may be inhibited by the addition of ubiquitin aldehyde during in vitro ubiquitylation. Addition of ubiquitin aldehyde before the in vitro reaction, however, may artificially increase the amount of ubiquitin-modified substrate detected.

Caution must be exercised when precipitating proteins that will be used in enzymatic assays. Lysis of cells should be carried out under relatively gentle conditions using nonionic detergents such as Triton X-100 or NP-40. Alkylating agents such as N-ethyl maleimide or iodoacetamide must be avoided so as to prevent inactivation of the ubiquitylation machinery.

When immunoprecipitating, consider that protein A and protein G have differential preferences for antibody subtypes and species (Table 7.2.1). If there is concern about antibody binding, protein G is the safer bet, but protein A is considerably less expensive. For further discussion of immunoprecipitation see *UNIT 7.2* and Coligan et al. (2006).

Detection of ubiquitylation in vivo

To detect steady-state ubiquitin modification, the presence of DUbs warrants harsher lysis conditions. Alkylating agents and harsh detergents or chaotropic salts will help to inhibit DUbs and allow for the detection of ubiquitylation. Working quickly will also limit the amount of time the substrate of interest is exposed to DUbs.

Inhibition of ubiquitylation of protein and degradation

Mutation of E3 (or E2) active sites, may not give complete inhibition of E3 activity. The reason for this, first of all, is that loss of a particular E3 may be compensated by other E3s in the cell. Additionally, it is the authors' impression that RING-finger proteins sometimes have residual activity, even with one of their zinc-binding residues is mutated. For this reason the authors frequently mutate two or more coordinating residues for the zinc ligand.

Be careful, when interpreting results, to take into account all of the protein in the sample. Inhibiting the proteasome will increase the total level of any protein degraded in a proteasome-dependent manner. The inhibition may increase the fraction of target protein that is ubiquitin modified. This makes the target appear depleted at its unmodified molecular weight. Therefore, any increase or decrease in protein level has to be determined by looking at both ubiquitin-modified and unmodified protein levels.

Some substrate proteins are known to give slightly ambiguous results in proteasome inhibition assays. Foremost among these is the epidermal growth factor receptor (EGFR), which appears to be degraded in the lysosome, but requires proteasome activity, possibly associated with Cbl proteins, for its degradation. Also, consider that there is at least one example of ubiquitin-independent proteasomal degradation—ornithine decarboxylase (Murakami et al., 1992, 1993; Mahaffey and Rechsteiner 1999; Newman et al., 2004).

Some researchers have used quantitative northern blotting or RT-PCR to demonstrate knockdown of expression. However, just because RNA levels may be reduced, it is impossible to know intrinsically how translation may compensate using even a small amount of remaining RNA. Therefore, the use of antibody to detect the ablated protein is greatly preferred in most experiments.

NEDD8 conjugation

The protocols for expressing and testing NEDD8 conjugating system proteins resemble those outlined for the ubiquitin system. Namely, the purification protocol for APP-BP1/Uba3 resembles that of mouse E1 or VBC-Cul2 E3. Also, the protocol for production of NEDD8 or Ubc12 resembles that of ubiquitin or E2s for ubiquitin, respectively. The protocol for in vitro neddylation resembles that for in vitro ubiquitination. Therefore, critical parameters and troubleshooting are almost identical to those for the previously described protocols. However, there are a couple of points that should be stressed.

The baculovirus expression system is a suitable system to express multimeric protein complexes. Since E1 for NEDD8 is the APP-BP1/Uba3 heterodimeric complex, use a baculovirus expression system to express them. To avoid contamination of incomplete complex, the MOI of His_6-APP-BP1 baculovirus infection should be higher than that of Uba3. NEDD8 is a 76-amino acid protein. However, NEDD8 cDNA encodes additional amino acids at the C-terminus of the protein (GGLRQ in human). Although this extension is cleaved by C-terminal hydroxylase to produce mature NEDD8 in mammalian cells, *E. coli* has no C-terminal hydroxylase for NEDD8. Therefore, C-terminal extension of NEDD8 must be removed in a bacterial expression plasmid for NEDD8. Because both APP-BP1/Uba3 and Ubc12 are extremely sensitive to oxidation, reducing agents should be added to the system during purification. However, strong reducing agents such as DTT are not suitable for the purification of His_6-tagged proteins by Ni-NTA column because they may reduce the nickel ions and thereby prevent them from binding to His_6-tagged proteins. Therefore, add 10 to 20 mM of 2-mercaptoethanol (2-ME) to lysis buffer.

Labeling and detection of ubiquitin

If care is taken in planning, few problems arise in labeling ubiquitin. However, there are a few caveats. Thrombin, used in the cleavage of GST-Ub, can be dissolved in either PBS or TBS; however, NaCl must be present in the buffer. Thrombin can be finicky; hence, once a reliable source is identified, one should stick to it. Removal of thrombin with benzamidine-Sepharose can be incomplete, so this step may need to be repeated if other proteins integral to the assays have potential thrombin cleavage sites. There is always the potential for beads to be carried over after cleavage of GST-Ub or from the benzamidine-Sepharose. It is also possible for a small amount of non-bead-associated, uncleaved GST-Ub to be present. One way to prevent contaminating any ubiquitylation assay with ^{32}P-labeled GST-ubiquitin is to add a small amount of glutathione-Sepharose to the tube of labeled ubiquitin to absorb this material.

Both [^{32}P] or [^{125}I]ubiquitin can be prone to radiodegradation. For [^{32}P]ubiquitin it is best to label at least every 3 weeks.

Because of its high degree of conservation, ubiquitin is not very antigenic; thus, generation of high-affinity antibodies can be problematic. Indeed, lots of commercially available polyclonal anti-ubiquitin antibodies are highly variable. Partially because of issues of immunoreactivity, scientists in the field have historically taken extra steps to increase the ability of antibodies to detect their proteins. This is the reason for recommending glutaraldehyde fixation of PVDF or autoclaving of nitrocellulose in the immunoblotting protocol. At times, the authors have achieved good results without glutaraldehyde treatment. However, it is recommended that such fixation be initially employed; further judgments can then be made as to the need for this step. Blocking of membrane should be done in BSA or casein, not milk, because milk can potentially include ubiquitylated protein. When planning an experiment that involves immunoblotting with anti-ubiquitin to determine whether an immunoprecipitated protein, for example, is ubiquitylated, it is essential to have appropriate negative controls. Because ubiquitylation is such a prevalent modification and such a low percentage of any protein is found ubiquitylated at steady state, care must be exercised that ubiquitylated species represent the protein of interest and not nonspecifically associated material.

Serum preparation and construction of a ubiquitin affinity column

It is important to test serum bleeds soon after they are collected. Many antigens are toxic to rabbits, and rabbits have been known to die before any appreciable amount of serum has been collected. When purifying the antibodies, remember to store every fraction that contains detectable antibody. Often, the highest affinity antibodies come off of a purification column after the bulk of the material has been eluted.

Preparation of E1

Most E1s, whether laboratory generated wheat E1 or commercially purchased rabbit E1, are extremely sensitive to freeze/thaw cycles; therefore, they should be stored in small aliquots at −80°C after their initial thaw and never be reused. Baculovirus-expressed mouse E1, however, can be stored in 50% glycerol at −20°C for long periods of time (months) with little or no loss of activity.

E2 production

When expressing proteins in bacteria, major considerations are what plasmids and bacterial strains to use. Most bacterial expression systems take advantage of the lac operon genes. This permits a gene under the control of the lac promoter to be repressed by the lacIq gene product (the lac repressor) until an inducer, such as IPTG, is added. The lac repressor element has been employed to repress genes not under the control of the lac promoter. These include the tac promoter in pGEX vectors and a hybrid trp/lac promoter in pTrc vectors. Perhaps the most widely used system currently is that employed by Novagen's pET vectors. This system uses a variation of the lac operon in which the lac repressor reduces expression of T7 from the DE3 plasmid found in certain BL21 strains. In addition, lacIq represses expression of a transgene under the control of the T7 promoter. In this way, unwanted or leaky expression is suppressed both at the promoter and by controlled expression of the driving RNA polymerase. The key to any of these systems is the presence of an intact lacIq gene, and in the case of the pET system, the DE3 plasmid. While many *E. coli* strains can be used to express proteins using the lac operon, the BL21 strain is generally recommended for its reduced protease activity. BL21 cells are also readily available with DE3. Other variations of BL21 available compensate for leaky expression from T7 (pLysS strains) by degrading T7 polymerase until induction. These cells are recommended for longer proteins, as the leaky expression will cause the production of a large number of incomplete transcripts and truncated proteins. Another source of incomplete protein production is the bacterial scarcity of tRNAs for GC-rich codons found in cDNAs from eukaryotic species. Stratagene offers two strains of BL21 that have mammalian codon bias, BL21(DE3) Codon plus RP or Codon plus RIL. The mammalian codon bias is provided by plasmids that encode GC-rich arginine and proline tRNAs or arginine, isoleucine, and leucine tRNAs (Sambrook et. al., 1989).

When producing IVT proteins, a major consideration is the presence of excess protein in the wheat or rabbit machinery. These proteins tend to form aggregates upon heating. The aggregates can sequester free radioactive material, and the result is clouding at the top and bottom of the gel upon autoradiography. If the extent of clouding is high, it may conceal or obscure the signal from the desired translation product. Heating to 65° to 70°C rather than boiling samples before electrophoresis or heating to lower temperature for longer times, for example 37°C for 30 min, may help this

problem. In addition, spinning out insoluble material after translation, immunoprecipitating the products, or fixing the gel for 30 min in 10% acetic acid/25% methanol will further reduce or eliminate this problem. If no translation product is seen, purifying or linearizing the plasmids is recommended. The authors find that commercial wheat germ extracts or rabbit reticulocytes do not translate well even after a single freeze/thaw cycle. Even when using quick systems where the only necessary addition to the reaction is DNA and radioactivity, the authors have found that addition of ribonuclease inhibitor improves the overall quality of translation products.

When using tagged proteins that will be purified, a C-terminal tag will allow for purification of the full-length protein away from truncated or degraded proteins, but the presence of the tag will need to be checked for effects on function. Generally, the authors find that placement of tags at N-termini has little effect on E2 activity. In all cases, the tagged protein must be tested for function. Where the tag interferes with function, purification may require using untagged E2s and employing more complex chromatographic methods.

The levels of inducing agent, bacterial density, time, and temperature may all be varied in order to maximize protein yield and complete protein translation. IPTG may be varied from 0.1 to 1 mM with proteins that express well; usually smaller ones require less. The OD_{600} of the cultures may be varied from 0.6 to 1.0; the key is to have the bacteria in logarithmic growth phase. The time of induction may be varied from 30 min to 3 hr; this generally depends upon the OD_{600} of the culture and the ability of the plasmid to express protein well. Longer incubation generally does not help if bacteria have entered stationary phase or if only a small amount of protein is needed. Larger proteins should be induced earlier and for a longer period of time. Finally, most *E. coli* machinery works best at 37°C. However the bacteria also contain proteases, so larger proteins may be produced with less degradation if their cultures are induced at 22° to 30°C. In some cases optimal induction temperature may be as low as 16°C. Smaller proteins generally produce well at the higher temperature.

E3 production

When expressing E3s in bacteria, one often encounters expression or solubility issues that do not generally arise with E2 production. This derives in part form the larger size of E3s and their potential to be sequestered into inclusion bodies. This can be assessed by evaluating a small amount of post-lysis protein pellet by SDS-PAGE and comparing it to pellet from untransfected cells. If the protein of interest is found in the inclusion body, it will be necessary to extract protein from the inclusion body using buffers containing a high concentration of SDS, urea, or guanidine, followed by refolding. Commercial kits are available for inclusion body extraction and refolding. There is no guarantee that this approach will yield active E3. The second approach is to clone the protein with a solubility tag such as NusA, or MBP. A trial-and-error approach will be necessary to determine the optimal tag. Low levels of expression also often correlate with protein size, with larger proteins expressing more poorly than smaller ones. Often, this is caused by differences in codon usage between bacteria and eukaryotes. Certain bacterial strains, such as Stratagene's CodonPlus BL21 strains, compensate for this codon preference by expressing cDNAs for the less abundant tRNAs. For all E3s, obtaining active protein can also be an issue. For RING-finger proteins, activity can often be improved by optimizing zinc levels. For HECT-domain E3s, maintaining the active site cysteine in a free form by avoiding alkylating agents and maintaining an optimal reducing environment are crucial to activity.

When performing IVT of E3s, other types of proteasome inhibitors may be substituted for MG132, which like ALLN is a peptide aldehyde. Other inhibitors to be considered include members of the vinyl sulfone family (Mc Cormack et al., 1997; Naujokat et al., 2000; Groll and Huber, 2004) and lactacystin (Imajoh-Ohmi et al., 1995; Maki et al., 1996), which continues to be considered a relatively specific inhibitor of proteasomes. Another approach to inhibiting proteasomes is use of the nonhydrolyzable ATP analog ATP-γ-S. Its use has declined with the discovery of inhibitors of specific proteasome inhibitors.

Anticipated Results

Activity assays

When testing E1 or E2s in thiolester formation assays with ubiquitin, activity is determined by the presence of a band on SDS-PAGE migrating at 8 kDa above the molecular weight of the unmodified protein. These bands are detected either as a radiolabeled [^{32}P]ubiquitin signal by autoradiography or as an anti-ubiquitin immunoreactive band. The samples are run under nonreducing conditions

in order to detect the ubiquitin thiolester. When a similar sample is resolved under reducing conditions, i.e. in the presence of 2-ME or DTT, the thiolester band should disappear (see Fig. 15.9.2). As the ubiquitin is often added in excess, the proportion of ubiquitin in the higher-molecular-weight form should be relatively low. On the other hand, the proportion of E1 or E2 in the higher-molecular-weight form should be relatively high. The activity of each E1 batch or each E2 will be relative to the percentage of active protein that was produced. The molecular weight of unmodified E1 from most sources is about 114 to 118 kDa; therefore expect the E1-ubiquitin thiolester to migrate at 122 to 126 kDa. While there is at least one E2 (Birc6) as large as 528 kDa, the molecular weight of E2s is typically 14 to 34 kDa. Therefore, bands representing E2 ubiquitin thiolesters run in the 22- to 42-kDa range. It appears in some cases that E2s may form multi-ubiquitin changes in the absence of E3, ube2K being the best example of this, and that some E2s may be self-modifying. Therefore, when looking at E2 activity, look carefully at all of the bands in the gel and consider which are disappearing (active-site thiolesters) and which cannot be reduced (ubiquitin chains or nonreducible ubiquitin modification of the E2).

E3 activity assays differ in that one is generally testing the ability of the E3 to be permanently modified. The ability of the E3 to modify itself with ubiquitin is determined by several factors. These include whether the E3 is folded properly and which E2 is present. For RING fingers, proper folding is often determined by the amount of zinc present. Most E3 proteins demonstrate some ability to modify themselves when employing ube2d1, ube2d2, or ube2d3 as the ubiquitin-conjugating enzyme; however, this is not always the case. When one has found a productive E2-E3 pair, the E3 may be modified by a single ubiquitin (monoubiquitylation), by a single ubiquitin on multiple lysines (multi-monoubiquitylation), or by ubiquitin chains (multi-ubiquitylation). Monoubiquitylation is indicated by a band migrating 8 kDa above the molecular weight of the unmodified E3. Multi-monoubiquitylation is determined by a ladder of bands separated by 8 kDa with the first band migrating 8 kDa above the molecular weight of the unmodified E3. Modification by multi-ubiquitin chains may resemble multiple monubiquitins or may result in a smear of ^{32}P or anti-Ub signal running up to the top of the gel. Which pattern is obtained sometimes depends upon the amount of E3 present. Less E3 will result in a smear, while an excess results in the laddering pattern.

Inhibition of ubiquitylation of protein and degradation

Mutation of the active site of E3s will often result in the stabilization of substrate, as is the case for p53 when Hdm2 is mutated. It will also stabilize the E3 itself. This is seen with Hdm2 and Siah1. However, the authors have not seen appreciable stabilization of AO7 with RING mutation.

siRNA knockdown of a protein can be detected by immunoblotting. An effective knockdown will show about 80% to 100% loss of the targeted protein. Using a plasmid-based method, knockdown may take up to 3 days. Using oligonucleotides, loss of protein may be detected in a matter of 8 hr. This is based upon using Ambion's pSilencer vector in combination their Silencer oligonucleotide kit. This does not, however, mean that all genes will act the same way. Regardless of the method used, the loss of the gene product should be monitored for several days to determine optimal time required for maximum effect.

If the degradation that is observed is truly the result of 20S proteasome activity, expect to see an increase in protein level with samples exposed to ALLN, MG132, and lactacystin. Ammonium chloride and ALLM should show no difference when compared to untreated control samples. If lysosomal proteins are involved, only ammonium chloride is expected to increase the level of the target protein. If calpains are responsible for degrading the target protein, expect to see increased protein levels with ALLN, ALLM, and MG132, but not with lactacystin.

E1 production

When producing E1 in a baculovirus system, three 175-cm^2 flasks of *Sf*9 cells should produce 4.5 to 5 ml of crude lysate. After purification, this should produce 3.5 to 5 ml of eluate and 7 to 10 ml of glycerol stock. The amount of protein produced will vary, but should be in the range of 40 to 50 μg E1 per ml of glycerol stock. An important factor to keep in mind is that not all of the protein will be active; therefore a small amount should be tested to determine its relative activity.

E2 production

From a 100-ml culture of a 28-kDa protein, e.g., glutathione-*S*-transferase, expect as much as 250 μg of protein. For a larger protein,

e.g., E2-230K, a 100-ml culture may produce closer to 2.5 μg. Any purification will generally reduce the overall yield. For expression of E2s in IVT systems, incorporation of radioactivity will depend upon the number of methionines in the protein. For example E2D2 (UbcH5B) contains four methionines in a 148-amino acid protein (2.7%), while E2G2 (MmUbc7) contains nine in a 166-amino acid protein (5.4%). However, the authors generally see about 10,000 to 20,000 cpm/μl for E2D2 representing 1 to 2 fmol/μl of radiolabeled E2, assuming that radioactive methionine is incorporated evenly into each molecule. A sample calculation is shown below. It assumes that the scintillation counter detects methionine with 100% efficiency, e.g., radioactive methionine is (1000 Ci/mmol) (2.2×10^6 dpm/μCi) = 2.2×10^{15} dpm/mmol. 10,000 cpm/2.2×10^{15} dpm/mmol = 4.54×10^{-12} mmol or 4.54 fmol methionine incorporated. However, this represents total incorporated methionine. With four methionines/molecule, the total number of labeled molecules will be 25% of the total or (4.54 fmol)(25 %) = 1.14 fmol of radioactive E2.

E3 production

Results for E3 production in bacteria are expected to be similar to those for E2 production. The single most significant factor determining yields of E3 appears to be the size of the protein. Larger proteins often require longer induction, lower temperatures, and more inducing agent in order to get yields comparable to much smaller proteins. For example, it is possible to purify c-cbl, a 90-kDa protein, at 1 μg/ml from a 100 ml culture. AO7, a 50-kDa protein, can be purified at 20 μg/ml.

When expressed in in vitro translation systems, radiolabeled E3s may be produced at a rate proportional to their size and the number of naturally occurring methionine residues in the protein. Typically 1 μl of a 50 μl in vitro translation mixture will incorporate between 10,000 cpm and 100,000 cpm of [^{35}S]methionine.

Time Considerations

Most of the activity assays described in this unit require up to 2 hr to prepare the E3s on glutathione-Sepharose, 1 to 3 hr to carry out the reaction, 1 to 2 hr to perform gel electrophoresis, 1 hr to dry gels, and 5 min to overnight to detect radioactive signals. Therefore, a typical in vitro E3 reaction will require ~1 day. Less time is required when performing E1 or E1-E2 thiolester assays because there is no E3 preparation time and the reactions are incubated only 5 min. Thiolester formation can be done in less than 4 hr. Expression of proteins in bacteria is by far the most common method used in the authors' laboratory. Typically, researchers should schedule a week ahead if they will require fresh as opposed to thawed proteins. Preparation of radiolabeled proteins by in vitro translation can require as little as 3 hr if using a commercial kit or 8 hr if it is necessary to make the RNA first. Baculovirus preparation of E1 or multi-subunit E3s is by far the most time-consuming method that the authors use. This may require 17 days total with 5 days for virus production, 8 days for virus titering, 3 days for infection to produce protein, and an additional day to lyse cells, collect protein lysates, and purify the protein of interest.

For detecting protein ubiquitylation in cells, direct immunoblotting can be done in 1 day. If immunoprecipitation is required, an additional 1 day is needed to let antibody bind to protein A or G beads (2 to 4 hr) and to let target protein bind to immobilized antibody (1 to 4 hr). When transfection of E2, E3, or ubiquitin is involved, an additional 2 days are need to seed the cells and allow transfected proteins to be expressed in cells.

Measuring Retrograde Transport to the *Trans*-Golgi Network

After internalization from the plasma membrane, most molecules are delivered to early/recyling endosomes. From here, two principle routes have been described: (1) the molecules return to the plasma membrane, or (2) they are targeted to late endosomes/lysosomes for degradation. Some molecules can escape recycling and degradation, however, and reach other compartments in the cell, such as the Golgi apparatus, the endoplasmic reticulum (ER), and in some instances the cytosol. This pathway is termed the retrograde route (Johannes and Goud, 1998).

Shiga toxin was the first protein that was convincingly shown to be transported from the plasma membrane to the ER (Sandvig et al., 1992). The initial morphological observation was later confirmed using protein biochemistry (Johannes et al., 1997). Similar observations were described for the protein toxins ricin (Rapak et al., 1997) and cholera toxin (Fujinaga et al., 2003). Some endogenous proteins can also traffic between endosomes and the *trans*-Golgi network (TGN), and in the case of TGN38 and the mannose-6 phosphate receptors, evidence was provided that they, at least in part, use the same pathway as Shiga toxin (Ghosh et al., 1998; Mallard et al., 1998; Saint-Pol et al., 2004).

The receptor-binding non-toxic B-subunit of Shiga toxin (STxB) has proven a valuable marker for the retrograde route. Indeed, STxB-based tools permit morphological and biochemical characterization of retrograde transport. In a previous methods report (Mallard and Johannes, 2003), the authors described experimental set-ups for the purification of STxB and quantification of its endocytosis and retrograde transport to the TGN and the ER. In this unit, the authors describe the extension of STxB methodology to the generalized study of cargo-protein transport between early/recycling endosomes and the TGN (sulfation-site peptide coupling to model cargo proteins; see Support Protocol 1). Basic Protocol 1 describes the measure of early/recycling endosomes-to-TGN transport in intact cells, using the sulfation assay. The Alternate Protocol details a method to study early/recycling endosomes-to-TGN transport on permeabilized cells. Support Protocol 2 describes the preparation of Tris-tricine mini gels, which are used to analyze low-molecular-weight protein substrates. Support Protocol 3 elaborates on the chemical coupling scheme by introducing full-size horseradish peroxidase (HRP) onto STxB for whole mount ultrastructural analysis of the Shiga toxin–containing early/recycling endosome (Saint-Pol et al., 2004). Finally, an improvement of the STxB endocytosis assay is explained in Basic Protocol 2.

QUANTITAVE ASSAY TO MEASURE RETROGRADE TRANSPORT OF CARGO PROTEINS IN INTACT CELLS

BASIC PROTOCOL 1

The STxB-based sulfation assay for the retrograde route, as described previously (Johannes et al., 1997; Mallard et al., 1998), is based on the use of a STxB variant to which a tandem of protein sulfation recognition sites is added by genetic fusion. Bacteria lack sulfotransferase activity, and STxB-Sulf2 is purified as a non-sulfated protein. Upon retrograde transport to the TGN in higher eukaryotic target cells, STxB-Sulf2 becomes the substrate of a *trans*-Golgi/TGN localized sulfotransferase that catalyzes the post-translational transfer of radioactive sulfate from the medium onto a tyrosine residue within the sulfation recognition sites. After cell lysis, immunoprecipitation, and gel electrophoresis, sulfated STxB-Sulf2 can be detected and quantified.

Current Protocols in Cell Biology (2006) 15.10.1-15.10.21

The sulfation reaction on sulfation-site-modified cargo protein allows the detection and quantification of its arrival in the TGN, following binding to cells and uptake at the plasma membrane. The sulfation reaction protocol on intact cells is described below. The Alternate Protocol describes a permeabilized cell assay for the study of early/recycling endosomes-to-TGN transport step.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Materials

HeLa cells
DMEM3+ (see recipe)
DMEM without sulfate (Invitrogen), cold and 37°C
Sulfation substrate: e.g., STxB-Sulf2, CTxB-Sulf2, *or* anti-GFP-Sulf2 (see Support Protocol 1)
Radioactive sulfate ($^{35}SO_4^{2-}$; Amersham Pharmacia Biotech, specific activity of at least 50 μCi/μl)
RIPA buffer (see recipe)
Protease inhibitor cocktail (PIC; see recipe)
13C4 monoclonal anti-STxB antibody (hybridoma from ATCC #CRL 1794)
Protein G–Sepharose beads 4 fast flow (Amersham Pharmacia Biotech) equilibrated with RIPA buffer
Streptavidin agarose beads (Pierce) equilibrated with RIPA buffer
Washing buffer: 50 mM Tris·Cl, pH 8.0
1.5× SDS sample buffer
Tris-tricine mini-gels (see Support Protocol 2)
Fixation buffer: 40% ethanol, 10% acetic acid

24-well tissue culture dishes
37°C, 5% CO_2 incubator
1.5-ml tubes
End-over-end rotator
Glass microfiber GF/C filters
Microbeta scintillation counter
Thermal cycler
Micropipettor
Gel dryer
PhosphorImager and appropriate screens

Prepare cells

1. Prior to starting the experiment (12 to 15 hr before start), plate 1×10^5 HeLa cells in 1 ml DMEM3+ in each well of a 24-well tissue culture dish.
2. To deplete endogenous sulfate, wash cells three times with 0.5 ml DMEM without sulfate per well.
3. Replace the medium with 0.5 ml DMEM without sulfate per well and incubate cells 90 min in a 37°C, 5% CO_2 incubator.

Perform sulfation

4. Place cells on ice and replace the medium with 0.25 ml ice-cold DMEM without sulfate and containing a sulfation substrate, e.g., 1 μM STxB-Sulf2, 1 μM CTxB-Sulf2, or 15 μg/ml anti-GFP-Sulf2. Incubate cells 30 min on ice.
5. Discard medium and wash three times with 0.5 ml cold DMEM without sulfate.

6. To allow internalization, replace medium with 0.25 ml of 37°C DMEM without sulfate and containing 0.5 mCi/ml $^{35}SO_4^{2-}$. Incubate in a 37°C, 5% CO_2 incubator (typically 20 to 40 min).

7. Put cells on ice and wash three times with 0.5 ml of ice-cold DMEM.

Immunoprecipitate the marker

8. Lyse cells as follows:

   a. Place 24-well tissue culture dishes on ice.

   b. To each well, add 0.5 ml of ice-cold RIPA buffer containing 1× PIC.

   c. Use a pipet tip to scrape off cells and transfer lysates to 1.5-ml tubes.

   d. To each well, add another 0.5 ml of ice-cold RIPA buffer containing 1× PIC and transfer to 1.5-ml tubes.

9. For STxB, add 10 μg/ml 13C4 monoclonal anti-STxB and 80 μl protein G–Sepharose beads to the cell lysate. For anti-GFP-Sulf2, add 80 μl protein G–Sepharose beads to the lysates. For CTxB, add 100 μl strepavidin agarose. Incubate with end-over-end rotation for ≥90 min at 4°C.

   The used marker is immunoprecipitated. STxB-Sulf2 is immunoprecipitated with anti-STxB antibody and protein G-Sepharose beads, whereas, anti-GFP-Sulf2 or CTxB-Sulf1, which contains biotin, is directly immunoprecipitated by protein G-Sepharose beads or streptavidin agarose beads, respectively.

10. Centrifuge tubes 2 min at 800 × *g*, 4°C.

11. Aspirate supernatant, add 1 ml of washing buffer, gently resuspend beads, and centrifuge again as in step 10.

Determine total sulfation counts

12. Precipitate 900 μl of supernatant by adding 100 μl of 100% trichloroacetic acid (TCA). Incubate at least 1 hr at 4°C.

13. Filter on glass microfiber GF/C filters.

14. Count filters in a Microbeta scintillation counter.

    At this step, the supernatant contains all of the proteins that have not been immunoprecipitated, i.e., endogenous proteins. Among these proteins, some, such as the proteoglycans, are natural substrates for sulfotransferase and thus have been labeled by radioactive sulfate during the assay. Precipitating and filtrating the supernatant permits measurement of the amount of radioactivity of endogenous proteins. It defines the total sulfation level. If it is assumed that this level is equal in all conditions (only the retrograde transport and thus the sulfation of the marker should be affected), it can be used to normalize the results. It compensates for the variation of sulfotransferase and cell number that could be induced by cell treatments (e.g., siRNA, drugs).

Analyze sulfated substrate

15. Dry beads by removing the fluid around the beads with a microsyringe, and immediately add 25 μl of 1.5× SDS sample buffer without reducing agent.

16. Resuspend beads by briefly vortexing, heat 5 min to 95°C in a thermal cycler.

17. Load the samples (all 25 μl) on Tris-tricine mini gels using a microsyringe.

18. Connect the power supply to the electrophoresis cell and run for 1.5 hr at 25 mA for each 1-mm gel.

19. Fix gel for 20 min in fixation buffer.

20. Dry the gel (2 hr at 70°C) and expose it in a PhosphorImager cassette.

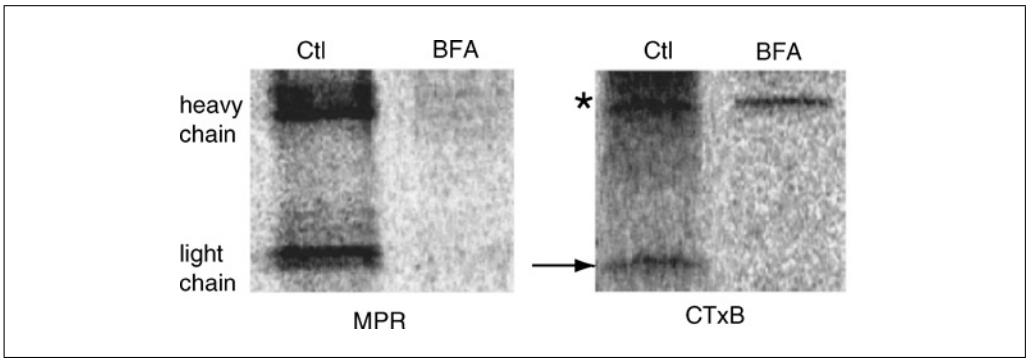

Figure 15.10.1 Sulfation analysis using sulfation site peptide–tagged CTxB and anti-GFP antibody. Note that brefeldin A (BFA) treatment prevents sulfation. The arrow indicates the sulfation product of sulfation-site peptide–tagged CTxB. The asterisk indicates high-molecular-weight material that has not entered the gel.

21. Quantify bands corresponding to sulfated STxB-Sulf$_2$ or other sulfated substrate.

Figure 15.10.1 shows a typical sulfation analysis experiment using CTxB-Sulf2 or anti-GFP-Sulf2. Both proteins are sulfated when incubated with HeLa cells. In the case of anti-GFP-Sulf2, HeLa cells were used that stably express GFP-tagged MPR300 (Waguri et al., 2003). Brefeldin A strongly alters Golgi structure and inhibits retrograde transport (Mallard et al., 1998). Under these conditions, an inhibition of CTxB and anti-GFP sulfation is observed.

ALTERNATE PROTOCOL

PERMEABLIZED CELL ASSAY FOR MEASURING TRANSPORT OF CARGO PROTEINS FROM EARLY/RECYCLING ENDOSOMES TO THE TGN

This protocol describes a permeabilized cell assay that reconstitutes early/recycling endosomes-to-TGN transport of STxB under conditions that allow modification of the activity of the cytosol using macromolecular tools (Mallard et al., 2002). In this assay, STxB-Sulf2 is internalized into early/recycling endosomes of HeLa cells at low temperature (19.5°C), conditions under which retrograde transport to the TGN is inhibited. After permeabilization of the plasma membrane using streptolysin O (SLO), cells are shifted to 37°C in the presence of exogenous cytosol, an energy regeneration system, radioactive sulfate, and tools that allow modification of the activity of the cytosol (e.g., antibodies, mutant proteins, peptides). At the end of the sulfation reaction, cells are lysed and radiolabeled sulfated STxB-Sulf2 is analyzed by SDS-PAGE.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

Additional Materials *(also see Basic Protocol 1)*

HeLa S3 cells for cytosol preparation
Phosphate-buffered saline (PBS)
HK buffer (see recipe)
ICT/DTT buffer (see recipe), ice cold and at 37°C
Streptolysin O (SLO; see recipe)
ATP-regenerating system (see recipe)

Potter-Elvehjam homogenizer
Ultracentrifuge
15- and 50-ml tubes
Dialysis membrane (10 kDa MWCO)
1.5-ml microcentirifuge tubes

Prepare HeLa cell cytosol

1. Pellet at least 10^9 HeLa S3 cells 5 min at 300 × *g*, 4°C.
2. Wash cells three times with 50 ml PBS centrifuging as in step 1.
3. Resuspend the cells in ice-cold HK buffer supplemented with protein inhibitor cocktail (PIC): 1 vol buffer for 1 vol cells.
4. Homogenize cells using a bead homogenizer (e.g., from HGM) or a Dounce homogenizer. Homogenize up and down ~25 times on ice. Check the completeness of homogenization by trypan blue exclusion (*UNIT 1.1*). Transfer the homogenate to a 15-ml tube.
5. Centrifuge the homogenate 5 min at 3000 × *g*, 4°C. Transfer the supernatant to a 15-ml tube.
6. Centrifuge the supernatant 45 min at 100,000 × *g*, 4°C. Collect the supernatant.
7. Using a 10-kDa dialysis membrane, dialyze the supernatant three times against 2 liters of ICT/DTT buffer at 4°C. Change dialysis buffer every 2 hr. Freeze at −80°C.

Collect and treat cells for in vitro transport assay

8. Before the start of the experiment (16 hr before), plate 1.2×10^5 cells/well in 24-well tissue culture plates.
9. Wash cells three times with 0.5 ml of sulfate-free DMEM using a Pasteur pipet to remove the medium.
10. Incubate cells in sulfate-free DMEM 90 min in a 37°C, 5%$C0_2$ incubator.

    This is the sulfate starvation step.

Bind STxB-Sulf2 to cells

11. Place cells on ice and incubate 30 min with 1 μM STxB-Sulf2 in sulfate-free DMEM.

    This allows cell-surface binding of STxB-Sulf2.

12. Shift cells to 19.5°C for 40 min.

    At this temperature, STxB accumulates in early/recycling endosomes.

13. Place cells on ice again and wash three times with 0.5 ml of 4°C ICT/DTT buffer.

Permeabilize cells

14. To each well, add 250 μl SLO at 2 μg/ml in ICT/DTT buffer. Incubate 10 min on ice.

    The SLO reagent binds to the plasma membrane. After the shift to 37°C (step 16), the plasma membrane is permeabilized. Endogenous cytosol diffuses out of the cell.

15. Maintain cells at 4°C and wash cells three times with 0.5 ml of 4°C ICT/DTT buffer.

    This will remove the free SLO.

16. Add 0.5 ml of pre-warmed ICT/DTT buffer at 37°C to each well, and then transfer plate to 37°C for 10 min.

Carry out transport assay

17. Add transport mix containing ATP-regenerating system, 1 mCi/ml (^{35}S)sulfate, 3 mg/ml of HeLa cell cytosol, and STxB-Sulf2 in ICT/DTT buffer.
18. Incubate cells 30 min at 37°C.

    In this condition, the STxB-Sulf2 will be transported to TGN and sulfated.

19. Place cells on ice and gently wash each well once with 0.5 ml of ice-cold ICT/DTT.

Collect and analyze labeled proteins

20. Lyse cells two times with 0.5 ml RIPA/PIC buffer and transfer lysed cells to 1.5-ml microcentrifuge tubes containing: 10 μg/ml 13C4 anti-STxB antibody and 80 μl of protein G–sepharose beads equilibrated in RIPA buffer.

21. Continue experiment as described in Basic Protocol 1, steps 15 to 21.

SUPPORT PROTOCOL 1

CHEMICAL COUPLING OF PROTEINS WITH SULFATION SITES INTO A PROTEIN OF INTEREST

The following protocol describes an adaptation of the sulfation methodology to other cargo proteins of the retrograde route. The genetic fusion approach is replaced by a chemical coupling procedure that allows the introduction of peptides with sulfation sites onto purified proteins. In some instances, the model cargo has free sulfhydryl groups, and the sulfation peptide can be coupled in a one-step reaction. In other instances, it is necessary to first introduce free sulfhydryls onto the molecule of interest, followed by sulfation-site peptide coupling. This protocol uses the *N*-succinimidyl *S*-acetylthioacetate (SATA) reagent for introducing sulfhydryl groups onto proteins. The advantages are: (1) SATA reacts with molecules in nondenaturing conditions; (2) it introduces stable and covalent links through the interaction of its *N*-hydroxysuccinimide function with primary amines of the protein to yield an amide bond; and (3) the sulfhydryl group introduced is protected, which reduces the risk of intra- or inter-chain disulfide bonding. This protocol is written for two proteins that do not have natural free sulfhydryl groups. The first protein is the B-subunit of cholera toxin. Cholera toxin has the same subunit structure as Shiga toxin. Its homopentameric B-subunit (CTxB) binds to the glycosphingolipid GM1. GM1-bound CTxB is targeted from the plasma membrane to the ER, via the TGN/Golgi apparatus (Fujinaga et al., 2003), as described for STxB. The second protein is an antibody directed against the GFP moiety of a fusion protein between GFP and the cation-independent mannose 6-phosphate receptor (CI-MPR). A cell line has been described that stably expresses GFP-CI-MPR (Waguri et al., 2003). A recent work showed that this protein follows the retrograde route (Saint-Pol et al., 2004).

The experimental procedures of the coupling strategy are described below and are illustrated in Figure 15.10.2.

Materials

N-Succinimidyl *S*-acetylthioacetate (SATA; Pierce)
Dimethyl sulfoxide (DMSO)
Protein of interest; e.g., CTxB and anti-GFP antibody
50 mM sodium phosphate/1 mM EDTA buffer, pH 7.5
Bromoacetylated sulfation site peptide with or without biotin group (see Fig. 15.10.1)
10× deacetylation solution (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Dialysis cassettes: 10-kDa molecular weight cutoff (MWCO; Pierce), optional
PD-10 desalting columns (Amersham Pharmacia Biotech), optional
Additional reagents and equipment for measuring protein concentration using the Bradford assay (*APPENDIX 3H*) and SDS-PAGE (*UNIT 6.1*)

NOTE: Should the cargo protein naturally contain free sulfhydryl groups, such as in STxB/Cys, start at step 6.

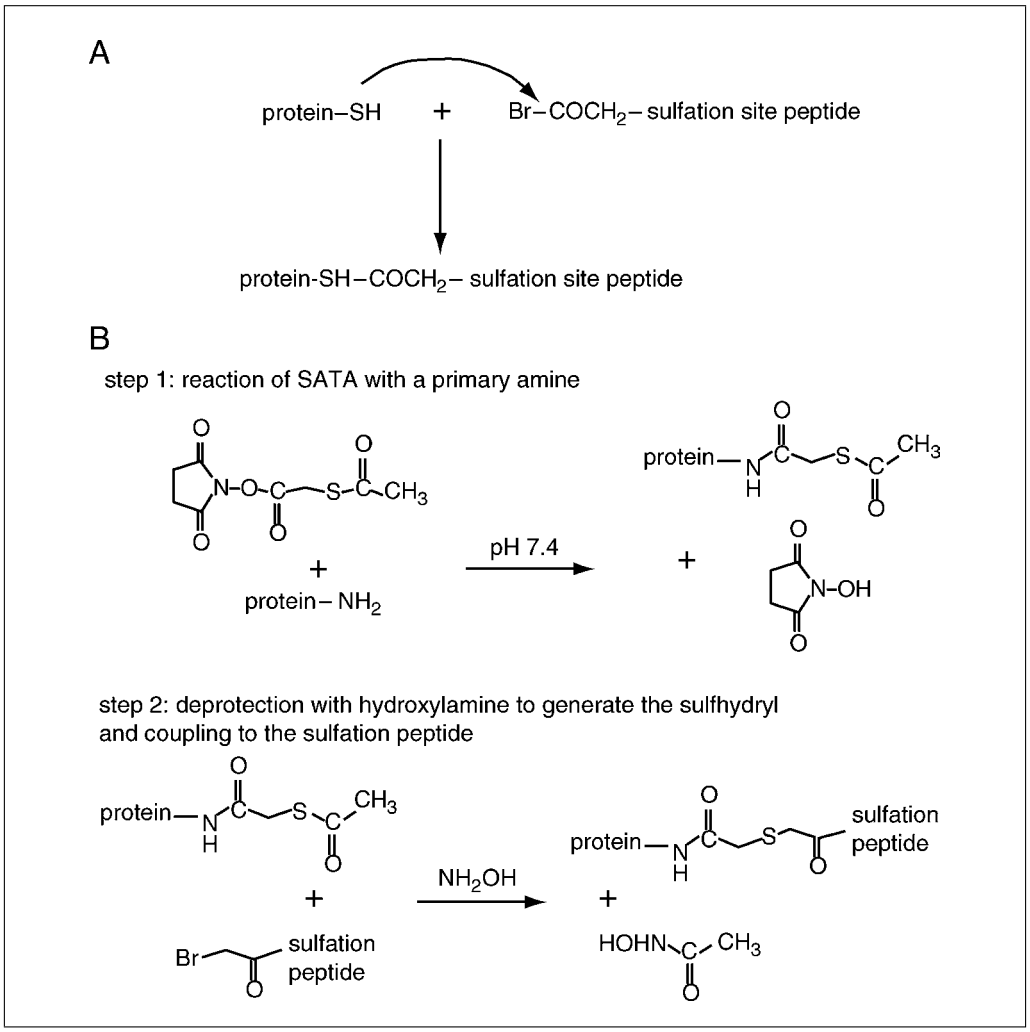

Figure 15.10.2 Experimental strategies for coupling sulfation site peptides to cargo proteins. (**A**) One-step reaction of bromoacetylated peptides with cargo proteins carrying free sulfhydryl groups (e.g., STxB/Cys). (**B**) Reaction scheme for introducing protected sulfhydryl groups onto cargo proteins (step 1) followed by concomitant deprotection and sulfation site peptide coupling (step 2). Sulfation peptide sequence: BrCOCH2-TSEEPEYGEEEPEYGEE(±biotin).

Modify sulfhydryl group

1. Prepare SATA stock solution at 100 mM in DMSO.
2. Prepare the protein of interest in 50 mM sodium phosphate/1 mM EDTA buffer, pH 7.5, at a concentration of 50 to 100 μM.

   For CTxB and anti-GFP antibody, the authors have worked with solutions at 100 μM and 50 μM, respectively. Typical volumes of coupling reactions are 20 to 200 μl.
3. Add the SATA reagent to the protein sample.

   In general, use a ten-fold molar excess of the SATA reagent over the protein when the protein concentration is >5 mg/ml. If the protein concentration is <5 mg/ml, try to concentrate it using Nanosep 10-kDa microconcentration chambers (PallFiltron), otherwise add 20- to 50-fold-molar excess of SATA reagent.

   For CTxB and anti-GFP antibody, the concentration is ~5 mg/ml.

   Typically, the volume of DMSO should not exceed 10% of the final reaction volume.

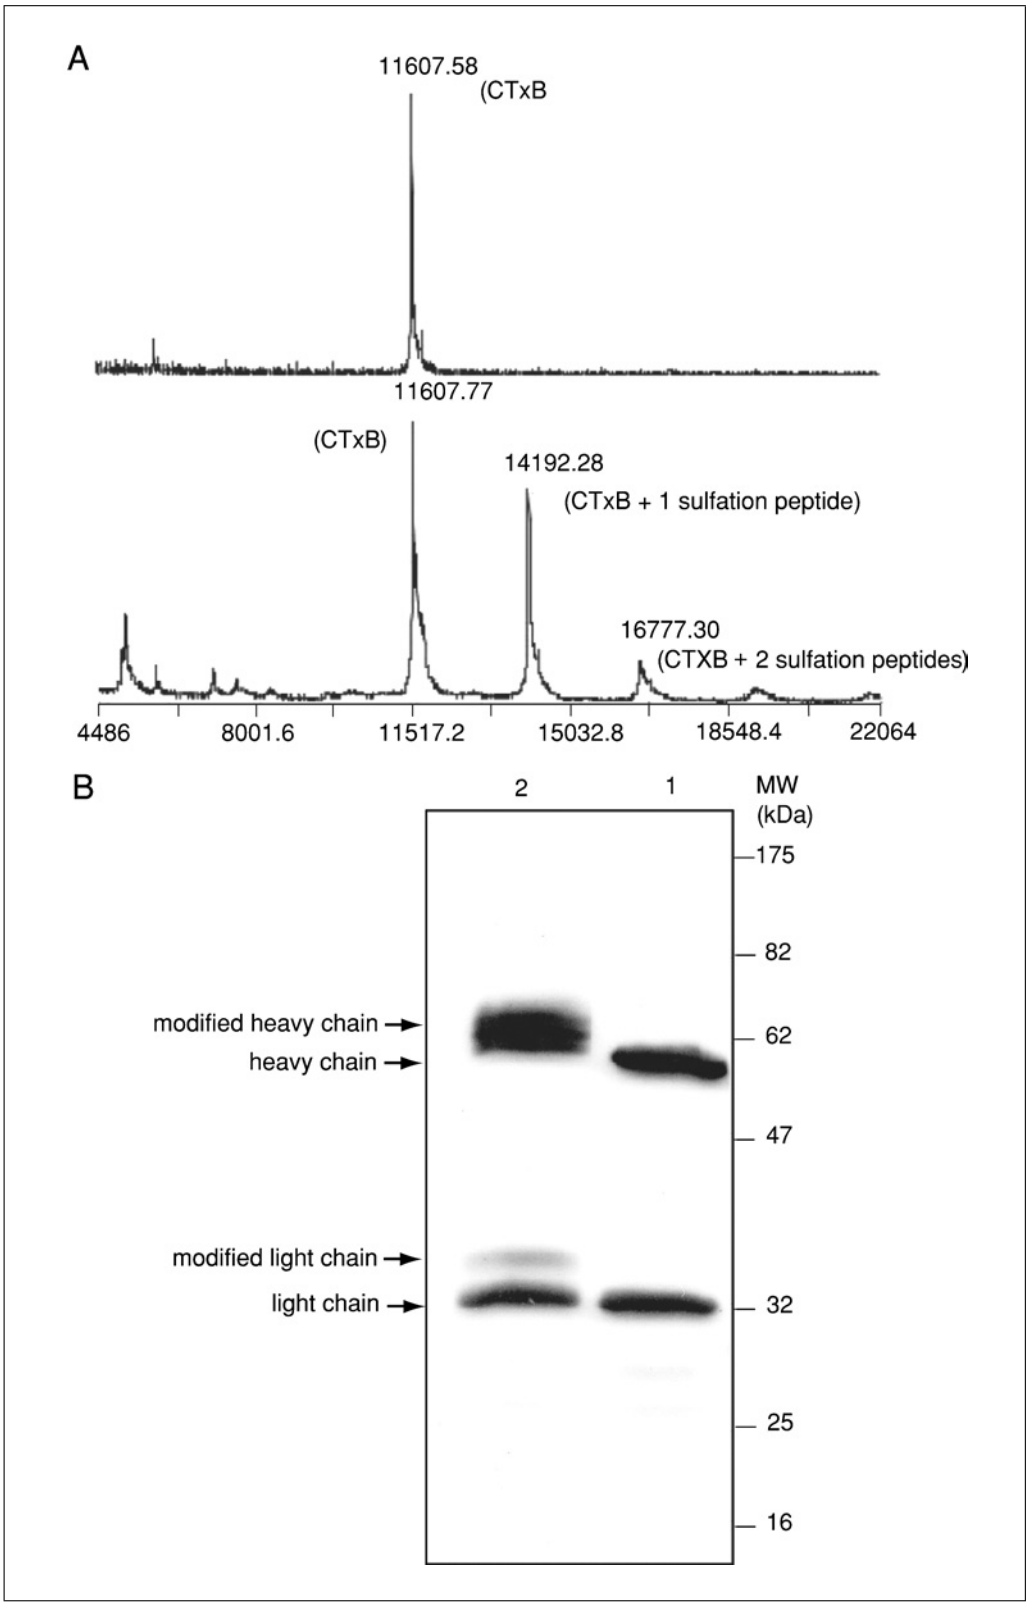

Figure 15.10.3 Analysis of sulfation-site peptide coupling to CTxB and anti-GFP antibody. (**A**) MALDI-TOF analysis of uncoupled CTxB (upper panel) and sulfation-site peptide coupled CTxB (lower panel). Note that after sulfation-site peptide coupling, some B-chains remain unmodified, some carry one sulfation-site peptide, and exceptionally also two sulfation-site peptides. Because CTxB is a homopentamer of B-chains, it is reasonable to assume that statistically, at least one sulfation site coupled B-chain is present per pentamer. (**B**) Western analysis of uncoupled (lane 1) and sulfation site peptide–coupled (lane 2) anti-GFP antibody. Unmodified and sulfation site peptide–modified heavy and light chains are indicated by arrows.

4. React for 30 min at room temperature gently shaking in a rotary incubator.
5. Remove uncoupled SATA reagent by dialysis three times, 1 hr each time, against 0.5 liters of 50 mM sodium phosphate/1 mM EDTA buffer, pH 7.5, with 10-kDa MWCO dialysis cassettes or by gel filtration through a PD-10 desalting column equilibrated with 25 ml of 50 mM sodium phosphate/1 mM EDTA buffer, pH 7.5.

Couple bromoacetylated sulfation-site peptide

6. Measure the concentration of activated protein using the Bradford assay (*APPENDIX 3H*), and incubate with ten-fold molar excess of the bromoacetylated sulfation-site peptide in presence of 1× deacetylation solution.

   In the case of CTxB, use biotin-tagged bromoacetylated sulfation-site peptide.

   Should the cargo protein naturally contain free sulfhydryl groups, the deacetylation solution can be omitted.

7. React 2 hr at room temperature gently shaking in a rotary incubator.
8. Then dialyze against PBS buffer to remove hydroxylamine and free peptide.
9. Determine the yield of the conjugation reaction either by MALDI-TOF mass spectroscopy for small proteins (typically <25 kDa) or by SDS-PAGE (*UNIT 6.1*) analysis for large proteins such as antibodies.
10. Snap freeze proteins in liquid nitrogen and store at −20°C.

    Figure 15.10.3A presents the MALDI-TOF analysis of sulfation site peptide coupling to CTxB. The authors estimate that about two B-chains per pentamer are sulfation-site peptide modified. Figure 15.10.3B presents the results of sulfation-site peptide coupling to anti-GFP antibody. The sulfation-site peptide–modified antibody is indicated by an arrow.

PREPARING TRIS-TRICINE GELS

SUPPORT PROTOCOL 2

Tris-tricine gels are adapted for low-weight proteins. They are used to separate sulfated STxB or CTxB from radioactive contaminants such as free radiolabeled sulfate or sulfated endogenous proteins remaining after immunoprecipitation.

Materials

Acrylamide solution A (see recipe)
Tris-tricine gel buffer (see recipe)
Glycerol
10% (w/v) ammonium persulfate (APS) solution in water
Tetramethyl-1-,2-diaminomethane (TEMED)
Acrylamide solution B (see recipe)
10× cathode buffer (see recipe)
10× anode buffer (see recipe)
Glass plates and electrophoresis apparatus (BioRad)
Pasteur pipets
Teflon combs
Glass microfiber GF/C filters (Whatman)

Prepare separating Tris-tricine gels

1. Assemble the glass-plate sandwich of the electrophoresis apparatus according to manufacturer's instructions.

2. Prepare the separating gel. For two BioRad gel chambers:

   1.7 ml acrylamide solution A
   1.7 ml Tris-tricine gel buffer
   0.7 g glycerol
   1.1 ml water
   Mix and add 50 μl of 10% APS solution and 5 μl TEMED.

3. Immediately apply separating gel solution to gel chamber, using a Pasteur pipet.
4. Slowly cover the top of the gel with water.

   The overlay provides an oxygen-free environment that favors polymerization.

5. Allow the gel to polymerize 30 to 60 min at room temperature.
6. Pour off the water.

Prepare stacking gel

7. Prepare the stacking gel solution as follows:

   0.24 ml acrylamide solution B
   0.78 ml Tris-tricine gel buffer
   2 ml water
   Mix and add 24 μl of 10% APS solution and 2.4 μl TEMED.

8. Immediately pour stacking gel solution into gel chamber, above the separating gel, using a Pasteur pipet.
9. Insert a Teflon comb. If necessary, add additional stacking gel to fill gel chamber completely.
10. Allow the stacking gel solution to polymerize 30 to 60 min at room temperature.

    The gel can be stored for 1 day at 4°C wrapped in humidified tissue.

11. Carefully remove the Teflon comb. Rinse wells with water. Mount gel in the apparatus.
12. Fill the internal buffer chamber with 10× cathode buffer and fill the external buffer chamber with 10× anode buffer.

SUPPORT PROTOCOL 3

CHEMICAL COUPLING OF HRP TO STxB

This protocol describes a method for the chemical coupling of horseradish peroxidase (HRP) to STxB for use in whole-mount experiments. The whole-mount technique allows an ultrastructural analysis of membrane systems that have been fixed from inside using an HRP-catalyzed polymerization reaction. Due to the possibility of removing endogenous cytosol before general fixation, no ultrafine sectioning is required, and cells can be analyzed, as a whole, under the electron microscope. Immunolabeling permits the detection of antigens on the cytosolic side of membranes. For the endocytic membrane system, the study by Stoorvogel and colleagues (Stoorvogel et al., 1996) was a milestone. The authors have recently adopted the whole-mount technique to the Shiga toxin–containing early/recycling endosomes (Saint-Pol et al., 2004).

For this purpose, a STxB variant is used in which a cysteine residue is placed at the C-terminus to avoid the formation of inter-chain disulfide bonds. This variant is termed STxB/Cys (Haicheur et al., 2003). The coupling reaction between HRP and STxB/Cys is performed in two steps using the heterobifunctional crosslinking agent

MBS (maleimidobenzoyl-*N*-hydroxusuccinimide ester). In the first step, MBS is reacted via its *N*-hydroxysuccinimide function with primary amines of HRP. After removal of free crosslinker, activated HRP reacts with STxB/Cys via its maleimide group. The coupling product is purified by gel filtration and immunoaffinity chromatography.

Materials

Horseradish peroxidase (HRP; Sigma-Aldrich)
Water-soluble crosslinker: sulfo-MBS (Pierce)
100 mM HEPES buffer, pH 7.4
PD-10 desalting columns (Sephadex G-25, Amersham-Pharmacia Biotech)
PBS/10 mM EDTA buffer, pH 8
100 μM STxB/Cys
1 M NH_4Cl
Superdex 200 (GE Bioscience)
13C4 monoclonal anti-STxB antibody (hybridoma from ATCC #CRL 1794)
Glycine buffer, pH 2.2

Nanosep 10-kDa microconcentration chambers for 0.1-0.5 ml (PallFiltron)
Gel filtration chromatography columns

Activate HRP

1. Reconstitute 10 mg of HRP in 500 μl HEPES buffer.
2. Dissolve 1 mg sulfo-MBS in 50 μl HEPES buffer. Immediately transfer to 450 μl HRP at 20 mg/ml in HEPES buffer.
3. React for 30 min at room temperature.
4. Equilibrate PD-10 desalting column with 25 ml PBS/10 mM EDTA buffer, pH 8.
5. Add the reaction volume onto the column. Elute in 0.5-ml aliquots using PBS/10 mM EDTA buffer, pH 8.
6. Monitor the protein elution using the Bio-Rad protein assay.

   The maleimide-activated HRP should elute in fractions six to nine.

7. If necessary, concentrate maleimide-activated HRP to 10 mg/ml, using the nanosep 10-kDa microconcentration chambers.

Couple HRP to STxB/Cys

8. Add 400 μl of 100 μM STxB/Cys in PBS/10 mM EDTA buffer, pH 8, to the maleimide-activated HRP. Incubate the reaction for 16 hr at room temperature in the dark.

   In the coupling reaction, the latter protein is in 5 molar excess over STxB/Cys.

9. Quench the reaction by adding 50 mM NH_4Cl.
10. Using HPLC chromatography, separate conjugated STxB/Cys-HRP from uncoupled STxB/Cys on a Superdex 200 gel filtration column. Remove uncoupled HRP using a 13C4 immunoaffinity column (monoclonal anti-STxB antibody). Elute this column with glycine buffer, pH 2.2 into tubes containing Tris·Cl, pH 7.4, and sodium hydroxide to neutralize the acidic eluate. Adjust pH after elution if necessary.
11. Characterize the coupling product by gel electrophoresis and western blotting.

    An example of whole-mount analysis using STxB/Cys-HRP in HeLa cells is represented in Figure 15.10.4.

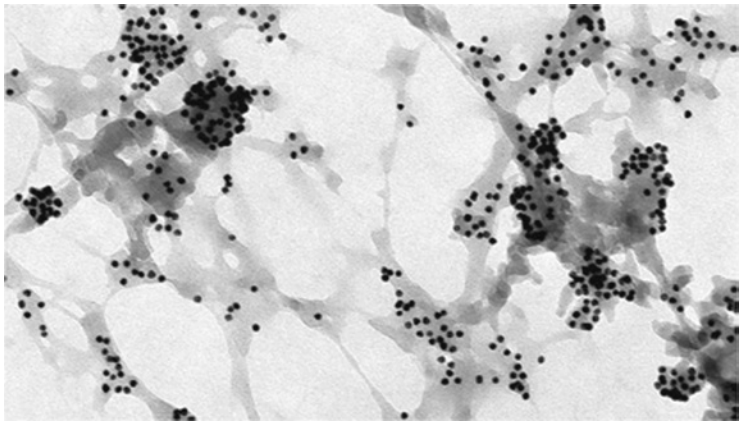

Figure 15.10.4 Whole-mount analysis of clathrin localization on early/recycling endosomes containing STxB-HRP. STxB-HRP-containing tubular membranes appear dark, due to the formation of the polymerization product. 10-nm gold particles indicate immunolocalization of clathrin.

BASIC PROTOCOL 2

STxB INTERNALIZATION ASSAY

This protocol describes a recent improvement to a previously described endocytosis assay for STxB (Mallard and Johannes, 2003).

A STxB variant, termed STxB-K3, which carries three lysine residues at the C-terminus, is biotinylated using cleavable NHS-SS-biotin reagent, yielding STxB-K3-SSbiot (see Support Protocol 4). This protein is bound on ice to plasma membrane Gb3, the cellular Shiga toxin receptor. After a shift to 37°C for variable times, cells are placed on ice again and treated, or not, with the membrane-impermeable reducing agent MESNA. After cell lysis, biotinylated STxB is revealed using ELISA. The ratio of the signal obtained on MESNA-treated cells over total signal in MESNA-untreated cells reflects the endocytosis of STxB at each time point. The endocytosis of transferrin is tested in parallel on the same cells as a marker for clathrin-dependent endocytosis.

Materials

HeLa cells
PBS++ (see recipe)
DMEM without serum, 37°C
Phospahte-buffered saline (PBS; *APPENDIX 2A*)
PBS/2mM EDTA
PBS++ supplemented with 5 mM glucose, room temperature and ice cold
STxB-K3, biotinylated (STxB-K3-SSbiot; see Support Protocol 4)
Transferrin, biotinylated (transferrin-SSbiot)
MESNA buffer (see recipe)
300 mM iodoacetamide (Sigma) in TNB buffer (see recipe for TNB buffer)
Blocking buffer (see recipe)
13C4 monoclonal antibody anti-STxB (hybridoma from ATCC #CRL 1794) *or* polyclonal anti-transferrin antibody (Les Makin)
Saturation buffer (see recipe)
Streptavidin-conjugated HRP (Roche)
Hydrogen peroxide solution (H_2O_2, Sigma)
O-Phenylenediamine tablets (OPD, Sigma)
Citrate buffer (see recipe)
6 N hydrogen sulfate (H_2SO_4)

15-cm petri dishes
37°C, 5% CO_2 incubator
PD-10 columns desalting (Sephadex G-25, Pharmacia Biotech)
Centrifuge
1.5-ml microcentrifuge tubes
96-well ELISA dishes
Microtiter plate reader

Additional reagents and equipment for cell counting (*UNIT 1.1*)

Prepare cells for assay

1. Plate 1×10^6 HeLa cells/dish 2 days before the experiment. Allow the cells to reach 80% confluency (5×10^6 cells/dish) on the day of the experiment.
2. Wash two dishes of cells two times with 10 ml of PBS++ per dish, then add 15 ml of pre-warmed DMEM without serum to each dish of cells. Incubate 1 hr in a 37°C, 5% CO_2 incubator.

   This is the serum starvation step.

3. Wash cells two times with 10 ml PBS and once with 8 ml PBS/2 mM EDTA. Incubate 10 min in 1 ml PBS/2 mM EDTA at 37°C.
4. Suspend detached cells in 10 ml of PBS++ supplemented with 5 mM glucose and count (*UNIT 1.1*).
5. Centrifuge 3×10^6 cells for 5 min at $300 \times g$, 4°C. Wash cells two times with 10 ml PBS++ supplemented with 5 mM glucose.

Label cell surfaces

6. Resuspend the cells in 300 µl ice-cold PBS++ supplemented with 5 mM glucose containing 0.5 µM STxB-K3-SSbiot and 200 nM transferrin-SSbiot. Incubate 30 min at 4°C. Mix cells gently every 5 min to prevent sedimentation.

   This is the cell surface binding step.

7. Dilute the cells in 12 ml PBS++ supplemented with 5 mM glucose and wash two times with 12 ml PBS++ supplemented with 5 mM glucose, centrifuging 5 min at $300 \times g$, 4°C.

   This step allows for the removal of unbound STxB-K3-SSbiot and unbound transferrin-SSbiot.

Perform endocytosis assay

8. Resuspend cells in 500 µl PBS++ supplemented with 5 mM glucose and transfer 50-µl aliquots to 1.5-ml microcentrifuge tubes, eight per time point.

   Typically, endocytosis is tested in duplicate at 0, 5, 10, 20, and 40 min. For a typical experiment (with or without MESNA buffer, control versus experimental condition, each point in duplicate), eight tubes per time point are used.

9. Incubate cells at 30°C or 37°C for the indicated times, then place tubes on ice.

   Endocytosis is slower at 30°C, which may allow for easier detection of differences between conditions.

10. To half of the tubes, add 50 µl MESNA buffer. Incubate 30 min on ice.

    MESNA will cleave the disulfide bond between the biotin group and STxB-K3 or transferrin. It will act on cell surface–exposed proteins but not on internalized proteins.

11. Inactivate MESNA by adding 100 µl of 300 mM ioadoacetamide in TNB buffer to the MESNA tubes. Incubate cells 30 min on ice.

12. Centrifuge cells 20 sec at 300 × *g*, 4°C. Discard the supernatant using a Pasteur pipet.

Detect by ELISA

13. Lyse cells in 400 µl blocking buffer.

14. Load the cell lysates in 96-well ELISA dishes, 200 µl in a 13C4 anti-STxB antibody–coated well and 200 µl in an anti-transferrin antibody–coated well. Incubate dishes overnight at 4°C.

15. Wash wells two times with 400 µl PBS, and once with 400 µl saturation buffer decanting each wash by inverting plates. Incubate 5 min at room temperature.

16. Wash again two times with 400 µl PBS.

17. Add 200 µl of 1:5000 (v/v) streptavidin-conjugated HRP diluted in saturation buffer, to each well, and incubate dishes 1 hr at room temperature in the dark.

18. Wash again, as described in step 15.

19. Add 10 µl of hydrogen peroxide solution to freshly dissolved OPD tablet in 25 ml citrate buffer, pH 5.5. Transfer 200 µl to each well.

20. Incubate until yellow color appears (~5 min), then stop the reaction by adding 50 µl of 6 N H_2SO_4.

21. Read the absorbance values at 490 nm on a microtiter plate reader.

Analyze data

22. To determine the percentage of internalized STxB and transferrin at each time point and in each experimental condition, divide the signal obtained on the +MESNA sample (internalized) by the signal obtained on the –MESNA sample (total cell associated).

A typical result is shown in Figure 15.10.5.

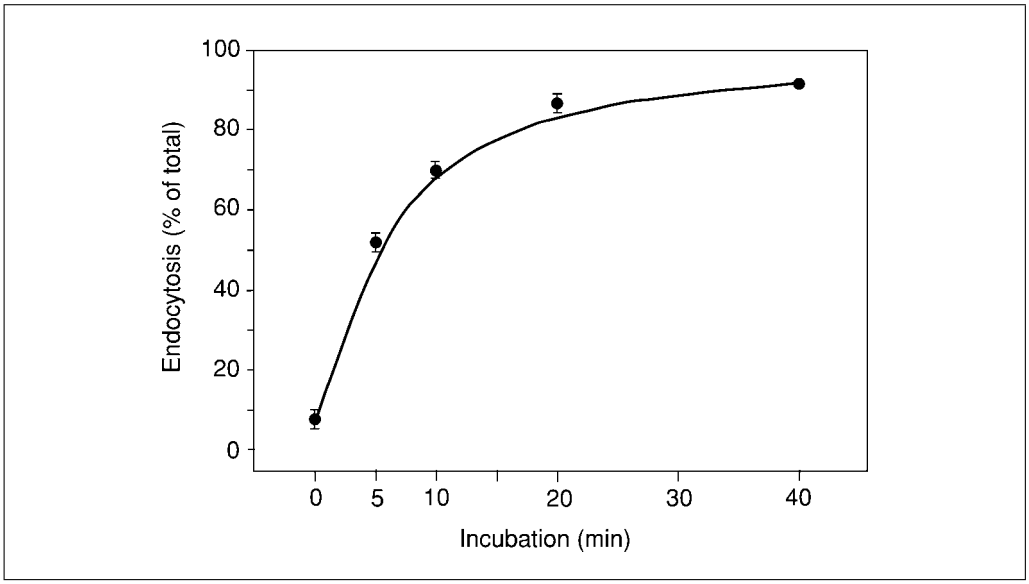

Figure 15.10.5 Internalization kinetics of STxB in HeLa cells at 30°C.

BIOTINYLATION OF STxB-K3

Proteins are typically labeled with biotin to tag them for later recovery or for detection with biotin-binding proteins, such as avidin or streptavidin. Some applications of this approach include identification and purification, measurement of ligand internalization, and temporal changes in protein distribution inside cells using light or electron microscopy. To measure the internalization kinetics of STxB, the authors use a biotinylated STxB variant termed STxB-K3, which carries three additional lysine residues at its C-terminus (Johannes et al., 2003).

Materials

STxB-K3 protein
PBS (*APPENDIX 2A*)
1 M carbonate buffer, pH 9.5
NHS-SS-biotin in DMSO
1 M NH_4Cl
Dialysis membrane (10-kDa)

1. Dialyze 0.5 ml of purified STxB-K3 protein (1 mg/ml) two times for 1 hr each time, against PBS buffer at 4°C using a 10-kDa membrane to remove traces of interfering buffer components that may have been introduced during purification.

   Avoid buffers containing primary amines (e.g., Tris or glycine) as they compete with the biotin-labeling reaction.

2. Add 18 µl of 1 M carbonate buffer, pH 9.5.

3. Add 60 µl of freshly prepared NHS-SS-biotin in DMSO (1 mg/ml) to the protein.

   Sulfo-NHS-SS-biotin is a thiol-cleavable amine-reactive biotinylation reagent that contains an extended spacer arm to reduce steric hindrances associated with avidin binding

4. Incubate 30 min on ice. Mix occasionally.

5. Terminate the reaction by adding 1 M NH_4Cl (50 mM final concentration), and keep the reaction 15 min on ice.

6. Remove unreacted biotin by dialysis three times for 1 hr each against PBS buffer at 4°C using a 10-kDa membrane.

   Alternatively, excess biotin may be removed by gel filtration chromatography using PD-10 columns. Collect at least ten fractions, each containing 0.5 ml.

7. Read the absorbance of the biotinylated protein by Bradford assay at 595 nm (A_{595}).

   If a gel filtration column is used, pool fractions that correspond to the peak of absorbance.

8. Store the biotinylated STxB-K3 protein for several years at –80°C.

9. Verify biotinylation by immunoblot analysis of electrotransferred protein using streptavidin-HRP (*UNIT 6.2*) or by MALDI-TOF.

REAGENTS AND SOLUTIONS

Use deionized, distilled water or equivalent in all recipes and protocol steps. For common solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acrylamide solution A

Add 1.135 g bisacrylamide to 100 ml of protogel solution (30% acrylamide/0.8% bisacrylamide); store up to 6 months at 4°C.

Acrylamide solution B

Add 0.138 g bisacrylamide to 100 ml of protogel solution (30% acrylamide/0.08% bisacrylamide); store up to 6 months at 4°C.

Anode buffer, 10×

242 g Tris
800 ml H_2O
Adjust to pH 8.9 with HC1
Add H_2O to 1 liter
Store up to 6 months at room temperature

ATP-regenerating system

10 mM HEPES buffer, pH 7.2
1 mM ATP
0.2 mM GTP
0.05 mM UTP (Bohringer)
5 mM creatine phosphate (Sigma)
15 μg/ml creatin kinase (Bohringer)
Store up to 6 months at −80°C

Blocking buffer

1% (v/v) Triton X-100
0.1% (w/v) SDS
0.2% (w/v) BSA
50 mM NaCl
1 mM EDTA
10 mM Tris·Cl, pH 7.4
Store up to 2 weeks at 4°C

Cathode buffer, 10×

121 g Tris
179.5 g Tricine
800 ml H_2O
50 ml 20% (w/v) SDS
Adjust to pH 8.25 with HC1
Store up to 6 months at room temperature

Citrate buffer

50 mM Na_2HPO_4
30 mM citric acid, pH 5
Store up to 6 months at 4°C

Deacetylation solution, 10×

50 mM sodium phosphate
25 mM EDTA
0.5 M hydroxylamine-HCl, pH 7.5
Prepare fresh

DMEM3+

Dulbecco's modified Eagle's medium (DMEM; GIBCO) supplemented with:
10% (w/v) fetal calf serum
0.01% (w/v) penicillin/streptomycin (GIBCO)

continued

5 mM pyruvate
4 mM glutamine
Store up to 1 month at 4°C.

HK buffer

90 mM KCl
50 mM HEPES, pH 7.1
Store up to 6 months at room temperature

ICT/DTT buffer

78 mM KCl
4 mM $MgCl_2$
8.4 mM $CaCl_2$
10 mM EGTA
50 mM HEPES/KOH, pH 7.2
1 mM DTT
Store up to 6 months at −20°C

MESNA buffer

100 mM 2-mercaptoethanesulfonic acid (MESNA; Sigma)
TNB buffer (see recipe)
Prepare fresh

PBS++

1× phosphate-buffered saline (PBS; *APPENDIX 2A*)
0.5 mM $CaCl_2$
1 mM $MgCl_2$
Store up to 6 months at 4°C

Protease inhibitor cocktail (PIC)

In DMSO, add:
1 mg/ml aprotinin
1 mg/ml leupeptin
1 mg/ml pepstatin
1 mg/ml antipaïn
1 M benzamidin
40 mg/ml PMSF
Store up to 6 months at −20°C

RIPA buffer

1× PBS (*APPENDIX 2A*)
1% (v/v) Nonidet P40 (NP-40)
0.5% (v/v) deoxycholic acid
0.5% (w/v) SDS
Store up to 6 months at 4°C

Saturation buffer

10 mM Tris·Cl (*APPENDIX 2A*)
50 mM EDTA
0.2% (w/v) BSA
0.1% (w/v) SDS
1% (v/v) Triton X-100, pH 7.4
Store up to 6 months at 4°C

Streptolysin O (SLO)

200 μg/ml streptolysin O in potassium acetate buffer (115 μM) containing:
1 mg/ml BSA
2 mM DTT
Store up to 5 years at –80°C

TNB buffer

50 mM Tris·Cl (*APPENDIX 2A*)
100 mM NaCl
0.2% (w/v) BSA, pH 8.60
Store up to 2 weeks at 4°C

Tris-tricine gel buffer

91 g Tris
800 ml H_2O
Adjust to pH 8.5 with HCl
Add 15 ml 20% (w/v) SDS
Bring up to 1 liter with H_2O
Store up to 6 months at room temperature

COMMENTARY

Background Information

Many studies on the molecular mechanisms of retrograde transport were done with Shiga toxin. This toxin and the related verotoxins (or Shiga-like toxins) form a family of structurally and functionally related proteins that are associated with disease in humans and animals. Shiga toxin is produced by *Shigella dysenteriae*, whereas verotoxins are produced by enterohemorrhagic *Escherichia coli* strains. These toxins are composed of two subunits, A and B, which associate in a noncovalent manner. The A-subunit is a ribosomal RNA *N*-glycosidase that inhibits protein biosynthesis by removing a specific adenine base from a highly conserved region of the 28S rRNA molecule. The receptor-binding nontoxic B-subunit is a homo-pentamer. In the case of Shiga toxin, the B-subunit (abbreviated STxB for Shiga toxin B-subunit) binds with high affinity to the glycosphingolipid globotriaosyl ceramide (Gb3 or CD77). In the absence of the A-subunit, the STxB conserves its pentameric structure, the capacity to bind Gb3, and the intracellular trafficking characteristics of the holotoxin.

Using morphological and biochemical tools based on STxB, it was shown that retrograde transport between early/recycling endosomes and the TGN involves two SNARE complexes around the heavy chain tSNAREs syntaxin 16 (Mallard et al., 2002) and syntaxin 5 (Tai et al., 2004), the GTPase Rab6a′ (Mallard et al., 2002), the tethering molecule Golgin 97 (Lu et al., 2004), and possibly also the conserved oligomeric Golgi (COG) tethering complex (Zolov and Lupashin, 2005). Retrograde sorting on early/recycling endosomes requires clathrin (Lauvrak et al., 2004; Saint-Pol et al., 2004), dynamin (Lauvrak et al., 2004), and the clathrin-binding protein epsinR (Saint-Pol et al., 2004). Furthermore, STxB association with membrane microdomains of the raft-type was correlated with efficient retrograde transport (Falguières et al., 2001). Other proteins such as the GARP complex in yeast (Conibear et al., 2003) or the retromer complex in yeast and mammals (Arighi et al., 2004; Seaman, 2004) were also involved in retrograde transport between endosomes and the TGN, but their implication in Shiga toxin transport remains to be shown. It should also be pointed out that the early/recycling endosomes-to-TGN pathway of Shiga toxin is different from the classical mannose-6-phosphate receptor recycling pathway between late endosomes and the TGN, as described by the Pfeffer group (Diaz and Pfeffer, 1998).

A critical question is whether the trafficking machinery that was identified for retrograde STxB transport at the early/recycling endosomes-TGN interface also controls retrograde transport of other exogenous and endogenous proteins. Based on the STxB-based retrograde trafficking assays, the protocols in this unit describe a generalized methodology

that allows addressing this question in a quantitative manner. Furthermore, the permeabilized cell assay that is described in this unit complements the intact cell approaches. In both cases, specific limitations exist, such as adaptation phenomena in intact cell approaches if one uses long treatments required for overexpression or RNAi, or permeabilization artifacts in the reconstitution assays. However, it is unlikely that the same limitations apply in each case, and it seems reasonable to assume that concomitant use of several approaches (single-cell and population-based intact cell techniques and reconstitution assays) allows a maximum of confidence in the conclusions that are reached as a result of each experimental series.

It should be kept in mind that retrograde transport efficiency of specific cargo molecules varies between cell types. A well-studied example is Shiga toxin. While it appears that retrograde transport is quantitative in cancer cell lines such as HeLa cells (Johannes et al., 1997; Mallard et al., 1998), other cells do not sort Shiga toxin to the retrograde route, as for example observed in human monocyte-derived macrophages and dendritic cells (Falguières et al., 2001), and these cells are totally resistant to the toxin (Falguières and Johannes, 2006). In the mouse dendritic cell line D1, Shiga toxin is partly targeted to late endosomes/lysosomes, and partly to the retrograde route, thus representing an intermediate situation (Haicheur et al., 2003).

Critical Parameters

For the sulfation assay, cells other than Hela cells can also be used, e.g., A431, Vero, and others. The general requirements are that cells should express Gb3, and STxB should be transported to the TGN.

For the sulfation peptide–coupling methodology, the availability of a recognition molecule (e.g., natural ligand, antibody) is an indispensable requirement, and it must be verified that such recognition does not alter the trafficking characteristics of the cellular cargo molecule (lipid or protein), which is under analysis. If the recognition molecule is itself the cargo that is to be analyzed (e.g., bacterial or plant toxins), it also needs to be verified that sulfation site tagging does not alter its activities. The nature of such tests may depend on the cargo molecule itself. In the case of protein toxins, cell intoxication is a convenient independent way of testing trafficking and activity.

As with any biochemical technique, the sulfation analysis is prone to experimental artifacts. These include, but are not limited to, modification of sulfotransferase activity itself and a possible relocalization of the enzyme. Sulfotransferase activity is tested by measuring the level of endogenous sulfation, and can thus be controlled for within some limitations. The relocalization of the enzyme is more difficult to assess, because relatively small changes could have major effects. It is therefore indispensable, as noted above, to combine several approaches. Indeed, the relocalization problem is unlikely to apply to the reconstitution assay, if one considers the short incubation time (30 min). Furthermore, analysis of cargo trafficking to the TGN/Golgi using immunofluorescence and/or electron microscopy techniques at the single-cell level yields valuable information on where the cargo protein is blocked in a given experimental situation, and at the same time, this indirectly controls for possible (and as yet hypothetical) sulfotransferase relocalization.

Data obtained with the sulfation assay are relative measures, i.e., sulfation efficiency in a given experimental condition, compared to sulfation efficiency under control conditions. Thus, it is necessary to verify that experimental conditions do not change the number of cell-associated cargo molecules, which would have a direct impact on the sulfation signal.

The sensitivity of the sulfation assay depends on several factors, such as expression levels of the cargo molecule (or its receptor), the stoichiometry of the sulfation site modification, the efficiency of retrograde transport, possibly the residence time in the TGN, and other factors. At this stage, it is impossible to propose an algorithm for predicting feasibility, which must be established experimentally.

The immunoprecipitation step in the sulfation protocol permits the concomitant analysis of retrograde transport of several cargo proteins at the same time on the same cells. On a practical note, ensure that the sensitivity of detection for each component is compatible with this approach.

The protein coupling protocol, as described in this unit for HRP, can also be applied to other proteins. The authors' experience suggests that any protein can be coupled, provided that it is soluble in biological buffers and that it does not aggregate. Successful coupling examples include bovine serum albumin, ovalbumin, and antigenic proteins from HIV and human cancers. The reaction conditions (stoichiometry of

SMBS over STxB/Cys, incubation times, etc.) need to be optimized in each case.

The STxB endocytosis assay, as described in this unit, yields more robust results than the previous version (Mallard and Johannes, 2003), and it is possible to analyze more conditions at the same time. Furthermore, several markers may be analyzed at the same time on the same cells, e.g., STxB and transferrin.

Troubleshooting

For the sulfation assay, only sulfate with high specific activity should be used (typically at least at 50 μCi/μl). As mentioned above, tests need to be performed so that chemical cross-linking does not change the activity of the retrograde transport ligands and receptors. It should also be kept in mind that some cell lines may not express given receptors (e.g., Gb3 expression is very heterogeneous between cell lines), and that overlap between Gb3 and GM1 expression varies significantly between cell lines as well. In its current format for STxB trafficking, the permeabilized cell assay is sensitive to reaction conditions (cytosol, cells in good shape, quality of SLO batch), in that even in control conditions, the sulfation signal is rapidly lost if the conditions are suboptimal. The endocytosis assay critically depends on the quality of the 13C4 antibody preparation.

Anticipated Results

The methods presented in this unit have been developed in the authors' group (Johannes et al., 1997; Mallard et al., 1998; Falguières et al., 2001; Mallard et al., 2002; Saint-Pol et al., 2004), but they are now also used by other laboratories (Lauvrak et al., 2004; Lu et al., 2004; Natarajan and Linstedt, 2004). Using STxB in the sulfation assay, robust signals can be detected on 1×10^5 cells, and sulfation becomes detectable ~10 to 20 min after uptake from the plasma membrane (Mallard et al., 1998). The exact kinetics differs between cell types. For sulfation analysis with CTxB or anti-GFP on GFP-MPR HeLa cells, 1×10^6 cells should be used. The anticipated results for the endocytosis assay are shown in Figure 15.10.5.

Time Considerations

Sulfation-site peptide and HRP coupling can be done in 2 to 3 days, including MALDI-TOF or immunoblot analysis of the coupling product. The sulfation assay on intact cells takes 3 days starting with establishing the cells in culture (day 1), performing the assay (day 2), and developing the autoradiogram (day 3). The endocytosis assay can be done in 3 days, starting with establishing the cells in culture (day 1), performing the assay (day 2), and finishing the ELISA test on day 3.

Acknowledgements

The authors would like to thank Danièle Tenza and Graça Raposo for the whole-mount figure, Wolfgang Faigle for mass spectrometry analysis, and Christophe Lamaze for critical reading of the manuscript. Assays for Regulated Exocytosis of Mast Cell Granules

The mast cell has long been known as an important effector cell in allergy and asthma (Galli et al., 2005a). These cells, however, are also becoming increasingly recognized for their ability to participate in both innate and adaptive immune responses (Galli et al., 2005b). A key feature of mast cells is that they contain in their cytoplasm numerous (up to 1000) secretory granules that hold a vast array of inflammatory mediators and biologically active substances such as histamine, proteoglycans, proteases, and lysosomal hydrolases. Upon appropriate stimulation, mast cells release most of their granular content into the surrounding environment. This is made possible by their unique ability to activate inter-granular fusion events in addition to granule-to-plasma membrane fusion (compound exocytosis; Röhlich et al., 1971). This process of regulated exocytosis is therefore often also termed degranulation. Degranulation can be triggered by allergen-induced aggregation of allergen-specific IgE bound to high-affinity IgE receptors (FcεRI) expressed on the surface of the mast cell (Galli et al., 2005b). Degranulation is also triggered by non-IgE-mediated physiological and pathophysiological stimuli through a wide variety of receptors, which couple to distinct early signaling proteins such as nonreceptor tyrosine kinases or heterotrimeric GTP-binding proteins. Moreover, degranulation can also be triggered by various pharmacological agents (such as phorbol esters in combination with calcium ionophores) that bypass early receptor-mediated signals. This unit describes protocols that can be used to assay regulated exocytosis in mast cells both in vitro and in vivo. For the purpose of clarity, the authors focus on IgE-mediated stimulation protocols for rodent cells. However, in principle, all methods are adaptable to the use of other stimulants and human cells.

The assays described herein can be classified as follows:

I. Detection of released soluble mediators stored in cytoplasmic granules using assays based on in vitro colorimetric detection (β-hexosaminidase; Basic Protocol 1), radiolabel detection (serotonin; Alternate Protocol 1), or antibody detection (histamine; Alternate Protocol 2). These assays are frequently used in many laboratories specialized in the analysis of mast cell exocytosis.

II. Detection of the exposure of phosphatidylserine at the cell surface as a marker of degranulation (single cell assay; Basic Protocol 2).

III. In vivo assays for mast cell degranulation in murine models—plasma histamine (Basic Protocol 3) and body-temperature measurements (Alternate Protocol 3).

DETECTION OF SOLUBLE MEDIATORS

For ease of data comparison and to avoid the variability introduced by differing cell numbers or by differences in the absolute amount of granule content between various batches of cells, the extent of degranulation for most soluble mediators is usually expressed as the percent release of total content. Spontaneous release (that detected in the absence of cell stimulation) is usually subtracted to report the (net) stimulated degranulation. Total degranulation should be reported in situations where differences in experimental conditions or in the genetic makeup of the cells might not allow direct comparison or could differentially alter the spontaneous release. Regardless, spontaneous release (%) should be always be reported, because it provides an assessment of the resting state or viability of the mast cells. Therefore, for every experiment in which soluble mediators

Contributed by Ulrich Blank and Juan Rivera
Current Protocols in Cell Biology (2006) 15.11.1-15.11.18

are measured, the design of an experimental protocol should include determination of the following parameters: (1) released soluble mediator content in test supernatants after cell stimulation; (2) soluble mediator content in the test supernatants in the absence of cell stimulation; and (3) soluble mediator content both in the test supernatants and cell lysates as a measurement of total cellular content. Percent net specific release is then calculated according to the formula:

$$\%\text{Net specific release} = \frac{\text{release}_{\text{stimulated}} - \text{release}_{\text{spontaneous}}}{\text{content}_{\text{total}} - \text{release}_{\text{spontaneous}}} \times 100$$

Equation 15.11.1

BASIC PROTOCOL 1

Measurement of Histamine Release

Histamine (β-imidazole-ethylamine) is produced by the decarboxylation of histidine by the enzyme l-histidine decarboxylase. Mast cells and basophils represent the most important pool of cells capable of storing and promptly releasing histamine from their granules upon stimulation (MacGlashan, 2003). In vitro measurement of the histamine released from mast cells is therefore an excellent correlate of granule mediator release. Histamine exerts potent effects on various target tissues and is involved in neurotransmission, various brain functions, secretion of pituitary hormones, regulation of gastrointestinal and circulatory functions, and inflammatory reactions (Dy and Schneider, 2004). Its effects on smooth muscle, which are profound during anaphylactic shock, are well known. Histamine receptors (H1, H2, H3, H4) have been identified on a wide variety of cells and tissue with distribution in the immune system as well as in the central nervous system (MacGlashan, 2003; Dy and Schneider, 2004). Histamine is actively released from mast cells upon allergen interaction with cell-bound allergen-specific IgE or when cells are stimulated by various other physiological and pharmacological agents. Several methods have been developed for the in vitro measurement of histamine. Among these, the assay of histamine by fluorometry is an accurate and sensitive method for detection of this biologically active molecule (Siraganian, 1974). This method employs the coupling of histamine with *o*-phthalaldehyde at high alkaline pH to form a fluorescent product that can be easily detected by fluorometric means. Although sensitive, this method requires specialized instrumentation that is not available to all laboratories, and thus will not be detailed here.

A method of choice for most laboratories is the use of a competitive enzyme immunoassay. This assay is based on competition between the histamine in the sample to be assayed and an enzyme conjugate, histamine–alkaline phosphatase, used as a tracer for binding to a limited amount of antibody that recognizes acylated histamine. This assay can be used for measurement of histamine in plasma, urine, cell supernatants, cell lysates, and other liquid or solid biological samples. Because of its commercial availability (manufactured by Immuno Biological Laboratories, Hamburg, Germany, and distributed by Research Diagnostics Inc. in the United States), this assay has become the most commonly used assay for quantitative measurement of histamine release. The detailed procedure is provided with the assay kit from the manufacturer, and is briefly outlined in Basic Protocol 3. Several important points must be considered:

1. The monoamine histamine is too small to completely occupy the binding site on the antibody, and the antibody used in this assay was raised against a modified (acylated) histamine. Thus the histamine in the sample must be acylated in the same manner as the conjugated histamine. An effective and complete acylation reaction is key to obtaining reproducible results from experiments conducted on different days. One key to consistency in acylation of histamine is to dissolve or thaw the acylation reagent

immediately before use and keep aliquots (for one reaction) stored at −20°C. Do not freeze/thaw repeatedly.

2. The assay must be conducted within the linear range of the standards; thus, samples may require dilution to be within the range of concentrations of the standard. It is recommended that multiple dilutions and replicates be run within an experiment to determine what dilution(s) of the sample fall within the linear range of the assay.

3. The wash instructions should be followed explicitly. Two key points in obtaining reproducible results are to avoid the drying of the wells during the wash steps and to effectively remove all unbound components by filling the wells to the rim.

Measurement of Radiolabeled Serotonin Release

ALTERNATE PROTOCOL 1

Serotonin (5-hydroxytryptamine or 5-HT) is a major component of rodent mast cell granules. Methods to measure its release take advantage of the rapid incorporation of radiolabeled serotonin (5-[1,2-^{3}H(N)]-hydroxytryptamine binoxalate) in a selective manner into mast cell granules. This method can be used for cell lines, cultured bone marrow–derived mast cells (Support Protocol), or ex vivo–derived mast cells (such as peritoneal mast cells). It requires preincubation with the radiolabeled 5-HT prior to cell stimulation. This is a quantitative method, but one must keep in mind that it does not measure the total amount of serotonin in granules. It measures the secreted fraction of exogenously incorporated serotonin and is thus reported as the percent of total incorporated 5-HT. The procedure described is for nonadherent cells, but can be adapted as an adherent cell assay (using RBL-2H3 cells), as incorporation of 5-HT, cell stimulation, supernatant recovery, and determination of total cellular 5-HT can also be done on adherent cells. It can also be adapted to a 96-well microwell format.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in an appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

Materials

RBL-2H3 (ATCC no. CRL-2256) *or* bone-marrow mast cells (BMMC; see Support Protocol), in late log phase (3 to 4 days after feeding)
Tyrode's buffer (see recipe)
5-[1,2-^{3}H(N)]-hydroxytryptamine binoxalate (sp. act., 28.5 Ci/mmol; ViTrax Radiochemicals; *http://www.vitrax.com/*)
DNP-specific murine IgE (Sigma-Aldrich) *or* TNP-specific murine IgE (BD PharMingen)
Antigen: dinitrophenol conjugated to human serum albumin (DNP_{36}-HSA; Sigma-Aldrich), trinitrophenol conjugated to ovalbumin (TNP-OVA; Biosearch Technologies), or trinitrophenol conjugated to bovine serum albumin (TNP-BSA; Biosearch Technologies)
Tyrode's buffer–E (see recipe)
1% (v/v) Triton X-100
Scintillation fluid, water soluble

Centrifuge
Scintillation vials

Harvest and wash cells

1. Harvest 5×10^6 cells by centrifuging 10 min at $400 \times g$, room temperature, and removing the supernatant.

   Centrifugation force varies depending on cell type; for bone marrow mast cells (BMMC), 400 × g should be used.

2. Wash the cell pellet once by adding 25 ml prewarmed (37°C) Tyrode's buffer, centrifuging again 10 min at 400 × *g*, room temperature, and removing the supernatant.

Treat with radiolabeled serotonin and IgE

3. Gently resuspend cells at 0.5×10^6 cells/ml in 10 ml prewarmed (37°C) Tyrode's buffer containing 1 μCi/ml 5-[1,2-^{3}H(N)]-hydroxytryptamine binoxalate and 1 μg/ml DNP-specific murine IgE.

4. Incubate cells for 1 hr at 37°C with occasional mixing.

5. Centrifuge 10 min at 400 × *g*, room temperature, and remove the supernatant. Wash cells twice, each time by adding 10 ml Tyrode's buffer, centrifuging again as before, and removing the supernatant.

   The washings remove unincorporated 5-[1,2-^{3}H(N)]-hydroxytryptamine binoxalate and unbound DNP-specific IgE.

6. Gently resuspend cells to 0.5×10^7 cells/ml in 1.0 ml Tyrode's buffer (prewarmed to 37°C).

Perform degranulation reaction in presence of antigen

7. Prepare ten 1.5-ml microcentrifuge tubes containing duplicate doses of antigen (e.g., 0, 0.1., 10, and 100 ng/ml antigen) in 0.4 ml of 37°C Tyrode's buffer (with the 0 mg/ml tubes containing only the 0.4 ml of prewarmed Tyrode's buffer). To each tube, add a 0.1-ml aliquot of the mast cell suspension prepared in step 6.

   Antigen concentrations can be varied to determine suboptimal, optimal, or supraoptimal thresholds for degranulation; the concentrations depend on the molar ratio of hapten to the molecule used for conjugation (e.g., HSA). For DNP_{36} -HSA, the optimal dose for degranulation is in the range of 10 to 30 ng/ml for BMMC, peritoneal, and RBL 2H3 cells. Tubes without antigen are used to determine spontaneous release.

   The subscript 36 in DNP_{36}-HSA represents the average number of DNPs (dinitrophenyl) conjugated per HSA (human serum albumin) molecule.

8. Incubate cells at 37°C for 30 to 60 min.

   Degranulation of BMMC and peritoneal mast cells occurs more rapidly than RBL-2H3 cells and is complete in <30 min. RBL-2H3 cells require longer incubation times (45 min). Kinetic studies can be done on all cell types with detectable stimulated release as early as 1 min post-stimulation for BMMC and peritoneal mast cells.

9. To stop reaction, add 0.3 ml ice-cold Tyrode's buffer–E to each tube and place tubes on ice.

Collect cells and supernatant

10. Microcentrifuge cells 10 min at 400 × *g*, 4°C.

11. Remove 0.25 ml of the supernatant from the top of each tube and place on ice.

    The supernatants will contain radiolabeled 5-HT, released spontaneously or as a consequence of cell stimulation. These will be counted at step 15 to determine spontaneous release (blanks) or stimulated release (IgE/antigen-treated cells). It is possible to centrifuge the aliquots of supernatant 5 min at 1000 × g, 4°C, to ensure removal of any cells not pelleted in the initial centrifugation. This is usually unnecessary if tubes are removed gently from the centrifuge and the supernatant to be recovered is removed immediately.

12. Carefully aspirate remaining supernatant (avoiding the pellet) and discard as radioactive waste.

13. Add 0.25 ml of 1% Triton X-100 to the cell pellet and incubate for 15 min on ice to solubilize cells.

14. Microcentrifuge Triton X-100 solubilized cells 15 min at 12,000 × *g*, 4°C.

Determine total incorporated 5-HT, spontaneous release, and stimulated release

15. Take duplicate or triplicate 0.05-ml aliquots from each tube, transfer to scintillation vials each containing 5 ml scintillation fluid, and count on scintillation counter.

16. Calculate total incorporated 5-HT ($content_{total}$), spontaneous release ($release_{spontaneous}$), and stimulated release ($release_{stimulated}$).

    Total incorporated 5-HT is the sum of the cpm in supernatants and cell pellets.

    Spontaneous release is the cpm found in the supernatant of nonstimulated (no antigen) cells.

    Stimulated release is the cpm found in the supernatant of cells treated with antigen.

17. Calculate the net percent specific (stimulated) release using Equation 15.11.1

Measurement of β-Hexosaminidase Release

ALTERNATE PROTOCOL 2

β-hexosaminidase (EC 3.2.1.52) is a lysosomal enzyme that hydrolyzes terminal non-reducing *N*-acetyl-D-hexosamine residues in *N*-acetyl-β-D-hexosaminides (Aronson and Kuranda, 1989). It acts on glucosides, galactosides, and several oligosaccharides. Mast cell granules contain large quantities of this enzyme due to the lysosomal nature of their granules, which are also called secretory lysosomes. This results from the close connection between the endocytic and exocytic pathway in secretory cells of hematopoietic origin (Andrews, 2000). β-hexosaminidase release after stimulation correlates well with the release of histamine and can thus be used to measure degranulation (Schwartz et al., 1979). In comparison to direct or indirect measurements of released histamine or serotonin, this assay is relatively inexpensive, requires no specialized equipment, is highly reproducible, and does not require use of radioactive tracers. It has therefore become the method of choice in many applications. However, due to the ubiquitous nature of lysosomal hydrolases, it is not suitable for accurate measurement of mast cell/basophil exocytosis in a mixture of cells, e.g., in the measurement of degranulation of blood basophils, where measurement of histamine is the method of choice.

The assay exploits the hydrolytic property of β-hexosaminidase and measures catalysis of the following reaction:

$$p\text{-nitrophenyl acetyl-D glucosamine (pNAG)} + H_2O \xrightarrow{\text{enzyme}} p\text{-nitrophenol} + .$$

$$N\text{-acetyl-D-glucosamine}$$

Equation 15.11.2

The amount of *p*-nitrophenol formed is directly proportional to the amount of β-hexosaminidase in the supernatant or cell lysates, provided that the assay is performed in its linear range. This can be easily determined by assaying serial dilutions of the supernatant or cell lysates using the conditions detailed below. *p*-Nitrophenol absorbs light at 410 nm

Materials

RBL-2H3 cells (ATCC no. CRL-2256) *or* bone-marrow mast cells (BMMC; see Support Protocol), in late log phase (3 to 4 days after feeding)
Culture medium for RBL-2H3 cells (see recipe) *or* culture medium for BMMC (see recipe; if BMMC are used)
DNP-specific murine IgE (Sigma-Aldrich)
Tyrode's buffer (see recipe), room temperature and 37°C

Antigen: dinitrophenol conjugated to human serum albumin (DNP_{36}-HSA; Sigma-Aldrich)
0.5% (v/v) Triton X-100
pNAG substrate (see recipe)
Carbonate buffer (see recipe)
Culture medium for RBL-2H3 cells (see recipe) without IL-3

Flat-bottom 96-well microtiter plates
Refrigerated centrifuge with microtiter plate carrier
Microtiter plate reader

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

For RBL-2H3 cells

1a. Seed 200 µl of RBL-2H3 cells at 2.5×10^5 cells/ml in flat-bottom 96-well plates in culture medium for RBL-2H3 cells. Add IgE-anti-DNP for a final concentration of 0.5 µg/ml. Incubate for 1 hr (overnight incubation is also possible).

This protocol is optimized for the RBL-2H3 cell line and stimulation through the IgE receptor following sensitization with anti-DNP-IgE and triggering with specific antigen (DNP-HSA). Use of other mast cell lines or BMMC requires some variations in cell number and stimulation conditions that should be determined for each cell type prior to any specific experiment.

In this protocol, a commercially available DNP-specific IgE (Sigma-Aldrich) is used. However, various clones producing DNP-specific IgE exist and are described in the literature (Kitaura et al., 2005). IgE derived from these clones may be obtained from their originators and may also be used in this protocol.

2a. Centrifuge cells 5 min at 300 × g, room temperature, in a centrifuge with a microtiter plate carrier. Remove the medium from all wells.

3a. Add 200 µl/well of room temperature Tyrode's buffer and centrifuge 5 min at 300 × g, room temperature. Remove the supernatant from all wells. Repeat this wash a second time to remove unbound IgE.

4a. Add 100 µl/well of Tyrode's buffer prewarmed to 37°C and containing appropriate concentration of antigen (DNP_{36}-HSA, to wells for determination of total content) or solvent (to wells for determination of spontaneous release). Incubate 45 min at 37°C.

Maximal degranulation is usually achieved at antigen concentrations ranging from 10 to 30 ng/ml when DNP_{36}-HSA is used. Conditions for optimal degranulation may differ if the antigen is more or less haptenated.

The subscript 36 in DNP_{36}-HSA represents the average number of DNPs (dinitrophenyl) conjugated per HSA (human serum albumin) molecule.

5a. Stop the reaction by putting the plates on ice.

6a. To determine total cellular content, add 5 µl of 10% Triton X-100 (final concentration 0.5%) to the wells that were set up for this purpose. Incubate 5 min at room temperature, occasionally pipetting up and down to lyse cells.

7a. Centrifuge plate with cells 10 min at 300 × g, 4°C.

8a. Slightly incline 96-well plate and, using a pipettor and 100-µl pipet tip, transfer 50 to 70 µl of supernatant (taking care to not transfer any cells) or lysate to a 96-well plate for storage at −20°C or for immediate processing and measurement of β-hexosaminidase content (step 9a).

9a. In a well of a flat-bottom 96-well plate add 25 μl of supernatant (test, spontaneous, or total) to 50 μl of pNAG substrate. Cover and incubate 90 min in a 37°C incubator.

To verify that the assay is in the linear range, two-fold dilutions of total content can be made and tested in parallel.

10a. Stop the reaction by adding 150 μl carbonate buffer.

11a. Read the absorbance in a microtiter plate reader at 405 nm. To automatically subtract background noise, use a dual-wavelength setting of 405 nm and 630 nm.

The color is stable for a few hours at room temperature. Developed plates can also be stored at −20°C if the measurement cannot be done until a later time.

12a. Calculate results according to Equation 15.11.1.

For BMMC

1b. Harvest 0.5×10^7 BMMC (per sample) by centrifuging 10 min at 400 × g, room temperature.

2b. Resuspend cells in 0.5 ml culture medium for RBL-2H3 cells (omit IL-3) containing 0.5 μg/ml DNP-specific IgE and incubate 3 hr at 37°C.

3b. Centrifuge 10 min at 400 × *g*, room temperature, and remove supernatant. Wash cells twice, each time by adding 1 ml of room temperature Tyrode's buffer, centrifuging again as before, and removing the supernatant. Resuspend at a concentration of 2×10^6 cells/ml in prewarmed (37°C) Tyrode's buffer and incubate 5 to 10 min at 37°C.

4b. Distribute 250-μl aliquots of the cell suspension into 1-ml microcentrifuge tubes containing the appropriate concentration of stimulant (antigen, DNP-HSA) or solvent as control.

Refer to Alternate Protocol 1, step 7, for appropriate concentration ranges. Prepare concentration points in duplicate; also prepare duplicate 250-μl aliquots of Tyrode's buffer alone as no-antigen controls.

5b. Incubate for 15 to 30 min at 37°C.

6b. Stop the reaction by placing the tubes on ice for 5 min. Centrifuge 10 min at 400 × *g*, 4°C.

7b. Transfer supernatants to microcentrifuge tubes and place on ice while incubating remaining pelleted cells with 500 μl of 0.5% Triton X-100 to lyse the cells (for determination of total content).

8b. After 15 min on ice, transfer cell lysates to microcentrifuge tubes and microcentrifuge cell lysates and supernatants 1 min at 12,000 × *g*, 4°C.

9b. Transfer 200 μl of each supernatant and lysate to a new microcentrifuge tube.

Samples can be snap frozen on dry ice and stored at −20°C if they cannot be processed immediately.

10b. Transfer 20 μl of each sample to a 96-well plate and add 20 μl of 1 mM pNAG substrate. Incubate for 1 hr at 37°C.

11b. Add 200 μl carbonate buffer to stop the reaction.

12b. Read the absorbance at 405 nm in a microtiter plate reader. To automatically subtract background noise, use a dual-wavelength setting of 405 nm and 630 nm.

13b. Calculate results according to Equation 15.11.1.

MEASUREMENT OF REGULATED EXOCYTOSIS BY ANNEXIN V BINDING

Eukaryotic cells maintain an asymmetric distribution of lipids across the bilayer plasma membrane (Bretscher, 1972), and the phospholipid phosphatidylserine (PS) is found almost exclusively in the inner leaflet of the plasma membrane. Under certain physiological conditions, notably apoptosis, this asymmetry is lost and PS is translocated from the inner to the outer leaflet of the plasma membrane. Stimulation of mast cells (cell lines as well as primary mouse and human mast cells) also leads to the externalization of PS at the plasma membrane in a manner that is highly correlated with inflammatory mediator release (Martin et al., 2000). While PS exposure during apoptosis is irreversible, PS externalization during mast cell degranulation is reversible and thus not related to physiological cell death. Quantitative determination of PS at the plasma membrane represents, therefore, a convenient means of evaluating degranulation. It can be measured by annexin V binding using flow cytometry. Annexin V is a 35-kDa protein that specifically binds PS in a Ca^{2+}-dependent manner. It can be conjugated to the typical fluorophores used in cytofluorometry. As flow cytometry determines surface labeling of individual cells, this assay allows measurement of degranulation activity in a single mast cell, which is not possible in the assays measuring release of soluble mediators.

Materials

RBL-2H3 (ATCC no. CRL-2256) *or* bone-marrow mast cells (BMMC; see Support Protocol), in late log phase (3 to 4 days after feeding)
Culture medium for RBL-2H3 cells (see recipe) *or* culture medium for BMMC (see recipe; if BMMC are used)
1 M HEPES, pH 7.3
DNP- *or* TNP-specific murine IgE (Sigma-Aldrich)
Tyrode's buffer (see recipe)
Antigen: DNP-HSA *or* TNP-HSA (Sigma-Aldrich)
10× annexin V binding buffer (see recipe), ice cold
Biotinylated annexin V (Invitrogen)
0.1 mg/ml streptavidin-phycoerythrin (streptavidin-PE; Invitrogen) or streptavidin-allophycocyanin (streptavidin-APC; Invitrogen)
50-ml conical centrifuge tubes
Platform shaker
12 × 15–mm round bottom FACS analysis test tubes (Becton Dickinson)
Fluorescence activated cell sorter (FACS; Becton Dickinson)

Prepare cells

1. Collect required amounts of mast cells (~1×10^6 cells per final assay point) and wash them once in the appropriate culture medium.

   Adherent mast cells (e.g., RBL-2H3) are trypsinized before collection. Trypsinization may affect certain biological properties of cells, or eventually, also activate them. Therefore, it is advisable to check whether this procedure affects established stimulation parameters. In the case of IgE-dependent stimulation, it is known that trypsin does not affect the binding capacity of the FcεRI receptor. However, IgE is affected by trypsin, and, thus, cells have to be IgE sensitized after trypsinization.

2. In a 50-ml tube, resuspend cells in the appropriate culture medium, to a final density of 1×10^6 cells/ml.

3. Add IgE-anti-DNP to a final concentration of 0.5 μg/ml.

4. Incubate for 1 hr at room temperature with continuous shaking on a platform shaker. Take care that cells do not settle.

5. Centrifuge cells 5 min at 300 × *g*, room temperature, and remove the supernatant.

Wash cells

6. Wash cells twice, each time by adding 20 ml Tyrode's buffer, centrifuging 5 min at 300 × *g*, room temperature, and removing the supernatant.

   These washings are needed to remove unbound IgE.

7. Resuspend cells in Tyrode's buffer at 1×10^6 cells/ml. Transfer 1 ml per test sample into 12 × 15–mm round bottom FACS analysis tubes. Incubate the cells 5 min at 37°C.

Stimulate cells

8. Stimulate the cells by adding the appropriate concentration of antigen (DNP-HSA or TNP-HSA) or solvent.

   The solvent controls are for determination of PS exposure in unstimulated cells.

9. Stop the reaction by adding 3 ml of ice-cold 1× annexin V binding buffer and put tubes on ice.

10. Centrifuge cells 5 min at 300 × *g*, 4°C, and remove the supernatant.

11. Wash cells twice, each time by adding 3 ml of ice-cold 1× annexin V binding buffer, centrifuging again as before, and discarding the supernatant.

Treat with biotinylated annexin V

12. Resuspend cell pellet in 50 µl of 1× annexin V binding buffer containing 2 µg/ml biotinylated annexin V. Incubate 30 to 45 min on ice.

13. Centrifuge cells 5 min at 300 × *g*, 4°C, and discard the supernatant.

14. Wash the cells twice, each time by adding 3 ml of ice-cold 1× annexin V binding buffer, centrifuging again as before, and discarding the supernatant.

Detect with streptavidin-conjugated reagent and analyze by flow cytometry

15. Resuspend cell pellet in 50 µl of a 1:200 dilution of 0.1 mg/ml streptavidin-PE or streptavidin-APC stock in 1 × annexin V binding buffer. Incubate 30 min on ice

    Use the concentration of streptavidin conjugate recommended by the supplier.

    For the purpose of higher sensitivity, an indirect staining procedure using a PE- or APC-labeled secondary reagent is preferred over direct staining. However, if after preliminary determination staining with annexin-PE or annexin-APC suffices, direct staining with annexin-V-PE or annexin-V-APC can be performed.

16. Centrifuge cells 5 min at 300 × *g*, 4°C, and remove the supernatant.

17. Wash cells twice, each time by adding with 3 ml of ice-cold 1× annexin V binding buffer, centrifuging again as before, and removing the supernatant.

    It is advisable that cells also be treated with 10 µg/ml propidium iodide (Sigma-Aldrich) when using streptavidin-APC or with 0.01 µM Sytox Green nucleic acid stain (Invitrogen) when using streptavidin-PE before the last wash step, to distinguish dead cells that expose PS from degranulating PS-exposing cells. This can be done by adding 500 µl of annexin V binding buffer containing propidium iodide (10 µg/ml) or Sytox Green (0.01 µM) for 5 min at 4°C before the two washes described in this step.

18. Resuspend stained cell pellets in 500 µl of ice cold 1× annexin V binding buffer. Keep all tubes on ice until analyzed by flow cytometry.

19. Determine the mean fluorescence intensity (MFI) of live cells and calculate the relative expression levels as the ratio of MFI of annexin V staining between unstimulated and stimulated cells.

SUPPORT PROTOCOL

BONE MARROW EXTRACTION FOR PREPARATION OF BONE MARROW-DERIVED CULTURED MAST CELL (BMMC)

Materials

Mice, 8- to 12-weeks old
70% ethanol
Culture medium for BMMC (see recipe)
Culture medium for BMMC (see recipe) without IL-3 (but containing SCF)
Culture medium for BMMC (see recipe) without IL-3 or SCF

Dissection instruments
3-cc syringe with 30-G needle
Centrifuge
75-cm^2 tissue culture flasks

Additional reagents and equipment for euthanasia of mice (Donovan and Brown, 2006a)

1. Euthanize an 8- to 12-week-old mouse by CO_2 asphyxiation (Donovan and Brown, 2006a).
2. Wet fur with 70% ethanol and cut skin off legs (one at a time).
3. Remove foot by cutting below the ankle joint and cut leg off above hip.
4. Under a biological hood, trim away the muscle and cut off ends of bone.
5. Pass 3-ml of culture medium for BMMC through each end of the bone using a 3-cc syringe with a 30-G needle. Collect the medium in a 50-ml conical centrifuge tube.
6. Centrifuge 10 min at 400 × *g*, room temperature.
7. Wash three times with 20 ml culture medium for BMMC, resuspend in 10 ml of the same medium, and transfer to a 75-cm^2 tissue culture flask. Incubate.
8. Before BMMCs are used for assays, culture overnight in culture medium for BMMC without SCF (if that was used in the medium). At a time point 3 hr before experimental use, replace the medium with culture medium for BMMC without IL-3 or SCF and continue incubation until ready to perform experiment.

   The use of both SCF and IL-3 results in a mast cell with characteristics of connective tissue type mast cells. BMMC can be grown in medium containing IL-3 alone, resulting in a cell type with similarities to mucosal mast cells.

BASIC PROTOCOL 3

MEASUREMENT OF REGULATED EXOCYTOSIS USING THE PASSIVE SYSTEMIC ANAPHYLAXIS (PSA) METHOD

The following method is an adaptation of an established acute systemic anaphylaxis model (Pivniouk et al., 1999). The in vivo phase of this procedure is done within the confines of a procedure room in the animal facility in which the test animals are housed, and the procedure is not performed until IACUC approval of the method is provided in writing.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Mice
15 μg/ml IgE anti-DNP antibody (Sigma-Aldrich) in sterile PBS (*APPENDIX 2A*)

2.5 mg/ml dinitrophenol conjugated to human serum albumin (DNP-HSA; Sigma-Aldrich) in sterile PBS (*APPENDIX 2A*)

Phosphate-buffered saline (PBS; *APPENDIX 2A*), sterile

Histamine enzyme immunoassay kit (Beckman Coulter) containing:
- Anti–histamine antibody–coated microtiter plate
- Zero standard
- Histamine standards
- Control
- Histamine–alkaline phosphatase conjugate
- Conjugate diluent H
- Acylation reagent
- Release buffer
- 20× wash solution
- Substrate buffer (diethylamine)
- *p*-nitrophenylphosphate substrate tablets
- Stop solution (NaOH)

Gauze pads, sterile

Mouse cages

Heat lamp

1-ml syringes with 26-G, 1/2 in. needles

1-ml heparinized syringes with 23-G, 1-in. needles

500-µl EDTA-coated microtainer tubes

Microtiter plate reader

Semi-logarithmic graph paper

Additional reagents and equipment for injection of the mouse (Donovan and Brown, 2006b), euthanasia of the mouse (Donovan and Brown, 2006a), and blood collection via cardiac puncture (Donovan and Brown, 2006c)

Day 1: Sensitize mice

1. Organize mice into two groups of at least six for each phenotype to be tested.

   The first group will receive antigen challenge (see day 2) while the second group will receive vehicle challenge.

   An equal number of animals should be used for the two groups to allow for statistical comparison, and at least six animals should be used per group to minimize the standard error and increase the accuracy of the statistical evaluation.

   Different strains of mice can be used for this procedure. While the extent of the response may differ (i.e., Sv129 or BALB/c mice are stronger responders than C57/BL6 mice), all strains undergo an increase in circulating histamine. Optimally, mice should be between 6 and 12 weeks of age, but older mice still respond, though non-stimulated levels of circulating histamine are slightly increased with aging. No apparent gender differences are observed in the anaphylactic response.

2. Put each group of animals into a separate cage. Place each mouse under a heat lamp for 1 to 2 min prior injection to help visualize the tail vein.

3. To sensitize, inject mice intravenously in the tail vein (Donovan and Brown, 2006b) with 0.2 ml of 15 µg/ml mouse IgE anti-DNP antibody using a 1-ml syringe and a 26-G, 1/2 in. needle. After the injection, compress the site with sterile gauze to stop any bleeding and prevent the sample from leaking out of the injection site.

Day 2: Challenge and sacrifice mice and obtain blood samples

4. After 24 hr, challenge mice by injecting intravenously in the tail vein (Donovan and Brown, 2006b) with 0.2 ml of 2.5 mg/ml DNP-HSA (in sterile PBS) or sterile PBS (controls) as in step 3.

5. Sacrifice the animals 1.5 min following injection by asphyxiation in a sealed chamber using compressed CO_2 (Donovan and Brown, 2006a).

6. Immediately collect blood samples for determination of serum histamine levels by cardiac puncture (Donovan and Brown, 2006c) using a 1-ml heparinized syringe connected to a 23-G, 1-in. needle.

7. Transfer the blood sample into a 500-µl EDTA-coated microtainer tube and place immediately on ice to preserve the histamine in the sample.

   The microtainer can be microcentrifuged directly or placed inside a larger microcentrifuge tube which is in turn placed in the microcentrifuge.

8. Microcentrifuge the sample 15 min at 900 × *g*, 4°C, to isolate the plasma.

9. Using a sterile pipet, transfer the plasma to a clean microcentrifuge tube and immediately place on dry ice to freeze the sample for later analysis.

Analyze histamine content

For histamine measurement, follow the assay procedure, step 8, in the kit instruction manual.

10. Prepare serial dilutions of the plasma for histamine enzyme immunoassay measurement.

    The dilution factors usually range from 1:500 to 1:10,000.

11. Acylate 100 µl of histamine standards or diluted sera with 25 µl acylation reagent.

    Acylation of standards and samples is a rapid reaction that requires no incubation.

12. Add 50 µl of each acylated standard and sample to each well of an anti–histamine antibody–coated plate. Add 200 µl histamine–alkaline phosphatase conjugate. Incubate overnight at 4°C.

13. Wash wells three times, each time by filling all wells completely with 1× wash solution (prepared by diluting the 20× wash solution from the kit with distilled water), then manually tapping the solution out on clean absorbent paper placed on the benchtop.

14. Add 200 µl *p*-nitrophenylphosphate (pNPP). Incubate 30 min at room temperature.

15. Read the absorbance at 405 nm in a microtiter plate reader to detect the enzymatic activity bound to the plate.

    The color will be inversely proportional to the concentration of histamine in the plasma.

16. Plot a standard curve of absorbance at 405 nm versus histamine concentration of standards on semi-log paper.

17. Determine concentration of histamine by interpolation.

ALTERNATE PROTOCOL 3

DETECTION OF REGULATED EXOCYTOSIS BY PASSIVE SYSTEMIC ANAPHYLAXIS

Instead of measuring histamine release, it is possible to measure anaphylaxis by dye extravasation into tissues or by monitoring body temperature (Dombrowicz et al., 1993, 1997).

Additional Materials *(also see Basic Protocol 3)*

250 to 500 µg/ml IgE anti-DNP antibody (Sigma-Aldrich) or IgE anti-TNP (BD Pharmingen) in sterile PBS (*APPENDIX 2A*)

Antigen in 2% (w/v) Evans Blue (see recipe)
Formamide

Rectal temperature probe connected to a digital recorder (Cole-Parmer)
70-μm nylon cell strainer (BD Falcon)
Spectrophotometer

Day 1: Sensitize mice

1. Sensitize mice for IgE-induced passive systemic anaphylaxis by intravenous injection into the tail vein (Donovan and Brown, 2006b) of 50 to 100 μg antigen-specific IgE in 200 μl PBS.

   Control animals receive PBS only. Note that the injected dose of antigen-specific IgE is higher than that used in Basic Protocol 3; this is necessary in order to induce enough tissue edema to efficiently observe the extravasation of the dye. The larger dose of IgE also causes a larger drop in body temperature.

Day 2: Challenge animals

2. After 24 hr, measure the animal's body temperature using a rectal probe connected to a digital thermometer, then challenge the animals by intravenous injection into the tail vein (Donovan and Brown, 2006b) of 0.2 ml of antigen in 2% Evans Blue.

   Referring to the recipe for antigen in 2% Evans Blue (see Reagents and Solutions), DNP-HSA or DNP-KLH is injected when anti-DNP IgE is used; TNP-OVA or TNP-BSA is injected when anti-TNP IgE is used.

3. Monitor body temperature at various time points (e.g., every 10 min over 60 to 90 min) following antigen injection using a rectal probe connected to a digital thermometer.

   Anaphylactic shock causes decreased blood pressure, making body temperature difficult to maintain. Thus, loss of body temperature is a reasonable measure of the in vivo response to a systemic anaphylactic challenge, and these changes can be readily measured even at antigen challenge doses where death from anaphylactic shock is not an endpoint.

Measure vascular leakage using Evans Blue extravasation

4. At a time point 90 min following antigen challenge, euthanize animals who did not die during the course of the anaphylactic reaction by CO_2 asphyxiation (Donovan and Brown, 2006a).

   Death (number of mice that die out of a given number of mice challenged) can be an endpoint for anaphylactic shock, as it demonstrates the most severe reaction to the antigen challenge. Temperatures recorded on mice that die from anaphylactic shock can be used in the analysis up to the time of death. Alternatively, the challenge dose of antigen can be lowered to allow for temperature monitoring, recovery, and survival following shock.

5. Remove the ears and mince into 2 × 2–mm pieces. Transfer to a 1-ml microcentrifuge tube.

6. Extract the dye from the ear tissue by incubating overnight 1 ml formamide at 55°C.

7. Eliminate hairs and tissue fragments by rapid gravity filtration through a 70-μm nylon cell strainer, read the absorbance at 620 nm.

   IgG-induced PSA can be obtained using a similar procedure except that the concentration of antigen-specific IgG_1 must be 10 to 20 times higher than that of IgE to obtain a reaction of a similar magnitude.

   Absorbance at 620 nm is close to the peak absorbance of Evans Blue dye and reflects the extent of mast cell degranulation, which causes tissue edema leading to dye extravasation. Absorbance values are reported.

ALTERNATE PROTOCOL 4

DETECTION OF REGULATED EXOCYTOSIS BY ACTIVE SYSTEMIC ANAPHYLAXIS

Animals can also be immunized under conditions favoring an IgE-mediated immune response to a specific antigen. The anaphylactic response to antigen is measured 3 weeks after immunization. This protocol uses DNP-KLH as a specific antigen, but it may be adapted in principle to any other antigen for which an IgE-mediated immune response can be elicited (Dombrowicz et al., 1993, 1997).

Additional Materials *(also see Basic Protocol 3 and Alternate Protocol 3)*

1.5 μg/ml *Bordetella pertussis* toxin (Invitrogen) in PBS (*APPENDIX 2A*)
2.5 mg/ml DNP-KLH and 0.5% (w/v) aluminum hydroxide (Rehydragel, Reheis Inc.; *http://www.reheis.com*) in PBS (*APPENDIX 2A*)
0.5% (w/v) aluminum hydroxide (Rehydragel, Reheis Inc.; *http://www.reheis.com*) in PBS (*APPENDIX 2A*)

1. For active systemic anaphylaxis, inject control and experimental mice intravenously in the tail vein (Donovan and Brown, 2006b) with 200 μl of 1.5 μg/ml *Bordetella pertussis* toxin (i.e., 300 ng toxin) in PBS.
2. After 48 hr, inject animals intraperitoneally (Donovan and Brown, 2006b) with 500 μg DNP-KLH and 0.5% aluminum hydroxide in 0.2 ml PBS. Inject control animals with 200 μl of 0.5% aluminum hydroxide without DNP-KLH.
3. Challenge animals 3 weeks later as described in Basic Protocol 3, step 4 or Alternate Protocol 3, step 2.

   The injection of DNP-KLH in the presence of aluminum hydroxide causes the production of high titers of DNP-specific IgE; thus, the mice should respond to the challenge with any multivalent DNP-conjugated protein.
4. Measure histamine (Basic Protocol 3) if challenge was administered as in Basic Protocol 3, step 4, or hypothermia (Alternate Protocol 3) and vascular leakage (Alternate Protocol 3) if challenge was administered as in Alternate Protocol 3, step 2.

ALTERNATE PROTOCOL 5

DETECTING REGULATED EXOCYTOSIS BY PASSIVE CUTANEOUS ANAPHYLAXIS

Mast cells are present in high numbers in the skin, and mast cell degranulation in response to antigen can also be elicited by local sensitization with antigen-specific IgE followed by challenge by intravenous injection of specific antigen (Dombrowicz et al., 1993).

For materials, see Basic Protocol 3 and Alternate Protocol 3

1. Sensitize mice for IgE-induced passive cutaneous anaphylaxis (PCA) by injecting 20 μl of 2.5 μg/ml antigen-specific (e.g., DNP-specific) IgE (50 ng IgE) intradermally into the ear pinna. Inject the control ear with 20 μl PBS.
2. At a time point 24 to 48 hr later, challenge animals by intravenous injection of 100 μg of the cognate multivalent antigen (e.g., DNP_{36}-HSA) in 200 μl of 2% Evans Blue in PBS.
3. Measure dye extravasation (Alternate Protocol 3).

REAGENTS AND SOLUTIONS

Use deionized, distilled water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Antigen in 2% Evans Blue

Phosphate-buffered saline (PBS; *APPENDIX 2A*) containing:
5 mg/ml antigen: DNP-HSA (Sigma-Aldrich), DNP-KLH (Calbiochem), TNP-OVA (Biosearch Technologies), or TNP-BSA (Biosearch Technologies), depending on antibody used for sensitization
2% (w/v) Evans Blue (Sigma-Aldrich)
Prepare fresh

DNP-HSA or DNP-KLH is injected when anti-DNP IgE is used for sensitization; TNP-OVA or TNP-BSA is injected when anti-TNP IgE is used for sensitization (see Alternate Protocol 3).

Annexin V binding buffer, 10×

100 mM HEPES
NaOH, pH 7.3
1.5 M NaCl
50 mM KCl
10 mM $MgCl_2$
18 mM $CaCl_2$
Store up to 6 months at 4°C

Carbonate buffer, 0.1 M, pH 9.0

1.06 g Na_2CO_3
0.840 g $NaHCO_3$
Bring to 100 ml with distilled H_2O
Filter sterilize through 0.22-μm nylon filter
Store up to 6 months at room temperature

Citrate buffer, 0.1 M, pH 4.5

Prepare the following stock solutions:
0.1 M citric acid: dissolve 1.05 g citric acid in 50 ml H_2O (store up to 6 months at 4°C)
0.1 M sodium citrate: dissolve 1.47 g sodium citrate in 50 ml H_2O (store up to 6 months at 4°C)
Mix 26.5 ml of 0.1 M citric acid with 23.25 ml of 0.1 M sodium citrate. Filter sterilize and store up to 2 weeks at 4°C

Culture medium for BMMC

500 ml RPMI 1640 medium without glutamine (Biofluids)
6 ml 100× Penicillin-Streptomycin-Glutamine (Invitrogen)
12.5 ml 1 M HEPES (Invitrogen)
5 ml 100× nonessential amino acids (NEAA; Biofluids)
5 ml 100 mM sodium pyruvate (Biofluids)
175 μl 1% (v/v) 2-mercaptoethanol (Sigma-Aldrich)
60 ml fetal bovine serum (FBS)
10 ng/ml interleukin 3 (IL-3; PeproTech; omit where directed in protocols)
10 ng/ml stem cell factor (SCF; PeproTech; omit where directed in protocols)

Culture medium for RBL-2H3 cells

500 ml Earle's Minimal Essential Medium (EMEM; Biofluids)
100 ml fetal bovine serum (FBS)
6 ml 100× Penicillin-Streptomycin-Glutamine (Invitrogen)

pNAG substrate

Prepare 1 mM *p*-nitrophenyl acetyl-D-glucosamine (Sigma) in citrate buffer (see recipe), vortexing and warming to 37°C to dissolve. Store at −20°C in 5-ml aliquots (sufficient for one 96-well plate).

Tyrode's buffer

135 mM NaCl
5 mM KCl
5.6 mM glucose
1.8 mM $CaCl_2$
1 mM $MgCl_2$
0.5 mg/ml BSA Fraction V
20 mM HEPES
Adjust pH to 7.3 with NaOH
Store without BSA up to 6 months at 4°C

Tyrode's buffer–E

135 mM NaCl
5 mM KCl
5.6 mM glucose
1.5 mM EDTA
0.5 mg/ml BSA Fraction V
10 mM HEPES
Adjust pH to 7.3 with NaOH
Store without BSA up to 6 months at 4°C

COMMENTARY

Background Information

Measurement of exocytosis from mast cell granules represents a rapid and convenient means for evaluating the activation of mast cells and blood basophils. Although mast cells can be activated without concomitant degranulation, in particular when the stimulus is suboptimal (Gonzalez-Espinosa et al., 2003), most physiological stimuli activate these cells to release the mediators stored in their cytoplasmic granules. The appearance of exocytosed products occurs within a few minutes of cell activation and can be highly specific for these cells (see below). In contrast, release of cytokines and chemokines from mast cells requires hours following cell activation and is usually less specific, as most cytokines and chemokines can also be released by other cells. Interestingly, mast cells have been reported to represent one of the few types of cells, if not the only one in the body, that stores the inflammatory cytokine TNF in secretory granules from which it can be rapidly released (Beil et al., 1996). Additionally, mast cells and platelets are unique in secreting copious amounts of sphingosine-1-phosphate (S1P), a lipid ligand known to regulate the chemotactic response of various hematopoietic cells (Olivera and Rivera, 2005). Although not detailed here, the rapid appearance of TNF or S1P in body fluids might therefore be considered another possible indicator of mast cell activity in vivo.

Regardless, measurement of granule exocytosis is the starting point of most studies that evaluate the activation of mast cells. For in vitro studies with cultured cells, several methods have been developed in parallel. Mast cells and basophils represent the most important pool of cells capable of storing and promptly releasing histamine from their granules upon stimulation (MacGlashan, 2003). Measurement of histamine, therefore, represents an excellent and highly specific correlate of granular mediator release, and it is the

method of choice when one wants to determine mast cell activation in vivo, in a mixture of cells, or when measuring the activation of basophils in human blood. Using the described assay, histamine can be measured in plasma, urine, cell supernatants, cell lysates, or in any other liquid or solid biological sample. For in vivo experiments, the immediate consequences of the mobilization of histamine, such as the drop in body temperature or blood vessel permeability (dye extravasation), may also be monitored as a faithful correlate of mast cell activation. While not applicable for cell mixtures, other described assays correlate with the liberation of histamine and have frequently been used as a measure of mast cell degranulation. For example, measurement of externalization of PS at the plasma membrane using flow cytometry is a relatively new assay (Martin et al., 2000). As flow cytometry determines surface labeling of individual cells, this assay allows one to measure degranulation activity in a single mast cell, which is not possible in the assays measuring release of soluble mediators. Although it has not yet been reported, measurement of PS exposure may also allow determination of exocytosis in a mixture of cells by identifying the mast cell population via a specific surface marker (such as FcεRI c-kit). However, although PS accumulates specifically at the sites of granule exocytosis (Demo et al., 1999), the exact relationship between the exocytosis and PS exposure is still unknown. Notably, it is not known whether exposure simply represents the externalization of the inner leaflet of granule membrane or whether it corresponds to phospholipid scrambling that takes place due to the extensive mobilization of cellular membranes during the degranulation process.

Critical Parameters and Troubleshooting

All described assays (except for the in vivo experiments, which require experience with the handling of animals) are straightforward. The method of choice may be based on individual preference and, importantly, on the cost of reagents and equipment. However, for cell mixtures, the only accepted approach is the direct measurement of histamine. The histamine release observed from cell mixtures can be normalized by flow cytometric measurement of IgE receptor (FcεRI)– and c-kit-positive cells, indicating the relative numbers of mast cells in the mixture. Also, as mast cells and basophils contain high levels of histamine (relative to other cells), normalization to total histamine content may also be appropriate. To adequately measure spontaneous and stimulated release, it is critically important to carefully remove supernatants without removing any of the pelleted cells. Inclusion of cells in the analysis may modify results, especially when the stimulated release is low compared to total cellular content. All assays should be performed at 37°C, as lower temperatures alter the kinetics of release and can block exocytosis.

It is known that the percent of release varies between individual clones or cell lines. Subcloning of the RBL-2H3 mast cell line may yield clones that release between 10% and 90% of total granular content. Thus, in studies where individual clones are analyzed (for example in transfection experiments), care should be taken to analyze a number of clones to allow unambiguous interpretation of the results. Primary cultures of mouse and human mast cells may also show differences in releasing capacity, depending on background strain or individual. When IgE and antigen-dependent stimulation is used to induce degranulation in experiments comparing cells from different sources or that are genetically altered, the cell surface expression level of IgE receptors should be verified prior to conducting the experiment to assess whether stimulus strength may be a factor. Loading of equivalent numbers of receptors with IgE would then allow a fair comparison under circumstances where receptor numbers may differ.

Anticipated Results

When appropriately stimulated, mast cells can release up to 90% of total granular content. However, values can vary widely depending on whether cell lines, individual cloned lines, cultured primary cells, or ex vivo primary cells are used. Normally, values in the range of 30% to 60% of total granular content are considered satisfactory.

Time Considerations

For in vivo assays, an exact time scheme is given in the protocols. The in vitro degranulation assays or the annexin V binding assays can easily be performed within 1 day. Sensitization of cells with IgE requires 1 hr, but it can also be performed overnight. The subsequent washing step, antigen stimulation, and recovery of supernatants and total cell lysates require between 1 and 2 hr for all degranulation assays. The quantification of the released products usually requires another 2 hr for β-hexosaminidase measurements, 15 to 30 min for determination of released radiolabeled

serotonin, and 2 to 3 hr for determination of histamine. Supernatants and cell lysates can be rapidly frozen (in a dry ice/acetone bath), stored at –20°C or lower, and analyzed later. Samples should not be stored for prolonged periods (i.e., for weeks or longer). Flow cytometric analysis for the annexin V binding assay requires between 2 and 3 hr and should be performed immediately following cell stimulation.

Analysis of Regulated Secretion Using PC12 Cells

Laurent Taupenot[1,2]

[1]University of California at San Diego, La Jolla, California
[2]Veterans Affairs San Diego Healthcare System, San Diego, California

ABSTRACT

The catecholamine-secreting PC12 cell line derived from the rat adrenal medulla has long been considered a model system for neurosecretion and neuronal differentiation. PC12 cells contain a large number of secretory granules (otherwise known as large dense-core vesicles) for storage of small molecules, processing enzymes, neuropeptides, and peptide hormones. Secretory granule exocytosis in PC12 cells is tightly regulated by calcium and occurs in response to a secretagogue. This unit provides protocols for maintenance and transfection of PC12 cells. Several secretion assays are described to measure the release of secretory granule cargo molecules by detection of radioactive catecholamine, or by immunochemical or chemiluminescence detection of transfected regulated secretory proteins. *Curr. Protoc. Cell Biol.* 36:15.12.1-15.12.13. © 2007 by John Wiley & Sons, Inc.

Keywords: granule • PC12 • exocytosis • chromogranin • catecholamine

INTRODUCTION

Following its establishment by Greene and Tischler in 1976, the PC12 line of rat pheochromocytoma cells has been widely considered as a model of choice to study mechanisms underlying regulated exocytosis, secretory organelle biogenesis, secretory protein trafficking, catecholamine metabolism, and neurotrophin action. This unit provides protocols for maintenance and transfection of PC12 cells, and describes assays to monitor exocytosis of chromaffin secretory granules by radiodetection of preloaded radioactive norepinephrine (Basic Protocol 1), or by chemiluminescence (Basic Protocol 2), or immunochemical detection (Alternate Protocol) of ectopic regulated secretory proteins. There are also protocols for the routine culture (Support Protocol 1) and transfection (Support Protocol 2) of PC12 cells.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

MEASUREMENT OF RADIOLABLED CATECHOLAMINE RELEASE

BASIC PROTOCOL 1

Catecholamines are a major component of dense-core secretory granules (sometimes referred to as catecholamine storage vesicles) found in PC12 cells. These secretory organelles can be labeled with [^{3}H]-L-norepinephrine by a mechanism involving cell surface norepinephrine transporters (NET) and the catecholamine uptake system of the secretory granule membrane (VMAT). This procedure (and variants thereof) has been widely used to assess regulated secretion from chromaffin cells in culture and sympathetic neurons. The method is quantitative but measures the relative (%) rather than the absolute amount of catecholamine ([^{3}H]-norepinephrine) release. Thus, relative [^{3}H]-L-norepinephrine secretion (Sec) is calculated as a percentage of total radioactivity present

Current Protocols in Cell Biology 15.12.1-15.12.13, September 2007
Published online September 2007 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb1512s36

in the cells before stimulation, according to the following equation:

$$\text{Sec} = \frac{\text{Cpm}_{\text{rel}}}{\text{Cpm}_{\text{rel}} + \text{Cpm}_{\text{cell}}} \times 100$$

Equation 15.12.1

Total radioactivity is the sum of the amount released (Cpm_{rel}) plus the amount remaining in the cells (Cpm_{Cell}). The protocol described below is for PC12 cells but can be adapted to other catecholamine-secreting cells, including primary cultures of chromaffin cells and sympathetic neurons.

Materials

Early-passage PC12 cells or ATCC-PC12 cells (#CRL-1721)
Poly-L-lysine (Sigma, cat. no. P6282)
Rat tail collagen Type I (Upstate, cat. no. 08-115)
DMEM or F12K basal and complete culture media (see recipe)
Levo-[ring-2,5,6-^{3}H]-norepinephrine (specific activity 40 to 80 Ci/mmol; PerkinElmer Life and Analytical Sciences)
Calcium saline buffer (CaSB; see recipe)
Stimulation buffer (see recipe)
Scintillation fluid, water soluble
Triton X-100

6-well tissue-culture treated polystyrene plates (e.g., Falcon, Costar)
37°C, CO_2 incubator
Motorized pipetting aid
Scintillation vials
Orbital shaker
Liquid scintillation beta-counter

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

Grow PC12 cells in multi-well tissue culture plates

1. Seed PC12 cells onto poly-L-lysine-coated 6-well plates (early passage PC12 cells) or poly-L-lysine- and rat collagen-coated 6-well plates (ATCC-PC12 cells) at a 1:3 subcultivation ratio, using appropriate complete culture medium (see Support Protocol 1).

   Measurement of radiolabeled norepinephrine release involves several washing maneuvers that depend on good attachment of the cells to poly-L-lysine and collagen substrates. Thus, seeding early-passage PC12 cells on poly-L-lysine-coated 6-well plates is preferable to enhance the moderate adhesion of the cells to the tissue culture plastic. In the authors' experience, best results are obtained when cells are seeded 48 hr prior to the beginning of the secretion assay.

2. Grow the cells in a CO_2 incubator at 37°C, until confluency reaches 70% to 80%.

Load cells with [^{3}H]-L-norepinephrine

3. On the day of the study, remove old medium by tilting the plate and aspirating culture medium. Add 1.0 ml of prewarmed Levo-[ring-2,5,6-^{3}H]-norepinephrine ([^{3}H]-L-norepinephrine) labeling solution (0.7 μCi/ml in complete culture medium) to each well of the plate.

4. Incubate cells for 90 min in CO_2 incubator at 37°C.

   A 90-min incubation allows equilibration between intracellular and extracellular pools of [^{3}H]-L-norepinephrine.

5. Using a motorized pipetting aid, wash the cells twice with 2.0 ml prewarmed CaSB at 2-min intervals.

   This and subsequent washing steps to remove unincorporated [^{3}H]-L-norepinephrine can be performed outside a laminar-flow hood. By slightly tilting the plate, the washing buffer should be carefully added to the edge of each well to limit cell detachment.

6. Add 2 ml of basal culture medium per well, incubate cells in CO_2 incubator for 30 min at 37°C.

   This incubation step will further remove unincorporated [^{3}H]-L-norepinephrine. Incubation is performed in a CO_2 incubator to maintain the pH of the basal culture medium. During this period prepare CaSB solutions containing secretagogues ± antagonists/modulators.

7. Aspirate basal culture medium, wash the cells twice with 2.0 ml prewarmed CaSB at 2-min intervals.

   This last washing step will ensure complete removal of free [^{3}H]-L-norepinephrine.

Measure [^{3}H]-L-norepinephrine secretion

8. Using a pipettor add 1 ml of control buffer (CaSB) or stimulation solution to each well, incubate 15 min at 37°C.

   At 10-sec intervals, replace the content of each well with mock (control) solution to assess the basal (unstimulated) release, or with stimulation buffer [e.g., 60 μM nicotine in CaSB, 2 mM Ba^{2+} (BaSB; see recipe), or 55 mM KCl (KSB; see recipe)] to assess regulated secretion. When all the wells have the appropriate solution, incubate without further change for a total of 15 min. When exchanging buffers, do not allow the cells to become dry. Each condition is performed at least in triplicate. Maximum stimulation is usually achieved within 15 min, since few agonists stimulate release past this time period.

9. Terminate secretion by collecting the supernatant from each well into separate scintillation vials. Add 5 ml of scintillation fluid, and count for 2 min.

   After 15 min incubation, collection of released media should be done at the same pace as in the previous incubation step (i.e., every 10 sec) to ensure that each well has been exposed to mock or secretagogue for an equal amount of time (i.e., 15 min total).

10. To determine cellular content of [^{3}H]-L-norepinephrine, add 1 ml of 0.1% Triton X-100 (in CaSB). Incubate 10 min at room temperature with gentle rotation. Collect lysates in separate scintillation vials. Add 5 ml of scintillation fluid, and count for 2 min.

Calculate amount secreted

11. For each well express the amount of [^{3}H]-L-norepinephrine secreted by dividing the radioactivity of the release medium by the sum of the radioactivity present in the cell lysate and release medium according to Equation 15.12.1.

ROUTINE GROWTH AND MAINTENANCE OF PC12 CELLS

SUPPORT PROTOCOL 1

This protocol describes two routine methods to maintain PC12 cells in culture. A widely used clone of PC12 cells may be readily obtained from the ATTC's repository, and is derived from a single-cell clonal line established from a rat adrenal pheochromocytoma, an adrenal medullary tumor (Greene and Tischler, 1976). One characteristic of this line of PC12 cells is that the cells adhere poorly to plastic and tend to grow in small patches of loosely attached cells. Alternatively, the authors routinely use an early passage (passage 8)

of the original PC12 cell line generated by Greene and Tischler (referred to in this article as early-passage PC12 cells). In contrast to ATCC-PC12 cells, early-passage PC12 cells adhere fairly well to tissue culture plastic, and tend to form confluent monolayers.

Materials

Early-passage PC12 cells or ATCC-PC12 cells (#CRL-1721)
DMEM or F12K complete culture media (see recipe)
100 μg/ml poly-L-lysine hydrobromide solution (Sigma, no. P6282)
100 μg/ml rat tail collagen Type I (Upstate, no. 08-115) in PBS (*APPENDIX 2A*)

100-mm cell culture dishes, tissue-culture treated polystyrene (e.g., Becton Dickinson-Falcon, Corning-Costar)
37°C, 6% CO_2, humidified incubator

Propagation of early-passage PC12 cells

1a. Grow cells in 100-mm cell culture dishes in 10 ml complete DMEM culture medium, in a humidified incubator, 6% CO_2, 37°C.

2a. Passage cells as necessary from a subcultivation ratio of 1:3 up to a 1:7, as needed for experiments.

Cells' doubling time is ~48 hr. Cells may be passaged when the confluency reaches ~70% to 80%. No trypsinization is necessary as PC12 cells can be easily detached from the tissue culture plastic by gently pipetting up and down in 10 ml fresh complete DMEM.

Propagation of ATCC-PC12 cells

1b. Coat 100-mm cell culture dishes by adding sufficient 100 μg/ml poly-L-lysine solution to cover the surface and incubate 60 min at 37°C. Remove poly-L-lysine solution and add sufficient 100 μg/ml rat tail collagen Type I solution to cover the surface and incubate 120 min at room temperature.

ATCC-PC12 cells adhere poorly to plastic; it is thus critical to coat the tissue culture dish with adhesion substrata. ATCC-PC12 cells attach reasonably well to a tissue culture substratum containing both poly-L-lysine and collagen.

2b. Wash the cell culture dishes two times, each time with 5 ml sterile water.

Coated dishes can be sealed with parafilm and stored for up to 3 weeks at 4°C.

3b. Grow cells in coated 100-mm culture dishes containing 10 ml of complete F12K culture medium, in a humidified incubator, 6% CO_2, 37°C.

4b. Passage as necessary to a subcultivation ratio of 1:3 up to a 1:5, as needed for your experiments.

ATCC-PC12 cells' proliferation rate is lower than the early-passage PC12 cells, with an estimated doubling time of ~72 hr. Although ATCC-PC12 cells never form a confluent monolayer, the formation of large clumps and loss of attachment to the tissue culture substratum is generally a sign of over-confluency, and thus of a need to passage the cells. For instance, ATCC-PC12 cells subcultivated at a ratio of 1:3 in a 100-mm dish are typically passaged twice a week by pipetting up and down in 10 ml fresh complete F12K medium.

BASIC PROTOCOL 2

MEASURING EXOCYTOSIS AFTER TRANSIENT TRANSFECTION OF THE REGULATED SECRETORY REPORTER PROTEIN CgA-EAP

As noted below, high-efficiency transfection of PC12 cells, and sympathoadrenal cells in general, is relatively difficult to achieve. Thus, one might find it difficult to study the influence of an exogenous, transiently (transfection) expressed protein on the exocytotic machinery of PC12 cells by merely assessing the secretion of catecholamine from [^{3}H]-L-norepinephrine-labeled cells. Indeed, this approach would provide information largely

determined by the exocytotic response of nontransfected cells, rather than from the cells expressing the protein of interest. This potential limitation of the [^{3}H]-L-norepinephrine labeling technique may be circumvented by co-transfecting a reporter protein specifically targeted to secretory granules, allowing the investigation of the effect of a co-expressed protein on the secretory pathway, in the same cell.

This protocol describes the use of CgA-EAP (Taupenot et al., 2005, Courel et al., 2006), a regulated secretory chimeric protein comprising an engineered form of secreted embryonic alkaline phosphatase (EAP) fused in-frame to the carboxy-terminus of chromogranin A (CgA), a member of the granin family of regulated secretory proteins targeted to the cores of biogenic amine- and peptide-containing secretory granules of neuroendocrine and neuronal cells, including chromaffin granules (Taupenot et al., 2003). Expression of CgA-EAP is under the control of the highly active human cytomegalovirus promoter (pCMV-CgA-EAP(N2)]. Detection of the EAP chimeric protein enzymatic activity is achieved by chemiluminescence with the substrate 3-(4-methoxyspiro[1,2-dioxetane-3,2′-(5′chloro)tricyclo[3.3.1.1(3,7)]decan]-4-yl) phenyl phosphate (CSPD). The assay is commercially available from Applied Biosystems (Phospha-Light SEAP) or Clontech (GreatEscAPe SEAP). The detection limit of EAP by chemiluminescence is ~0.1 pg/ml. Human growth hormone (hGH) may be used as an alternative reporter to analyze regulated secretion in PC12 cells (see Alternate Protocol).

The relative secretion rate (*Sec*) is calculated as a percentage of total exogenous regulated secretory protein (EAP enzymatic activity or hGH amount) present in the cells before stimulation, according to the following equation:

$$\text{Sec} = \frac{\text{RSP}_{\text{rel}}}{\text{RSP}_{\text{rel}} + \text{RSP}_{\text{cell}}} \times 100$$

Equation 15.12.2

Total exogenous regulated secretory protein (RSP) is defined as the sum of the amount released (RSP_{rel}) plus the amount remaining in the cells (RSP_{cell}).

Volumes indicated in this protocol are given for one well of a 6-well cell culture plate. The procedure can be scaled up or down to other vessel sizes (for instance, 12-well cell culture plate) by adjusting volumes in proportion to the surface area. Secretagogue-stimulated release assay of transfected reporter proteins may be performed outside a laminar-flow hood.

Materials

Early-passage PC12 cells or ATCC-PC12 cells (see Support Protocol 1)
pCMV-CgA-EAP(N2) [available from the authors]
Expression plasmid containing transgene of interest
Calcium saline buffer (CaSB; see recipe)
Stimulation buffer (see recipe)
0.1% (v/v) Triton X-100 in CaSB
Secreted Alkaline Phosphatase Chemiluminescence assay kit (e.g., Phospha-Light, Applied Biosystem, no. T1017) containing:
  Assay Buffer
  Reaction Buffer Diluent
3-(4-methoxyspiro[1,2-dioxetane-3,2′-(5′chloro)tricyclo[3.3.1.1(3,7)]decan]-4-yl) phenyl phosphate (CSPD)
37°C incubator
Cell scraper

Ethanol/dry ice or liquid N_2 baths
Luminometer (tube or plate)
Absorbance microplate reader

Additional reagents and equipment for co-transfecting PC12 cells (Support Protocol 2)

Transfect reporter protein

1. Co-transfect PC12 cells with the plasmid encoding the reporter protein [pCMV-CgA-EAP(N2)] together with an expression plasmid containing a transgene of interest (see Support Protocol 2).

   Each condition is studied at least in triplicate, including mock-transfected cells for subsequent assay background determination. Design of co-transfection experiments should include a control group where cells are co-transfected with an empty vector, preferably containing a similar promoter (e.g., CMV, SV40) to that mediating the expression of the protein of interest.

Perform secretagogue-stimulated secretion assay of reporter protein

2. Wash the cells twice with 2.0 ml of prewarmed CaSB at 2-min intervals.

   The secretagogue-stimulated release assay for the reporter proteins is typically performed 24 to 48 hr post-transfection, depending on the transfection efficiency and the sensitivity of the assay used to detect expression of the transgene. The washing steps remove any excess of serum that may contribute to high assay background. By slightly tilting the plate, aspirate the medium and add washing buffer to the edge of each well to limit cell detachment.

3. Add 700 µl of prewarmed CaSB or stimulation buffer to each well, incubate 15 min at 37°C.

   At 10-sec intervals, replace the content of each well with mock (control) solution to assess the basal (unstimulated) release, or with stimulation buffer [e.g., 60 µM nicotine in CaSB, 2 mM Ba^{2+} (BaSB; see recipe), or 55 mM KCl (KSB; see recipe)] to assess regulated secretion. When all the wells have the appropriate solution, incubate without further change for a total of 15 min. When exchanging buffers, do not allow the cells to become dry. Each condition is performed at least in triplicate. Maximum stimulation is usually achieved within 15 min, since few agonists stimulate release past this time period.

4. Terminate secretion by collecting the release medium from each well into individual microcentrifuge tubes. Centrifuge 3 min at 1700 × *g*, 4°C, to pellet any detached cells. Keep the tubes on ice until further processing.

   After 15 min incubation, collection of release medium should be done at the same pace as in the previous incubation step (i.e., every 10 sec) to ensure that each well has been exposed to mock or secretagogue for an equal amount of time (i.e., 15 min total). Microcentrifuge tubes should be kept on ice until further processing.

5. Add 700 µl of 0.1% Triton X-100 (in CaSB) to each well, and harvest cells using a cell scraper.

6. Transfer cell suspension into individual microcentrifuge tubes, and further disrupt cells by two cycles of quick freeze/thaw (using ethanol/dry ice or liquid N_2 bath). Clear lysates from cell debris by centrifuging 5 min at ~20,000 × *g*, 4°C. Save supernatants and keep on ice until further processing.

   Preparation of cell lysates in steps 5 and 6 allows the determination of the cellular content of reporter protein.

Detect CgA-EAP release by chemiluminescence

This protocol is an adaptation of Applied Biosystem's instructions for Phospha-Light chemiluminescence assay kit, which includes a heat inactivation step at 65°C in the presence of phosphatase inhibitors. Such a maneuver is designed to substantially

reduce nonspecific chemiluminescence due to endogenous alkaline phosphatases while preserving the enzymatic activity of EAP, which is heat stable and resistant to several phosphatase inhibitors (Berger et al., 1988). In PC12 cells, the assay background due to endogenous alkaline phosphatase is typically low, and it is not substantially reduced after heat inactivation and differential inhibition. Thus inactivation of endogenous alkaline phosphatases may not be required when using PC12 cells. Nevertheless, a control group of mock-transfected PC12 cells should be included in the design of every experiment to estimate the background (nonspecific chemiluminescence) of the assay (see step 13). The following volumes are given for one sample.

7. Equilibrate 50 µl of Assay Buffer to room temperature.
8. Prepare 50 µl of reaction buffer by adding 2.5 µl CSPD stock to 47.5 µl of Reaction Buffer Diluent.
9. Add 50 µl sample from step 4 (release medium) or step 6 (cell lysate) into a vessel (tube or microtiter plate) suitable for luminometry.

   A standard curve can be made with known amounts of purified placental alkaline phosphatase provided with the kit to determine the high end detection limit. The assay must be conducted within its linear range. Therefore, samples may be diluted with CaSB to remain within the range of concentration of the standard.

10. Add 50 µl Assay Buffer, mix, incubate for 5 min at room temperature.
11. Add 50 µl of reaction buffer, mix, incubate for 30 min at room temp.

    Perform incubation in the dark as CSPD substrate is sensitive to light.

12. Read chemiluminescence light output for 5 to 10 sec (expressed as relative light units, RLU) in the luminometer.
13. Calculate CgA-EAP relative (%) secretion. For each well express the amount of EAP activity secreted by dividing relative light units (RLU) of the secreted medium by the sum of RLU present in the secreted medium plus the cell lysate, according to Equation 15.12.2.

    ~10% to 20% of the chemiluminescence measured in the release medium from CgA-EAP expressing PC12 cells may be due to assay background (that is from the nonspecific chemiluminescent background of the assay reagents alone), and should be subtracted from RSP_{rel} prior calculation of the relative secretion rate of CgA-EAP. In contrast, the chemiluminescence background of cellular lysate from naive PC12 cells is negligible as compared to the 1000 to 10,000 higher chemiluminescence output of EAP enzymatic activity in CgA-EAP expressing cells.

MEASUREMENT OF HUMAN GROWTH HORMONE RELEASE

ALTERNATE PROTOCOL 1

Human growth hormone (hGH) may be used as an alternative reporter to analyze regulated secretion in PC12 cells. When expressed in PC12 cells, hGH is sorted to the regulated pathway of secretion and released by exocytosis in response to a secretagogue (Wick et al., 1993; for review see Sugita, 2004). Vectors allowing expression of hGH in PC12 cells include pXGH5 plasmid where the expression of the hormone is driven by the mouse metallothionein I promoter (Wick et al., 1993).

Several methods based on the use of monoclonal or polyclonal antibodies have been developed for in vitro measurement of hGH, including immunoradiometric (IRMA), colorimetric enzyme-linked immunosorbent (ELISA), and chemiluminescence enzyme immunoassays (CLEIA). All these assays are readily available as commercial kits. ELISA has become a method of choice for quantitative measurement of hGH, with the clear advantage that it is nonradioactive, and therefore does not require tedious procedures

associated with handling of radioactive substances. The authors currently use Roche Applied Science's colorimetric microplate hGH ELISA kit, which has a linear range of detection of ~5 to 400 pg hGH/ml.

The experimental design for the analysis of the secretagogue-stimulated exocytosis of hGH from transiently transfected PC12 cells is identical to that of CgA-EAP (Basic Protocol 2, steps 1 to 6) and can be summarized as follow:

Additional materials (also see Basic Protocol 2)

Human growth hormone ELISA kit (e.g., Roche Applied Science, no. 11585878001)

1. Co-transfect PC12 cells with a plasmid encoding hGH (e.g., pXGH5) together with an expression plasmid expressing the protein of interest (see Basic Protocol 2, step 1).
2. Perform secretagogue-stimulated secretion assay, then collect secreted media and cell lysates.
3. Quantify hGH in the secreted media and cell lysates in a microplate reader. The detailed procedure for quantification of hGH by ELISA is provided by the assay kit from the manufacturer (e.g., Roche Applied Science hGH ELISA, cat. no. 11585878001).
4. Calculate the relative (%) secretion of hGH. For each well express the amount of hGH secreted by dividing the absorbance at 405 nm of the release medium by the sum of the absorbance at 405 nm of the release medium plus cell lysate according to Equation 15.12.2.

SUPPORT PROTOCOL 2

TRANSFECTION OF PC12 CELLS USING CATIONIC LIPIDS

Many commercial cationic lipid–based transfection reagents are available for transient and stable transfection of DNA in PC12 cells. However, one should keep in mind that high-efficiency transfection of PC12 cells is relatively difficult to achieve. The following protocol describes the transfection of PC12 cells using the cationic lipid transfection reagent GenePORTER 2 (Genlantis). The authors found that this product provides a substantially higher transfection efficiency than several other popular lipid-based transfection reagents. For instance, transfection efficiency evaluated by the expression of the transgene enhanced GFP (EGFP) 48 hr post-transfection typically reaches 15% to 20%.

Masses and volumes indicated in the protocol are given for one well of a 6-well cell culture plate. Transfection can be scaled up or down to other vessel sizes by adjusting the amounts of plasmid DNA transfection reagent, and culture medium in proportion to the surface area. All of the procedures should be performed in a laminar-flow hood to maintain sterility of the cell culture.

Materials

Early-passage PC12 cells or ATCC-PC12 cells (#CRL-1721)
Poly-L-lysine (Sigma, no. P6282)
DMEM or F12K complete culture medium (see recipe)
Rat tail collagen type I (Upstate, cat no. 08-115)
Cationic lipid reagent GenePORTER 2 (Genlantis)
Plasmid DNA, purified by anion-exchange chromatography (e.g., Qiagen)
DNA diluent (Genlantis)

6-well cell culture plates, tissue-culture treated polystyrene (e.g., Becton Dickinson-Falcon, Corning-Costar)
37°C CO_2 incubator
Clear polystyrene plastic snap tubes (e.g., Becton Dickinson Falcon)

Prepare cells and reagents for transfection

1. At a time point 24 hr before transfection, split nearly confluent PC12 cells onto poly-L-lysine coated 6-well plates (early passage PC12 cells) or poly-L-lysine- and rat collagen-coated 6-well plates (ATCC-PC12 cells) at a 1:4-1:5 subcultivation ratio, using appropriate complete culture medium (see Support Protocol 1).
2. Culture cells overnight in a CO_2 incubator at 37°C so as to achieve ~40% to 50% confluency.

   Transfection efficiency is influenced by culture confluency. Best results are typically obtained when transfection is performed in PC12 cells cultured at a moderate density, i.e., in a mid-log growth phase.
3. Add 12.5 µl of GenePORTER 2 reagent to 50 µl of appropriate serum-free culture medium (DMEM or F12K) in a polystyrene tube. Mix by gently flicking the tube 4 to 5 times.
4. Dilute 2.5 µg of DNA into 62.5 µl of Genlantis' DNA diluent in a polystyrene tube. Mix by gently flicking the tube 4 to 5 times, and leave at room temperature for no more than 5 min.

   For co-transfection of several plasmids, DNA can amount to a total of 5 µg per well of a 6-well cell culture plate. In that case, maintain the ratio of GenePORTER 2 reagent (5 µl/µg of plasmid), Genlantis' DNA diluent (25 µl/µg of DNA), and basal culture medium diluent (4 µl/µl of GenePORTER 2 reagent).
5. Combine DNA solution with the diluted GenePORTER reagent, and incubate for 10 min at room temperature to allow complex formation.
6. Add 875 µl of prewarmed complete culture medium to the tube containing the DNA/GenePORTER 2 solution.

Transfect the cells

7. Aspirate culture medium from the well, and replace with 1.0 ml of DNA/GenePORTER solution.
8. Incubate cells with the transfection complex for 5 hr in a 5% CO_2 incubator at 37°C.
9. Remove transfection solution from the cells, and add 2.0 ml of appropriate fresh prewarmed complete culture medium.
10. Grow cells in a CO_2 incubator at 37°C in preparation for assay of the reporter gene (see Basic Protocol 2 and Alternate Protocol).

    Depending on the promoter activity, the translation of the transgene and its intracellular targeting, the assay for the reporter gene may be performed 24 to 72 hr post-transfection.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Barium stimulation buffer (BaSB)

150 mM NaCl
5 mM KCl
2 mM $BaCl_2$ (no calcium)
10 mM HEPES
Adjust to pH 7.4 with HCl
Store up to 1 month at 4°C

Calcium saline buffer (CaSB)

150 mM NaCl
5 mM KCl
2 mM $CaCl_2$
10 mM HEPES
Adjust to pH 7.4 with HCl
Store up to 1 month at 4°C

CaSB may be supplemented with secretagogues (e.g., nicotine 60 μM, PACAP 250 nM, ATP 100 μM) to stimulate the exocytotic response of PC12 cells.

F12K medium

410 ml F12K medium (Invitrogen, cat. no. 21127)
75 ml heat-inactivated horse serum (Gemini Bio-Products, cat. no.100-508)
12.5 ml heat-inactivated fetal bovine serum (Gemini Bio-Products, cat. no. 100-106)
5 ml 100× penicillin-streptomycin-glutamine (Invitrogen, cat. no. 10378-016)
Filter sterilize with 0.22-μm pore-size unit (e.g., Nalge Nunc, Corning)
Store up to 1 month at 4°C

This medium is used for culturing ATCC-PC12 cells.

DMEM medium

500 ml DMEM medium (Invitrogen, cat. no. 11965)
50 ml heat-inactivated horse serum (Gemini Bio-Products, cat. no. 100-508)
25 ml heat-inactivated fetal bovine serum (Gemini Bio-Products, cat. no. 100-106)
6 ml 100× penicillin-streptomycin-glutamine (Invitrogen, cat. no. 10378-016)
Filter sterilize with 0.22-μm pore-size unit (e.g., Nalge Nunc, Corning)
Store up to 1 month at 4°C

This medium is used for culturing early passage PC12 cells.

Potassium stimulation buffer (KSB)

100 mM NaCl
55 mM KCl
2 mM $CaCl_2$
10 mM HEPES
Adjust to pH 7.4 with HCl
Store up to 1 month at 4°C

COMMENTARY

Background Information

The constitutive and regulated secretory pathways represent the classical routes for secretion of proteins (Kelly, 1985). The constitutive pathway exists in every cell type, allowing rapid transport of proteins in small vesicles originating from the *trans*-Golgi network, and destined for rapid fusion with the plasma membrane. In contrast, the regulated secretory pathway found in endocrine, neuroendocrine, and neuronal cells is characterized by the sorting and concentration of a pool of secretory proteins into specialized intracellular organelles with a typical electron-dense appearance on transmission electron microscopy, prompting the morphologic term dense-core secretory granules. These granules may remain in the cell for an extended period of time after their formation, until the cell is stimulated for Ca^{2+}-dependent exocytotic fusion with the plasma membrane by a secretagogue characteristic of a particular cell type.

PC12 cells contain dense-core (chromaffin) granules that store small molecules (e.g., catecholamine, nucleotides, ascorbic acid, and Ca^{2+}), and peptide hormones and neuropeptides, including chromogranin-secretogranins (granins; Fig. 15.12.1). PC12 cells have become an important model to study the mechanisms of regulated neuroendocrine secretion,

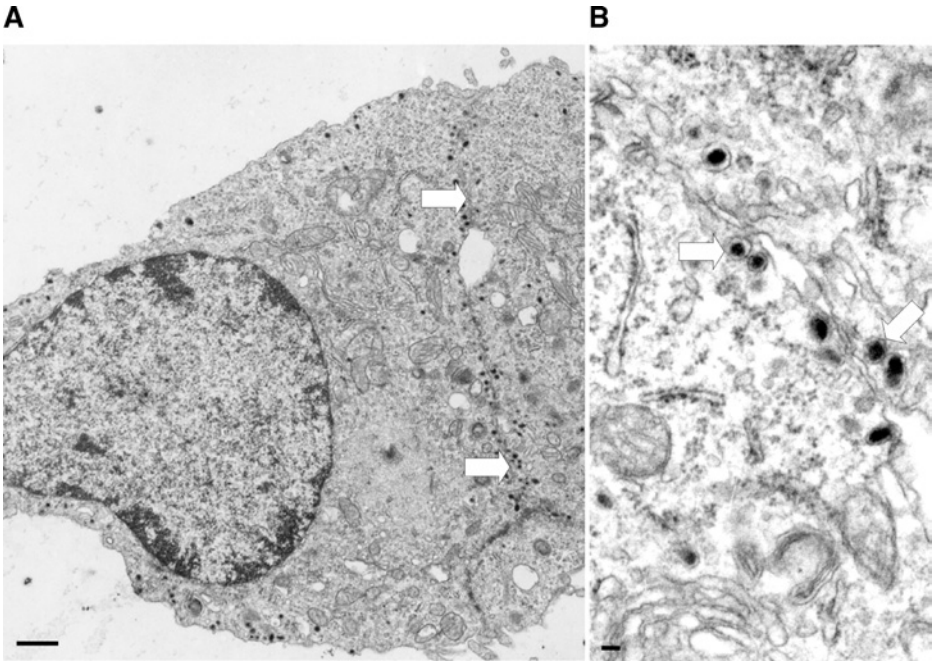

Figure 15.12.1 Electron micrograph of early passage PC12 cells. Dense-core secretory granules (arrows) are seen in the vicinity of or docked at the plasma membrane (**A**). Scale bar = 1 μm. High magnification electron micrograph in (**B**) shows the presence of electron-dense, membrane-delimited vesicles of ~100 to 130 nm in diameter (arrows). Scale bar = 100 nm. Cells were fixed in 2% paraformaldehyde and 2.5% glutaraldehyde and post-fixed in 1% OsO_4.

allowing the discovery of several components of the machinery that controls the various stages of the regulated exocytotic pathway (for review see Martin and Grishanin, 2003). A rise in intracellular Ca^{2+} is an essential requirement for the initiation of dense-core granule exocytosis, which may be stimulated in PC12 cells by a variety of extracellular triggers including secretagogues stimulating physiological pathways [60 μM nicotine (acting as a nicotinic cholinergic agonist), 250 nM pituitary adenylyl cyclase polypeptide (PACAP), 100 μM ATP], as well as nonphysiological stimuli [2 mM $BaCl_2$, Ca^{2+} ionophores (e.g., 10 μM A23187)], or by a depolarizing concentration of potassium (55 mM KCl; Mahata et al., 1997; Taupenot et al., 1999).

Critical Parameters and Troubleshooting

Procedures to maintain PC12 cells in culture are straightforward and require a basic knowledge of techniques for mammalian cell tissue culture (*UNIT 1.1*).

All the secretagogue-stimulated assays should be performed on healthy cells, growing at subconfluency to limit cell detachment during washing and buffer exchange. Buffers should be prewarmed to 37°C, as lower temperatures may reduce exocytosis.

Careful washing to remove unincorporated [^{3}H]-L-norepinephrine is critical to adequately measure basal (unstimulated) versus secretagogue-stimulated release, particularly if stimulated release of [^{3}H]-L-norepinephrine is low relative to its cellular content. For the same reason, it is important to limit cell detachment into the secreted medium during the stimulation step. In a typical experiment, basal release of [^{3}H]-L-norepinephrine from PC12 cells should be ~5% of total cellular content, and secretagogue stimulation should yield between 2 to 6 times basal release, depending on the secretagogue.

As noted earlier, studying the influence of a protein on the exocytotic response of [^{3}H]-L-norepinephrine-labeled PC12 cells may be limited by a low transfection efficiency, which is often observed with lipid-based transfection reagents. However, a modest expression of CgA-EAP or hGH is usually sufficient to report on the regulated secretory pathway in PC12 cells after stimulation with potent secretagogues such as Ba^{2+}, KCl, or ATP, since the proteins can readily be detected in the secreted medium and cell lysate with high sensitivity by

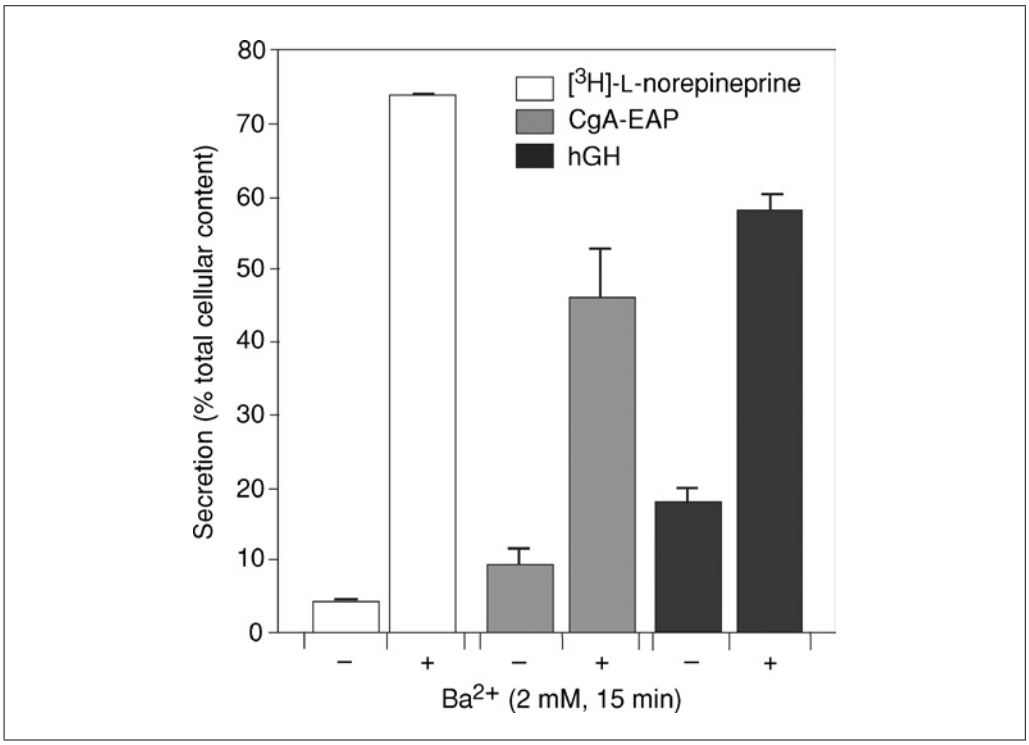

Figure 15.12.2 Detection of secretagogue stimulated exocytosis of secretory granules in PC12 cells. Cells labeled with [^{3}H]-norepinephrine, or transfected for 48 hr with CgA-EAP or hGH, were incubated for 15 min in secretion medium alone (CaSB, *mock*) or with 2 mM $BaCl_2$.

chemiluminescence or ELISA. Basal (unstimulated) release of CgA-EAP from PC12 cells is typically low at ~5% to 8% of total cellular content. On the other hand, basal secretion of hGH may be elevated when overexpressed in PC12 cells (reaching up to 20% of total hormone cellular content), which may suggest some degree of entry of the hormone into the constitutive (secretagogue-insensitive) pathway of secretion (Fig. 15.12.2; Sugita et al., 2004; Taupenot et al., 2005; Courel et al., 2006).

Anticipated Results

Following a 15-min stimulation period, PC12 cells can release up to 80% of total [^{3}H]-L-norepinephrine cellular content, but only up to 50% of the total cellular content of regulated secretory protein reporter, in response to the same stimulation. While [^{3}H]-L-norepinephrine primarily labels mature secretory granules, the expressed reporter must first route through several intracellular compartments of the early secretory pathway of PC12 cells (endoplasmic reticulum, *cis* and *trans* Golgi), prior storage into dense-core secretory granules. Hence, the total cellular content of regulated secretory protein reporter includes an intracellular pool of protein unavailable for exocytotic release. Consequently, the *relative* (%) secretion of a regulated secretory protein in response to a secretagogue is typically lower than that of [^{3}H]-L-norepinephrine, although the *absolute* exocytotic rate is expected to be the same. Shown in Figure 15.12.2 are representative secretory responses to Ba^{2+} stimulation (2 mM, 15 min) of PC12 cells labeled with [^{3}H]-L-norepinephrine, or transfected for 48 hr with CgA-EAP or hGH.

Time Considerations

Cell culture. Plating the cells on substratum-coated culture plates is done 24 to 48 hr prior transfection and usually requires up to 3 hr, including the time needed to coat the tissue culture dish with collagen and/or poly-L-lysine.

Transfection. Transfection is typically performed in the morning. Depending on the number of conditions being tested, the initial transfection procedure may require up to 2 hr, and will be followed by incubation with the transfection complex, which will be replaced with fresh complete culture medium after 5 hr. Thus the total procedure can be performed within one working day.

Radiolabeled catecholamine secretion assay. Depending on the number of conditions being tested, labeling of cells and completing

the secretagogue-stimulated release of [^{3}H]-L-norepinephrine assay requires between 4 and 5 hr.

Reporter secretory granule protein release assay. This procedure is typically performed 48 hr post-transfection and takes <2 hr. Secreted media and cell lysates may be processed the same day for chemiluminescence determination (CgA-EAP; Basic Protocol 2) or immunoassay (hGH; Alternate Protocol). Alternatively, samples may be quickly frozen, stored at −20°C or lower, and analyzed later.

Analysis of Endocytic Trafficking by Single-Cell Fluorescence Ratio Imaging

Herve Barriere[1] and Gergely L. Lukacs[1]

[1]McGill University, Department of Physiology, Montreal, Quebec, Canada

ABSTRACT

The post-endocytic sorting of internalized membrane proteins plays a critical role in numerous physiological processes, including receptor desensitization, degradation of non-native plasma membrane proteins, and cell surface retrieval of receptors from early endosomes upon ligand dissociation. Here, we describe a fluorescence ratiometric image analysis (FRIA) method used to determine the post-endocytic fate and transport kinetics of transmembrane proteins based on the pH measurement of internalized cargo-containing compartments in living cells. The method relies on the notion that the pH of a cargo-containing transport vesicle (vesicular pH, pH_v) could be taken as an indicator of its identity, considering that endocytic organelles (e.g., sorting endosome, recycling endosome, late endosome/MVB, and lysosome) have characteristic pH_v. The pH-sensitive FITC-conjugated secondary antibody is attached to the cargo via a primary antibody, recognizing the cargo extracellular domain. The pH_v is determined by single-cell FRIA. Internalized cargo colocalization with organellar markers, as well as pH_v measurement of recycling endosome, lysosome, and the TGN are discussed to validate the technique and facilitate data interpretation. *Curr. Protoc. Cell Biol.* 40:15.13.1-15.13.21. © 2008 by John Wiley & Sons, Inc.

INTRODUCTION

Endocytosis entails the cellular uptake of macromolecules (e.g., hormones, nutrients, and viruses) from the extracellular space, as well as polypeptides and lipids from the plasma membrane (Mukherjee et al., 1997). Endocytosis is critical for preserving homeostasis at the cellular, organ, and organism level by regulating cell surface receptor density and cell polarity and motility, providing nutrient uptake, and antigen presentation, just to mention a few examples (Mukherjee et al., 1997). Trafficking pathways of incoming cargo molecules, regardless of their specific entry route, seem to converge at early endosomes (Mukherjee et al., 1997; Sharma et al., 2003). Subsequent maturation of early endosomes coincides with their progressive acidification by vacuolar H^+-ATPase and formation of the tubular endosomal network (TEN), one of the critical structures where endocytic cargo sorting occurs (Mukherjee et al., 1997; Sun-Wada et al., 2004; Bonifacino and Rojas, 2006).

The biochemical and functional subcompartmentalization of the TEN, in concert with coat protein assembly at the cytoplasmic surface, ensure the concentration and packaging of transmembrane cargo molecules according to their destination (Bonifacino and Traub, 2003). Three major destinations have been delineated from the TEN (Mukherjee et al., 1997; Katzmann et al., 2002). Numerous membrane proteins recycle back to the plasma membrane by bulk flow that traverses the recycling endosomal compartment that represents the default trafficking route. Recent evidence, however, suggests the existence of a signal-dependent recycling pathway as well (Bonifacino and Traub, 2003; Maxfield and McGraw, 2004; von Zastrow and Sorkin, 2007). Another subset of cargo molecules are

Current Protocols in Cell Biology 15.13.1-15.13.21, September 2008
Published online September 2008 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb1513s40

routed to late endosome/lysosome and lysosome-like organelles relying on a variety of lysosomal sorting signals [e.g., Tyr-, di-Leu- or ubiquitin (Ub)-based motifs; Marks et al., 1996; Janvier and Bonifacino, 2005). The third possible destination is represented by the trans-Golgi network (TGN; Humphrey et al., 1993; Ghosh et al., 2003) and mediated by retrograde transport (Bonifacino and Traub, 2003; Bonifacino and Rojas, 2006).

Immuno-colocalization of cargo with markers of early and recycling endosomes, late endosomes-MVB, lysosomes, and TGN provide valuable information regarding the steady-state, as well as dynamic distribution of transmembrane proteins and the regulation of their post-endocytic sorting at the light and electron microscopy level. The post-endocytic fate of selected cargo molecules can also be monitored by biochemical assays taking advantage of covalent modification of sugar residues (e.g., sialic acid) or proteolytic processing by organelle-specific proteases (e.g., cathepsin D, metalloproteinases). In this unit, we describe an alternative method for determining the post-endocytic fate and transport kinetics of membrane proteins based on ratiometric pH_v measurements of internalized cargo-containing vesicles.

Since the pH_v of sorting endosomes, recycling endosomes, late endosomes/MVB, lysosomes, and the *trans*-Golgi network (TGN) have relatively well-defined and characteristic pH (see Table 15.13.1 and references therein), the pH_v of cargo-containing transport vesicles could be taken as an indicator of cargo localization. The pH_v is determined by single-cell fluorescence ratiometric image analysis (FRIA). The FRIA technique was originally described for lysosomal pH determination following the labeling of the lysosomal compartment with the fluid-phase marker, dextran, conjugated to the pH-sensitive fluorescein isothiocyanate (FITC; Ohkuma and Poole, 1978).

Transmembrane cargo labeling with the pH-sensitive fluorophore is usually accomplished by primary antibody (Ab) and FITC-conjugated secondary Fab capture in live cells. The primary Ab recognizes the extracellular domain of the cargo (Basic Protocol). As an alternative approach, high-affinity FITC-conjugated ligand (e.g., FITC-transferrin) could be employed if the transmembrane cargo has ligand-binding capacity. The advantage of the FRIA is its sensitivity and capacity to monitor cargo partitioning among multiple cellular compartments simultaneously. The major weakness is its inability to discriminate cargo distribution between organelles with overlapping pH_v (see Table 15.13.1). Therefore, validation of results is required to discriminate between endocytic cargo accumulation in the TGN and recycling endosomes by morphological and/or biochemical techniques (Support Protocol 5.).

The Basic Protocol is a method for determining the destination and sorting kinetics of model membrane proteins following their synchronized internalization in complex with FITC-labeled Ab. This protocol is recommended for cargo molecules that exhibit relatively high cell surface density. If the plasma membrane density of the cargo precludes the labeling of internal compartments by synchronized internalization, continuous Ab capture is used to increase the sensitivity of the assay, as described in the Alternate Protocol. We used these methods to uncover the Ub configuration that is necessary and sufficient as a lysosomal sorting signal in mammalian cells (Barriere et al., 2007). Determination of the fluorescence intensity ratio as a function of vesicular pH provides the in situ calibration for FRIA experiments and is described in Support Protocol 1. Considering that cell-specific variations may occur in the steady-state pH_v of organelles, pH_v measurements of recycling endosomes, lysosomes, and the TGN are included in Support Protocols 2, 3, and 4, respectively. Finally, additional control experiments are included to rule out premature dissociation of Abs from cargo molecules during live-cell imaging (Support Protocol 6).

MONITORING SYNCHRONIZED ENDOCYTIC TRAFFICKING OF TRANSMEMBRANE PROTEINS BY FLUORESCENCE RATIOMETRIC IMAGE ANALYSIS OF VESICULAR pH

BASIC PROTOCOL

To monitor the role of Ub in the post-endocytic sorting of transmembrane cargoes, the truncated CD4 consisting of the extracellular and transmembrane domains (CD4Tl) and its chimeric variants (CD4Tl fused to Ubs) are expressed in HEK 293 and COS-7 cells (Barriere et al., 2007). Due to the autonomous and transferable nature of sorting signals, this methodology has been widely used to identify sorting motifs in the context of different transmembrane reporter molecules (Maxfield, 1982; Presley et al., 1993; Lukacs et al., 1997; Demaurex et al., 1998). Fusing unextendable, wild-type or tetrameric mono-Ub variants to CD4Tl, this experimental design permits dissection of the role of Ub configuration as a lysosomal sorting signal in mammalian cells.

This protocol illustrates the distinct post-endocytic sorting of CD4Tl and CD4Tl-Ub following synchronized internalization. First, the anti-CD4 primary and FITC-conjugated secondary Fab are bound to CD4Tl and CD4Tl-Ub-expressing HEK 293 cells on ice. Then internalization is initiated by raising the temperature to 37°C for 1 to 30 min, followed by FRIA using an inverted epifluorescence microscope (Fig. 15.13.1). Cells are illuminated alternately with 495 nm and 440 nm fluorescent light and the emitted fluorescence is detected at 535 nm with a cooled CCD camera. Since FITC fluorescence at 495 nm excitation, but not at 440 nm, is sensitive to pH, normalization ensures that the fluorescence light intensity ratio ($495_{nm}/440_{nm}$) is primarily pH-dependent and independent of the dye concentration (Geisow, 1984).

Materials

HEK 293 cells expressing CD4Tl and CD4Tl-Ub (Invitrogen; see Barrier et al., 2006 for a description of cell lines)
DMEM-F: DMEM supplemented with 10% (v/v) fetal bovine serum (FBS)
COS-7 cells (ATCC, CRL-1651), optional
Fugene 6 (Roche)
H-DMEM-F: DMEM without bicarbonate and phenol-red (Invitrogen) supplemented with 5% (v/v) bovine serum (BS) and 15 mM HEPES

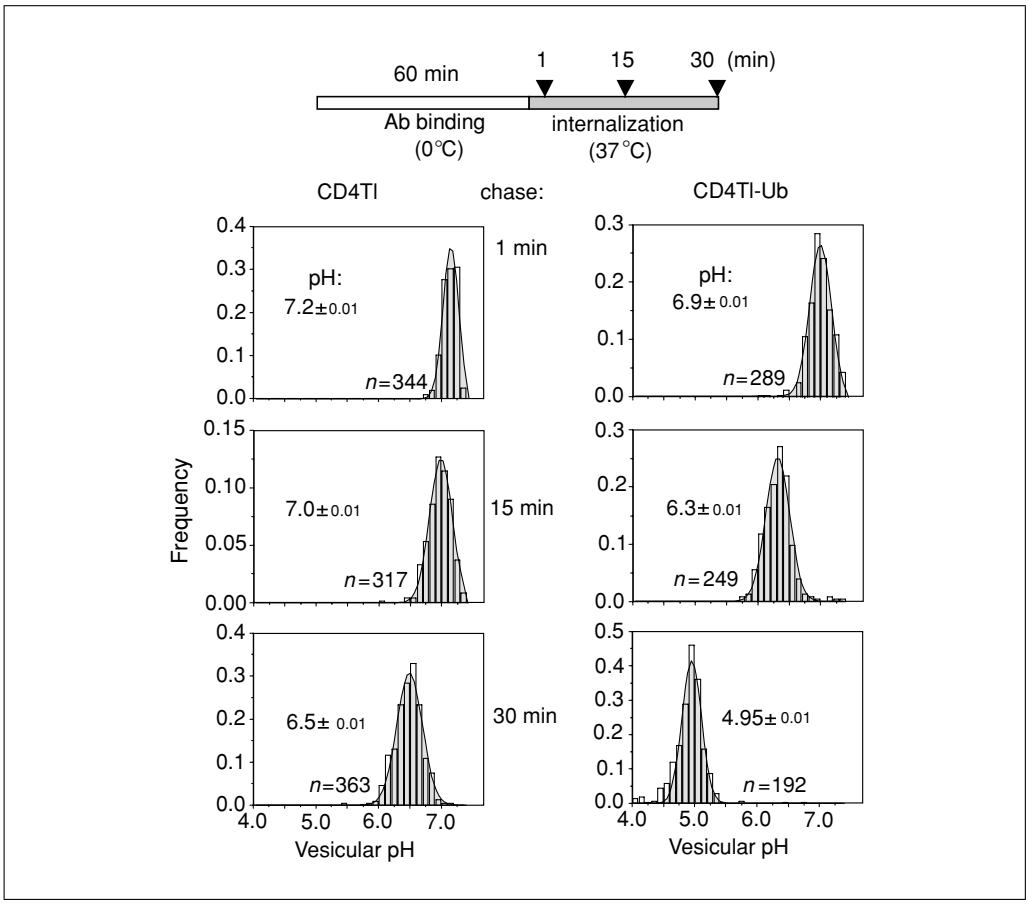

Figure 15.13.1 The lysosomal delivery kinetics of CD4TI-Ub. Anti-CD4 and FITC-conjugated secondary Fab was bound to HEK 293 cells transfected with CD4TI or CD4TI-Ub for 1 hr at 0°C. The temperature was then raised to 37°C for 1, 15, or 30 min and the pH_v was measured by FRIA. The mean pH_v (±SEM) and the number of vesicles analyzed are indicated.

Anti-CD4 antibody OKT4 (Harlan Bioproducts)
FITC-conjugated goat anti–mouse secondary Fab (Jackson ImmunoResearch Laboratories)
PBS++ solution (see recipe)
Modified Ringer's solution (see recipe)
K^+-rich buffer (see recipe)
Nigericin (Sigma-Aldrich, cat. no. N-7143)
Monensin (Sigma-Aldrich, cat. no. M-5273)

25-mm glass coverslips with standard no. 1 or no. 1.5 thickness, sterile, coated with poly-L-lysine
6-well culture plates (Falcon, cat. no. 353046)
Tissue culture incubator at 37°C with 5% CO_2
35-mm tissue culture dish
Perfusion chamber (MSC-TD, Warner Instruments)
Thermostated coverslip holder: Bipolar temperature controller (Med Systems, TC-202)
Microscope: inverted fluorescence microscope (e.g., Zeiss Axiovert 100 TV) equipped with:
Planachromat objective (63× NA 1.4, Carl Zeiss MicroImaging)
Objective heater (TempControl mini, Carl Zeiss MicroImaging)
Cooled CCD camera (e.g., Hamamatsu ORCA-ER CCD)

Filter set for BCECF: excitation filters, D495/10 and D440/20 and emission filter, D535/25 (Chroma)
Lambda 10-2 filter wheel (Sutter Instrument), containing the D495/10 and D440/20 excitation filters and used during image acquisition in step 10
Lamp: X-Cite 120 fluorescence illumination system (EXFO) allowing the adjustment of the Hg-lamp intensity (EXFO Life Sciences Division)
MetaFluor (MDS Analytical Technologies) Imaging System (for ratiometric fluorescence ion measurements and run on a PC computer)
OriginPro7 software
Ice bucket [used for cooling the cells at 4°C (e.g., steps 2, 3, 5, and 8)]
Vacuum and perfusion [used for replacing medium (see step 11)]

Prepare cells

1a. *For stably expressing cells:* At least 24 hr before the experiment, seed HEK 293 cells stably expressing CD4 chimera on poly-L-lysine-coated glass cover slips. Use 6-well tissue culture plates and 2 ml DMEM supplemented with 10% (v/v) FBS. Prepare mock transfected cells as well to verify that the fluorescent signal is negligible.

To prepare poly-L-lysine-coated coverslips follow the instructions provided by the manufacturer (Sigma, cat. no. P8920).

By the time of the FRIA, cells should be at 60% to 70% confluency.

1b. *For transiently expressing cells:* If CD4 chimeras are expressed transiently, transfect HEK 293 or COS-7 cells with the CD4 plasmid using Fugene 6 according to the manufacturer's instructions 24 to 48 hr before the measurement.

Label with the pH-sensitive probe

2. Working on ice, rinse the cells twice, each time with 2 ml ice-cold H-DMEM-F gently to avoid cell loss.

3. Bind the primary anti-CD4 antibody OKT4 (1:400 to 1:800 dilution) in 0.8 ml H-DMEM-F for 1 hr on ice.

Optimize the antibody concentration to maximize the fluorescence signal and minimize the background fluorescence. This could be achieved by using serial dilutions of the primary and secondary antibodies on transfected and nontransfected cells in pilot studies in concert with quantitative fluorescence video image analysis.

4. Rinse the cells three times, each time with 2 ml ice-cold H-DMEM-F.

5. Bind FITC-conjugated goat anti–mouse Fab (1:500 dilution) in 0.8 ml H-DMEM-F for 1 hr on ice.

6. Rinse the cells three times, each time with 2 ml ice-cold H-DMEM-F.

Internalization

7. Induce endocytosis of cargo complexed with FITC-labeled Ab by adding 2 ml prewarmed DMEM-F and transferring the plate into the tissue culture incubator (37°C) for 1 to 30 min.

8. To terminate the internalization rinse the cells with 2 ml ice-cold PBS++ solution and place the coverslip in a 35-mm tissue culture dish on ice in 2 ml modified Ringer's solution.

Acquire fluorescent ratio images

9. Mount the coverslip in the perfusion chamber and add 0.8 ml of modified Ringer's solution (25°C). Place the chamber in the thermostated coverslip holder prewarmed to 25°C. Maintain the microscope objective temperature at 25°C with a dedicated heater.

10. Acquire image pairs at 495 and 440 nm excitation wavelengths by selecting at least 10 to 15 areas on the coverslip. Do this step as quickly as possible to avoid significant cargo processing.

    It is advised that the first coverslip be used to adjust the exposure time, the camera gain and the fluorescence light intensity, and/or the lamp intensity to avoid photobleaching and saturation of the CCD camera. This is particularly important when cargo molecules partition between lysosomes and recycling endosomes in the same experiment.

Perform single-point in situ pH calibration

After completing image acquisition, single-point calibration is performed to verify that the microscope optical characteristics correspond to that observed by multi-point calibration.

11. Aspirate the modified Ringer's solution and add 0.8 ml of freshly prepared K^+-rich medium containing 10 μM nigericin and 10 μM monensin (pH 6.5, 25°C).

12. To ensure that vesicular H^+ concentration is equilibrated with the extracellular medium pH, replace the K^+-rich medium (0.8 ml) once more.

    The equilibration time required for clamping the intracellular pH to 6.5 may vary according to the vesicles and cells analyzed. Therefore, it is important to ascertain that the fluorescence ratio reaches a steady-state value by repeated image acquisition during a ~5 min time period.

13. Record the fluorescence ratio as in step 10. If the fluorescence ratio is different from that observed by the multi-point calibration technique, recalibrate the system (see Support Protocol 6).

Vesicular pH analysis

14. Setup the Metafluor program to obtain the average fluorescence intensity values of selected regions of interest (ROI) at 495 nm and 440 nm excitation wavelength in an Excel table.

    The average fluorescence intensity represents the integrated fluorescence intensity divided by the area of the ROI.

15. Select all of the ROIs corresponding to labeled vesicles in the first cell.

    Use the image obtained at 495 nm excitation wavelengths for the selection since the signal-to-noise ratio is better at 495 nm than at 440 nm. Identify as many vesicles as possible. Avoid analyzing vesicles that are in the proximity of the plasma membrane.

16. In the same cells also select three to six cytoplasmic ROIs that are free of labeled vesicles.

    These ROIs with comparable size to that of selected in step 15 will be used to calculate the background fluorescence.

17. Acquire the mean fluorescence intensity value of ROIs for all cells repeating steps 15 and 16.

18. The Excel file contains the mean fluorescence intensity value for each ROI at 495 nm and 440 nm excitation wavelengths and the background signal for each cell. Calculate the mean background fluorescence intensity at 495 nm and 440 nm excitation wavelengths for each cell. Subtract the mean background fluorescence values from the mean fluorescence intensity of each ROI at 495 nm and 440 nm excitation wavelengths to obtain the specific fluorescent signal.

    The mean fluorescence intensity of ROIs of the labeled vesicles should be at least 2-fold higher than the background fluorescence intensity.

19. Calculate the fluorescence ratio intensity values by dividing the mean fluorescence intensity at 495 nm by the mean fluorescence intensity at 440 nm for each ROI. The intensity values are corrected with the respective background fluorescence intensity. Based on the multi-point calibration curve, convert the fluorescence ratio values of ROIs to pH_v values (see Support Protocol 6).

    It is recommended to use a macro routine for executing background subtraction and transforming the ratio values into pH_v if a large number of vesicles are analyzed.

20. Plot the frequency distribution of pH_v values with the OriginPro 7.0 software using single- or multi-component Gaussian distribution. Calculate the mean pH_v for the individual peak.

    Partitioning of the cargo molecule into various organelles can be estimated based on the fractional distribution of vesicles in the individual peak relative to the total number of vesicles.

MONITORING POST-ENDOCYTIC TRAFFICKING OF TRANSMEMBRANE PROTEINS FOLLOWING CONTINUOUS LABELING OF CARGO WITH pH-SENSITIVE FLUOROPHORE

ALTERNATE PROTOCOL

If the steady-state expression of the cargo molecule at the cell surface is insufficient for synchronized labeling and endocytosis (see the Basic Protocol), association of Ab with a larger cohort of membrane proteins can be achieved by continuous labeling in the presence of extracellular primary and FITC-labeled secondary Fab at 37°C. This protocol describes the determination of CD4Tl, CD4Tl-Ub, and CD4Tl-UbR post-endocytic sorting after 1 hr labeling and 30 min chase at 37°C by the FRIA technique. Although the temporal resolution of this assay is reduced as compared to that described in the Basic Protocol, the lysosomal targeting of CD4Tl-Ub and the highly efficient recycling of CD4Tl and CD4Tl-UbR can be readily demonstrated (see Fig 15.13.2). This assay uses transiently transfected cells, but similar results are obtained in stable cell lines as well (Barriere et al., 2007).

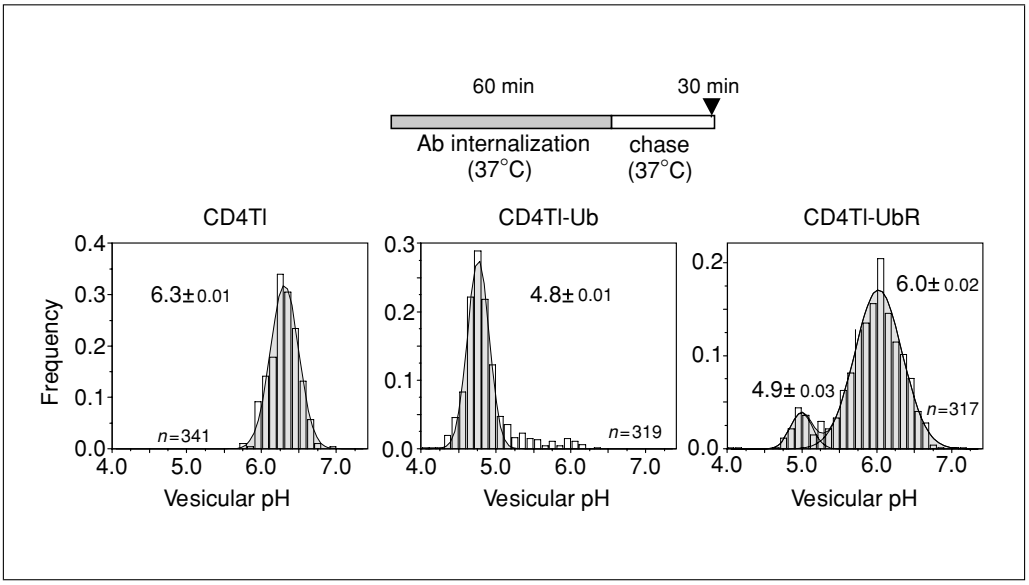

Figure 15.13.2 CD4Tl-, CD4Tl-Ub-, and CD4Tl-UbR-expressing HEK 293 cells were allowed to internalize anti-CD4 primary Ab and FITC-conjugated secondary Fab for 1 hr at 37°C and chased for 30 min in Ab-free medium before FRIA. The mean pH_v (±SEM) and the number of vesicles analyzed are indicated. Similar results were obtained in COS-7 cells.

Additional Materials *(also see Basic Protocol)*

COS-7 *or* HEK 293 cells, 70% confluent in 60-mm dishes
pCDNA3 expression vector encoding CD4Tl, CD4Tl-Ub, or CD4Tl-UbR
Fugene 6 (Roche)

Prepare cells

1. Transfect <70% confluent COS-7 (or HEK 293) cells with the pCDNA3.1 expression vector encoding CD4Tl, CD4Tl-Ub, or CD4Tl-UbR using Fugene6 according to the manufacturer's instruction. Prepare mock-transfected cells for control measurements.

   These constructs have been described in Barriere et al. (2006).

2. After 24 hr of transfection, seed the cells on glass coverslips as described in the Basic Protocol, step 1a.

Label chimeras with pH-sensitive probe

3. Incubate the cells on each coverslip with anti-CD4 antibody and FITC-conjugated goat anti–mouse Fab for 1 hr in 1 ml DMEM-F at 37°C in tissue culture incubator.

   Antibody concentrations are identical to the concentrations used in Basic Protocol steps 3 and 5.

Chase and image

4. Thoroughly wash away the extracellular Ab with 2 ml PBS++ solution at room temperature and resume the incubation of cells in 2 ml DMEM-F for 30 min at 37°C in the tissue culture incubator.

   Different chase periods would provide information about the transport kinetics of the cargo.

5. Terminate the chase and image the coverslip as described in the Basic Protocol, step 10.

6. Carry out single-point pH calibration (see the Basic Protocol, steps 11 to 13).

7. Perform data analysis (see the Basic Protocol, step 14).

SUPPORT PROTOCOL 1

PERFORMING MULTI-POINT IN SITU pH CALIBRATION

To calibrate the fluorescence ratio values as a function of pH_v, FRIA is performed after clamping the luminal pH of intracellular organelles loaded with primary Ab and FITC-conjugated secondary Fab. To optimize signal-to-noise ratio, calibration is usually, but not exclusively, performed on cells expressing a cargo molecule that is retained intracellularly (e.g., CD4Tl-Ub). If the cargo recycles with high efficiency, plasma membrane bound Abs should be removed by an acid wash (see Support Protocol 6 and Troubleshooting). Following the loading of intracellular vesicles with FITC-conjugated Fab, the luminal pH of intracellular compartments is clamped to the extracellular pH in the presence of monensin and nigericin, ionophores that mediate H^+/Na^+ and H^+/K^+ exchange (Harold and Baarda, 1968; Tartakoff et al., 1978). A multi-point calibration curve is obtained by conducting FRIA at various extracellular pH in the range of 7.4 to 4.5. The theoretical basis of this method has been described in Geisow (1984). For each pH value, ~300 vesicles are determined, and the mean pH_v is calculated, based on single-peak Gaussian distribution of pH_v (Fig. 15.13.3A,B). Considering that the pH sensitivity of FITC is reduced at pH <5.4 (pK_a ~6.4), the methodology at pH_v <5.4 can be validated using a mixture of Oregon-Green-dextran (70%) and FITC-dextran (30%). The combination of dyes increases the pH-sensitivity at acid pH, since the Oregon-Green pK_a is ~4.7 (Delmotte and Delmas, 1999). The Oregon-Green/FITC-dextran loading protocol provides similar lysosomal pH_v values to those obtained with FITC-dextran

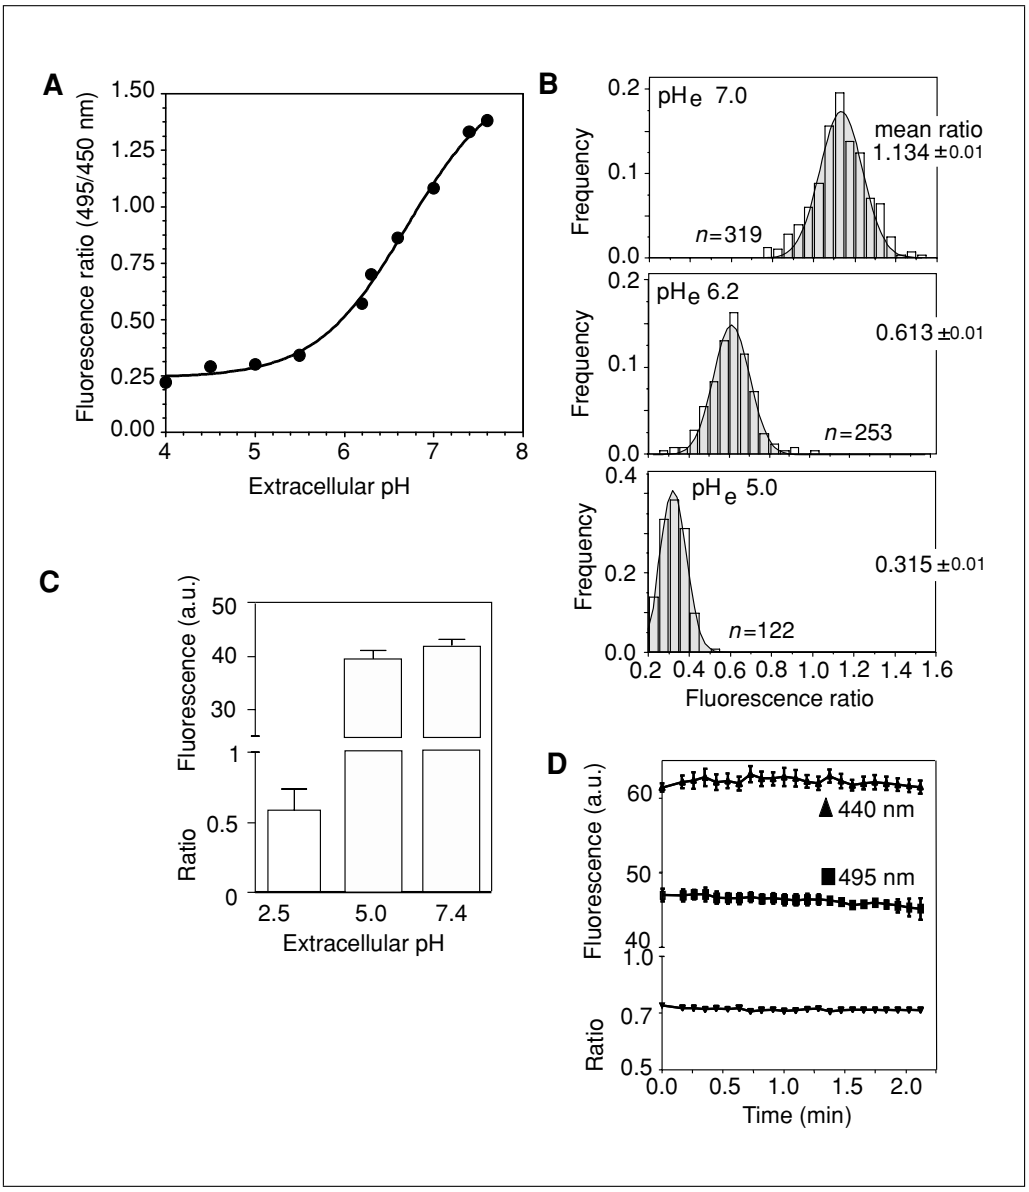

Figure 15.13.3 Calibration curve using CD4TI-Ub transfected HEK 293 cells. (**A**) Anti-CD4 primary Ab and FITC-conjugated secondary Fab are internalized for 1 hr at 37°C and chased for 30 min before FRIA. Calibration is performed as described in Support Protocol 1. (**B**) Distributions of fluorescence ratios of intracellular vesicles after clamping the cells at the indicated extracellular pH (pH_e). (**C**) Measurement of antibody-cargo dissociation in acidic environment. The cell surface antibody binding is determined as described in Support Protocol 6 at the indicated extracellular pH. (**D**) Example of photobleaching control experiment. Fluorescence intensities at 495 nm and 440 nm excitation wavelengths and the measured ratio are recorded every 5 sec for 2-min period in HEK 293 CD4TI-expressing cells. Internalization of Ab was performed as described in the Basic Protocol. Data were obtained on 25 vesicles (means ± SEM).

alone, suggesting that the extrapolating procedure for pH_v <5.4 in the presence of FITC alone is fairly reliable (Barriere et al., 2007).

Additional Materials *(also see Basic Protocol)*

Prism4 software

Prepare cells

1. Prepare the same cell type (stably or transiently expressing) used for cargo trafficking studies in the Basic Protocol (step 1a or 1b).

Prepare calibration solutions

2. Prepare 50-ml aliquots of K^+-rich medium and adjust the pH to 4.5, 5.0, 5.5, 6.0, 6.3, 6.6, 6.9, 7.2, and 7.4. Add nigericin (10 μM) and monensin (10 μM) from 10 mM stocks before the experiment.

   Note that the buffer composition of the calibration medium should be changed according to its final pH. Use 20 mM MES and 20 mM HEPES for medium with pH ≤ 5.5 and pH >5.5, respectively. The pH of the medium should be adjusted with 1 M KOH at 25°C and filter sterilized. Do not store buffers >4 weeks at 4°C and check the medium pH prior to use at 25°C.

Label chimeras with pH-sensitive probe

3. Internalize anti-CD4 primary IgG and FITC-conjugated secondary Fab in complex with CD4Tl-Ub as described in the Alternate Protocol.

   The internalization time could be extended to increase the fluorescence signal-to-noise ratio.

4. Wash the cells three times, each time with 2 ml PBS++ solution at room temperature.

Acquire fluorescence ratio images

5. Place the coverslips in the perfusion chamber and add 0.8 ml K^+-rich calibration medium containing 10 μM nigericin and 10 μM monensin at 25°C.

6. Incubate for 1 to 2 min and replace the medium to facilitate fast equilibration of the intracellular and extracellular pH (identical volume as step 5).Wait an additional 2 to 3 min and proceed with image acquisition by selecting 10 to 20 areas on the coverslip.

   It is critical to use identical or very similar acquisition parameters, including exposure time, light intensities, and camera gain, during the calibration and the FRIA experiment. If the emitted fluorescence light intensities are either below or above the detection limit, adjust the illumination light intensity, camera gain, and/or exposure time appropriately.

Determine the relationship between the fluorescence ratio value and the pH_v in situ

Calculation of the intracellular vesicle pH is based on the relationship between fluorescence ratio and pH_v values, established by the in situ multi-point calibration technique, as described in steps 1 to 5 (Fig. 15.13.3A).

7. Fit the fluorescence ratios of intracellular vesicles clamped to pH 4.5 to 7.4 by nonlinear regression analysis according to a modified version of the Henderson-Hasselbalch equation, as described originally in Geisow (1984):

$$pH_i = pK_a - \log_{10}\left(\frac{R_{max} - R_i}{R_i - R_{min}}\right)$$

   where R_i is the fluorescence ratio ($I_{495\ nm}/I_{440\ nm}$) after background subtraction and R_{max} and R_{min} are the asymptotes of minimum and maximum ratio values at highly acidic and alkaline pH, respectively. The apparent dissociation constant of FITC is indicated by pK_a, and pH_i is the intracellular pH. Rearranging the equation for defining R yields (Erdahl et al., 1995):

$$R_i = \frac{R_{min} + R_{max}10^{(pH_i - pK_a)}}{10^{(pH_i - pK_a)} + 1}$$

8. Based on measured ratio values at different pH, iterate the R_{max} and R_{min} values with the Prism4 (GraphPad Software) software. Calculate the cargo-containing pH_v with Excel, using the extrapolated constants and the calculated R value.

MEASURING THE pH OF RECYCLING ENDOSOMES

SUPPORT PROTOCOL 2

To correlate the pH_v of cargo-containing vesicles with organelle identity in your favorite cellular model, determination of the luminal pH of specific organellar compartments is recommended prior to the FRIA. Support Protocols 2, 3, and 4 describe the pH measurements of recycling endosomes, lysosomes, and the TGN, respectively. Since the recycling pathway of internalized transferrin receptor (TfR) is well documented and ~80% of the cellular TfR pool is confined to recycling endosomes at steady-state (Mukherjee et al., 1997), FITC-transferrin (Tf) is used to monitor the pH of recycling endosomes (Fig. 15.13.4A).

Additional Materials *(also see Basic Protocol)*

FITC-Transferrin f (FITC-Tf; Molecular Probes)
Holotransferrin Sigma, cat. no T-0665)
Ovalbumin (Sigma, cat. no. A-5503)

Prepare cells

1. Prepare the same cell type (stably or transiently expressing) used for cargo trafficking studies in the Basic Protocol (step 1a or 1b).

Load cells with FITC-transferrin

2. Deplete endogenous Tf by incubating COS-7 or HEK 293 cells in 2 ml serum-free DMEM for 45 min at 37°C in a tissue culture incubator.

This protocol could be adapted to any cell lines expressing the Tf receptor.

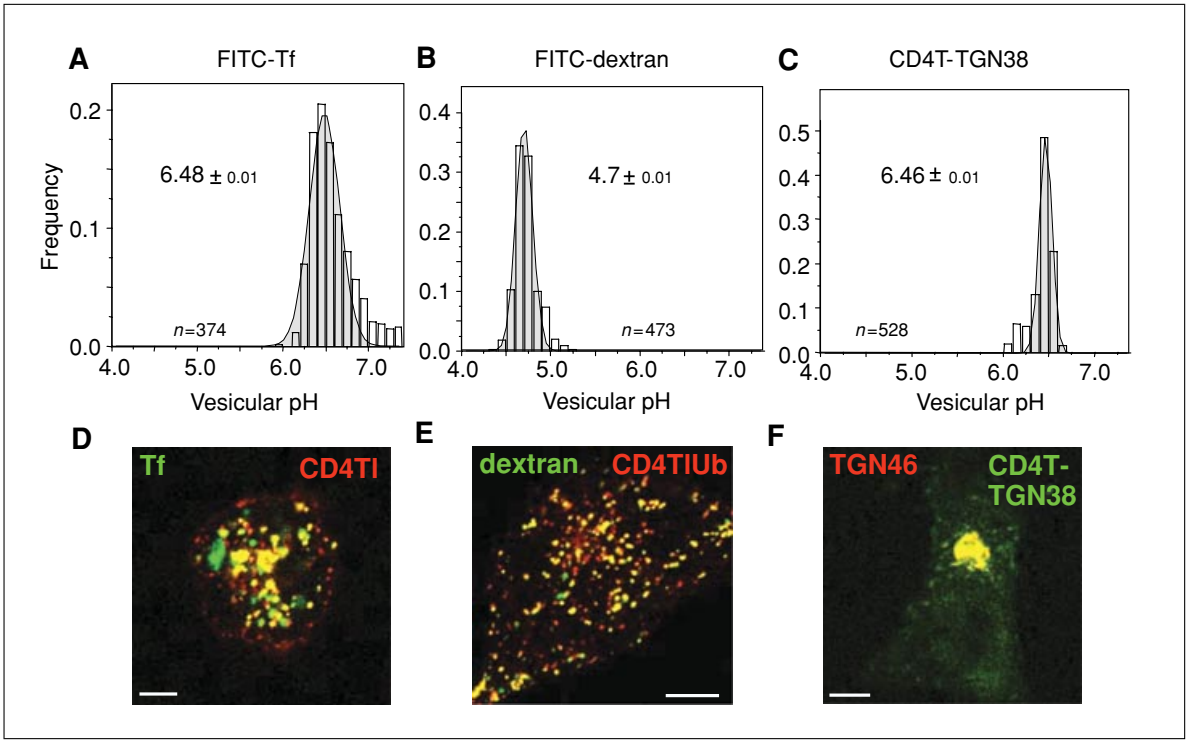

Figure 15.13.4 Colocalization and luminal pH determination studies for recycling endosomes, lysosomes, and the TGN. FRIA was carried out for recycling endosomes (**A**), lysosomes (**B**), and the TGN (**C**) using FITC-conjugated Tf, dextran, and FITC-Ab labeled CD4 as described in Support Protocols 2, 3 and 4 respectively. Subcellular colocalization of internalized CD4TI (**D**), CD4TI-Ub (**E**), and CD4T-TGN38 (**F**) chimeras with the respective organellar markers in HEK 293 cells was performed as described in the Support Protocol 5. Single optical sections were obtained by laser confocal fluorescence microscopy. Bar = 10 μm. For color version of this figure see *http://currentprotocols.com.*

3. Load the cells in 1 ml serum-free DMEM containing 5 μg/ml FITC-Tf for 1 hr at 37°C in the tissue culture incubator.
4. Transfer the cells to ice and rinse four times, each time with 2 ml of H-DMEM-F containing 1 mg/ml ovalbumin and 0.1 mg/ml holotransferrin.

Chase

5. Chase the cells for 2 min to decrease the cell-surface amount of FITC-Tf in 2 ml H-DMEM-F at 37°C.
6. Acquire fluorescence ratio images (see the Basic Protocol, steps 9 to 10).
7. Carry out single-point pH calibration (see the Basic Protocol, steps 11 to 13).
8. Analyze vesicular pH (see the Basic Protocol, steps 14 to 20).

SUPPORT PROTOCOL 3

MEASURING THE pH OF LYSOSOMES

Selective labeling of the lysosomal compartment can be achieved by the fluid-phase marker, FITC-dextran (Lencer et al., 1990; Poet et al., 2006). Following the FITC-dextran uptake, an extended chase in dextran-free medium ensures that early and late endosomes are free of the fluorophore. Colocalization of FITC-dextran loaded lysosomes with Lamp1 can validate the specificity of the dextran labeling (Falcon-Perez et al., 2005; Barriere et al., 2007).

Additional Materials *(also see Basic Protocol)*

FITC-Dextran (mol. wt. 10 kDa anionic; Molecular Probes)
Dextran (mol. wt. 68.8 kDa; cat. no. D4876)

Prepare cells

1. Prepare the same cell type (stably or transiently expressing) used for cargo trafficking studies in the Basic Protocol (step 1a or 1b).

Label lysosomes with FITC-dextran

2. Incubate cells with 5 μg/ml FITC-dextran overnight in 2 ml DMEM-F in the tissue culture incubator at 37°C.

   Filter sterilize the dextran solutions using a 0.22-μm disposable sterile filter unit to avoid contamination of the cells.

3. Rinse the cells three times, each time with 2 ml PBS++ solution.
4. Incubate the cells in 2 ml DMEM-F containing 100 μg/ml dextran for 3 hr in the tissue culture incubator at 37°C.
5. Acquire fluorescence ratio images (see the Basic Protocol, steps 9 to 10).
6. Calibrate the single-point in situ pH (see the Basic Protocol, steps 11 to 13).
7. Analyze vesicular pH (see the Basic Protocol, steps 14 to 20).

   Representative results of pH_v determination of FITC-dextran loaded lysosomes are illustrated in Figure 15.13.4B, top panel.

SUPPORT PROTOCOL 4

MEASURING THE pH OF THE *TRANS*-GOLGI NETWORK (TGN)

Considering the potential overlap in the pH of recycling endosomes and the TGN (Table 15.13.1), it is important to establish the luminal pH of the TGN in the expression system used for the FRIA. In case of overlapping pH_v, immunolocalization studies are required to distinguish between the recycling and retrograde transport route of cargo molecule (see Support Protocol 5).

Internalized TGN38 and furin are targeted via retrograde transport to the TGN from early endosomes. The localization signal of TGN38 and furin has been identified in the cytoplasmic tails using transmembrane reporter molecules (Bosshart et al., 1994; Molloy et al., 1994; Mallet and Maxfield, 1999). Chimeras bearing the TGN localization signal are instrumental in measuring the pH_v of the TGN (Humphrey et al., 1993; Demaurex et al., 1998; Machen et al., 2003). Relying on a similar strategy, we constructed a CD4T-TGN38 chimera to specifically label the TGN with primary anti-CD4 and FITC-conjugated secondary Fab.

Additional Materials *(also see Basic Protocol)*

Expression plasmid encoding the CD4T-TGN38 chimera, pCDNA3.1 (Invitrogen)
Fugene 6 (Roche)

1. Transfect <70% confluent COS-7 (or HEK 293) cells with the pCDNA3.1 expression vector encoding the CD4T-TGN38 chimera using Fugene 6 according to the manufacturer's instruction. Prepare mock-transfected cells for control FRIA measurements.

   The cytoplasmic tail of the TGN38 was fused to the extracellular and transmembrane domain of CD4 (CD4T-TGN38) as described for the Tac-TGN38 chimera (Bosshart et al., 1994). The CD4T construct was described in Barriere et al. (2006). Significant colocalization of the CD4T-TGN38 chimera with the endogenous TGN46 verified that the chimera was accumulated in the TGN (Figure 15.13.4C,F, H. Barriere, unpub. observ.).

2. After 24 hr of transfection, seed the cells on glass coverslips as described in the Basic Protocol, step 1a.

3. Incubate the cells with anti-CD4 primary Ab (1:500 dilution) and FITC-conjugated goat anti–mouse Fab (1:500 dilution) for 4 to 6 hr in 1 ml DMEM-F to label the TGN.

   Extended labeling is necessary due to the limited expression and slow exocytosis/endocytosis of the chimera.

4. To eliminate the Ab from the cell surface, wash the cells twice, each time with 2 ml PBS++ solution and incubate with 2 ml Ab-free DMEM-F at 37°C for 1 hr.

5. Acquire fluorescence ratio images (see the Basic Protocol, steps 9 to 10).

6. Perform single-point pH calibration (see the Basic Protocol, steps 11 to 13).

7. Analyze vesicular pH (see the Basic Protocol, steps 14 to 20).

   Representative results of the TGN pH_v determination are illustrated in Figure 15.13.4C.

VERIFYING THE POST-ENDOCYTIC FATE OF INTERNALIZED MEMBRANE PROTEIN BY IMMUNOLOCALIZATION

SUPPORT PROTOCOL 5

Subcellular distribution of internalized cargo, determined by FRIA, should be validated by colocalization studies using organelle markers. To selectively visualize the internalized cargo pool, endocytosed molecule is labeled with the Ab capture assay as described for the FRIA experiment (Alternate Protocol). Although both recycling endosomes and lysosomes could be labeled with FITC-Tf and FITC-dextran uptake as described in Support Protocols 2 and 3, respectively, these organelles, similar to the TGN, could be also identified by indirect immunostaining. Detection of organelle-specific antigens, e.g., TfR or rab11 (recycling endosomes), Lamp1, Lamp2 and CD63 (MVB/lysosomes), and TGN46 or TGN38 (TGN), can be performed by commercially available primary and secondary antibodies. Use identical internalization and chase period as for the FRIA studies to ascertain that colocalization results are comparable to that of pH_v measurements.

Additional Materials *(also see Basic Protocol)*

Antibodies:
Anti-TGN46 (AHP500; AbD Serotec)
TRITC-conjugated goat anti-mouse Fab (Jackson ImmunoResearch Laboratories)
TRITC-Tf (Jackson ImmunoResearch Laboratories)
4% (v/v) paraformaldehyde solution (see recipe)
1 M glycine containing PBS++ solution (see recipe)
Mounting medium (e.g., Vectashield H-1200, Vector Laboratories)
Laser confocal fluorescence microscope (e.g., LSM 510 Carl Zeiss)

Prepare cells

1. Prepare the relevant cells and transiently transfect (as described in the Basic Protocol, step 1b) with the CD4T-TGN38 expression construct.

Label internalized cargo by Ab capture

2. Internalize the relevant primary and secondary Abs complexed with cargo molecule of interest as described in the Alternate Protocol.

   The use of secondary TRITC- or Cy3-conjugated Fab is recommended to minimize photobleaching. If only mouse primary Ab is available for organelle identification, immunostaining should be performed with rabbit anti-CD4 Ab.

3. Load recycling endosomes and lysosomes with FITC-Tf and FITC-dextran as described in Support Protocols 2 and 3.

   It's possible to label two different cargoes simultaneously. For example during the 45 min TRITC-Tf (5 μg/ml) loading period, CD4Tl labeling can be carried out for the first 15 min with anti-CD4 Ab.

Chase

4. Incubate the cells in 2 ml Ab-free medium for 30 min or as performed in the FRIA experiment.

Fix the cells

5. Wash the cells twice, each time with 2 ml ice-cold PBS++ solution.
6. Fix the cells in 1 ml 4% paraformaldehyde (PFA) solution for 10 min at room temperature.
7. Wash the cells three times (5 min each), each time with 2 ml PBS++ solution, then once with 0.1 M glycine containing PBS++ solution to quench the PFA.
8. Mount the cells in mounting medium.

Acquire fluorescence confocal images

9. Collect single optical sections with the laser confocal fluorescence microscope.
10. Analyze the extent of colocalization quantitatively using an appropriate software program (e.g., Volocity, PerkinElmer).

SUPPORT PROTOCOL 6 DETERMINING THE ANTIBODY-CARGO COMPLEX STABILITY IN ACIDIC ENVIRONMENTS

Ab dissociation from cargo molecules in the acidic environment of the endosomal compartment may compromise the validity of the FRIA. To assess the primary and secondary Ab dissociation from CD4 chimeras (or other cargo) in an acidic environment mimicking the late endosomes, cell surface Ab binding is measured at different extracellular pH by an ELISA-based immunoperoxidase assay with AmplexRed as the fluorescent substrate.

The results can also be informative regarding the necessary and sufficient extracellular H^+ concentration to strip excessive Ab binding from the plasma membrane in FRIA studies.

Additional Materials *(also see Basic Protocol)*

HRP-conjugated anti–mouse Fab antibody (Jackson ImmunoResearch Laboratories)
Acetic acid buffer adjusted to pH 2.5 and 5.0
Recovery buffer (see recipe)
AmplexRed kit (Molecular Probes, cat. no. A22170)
BCA assay kit (BioRad)

12-well culture plates
96-well black plates (Greiner)
Fluorescent plate reader (e.g., POLARstar OPTIMA; BMG Labtech) with 560 and 590 nm excitation and emission wavelengths, respectively
Spectrophotometer

Prepare cells

1. Seed ($\sim 2 \times 10^5$ cells/well) mock- and CD4Tl-transfected HEK 293 cells with 1 ml DMEM-F in a 12-well plate 24 hr before the start of the experiment to obtain an 80% to 90% confluent culture the next day.

   Each measurement is done in triplicate. Nonspecific binding of the primary and secondary Ab is measured in mock-transfected cells.

Label cell surface resident cargo molecules with antibody

2. Rinse cells twice, each time with 1.5 ml ice-cold H-DMEM-F.

   All rinses should be gentle to avoid the loss of cells.

3. Add anti-CD4 Ab (1:500 dilution) in 0.6 ml H-DMEM-F and incubate the cells on ice for 60 min.

4. Wash cells four times, each time with 1.5 ml ice-cold PBS++ solution.

5. Incubate with HRP-conjugated secondary Fab (1:3000 to 1:10,000 dilution) in 0.6 ml H-DMEM-F for 60 min on ice.

   The dilution of the secondary antibody should be optimized in pilot studies to maximize the signal-to-noise ratio.

6. Wash cells six times, each time with 1.5 ml ice-cold PBS++ solution.

Perform an acid wash

7. Incubate the cells in 1 ml ice-cold acetic acid buffer at pH 5.0 and 2.5 and in H-DMEM-F for 2 min.

8. Wash twice, each time with 1.5 ml ice-cold PBS++ solution.

9. Incubate cells 3 min in 1 ml cold recovery buffer.

10. Repeat steps 7 to 9 three to four times.

Measure the cell surface bound antibody

11. Aspirate the remaining buffer and add 250 µl of the AmplexRed assay working solution prepared according to the manufacturer's description.

12. Incubate the reaction on ice for 5 to 20 min.

    Wrap the plate with aluminum foil to avoid photobleaching.

13. Transfer 100 µl of the reaction mixture to a 96-well black plate.

14. Determine the fluorescence signal in the 96-well plate using a fluorescence plate reader at 560 nm excitation and 590 nm emission wavelengths.
15. Determine the cellular protein content in each well using the BCA assay kit according to the manufacturer's instruction.
16. Normalize the fluorescence intensity by the cellular protein content.
17. Calculate the specific Ab binding. Subtract the background fluorescence, measured on mock-transfected cells, from the total fluorescence signal.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acetic acid buffer

0.2 M acetic acid
0.2 M NaCl
Adjust to pH 2.5 and 5.0 with 1 N NaOH
Store up to 5 days at 4°C

K^+-rich buffer (for in situ pH calibration)

10 mM NaCl
135 mM KCl
10 mM glucose
1 mM $CaCl_2$
1 mM $MgCl_2$
20 mM MES for pH $\leq$5.5
20 mM HEPES for pH >5.5
Adjust pH with 1 N KOH
Store up to 3 weeks at 4°C

Modified Ringer's solution

140 mM NaCl
5 mM KCl
10 mM HEPES
10 mM glucose
1 mM $CaCl_2$
1 mM $MgCl_2$
Adjust the pH to 7.3 using 1 N NaOH
Store up to 3 weeks at 4°C

Paraformaldehyde solution 4%

Add 1g paraformaldehyde (PFA; Sigma Aldrich) to 20 ml PBS
Heat to 65°C dissolve
Add 750 µl of 1 M sucrose
Adjust volume to 25 ml with PBS
Filter and store the solution in the dark up to 1 week at 4°C

PBS++ solution

PBS 1× (*APPENDIX 2A*)
1 mM $CaCl_2$
1 mM $MgCl_2$
5% BSA
Store up to 2 weeks at 4°C

Recovery buffer

150 mM NaCl
20 mM HEPES
1 mM $CaCl_2$
5 mM KCl
1 mM $MgCl_2$
Adjust to pH 7.4 with 1 N NaOH
Store up to 3 weeks at 4°C

COMMENTARY

Background Information

Each of the endo-lysosomal and biosynthetic compartments has a characteristic luminal pH that is essential for its physiological function (Mukherjee et al., 1997). The luminal pH of these organelles can be monitored after selective loading with pH-sensitive fluorophores (e.g., FITC), using quantitative fluorescence ratio image analysis (Ohkuma and Poole, 1978; Maxfield, 1989). In light of the tightly regulated pH_v of organelles, measuring the pH_v of cargo-containing vesicles can reveal the trafficking pathway of internalized membrane proteins. Either FITC-conjugated antibody or a specific ligand (e.g., Tf and EGF) with high affinity binding to the extracellular domain of cargo molecules can serve as a selective label. If the cell surface density of the cargo molecule is high, direct labeling with FITC-conjugated primary IgG or monovalent Fab is recommended to minimize cargo oligomerization. If monovalent primary antibodies are not available, the possible side effect of cross-linking has to be evaluated by comparing the antibody complexed cargo trafficking to that of the native molecule. These experiments help to rule out the possibility that oligomerization provokes lysosomal targeting as described for the cross-linked TfR (Weissman et al., 1986). If the plasma membrane cargo density is low and the intracellular pool is relatively small, amplification of the fluorescence signal intensity can be achieved by indirect staining with primary and FITC-conjugated secondary Fab, as described in the Basic and Alternate Protocols. Since complex formation of OKT4 and secondary Ab with CD4 had no influence on the internalization and trafficking of CD4 (Barriere et al., 2007), we choose to use the indirect labeling approach to amplify the fluorescent signal. The pH-sensitive fluorophore can also be attached to high-affinity ligands (e.g., Tf and EGF), as illustrated in Support Protocol 2.

Endosomal acidification induces the dissociation of a subset of ligands from their receptors, followed by the receptor delivery to the cell surface or TGN and the ligand into lysosomes (DiPaola and Maxfield, 1984; Davis et al., 1987). Similarly, Ab dissociation from cargo molecule may take place in acidic endosomes, compromising the validity of the assay. Therefore, the stability of FITC-conjugated Ab association with cargo has to be verified under acidic conditions. Support Protocol 6 describes the assessment of the stability of Ab-cargo complex at an acidic pH. Another caveat of the FRIA technique is that the pH_v of the TGN and the recycling endosomes may overlap (pH_v ~6.2 to 6.8), depending on the cell type and pH detection method (see Table 15.13.1). Therefore, assessment of the pH_v of the TGN and recycling endosomes is recommended in the specific experimental model. If the pH_v of recycling endosomes and the TGN pH_v overlap, co-immunolocalization of internalized cargo molecules with markers of recycling endosomes (e.g., TfR and rab11) and the TGN (e.g., TGN46) is necessary to distinguish between cargo destinations (Support Protocol 5). As a complementary approach, the recycling rate of cargo molecules can be measured as described for CD4-Ub chimeras (Barriere et al., 2007).

Critical Parameters and Troubleshooting

The sensitivity of the FRIA technique depends on the receptor/cargo cell surface density, internalization and recycling rate, copy number in the individual vesicle, the signal intensity of the fluorescent probe, and the fluorescence detection efficiency of the imaging system. Since the fluorescence excitation light intensity should be kept at a minimum to avoid photobleaching, it is important to use a cooled CCD camera with high quantum efficiency for image acquisition. Considering the possibility that overexpression may interfere with the intracellular itinerary of cargo by saturating the relevant sorting machinery, the cargo expression should be carefully optimized in

heterologous expression systems (Marks et al., 1996). Comparison of exogenous and endogenous protein trafficking is necessary to validate data obtained by overexpression and to demonstrate that the sorting pathway is independent of the expression level. The adverse effect of transient overexpression can be minimized by selecting stably transfected cell lines with appropriate transgene level. Control experiments should verify that heterologous expression does not interfere with the sorting pathway and kinetics of other transmembrane polypeptides with different destinations (e.g., TfR and Lamp1).

Besides enhancing cargo expression level to some extent, the detection sensitivity can be increased by adjusting the camera gain and/or extending the exposure time to fluorescence excitation light. The former method is preferred, considering that extensive illumination results in the bleaching of FITC and the loss of pH sensitivity. If the recycling efficiency is limited, the internal cargo pool can be enhanced by extending the internalization time as described in the Alternate Protocol. Selecting the Ab with the highest specific fluorescence label or ligand with the lowest nonspecific binding also improves the signal-to-noise ratio. Ab should be stored in 50% glycerol at −20°C, if not otherwise recommended. If the Ab is sensitive to glycerol, freeze the Ab in small aliquots. After thawing, the antibody can be stored for up to 5 days at 4°C. Finally, stored Ab may aggregate, and that could lead to a nonspecific signal. Aggregates can be cleared by centrifugation in a benchtop microcentrifuge at maximum speed before labeling the cell.

Reliable data acquisition requires at least a two-fold higher signal above the background fluorescence. A number of approaches can enhance the low signal-to-noise ratio. (1) Optimization of Ab dilution in pilot experiments should help to select the primary and secondary Ab concentrations and medium composition to maximize the specific signal over the background fluorescence. (2) The concentration dependence of various serum preparations (e.g., FBS and BS) and other blocking agents (e.g., BSA and ovalbumin) should be evaluated to curtail nonspecific antibody or ligand binding. (3) The medium should be free of phenol red to reduce autofluorescence. (4) Increasing the cell surface expression of cargo molecule within a reasonable limit (but see possible adverse effects above) can be accomplished by using a transient expression system and/or nonspecific transcriptional activators e.g., by pre-incubating the cells in the presence of Na-butyrate (1 to 4 mM) for 24 hr (Loffing et al., 1999; Moyer et al., 1999). (5) Increasing internalization time may increase the fluorescence signal by enhancing the labeled cargo pool size, although this would diminish the kinetic resolution of the FRIA. (6) Photo-damage of the excitation fluorescence filter set diminishes the signal-to-noise ratio. Regular visual examination of filters and replacing them in a timely manner should address this problem. (7) Proper adjustment of the camera gain, excitation light intensity, and exposure time may contribute to obtaining high-quality images. (8) Finally, it is important to work with cell lines that are free of contamination. Even latent mycoplasma infection can dramatically reduce transfectability and specific Ab binding of the cell.

Although FITC is relatively sensitive to photobleaching, the pK_a of FITC renders this fluorophore one of the best candidates for monitoring the pH of early and late endocytic compartments. However, precautions should be taken to avoid FITC photobleaching. To this end, the illumination light intensity and the exposure time of the sample should be minimized, while the cooled CCD gain is increased. Narrowing the excitation filter bandwidth and/or application of neutral density filters could also reduce the excitation light intensity and photobleaching. Verification that photobleaching is not a confounding factor during the course of the experiment should be demonstrated by successive image acquisition of the same field in a relatively short period of time, and plotting the fluorescence light intensities at 440 and 495 nm excitation wavelengths, as well as the fluorescence ratio values (Fig. 15.13.3D).

When using antibody labeling as a fluorescent probe, verify that the Ab does not modify the trafficking pathway of the respective cargo using e.g., coimmunolocalization and metabolic pulse-chase experiment (Subtil et al., 1994), since Ab-mediated cross-linking may direct plasma membrane proteins for lysosomal degradation. If this is the case, application of FITC-labeled monovalent Fab may rectify the problem (Weissman et al., 1986).

Anticipated Results

The FRIA method discussed in this unit has been used previously to follow the post-endocytic fate of various plasma membrane proteins in living cells (Piguet et al., 1999; Sharma et al., 2004; Barriere et al. 2007). We have utilized FRIA to demonstrate profound

changes in the cystic fibrosis transmembrane conductance regulator (CFTR) chloride channel endocytic sorting by the most prevalent CF-causing mutation, the deletion of the F508 amino acid residue (Sharma et al., 2004). Although the mutant CFTR is largely trapped in the ER, small amounts can be accumulated at the cell surface at reduced temperatures in the presence of chemical chaperone. Monitoring the intracellular trafficking of CFTR by FRIA clearly showed that the mutation provoked the efficient lysosomal accumulation of the internalized channel, in contrast to its wild-type counterpart that was targeted back to the cell surface (Sharma et al., 2004). In these studies CFTR was labeled with anti-HA primary and FITC-conjugated secondary antibody, taking advantage of the 3HA exofacial epitope in CFTR (Sharma et al., 2004). Predominant accumulation of the mutant in a highly acidic vesicular compartment was indicated by the single peak Gaussian distribution and mean pH_v (5.5 $\pm$ 0.1) of labeled CFTR-containing vesicles, as anticipated based on its accelerated metabolic turnover at the cell surface (Sharma et al., 2004). Supporting evidence for MVB/lysosomal accumulation was provided by the mutant channel coimmunolocalization with lysosomal markers and its severely attenuated recycling (Sharma et al., 2004). In sharp contrast, endocytosed wild-type CFTR was detected in a vesicular compartment with mean pH_v of 6.5 $\pm$ 0.1, consistent with its sorting into the recycling endosomes. This inference and the lack of accumulation of the wild-type CFTR in the TGN was substantiated by immunocolocalization with transferrin, a marker of the recycling endosomes and by direct determination of the fast recycling of internalized wild-type CFTR (Sharma et al., 2004).

Other examples for the utility of FRIA shown in this unit and published by Barriere et al. (2007) demonstrate that the technique was instrumental in elucidating the molecular requirement of ubiquitination as a lysosomal sorting signal. This experimental paradigm took advantage of the autonomous and transferable nature of lysosomal sorting signals (Bonifacino and Traub, 2003), enabling us to generate CD4 chimeras with unextendable mono-Ub, poly-Ub chain, and tetrameric mono-Ub, but it could be applied for other endocytic sorting signals as well. Rapid and high-fidelity lysosomal accumulation of the CD4 reporter molecule as detected by FRIA was indicated by the single peak Gaussian pH_v distribution and mean pH_v (4.9$\pm$0.01) for chimeras harboring poly-Ub chain or the tetrameric mono-Ub (Fig. 15.13.1 and Fig. 15.13.2; Barriere et al., 2007). In contrast, the CD4 chimera with unextendable mono-Ub accumulated in the recycling compartment, suggested by the mean pH_v (6.0$\pm$0.02, Fig. 15.13.2; Barriere et al., 2007). As pointed out in preceding paragraphs, the mildly acidic pH_v ($\sim$6.2 to 6.6) could indicate cargo accumulation in recycling endosomes or the TGN (see Table 15.13.1). Therefore, complementary assays were required to distinguish between cargo destination to TGN and/or recycling endosomes. Co-immunolocalization with organelle markers (see Support Protocol 5) and direct monitoring of the recycling efficiency of the CD4-UbR demonstrated that the chimera with unextendable Ub was predominantly routed toward the recycling compartment (Barriere et al., 2007). These examples provide compelling evidence that the FRIA technique in concert with complementary methods can serve to elucidate endocytic cargo destinations, as well as the molecular composition of autonomous sorting signals. Finally, using the synchronized labeling protocol and the FRIA technique, valuable information can be obtained for interorganellar transport kinetics of endocytic cargo as described in the Basic Protocol (Fig. 15.13.1). Frequent sampling with FRIA during the chase period can reveal the kinetics of cargo transfer from early endosomes (pH_v $\sim$5.9 to 6.0) to late endosomes (pH_v $\sim$5.4 to 6.0) and subsequent accumulation in multivesicular bodies/lysosomes (pH_v <5.5; Fig. 15.13.2).

Time Considerations

Each individual experiment is easily performed within 1 day if the cell line constitutively expresses the cargo. A half-day should be reserved for data analysis.

Quantitative Analysis of Endocytosis and Turnover of Epidermal Growth Factor (EGF) and EGF Receptor

Alexander Sorkin[1] and Jason E. Duex[1]

[1]Department of Pharmacology, University of Colorado Denver Medical School, Aurora, Colorado

ABSTRACT

Binding of epidermal growth factor (EGF) to the EGF receptor (EGFR) initiates signal transduction, ultimately leading to altered gene expression. Ligand-activated EGFR is also rapidly internalized and then targeted to lysosomes for degradation or recycled back to the plasma membrane. Endocytosis is a major regulator of EGFR signaling. Therefore, elucidation of the mechanisms of EGFR endocytosis is essential for a better understanding of EGFR biology. In order to achieve a comprehensive analysis of these mechanisms, reliable methods for measuring the rates of EGFR protein turnover and the rate parameters for individual steps of EGFR endocytic trafficking must be employed. The protocols in this unit describe methodologies to measure the rates of EGFR synthesis and degradation, to monitor EGF-induced down-regulation of surface EGFR, to measure the kinetic rate parameters of internalization, recycling, and degradation of radiolabeled EGF, and to perform radioiodination of EGF by the chloramine T method. *Curr. Protoc. Cell Biol.* 46:15.14.1-15.14.20. © 2010 by John Wiley & Sons, Inc.

Keywords: EGF receptor • endocytosis • recycling • degradation • synthesis

INTRODUCTION

At the molecular level, binding of a growth factor to EGFR triggers several signal-transduction cascades, ultimately leading to altered gene expression. There are at least six ligands of EGFR, with EGF being the best characterized. Upon ligand binding, activated EGFR is rapidly internalized through clathrin-dependent and -independent pathways of endocytosis. After internalization to early endosomes, ligand-receptor complexes are either retained in endosomes during their maturation into late endosomes or recycled back to the plasma membrane. Acceleration of internalization and degradation of EGFR by EGF results in dramatic decreases in the amount of EGFR at the cell surface (termed ligand-induced receptor down-regulation) and an eventual decrease of total cellular EGFR protein. The efficiency of receptor targeting to late endosomes and subsequent degradation by lysosomal enzymes determines the overall rate of ligand-induced receptor down-regulation.

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated area, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1D*).

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

BASIC PROTOCOL 1

MEASURING EGFR PROTEIN SYNTHESIS

The turnover rate of a protein is a function of its rates of biosynthesis and degradation. Transmembrane proteins like EGFR are synthesized by ribosomal complexes that are associated with the endoplasmic reticulum (ER), allowing for the simultaneous translocation of the nascent transmembrane protein through the ER membrane. EGFR is N-glycosylated in the Golgi complex and then delivered to the plasma membrane (Todderud and Carpenter, 1989). Fully glycosylated EGFR protein runs on SDS-PAGE as a ~170-kDa band.

Measurement of the rate of EGFR biosynthesis relies on determining the rate of incorporation of radiolabeled amino acids (methionine and cysteine) into EGFR (see *UNIT 7.1*). These two amino acids are the only ones that contain sulfur and, therefore, can be labeled with the ^{35}S isotope. ^{35}S offers a stronger radioactivity and other advantages as compared to ^{14}C, ^{3}H, and other isotopes used for radiolabeling of proteins in the research laboratory. Methionine and cysteine are rapidly transported into the cell by a concentration gradient–dependent mechanism. The cellular concentration of labeled amino acids is, therefore, maintained constant during the assay if the concentration of these amino acids is constant in the medium. Hence, the amount of the label incorporated into EGFR per unit of time can be used as a measure of the rate of EGFR biosynthesis. Since all newly synthesized proteins incorporate labeled amino acids, EGFR has to be isolated from cell lysates by immunoprecipitation (*UNIT 7.2*) followed by SDS-PAGE (*UNIT 6.1*). The amount of radioactivity associated with EGFR bands is then measured at each time point.

Materials

EGFR-expressing cells (most cultured cells of epithelial and fibroblast origin express EGFR at levels from 5,000 to 2,000,000 per cell)
Complete DMEM (*UNIT 1.1*; use 5% to 10% FBS) or other appropriate cell culture medium
DMEM or other appropriate culture medium free of L-methionine, L-cysteine, and L-glutamine (Invitrogen)
EasyTag ^{35}S-labeled amino acids (PerkinElmer)
Phosphate-buffered saline (DPBS; Invitrogen
TGH lysis buffer (see recipe) containing 150 mM NaCl
EGFR antibody mAb528 (mouse hybridoma, ATCC #HB8509)
20% (v/v) protein A–Sepharose resin (Sigma) in 50 mM HEPES
TGH lysis buffer (see recipe) containing no NaCl and 500 mM NaCl
2× sample buffer for SDS-PAGE (see recipe for 1×)
7.5% acrylamide gel (*UNIT 6.1*)
EGFR antibody 1005 (Santa Cruz Biotechnology)

60-mm plastic culture dishes
Rubber policemen
Platform rotator (e.g., Nutator from Clay Adams)
Image analysis software: e.g., ImageJ (NIH freeware)

Additional reagents and equipment for cell culture (*UNIT 1.1*), determining protein concentration (*APPENDIX 3H*), SDS-PAGE (*UNIT 6.1*), immunoblotting and immunodetection (*UNIT 6.2*), and phosphor imaging (*UNIT 6.3*)

Label cells

1. Seed EGFR-expressing cells at ~ 0.5–1.0 × 10^6 per 60-mm dish in 3 ml of complete DMEM (with 5% to 10% FBS depending on the cell line). Grow the cells for 2 days or until the cells are confluent.

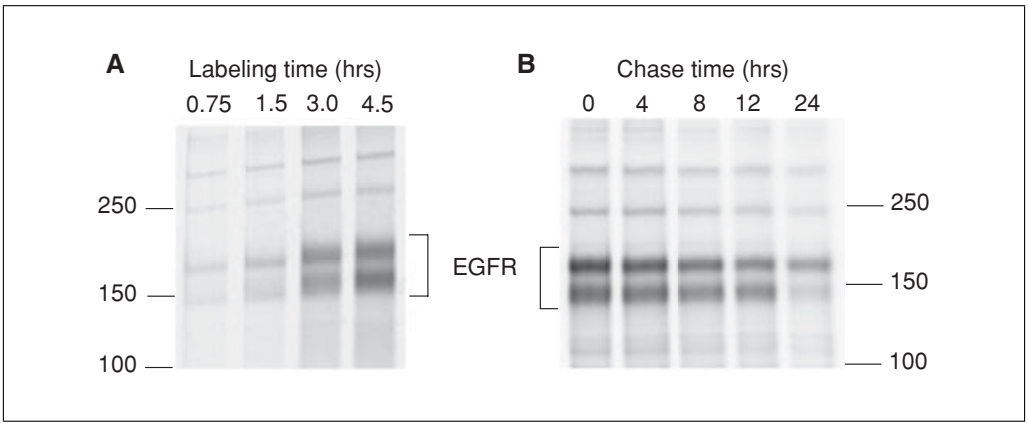

Figure 15.14.1 Examples of EGFR biosynthesis and degradation experiments. (**A**) Squamous cell carcinoma (SCC2) cells (~10^6 EGFR/cell) were incubated with the [^{35}S]amino acid labeling mix in the methionine-free medium containing 5% dialyzed FBS for 45 min to 4.5 hr. The cells were solubilized and EGFR-immunoprecipitated as described in Basic Protocol 1. (**B**) SCC2 cells were incubated with the [^{35}S]amino acid labeling mix in the methionine-free medium containing 5% dialyzed FBS for 4 hr. After washing, the cells were incubated in complete medium containing 5% FBS for 1 hr before initiating chase times of 0 to 24 hr. The cells were solubilized and EGFR immunoprecipitated as described in Basic Protocol 1. Note that EGFR immunoprecipitated from SCC2 cells runs as a doublet of 170- and 150-kDa (probably degradation-product) bands.

A basic experiment will require a minimum of four time points for each experimental condition, with two dishes per time point. Repeat the entire experiment a minimum of two times.

The SCC2 cells used in Figure 15.14.1 are grown in 5% FBS, whereas many other cell types require 10% FBS.

The amount of cells to use depends on the abundance of EGFR in the particular cell line. This protocol is geared towards cell lines that express high levels of EGFR (>100,000 receptors per cell).

2. Wash cells once with 3 ml DMEM lacking FBS, L-methionine, L-cysteine, and L-glutamine.
3. Add 3 ml of freshly prepared ^{35}S protein labeling medium to each dish and incubate the cells at 37°C for appropriate periods of time (e.g., 0.75, 1.5, 3.0, and 4.5 hr, as in Fig. 15.14.1A).
4. After each desired labeling time, place the cells on ice, collect radiolabeled medium, and dispose of it according to proper institutional procedures for radioactive waste.

   Properly dispose of all radiolabeled medium, subsequent washes, extracts and disposable labware.

5. Wash the cells three times with 3 ml ice-cold PBS. Aspirate as much as possible of the PBS after the last wash. Store dishes with washed monolayers at −70°C until further analysis.

   All dishes from the different time points of the pulse-chase are eventually frozen. Subsequent thawing and solubilization, and all remaining steps of the protocol, are performed simultaneously to minimize sample variability.

Lyse the cells

6. Place the frozen dishes on ice to thaw.
7. Add 300 µl of freshly prepared ice-cold TGH lysis buffer (with 150 mM NaCl) to each dish. Scrape the cells using a rubber policeman and transfer the lysates to 1.5-ml tubes.

8. Carry out the lysis for 10 min by gently rotating tubes on a platform rotator at 4°C.

9. Clear the lysates by microcentrifugation for 10 min at 15,000 × *g*, 4°C, and transfer the supernatants to new tubes.

10. Determine protein concentration (BradFord or Lowry assay; *APPENDIX 3H*) for each sample to assure that an equal amount of protein is added to each immunoprecipitation reaction.

11. Save an 10-µl aliquot of each cell extract for future analysis of immunoprecipitation efficiency.

Immunoprecipitate EGFR

12. Add 20 µg of affinity-purified mouse monoclonal EGFR antibody 528 (mAb528) to each tube containing an equal amount of protein and mix the tubes gently on a platform rotator for 2 hr or longer at 4°C (this amount of mAb528 is sufficient for cells with >100,000 receptors per cell, e.g., human epidermal carcinoma A-431 and human head-and-neck squamous cell carcinoma SCC2 cells).

    The amount of mAb528 needed will vary depending upon the abundance of EGFR in a particular cell line. Other antibodies that efficiently precipitate EGFR can be used. The dose of antibodies necessary for efficient immunoprecipitation should be determined in preliminary experiments using unlabeled cell lysates and immunoblotting.

13. Add 200 µl of protein A–Sepharose (20% v/v suspension in 50 mM HEPES) and continue the incubation for 1 hr at 4°C.

14. Pellet the protein A–Sepharose and bound EGFR immunoprecipitates by microcentrifugation for 2 min at 2000 × *g*, 4°C.

15. Collect supernatants and save 10-µl aliquots for future analysis of immunoprecipitation efficiency.

16. Wash the immunoprecipitates (pellets) three times with 1 ml of TGH lysis buffer containing decreasing amounts of NaCl (500 mM, 150 mM, and finally 0 mM NaCl).

17. Mix washed immunoprecipitates with 2× sample buffer for SDS-PAGE at a ratio of 1:1. Mix aliquots of cell extracts and supernatants from immunoprecipitation reactions at a ratio of 1:4 with 4× sample buffer for SDS-PAGE. Heat all samples at 95°C for 5 min, and subject to SDS-PAGE in a 7.5% acrylamide gel (*UNIT 6.1*).

Analyze labeling

18. Cut out the very bottom part of the gel (2 cm) containing most of the unincorporated low-molecular-weight radioactivity, and dispose of it in a designated ^{35}S waste container.

19. Transfer the portion of the gel that contains aliquots of cell extract input and output to nitrocellulose for subsequent analysis by immunoblotting with EGFR antibody 1005 and an appropriate loading control (see *UNIT 6.2*).

20. Carefully place the portion of the gel that contains the immunoprecipitation reactions onto chromatography paper and vacuum dry (*UNIT 6.3*).

21. For quantification of radioactivity using a phosphor imager, place the dried portion of the gel containing the immunoprecipitation reactions against an appropriate phosphor imaging screen in a phosphor imaging cassette. Expose for the necessary time (typically 12 to 48 hr), being careful not to generate a saturating signal.

22. Perform analysis of the phosphor imaging screen on an imager such as a Typhoon8600.

23. Quantify signal intensities using software such as ImageJ.

MEASURING EGFR PROTEIN DEGRADATION

ALTERNATE PROTOCOL 1

After synthesis and delivery to the cell surface, EGFR is turned over, typically with half-lives ranging from 8 to 24 hr, or longer, depending on the cell type and the level of EGFR expression. These turnover rates can be dramatically accelerated if EGFR is activated by EGF or other ligands. Measurement of the degradation rate involves pre-labeling of cells with [^{35}S]methionine and cysteine, followed by a chase incubation in the presence of an excess of the corresponding unlabeled amino acids. Since it takes several minutes for the newly synthesized receptor to acquire post-translational modifications in the Golgi complex and reach the plasma membrane, the pre-labeled cells are incubated without the label for ~30 min prior to the beginning of the chase incubation. This allows most of the newly labeled synthesized receptors to complete glycosylation and move to the plasma membrane. As in the biosynthesis assay, EGFR is immunoprecipitated before and during the chase incubation, electrophoresis is performed, and the amount of radioactivity in each EGFR band is measured. In contrast to the biosynthesis assay, the amount of labeled EGFR decreases during the chase incubation due to degradation. An example of a degradation experiment is shown in Figure 15.14.1B.

Additional Materials *(also see Basic Protocol 1)*

Experimental compounds of interest (e.g., EGF)

1. Prepare the cell cultures as in Basic Protocol 1, steps 1 and 2.

2. Add 3 ml of freshly prepared [^{35}S]protein labeling medium to each dish and incubate the cells at 37°C for 4 hr or longer.

   Incubation of cells with labeling medium for less than 4 hr may result in labeling of only a small pool of EGFR, since the half-life of EGFR is typically 8 to 24 hr. However, long incubations of some cells (in particular, cancer cells with enhanced metabolism) in methionine-cysteine-free medium and dialyzed serum may cause a substantial toxicity.

3. After an appropriate incubation time, dispose of the radioactive medium properly and rinse the cells with 3 ml of DMEM lacking FBS, L-methionine, L-cysteine, and L-glutamine.

4. Add 4 ml of fresh, complete medium with 10% (v/v) FBS to each dish. Incubate the cells at 37°C for 30 min to allow newly synthesized EGFR to reach the plasma membrane.

5. Following the 30-min incubation time, add any desired experimental compounds (for instance, EGF at 1 to 200 ng/ml dosage) and chase the cells for appropriate times at 37°C (e.g., 0, 4, 8, 12, and 24 hr as in Fig.15.14.1B).

   The range of chase incubations is discussed below in Commentary.

6. At the end of each chase incubation period, wash the appropriate dishes three times with 3 ml ice-cold PBS and store at −70°C for later analysis.

7. Thaw and lyse the labeled cultures, immunoprecipitate, and analyze the samples by following steps 6 through 23 of Basic Protocol 1.

MEASURING EGFR DOWN-REGULATION

Calculation of the number of EGFR molecules at the cell surface is based on measuring the number of EGF binding sites per intact cell. Because the stoichiometry of the EGF-EGFR interaction is 1:1, radiolabeled [^{125}I]EGF with known specific activity can be used to determine the number of EGF binding sites or surface EGFR per cell. This [^{125}I]EGF binding assay is performed at 4°C to avoid the uptake of [^{125}I]EGF inside the cell due to endocytosis. For an example of results of a down-regulation experiment, see Figure 15.14.2.

Materials

EGFR-expressing cells (most cultured cells of epithelial and fibroblast origin express EGFR at levels from 5,000 to 2,000,000 per cell)
Complete DMEM (*UNIT 1.1*; use 5% to 10% FBS) or other appropriate cell culture medium
Recombinant human culture-grade EGF (BD Biosciences, cat. no. 354052)
Binding medium; DMEM or other medium containing 0.1% (w/v) BSA
Sodium acetate buffer, pH 4.5: 0.2 M sodium acetate, pH 4.5 (*APPENDIX 2A*)/0.5 M NaCl
1 to 200 ng/ml [^{125}I]EGF (sp. act. ~200,000 cpm/ng; Support Protocol)
1 N NaOH
12-well plastic culture plates

Additional reagents and equipment for cell culture (*UNIT 1.1*)

Prepare cells

1. Seed EGFR-expressing cells at ~0.125–0.250 × 10^6 cells per well of a 12-well dish in 2 ml of complete DMEM (with 5% to 10% FBS depending on the cell line). Grow the cells for 2 days or until the cells are confluent.

   A basic experiment will require a minimum of four time points for each experimental condition, with four wells of a 12-well dish per time point. Repeat the entire experiment a minimum of two times. Three additional wells are used for cell counting.

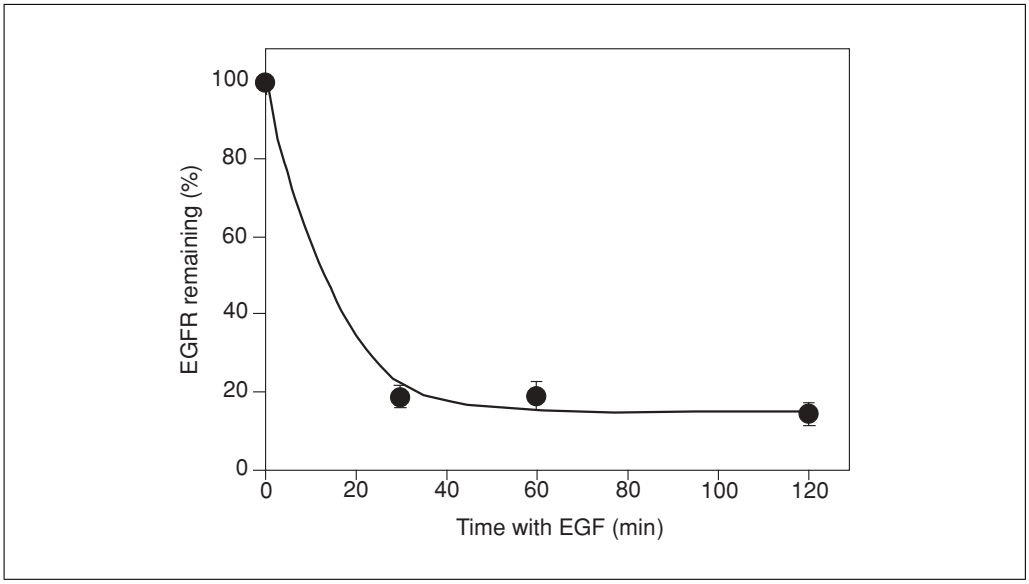

Figure 15.14.2 Example of EGFR down-regulation experiment. Porcine aortic endothelial cells stably expressing EGFR were incubated with 100 ng/ml EGF for 30 to 120 min at 37°C, acid washed, and further incubated with 50 ng/ml [^{125}I]EGF for 1 hr at 4°C. The cells were solubilized in NaOH. The specific radioactivity of cell lysates was determined and expressed as percent of the specific radioactivity associated with cells that were not incubated with unlabeled EGF (mean ± SE).

A confluent monolayer helps to maximize specific binding of [^{125}I]EGF to cells and minimize nonspecific binding of [^{125}I]EGF to plastic surfaces of culture dishes.

Incubate cells with and without EGF

2. Incubate the cells with or without unlabeled EGF in binding medium (1 ml/well of 1 to 200 ng/ml) for various lengths of time at 37°C starting from the longest incubation time.

   The start of shorter incubations is delayed to make it possible harvest all cells in the 12-well plate in the same time.

   Possible lengths of incubations with EGF and EGF concentrations are discussed in Commentary.

3. At the end of the longest incubation time, place the cells on ice and rinse once with 1 ml ice-cold medium to remove unbound EGF.

4. Strip surface-bound, unlabeled EGF by incubating the cells with sodium acetate buffer, pH 4.5, for 2.5 min (1 ml/well) at 4°C, then washing the cells twice, each time with 1 ml ice-cold culture medium, to neutralize the acid.

   This is an important step that has been omitted in many studies. If cold EGF is not stripped from receptors, binding of [^{125}I]EGF at step 5 will be underestimated. The mild acidic wash does not affect EGFR properties.

Incubate the cells with labeled EGF

5. Incubate the cells in 1 ml of binding medium containing saturating concentrations of [^{125}I]EGF (up to 200 ng/ml) alone (specific binding) or together with a 50-fold molar excess of unlabeled EGF (controls for nonspecific binding) at 4°C for 1 hr.

6. Rinse the wells three times with 1 ml ice-cold DMEM or other medium to remove unbound [^{125}I]EGF. Aspirate the medium as much as possible after the last wash.

   There are high- and low-affinity EGF binding sites in most studied cells. The mechanisms determining the EGF binding affinity are unknown. If [^{125}I]EGF is used at low concentrations it may predominantly bind to high-affinity receptors that would yield misleading results. The number of high-affinity sites may not be proportional to the total receptor number under various experimental conditions.

Measure radioactivity

7. Lyse the cells in 1 ml of 1 N NaOH for 1 hr or longer at 37°C to determine cell-bound radioactivity.

8. Measure nonspecific binding for each time point in the presence of unlabeled EGF (see step 5).

   Typically nonspecific binding is not more than 10% to 20% of the total [^{125}I]EGF binding.

Make calculations

9. Calculate the specific binding by subtracting the nonspecific radioactivity from total bound radioactivity for each time point of the time course.

10. Translate cpm values into the number of EGFR molecules per well (number of surface EGFRs) based on the specific activity of each [^{125}I]EGF preparation.

    No. of EGFRs per well = [(cpm/well)/(spec.act. – cpm/ng)] × 10^{11}.

11. Divide the number of surface EGFR per well by the number of cells in the well to obtain a number of EGFRs per cell.

    No. of EGFRs per cell = (EGFR/well)/(no. of cells/well).

MEASURING INTERNALIZATION OF [^{125}I]EGF

Binding of EGF to EGFR at the cell surface results in acceleration of internalization of receptors. After internalization into early endosomes, EGF-receptor complexes are either recycled back to the plasma membrane or sorted to late endosomes and lysosomes where both EGF and EGFR are degraded. Availability of EGF, its high level of stability, and the ease in preparing fully active labeled forms of EGF has led to wide use of various EGF conjugates for the quantitative analysis of EGFR endocytosis. Endocytosis assays that use radiolabeled EGF ([^{125}I]EGF) remain the gold standard of quantitative endocytosis assays because ^{125}I-radioactivity detection is highly sensitive and linear within a large range of radioactivity concentrations.

The internalization assay is based on short incubations of cells with [^{125}I]EGF followed by separation of surface bound [^{125}I]EGF from intracellular (internalized) [^{125}I]EGF. Internalization is highly temperature-dependent and, therefore, this assay is performed at 37°C. The internalization is stopped by placing cells on ice followed by the stripping of surface [^{125}I]EGF. The most reliable method to strip [^{125}I]EGF bound to surface receptors without affecting intracellular [^{125}I]EGF is a low-pH treatment (pH 2.5 to 2.8; Haigler et al., 1980). The stripped [^{125}I]EGF is then quantitated as the surface-bound [^{125}I]EGF, whereas acid-wash-resistant [^{125}I]EGF corresponds to internalized [^{125}I]EGF. The ratio of internalized to surface [^{125}I]EGF (I/S) plotted against incubation time is considered to be a measure of the apparent internalization rates. Internalization is considered to be a first-order kinetics process. Therefore, the specific rate of internalization depends on the concentration of EGF-receptor complexes at the cell surface. The precise and easy calculation of the internalization rate constant k_e can be performed if the [^{125}I]EGF concentration at the cell surface remains constant during the time-course of [^{125}I]EGF uptake. Under these conditions, the I/S ratio displays a linear dependence on time, and, therefore, k_e corresponds to the linear regression coefficient of I/S dependence on time. See Wiley and Cunningham (1982) for detailed explanations.

NOTE: Rapid handling of all steps of this procedure, particularly washes, is critical because of the short incubations of cells with [^{125}I]EGF.

Materials

EGFR-expressing cells (most cultured cells of epithelial and fibroblast origin express EGFR at levels from 5,000 to 2,000,000 per cell)
Complete DMEM (*UNIT 1.1*; use 5% to 10% FBS) or other appropriate cell culture medium
Binding medium; DMEM or other medium containing 0.1% (w/v) BSA
0.1 to 200 ng/ml [^{125}I]EGF (sp. act., ~200,000 cpm/ng; Support Protocol)
Recombinant human culture-grade EGF (BD Biosciences, cat. no. 354052)
Sodium acetate buffer, pH 2.8: 0.2 M acetic acid/0.5 M NaCl, pH 2.5 to 2.8
1 N NaOH

12-well plastic cell culture plates
γ-counter vials
γ counter

Additional reagents and equipment for cell culture (*UNIT 1.1*)

Prepare cells and binding medium

1. Seed EGFR-expressing cells at 0.125 to 0.25 × 10^6 cells/well in 12-well plates in 2 ml of DMEM containing 5% to 10% FBS and grow for 2 days or until confluent.

Typically, each experiment includes at least five time points, each represented by two to four wells of a 12-well dish. The time-course experiment needs to be repeated at least twice to obtain statistically significant data.

The use of confluent monolayers helps to minimize nonspecific binding of [^{125}I]EGF to plastic surfaces of a culture dish.

UNIT 1.1 describes basic cell culture techniques.

2. Prepare [^{125}I]EGF-containing binding medium (see Commentary for consideration of [^{125}I]EGF concentrations) and the same [^{125}I]EGF-containing medium supplemented with 50× to 100× molar excess of unlabeled human recombinant EGF ("nonspecific" medium).

   For each 12-well plate, 3 ml each of "specific" (not containing unlabeled EGF) and "nonspecific" medium are needed and should be warmed to 37°C prior to the assay.

   IMPORTANT NOTE: *Prepare 6.5 ml of [^{125}I]EGF-containing medium and then add unlabeled EGF to 3 ml of this medium. After the experiment, the remaining ~0.5 ml is used to measure the specific activity of [^{125}I]EGF.*

3. Place the plate in a water bath at 37°C.

Bind [^{125}I]EGF to the cells

4. Quickly wash two wells with 1 ml of warm (37°C) binding medium without labeled or unlabeled EGF. To these wells, add 0.5 ml of specific or nonspecific [^{125}I]EGF-containing medium (one well each).

   These cells correspond to a 6-min time point.

   It is advisable to add specific and nonspecific medium to the two wells simultaneously using a pipettor in each hand.

5. Repeat the same procedure (step 4) with the other five pairs of wells at 1-min intervals while the dish is kept at 37°C.

   In this way each pair of wells (specific and nonspecific) receives the radioactive medium at precisely 1-min intervals.

Remove unbound [^{125}I]EGF

6. After the last pair of wells has incubated for 1 min, place the dish on ice and rapidly aspirate the radioactive medium and discard as radioactive waste.

7. Rapidly wash the monolayers three times with the ice-cold medium by adding ~1 ml per well, followed by vacuum aspiration to remove as much unbound [^{125}I]EGF as possible after the last wash.

   This step is performed as quickly as possible to minimize the dissociation of [^{125}I]EGF from surface receptors during washes.

Strip the surface-bound [^{125}I]EGF

8. Strip surface-bound [^{125}I]EGF from all wells by incubating cells for 5 min with sodium acetate buffer, pH 2.8, at 1 ml/well, 4°C. Collect this acid wash in γ-counter vials, perform another short rinse with 0.5 ml/well of acetate buffer, pH 2.8, and combine with the original wash in the vial to determine the amount of surface-bound [^{125}I]EGF by gamma counting.

Measure internalized [^{125}I]EGF

9. Lyse the cells in 1 ml of 1 N NaOH for 1 hr at 37°C to determine the amount of internalized [^{125}I]EGF by gamma counting.

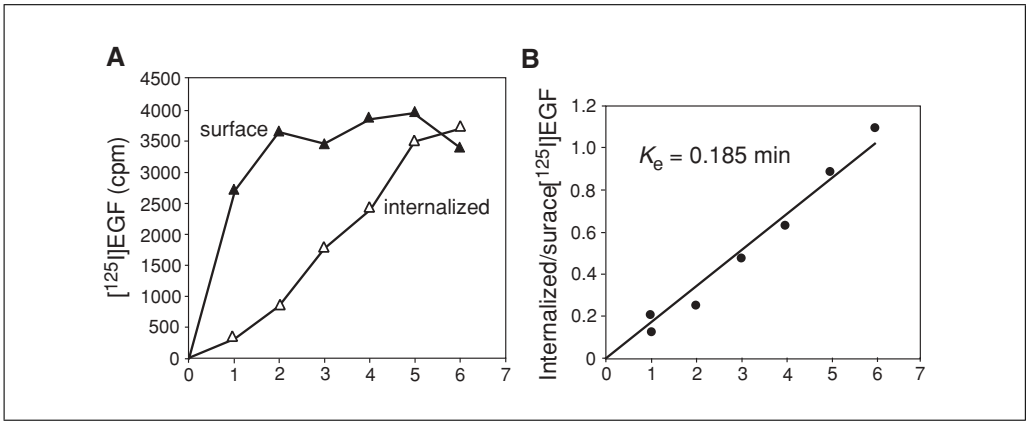

Figure 15.14.3 Example of the [^{125}I]EGF internalization assay. NIH 3T3 cells stably expressing EGFR tagged with GFP were incubated with 1 ng/ml [^{125}I]EGF for 1 to 6 min according to Basic Protocol 3. (**A**) The specific [^{125}I]EGF radioactivity of acid-wash (surface) and acid-resistant [^{125}I]EGF (internalized) are plotted against time. (**B**) The ratio of internalized to surface [^{125}I]EGF is plotted against time. The linear regression coefficient was calculated to obtain the k_e value.

Perform calculations

10. Calculate the specific radioactivity of the acid-sensitive (surface) and acid-insensitive (internalized) fractions by subtracting nonspecific counts from the corresponding counts of specific wells (Figure 15.14.3A).

    Nonspecific radioactivity is typically not more than 3% to 10% of the total counts.

    Internalization is considered to be a first-order kinetics process. Therefore, the specific rate of internalization depends on the concentration of EGF-receptor complexes at the cell surface.

11. To estimate the rate of internalization, plot the ratio of specific internalized to specific surface radioactivity (I/S) against time (Figure 15.14.3B).

    The slope of this plot corresponds to the apparent rate of internalization. If this slope is linear, it can be used to calculate the rate constant of internalization (k_e). k_e is the linear regression coefficient of the dependence of I/S ratio on time. Such a simple calculation of the values is, however, possible only if the amount of occupied surface receptors stays relatively constant during the time course of [^{125}I]EGF uptake.

    Figure 15.14.3 shows an example of internalization data from one 12-well plate. In Figure 15.14.3A the amount of surface [^{125}I]EGF is relatively constant (does not decrease due to EGF-induced down-regulation of surface EGFR). This results in a near linear dependence of I/S [^{125}I]EGF ratio on time and, therefore, allows calculation of the k_e value (Fig. 15.14.3B).

BASIC PROTOCOL 4 MEASURING [^{125}I]EGF RECYCLING AND DEGRADATION

The rationale to use [^{125}I]EGF for estimating both the recycling and degradation rates of EGFR is underscored by two important facts. First, EGF, which is sorted at the early endosome for degradation in the lysosome, does not significantly dissociate from the internalized EGFR until it reaches the lysosome (Sorkin et al., 1988). Second, degradation of [^{125}I]EGF results in a product that can be biochemically separated from intact [^{125}I]EGF which has been recycled or remains internalized. The recycling/degradation assay is based on loading early endosomes with [^{125}I]EGF-receptor complexes by allowing cells to endocytose [^{125}I]EGF. The endocytosis is then stopped at 4°C, and [^{125}I]EGF that has not been internalized is stripped from the cell surface by the mild acidic wash treatment. When cells are returned to 37°C, a pool of [^{125}I]EGF-receptor complexes are recycled back to the cell surface, where [^{125}I]EGF is released from the receptor or

re-internalized. Another pool of internalized [^{125}I]EGF-receptor complexes are sorted from early endosomes to late endosomes and lysosomes where [^{125}I]EGF-receptor complexes are degraded by proteolytic enzymes. This degradation results in the release of mono- and di-[^{125}I]iodotyrosines, which readily penetrate membranes and accumulate in the extracellular medium. This form of ^{125}I radioactivity is not precipitable by trichloroacetic acid (TCA) and is used as a measure of the rate of [^{125}I]EGF degradation. Only negligible amounts of TCA-soluble ^{125}I can be detected in the cells. On the other hand, intact [^{125}I]EGF (TCA-precipitable) detected in the medium and at the cell surface (acid-wash stripped) after the chase incubation of [^{125}I]EGF-loaded cells corresponds to [^{125}I]EGF-receptor complexes that have recycled from endosomes to the plasma membrane.

Recycling and degradation can also be considered first-order processes. This means that their rates are proportional to the concentration of [^{125}I]EGF in early/sorting endosomes. However, the calculation of specific rate constants is difficult due to heterogeneity of endosomal compartments and the decrease in the concentration of [^{125}I]EGF in early/sorting endosomes during the chase time. Also, the presence of unlabeled EGF (Basic Protocol 4) and re-internalization of [^{125}I]EGF-receptor complexes (Alternate Protocol 2) make calculations of specific rate constants challenging. Therefore, it is important to interpret the results of the recycling/degradation assay described in these protocols only as apparent rates. In theory, kinetic rate parameters can be calculated by using computational modeling that takes into account all EGF-receptor association-dissociation parameters and apparent trafficking rates (see, for example, Resat et al., 2003). For a schematic of the assay and example of results, see Figure 15.14.4.

Materials

EGFR-expressing cells (most cultured cells of epithelial and fibroblast origin express EGFR at levels from 5,000 to 2,000,000 per cell)
Complete DMEM (*UNIT 1.1*; use 5% to 10% FBS) or other appropriate cell culture medium
Binding medium: DMEM or other medium containing 0.1% (w/v) BSA
1 to 200 ng/ml [^{125}I]EGF (sp. act., ~200,000 cpm/ng; Support Protocol)
Recombinant human culture-grade EGF (BD Biosciences, cat. no. 354052)
Sodium acetate buffer, pH 4.5: 0.2 M sodium acetate buffer, pH 4.3 to 4.5 (*APPENDIX 2A*)/0.5 M NaCl
Sodium acetate buffer, pH 2.8: 0.2 M acetic acid/0.5 M NaCl, pH 2.5 to 2.8
1 N NaOH
10% (w/v) trichloroacetic acid (TCA)/2% (w/v) phosphotungstic acid (PTA) in H_2O

35-mm plastic cell culture dishes
γ-counter vials
γ counter
Refrigerated centrifuge

Additional reagents and equipment for cell culture (*UNIT 1.1*)

Prepare cells

1. Seed 0.25 to 0.50 $\times$ 10^6 cells in 35-mm culture dishes in 2 ml of DMEM containing 5% to 10% FBS and grow for 2 days or until confluent.

   UNIT 1.1 describes basic cell culture techniques.

   Typically, at least five time points are required, each represented by two to three dishes. The entire time-course experiment should be repeated at least twice.

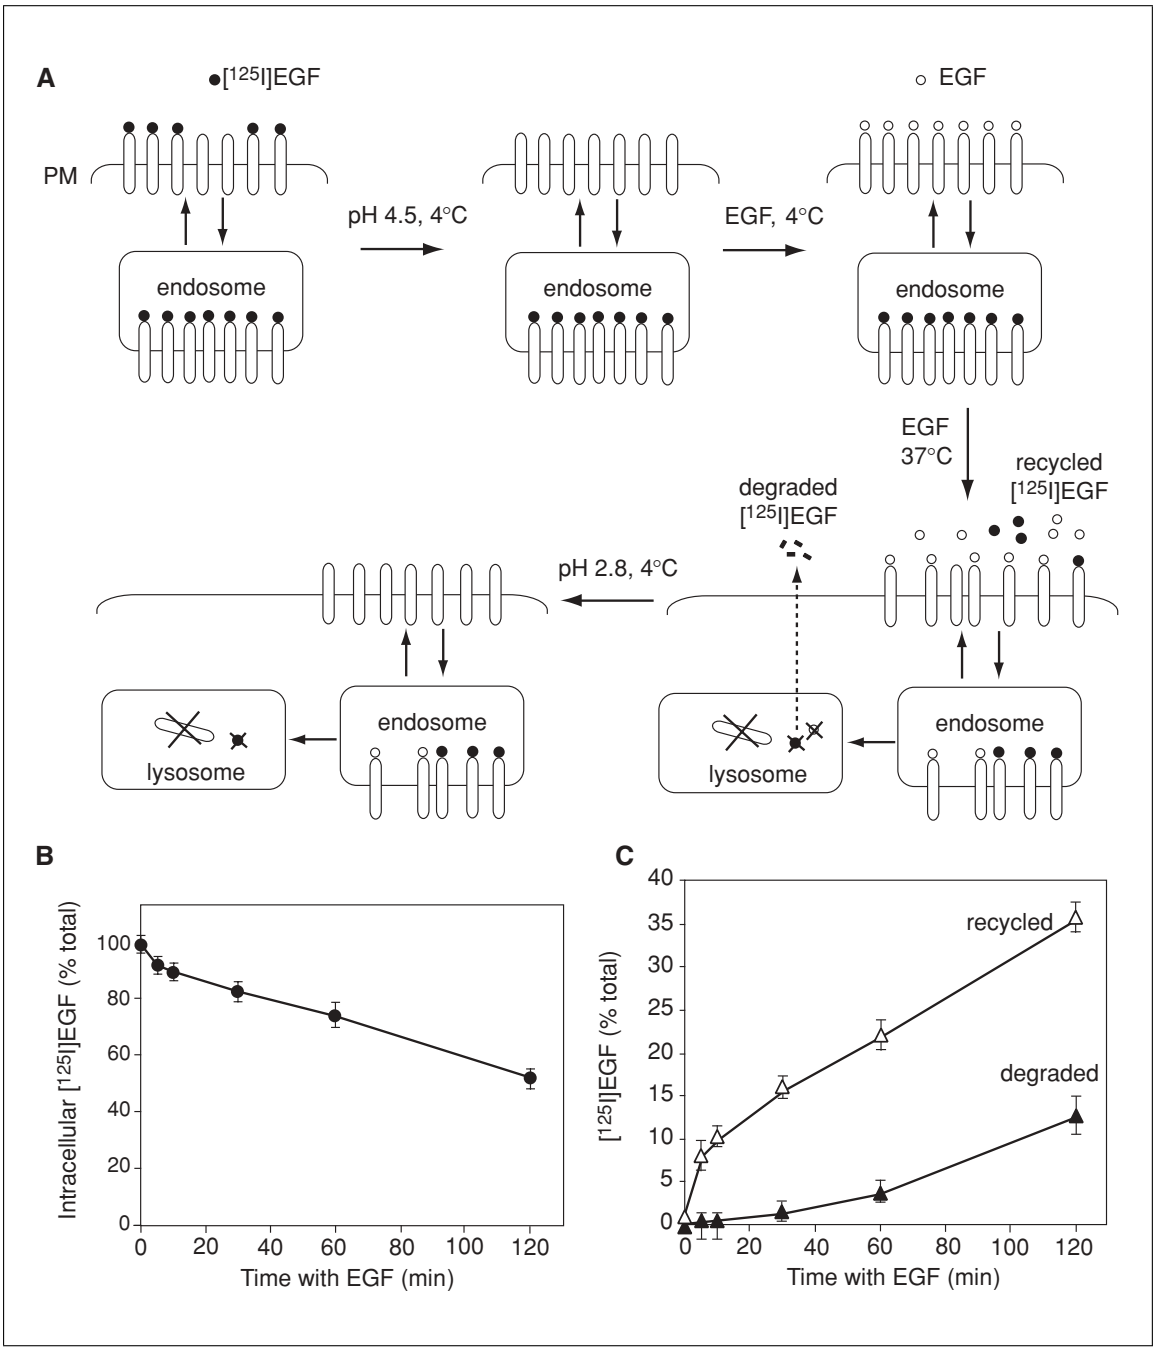

Figure 15.14.4 [^{125}I]EGF recycling/degradation assay (Basic Protocol 4). (**A**) Schematic representation of the main steps of the assay. PM, plasma membrane. (**B**) and (**C**) Representative example of the [^{125}I]EGF recycling/degradation experiment. Mouse embryonic fibroblasts were incubated with 5 ng/ml [^{125}I]EGF for 5 min at 37°C, and [^{125}I]EGF that has not been internalized was stripped by the acid wash. [^{125}I]EGF-loaded cells were incubated with unlabeled EGF at 4°C and then chased with unlabeled EGF for 0 to 120 min according to the protocol. The specific radioactivities of all fractions were determined and expressed as percent of the total radioactivity associated with cells and present in the medium (mean ±SE). The amount of intracellular [^{125}I]EGF (NaOH lysates) plotted against the chase time is shown in (B), whereas the time course of [^{125}I]EGF recycling (surface plus medium trichloroacetic acid/phosphotungstic acid-insoluble [^{125}I]EGF) and degradation (trichloroacetic acid/phosphotungstic acid ^{125}I-radioactivity) is shown in (C).

2. Incubate the cells at 37°C with 1 ml [^{125}I]EGF in binding medium for 5 to 10 min (see Commentary for consideration of [^{125}I]EGF concentration and incubation times) to allow for accumulation of [^{125}I]EGF-receptor complexes in early endosomes. Incubate control dishes with the same [^{125}I]EGF-containing medium supplemented with a 50-fold molar excess of unlabeled EGF to determine nonspecific radioactivity.

   Because handling of multiple dishes in this type of experiments is difficult, it is recommended to use two "specific" dishes and one "nonspecific" dish for each time point of the chase incubation (step 7 below). The entire time-course experiment can be repeated to ensure the statistical significance of the data.

3. After 37°C incubation, place the dishes on ice and then rapidly wash three times with 1 ml of ice-cold DMEM. Briefly rinse cells with DMEM (2 ml/dish) to neutralize the acid.

4. Incubate the cells with 1 ml/dish of sodium acetate buffer, pH 4.5, for 2.5 min, remove supernatants, and then rinse briefly with 1 ml of the same buffer to remove [^{125}I]EGF that had not been internalized during the 37°C incubation.

5. Combine both of the acidic washes from step 4 to determine the amount of [^{125}I]EGF at the cell surface by gamma counting.

   At this point the cells contain[^{125}I]EGF only in endosomes and are referred to as "[^{125}I]EGF-loaded cells."

6. Incubate the [^{125}I]EGF-loaded cells in binding medium containing 200 ng/ml unlabeled EGF for 40 min at 4°C to occupy surface EGFRs, and aspirate the medium.

   This EGF concentration is sufficient to occupy >90% of surface receptors in all types of cells, including cells expressing the highest levels of EGFR.

7. Add 1 ml fresh pre-warmed (37°C) medium containing 200 ng/ml EGF. Rapidly place the cells in the water bath or incubator (for incubations longer than 15 min) at 37°C to allow trafficking of [^{125}I]EGF-receptor complexes in loaded cells. Keep three dishes (two "specific" medium and one nonspecific medium) on ice for the zero chase time point.

   The lengths of chase incubations are discussed in the Commentary, below.

   An excess of unlabeled EGF bound to surface receptors and in the medium minimizes re-internalization of recycled [^{125}I]EGF-receptor complexes and rebinding of dissociated [^{125}I]EGF from the medium.

8. While other dishes are incubating at 37°C, add 1 ml prewarmed medium to zero-time dishes and immediately collect the medium in γ-counter vials.

   This step is necessary to have the zero-time dishes exposed to medium that is the same as that used for the chase incubation of other dishes in step 7.

9. At the end of each of the chase incubations, place the dishes on ice, add 1 ml medium, and collect the medium into γ-counter vials.

10. Strip surface-bound [^{125}I]EGF from all wells by incubating cells for 5 min with sodium acetate buffer, pH 2.8, at 1 ml/dish, 4°C. Collect this acid wash in γ-counter vials, perform another short rinse at 0.5 ml/dish, and combine this rinse with the original wash to determine the amount of surface-bound (recycled) [^{125}I]EGF by gamma counting.

11. Solubilize the cells in 1 N NaOH for 1 hr to measure the amount of intracellular [^{125}I]EGF.

12. Mix the medium collected at step 8 with 0.3 ml of 10% (w/v) TCA/2% (w/v) PTA and incubate 1 hr or longer at 4°C. Centrifuge 10 min at 5000 × *g*, 4°C.

    Because of its small size, EGF polypeptide is not efficiently precipitated by TCA alone. Therefore, addition of PTA is important for complete precipitation of [^{125}I]EGF.

13. Transfer supernatants to new γ-counter tubes to determine the amount of degraded [^{125}I]EGF by gamma counting.

14. Dissolve the pellets in 1 ml of 1 N NaOH to determine the amount of [^{125}I]EGF by gamma counting.

Make calculations

15. First, obtain specific counts by subtracting nonspecific radioactivity of all fractions from the counts of the same fractions of corresponding specific dishes.

16. Calculate the total amount of [^{125}I]EGF specifically associated with cells for each dish as the sum of the second (pH 2.8) acid wash (surface [^{125}I]EGF, step 10), intracellular [^{125}I]EGF (step 11), intact-medium [^{125}I]EGF (TCA-precipitated radioactivity, step 12), and degraded-medium [^{125}I]EGF (step 13).

17. Calculate the amount of recycled [^{125}I]EGF by summing the surface [^{125}I]EGF and intact medium [^{125}I]EGF.

18. Calculate the percent of each [^{125}I]EGF pool (intracellular, recycled, and degraded) relative to the total cell-associated [^{125}I]EGF for each time point.

    The example of the dynamics of recycled, degraded and intracellular [^{125}I]EGF is presented in Figure 15.14.4B and C.

19. Calculate the ratios of the percent of recycled and degraded [^{125}I]EGF to percent of intracellular [^{125}I]EGF and plot against time.

    The slopes of these graphs correspond to the apparent recycling and degradation rates, respectively.

ALTERNATE PROTOCOL 2

MEASURING [^{125}I]EGF RECYCLING/DEGRADATION IN THE ABSENCE OF EXCESS UNLABELED EGF

This assay for recycling/degradation differs from Basic Protocol 4 at the step of incubation of [^{125}I]EGF-loaded cells at 37°C, during which no unlabeled EGF is added.

For materials, see Basic Protocol 4.

1. Follow steps 1 through 4 of Basic Protocol 4 to prepare cells and load the cells with labeled EGF.

2. Initiate trafficking of [^{125}I]EGF-receptor complexes in loaded cells by incubating the cells in fresh binding medium with neither labeled nor unlabeled EGF at 37°C for 0 to 60 min or longer.

    See Commentary for considerations in the choice of the chase incubation time.

3. Follow steps 7 to 19 in Basic Protocol 4 to measure the various EGF pools in the cells.

SUPPORT PROTOCOL

PREPARATION OF [^{125}I]EGF

For the binding and trafficking of EGF studies, it is necessary to have [^{125}I]labeled EGF. This protocol describes the chloramine T method for labeling proteins.

Materials

0.05 M sodium phosphate buffer, pH 7.5 (*APPENDIX 2A*) containing 0.075 M NaCl
20 mg/ml BSA in 0.05 M sodium phosphate buffer, pH 7.5 (*APPENDIX 2A*) containing 0.075 M NaCl
Receptor-grade mouse EGF (BD Biosciences, cat. no. 354010)
0.5 M sodium phosphate buffer, pH 7.5 (*APPENDIX 2A*)
0.1 mCi/μl Na[^{125}I] (PerkinElmer; cat. no. NEZ33A)
2 mg/ml chloramine T (Sigma) in 0.05 M sodium phosphate buffer, pH 7.5 (see *APPENDIX 2A* for buffer); prepare fresh
4 mg/ml sodium metabisulfite in 0.05 M sodium phosphate buffer, pH 7.5 (see *APPENDIX 2A* for buffer); prepare fresh

PD-10 (G-25) Sepharose disposable column (GE Healthcare)
γ counter

NOTE: The entire procedure is carried out at room temperature.

Prepare the column

1. Wash a PD-10 (G-25) Sepharose disposable column with 50 ml Milli-Q water and equilibrate with 50 ml 0.05 M sodium phosphate buffer, pH 7.5. containing 0.075 M NaCl.

2. Load 1 ml of 20 mg/ml BSA in 0.05 M sodium phosphate buffer, pH 7.5, containing 0.075 M NaCl onto the column.

Label the EGF

3. In a 1.5-ml microcentrifuge tube, mix 24 μl of 0.5 M sodium phosphate buffer, pH 7.5, 28 μl of 0.05 sodium phosphate buffer, pH 7.5, and 5 μg of receptor-grade mouse EGF (5 μl of 1 mg/ml EGF in water).

   This gives a precisely 100 mM final sodium phosphate concentration in the mixture.

   The following steps are performed in a designated fume hood.

4. Add 10 μl of 0.1 mCi/μl Na[^{125}I] (1 mCi) to the EGF mixture from step 3 and initiate the reaction by adding 10 μl of 2 mg/ml chloramine T in the dark.

5. After a 40-sec incubation in the dark, stop the reaction by adding 20 μl of 4 mg/ml sodium metabisulfite.

   Both the chloramine T and sodium metabisulfite solutions should be freshly prepared.

Separate the ^{125}I-labeled EGF

6. Mix 100 μl of 20 mg/ml BSA in 0.05 M sodium phosphate buffer, pH 7.5, containing 0.075 M NaCl into the reaction mixture (final volume ~200 μl) and load onto the PD-10 column. Allow the column to equilibrate for 3 min.

7. After 3 min of equilibration, start gel filtration by eluting with 0.05 M sodium phosphate buffer, pH 7.5, containing 0.075 M NaCl.

8. Allow the first 1.8 ml to flow through.

9. Collect subsequent fractions at the rate of 10 drops per tube into 10 tubes, each containing 50 μl of 20 mg/ml BSA.

   BSA serves as a protein carrier to minimize binding of [^{125}IEGF] to the tube walls.

10. Measure the amount of radioactivity in 2 μl from each tube in the γ counter and plot the number of counts against the tube number.

11. Based on the curve, combine the first peak (usually tubes 2 to 5 or 2 to 6) and mix in a larger plastic tube.

12. Measure the specific activity of the final [^{125}I]EGF preparation in a 2-μl sample of the pool.

13. Divide the final [^{125}I]EGF preparation into 0.1-ml aliquots and store at −20°C.

Make calculations

14. Calculate the specific activity of the preparation.

Considering that the approximate yield of EGF in this procedure is 90%, then the total amount of [^{125}I]EGF is ∼4.5 μg. Typically, the volume of the peak is ∼2 ml, which results in the final concentration of [^{125}I]EGF being ∼2.25 ng/μl. The amount of radioactivity is usually ∼450,000 cpm per μl in our experiments. Therefore, the specific activity of [^{125}I]EGF is 450,000 cpm/2.25 ng = 200,000 cpm/ng.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Sample buffer for SDS-PAGE, 1× (prepare at 2× or 4× concentration as indicated for protocol)

50 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
10% (v/v) glycerol
2% (w/v) SDS
5% (v/v) 2-mercaptoethanol
Bromphenol blue (a few small crystals per 15 ml)
Store up to 1 year at room temperature

[^{35}S]Protein labeling medium

DMEM free of L-methionine, L-cysteine, and L-glutamine (Invitrogen) supplemented with:
5% to 10% (v/v) dialyzed FBS (typically)
300 μCi Easy-Tag ^{35}S-labeled amino acids
Prepare fresh

TGH lysis buffer

1% (v/v) Triton X-100
10% (v/v) glycerol
50 mM HEPES, pH 7.4
150 mM NaCl (or 0 mM or 500 mM as specified in protocol)
2 mM EGTA
2 mM EDTA
1 mM phenylmethylsulfonyl fluoride
10 ng/μl aprotinin
10 ng/μl leupeptin
Store up to 2 to 3 months at 4°C

COMMENTARY

Background Information

EGFR is a member of the ErbB tyrosine kinase family. EGFR is an important regulator of eukaryotic development and is involved in regulation of proliferation, survival, and differentiation of many types of cells in adult organisms. EGFR and other ErbBs are frequently overexpressed in various types of human carcinoma, glioblastoma, and glioma. In recent years, EGFR became an important diagnostic and prognostic marker in several carcinomas. Several EGFR inhibitors have been

developed and approved for clinical use as anti-cancer targeted therapies.

Endocytosis and lysosomal degradation of active EGFR is thought to serve as the negative feedback loop in the regulation of EGFR signaling. However, endocytic trafficking regulates more than just receptor down-regulation. Several lines of evidence suggest that EGF-receptor complexes continue to signal after endocytosis and that signaling from endosomes may generate outcomes different from those triggered from the plasma membrane. Thus, mechanisms of EGFR endocytosis and its role in signaling has been the subject of more than 1000 publications. However, the large amount of data in the field is impossible to reconcile into a single reasonable model. One of the major reasons for such a slow pace towards the complete understanding of EGFR trafficking is the use of incomparable and often inadequate methodologies by different laboratories. This underscores the importance of standardizing the methodological approaches to monitoring EGFR endocytosis, specifically the methodologies that allow for reliable quantification of kinetics rates. Therefore, we focus this article on describing standard quantitative methods used to measure the rates of EGFR turnover (synthesis and degradation), EGFR down-regulation, and EGF internalization, both recycling and degradation.

Methods to study EGF and EGFR endocytosis using [^{125}I]EGF were the first to be introduced and remain the most quantitative and sensitive. Most of these methodologies are designed to study active, EGF-occupied receptors. However, similar methods using ^{125}I-labeled antibodies have been developed to study the kinetics of endocytosed EGFR which is not occupied by ligand (Wiley et al., 1991). It is important to be aware that cross-linking of EGFR by antibodies can alter trafficking parameters. Therefore, Fab fragments are the most appropriate in this type of experiment. Also, methods should use only those antibodies that do not interfere with any functions of EGFR. Other conventional methods of measuring surface receptor density and receptor endocytosis include those using surface biotinylation and reversible biotinylation (Shtiegman et al., 2007). These methods can also be used to study the endocytic trafficking of EGFR. However, they involve multiple steps, including pull-downs and SDS-PAGE. Each of these steps increases the chances of experimental error while not being as sensitive and quantitative as the methods using [^{125}I]EGF.

Critical Parameters and Troubleshooting

Consideration of EGFR expression levels

The design and interpretation of the quantitative analysis of EGFR turnover and trafficking must take into consideration the expression levels of EGFR in the cell line to be studied. Normal mammalian cells express from 5,000 (most epithelial and fibroblast cells) to 200,000 (hepatocytes) EGFR per cell. Cancer cells express up to 2–3 $\times$ 10^6 EGFR/cell. Recombinant EGFR can be stably expressed in cells at different levels to directly analyze the dependency of the parameters of the EGFR biosynthesis, endocytosis, recycling, and degradation on the EGFR concentration in the cell.

Synthesis of EGFR

In Basic Protocol 1 it is important to use the shortest time course possible because ^{35}S-labeled amino acids can be rapidly depleted from the medium. A significant decrease in available free [^{35}S]amino acids will result in nonlinear incorporation, and thus an inaccurate determination of the rate of EGFR biosynthesis. Different cell lines have different rates of metabolism, and, therefore, different rates of methionine/cysteine incorporation. Control experiments using variable concentrations of labeled amino acids and incubation times should be performed to confirm linear incorporation of radiolabeled methionine/cysteine for the desired concentration and pulse time. For most cell lines, this will be in the 1- to 4-hr range. Alternatively, unlabeled methionine/cysteine may be simultaneously added to extend the half-life of labeled methionine/cysteine in the medium.

EGFR degradation

Two types of methods have been used to determine the rates of EGFR degradation. In the first method, the amount of EGFR is determined by immunoblotting (*UNIT 6.2*) of lysates from cells incubated without or with EGF and in the presence of an inhibitor of protein synthesis, such as cycloheximide. This assay relies on the assumption that cycloheximide completely inhibits protein synthesis and does not have other, unrelated effects.

The second method, which is described in the Alternate Protocol 1, involves radiolabeling of cellular proteins followed by chasing the cells in the absence of label and subsequent immunoprecipitation of EGFR at various time points. In this method, inhibition of synthesis is not necessary. The amount of time

cells are incubated with labeled amino acids in these experiments should be sufficient to label a significant pool of EGFR. This is especially important in cells with high levels of EGFR expression, in which the turnover of the receptor is very slow.

Down-regulation assay

Typically, the effect that low amounts of EGF have on EGFR surface expression is difficult to detect in cells expressing moderate and high levels of EGFR. Under these conditions, there is not a significant number of EGFR being internalized in these cells. However, low EGF concentrations can be used in experiments with cells expressing low EGFR levels. When measuring the number of [^{125}I]EGF binding sites at the cell surface, the time of incubation with [^{125}I]EGF at 4°C must be 1 hr or longer. This time is necessary to reach a binding equilibrium for [^{125}I]EGF at 4°C in various types of cells.

Internalization

It has been demonstrated that EGF-induced internalization of EGFR via the clathrin-dependent pathway is saturated if too many EGF-receptor complexes are present at the cell surface. This is typically observed with [^{125}I]EGF concentrations higher than 1 to 2 ng/ml when [^{125}I]EGF occupies more than 10,000 to 15,000 receptors per cell. Therefore, these low concentrations of [^{125}I]EGF are recommended for experiments comparing clathrin-dependent endocytosis of EGFR mutants or the effects of inhibitors and modulators of this process.

One caveat of this type of internalization experiment is the possible underestimation of the internalization rate because of rapid recycling of internalized [^{125}I]EGF. Thus, the internalization assay must be performed using a short time course so that the bulk of internalized [^{125}I]EGF does not have time to return to the cell surface.

It is also important to note that Basic Protocol 3 uses a low-pH wash with acetate to strip [^{125}I]EGF from the cell surface. This treatment removes ~95% of surface-bound [^{125}I]EGF. In fact, a 1-min treatment with the pH 2.5 to 2.8 acetate buffer is sufficient to strip 90% of surface [^{125}I]EGF. However, other low-pH buffers can also be used. For instance, glycine-Cl buffer has been used in other studies (Wiley et al., 1991). Also, addition of 2 M urea further improves the efficiency of stripping (Wiley et al., 1991).

Recycling and degradation

In the recycling/degradation assay, it is important to load the cells with sufficient concentrations of [^{125}I]EGF for a sufficient amount of time to obtain a substantial concentration of [^{125}I]EGF in early endosomes. These parameters should be chosen based on both EGFR cellular levels and internalization rates for each particular cell type. The initial incubation time should be 5 to 10 min in most cell types and not longer than 15 min in cells with the slowest endocytic trafficking. This helps ensure that most endosomal [^{125}I]EGF is still in early endosomes and has not been sorted to late compartments or back to the plasma membrane. Similarly, it is critical to keep the loading time consistent between all samples in the experiment to obtain comparable pools of endosomal [^{125}I]EGF. Thus, it is advisable to limit the number of variants in each experiment, depending upon the experience level of the investigator with this type of experiments.

This report offers two versions of the recycling/degradation assay (Basic Protocol 4 and Alternate Protocol 2). Basic Protocol 4 is designed to prevent any rebinding and reinternalization of [^{125}I]EGF after one round of recycling because of the presence of an excess of unlabeled EGF during the chase incubation. However, the caveat of this protocol is that unlabeled EGF-receptor complexes compete with [^{125}I]EGF-receptor complexes during sorting to recycling and degradation pathways. This is especially important for estimating the degradation rates of [^{125}I]EGF, because the degradation pathway has been shown to be saturable (Herbst et al., 1994). On the other hand, Alternate Protocol 2 is designed to avoid interference of unlabeled EGF, although recycled [^{125}I]EGF can dissociate and rebind as well as re-internalize before dissociation from the receptor at the cell surface. Typically, degradation products of [^{125}I]EGF (TCA-soluble) can be detected after about 30 min of chase incubation in [^{125}I]EGF-loaded cells. However, it is necessary to extend the time of chase incubation to 2 to 4 hr to enable detection of significant amounts of degraded [^{125}I]EGF. Thus, in experiments aiming to measure recycling rates, short chase incubations are recommended (1 to 15 min). In experiments focusing on degradation rates, a time course of 30 to 240 min is recommended. Finally, it should be noted that as an alternative to trichloroacetic acid/phosphotungstic acid precipitation, a G-25 gel filtration procedure

can be used to separate intact [^{125}I]EGF and low-molecular-weight products of [^{125}I]EGF degradation (Wiley et al., 1991).

Iodination

The protocol for EGF iodination using chloramine T was developed and optimized in the laboratories of Stanley Cohen and Graham Carpenter (Carpenter and Cohen, 1976). This protocol is designed to carry out iodination under mild conditions, avoid excessive exposure to chloramine T, and avoid formation of highly reactive [^{125}I]EGF products that can covalently cross-link to the plasma membrane. It is critical to limit the time of iodination to 40 sec. Alternative protocols of EGF iodination can also be used. For instance, EGF can be iodinated using Iodobeads (Pierce). In our experience, the specific activity of [^{125}I]EGF made using Iodobeads is lower as compared with preparations obtained using the chloramine T protocol.

Anticipated Results

Biosynthesis of EGFR

In the biosynthesis assay, the amount of labeled EGFR should correlate in a linear fashion with the time of label incorporation. The apparent rate of the label incorporation into newly synthesized EGFR varies depending on the cell type.

EGFR degradation

The half-life of EGFR ranges from 8 to 24 hr (low to high levels of receptor respectively) and even longer in other cells. The half-life of EGFR is dramatically shortened following EGF stimulation, to as low a value as $t_{1/2} =$ 1 hr in cells expressing low levels of the receptor. Examples of EGFR biosynthesis and degradation analysis performed in our laboratory have recently been published (Duex and Sorkin, 2009).

EGFR down-regulation

Significant EGFR down-regulation in cells treated with high EGF concentrations (20 to 100 ng/ml) is observed beginning at 15 to 20 min after EGF stimulation. The amount of surface EGFR usually stabilizes after 30 to 60 min of EGF stimulation. Therefore, a complete dynamics of the down-regulation process can be observed within the range of incubation times ranging from 15 to 120 min.

EGF internalization

The values of k_e measured in various types of cells using low [^{125}I]EGF concentrations (clathrin-mediated pathway) are typically within the range of 0.15 to 0.40 min^{-1}. This range in values is quite similar to the rate constants measured for other clathrin-coated pit-internalized cargo, such as the transferrin receptor. k_e values measured using high EGF concentrations (resulting in a significant contribution from clathrin-independent pathways) are typically below 0.1 min^{-1} and can be as low as 0.03 min^{-1}. Such values correspond to the rates of constitutive endocytosis of membrane proteins.

EGF recycling and degradation

In both Basic Protocol 4 and Alternate Protocol 2, recycling of [^{125}I]EGF is evident immediately when the [^{125}I]EGF-loaded cells are chased at 37°C. The protocols can produce similar kinetics of [^{125}I]EGF recycling if a short time course is used for the chase (5 to 10 min). However, in Alternate Protocol 2, re-internalization of [^{125}I]EGF results in a slight underestimation of the recycling rates, especially, at longer chase times. Typically, as much as 50% of endosomal [^{125}I]EGF in [^{125}I]EGF-loaded cells is recycled during a 2-hr chase if re-internalization is prevented (Alternate Protocol 2). In contrast, under conditions of this protocol, only about 20% to 25% of endosomal [^{125}I]EGF is recycled. In both protocols, degradation products of [^{125}I]EGF can be detected after about 30 min of chase incubation of [^{125}I]EGF-loaded cells. At maximum, 10% to 20% of endosomal [^{125}I]EGF is degraded after 2 to 4 hr of chase incubation in the presence of excess cold EGF (Basic Protocol 4), whereas up to 40% to 50% of internalized [^{125}I]EGF is degraded in the absence of unlabeled EGF during the same time (Alternate Protocol 2).

Iodination

Typically, the specific activity of [^{125}I]EGF is within the range of 120,000 to 200,000 cpm/ng.

Time Considerations

Synthesis of EGFR

The incubation of cells with radiolabeled methionine/cysteine is up to 6 hr. Since the cells are frozen at −70°C at the end of the incubation, the experiment can be interrupted at this step and continued later. Preparation of cell lysates takes ∼1 hr. A minimal time of incubation of lysates with primary antibodies is 2 hr, although the incubation can be run overnight. Subsequent incubation with protein A–Sepharose, washes and loading the samples

for SDS-PAGE take ~2 hr. Thus, the minimal length of the entire assay until starting electrophoresis is ~11 hr.

EGFR degradation

The cells are labeled with the [^{35}S]amino acid mix for 4 to 16 hr. Subsequent washes and a 30 to 60 min preincubation take ~1 to 1.5 hr. The longest chase incubation of cells in unlabeled medium should extend to at least 4 hr for cells with low levels of EGFR and up to 30 hr for cells with high EGFR levels. If the goal of the experiment is to measure the degradation rates of EGF-activated EGFR, the length of the longest chase incubation can be reduced to 2 and 10 hr in cells with low and high EGFR levels, respectively. The time required for cell lysis and EGFR immunoprecipitation is the same as described above for the EGFR biosynthesis assay. Therefore, the length of the entire experiment until SDS-PAGE can be from 12 hr at minimum and up to 2 days.

EGFR down-regulation

A typical experiment includes a 2-hr incubation with unlabeled EGF, 15-min cell washing, 1-hr incubation with [^{125}I]EGF, 5-min washing, and about 1-hr solubilization with NaOH. Therefore, the entire experiment with two to three 12-well plates, including radioactivity counting, can be completed in 5 hr.

EGF internalization

One internalization experiment (one 12-well plate) is performed in about 20 min followed by a 1-hr cell solubilization in NaOH. More internalization experiments can be carried out during solubilization of the first set of cells. Practically, internalization measurements in four 12-well plates can be accomplished within 3 hr, including radioactivity counting on a γ-counter.

EGF recycling and degradation

Loading of cells with [^{125}I]EGF including the first acid wash in Basic Protocol 4 and Alternate Protocol 2 takes ~20 min. In Basic Protocol 4, pre-incubation of loaded cells with unlabeled EGF and the following chase can take together up to 5 hr. In Alternate Protocol 2, the manipulations with loaded cells are ~1 hr shorter. The acid wash treatment of the last time point takes only 10 min, but the trichloroacetic acid/phosphotungstic acid precipitation procedure and separation of the soluble from the insoluble radioactivity takes at least 2 hr. Therefore, a degradation/recycling experiment can last up to 7.5 hr, although it can be done in a significantly shorter period of time if the main goal is to measure the recycling rates.

Iodination

The total length of the iodination procedure is ~3 hr.

Documenting GLUT4 Exocytosis and Endocytosis in Muscle Cell Monolayers

Shuhei Ishikura,[1] Costin N. Antonescu,[1] and Amira Klip[1]

[1]Program in Cell Biology, The Hospital for Sick Children, Toronto, Ontario, Canada

ABSTRACT

The elevated blood glucose following a meal is cleared by insulin-stimulated glucose entry into muscle and fat cells. The hormone increases the amount of the glucose transporter GLUT4 at the plasma membrane in these tissues at the expense of preformed intracellular pools. In addition, muscle contraction also increases glucose uptake via a gain in GLUT4 at the plasma membrane. Regulation of GLUT4 levels at the cell surface could arise from alterations in the rate of its exocytosis, endocytosis, or both. Hence, methods that can independently measure these traffic parameters for GLUT4 are essential to understanding the mechanism of regulation of membrane traffic of the transporter. Here, we describe cell population–based assays to measure the steady-state levels of GLUT4 at the cell surface, as well as to separately measure the rates of GLUT4 endocytosis and endocytosis. *Curr. Protoc. Cell Biol.* 46:15.15.1-15.15.19. © 2010 by John Wiley & Sons, Inc.

INTRODUCTION

Glucose is the primary energy source used in mammals. The elevated blood glucose levels that occur after a meal are rapidly returned to normal through enhanced glucose uptake into muscle and adipose tissues. In muscle fibers and adipocytes, glucose is stored as glycogen or triglycerides, respectively, and only a fraction is immediately oxidized to produce energy through oxidative phosphorylation and anaerobic glycolysis. It is precisely the entry into muscle and fat cells that is the rate-limiting step in the metabolism of glucose (Klip et al., 1982; D'Amore and Lo, 1986; Cline et al., 1998). This transport step is mediated by the insulin-regulated glucose transporter, GLUT4 (Zisman et al., 2000). In the basal (unstimulated) state, GLUT4 constitutively cycles to and from the plasma membrane (Fig. 15.15.1) and the steady-state distribution of GLUT4 favors intracellular compartments due to its fast endocytosis and slow exocytosis (Zaid et al., 2008). Insulin, released in response to the rising blood glucose concentration, stimulates glucose uptake into muscle and fat tissues by increasing the amount of GLUT4 at the cell surface.

The dynamic nature of this process is, however, missed by most biochemical and cell biological methods that simply document the net change in surface GLUT4. A gain in cell surface GLUT4 could conceivably be due to either an increase in the rate of exocytosis or a decrease in the rate of endocytosis of the transporter, or both. Hence, kinetic analyses that can differentiate between these two membrane traffic parameters are required to understand the mechanism of regulation of GLUT4 traffic. The purpose of this unit is to describe enzyme-linked immunosorbent assay (ELISA)–based methods to measure the amount of cell surface GLUT4. To separately determine the exocytic and endocytic rates of GLUT4, we describe the methods for measuring the amount of cell surface GLUT4 at steady-state (Basic Protocol 1), GLUT4 endocytosis (Basic Protocol 2), and GLUT4 exocytosis (Basic Protocol 3).

Current Protocols in Cell Biology 15.15.1-15.15.19, March 2010

DOI: 10.1002/0471143030.cb1515s46

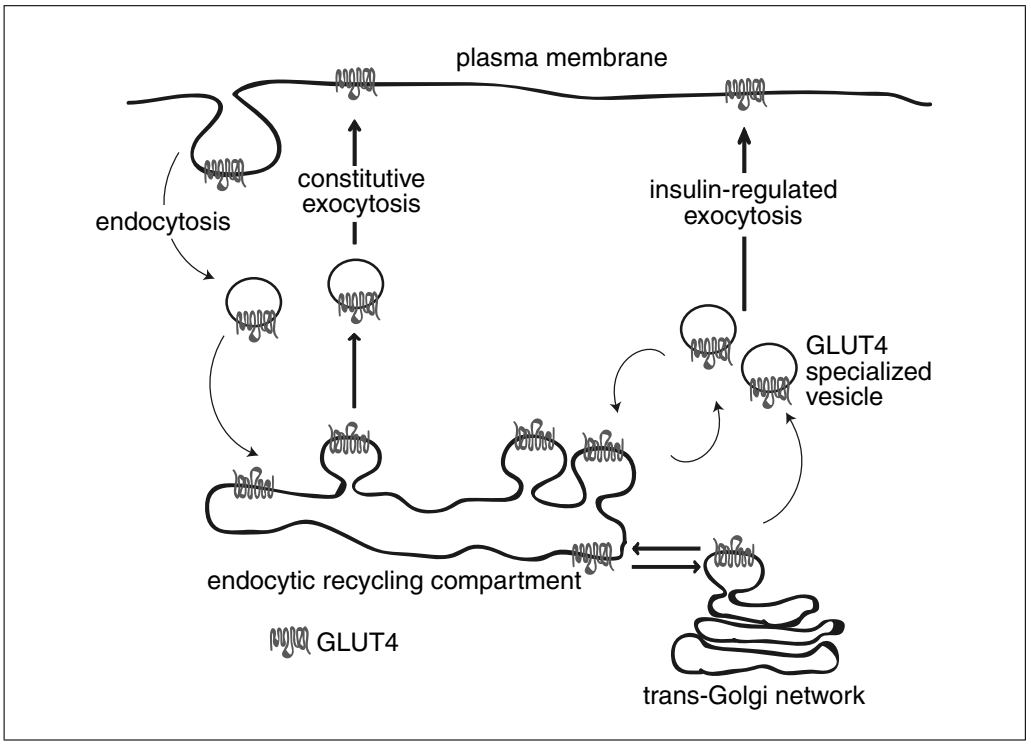

Figure 15.15.1 Schematic representation of GLUT4 traffic in muscle and fat cells. GLUT4 cycles between the intracellular compartments and the plasma membrane. Approximately half of intracellular GLUT4 is located in GLUT4 specialized vesicles, which are segregated from the endocytic recycling compartment and the trans-Golgi network. In the absence of stimuli, the steady-state distribution of GLUT4 favors intracellular compartments due to fast endocytosis and slow exocytosis. Insulin increases cell surface GLUT4 mainly by stimulating exocytosis from the GLUT4 specialized vesicle compartment.

Cell line stably expressing epitope-tagged GLUT4

Measurements of GLUT4 membrane traffic kinetics are vastly aided by introduction of epitopes (*myc* or HA) into exofacial portions of the transporter (GLUT4*myc* or GLUT4-HA). Using such chimeric transporters, GLUT4 molecules present at the cell surface can be distinguished from those within the cell by labeling intact cells with anti-HA or anti-*myc* antibodies (Fig. 15.15.2). When the epitope-tagged GLUT4 cDNA constructs are transiently transfected in muscle or fat cells, assays for detection of cell surface GLUT4 must account for the vast disparity in expression levels of the exogenous transporters between cells. Hence, following transient expression of GLUT4*myc* or HA-GLUT4, one is limited to implementing single cell–based immunofluorescence assays, and the relative amount of cell surface GLUT4 must be normalized to the expression level of the exogenous transporter in each cell. Therefore, these methods are time- and resource-consuming, and require knowledgeable implementation of quantitative tools to analyze fluorescence images (Antonescu et al., 2008a). Alternative strategies to document the traffic kinetics involve the generation of cells that stably express epitope-tagged GLUT4. Stable expression ensures that all cells express the same amount of epitope-tagged GLUT4, allowing direct comparison of the relative amount of cell surface GLUT4 between conditions without requiring normalization to total epitope-tagged GLUT4 expressed in each cell.

L6 cells are originally derived from rat skeletal muscle, and propagate as mononucleated myoblasts, but differentiate into multinucleated myotubes upon incubation in low-serum-containing medium (Yaffe, 1968; Richler and Yaffe, 1970; Mandel and Pearson, 1974; Yaffe and Saxel, 1977). The myotubes express several proteins typical of skeletal muscle,

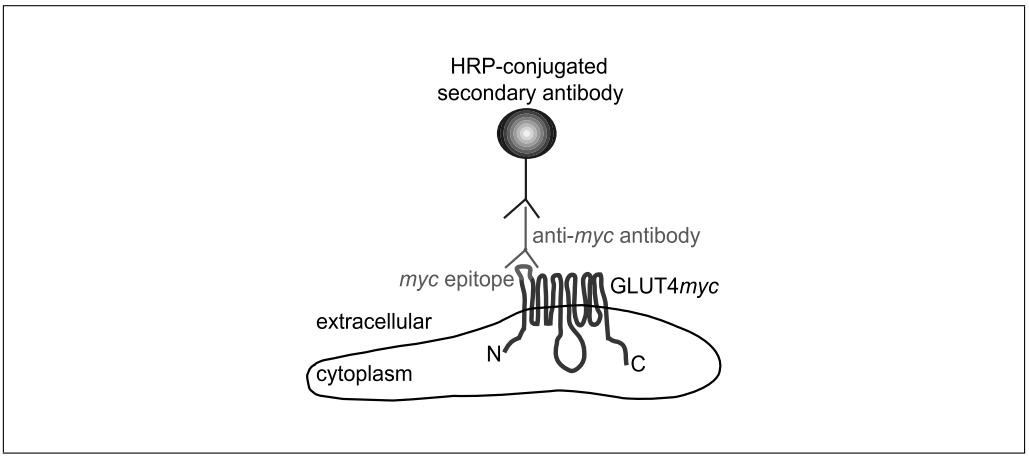

Figure 15.15.2 Detection of cell surface GLUT4*myc* in intact cells by antibody labeling of exofacial epitope coupled to colorimetric assay. Diagram depicting a plasma membrane–inserted GLUT4 molecule with *myc*-epitope engineered into the first exofacial loop of the transporter. Anti-*myc* antibodies bound to GLUT4*myc* are detected by HRP-conjugated secondary antibodies.

and insulin stimulates glucose uptake in the myotubes to a similar extent as mature skeletal muscle (Antonescu et al., 2005a). To create a GLUT4 molecule with an exofacially accessible epitope, a DNA sequence coding for a fragment of the human c-*myc* epitope (AEEQKLISEEDLLK) was inserted into the first ectodomain of the rat GLUT4 cDNA (Kanai et al., 1993). The corresponding cDNA construct was used to create L6 muscle cell lines in culture stably expressing *myc*-tagged GLUT4*myc* (L6-GLUT4*myc*; Wang et al., 1998), which have been extensively characterized (Huang et al., 2002, 2005; Niu et al., 2003; JeBailey et al., 2004, 2007; Foster et al., 2006; Diaz et al., 2007; Antonescu et al., 2008b) . By allowing measurement of the dynamic availability of the *myc*-epitope to the extracellular milieu (Fig. 15.15.2), L6 cells are an ideal model in which to study GLUT4 traffic in a skeletal muscle background. These assays can be performed on either confluent L6 myoblasts or differentiated L6 myotubes.

MEASURING STEADY-STATE CELL SURFACE GLUT4*myc*

BASIC PROTOCOL 1

Measurement of the amount of cell surface GLUT4*myc* at steady state is achieved through detection of the exofacial *myc* epitope in intact L6 muscle cells in culture (Fig. 15.15.2). Cells are labeled with anti-*myc* antibodies, and subsequently labeled with secondary antibodies coupled to horseradish peroxidase (HRP; Fig. 15.15.3A). The amount of cell-surface bound HRP activity is detected by the amount of chromogen formed from the HRP substrate *o*-phenylenediamine (OPD; Fig. 15.15.3B), which is proportional to the amount of cell-surface GLUT4*myc*. Importantly, this reaction remains linear with respect to the amount of HRP present over a large range of enzyme concentrations (Fig. 15.15.3C), indicating that absorbance is linearly related to the amount of cell surface GLUT4*myc*.

Materials

GLUT4*myc* cells [L6-GLUT4*myc*; Wang et al., 1998; L6 cell lines can be obtained from ATCC (*http://www.atcc.org*, cat. no. CRL-1458); these cells can be made to stably express epitope-tagged GLUT4 as desired; for further inquiries regarding currently existing L6-GLUT4*myc* stable cell lines, please contact Dr. Amira Klip (*amira@sickkids.ca*)]

L6 growth medium (see recipe) *or* L6 differentiation medium (see recipe)

α-modification of Eagle's medium (α-MEM; Wisent Bioproducts; *http://www.wisent.ca/*)

Stimulatory agents: e.g., human insulin (Humulin R, Lilly), sucrose (Sigma-Aldrich), or platelet-derived growth factor (PDGF; Sigma-Aldrich)

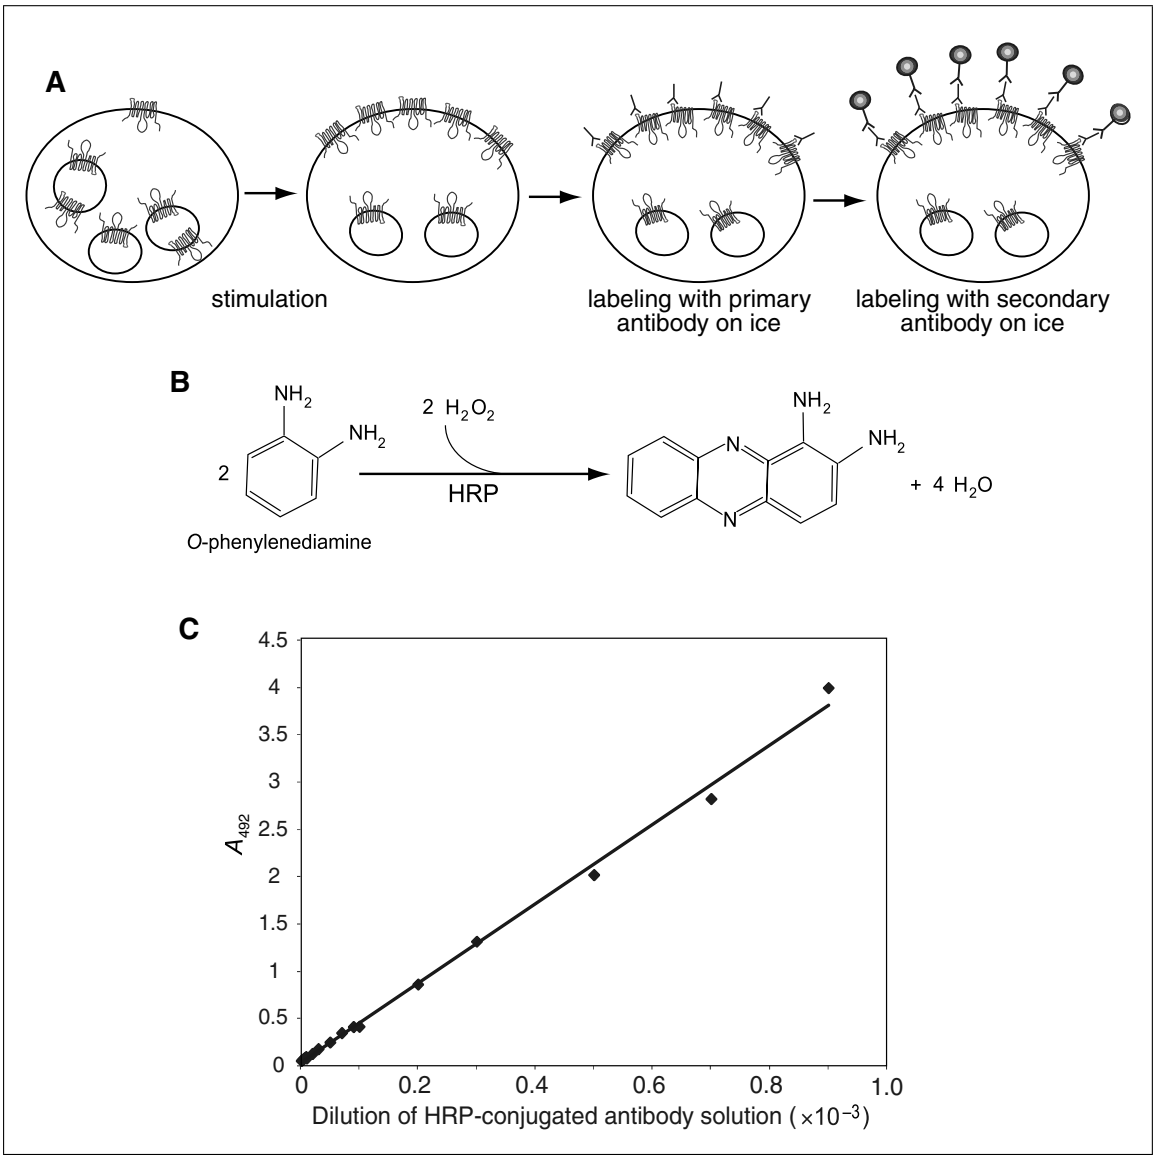

Figure 15.15.3 Measurement of steady-state cell surface GLUT4*myc* in intact cells. (**A**) Diagram depicting the labeling of cell surface–exposed GLUT4*myc* in intact cells with anti-*myc* antibodies, while intracellularly located transporters remain unlabeled. Upon stimulation, there is an increase in cell surface transporters at the expense of the intracellular content of GLUT4*myc*, reflected by an increase in cell surface-bound *myc*-antibodies. (**B**) Diagram of chemical reaction by which *o*-phenylenediamine (OPD) is converted to a chromogenic product by HRP. (**C**) 200 μl of OPD assay solution was incubated with various amounts of HRP-conjugated secondary antibody, as indicated. Each reaction was stopped simultaneously by addition of 50 μl of 3 M HCl, followed by measurement of absorbance at 492 nm. Shown are the absorbance values of each HRP-conjugated secondary antibody concentration.

PBS+: phosphate-buffered saline (PBS; see recipe) supplemented with 1 mM $CaCl_2$ and 1 mM $MgCl_2$

Blocking solution: PBS+ (see above) 5% (v/v) goat serum (Sigma-Aldrich)

Anti-*myc* rabbit polyclonal antibody (Sigma-Aldrich)

4% (w/v) paraformaldehyde in PBS+, ice cold

PBS+ (see above) containing 100 mM glycine

Horseradish peroxidase (HRP)–conjugated goat anti-rabbit antibody (Jackson Immunoresearch)

OPD assay solution (see recipe)

3 N HCl or H_2SO_4

24-well culture plates (BD Biosciences)
96-well microtiter plate
Spectrophotometer with microtiter plate reader

Plan the experiment and seed cells

1. Seed GLUT4*myc* cells at a density of 2.0–3.0 $\times$ 10^4 cells per well of a 24-well plate in 0.5 ml/well L6 growth medium or L6 differentiation medium.

   For experiments on myoblasts, cells are subsequently grown to confluence, typically for 36 to 48 hr in L6 growth medium. For experiments on myotubes, cells are placed in L6 differentiation medium at the time of seeding and grown for ~7 days to allow for myoblast differentiation into myotubes.

2. Set up the cultures so that each condition to be assayed is done in triplicate (three wells/condition) with a well for an (unlabeled) control for each condition.

   Thus, a 24-well plate can be used to assay at most six experimental conditions.

Measure steady-state cell surface GLUT4myc

3. Aspirate medium from cells and wash cells once by adding and then removing 0.5 ml per well prewarmed serum-free α-MEM. Replace medium with serum-free α-MEM (at least 250 μl/well) and incubate for 3 to 5 hr at 37°C.

4. Stimulate cells as required by incubating cells for the appropriate amount of time in 250 μl of serum-free α-MEM containing the appropriate agent.

5. Subsequently, place cells on ice and wash thee times, each time by adding and then removing 0.5 ml per well ice-cold PBS+.

   These washes are performed to remove residual medium.

6. Aspirate PBS+ from cells and place the intact cells in 250 μl/well of blocking solution for 20 min on ice.

7. Prepare ≥5 ml/plate of a solution of ice-cold blocking solution containing 1 μg/ml rabbit polyclonal anti-*myc* antibody (*myc*-labeling solution).

8. Aspirate blocking solution from cells and add 250 μl of the *myc*-labeling solution to each well, except for unlabeled control wells. Instead, add 250 μl of blocking solution to the control wells. Incubate cells on ice for 1 hr.

9. Aspirate *myc*-labeling solution from cells and wash eight times, each time with 0.5 ml per well ice-cold PBS+. Aspirate medium from each well for the first three washes; in subsequent washes dump the wash solution by inverting the plate to remove solution from wells.

10. Fix cells for 10 min in 0.5 ml/well ice-cold PBS+ containing 4% PFA.

11. Aspirate fixative solution and quickly wash cells in 0.5 ml per well PBS+. Quench fixative in 0.5 ml/well PBS+ containing 100 mM glycine (quenching solution) for 10 min on ice.

12. Aspirate quenching solution. Incubate cells in 0.5 ml/well blocking solution for 15 min at room temperature.

13. Prepare 7 ml/plate of ice-cold blocking buffer containing a 1:750 dilution of horseradish peroxidase (HRP)–conjugated goat anti-rabbit antibody (secondary labeling solution).

14. Aspirate blocking buffer, add 250 μl of secondary labeling solution to each well, and incubate for 1 hr on ice.

15. Aspirate solution from cells and wash six times, each time by adding and then removing 0.5 ml per well ice-cold PBS+.

Detect bound antibody

16. Prepare 12.5 ml/plate OPD assay solution immediately before use.

17. Aspirate any remaining PBS+ from cells and quickly add 500 µl of OPD assay solution to each well.

    It is essential that a minimal amount of time elapses between addition of the reagent to the first and last wells, as the amount of chromogenic product formed depends on the length of incubation of cells with the OPD reagent and should be as close to constant for all wells as possible.

18. After sufficient color develops (i.e., yellow is visible by eye in each well to which anti-*myc* antibody solution was added, typically after 5 to 20 min), add 125 µl of 3 N HCl (or equivalent normality of H_2SO_4 or other adequate strong acid) to halt the OPD chromogenic reaction.

    Note that 3 N HCl solution should be added to wells in the same order as was used for addition of the OPD assay solution to ensure constant time of incubation for each well.

Quantify labeling

19. Transfer 200 µl from each well to designated wells of a 96-well microtiter plate and read absorbance at 492 nm.

20. Determine the relative amount of cell surface GLUT4*myc* (csG4) for each stimulated condition (*s*) following normalization to that of the basal state (also see Anticipated Results):

$$\mathrm{csG4}(s) = \frac{A_{492}(s) - A_{492}\,(\text{unlabeled control }(s))}{A_{492}(basal) - A_{492}\,(\text{unlabeled control }(basal))}$$

BASIC PROTOCOL 2

MEASURING GLUT4*myc* ENDOCYTOSIS

Measurement of the rate of GLUT4*myc* endocytosis is achieved through first labeling the exofacial *myc* epitope in intact L6 muscle cells in culture and then measuring the loss of label from the cell surface as GLUT4*myc* undergoes endocytosis. Following labeling of intact cell surface GLUT4*myc* with anti-*myc* antibodies on ice, cells are rewarmed to 37°C to allow GLUT4*myc* internalization (Fig. 15.15.4). The amount of *myc*-antibody-bound GLUT4*myc* remaining at the cell surface is detected by labeling with secondary antibodies coupled to HRP. Cell-surface HRP-bound GLUT4*myc* is subsequently detected as described in Basic Protocol 1.

For materials, see Basic Protocol 1.

Plan the experiment and seed cells

1. Seed GLUT4*myc* cells at a density of 2.0–3.0 × 10^4 cells per well of a 24-well plate in 0.5 ml/well L6 growth medium or L6 differentiation medium.

   For experiments on myoblasts, cells are subsequently grown to confluence, typically for 36 to 48 hr in L6 growth medium. For experiments on myotubes, cells are placed in L6 differentiation medium at the time of seeding and grown for 7 days to allow for myoblast differentiation into myotubes.

2. To prepare for the experiment, note that a separate 24-well plate is required for each timepoint of GLUT4*myc* endocytosis to be assayed. Also note that a separate

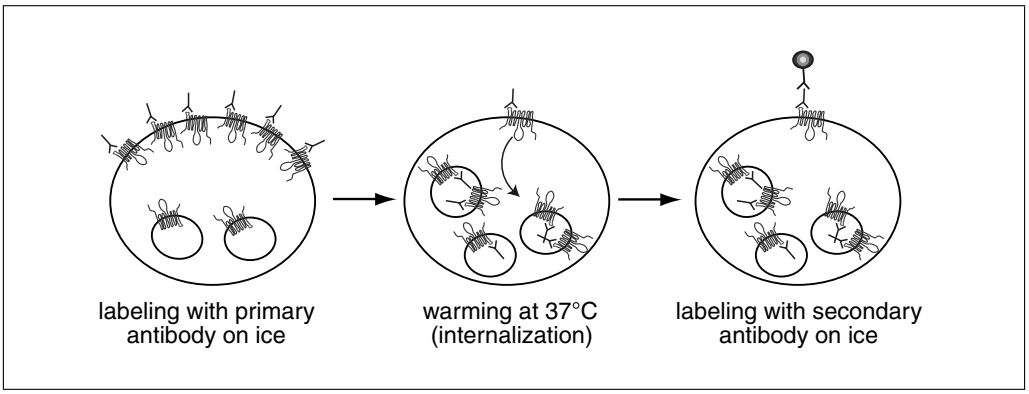

Figure 15.15.4 Measurement of GLUT4*myc* endocytosis in intact cells. Diagram depicting measurement of GLUT4*myc* endocytosis: cells are first stimulated at 37°C as required then placed on ice and labeled with anti-*myc* antibodies at 4°C. Subsequently, cells are rewarmed to 37°C for fixed amounts of time, thereby allowing internalization of some anti-*myc* antibody bound GLUT4*myc* molecules.

24-well plate without internalization (0 min, termed control without internalization) is required for each experiment.

Typically, GLUT4myc endocytosis is measured at 2, 5, and 10 min (Antonescu et al., 2008b), although more timepoints can be assayed if desired.

3. Also note that each condition to be assayed must be done in triplicate (three wells/condition) for each timepoint, with a well for an (unlabeled) control for each condition.

Thus, each 24-well plate (representing a single timepoint) can be used to assay at most six experimental conditions.

Prepare cells for GLUT4 assay

4. Aspirate medium from cells and wash cells once by adding and then removing 0.5 ml/well prewarmed serum-free α-MEM. Replace medium with serum-free α-MEM and incubate for 3 to 4 hr at 37°C.

5. Stimulate cells as required by incubating cells for the appropriate amount of time in 250 µl of serum-free α-MEM containing the appropriate agent.

6. Subsequently, place cells on ice and wash three times, each time by adding and then removing 0.5 ml/well ice-cold PBS+.

These washes are performed to remove residual medium.

Block and label with antibody

7. Aspirate PBS+ from cells and place the intact cells in 250 µl/well of blocking solution for 20 min on ice.

8. Prepare ≥5 ml/plate of a solution of ice-cold blocking solution containing 1 µg/ml rabbit polyclonal anti-*myc* antibody (*myc*-labeling solution).

9. Aspirate blocking solution from cells and add 250 µl of the *myc*-labeling solution to each well except for unlabeled control wells. Instead, add 250 µl of blocking solution to the control wells. Incubate cells on ice for 1 hr.

10. Aspirate *myc*-labeling solution from cells and wash five times, each time with 0.5 ml/well ice-cold PBS+. Aspirate medium from wells for the first three washes; in subsequent washes dump the wash solution by inverting the plate to remove solution from wells.

Measure GLUT4 endocytosis

11. For the 24-well plates to be used to measure internalization for 2, 5, and 10 min (or other time points, except the 0 min control without internalization), quickly wash cells twice in 0.5 ml/well PBS+, prewarmed to 37°C. For control without internalization, wash cells twice in 0.5 ml/well ice-cold PBS+ and retain these cells on ice until step 13 (bypass step 12 for this control).

12. Quickly aspirate solution from cells and add 0.5 ml/well prewarmed α-MEM containing the appropriate stimulus. Incubate cells in a 37°C incubator for 2, 5, or 10 min.

    It is essential to perform steps 11 to 12 rapidly to ensure that a minimum of time elapses between rewarming of cells in PBS+ (step 11) and addition of stimulus-containing α-MEM (step 12).

13. Subsequently, quickly replace cells on ice and wash all plates twice by adding and removing 0.5 ml/well ice-cold PBS+. Also perform this and all subsequent steps for the "control without internalization" plate of cells.

Fix cells

14. Fix cells for 10 min in 0.5 ml/well ice-cold PBS+ containing 4% PFA.

15. Aspirate fixative solution and quickly wash cells in 0.5 ml/well PBS+. Quench fixative in 0.5 ml/well PBS+ containing 100 mM glycine (quenching solution) for 10 min on ice.

16. Aspirate quenching solution. Incubate cells in 0.5 ml/well blocking solution for 15 min on ice.

Label with secondary antibody

17. Prepare 7 ml/plate of ice-cold blocking buffer containing a 1:750 dilution of horseradish peroxidase (HRP)–conjugated goat anti-rabbit antibody (secondary labeling solution).

18. Aspirate blocking buffer, add 250 μl of secondary labeling solution to each well, and incubate for 1 hr on ice.

19. Aspirate solution from cells and wash six times, each time by adding and then removing ml/well ice-cold PBS+.

Detect labeling

20. Prepare 12.5 ml/plate OPD assay solution (see Reagents and Solutions) immediately before use.

21. Aspirate any remaining PBS+ from cells and quickly add 500 μl of OPD assay solution to each well.

    It is essential that a minimal amount of time elapses between addition of the reagent to the first and last wells, as the amount of chromogenic product formed depends on the length of incubation of cells with the OPD reagent and should be as close to constant for all wells as possible.

22. After sufficient color develops (i.e., yellow is visible by eye in each well to which anti-*myc* antibody solution was added, typically after 5 to 20 min), add 125 μl of 3 N HCl (or equivalent normality of H_2SO_4 or other adequate strong acid) to halt the OPD chromogenic reaction.

    Note that 3 N HCl solution should be added to wells in the same order as was used for addition of the OPD assay solution to ensure constant time of incubation for each well.

Quantify labeling

23. Transfer 200 µl from each well to designated wells of a 96-well microtiter plate and read absorbance at 492 nm.

24. Express the rate of GLUT4 endocytosis in two different ways (Fig. 15.15.6B):

    a. *GLUT4myc not internalized* (G4NI; i.e., remaining at the cell surface) at each time point (t) and each stimulus condition (s) is determined as follows (also see Anticipated Results):

$$\text{G4NI}\ (t,s) = \frac{A_{492}(t,s) - A_{492}\ (\text{unlabeled control}\,(t,s))}{A_{492}(0\ \text{min},s) - A_{492}\ (\text{unlabeled control}\ (0\ \text{min},s))}$$

    b. *GLUT4myc internalized* (G4I) at each time point (t) and each stimulus condition (s) is determined as follows (also see Anticipated Results):

$$\text{G4I}\ (t,s) = 1 - G4\text{NI}\ (t,s)$$

MEASURING GLUT4*myc* EXOCYTOSIS

BASIC PROTOCOL 3

Measurement of the rate of GLUT4*myc* exocytosis is achieved in two stages (Fig. 15.15.5). During the first stage, GLUT4 at the cell surface is labeled with anti-*myc* antibodies (on ice), followed by extensive washing to remove unbound anti-*myc* antibodies. GLUT4 thus labeled at the cell surface is then allowed to internalize from the cell surface for 2 hr at 37°C, achieving homogenous mixing of labeled transporters with all pools of intracellular GLUT4 (Fig. 15.15.1). In the second stage, the rate of arrival of previously *myc*-antibody-labeled GLUT4 molecules to the cell surface is measured over time. This measurement is achieved via detection of anti-*myc* labeling with secondary antibodies coupled to HRP at saturating concentrations. Cell-surface HRP-bound GLUT4*myc* is subsequently detected as described in Basic Protocol 1.

For materials, see Basic Protocol 1.

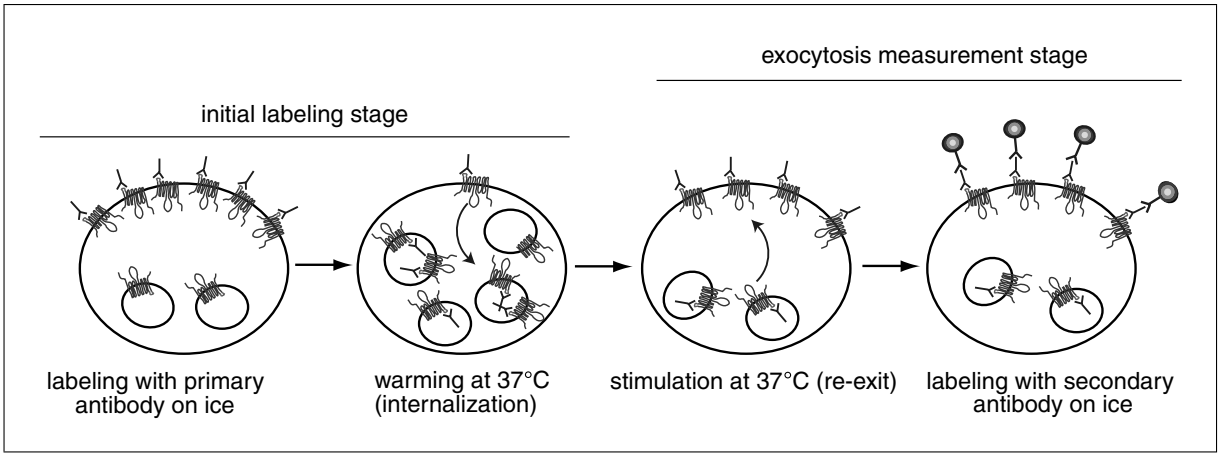

Figure 15.15.5 Measurement of GLUT4*myc* exocytosis in intact cells. Diagram depicting measurement of GLUT4*myc* exocytosis: cells are placed on ice and labeled with anti-*myc* antibodies at 4°C. Subsequently, cells are warmed to 37°C for 2 hr, thereby allowing internalization of anti-*myc* antibody–bound GLUT4*myc* molecules. After internalization, cells are treated with stimuli, thereby allowing re-exit of antibody-bound GLUT4*myc*. Finally, anti-*myc* antibody bound GLUT4*myc* are detected by HRP-conjugated secondary antibodies.

Plan experiment and seed cells

1. Seed GLUT4*myc* cells at a density of 2.0–3.0 × 10^4 cells per well of a 24-well plate in 0.5 ml/well medium.

   For experiments on myoblasts, cells are subsequently grown to confluence, typically for 36 to 48 hr in L6 growth medium. For experiments on myotubes, cells are placed in L6 differentiation medium at the time of seeding and grown for 7 days to allow for myoblast differentiation into myotubes.

2. To prepare for the experiment, note that a separate 24-well plate is required for each timepoint of GLUT4*myc* exocytosis to be assayed. Also required for each experiment is a separate 24-well plate for total amount of GLUT4 without exocytosis (termed control without exocytosis).

   Typically, GLUT4myc exocytosis is measured at 5, 10, and 20 min, although other timepoints can be assayed if desired.

3. Also note that each condition to be assayed must be done in triplicate (three wells/condition) for each timepoint, with a well for an (unlabeled) control for each condition.

   Thus, each 24-well plate (representing a single timepoint) can be used to assay at most six experimental conditions. Since all values measured are typically expressed relative to basal (unstimulated) cells, this condition must be included in every experiment.

Perform initial labeling of GLUT4myc with anti-myc antibodies

4. Aspirate medium from cells and wash cells once by adding and then removing 0.5 ml/well prewarmed serum-free α-MEM. Replace medium with 0.5 ml/well serum-free α-MEM and incubate for 2 hr at 37°C.

5. Stimulate cells with 250 µl of serum-free α-MEM (per well) containing 100 nM insulin for 30 min.

   This stimulation with insulin increases the amount of GLUT4myc that becomes labeled with anti-myc antibody at step 9.

6. Subsequently, place cells on ice and wash three times, each time by adding and then removing 0.5 ml/well ice-cold PBS+.

   These washes are performed to remove residual medium.

7. Aspirate PBS+ from cells and place the intact cells in 250 µl/well of blocking solution for 20 min on ice.

8. Prepare ≥5 ml/plate of a solution of ice-cold blocking solution, containing 1 µg/ml rabbit polyclonal anti-*myc* antibody (*myc*-labeling solution).

9. Aspirate blocking solution from cells and add 250 µl of *myc*-labeling solution to each well except for unlabeled control wells. Instead, add 250 µl of blocking solution to the control wells. Incubate cells on ice for 1 hr.

10. Aspirate *myc*-labeling solution from cells and wash five times in 0.5 ml/well ice-cold PBS+. Aspirate medium from wells for the first three washes; in subsequent washes dump the wash solution by inverting the plate to remove solution from wells.

11. For the 24-well plates to be used to measure exocytosis, quickly wash cells twice in 0.5 ml/well PBS+ prewarmed to 37°C.

Measure GLUT4myc exocytosis

12. Quickly aspirate solution from cells and add 0.5 ml/well prewarmed α-MEM. Incubate cells at 37°C for 2 hr.

13. Subsequently, quickly aspirate solution from cells and immediately treat cells by incubating cells in 250 µl of serum-free α-MEM containing the appropriate stimulus

for the desired timepoints for exocytosis measurement. Do not perform this step for the "control without exocytosis" plate. For this plate, skip step 13 and proceed directly to step 14.

14. Subsequently, quickly replace cells on ice and wash all plates twice with 0.5 ml/well ice-cold PBS+.

Fix cells

15. Fix cells for 10 min in 0.5 ml/well ice-cold PBS+ containing 4% PFA.

16. Aspirate fixative solution and quickly wash cells in 0.5 ml/well PBS+. Quench fixative in 0.5 ml/well PBS+ containing 100 mM glycine (quenching solution) for 10 min on ice.

17. Aspirate quenching solution. Incubate cells in 0.5 ml/well blocking solution for 15 min on ice.

Label with secondary antibody

18. Prepare 7 ml/plate of ice-cold blocking buffer containing a 1:750 dilution of horseradish peroxidase (HRP)–conjugated goat anti-rabbit antibody (secondary labeling solution).

19. Aspirate blocking buffer, add 250 µl of secondary labeling solution to each well, and incubate for 1 hr on ice.

20. Aspirate solution from cells and wash six times in 0.5 ml/well ice-cold PBS+.

Detect labeling

21. Prepare 12.5 ml/plate OPD assay solution (see Reagents and Solutions) immediately before use.

22. Aspirate any remaining PBS+ from cells and quickly add 500 µl of OPD assay solution to each well.

    It is essential that a minimal amount of time elapses between addition of the reagent to the first and last wells, as the amount of chromogenic product formed depends on the length of incubation of cells with the OPD reagent and should be as close to constant for all wells as possible.

23. After sufficient color develops (i.e., yellow is visible by eye in each well to which anti-*myc* antibody solution was added, typically after 5 to 20 min), add 125 µl/well of 3 N HCl (or equivalent normality of H_2SO_4 or other adequate strong acid) to halt the OPD chromogenic reaction.

    Note that 3 N HCl solution should be added to wells in the same order as was used for addition of the OPD assay solution to ensure constant time of incubation for each well.

Quantify labeling

24. Transfer 200 µl from each well to designated wells of a 96-well microtiter plate and read absorbance at 492 nm.

25. Express the rate amount of antibody-bound GLUT4*myc* undergoing exocytosis (G4Exo) following time (t) of exocytosis in any stimulated condition (s) relative to that observed in the control without exocytosis condition:

$$\text{G4Exo}\ (t,s) = \frac{A_{492}(t,s) - A_{492}(\text{unlabeled control})}{A_{492}(\text{control without exocytosis}) - A_{492}(\text{unlabeled control})}$$

Additionally, the amount of exocytosis in a stimulated condition can be normalized to that in the basal state (see Anticipated Results).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

L6 differentiation medium

α-modification of Eagle's medium (α-MEM; Wisent Bioproducts; *http://www.wisent.ca/*) supplemented with:
2% (v/v) fetal bovine serum (HyClone)
1% (v/v) antibiotic solution (Wisent Bioproducts)
If sterilized, store up to 4 months at 4°C; otherwise use immediately

L6 growth medium

α-modification of Eagle's medium (α-MEM; Wisent Bioproducts; *http://www.wisent.ca/*) supplemented with:
10% (v/v) fetal bovine serum (HyClone)
1% (v/v) antibiotic solution (Wisent Bioproducts)
If sterilized, store up to 4 months at 4°C; otherwise use immediately

OPD assay solution

Dissolve one 20 mg tablet of *O*-phenylenediamine (OPD) and 20 µl of 30% H_2O_2 per 50 ml of 0.05 M phosphate-citrate buffer, pH 5.0 (see recipe).

Phosphate-buffered saline (PBS)

0.137 M NaCl
2.7 mM KCl
10 mM Na_2HPO_4
1.8 mM KH_2PO_4, pH 7.4
Store indefinitely at room temperature but verify pH following extensive storage.

Phosphate/citrate buffer, pH 5.0

Add 25.7 ml of 0.2 M dibasic sodium phosphate to 24.3 ml of 0.1 M citric acid and 50 ml of water, and adjust the pH to 5.0, as necessary. Store indefinitely at room temperature, but verify pH following extended storage.

COMMENTARY

Background Information

The cell biology of GLUT4 traffic

Insulin stimulates glucose uptake into muscle and adipose tissues by increasing the amount of GLUT4 at the cell surface. In these cells, GLUT4 exists in multiple subcellular compartments including the plasma membrane, endosomal network, and a post-endosomal membrane compartment (Fig. 15.15.1). GLUT4 constitutively traverses the plasma membrane and these intracellular compartments, and this process is regulated by insulin, resulting in an increase in cell surface GLUT4 (termed GLUT4 translocation). Importantly, in insulin-resistant states, as in type 2 diabetes, GLUT4 translocation is impaired. Therefore, understanding the itinerary of GLUT4 traffic and its regulatory inputs is of fundamental importance.

In the absence of stimuli, the steady-state distribution of GLUT4 favors intracellular compartments due to its fast endocytosis and slow exocytosis. In the basal state, 5% to 10% of GLUT4 is found on the cell surface in L6 myoblasts, myotubes, and 3T3-L1 adipocytes (Li et al., 2001; Zeigerer et al., 2002). Using strategies such as those outlined in this chapter to measure the distinct kinetic parameters of exocytosis and endocytosis in L6 muscle cells, 3T3-L1 adipocytes, and rat adipocytes, it has consistently been found that insulin increases the rate of exocytosis of GLUT4 (reviewed by Zaid et al., 2008). While insulin also effects a small and debated decrease in GLUT4 endocytosis in 3T3-L1 adipocytes (Blot and McGraw, 2006), the hormone is without effect on the endocytosis of the transporter in L6 muscle cells (Li et al., 2001; Antonescu et al., 2008b,

2009). Hence, insulin acts to increase cell surface GLUT4 primarily by increasing its rate of exocytosis.

The mechanism by which insulin promotes exocytosis of GLUT4-containing vesicles has been increasingly documented (reviewed by Zaid et al., 2008). Upon binding to its receptor, insulin initiates phosphatidylinositol-3-kinase (PI3K)-dependent activation of the serine/threonine kinase Akt, which in turn phosphorylates the Akt substrate of 160 kDa (AS160). Phosphorylation of AS160 is thought to inactivate its Rab-GAP activity, thereby promoting GTP-loading of selective Rab proteins that impinge on GLUT4 membrane traffic (Ishikura et al., 2007). In L6 muscle cells, regulation of Rabs 8A and 14 via AS160 is required for insulin-stimulated GLUT4 exocytosis (Ishikura et al., 2007), while in 3T3-L1 adipocytes, Rab10 participates instead (Sano et al., 2007). Rab proteins are thought to affect membrane traffic by binding to certain effector molecules preferentially in the GTP-bound state; GTP-Rab8A may regulate GLUT4 exocytosis by binding to myosin Vb (Ishikura and Klip, 2008; Randhawa et al., 2008).

It remains unknown whether these Rab proteins function within endosomal compartments or at the plasma membrane in order to increase GLUT4 exocytosis (see Fig. 15.15.1). However, insulin increases the rate of fusion of GLUT4 vesicles with the plasma membrane (reviewed by Zaid et al., 2008). Insulin-stimulated GLUT4-containing vesicles fuse with the plasma membrane in a manner that requires the SNARE proteins VAMP2, SNAP23, and syntaxin 4 (Foster et al., 1998; Kawanishi et al., 2000), and that is regulated by Munc18c (Tamori et al., 1998; Thurmond et al., 2000; D'Andrea-Merrins et al., 2007). Insulin also engages other cellular elements in GLUT4 membrane traffic (reviewed by Zaid et al., 2008), including release of GLUT4 from TUG (Bogan et al., 2003; Yu et al., 2007; Schertzer et al., 2008), binding of GLUT4 to α-actinin-4 (Talior-Volodarsky et al., 2008), and participation of the dynamic actin cytoskeleton (Tsakiridis et al., 1999; Patel et al., 2003; JeBailey et al., 2004; Torok et al., 2004), and several motor proteins (Imamura et al., 2003; Semiz et al., 2003; Bose et al., 2004; Randhawa et al., 2008). Thus, insulin regulates GLUT4 traffic through diverse input at multiple stages, which in sum achieves an increase in the rate of GLUT4 exocytosis and hence in the net amount of cell surface GLUT4 (reviewed by Zaid et al., 2008).

Aside from insulin, other physiologically important stimuli also increase cell surface GLUT4. Muscle contraction, as occurs during exercise, causes an increased energy demand in skeletal muscle which is accommodated by an increase in cell surface GLUT4 (reviewed by Wijesekara et al., 2006). Due to technical limitations of achieving contraction in L6 cells in culture, it is not possible to directly observe the regulation of GLUT4 membrane traffic in this state. However, exogenous activation of the signaling pathways initiated by muscle contraction, specifically a rise in intracellular Ca^{2+} and activation of AMP-activated protein kinase (AMPK), can be emulated by treatment of cells with dinitrophenol (DNP), which accordingly also provokes a gain in surface GLUT4. Interestingly, in this case, using the strategies described in this unit, it is found that the regulation occurs largely through a reduction in the rate of GLUT4 endocytosis (Antonescu et al., 2008b). By analogy, muscle contraction may increase cell surface GLUT4 through a reduced rate of GLUT4 endocytosis, although this requires experimental verification in mature, contracting muscle fibers. Such experiments await the availability of methods to accurately detect GLUT4 traffic in intact muscle fibers, ideally expressing tagged GLUT4.

Unlike the regulation of GLUT4 exocytosis by insulin, much less is known about the mechanism by which muscle contraction may regulate GLUT4 endocytosis. GLUT4 internalization occurs by both clathrin-dependent and -independent mechanisms in 3T3-L1 adipocytes and L6 muscle cells (Blot and McGraw, 2006; Antonescu et al., 2008b, 2009). Stimulation of L6 muscle cells with DNP reduces GLUT4 internalization via the clathrin-independent route, suggesting that the signaling pathways involving intracellular Ca^{2+} and AMPK activation target this route of internalization to augment cell surface GLUT4 (Antonescu et al., 2008b). The molecules participating in the clathrin-independent internalization in L6 muscle cells remain poorly understood, but they do not involve caveolae and require the GTPase dynamin. These characteristics are also shared by the internalization of the interleukin 2 receptor β subunit (IL-2Rβ) (Antonescu et al., 2008b, 2009). Further investigation of the molecular machinery of this route of internalization will aid in understanding the mechanism by which muscle contraction regulates GLUT endocytosis.

Critical Parameters and Troubleshooting

Cell culture prior to seeding

L6 muscle cells are grown and cultured as myoblasts prior to seeding for these experiments. Experiments can then be done on L6 myoblasts or following differentiation of L6 cells into myotubes by incubation of confluent myoblasts in low-serum medium (containing 2% FBS) for approximately 5 to 7 days. Of note, L6 cells can begin to partially differentiate into myotubes even in regular growth medium (containing 10% FBS) upon attaining confluence. Once differentiation is thus initiated, L6 cells exhibit altered morphology and other parameters relative to undifferentiated L6 myoblasts, although they remain mononuclear. Furthermore, these partly differentiated cells are less efficient at completing differentiation into multinucleated myotubes upon seeding in low-serum conditions. Hence, it is important to ensure that myoblasts never reach more than ~50% confluence prior to seeding for experiments. Typically, this is best achieved by passaging cells every 48 hr, and never less frequently than every 72 hr.

Cell density for seeding

Upon seeding cells, it is important to follow the indicated cellular density. This will allow experiments to be done on myoblasts (typically 48 hr after seeding) on a confluent monolayer, and allow optimal differentiation into myotubes (over ~7 days). Performing experiments on myoblasts that are not fully confluent may result in detachment of cells from the 24-well plate during the experiment. This is a particularly important consideration in measurement of endocytosis (Basic Protocol 2) and exocytosis (Basic Protocol 3), which require extensive cellular manipulation during the assays.

Note that when intending to perform experiments on myoblasts, care must also to taken not to seed more cells than indicated because, when cells reach confluence too rapidly, differentiation is initiated, which could result in early, partial differentiation. This could produce measurements that are difficult to interpret. Hence, seeding cells at the indicated density is critical to ensure consistent, reproducible measurements of GLUT4 traffic parameters.

Transfection or infection of L6 cells prior to assays

The assays described in this unit all allow measurement of GLUT4 traffic parameters following various transfection protocols. However, care must be taken when considering such strategies to ensure that a vast majority of cells are successfully transfected. Due to the fact that the ELISA-based assays described here measure the relative amount of cell surface GLUT4 in a population of cells, transfection methods that achieve less than ~70% efficiency will likely not allow detection of a possibly altered GLUT4 traffic phenotype.

Several methods to transfect L6 myoblasts with siRNA have been used in L6 myoblasts and myotubes, including Oligofectamine (Invitrogen) and CellPhect (GE Life Science; Jebailey et al., 2004; Antonescu et al., 2005b, 2008a; Huang et al., 2005). Currently, no lipid cationic method for transient transfection of L6 myoblasts with longer oligonucleotides encoding cDNAs or shRNAs has been identified that achieves sufficiently elevated transfection efficiency for use with the methods described in this unit. However, exogenous expression of various proteins can be achieved by either creating stably transfected cell lines or by infection with adenoviral or lentiviral strategies, a strategy we previously employed to express dominant-negative mutants of p38MAPK α and β (Antonescu et al., 2005b). Of note, should transfection efficiency remain limited to a small percentage of L6 cells for a particular circumstance, we refer the reader to single-cell, fluorescence-based assays for measuring GLUT4 traffic parameters that we have previously described (Antonescu et al., 2008a), which, although resource- and labor-intensive, are suitable under those conditions.

Normalization to eliminate differences due to cell density between conditions

Some experimental treatments, such as siRNA knockdown of certain proteins, or prolonged treatment with particular inhibitors, can result in differences in cell growth or attachment. This can, in turn, result in differences in cell density between conditions when performing the experiment. Thus, it is important to normalize for cell density during such experiments in order to accurately determine the relative differences in cell surface GLUT4. This can be achieved by seeding an extra well per condition (of a 24-well plate) that is used to measure total protein concentration, followed by normalization of the amount of cell surface GLUT4 to protein concentration in each condition.

Obtaining a source of optimal antibody

Prior to beginning the experiments described in this unit, it is essential to obtain

a source of anti-*myc* antibodies that provides an appropriate strength of signal relative to background. Importantly, not all commercially available antibodies are suitable for this assay. This can be done by performing the steady-state cell surface GLUT4*myc* assay described in Basic Protocol 1 simultaneously on L6 myoblasts that express GLUT4*myc* (L6-GLUT4*myc*) and on cells that do not (wild-type cells). Appropriate antibodies for the experiments described in this unit will result in cell surface GLUT4*myc* labeling at least ten times greater than that observed on wild-type cells. After this initial characterization of the anti-*myc* antibody, it may be necessary to determine the labeling of wild-type cells in each subsequent assay in order to obtain a value for background, nonspecific anti-*myc* antibody labeling. This value is then subtracted from the value of cell surface GLUT4*myc* measured in all conditions.

Appropriate washing of excess antibodies

Following labeling with anti-*myc* and HRP-conjugated antibodies, it is essential to remove all unbound antibodies before proceeding to the next stages of the assay. This is done by washing the cells with ice-cold PBS+ for the indicated number of times. Importantly, aspiration of wash instead of dumping excess PBS+ (by turning 24-well plate upside down) allows complete removal of antibodies. This in turn results in lower volume retained between washes, and decreased nonspecific labeling of each antibody. Hence, performing the washing stages as indicated ensures optimal signal-to-noise of antibody labeling.

Timing during endocytosis and exocytosis experiments

For the experiments described in Basic Protocol 2 (GLUT4*myc* endocytosis) and Basic Protocol 3 (GLUT4*myc* exocytosis), timing is crucial during particular stages of the assay. For GLUT4*myc* endocytosis, the time for which cells are rewarmed must be precisely followed. Following washing to remove anti-*myc* antibody in ice-cold PBS+, a minimum of time should elapse from the first wash in 37°C PBS+ and addition of 37°C α-MEM containing appropriate stimulus. Furthermore, immediately after the desired time of internalization has elapsed, cells must be rapidly washed in ice-cold PBS+ and quickly placed in fixative solution. Failure to add fixative solution immediately after the desired time of internalization has elapsed may result in continued internalization of GLUT4*myc* beyond the desired timepoint. For the GLUT4myc exocytosis protocol, similarly to the measurement of GLUT4myc endocytosis, a minimum of time should elapse during and between the stages that require a change in temperature of the cells (from 4° to 37°C or vice versa).

Anticipated Results

The colorimetric ELISA-based methods to measure the amount of cell surface GLUT4 described in this unit have been used in previously publications (Wang et al., 1998; Huang et al., 2002; Niu et al., 2003; JeBailey et al., 2004, 2007; Huang et al., 2005; Foster et al., 2006; Diaz et al., 2007; Antonescu et al., 2008b). An example of measurement of cell surface GLUT4 at steady-state (Basic

Figure 15.15.6 *(continued on next page)* Results of cell surface GLUT4*myc* assays. (**A**) L6 myoblasts were stimulated with α-MEM containing either 100 nM insulin for 7 or 20 min, with platelet-derived growth factor (PDGF) for 7 min or 450 mM (hypertonic) sucrose, or left unstimulated (control). Cell surface GLUT4*myc* was measured as described in Basic Protocol 1. Shown are the mean ± SE for each condition. *, $p < 0.05$ relative to control. (**B**) L6 myoblasts were stimulated with α-MEM containing 100 nM insulin for 20 min, or left unstimulated (basal). GLUT4*myc* internalization was measured as described in Basic Protocol 2. Shown are the means ± SE of GLUT4*myc* remaining at the cell surface (i) or GLUT4*myc* internalized (ii) at various times in the continued presence or absence of insulin, as indicated. Also shown for each condition is a single exponential decay (i) or association (ii) curve determined by nonlinear regression analysis. (**C**) In L6 myoblasts, GLUT4*myc* internalization was measured for 120 min following initial labeling, as described in Basic Protocol 2. Shown in panel i are the mean ± SE for each condition of GLUT4 remaining at the cell surface for the indicated times. In parallel, GLUT4*myc* exocytosis was measured in the presence (closed markers) or absence (open markers) of insulin as described in Basic Protocol 3 in cells in which internalization of surface-labeled GLUT4*myc* had proceeded for 120 min. Shown on the same graph (i) are the means ± SE of GLUT4 exocytosis (depicted by bar marked exocytosis). GLUT4 exocytosis measurements in the presence of insulin at each timepoint were normalized to the corresponding timepoint of the basal state and shown ± SE in panel ii. Note that in panel ii, $t = 0$ corresponds to $t = 120$ of panel i, that of initiation of measurement of GLUT4 exocytosis.

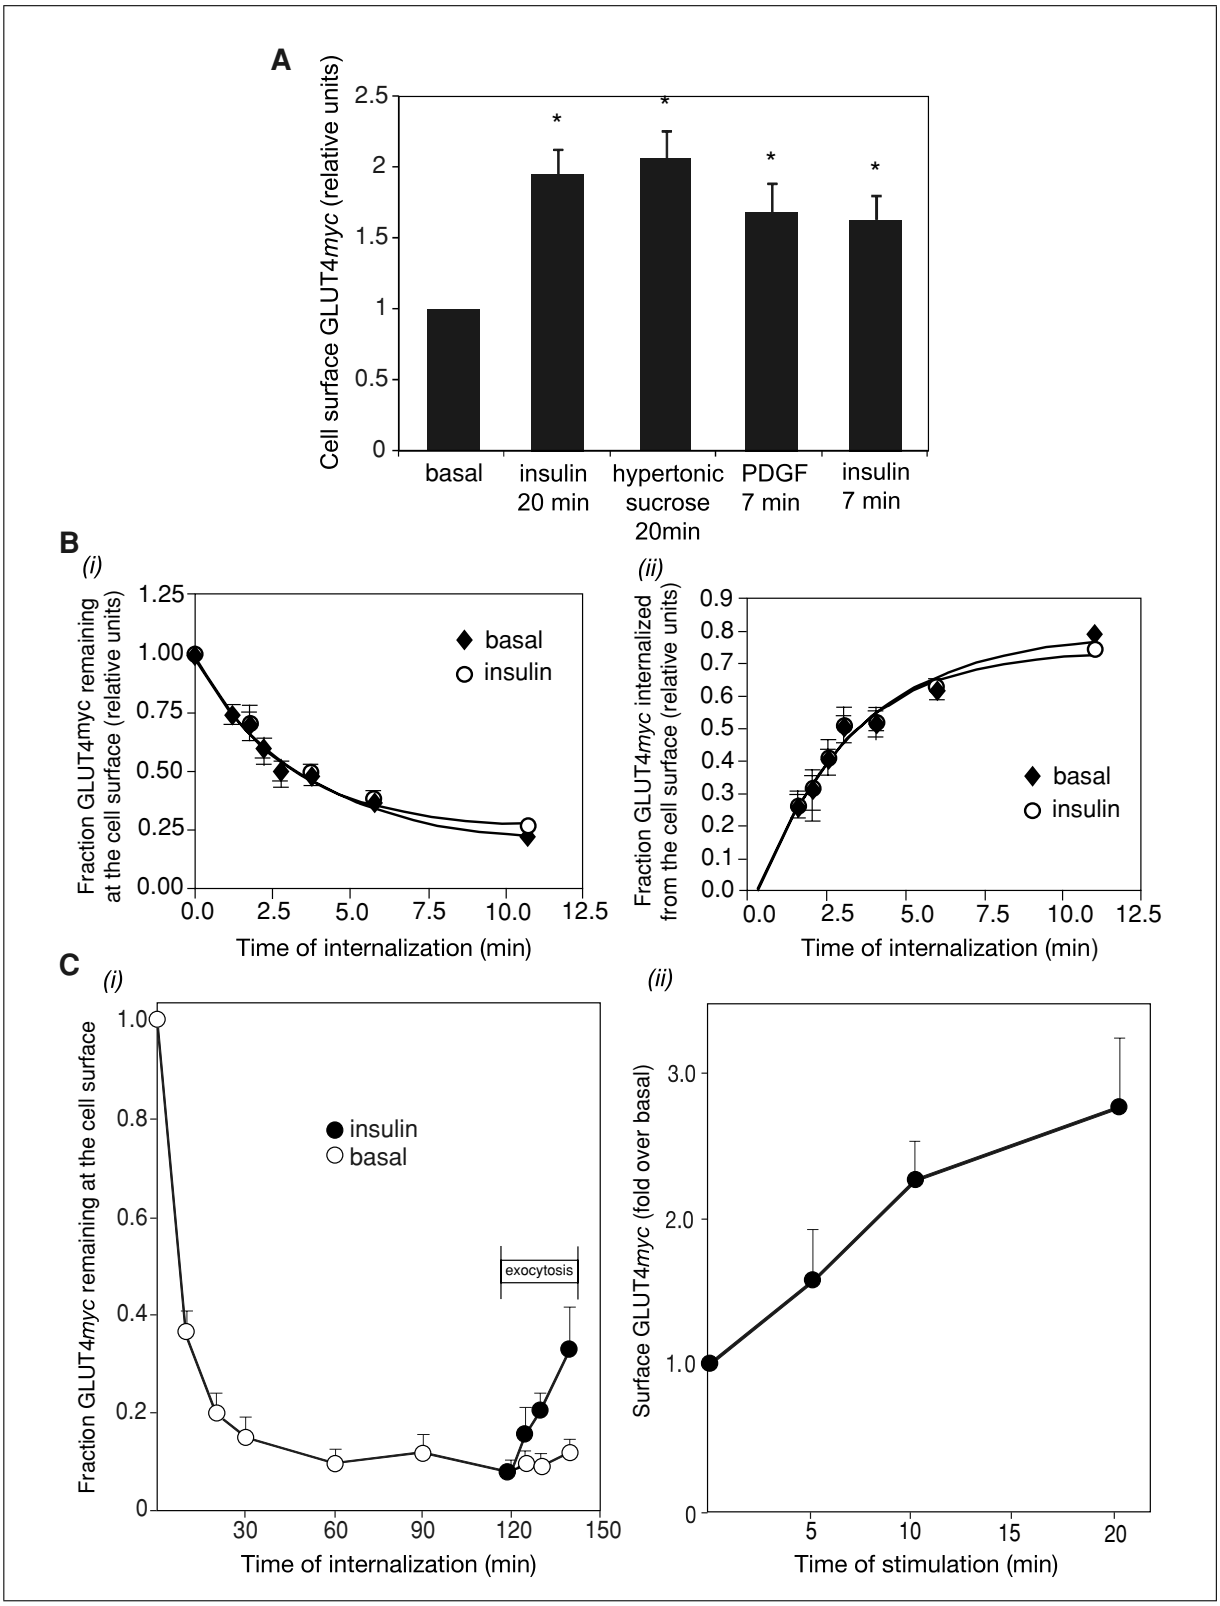

Figure 15.15.6 *(legend on previous page)*

Protocol 1) is shown in Figure 15.15.6A. Upon stimulation with insulin, cell surface GLUT4*myc* content is increased at ~2-fold. In addition to insulin, hypertonic sucrose and platelet-derived growth factor (PDGF) are also shown to elevate cell surface GLUT4 levels.

Representative data from a GLUT4*myc* endocytosis experiment (Basic Protocol 2) are shown in Figure 15.15.6B. Measurements of GLUT4*myc* internalization can be depicted as the amount of cell surface GLUT4*myc* remaining at the cell surface at various times of internalization (Fig. 15.15.6B,i). Alternatively, the same data can be depicted as the amount of *myc*-antibody-labeled GLUT4*myc* that has become inaccessible to detection by secondary antibodies, reflecting the amount of internalized GLUT4*myc* at various times (Fig. 15.15.6B,ii). In muscle cells, insulin does not affect the rate of GLUT4*myc* endocytosis.

Representative data from a GLUT4*myc* exocytosis experiment are shown in Figure 15.15.6C. We first demonstrate that GLUT4 initially labeled with *myc*-antibody at the cell surface internalizes and achieves a new steady state whereby the labeled transporter is located predominantly intracellularly. Internalization of GLUT4 from the cell surface is determined as described in Basic Protocol 2 for a period of 120 min (Fig. 15.15.6C,ii). After internalization for 120 min, ~10% of *myc*-antibody-labeled GLUT4*myc* localizes at the plasma membrane. Also performed in parallel (i.e., in the same experiment) is a measurement of GLUT4 exocytosis in cells that had internalized surface-labeled antibody-bound GLUT4 for 120 min (as described in Basic Protocol 3). The values of these measurements are also shown in Figure 15.15.6C,ii, and distinguished by a bar marked "exocytosis." The same values of GLUT4 exocytosis in the presence of 100 nM insulin were normalized to that in basal (unstimulated) cells (Fig 15.15.6C, ii). Upon stimulation with 100 nM insulin for 20 min, *myc*-antibody-labeled GLUT4*myc* content at the cell surface is increased at 2.7-fold over basal.

Time Consideration

Each individual experiment is readily performed within a single day. A possible modification of the assay to shorten the total time of each assay involves serum starvation of cells in medium containing 0.1% FBS overnight, prior to performing the experiment. Under such conditions, insulin achieves a similar increase in cell surface GLUT4 as when serum starvation is performed for 2 to 3 hr in α-MEM without FBS (JeBailey et al., 2007). However, the suitability of this modification to the assay for each condition to be assayed should first be verified by directly comparing the resulting effect on GLUT4*myc* traffic parameters between the different serum-starvation conditions.

CHAPTER 16
Antibodies as Cell Biological Tools

INTRODUCTION

Monoclonal and polyclonal antibodies are powerful tools for addressing cell biological questions. These immunological reagents can be used to detect and analyze proteins and carbohydrates, characterize the subcellular distribution of proteins, and purify proteins. In addition, when taken up by cells, antibodies can be used as tags to monitor the intracellular pathways of proteins and to inhibit protein activity. These diverse applications of antibody technology have been facilitated by advances in the understanding of the molecular genetics of antibody molecules and their three-dimensional structures. The development of methods for measuring antibody binding activity and for isolating antibodies has contributed to their widespread use and extensive range of applications.

The development of monoclonal antibodies, unique and powerful reagents for detecting and measuring interactions with specific protein epitopes, has revolutionized the use of antibodies in cell biological research. These antibodies are obtained by fusing immune B cells from the spleen with tumor cells to produce hybridomas. Hybridomas each secrete a single type of antibody—the monoclonal antibody—that has precise specificity and often high affinity (*UNIT 16.1*). Because the cloned hybridoma cell line is immortal, with appropriate care it can be maintained indefinitely and the antibodies it produces can be supplied in essentially limitless quantities. Preparations containing monoclonal antibodies include hybridoma supernatants, ascites fluid from a mouse inoculated with the hybridoma, and purified monoclonal antibody. *UNIT 16.1* describes how to produce monoclonal antibodies, including basic protocols for immunization, cell fusion, and hybridoma selection. The unit also includes methods for antigen preparation, suggestions for troubleshooting to ensure production of antibodies at high titer, and approaches for increasing the specificity of the antibody.

Polyclonal antibodies (*UNIT 16.2*) take less effort to prepare than monoclonal antibodies. The process consists simply of immunizing an animal of any one of a variety of species (including goat, horse, rat, mouse, and rabbit) with purified antigen and then, after the animal develops an immune response, isolating antibodies from its serum. Because polyclonal antibodies are essentially a collection of monoclonal antibodies with different epitope specificities and affinities, they are useful for analyses of denatured forms of a protein, for immunoprecipitation, and for immunoblotting. These types of analyses are often not successful with monoclonal antibodies because the single epitope recognized by the monoclonal antibody preparation may be destroyed during protein denaturation.

The choice of animal species for immunization depends in part on the amount of antiserum required for subsequent experiments. Mice, rats, and guinea pigs yield relatively low volumes of antiserum compared to rabbits and other larger animals. For this reason, rabbits are often the animals of choice. It is often desirable to produce polyclonal antibodies in other species, however, especially when an experiment requires two distinct types of antibodies that recognize different proteins (as is often the case in indirect immunofluorescence assays; see *UNIT 4.3*). *UNIT 16.2* contains a detailed protocol for immunizing animals to produce polyclonal antibodies, with discussion of the kinetics of the antibody response, when to boost, and the use of different adjuvants; advice on how to generate the highest-titer

Contributed by Jennifer Lippincott-Schwartz
Current Protocols in Cell Biology (2002) 16.0.1-16.0.2

antiserum is also included. Using these techniques, investigators can have polyclonal antibodies in hand for use in experiments within 6 to 8 weeks.

Purified antibody preparations are crucial when accurate concentrations of antibody are needed. For example, when chemical or structural modifications of antibody are being made for antibody binding studies. *UNIT 16.3* describes how to prepare purified forms of monoclonal and polyclonal antibodies. The purification methods that are discussed include ammonium sulfate precipitation, protein A and protein G affinity chromatography, ion-exchange chromatography, and combinations of these. Rapid assays for monitoring the activity of antibody are described for ensuring that antibody activity is not lost during purification. Commercial kits for purification and fragmentation of antibodies that are available for researchers who are unable to prepare antibodies themselves are also discussed in terms of their reliability and relative cost.

UNIT 16.4 describes how to cleave antibodies into functionally distinct subunits using proteolytic enzymes such as papain. Monovalent fragments of IgG produced by papain digestion are known as Fab fragments. These fragments usually retain the binding specificity of the intact IgG molecule. They are, therefore, desirable in binding studies since the Fc portion of IgG may cause artifacts due to binding to cells that bear the Fc receptor. In addition to describing papain digestion of IgGs, the unit discusses pepsin and ficin digestion methods which produce bivalent $F(ab')_2$ fragments and allow discrimination of different IgG subclasses. Both pilot and large-scale fragmentation protocols are described.

UNIT 16.5 describes how to conjugate antibodies with fluorescent dyes, with biotin, and with enzymes. Antibodies that are directly conjugated in this manner have proven to be essential for detecting multiple structures or functions within a specimen simultaneously. The alternative method for staining multiple epitopes is by using unconjugated primary antibodies detected with labeled secondary antibodies, but this usually results in significant cross-reactivity. *UNIT 16.5* describes several simple methods for directly conjugating antibodies so that their biological activity is retained. A basic method involves derivation of the amino group(s) on the antibody with dye, biotin, or enzyme. The methods are simple to perform and have high rates of success. Alternative, more complex methods are presented; these include attaching the label at a carbohydrate site or sulfhydryl group of the antibody. The Commentary includes a detailed discussion of the types of fluorophores and enzymes and their advantages and uses for conjugation. In addition there is discussion of the critical aspects of conjugation, including the choice of conjugating species and the optimal extent of labeling to preserve antibody affinity.

A powerful new approach to elucidating the important but bewilderingly complex signal transduction pathways of cells is to use antibodies that detect specific sites on proteins only after they become phosphorylated. For example, such antibodies can recognize with high sensitivity the addition of phosphate to specific tyrosine residues in a particular signaling or structural protein—if such phosphorylation regulates activation or inhibition of functional activity, the antibodies can be used to monitor activation, e.g., in homogenates or by immunofluorescence. *UNIT 16.6* provides methods for producing either polyclonal or monoclonal antibodies against specific phosphopeptides. In order to isolate polyclonal antibodies specific only for a unique tyrosine phosphopeptide, multistep affinity chromatography is applied to achieve appropriate specificity. Similarly, monoclonal antibodies are screened in several steps to identify a clone with sufficient specificity. Although these protocols focus on sites containing phosphorylated tyrosine, similar approaches can be used for producing antibodies that recognize specific serine- and threonine-phosphorylated peptides.

Jennifer Lippincott-Schwartz

Production of Monoclonal Antibodies

Highly specific antibodies can be obtained by fusing immune splenic B cells from the spleen with tumor cells to produce hybridomas, each of which will then secrete a single antibody. The desired antibody-producing hybridoma can be identified by a screening process. If this hybridoma is subjected to a cloning step in which clones are selected, such that all progeny are derived from a single cloned parental cell, a monoclonal antibody is obtained. Monoclonal antibodies have high specificity and can be produced in large quantities. Thus, these biological reagents have been used extensively as probes in a wide range of systems including the characterization of novel cell-surface and soluble proteins and carbohydrates, as enzyme catalysts, and for targeting in immunotherapy (see Commentary).

This unit describes the production of monoclonal antibodies beginning with basic protocols for immunization (see Basic Protocol 1) and cell fusion and selection (see Basic Protocol 2). Support protocols are provided for screening primary hybridoma supernatants for antibodies of desired specificity (see Support Protocol 1), establishment of stable hybridoma lines (see Support Protocol 2), cloning of these B cell lines by limiting dilution to obtain monoclonal lines (see Support Protocol 3), and preparation of cloning/expansion medium (thymocyte-conditioned medium; see Support Protocol 4). Figure 16.1.1 summarizes these stages and notes the protocols in this and subsequent units in which they are detailed. A major commitment of time and labor is necessary but, if successful, the monoclonal antibody may be an extremely valuable reagent that will be available in large quantities.

Submission of monoclonal antibodies to the American Type Culture Collection (ATCC) for distribution to the scientific community is encouraged. Moreover, the ATCC serves as a repository for cell lines should the line be lost in the investigator's laboratory due to unforeseen circumstances.

NOTE: All solutions and equipment coming into contact with living cells must be sterile and appropriate aseptic techniques should be used accordingly.

IMMUNIZATION TO PRODUCE MONOCLONAL ANTIBODIES

BASIC PROTOCOL 1

A wide variety of antigen preparations have been used successfully to produce monoclonal antibodies (see Critical Parameters discussion of antigen preparation). The following protocol provides an immunization schedule for the production of most antibodies, although several different schedules can be used. In this protocol, emulsified antigen is injected intraperitoneally into the species of choice. A booster injection is administered 10 to 14 days after the primary immunization. Three days after the booster injection, the animals' spleens are ready for cell fusion (Basic Protocol 2).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Antigen
Complete Freund's adjuvant (CFA; Sigma)
Animal: pathogen-free mouse, rat, or hamster (Armenian hamsters from Cytogen Research are recommended); see Critical Parameters for discussion of animal choice
Incomplete Freund's adjuvant (IFA; Sigma), optional

Contributed by Wayne M. Yokoyama
Current Protocols in Cell Biology (1999) 16.1.1-16.1.17

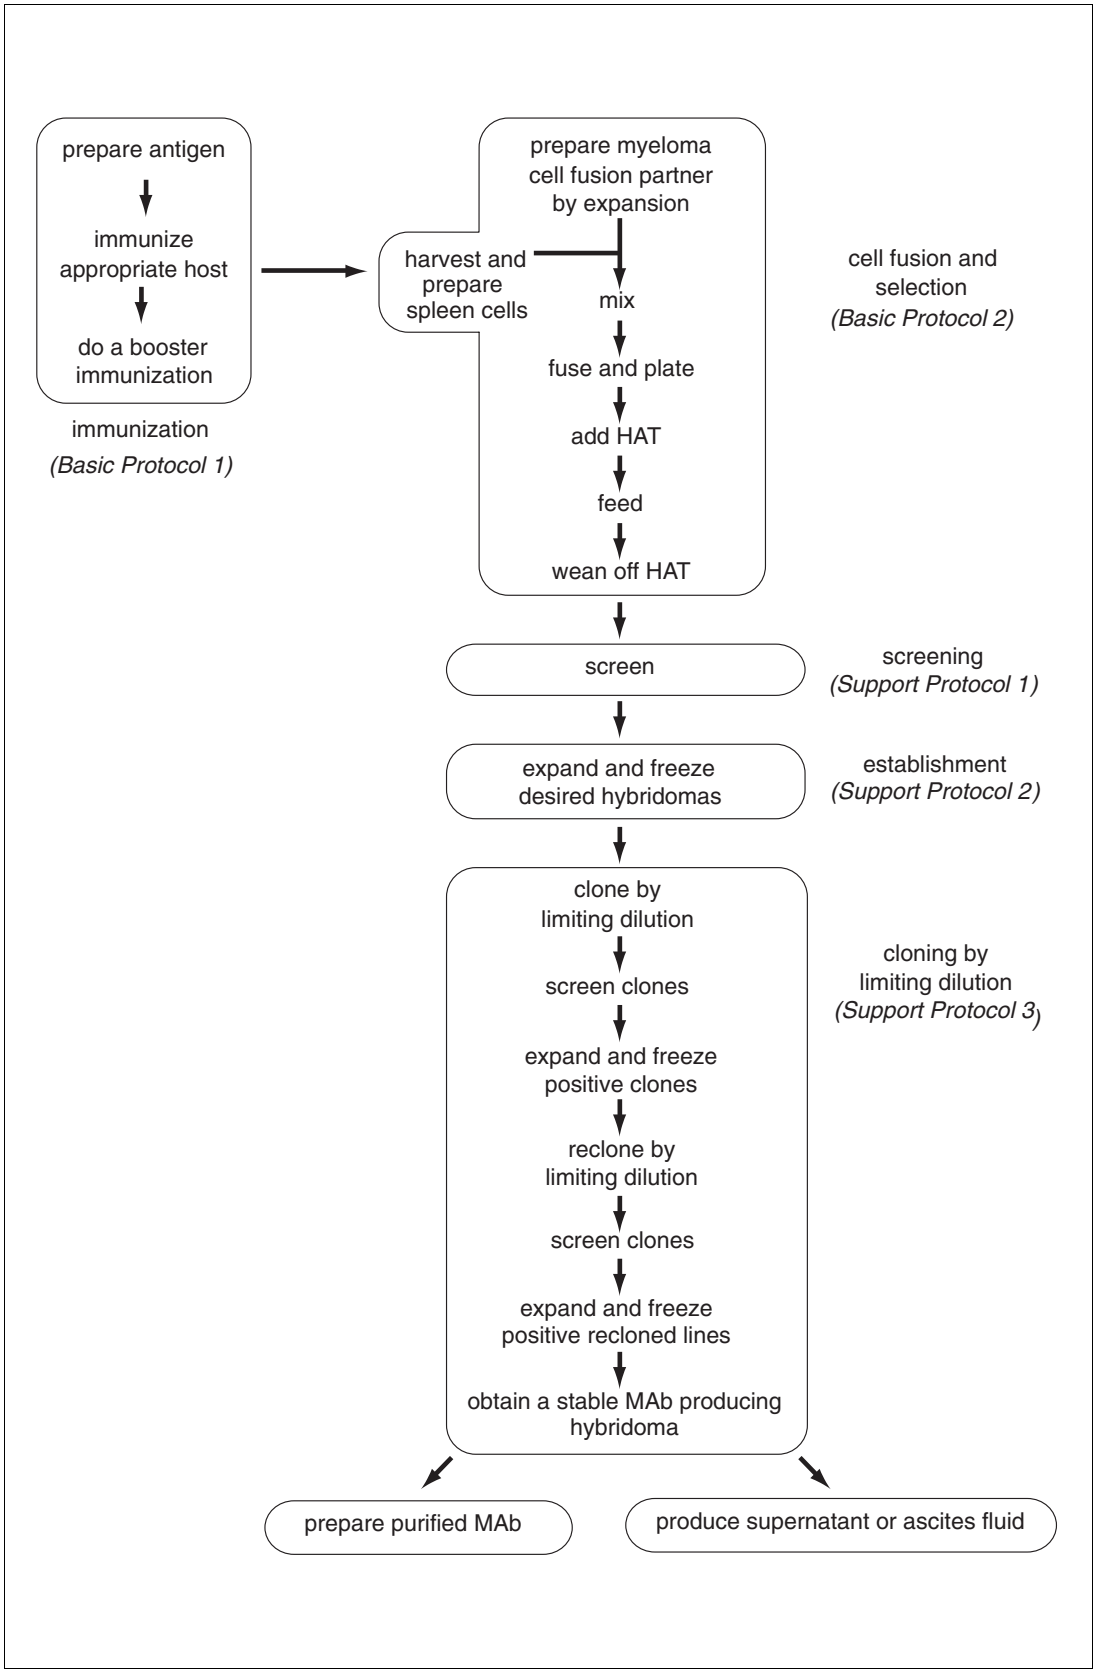

Figure 16.1.1 Stages of monoclonal antibody production, with references to the basic and support protocols in this unit that describe the steps.

1- to 2-ml glass syringes with Luer-Lok tips, sterile
3-way stopcock
20- and 22-G needles, sterile

CAUTION: CFA is an extremely potent inflammatory agent, and is hazardous to the investigator, particularly if introduced intradermally or into the eyes. Profound sloughing of skin or loss of sight may occur. Self-injection can cause a positive TB skin test and lead to a granulomatous reaction. Use gloves and protective eyewear when handling CFA.

1. Prepare antigen using 2×10^6 to 5×10^7 cells or 1 to 50 µg protein or peptide per animal to be immunized in normal saline.

   The antigen may be in any of several different forms depending on the desired property of the MAb and the method of screening (see Critical Parameters for discussion of antigen preparation and screening assays). If cells are the immunogen, wash three times in serum-free medium before immunization. Plan the immunization of several animals (enough for several fusions) so that primed and boosted animals will be ready 3 days before fusion (see Basic Protocol 2).

   To minimize the risk of introducing a pathogen into the rodent colony, screen cells for pathogens by antibody-production assay (Donovan and Brown, 1995).

2. Draw up antigen into a sterile 1- to 2-ml glass syringe with a Luer-Lok tip. Connect syringe to a 3-way stopcock.

3. Completely resuspend CFA to disperse the *Mycobacterium tuberculosis* bacilli which settle to the bottom of the container with time. Draw up a volume of CFA equal to the antigen volume in a syringe and connect to the antigen-containing syringe.

4. Emulsify antigen and CFA by discharging antigen into CFA, then discharging back and forth until a thickened mixture results. Test whether the emulsion is stable—a stable emulsion will not disperse when a drop of it is placed in water.

   Figure 16.2.1 illustrates the double-syringe device.

5. Transfer all of the CFA/antigen emulsion to one syringe and remove the other syringe and stopcock. Attach a sterile 20-G needle to the syringe containing the emulsion.

6. Inject emulsion intraperitoneally into the animal using <0.2 ml per mouse, 0.5 to 1 ml per rat, or 0.2 to 0.4 ml per hamster.

   Be careful not to force the syringe plunger since excessive pressure may dislodge the needle and spray the emulsion. Introduce the needle through the skin and tunnel the needle between the skin and peritoneal wall before entering the peritoneal cavity at a site distant from the dermal puncture site. Twirl needle before withdrawal to minimize leakage.

   Rats are generally anesthetized whereas mice and hamsters can be manipulated with one hand and do not require anesthetic.

7. Boost animal after 10 to 14 days with approximately the same dose of antigen as in step 5. If cell fusion is planned for 3 days after boosting, immunize with antigen alone in aqueous solution, or intact cells in suspension. If a fusion is not immediately planned, boost the animal with antigen emulsified in IFA (which does not contain *Mycobacterium tuberculosis* bacilli).

   Do not use CFA for the booster immunizations as this will cause intense inflammation and increased anti-TB antibody response.

   If desired, antibody titers can be assayed by ELISA or immunoprecipitation (UNIT 7.2), 7 to 10 days after the primary and booster immunizations.

BASIC PROTOCOL 2

CELL FUSION AND SELECTION OF HYBRIDOMAS

While animals should be immunized as soon as the decision has been made to produce a monoclonal antibody and the antigen has been prepared, do not perform cell fusion until the screening assay (Support Protocol 1) has been perfected. Artifactual results that may arise from conditioned media must be identified before cell fusion, because after a fusion there is only a finite amount of time available to assay for the desired monoclonal antibody.

Prior to cell fusion, the partner (myeloma) cell line is expanded and a booster injection of antigen is administered to the primed animals. On the day of fusion, the spleens are harvested. Spleen cells and partner cells are washed, harvested, and mixed. Cell fusion is performed at 37°C in the presence of polyethylene glycol (PEG). The resulting pellet is harvested and plated into tissue culture plates. After incubation with hypoxanthine, aminopterin, and thymidine (HAT) medium and feeding over ~2 weeks, the hybridomas are ready for screening (Support Protocol 1).

Materials

SP2/0-Ag14 myeloma cell line (drug-marked, nonsecretory; ATCC #CRL 1581)
Complete DMEM-10 and -20 media with 10 mM HEPES and 1 mM sodium pyruvate
Primed animal; mouse, hamster, or rat (10 to 14 days after primary immunization; see Basic Protocol 1)
Complete DMEM medium (*APPENDIX 2A*), serum-free
50% polyethylene glycol (PEG), sterile (see recipe)
Ammonium chloride solution (see recipe)
Complete DMEM-20 with 10 mM HEPES, 1 mM sodium pyruvate, and 1× HAT or 1× HT supplement (see recipe)

175-cm^2 flasks
Fine-mesh metal screen
50-ml conical polypropylene centrifuge tubes
Beckman TH-4 rotor or equivalent
96-well flat-bottom microtiter plates

Additional reagents and equipment for counting cells and assessing cell viability by Trypan blue exclusion (*UNIT 1.1*)

NOTE: All culture incubations should be performed in a humidified 37°C, 5%, CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Prepare myeloma cells (1 week before fusion)

1. One week before fusion, begin expansion of SP2/0-Ag14 myeloma cell line (the fusion partner cell line) in complete DMEM-10/HEPES/pyruvate (see Critical Parameters). By the day cell fusion is to be performed, the following total number of myeloma cells must be available (in multiple 175-cm^2 flasks containing 100 ml each), depending upon the source of the primed animal: mouse spleen, 1×10^8 cells in two or three flasks; hamster spleen, 2×10^8 cells in three or four flasks; and rat spleen, $5\text{-}10 \times 10^8$ cells in ten flasks.

   Two mouse or hamster spleens, or one rat spleen, will provide enough cells for the fusion (see step 7).

Boost primed animal (3 days before fusion)

2. Three days before fusion, boost primed animal(s) (see Basic Protocol 1, step 7).

Prepare reagents and split myeloma cells (1 day before fusion)

3. One day before fusion, prepare all reagents and media, particularly 50% PEG.
4. One day before fusion, split SP2/0-Ag14 myeloma cells (from step 1) into fresh complete DMEM-10/HEPES/pyruvate medium.

   Vigorous growth of the SP2/0-Ag14 cells is generally required for good fusion.

Check myeloma cells and prewarm reagents (day of fusion)

5. Use an inverted microscope to check the SP2/0-Ag14 myeloma cells to make sure they are growing vigorously (refractile and not pyknotic), they are not contaminated (no obvious bacteria or fungi), and there are enough cells for the fusion.

   It is better to postpone the fusion than to perform an ill-advised fusion, since the entire selection and screening effort will take ~3 weeks.

6. Prewarm the following in a 37°C water bath:

   Three 400- and three 600-ml beakers, each containing ~100 ml H_2O
   20 ml sterile complete serum-free DMEM
   5 ml sterile 50% PEG solution.

Harvest spleen and prepare cells

7. Sacrifice boosted animal(s) and aseptically harvest spleen(s).

   Do not use anesthetics for sacrifice. Instead, use cervical dislocation for mouse, or CO_2 asphyxiation for mouse, hamster, or rat to avoid introducing an anesthetic into the blood stream and therefore, into the cultures.

8. Transfer spleen to a sterile 100-mm-diameter petri dish filled with 10 ml sterile complete serum-free DMEM.

   Perform all subsequent steps in a laminar flow hood.

9. Tease spleen into a single-cell suspension by squeezing with angled forceps or by chopping with fine-tipped dissecting scissors. Remove debris and disperse cells further by passage through a fine-mesh metal screen.
10. Transfer spleen cell suspension to a sterile 50-ml conical centrifuge tube and fill with sterile complete serum-free DMEM.

    Do not use protein- or HEPES-containing medium because the PEG will precipitate proteins and HEPES can be toxic to cells during fusion.

11. Centrifuge 5 min in TH-4 rotor at 1500 rpm ($500 \times g$), room temperature, and discard supernatant.
12. Lyse red blood cells (RBC) by resuspending pellet in 5 ml ammonium chloride solution. Let stand 5 min at room temperature.
13. Add 45 ml sterile complete serum-free DMEM, and centrifuge as in step 11.
14. Resuspend pellet in 50 ml sterile complete serum-free DMEM. Centrifuge as in step 11. Repeat DMEM addition and centrifuging once (each repeat is a wash).
15. While spleen cells are being washed, separately harvest the SP2/0-Ag14 myeloma cells (from step 5) by transferring the cells to 50-ml conical centrifuge tubes. Centrifuge as in step 11. Resuspend myeloma cells in DMEM and pool all cells into one 50-ml conical centrifuge tube. Wash myeloma cells three times as in step 14.
16. Separately resuspend the spleen and myeloma cells in 10 ml complete serum-free DMEM. Count cells and assess viability in each cell suspension using a hemacytometer and trypan blue exclusion (*UNIT 1.1*).

    There should be nearly 100% viability of both suspensions.

17. On basis of cell counts (from step 16), calculate the amount of complete DMEM-20/HEPES/pyruvate needed to plate cells at ~16.1×10^6 total cells/ml. Prewarm this amount of complete DMEM-20/HEPES/pyruvate in 37°C water bath. Prepare 96-well flat-bottom plates by labeling them sequentially: one plate is required for each 10 ml of final cell suspension.

Perform cell fusion

18. Mix SP2/0-Ag14 myeloma and spleen cells at a 1:1 ratio in a 50-ml conical centrifuge tube. Fill the tube with complete serum-free DMEM.

    Other cell ratios work. Successful fusions have been performed with a ratio of myeloma/spleen cells as low as 1:20.

19. Centrifuge cell mixture 5 min at $500 \times g$, room temperature.

20. While cells are in the centrifuge, prepare three 37°C double-beaker water baths in the laminar flow hood by placing a 400-ml beaker (from step 6) containing 100 ml of 37°C water into 600-ml beaker containing 75 to 100 ml of 37°C water. Place the tubes of prewarmed 50% PEG solution and complete serum-free DMEM (from step 6) into two of the 37°C water baths in the hood.

21. Aspirate and discard supernatant from the mixed-cell pellet (from step 19).

22. Perform the cell fusion at 37°C by placing the tube containing the mixed-cell pellet in one of the double-beaker water baths in the laminar flow hood.

23. Using a 1-ml pipet, add 1 ml prewarmed 50% PEG to the mixed-cell pellet drop-by-drop over 1 min, stirring the cells with the pipet tip after each drop. Stir for an additional minute.

24. Using a clean pipet, add 1 ml prewarmed complete serum-free DMEM to the cell mixture drop-by-drop over 1 min, stirring after each drop. Repeat once with an additional 1 ml of prewarmed complete serum-free DMEM.

25. With a 10-ml pipet, add 7 ml prewarmed complete serum-free DMEM drop-by-drop over 2 to 3 min.

    Macroscopic clumps of cells should be obvious at this point.

26. Centrifuge 5 min at $500 \times g$, room temperature.

27. While the cells are in the centrifuge, rewarm the beaker water baths to 37°C and place in the hood. Place prewarmed complete DMEM-20/HEPES/pyruvate (from step 17) in the beaker water bath.

28. Discard the supernatant (from step 26). Place tube in the beaker water bath.

29. With a clean 10-ml pipet, forcefully discharge 10 ml prewarmed complete DMEM-20/HEPES/pyruvate to the cell pellet.

30. Repeat step 29 until the total volume of prewarmed complete DMEM-20/HEPES (calculated in step 17) is added. If necessary, allow clumps to settle and disrupt with the pipet tip. Further warming of cell suspension is no longer required.

    If the total volume exceeds 50 ml, gently aspirate and transfer to another sterile container such as a tissue culture flask.

31. Gently aspirate 10 ml of cell suspension with a 10-ml pipet. Add 2 drops (100 to 125 µl) of suspension to each well of a 96-well flat-bottom plate (continue until entire suspension is plated). Incubate overnight in a humidified 37°C, 5% CO_2 incubator.

Vigorous pipetting of the cell suspension should be avoided at this point, as the newly formed hybrids are unstable. Moreover, the vigorous addition of cells to the wells with repeating micropipettor is not advised. Use a pipet aid and hold the 10-ml pipet at a 45° angle with the tip 1 to 2 cm above the well, bracing the pipet with a finger from the opposite hand. To avoid introducing contaminants, do not hold hands above the plate. A steady, even flow of drops from the pipet will allow the most efficient delivery of cell suspension or medium to the wells. Use a fresh pipet to withdraw additional cell suspension.

As an optional step to minimize fibroblast overgrowth, permit the fibroblasts in bulk-fused cell suspension to adhere overnight to tissue culture flasks before seeding the 96-well plates.

Many investigators select their hybridomas under bulk conditions—i.e., they incubate large numbers of cells per well in larger plates or flasks. This makes feeding easier, but allows fast-growing hybridomas to overgrow the others. Since nonproducing hybridomas tend to grow faster, especially in the hamster-mouse fusions, hybridomas are isolated initially in multiple small wells in this protocol. The primary hybridomas tend to be monoclonal. This is especially important when screening procedures are used that require differential reactivities, e.g., to different cell lines by flow cytometry analysis or to different antigen preparations. In those cases, multiple hybridomas per well will obscure the reactivity of the MAb of interest.

Monitor and feed cells

32. After one day of incubation, check wells under an inverted microscope. If seeded with the appropriate number of cells, there should be a nearly confluent monolayer of highly viable cells on the bottom and obvious clumps of cells.

33. Add 2 drops complete DMEM-20/HEPES/pyruvate/HAT to each well with a 10-ml pipet (see step 31). Place in humidified 37°C, 5% CO_2 incubator.

    Use a separate pipet for each microtiter plate and keep the same covers with each plate to ensure that each plate remains a separate unit and to avoid spreading contamination. It cannot be overemphasized that it takes practice and meticulous attention to possible sources of contaminants to keep these plates sterile during the subsequent 2-to 3-week feeding and monitoring schedule.

    If plates become contaminated, discarding them is advised. Alternatively, contamination in one or two wells may be treated by aspirating the contents of the contaminated well with a sterile Pasteur pipet attached to a vacuum flask, rinsing the well with 70% ethanol, and wiping with a sterile cotton swab. Wash twice with ethanol. Finally, blot the well dry with the sterile cotton swab and blot the appropriate area of the cover with a sterile cotton swab soaked in 70% ethanol. Do not open contaminated plates while other plates are in the hood.

34. On days 2, 3, 4, 5, 7, 9, and 11, aspirate half the volume of each well using a sterile, short Pasteur pipet attached to a vacuum flask, holding pipet at a 45° angle and touching tip to surface of supernatant at the point where the liquid meets the opposite wall of the well. Feed the cells by adding 2 drops complete DMEM-20/HEPES/pyruvate/HAT from a 10-ml pipet (see steps 31 and 33) to each well, and return to humidified 37°C, 5% CO_2 incubator.

    Use a separate Pasteur pipet for each plate to minimize the spread of contamination. Since the frequency of successful viable hybridoma formation is $\leq 10^{-5}$, when HAT is added, profound cell death should be apparent at days 2 and 3 and the remaining viable cells should not be readily apparent until they have expanded. By day 7 to 9 for mouse-mouse fusions, day 11 for rat-mouse fusions, and day 14 for hamster-mouse fusions, clusters of hybridoma cells should become visible under the inverted microscope. If profound cell death is not apparent on days 2 and 3, check the medium containing HAT and the parental cell line by incubating an aliquot of the parental myeloma line with the medium containing HAT.

    The feeding schedule is not rigid except for the first 4 days, when it is necessary to remove the toxic products of cell death. Thereafter, feedings will depend on the actual number of

cells deposited in the wells, efficiency of fusion, and appearance and growth of hybridomas. Do not allow medium to become yellow (acidic) for more than a day. Examine plates daily, even if cells are not scheduled to be fed, and feed plates if acidic wells are noted.

35. On day 14, repeat feeding protocol outlined in step 34 except use complete DMEM-20/HEPES/pyruvate/HT to feed cells. Return to 37°C, 5% CO_2 incubator.

    Cells do not require more than one change of complete DMEM-20/HEPES/pyruvate/HT. After this change, the aminopterin (from prior addition of HAT medium) is apparently diluted out enough so that the cells can survive without additional HT.

36. On day 15 and subsequently, feed wells as noted using complete DMEM-20/HEPES/pyruvate without HAT or HT. The hybridomas are ready for screening when most of the wells containing growing cells demonstrate 10% to 25% confluence and when those with denser populations turn yellow within 2 days after feeding (see Support Protocol 1).

    If the screening assay requires a [^{3}H]thymidine incorporation assay, be aware that the large amount of thymidine in complete DMEM-20/HEPES/pyruvate with HAT and HT will serve as a cold-label inhibitor of [^{3}H]thymidine incorporation. At least 3 to 4 changes of complete DMEM-20/HEPES/pyruvate without HT are required to dilute out excess thymidine.

SUPPORT PROTOCOL 1

SCREENING PRIMARY HYBRIDOMA SUPERNATANTS

The vast majority of wells will not contain the desired antibody or may contain nonproducing hybridomas. The purpose of screening is to discover which wells (<1% to 5%) contain hybridomas that secrete the antibody of desired specificity (note that the antibody is not yet monoclonal.) Screening should be performed when most of the growing wells demonstrate 10% to 25% confluence when viewed with an inverted microscope or when some of the denser wells begin to turn yellow within 2 days after feeding. This point may be reached 10 to 14 days after a mouse-mouse or rat-mouse fusion, and 14 to 21 days after a hamster-mouse fusion. Although the most dense wells can be screened first and the less dense wells when they become more dense, this duplicates the effort required and is not recommended. Thus, the wells are fed and 2 days later, aliquots of the supernatants are tested in the screening assay for the presence of the desired antibody.

Additional Materials *(also see Basic Protocol 2)*

Growing hybridomas (Basic Protocol 2)

Additional reagents and equipment for ELISA (*APPENDIX 3*) and indirect immunofluorescence (*UNIT 4.3*)

1. Estimate the number of wells with growing hybridomas using an inverted microscope. Determine whether it will be more efficient to screen all wells or only the wells that contain hybridomas.

2. Allow hybridomas in the viable wells to grow in a humidified 37°C, 5% CO_2 incubator without feeding for ≥2 days.

    This is usually enough time to build a saturating titer of antibody in the culture supernatant.

3. Remove 100 µl from each well to be tested and use in a screening assay, such as an ELISA or indirect immunofluorescence (see Critical Parameters).

    A micropipettor with disposable sterile tips is convenient. Use a new pipet tip with each well. If all wells are screened, a multichannel pipet is convenient for transfer to another 96-well assay plate.

    For each sample, keep track of the plate number and well by its row letter and column number. This is frequently the origin of the MAb's name.

4. After harvesting one entire plate, feed wells with fresh complete DMEM-20/HEPES before harvesting the next plate (Basic Protocol 2, step 33).

ESTABLISHMENT OF HYBRIDOMA LINES

SUPPORT PROTOCOL 2

Once candidate hybridomas are identified (see Support Protocol 1), they are expanded and fed, then the cells are both frozen and cloned by limiting dilution (see Support Protocol 3). This additional work ensures that viable antibody-producing hybridomas are available after the screening process. Unfortunately, this must be done for all candidate lines before the monoclonal antibody specificity is fully characterized. To limit the amount of extra work involved, select the twenty best candidate wells. All twenty should be frozen and limiting-dilution plates set up while the supernatants are checked.

Additional Materials *(also see Basic Protocol 2)*

Growing hybridomas (Basic Protocol 2)
Cloning/expansion medium (Support Protocol 4)
24-well microtiter plates

Additional reagents and equipment for cryopreservation of cells (*UNIT 1.1*)

1. When the growing hybridoma is 25% to 50% confluent in the 96-well plate (master well), expand the candidate hybridoma to a well in a 24-well plate by resuspending the cells in the master well with a sterile pipet (a micropipettor set at 100 µl is convenient). Transfer the entire contents of the master well to a well in the 24-well plate.

   Sufficient numbers of cells will remain to serve as backup to the expanded cells.

   If a small number of cells are transferred, they may not expand. However, if there are fibroblasts in the master well, the hybridoma cells should be transferred as soon as possible to avoid fibroblast overgrowth in the well (if necessary, transfer to another 96-well plate). When transferring cells from a well with fibroblasts, be careful not to scrape the bottom of the well (which will loosen the fibroblasts).

2. Feed cells in the master well with 3 drops complete DMEM-20/HEPES/pyruvate from a 1-ml pipet (Basic Protocol 2, step 33). Incubate cells in humidified 37°C, 5% CO_2 incubator.

3. Use a fresh pipet and feed cells in 24-well plate with 1 to 1.5 ml cloning/expansion medium. Incubate 2 to 3 days in humidified 37°C, 5% CO_2 incubator.

   Remember that there are only two wells in the world that contain this hybridoma and that each is a backup to the other in case of contamination or other undesirable circumstance. Therefore, once established, each is treated as an individual entity and fed with medium from different bottles and different pipets.

4. When cells in the 24-well plate are 25% to 50% confluent (2 to 3 days), they are ready to be used for cloning by limiting dilution (see Support Protocol 3).

   Repeat steps 1 to 3 as necessary when cells are 25% to 50% confluent in master well.

5. After taking cells for limiting-dilution cloning, transfer remainder of cells in the 24-well plate to a 4-ml sterile capped tube and feed the cells in the 24-well plate with complete DMEM-20/HEPES/pyruvate.

6. Centrifuge the cells in the 4-ml tube 5 min at 500 × *g*, room temperature. Keep supernatant for further characterization of the antibody and as a control, and freeze cell pellet (*UNIT 1.1*).

   The supernatant usually contains sufficient antibody that could be reassayed in the original screening test and/or in any confirmatory test. The cell line is not established until stable

clones can be identified, frozen, and successfully thawed. If the limiting-dilution plate does not yield an antibody-producing line, the original cells from the 24-well plate can be thawed, seeded back into a 24-well plate, grown overnight, used to seed another series of limiting-dilution plates, and refrozen for safekeeping.

SUPPORT PROTOCOL 3

CLONING BY LIMITING DILUTION

Monoclonal antibodies are secreted by the progeny of a single cell that can produce only a single antibody (assuming a nonsecretory fusion-partner line). Cloning is required to ensure that the problems of polyspecificity are avoided and the risk of overgrowth by nonproducing cells is minimized. Although cloning can also be performed by the soft-agar technique, clones derived by this technique must be adapted to liquid culture before the supernatants can be tested (Coffino et al., 1972). Since cloning by limiting dilution allows direct testing of the supernatants, this method is much more advantageous (hence, the soft-agar technique will not be discussed here).

Additional Materials *(also see Basic Protocol 2)*

Candidate hybridoma line (Support Protocol 2)
Cloning/expansion medium (Support Protocol 4)

1. Resuspend the candidate hybridoma line (Support Protocol 2, step 4) in their wells and count and assess viability of a small aliquot (50 µl) of cells using a hemacytometer and Trypan blue (*UNIT 1.1*).
2. Prepare 10 ml of cells at 50 viable cells/ml and 10 ml at 5 viable cells/ml in cloning/expansion medium.

   The degree of dilution is usually very large and thus serial dilution may be needed.
3. Seed a 96-well plate with the cell suspensions at 200 µl/well. Incubate 7 to 10 days in a humidified 37°C, 5% CO_2 incubator.

   There will be enough to seed half of the wells in the plate with each dilution at final concentrations of 10 cells/well and 1 cell/well.
4. Determine which dilution was optimal for monoclonal growth by determining the number of wells that show growing hybridomas.

   Usually hybridoma growth is obvious by macroscopic visualization of the well bottoms. A microplate reading mirror (Flow Laboratories or Dynatech) is useful to avoid the necessity of holding the plate above one's head.

   Poisson statistics indicate that if <22% of the wells have growing cells (the proportion expected if the cells were seeded at 0.3 per well and had a cloning efficiency of 100%), then 88% of these wells have only one clone. However, primary hybridomas generally have a poor "plating efficiency" and thus, more cells need to be seeded in each well to derive a reasonable number of growing clones. Use the wells seeded with 1 cell/well if there are "growing" wells and, if necessary, the wells seeded with 10 cells/well. The frequency of antibody-producing clones is dependent on the time after the initial testing that the cloning plates were set up and the MAb species. Generally, the longer the wait before plating the primary hybridomas and the more phylogenetically distant from the mouse the source of spleen cells, the less frequent the positive clones.
5. Inspect wells for monoclonality with an inverted microscope before feeding cells, looking for tight single clusters of cells as evidence of monoclonal growth. Polyclonal growth is evidenced by more than one cluster of cells; if possible, do not use these wells.
6. Use the screening assay that was used in the initial identification of the master well (see Critical Parameters) to test the monoclonal wells for desired antibody activity on day 7 to 14. Use an aliquot of the original hybridoma supernatant (Support Protocol 2, step 6) as a positive control.

Mouse-mouse hybridomas could be checked as early as 7 days after plating, whereas hamster-mouse hybridomas may require up to 14 days for growth. If any of the wells begin to turn yellow, they should be tested. Since the wells were not fed, any well with growing cells should have readily detectable antibody if the cells produce the desired MAb. Wait 2 days before testing if the wells were fed.

7. When the desired clone is identified, expand and freeze the well as for the primary hybridoma (Support Protocol 2).
8. Reclone one of the positive hybridoma clones as in steps 1 to 3; seed two new 96-well plates at 0.3 cells/well (60 viable cells in 40 ml cloning medium).
9. Repeat steps 4 to 6.
10. Expand and freeze the recloned hybridoma (Support Protocol 2).
11. Wean the recloned cells to complete DMEM-10/HEPES/pyruvate by splitting the cells 1:2 every day (for 3 days) with complete DMEM-10/HEPES/pyruvate. At this point, the desired hybridoma should be stable as a cell line.

    Freeze multiple vials on different days with different aliquots of freezing medium (UNIT 1.1). Thaw representative vials and check cells for growth and supernatant for MAb activity in appropriate assay. The hybridoma can then be used for ascites production and for large-scale production of hybridoma supernatants. The isotype of the MAb can now be determined.

    Even recloned hybridomas have an unstable phenotype, especially some hamster-mouse hybridomas, which may require additional recloning. Prolonged cultures in vitro may result in loss of MAb production. To minimize this problem, frozen aliquots of cells known to produce the MAb are necessary and should be verified as sources of viable cells.

    An occasional cloned hybridoma will not tolerate complete DMEM-10/HEPES/pyruvate and will require higher concentrations of FBS. It may be necessary to wean cells first to DMEM-15 before weaning to DMEM-10. Mycoplasma contamination should be considered (see UNIT 1.5).

PREPARATION OF CLONING/EXPANSION MEDIUM

SUPPORT PROTOCOL 4

Many investigators add feeder cells (i.e., peritoneal washout cells, splenocytes, or thymocytes) to produce conditioned media that seem to enhance hybridoma growth and cloning. The direct addition of irradiated, freshly isolated cells to wells, however, sometimes results in contamination. Therefore, cell-free, sterile-filtered supernatants of all suspensions are recommended to enhance hybridoma cloning efficiencies.

The following procedure describes the preparation of a cell-free thymocyte-conditioned medium from mice. After sacrificing several mice and removing each thymus, a single cell suspension is prepared and grown for several days. The supernatant is harvested, filter sterilized, and stored at −20°C.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

1. Sacrifice 5 or 6 mice, avoiding use of anesthetics (see Support Protocol 2, step 7, annotation).

   Mice (e.g, BALB/c) should be 4 to 6 weeks old. Obtain pathogen-free mice from a reliable supplier that screens for mycoplasma contamination.

2. Aseptically remove the thymus. Tease thymus into a single-cell suspension (Basic Protocol 2, steps 8 to 11). Resuspend cells in 20 ml of complete DMEM-20/HEPES/pyruvate.
3. Add 10 ml thymus cells to a 75-cm^2 flask. Add complete DMEM-20/HEPES/pyruvate

medium to final amount of ~20 ml medium per thymus (maximum 60 ml cell suspension/flask). Incubate flask 4 to 5 days in upright position in a humidified 37°C, 5% CO_2 incubator.

4. Transfer suspension to a sterile 50-ml conical centrifuge tube. Centrifuge suspension 5 min at 1000 × *g*, room temperature, and harvest supernatant.
5. Filter sterilize supernatant through 0.45-µm filter. Freeze at –20°C in 10-ml aliquots.
6. Thaw and use at 10% to 20% final concentration in desired medium.

An alternative to feeder cells and thymocyte-conditioned medium is the use of a source of IL-6 (plasmacytoma growth factor), such as liposaccharide-stimulated P388D$_1$ supernatant.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ammonium chloride solution

0.02 M Tris·Cl, pH 7.2
0.14 M NH_4Cl
Store up to 6 months at 4°C

Complete DMEM-20/HEPES/pyruvate/HAT (or HT)

To complete DMEM-20 medium (*APPENDIX 2A*) containing 10 mM HEPES and 1 mM pyruvate, add 100× HAT (hypoxanthine/aminopterin/thymidine) or 100× HT supplement (*APPENDIX 2B*) to 1× final. Store at 4°C for up to 1 month.

100× HAT and 100× HT supplement are available commercially (e.g., Sigma).

50% polyethylene glycol (PEG)

Autoclave 10 g PEG 4000 (Merck or ATCC) in a Wheaton glass bottle and cool. Before it solidifies (at ~55°C), add 10 ml complete serum-free DMEM. This makes enough for ~20 fusions. The solution may be kept at room temperature for several months; it will become alkaline but this does not affect its performance.

Be sure not to use protein-containing medium because PEG precipitates proteins.

COMMENTARY

Background Information

Since the original description of a technique to produce monoclonal antibodies (MAbs) of defined specificity (Köhler and Milstein, 1975), MAbs have proven to be powerful tools to analyze a myriad of biological systems. As a testimony to the broad utility of this technique, the original authors noted above received the Nobel Prize for medicine in 1984. Furthermore, a search of Medline (computerized medical literature data) for 1975 to 1999 shows that more than 90,000 citations referred to MAb.

To produce MAb, a suitable host is immunized with an antigen and antibody-secreting B cells are immortalized by the fusion of the host immune B cells with a nonsecretory, drug-marked myeloma cell line. Since the unfused normal B cells cannot survive long in an in vitro culture, they derive immortality by fusion to a partner tumor cell line. The tumor line is resistant to the purine analogue 6-thioguanine because of deficiency of hypoxanthine-guanine phosphoribosyl transferase (HGPRT). This deficiency results in lethal sensitivity to aminopterin, which blocks de novo synthesis of purines. The normal B cell is not sensitive to aminopterin when hypoxanthine and thymidine are supplied, since it possesses the salvage pathways utilizing HGPRT which are necessary for survival. Thus, only hybridomas (normal B cells fused to tumor cells) will survive selection in HAT. If a hybridoma that produces the antibody of interest is identified and subjected to a cloning procedure that results in monoclonality (i.e., derivation of progeny cells

from a single cell), a MAb of desired specificity is produced.

Although monoclonal antibodies are powerful tools, it cannot be overemphasized that a major commitment is necessary to identify a MAb of interest. The work is tedious and labor intensive. Moreover, in some cases, specific polyclonal antisera, which are generally easier to produce, may be as suitable as—and in certain instances superior to—MAb. For example, specific antisera against defined synthetic peptides that will immunoprecipitate cell-surface antigens of interest can be made. Such antisera frequently will be useful in immunoblots whereas MAb, unless directly screened for such a purpose, may not recognize determinants on denatured antigens. Nevertheless, if the desired MAb is produced, this reagent has a wide variety of uses, particularly for the characterization of novel molecules, and as a specific antagonist or agonist of ligand-receptor interactions. Moreover, large quantities of the MAb can be readily purified.

There is a large body of literature on MAb production. More specific elaboration of the methods described here are discussed by Goding (1996) and Harlow and Lane (1999). Furthermore, many reports describing refinements of the basic technique are frequently published in the *Journal of Immunological Methods*. With general basic skills in animal handling, tissue culture, and screening assays, the novice should be able to produce MAb using the protocols in this unit. The major obstacle, as with any screening effort, is identification of the MAb of desired specificity. Because the technique produces many MAb-secreting hybridomas, the temptation exists to keep all or selected hybridomas even though they are not producing the MAb of initial interest. A large number of hybridomas secreting antibodies to unique antigens may be isolated, but the extra effort required is considerable. Nevertheless, it is a strategy that may prove useful while the attempt to identify the desired MAb proceeds. Many antibodies described in the literature are such by-products.

Critical Parameters

There are several major factors, other than technical, that should be considered before any MAb production project is begun.

While several fusion partners are available, the SP2/0-Ag14 myeloma is a good general-purpose cell line. The best sources of the cell line are ATCC or a laboratory actively producing hybridomas. Some sublines do not fuse well, perhaps due to some genetic variation or to undetected contaminants such as mycoplasma.

The SP2/0-Ag14 cells should grow in suspension with minimal adherence to the tissue culture flask. The cells should not be overgrown and the medium should not become acidic (yellow). Healthy cells will be refractile and none of the cells should be pyknotic when viewed with an inverted microscope. In general, the cells should be diluted (split) into fresh medium (≥1:5 if the cells will be used on the following day) when the cells in an undisturbed flask form a monolayer on the bottom of the flask ($1\text{-}2 \times 10^6$ cells/ml). If the cells do not appear healthy even when grown at lower densities, mycoplasma contamination should be suspected.

Freeze multiple large aliquots of cells (*UNIT 1.1*) so that only a few days of expansion after thawing will be necessary for future fusions. If planned correctly, a primed animal can be boosted, cells thawed on the same day, and a fusion performed 3 days later.

Choice of animal for immunization

The protocol on immunization (Basic Protocol 1) outlines the production of MAb by in vivo immunization and concentrates on the use of rodents for immunization. Specialized work may require the use of splenic injections, in vitro immunizations, or human monoclonals; these techniques are much more difficult to implement successfully and are not recommended for the novice. Other protocols designed to eliminate unwanted MAb against particularly immunogenic epitopes, involve the use of cytotoxic agents immediately after the initial immunization with the unwanted antigens and should be considered only after some experience has been gained (Sharpe et al., 1985).

Four animal species (mouse, rat, hamster, and rabbit) can be used for MAb production. The spleen cells from a given species must be able to produce stable MAb-producing hybridomas with a rodent myeloma cell line. Although several rat and mouse tumor cell partners exist and all have been successfully used, the SP2/0-Ag14 mouse cell line from ATCC is recommended because it is a drug-marked, nonsecretory myeloma that does not constitutively produce either light or heavy chains. Hybridomas derived from fusion to SP2/0-Ag14 will not make chimeric MAb. This cell line also forms stable hybridomas with mouse, rat, and hamster B cells. Rabbit MAb have been described (Raybould and Takahashi, 1988) but little collective experience has accumulated.

It is technically more difficult to produce stable MAb-producing hybridomas from animals that are phylogenetically distant from the mouse. First attempts at producing MAb should use either the mouse or rat. Of the two, the mouse is the best choice for most xenogeneic antigens, such as human antigens, because many more antibodies have been produced in the mouse. Isotype-matched MAbs to defined antigens are available commercially, and can be used as controls in the assays of interest. Moreover, the mouse is easier to handle, anti-Ig reagents specific for each mouse Ig isotype are more commonly available, and generally mouse MAb are easier than rat MAb to purify. If a mouse is to be immunized, the best choice is a BALB/c mouse, because the hybridomas resulting from fusion to SP2/0-Ag14 will be entirely of BALB/c origin and thus should grow in a BALB/c host for ascites fluid production. Moreover, BALB/c spleens are generally larger than spleens from other mouse strains.

In contrast, immunization of mice would not be appropriate for most mouse antigens unless an allotypic difference is known. Fortunately, the rat is a reasonable choice for many mouse antigens because rat MAb will frequently recognize framework determinants on mouse proteins. Most of the commonly available rat strains can be used, although this laboratory usually employs Lewis rats. If rat MAb are produced, the mouse anti-rat κ MAb, MAR 18.5 (ATCC) is useful, since MAR 18.5 recognizes rat κ light chains (present in 90% of rat MAbs) and binds protein A, and thus is easy to purify. Moreover, the hybridoma produces high titers of MAb in culture supernatants, making MAR 18.5 useful in detection and purification of rat MAbs.

Although there are mouse MAb that recognize many major, functionally important human cell-surface and soluble antigens, it has proven difficult, despite considerable effort, to produce rat MAb to several of the homologous mouse antigens. It is possible that these mouse molecules are not antigenic in rat. Some of these mouse molecules may be more antigenic in hamsters, presumably due to the greater phylogenetic distance involved (Schreiber et al., 1985). However, hamster MAb are more difficult to produce because of fibroblast overgrowth and instability of hybridomas. Hamsters are therefore not ideal choices for the novice until experience with several fusions is acquired. The Armenian hamster strain is the best suited for hybridoma production because the hybridomas are more stable and fibroblast overgrowth is less than with other available hamster strains. Unfortunately some Armenian hamster MAb are nonreactive with standard, commercially available anti-hamster immunoglobulin antibodies. However, many hamster MAb are reactive with protein A and/or with the mouse anti-rat κ MAb, RG7/7.6, which cross-reacts with hamster κ chains (Sanchez-Madrid et al., 1983). Finally, there are few serologic reagents available for hamster pathogens and thus it is wise to quarantine hamsters—and the hybridomas derived from them—in case there are occult infections that could be spread to other rodents (Donovan and Brown, 1995).

The sex of the host animal does not appear to be important. It is usually advisable to immunize young adult animals because the immunization schedule may be prolonged. Fusions of spleens from older hamsters (>6 months old) tend to have more fibroblasts.

Antigen preparation and immunization

Many types of antigen preparations have been used successfully including whole cells, partially purified lymphokines and cytokines, solubilized cell membranes and protein bands isolated from SDS-polyacrylamide gels (*UNIT 6.1*). The nature of the antigen preparation to be used is dependent on several factors, particularly the ease in preparing the antigen, the screening assay, and the desired specificity and property of the MAb.

Although it is desirable to immunize with a purified antigen to increase the frequency of hybridomas secreting the desired antibodies, in contrast to polyclonal antisera production, this is not a major requirement.

It is important to note that MAb are quite specific. It is possible to immunize with impure antigens or with multiple antigens, and with a highly specific screening assay, pick the MAb that identifies a specific antigen. In many instances, this is exactly the protocol used. For example, animals are usually immunized with whole cells to derive MAb that recognize a specific cell-surface antigen. The major advantage to whole-cell immunization is that the proteins will be in their native conformation and thus, the MAb produced can recognize these antigens in their native form. The major disadvantage to whole-cell immunization is the production of MAb to many other antigens, particularly those that have been previously produced (since they tend to be the most commonly made); immunization of rats with whole mouse T cell suspensions will produce ≥25% anti-Thy-1 MAb (W. M. Y., unpub. observ.).

Nevertheless, collective experience with whole-cell immunizations suggest that although the antigen preparation may be impure, it is important to consider the nature of the antigen relative to its native form.

Because protein purification frequently denatures molecules and synthetic peptides usually do not achieve native conformations, immunization with gel-purified proteins and synthetic peptides generally has resulted in the production of MAb that recognize the antigen in its denatured form. While such MAb may be useful for immunoprecipitation and immunoblot studies, often they are not useful for flow cytometry analysis of cell-surface antigens or functional assays that require binding of the antigen in its native conformation.

There are many immunization protocols used to produce MAb. The major requirements appear to be a primary immunization with an adjuvant and fusion 3 to 4 days after the boost. However, there are notable exceptions. For example, a single primary immunization and fusion 4 to 5 days later have been successfully used to produce MAb against cell-surface antigens (Logdberg et al., 1985). It is generally agreed that a successful fusion requires the presence of activated B cells.

Most injections can be given intraperitoneally with good results. Many investigators prefer to boost intravenously with antigen without adjuvant. While this can be done via tail vein in the mouse, this vein is inaccessible in the rat or Armenian hamster and intravenous injections are generally not used in these animals. *Be aware that intravenous injections may occasionally result in fatal systemic reactions.*

Many investigators screen their immunized animals for serum antibody titers before a final boost and fusion. This depends on the purity of the antigen and an assay that is not influenced by serum. However, many MAb have been successfully produced against cell-surface antigens without screening the sera before fusion even if whole cells are used to immunize.

Screening assays

The cell-fusion protocol outlined in this unit should yield hybridomas in ~50% of the wells. The purpose of the screening assay (Support Protocol 1) is to exclude all hybridomas that are unlikely to produce the MAb of interest and yet include all likely candidates. In that regard, a reliable assay that will detect a few false positives but no false negatives will help decrease the number of hybridomas from several hundred to ~20. Depending on the difficulty of the assay and the availability of the antigen, all wells can be screened for reactivity or—especially if most wells do not contain hybridomas—the wells can be screened first for visual evidence of growing hybridomas. Visual screening can be problematic since it requires inspection with an inverted microscope and a significant amount of bookkeeping to record which wells contain hybridomas (and which do not). More troublesome is the possibility of identifying a candidate hybridoma only to clone and save the wrong master well due to a bookkeeping error.

Screening assays should be perfected before the fusion is done. The assay should be rapid, with results available within 1 to 2 days, reliable, sensitive, and simple to perform in large numbers (hundreds to thousands of wells). In the protocol described here, the assay must be performed with 100-µl volumes. Alternatively, the supernatants from several wells could be pooled to screen fewer samples. One clever screening approach is to pool 50 µl from each well in each horizontal row and then separately pool 50 µl from wells in each vertical column of a single plate. The well containing the desired hybridoma can be pinpointed by the positive row and column. Because each supernatant is tested twice, the percentage of false positives is diminished. This technique should not be used for low-sensitivity assays as the supernatants are diluted significantly. Many different screening assays and techniques have been described. ELISA (*APPENDIX 3*) and radioimmunoassay (RIA; *APPENDIX 3*) have been popular because of the above considerations.

Because MAb are exquisitely specific, those which recognize the same antigen may bind to slightly different epitopes and thus have different functional properties. For example, if a MAb to a cell-surface antigen that inhibits ligand-receptor interaction is required, flow cytometry analysis may not be the best choice for the initial screening assay because a MAb that binds well by flow cytometry analysis may not be functionally active and vice versa. However, if the desired property of the MAb could be improved by a change of the heavy chain, it is possible to isolate isotype-switch variants that may improve the usefulness of a particular MAb. Such studies have been performed with isotype-switch variants of anti-CD3 MAb (van Lier et al., 1987). Nevertheless, the ideal screening assay should identify MAb with the desired property, not just the desired specificity.

Troubleshooting

The production of MAb is a prolonged procedure. Success requires the optimization of several steps. The antigen preparation and immunization protocol must be adequate; this can be checked by serum titers after immunization. If no hybridomas are produced, then the immunization protocol may not have produced activated B cells, an unlikely situation if an adjuvant was used. Alternatively, hybridoma formation and growth may be inadequate, particularly if the cells (spleen or fusion partner) were contaminated with mycoplasma or if the lot of fetal bovine serum (FBS) does not support hybridoma growth. Obtain the fusion partner from a reliable source, either a lab that is successfully producing hybridomas or from ATCC. Freeze aliquots of these cells as soon as possible. Obtain animals from specific pathogen-free suppliers and cage them in uncontaminated rooms. The FBS lot can be tested by assaying the cloning efficiency of stable hybridoma lines and using a lot that supports high-efficiency cloning.

If viable hybridomas are produced at the anticipated level but the desired MAb is not found, assay the master wells for other antibodies that should react with the immunogen. For example, if whole cells were used as immunogens and the original assay was a functional one (e.g., inhibition of proliferation), several wells should be screened for antibodies that recognize cell-surface antigens by flow cytometry; under these conditions, 25% to 50% of growing wells will produce antibodies that recognize cell-surface antigens. This result would prove that MAb were produced but that the desired specificity was not found. Unfortunately, this is a typical result and the source of the major commitment in time and labor that MAb production requires. The solution to the problem is to perform more fusions and screening. It is useful to consider alternatives to the immunization, choice of animals, and screening procedure.

During the cloning procedures, there are several problems that may be encountered. If none of the cloned hybridomas secrete the desired MAb, either the hybridoma was not producing the MAb initially or the clones have lost the ability to produce the MAb. An aliquot of supernatant from an expanded master well can be tested in confirmatory assays. If none of the clones produce the MAb of interest, the frozen master-well cells should be carefully thawed, reseeded in multiple cloning plates, and then refrozen. Beware that mycoplasma contamination will affect cloning efficiency adversely.

Anticipated Results

With the cell-fusion protocol outlined in this unit (Basic Protocol 2), hybridoma growth should be apparent on the days mentioned and ≥50% of the master wells will contain hybridomas. Depending on the purity of the antigen used and the immunization protocol, ≤1% to 5% of the wells will contain the desired hybridoma. If the screening assay demonstrates many positive wells, it is likely that these are false positives.

Cloning by limiting dilution of the primary hybridomas (Support Protocol 3) should yield ≥10 to 50 "growing" wells/plate when seeded as described. The second cloning under more stringent conditions should yield ≥10 wells when seeded at 0.3 cells/well. Remember that the cloning efficiency of the primary hybridomas is relatively poor. If no viable clones are derived, seed additional wells at higher density and/or use a source of IL-6 (plasmacytoma growth factor; Nordan and Potter, 1986; Bazin and Lemieux, 1989).

Time Considerations

The initial immunization to the final cloning of the desired MAb requires ≥2 to 3 months if the MAb is produced and identified in the first fusion. Usually, several fusions are required and thus, a fusion every 3 weeks may be necessary. During much of this time, especially during the 3 weeks after fusion, daily or every-other-day tasks are required. An entire day's work is required when the actual cell fusion and screening assays are performed. Feedings require 5 to 10 min/plate.

Production of Polyclonal Antisera

Production of good antisera depends in large part upon the quality, purity, and amount of available antigen as well as on the specificity and sensitivity of the assay. For protein antigens, if possible, the material should be biochemically homogeneous and, depending on the intended use, should be in either a native or denatured conformation. Be aware that minor contaminants are often (unfortunately) more antigenic than the immunogen of interest, and antisera resulting from immunization may have more activity against the contaminants than against the protein of interest. Antisera to be used for screening bacterial expression cDNA libraries or for immunoblots are best made against denatured protein, whereas those to be used for screening cDNAs expressed in eukaryotic transfection systems or for immunoprecipitation of native-cell-synthesized structures might best be made against native protein.

Although the advances offered by the development of monoclonal antibody techniques have revolutionized the specificity, uniformity, and quantity of antibodies, there remain many circumstances in which polyclonal antibodies are more desirable than monoclonal antibodies. Production of polyclonal antisera takes less time and effort than production of monoclonal antibodies, requires relatively simple and readily available equipment, and produces reagents that can be used for immunoprecipitation, immunoblotting, and enzyme-linked immunosorbent assays (ELISAs; *APPENDIX 3*). The protocols describe the production of polyclonal antisera specific for protein antigens in rabbits, rats, mice, and hamsters using complete Freund's adjuvant (CFA; see Basic Protocol) or other adjuvants (see Alternate Protocol). In addition, the unit presents a method for preparing serum from blood (see Support Protocol). Polyclonal antipeptide antisera can be produced by substituting carrier-conjugated peptides for the purified protein antigens.

Choice of animal for the production of antibodies depends upon the amount of antiserum desired, the evolutionary distance between the species from which the protein of interest has been derived and the species of the animal to be immunized, and prior experience with the immunogens. Rabbits are the usual animal of choice because they are genetically divergent from the human and mouse sources of the proteins most often studied. Rabbits, depending on their size, provide as much as 50 ml of serum from each bleed without significant harmful effects. For smaller-scale experiments, or for those that rely on precisely defined antibody specificities, inbred mouse strains may be the system of choice. Because mice are smaller, the volume of antigen suspension used for immunization is significantly less and the amount of serum that can be obtained from a single bleed does not exceed 0.5 ml. Rats and hamsters may be used when larger amounts of serum are needed, or when the greater evolutionary distance is advantageous. With repeated bleeding, as much as 5 ml of serum can be obtained from these species. Additional discussion of the choice of species for the production of monoclonal antibodies is given in *UNIT 16.1*.

The choice of adjuvant for in vivo animal use has become problematic in recent years. Freund's adjuvant has been reliably and widely used for over fifty years (Freund et al., 1937). However, there is a degree of distress and discomfort to the animal associated with its use which requires that the responsible investigator explore alternatives (McWilliam and Niemi, 1988). Most studies that have compared available alternatives to Freund's adjuvant have indicated that Freund's adjuvant gives antibody titers that are far superior to the commonly used commercially available adjuvants (Johnston et al., 1991; Deeb et al., 1992; Smith et al., 1992). However, in some instances TiterMax (Bennett et al., 1992) and Ribi Adjuvant Systems (Mallon et al., 1991) have performed as well as Freund's adjuvant. The use of these adjuvant systems as alternatives to Freund's adjuvant is described in the Alternate Protocol.

Current Protocols in Cell Biology (1999) 16.2.1-16.2.8

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

BASIC PROTOCOL

IMMUNIZATION TO PRODUCE POLYCLONAL ANTIBODIES USING FREUND'S ADJUVANT

In the presence of adjuvant, the protein antigen is injected intramuscularly, intradermally, or subcutaneously into an animal of the chosen species. Booster immunizations are started 4 to 8 weeks after the priming immunization and continued at 2- to 3-week intervals. Prior to the priming immunization, following the primary and each booster immunization, the animal is bled and serum prepared from whole blood (see Support Protocol).

Factors important in preparing specific high-titer antisera, procedures for modifying protein antigens to enhance their immunogenicity, and choice of host animal are discussed in the Commentary. Protocols for immunization prior to production of monoclonal antibodies (*UNIT 16.1*) should be reviewed for these purposes.

Materials

Rabbit, rat, mouse, or hamster of appropriate strain
Complete Freund's adjuvant (CFA; Sigma)
1 to 2 mg/ml purified protein antigen in PBS (*APPENDIX 2A*)
Incomplete Freund's adjuvant (IFA; Sigma)

50-ml disposable polypropylene centrifuge tubes
3-ml glass syringes with 19-, 21-, and 22-G needles
Double-ended locking hub connector (Luer-Lok, Becton Dickinson) *or* plastic 3-way stopcock

CAUTION: CFA is an extremely potent inflammatory agent, particularly if introduced intradermally or into the eyes and may cause profound sloughing of skin or loss of sight. Self-injection can cause a positive TB test and lead to a granulomatous reaction. Use gloves and protective eyewear when handling CFA.

1. Bleed the animal prior to immunization and collect blood sample in a 50-ml centrifuge tube. Prepare serum from blood and assay and store (see Support Protocol).

   This preimmune bleed is critical as a control to ensure that the antibody activity detected in later bleeds is due to the immunization.

2. Shake CFA to disperse insoluble *Mycobacterium tuberculosis* bacilli. Add 2 ml CFA to 2 ml of 0.25 to 0.5 mg/ml purified protein antigen in PBS at 4°C.

   These volumes produce immunogen sufficient to immunize 4 rabbits or up to 80 mice. Do not use Tris-based buffers for generating the emulsion.

   An effective and simple method for preparing purified protein antigen is by preparative SDS-PAGE (UNIT 6.1). If a standard-size 1.5-mm slab gel is used with a large-toothed comb, as much as 2 mg of a homogeneous protein can be loaded across the entire gel. Following electrophoresis, an edge can be sliced off with a razor blade, fixed and stained, and used to identify the region containing the protein band. The gel slice containing the protein may then be directly added to several milliliters of PBS (APPENDIX 2A) and emulsified as described below with an equal volume of CFA. The acrylamide serves as an additional component for the protein depot provided by the adjuvant.

3. Draw up the CFA/antigen mixture into a 3-ml glass syringe with a 19-G needle. Remove needle, expel as much air as possible, and attach syringe to the double-ended locking hub connector or the plastic 3-way stopcock (see Fig. 16.2.1). Attach an empty 3-ml glass syringe at the other end and force the mixture back and forth from

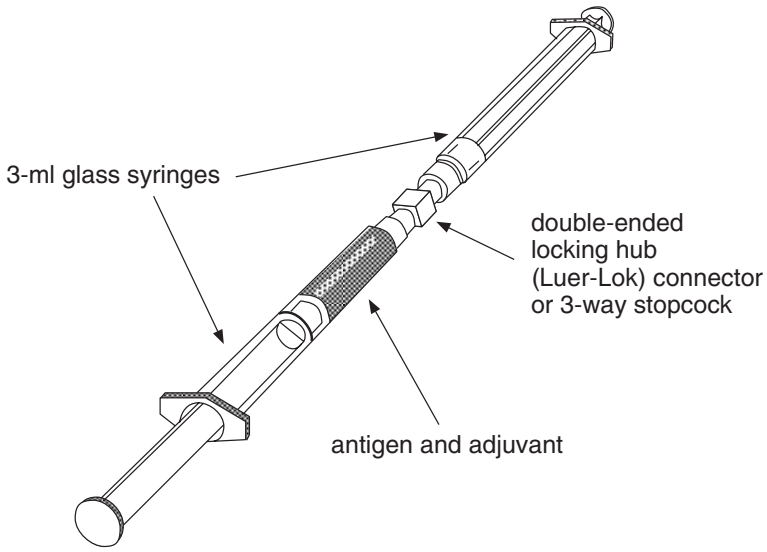

Figure 16.2.1 Double-syringe device for preparation of antigen-adjuvant emulsions.

one syringe to the other repeatedly. When the mixture is homogeneous and white, disconnect the connector or stopcock, attach a 21-G needle, and test whether the emulsion is stable by extruding a small drop onto the surface of 50 ml cold water in a 100-ml beaker. A good oil-in-water emulsion should hold together as a droplet on the surface of the water. If the drop disperses, mix the antigen using the hub-connected syringes until it forms an emulsion.

Heat will be generated by this procedure. Chill on a bed of ice from time to time to keep the mixture as close to 4°C as possible.

4. Transfer all of the adjuvant-antigen emulsion to one syringe and remove the connector or stopcock. Attach a 22-G needle to the syringe and remove air bubbles.
5. Restrain the animal and inject the adjuvant/antigen emulsion into multiple intramuscular (i.m.), intradermal (i.d.), or subcutaneous (s.c.) sites.

   For intradermal immunizations, use no more than 50 μl per site. For subcutaneous immunizations, use 100 μl per site. For intracellular inoculation of rabbits, use 300 μl in three sites in one leg muscle or 500 μl in each lumbar muscle.

   Discard the unused immunogen. For extremely valuable antigens, the emulsion may be stored at 4°C for several weeks and reemulsified before use. However, denaturation of protein antigens may take place under these conditions. For immunization of small rodents (e.g., mice), it is often better to carry out injections intraperitoneally (i.p.).

6. Bleed the animal 10 to 14 days following the priming immunization and collect blood sample. Prepare serum from blood (see Support Protocol).
7. Prepare antigen for booster immunizations, following steps 2 to 4. When CFA is the primary adjuvant, use IFA as the adjuvant for all subsequent immunizations.
8. Administer the first booster immunization 4 to 8 weeks after the priming immunization, bleed the animal 10 to 14 days later, and collect blood sample. Prepare serum from blood (see Support Protocol).

   Some investigators will administer the first booster immunization as early as 2 weeks after the primary immunization.

9. Administer further booster immunizations at 2- to 3-week intervals. Bleed animal 10 to 14 days after each boost and collect blood sample. Prepare serum from blood (see Support Protocol).

Repeated intradermal immunization should be avoided as it can cause skin ulceration. Following primary intradermal or subcutaneous immunization, it is preferable to boost with intramuscular injections for the rabbit. Some investigators prefer primary intramuscular injections with boosters at other sites.

ALTERNATE PROTOCOL

IMMUNIZATION TO PRODUCE POLYCLONAL ANTISERUM USING OTHER ADJUVANTS

For highly immunogenic antigens the use of Freund's adjuvant can certainly be avoided. For other immunogens it may be necessary to test a number of adjuvant systems. The use of two commercially available adjuvants is described in this protocol.

Additional Materials *(also see Basic Protocol)*

TiterMax #R-1 (CytRx; store <24 months at 4°C) *or* Ribi Adjuvant System (RAS; Ribi ImmunoChem; store at 2° to 8°C and do not freeze)
1-ml plastic syringes

1a. *Using TiterMax:* Emulsify aqueous antigen with TiterMax adjuvant (see Basic Protocol; follow steps 1 through 5, except use 0.5 ml antigen and 0.5-ml vial TiterMax in step 2 and plastic syringe in step 3).

TiterMax contains microparticulate silica coated with block copolymer CRL-8941, sorbitan mono-oleate, and squalene.

Although glass syringes are recommended for Freund's adjuvant emulsions, all-plastic syringes should be used with TiterMax.

Each reconstituted 0.5-ml vial will immunize 20 mice, 10 rabbits, or 1 goat. Unused antigen/adjuvant emulsion can be stored at 4°C, –20°C, or –70°C for as long as the antigen is stable. It may be necessary to re-emulsify before using.

1b. *Using Ribi Adjuvant System:* Warm the vial of RAS 5 to 10 min at 40° to 45°C. Add 2 ml antigen in PBS directly through the rubber stopper using a syringe with a 21-G needle. Vigorously vortex the vial 3 min at room temperature with the cap seal in place. The final volume of adjuvant/antigen is 2 ml containing 2% squalene oil.

Each vial of RAS contains 0.5 mg each of monophosphoryl Lipid A (MPL), synthetic trehalose dicorynomycolate (TDM), and cell wall skeleton (CWS) in 44 µl squalene and Tween 80.

Each reconstituted vial will immunize 10 mice or 2 rabbits or goats. Unused adjuvant/antigen emulsion can be stored several months at 4°C. However, if the entire vial will not be used initially, it is better to reconstitute to 1.0 ml with saline alone, store at 4°C, and mix aliquots 1:1 with antigen in saline as needed.

2. Transfer the antigen emulsion to a 1-ml syringe, attach a 22-G needle to the syringe, and remove air bubbles.

3. Restrain the animal and inject the adjuvant/antigen emulsion.

Rabbits should receive 40 µl TiterMax/antigen emulsion i.m. in each thigh. High antibody titers have been obtained with 30 to 50 µg of antigen per rabbit. Rabbits should be immunized with 1.0 ml RAS containing 50 to 250 µg of antigen in multiple sites: 0.05 ml i.d. at six sites, 0.3 ml i.m. in each thigh and 0.1 ml s.c. in the neck.

4. Bleed the animal and prepare antigen for booster immunization (see Basic Protocol, steps 6 and 7).

Serum antibody responses have been reported to be slower for both RAS and TiterMax than for Freund's adjuvant (Smith et al., 1992).

5. Administer booster immunizations at 4, 8, and 12 weeks. Bleed the animal 10 to 14 days after each booster immunization. Prepare serum from blood (see Support Protocol) and cease immunization when high antigen-specific titers have been achieved.

   Boosting with TiterMax may not be necessary for all antigens. If a second immunization is necessary, use soluble antigen in place of antigen/adjuvant at 4 weeks. If titers are still low after 10 to 14 days, a booster dose of antigen/TiterMax adjuvant can be given immediately. Increasing the amount of antigen may also help.

   Ribi ImmunoChem strongly recommends that booster injections of RAS adjuvant/antigen be repeated no more frequently than every 4 weeks.

PREPARATION OF SERUM FROM BLOOD

SUPPORT PROTOCOL

Each blood sample is allowed to stand 4 hr at room temperature and overnight at 4°C until a clot forms. After removal of the clot and debris, the serum is assayed and stored at –20°C.

Additional Materials *(also see Basic Protocol)*

Blood samples (see Basic Protocol)
Sorvall H-1000B rotor or equivalent

Additional reagents and equipment for immunoblotting (*UNIT 6.2*), immunoprecipitation (*UNIT 7.2*), ELISA (*APPENDIX 3*), or double-immunodiffusion assay in agar (*APPENDIX 3*)

1. Allow blood to stand in the 50-ml centrifuge tube 4 hr at room temperature to allow clot to form, then place overnight at 4°C to allow clot to retract.
2. Gently loosen the clot from the sides of the tube with a wooden applicator stick (do not break up the clot), then remove the clot from tube with the applicator.

   If a clot has not formed, initiate clotting by placing a wooden applicator stick into the tube containing the collected blood, then begin again at step 1.

3. Transfer serum to a 50-ml centrifuge tube. Pellet any remaining blood cells and debris by centrifuging 10 min in H-1000B rotor at 4000 rpm (2700 × *g*), 4°C, and save supernatant.
4. Assay antibody titer by the appropriate method: immunoprecipitation, immunoblotting, ELISA, or double-immunodiffusion assay in agar.
5. Store serum in aliquots in screw-top tubes at –20°C.

   Some sera lose activity on repeated freezing/thawing. Sera can be stored for up to 6 months at 4°C. If storing sera at 4°C for long periods of time, 0.02% sodium azide should be added to prevent bacterial growth.

COMMENTARY

Background Information

The kinetics of development of a specific antibody response upon immunization of a rabbit with antigen are illustrated in Figure 16.2.2. After the primary immunization, naive B cells are stimulated to differentiate into antibody-secreting plasma cells. For most soluble protein antigens, specific antibody begins to appear in the serum 5 to 7 days after the animal is injected. The antibody concentration (titer) continues to rise and peaks around day 12, after which it decreases. Similar kinetics are observed with mice, rats, hamsters, and rabbits.

In addition to differentiating into antibody-forming cells, the antigen-stimulated B cells proliferate to form a large population of mem-

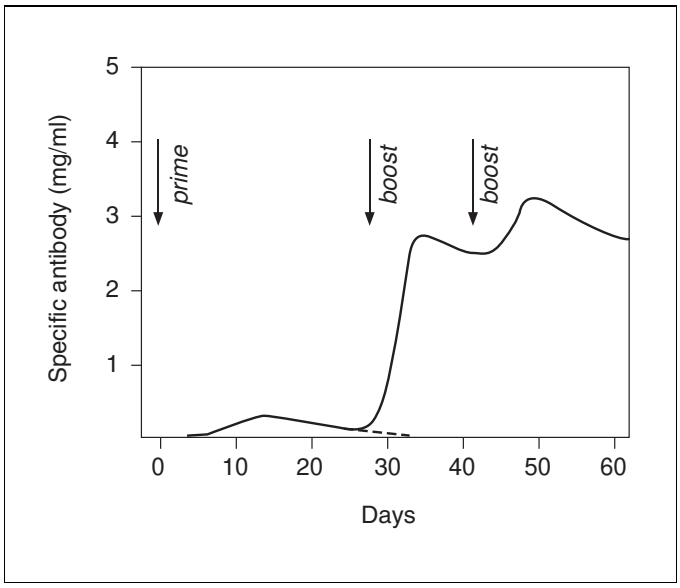

Figure 16.2.2 Kinetics of development of the specific antibody response. Arrows indicate when priming and boosting immunizations were administered. Actual amounts of specific antibody produced will vary considerably depending on immunogenicity of the protein.

ory B cells, which quickly become activated after the booster injection is administered. Thus, the lag period before the appearance of the specific antibody is much shorter after a booster injection than that observed for the initial immunization. In addition, a significantly higher titer of specific antibody is achieved and sustained for a longer period of time. The peak of antibody production occurs 7 to 14 days after boosting. As a consequence of the existence of the memory B cells, less antigen is required to stimulate a strong secondary response. Memory B cells are long-lived; therefore, a specific antibody response can be elicited as much as 6 months to a year after the last booster. Finally, the average affinity and degree of specificity of the antibody population for the antigen increase with repeated immunizations (Klinman and Press, 1975).

Adjuvants greatly enhance the specific antibody titer, as they allow the antigen to be released slowly, thus ensuring the continual presence of antigen to stimulate the immune system. Freund's adjuvant has been used extensively in the preparation of antigen because it induces a high, long-lasting antibody titer that is often still measurable 25 weeks or more after boosting. The presence of mycobacteria in complete Freund's adjuvant (CFA) activates the T cell population, providing necessary lymphokines for B cell stimulation and maturation. CFA may cause granuloma and subsequent necrotic abscesses, so it should be used only for primary immunization. Incomplete Freund's adjuvant (IFA) is adequate for booster injections. In the past decade, adjuvant research has concentrated on the production of effective adjuvants that minimize animal trauma. Wherever possible, to reduce animal discomfort, less noxious adjuvants should be used (see Alternate Protocol). In addition some countries are restricting the use of CFA in laboratory animals. Published comparisons of commercial adjuvants with the basic CFA/IFA protocol vary widely in their conclusions. In most cases, however, CFA/IFA produces higher titers of higher-affinity antibodies in a shorter time period (Johnston et al., 1991; Deeb et al., 1992; Smith et al., 1992). Conflicting results (Mallon et al., 1991; Bennett et al., 1992) may reflect differences in the immunogenicity of the antigens used.

Critical Parameters

New Zealand red or white rabbits are generally the best source of specific antisera because 30 to 50 ml of whole blood can be obtained at each bleed, depending on their body weight. The life span of a rabbit is 5 to 6 years, so a continual source of specific antiserum can be provided over a period of time by one rabbit after booster injections. In this regard, the recommended times between booster injections are not critical; the animal may be rested for several months between subsequent boosters, after the primary and secondary booster injections. Blood collection, however, must take place 10 to 14 days after each booster to ensure a high titer.

Preimmune serum from the same animal is the preferred negative control. If additional control serum is required, either immune serum from animals immunized with totally unrelated antigens or pooled serum from naive animals will be adequate. Occasionally, spurious anti-

body activities from nonimmunized animals may mimic the activity of the immune serum.

Antibody specificity may vary widely between individual animals with respect to the dominant antigenic epitopes recognized on a given protein antigen. Therefore, antiserum from a single animal should be used throughout a study. If more than one animal must be used for particular antisera, the antisera should be pooled. Large-scale production of antisera can be carried out in goats, sheep, and horses with appropriate veterinary guidance. If serum is taken from inbred animal strains, the variability in antibody specificity, as observed in outbred rabbits, is less of a problem.

The most important factor in producing a highly specific polyclonal antiserum is the purity of the antigen preparation used for immunization. The immune system is very sensitive to the presence of foreign proteins. Any contaminating proteins in the antigen preparation can potentially induce a strong immune response when injected in the presence of adjuvant. When antisera are employed in sensitive techniques such as immunoblotting or the screening of cDNA or genomic libraries, significant antibody titers to protein contaminants can be a major problem. Thus, the antigen preparation should contain no significant contaminating proteins. Ideally, there should be no visible contaminating bands when 10 to 20 μg are analyzed on an SDS-polyacrylamide gel stained with Coomassie brilliant blue (*UNITS 6.1*).

If the antiserum is to be used in functional assays, extra care must be taken to ensure that the immunizing antigen is in its native form, because antibodies directed to denatured forms of the protein antigen will interact weakly, if at all, with the antigen in its native conformation. On the other hand, antibodies used in immunoblots, immunoprecipitation of primary in vitro translation products, and immunoscreening of λgt11 expression libraries may be most effective if generated against a denatured protein with reduced and carboxymethylated disulfide bonds.

Troubleshooting

Inability to attain high-titer antiserum after several booster injections may be due to a variety of factors as described below.

Use of inappropriate adjuvant. Some experimentation may be necessary to optimize the antigen/adjuvant ratio for different antigens. If the alternate protocol still fails to produce a good antibody titer after three immunizations, switch to the Basic Protocol.

Inadequate antigen emulsification. If the emulsion fails the drop-on-water test described in the basic protocol (step 3), repeat the emulsification process. Be sure to use phosphate-buffered saline. Avoid plastic syringes and Tris-based buffers with CFA and IFA.

The antigen is a poor immunogen. In general, the immunogenicity of a protein is related to the degree to which it differs from "self" proteins (Benjamin et al., 1984). Large bacterial or viral proteins such as hemagglutinin or bacterial-coat proteins are highly immunogenic, whereas proteins from mammalian sources, such as polypeptide hormones or cell- surface receptors, may be poorly immunogenic due to tolerance. Protein antigens can be made more immunogenic in two ways. First, they can be chemically linked to a carrier protein that is known to be a good immunogen. Common carrier proteins include keyhole limpet hemocyanin (KLH), fowl immunoglobulin, and bovine serum albumin (BSA). Coupling peptides to carrier proteins is described in Maloy et al. (1991); the same protocols can be used to couple the protein antigen of interest to the desired carrier. Second, the immunogenicity of an antigen may be enhanced by its polymerization into large aggregates via a cross-linking agent such as glutaraldehyde. The protocol in Maloy et al. (1991) for the coupling of peptide antigens to a carrier protein with glutaraldehyde can also be used to polymerize any protein antigen. With both the coupling and polymerization procedures, any insoluble antigen complexes formed should be removed prior to immunization by centrifuging 10 min at 15,000 × *g*, 4°C.

Host animal's immune system may be compromised by bacterial or viral infection. Refer to Donovan and Brown (1995) for discussion of the consequences of poor animal husbandry. Utilize animals from reliable, pathogen-free sources and maintain them in appropriate infection-free facilities.

Only a few animals have been immunized. Because of the vagaries of immune-response genes in outbred animals such as rabbits, some antigens may not induce a good antibody response in a significant proportion of randomly selected animals. Thus, it is best to immunize several different animals and to screen the sera for the best responder. Obviously, this is less of a problem in homozygous inbred strains, but with a new antigen it is wise to test several strains for their antibody response.

An insufficient amount of antigen was used. Although recommended concentrations of antigen for rabbits are 0.25 to 0.5 mg/ml injected

into multiple sites, for a total of 1 to 2 ml in the same animal, good results can be obtained with $^1/_{10}$ to $^1/_{20}$ of the concentration in the same volume. It is always tempting to use less of a precious antigen, but often too low a dose leads to too low a response.

Anticipated Results

For large or nonevolutionarily related proteins, a titer of 5 to 10 mg/ml of serum can be expected after repeated boosts (hyperimmunization). When immunizing with small or highly conserved protein species, a titer of 1 to 2 mg/ml of specific antibodies is more likely. Antibody titers and affinity for the antigen will be low after primary immunization and the first booster immunization, but both titer and affinity will increase with subsequent immunizations.

Time Considerations

Preparation of the immunogen and immunization will take up to 3 hr on each occasion. Collection of antisera will take 1 to 2 hr, depending on the number and species of animals.

Collection of antiserum after the primary immunization will be at 10 to 14 days. This will be a low-titer, low-affinity serum. The first booster normally is given 4 to 8 weeks after the primary immunization but can be given as early as 2 weeks after the primary if time is critical. Ideally, there should be at least 19 days between the primary and the secondary bleeds. A second booster is given at 6 weeks with a bleed on day 52 to 59. This will usually be the first high-titer bleed. If a titer of <1 mg/ml of specific antibody is obtained, subsequent boosting immunization will be necessary.

Purification of Immunoglobulin G

For many applications, both monoclonal and polyclonal antibodies may be used in impure form: monoclonal antibodies may be used either as ascites fluid or as tissue culture supernatant, and polyclonal antibodies may be used as antiserum. Such unpurified antibodies are perfectly suitable for use in indirect flow cytometry assays, for most ELISAs, or for cytotoxicity studies if the concentration of antibody is not important. Purified antibodies must be used, however, when accurate concentrations are required, when chemical modifications such as labeling with fluorescent and radioactive probes for binding studies are required, or when structural modifications such as removal of the Fc portion to produce bivalent $F(ab')_2$ or monovalent Fab fragments are required. IgM can be modified and the single bivalent subunit (IgMs) of the pentamer produced as a low-molecular-weight alternative to intact IgM. Bivalent $F(ab')_2\mu$ fragments of IgM are more difficult to produce but are sometimes required. Detailed methods for production of these fragments are provided in *UNIT 16.4*.

Choice of procedure for antibody purification depends on the intended use of the antibodies and on the available resources. This unit presents purification methods that can be tailored to the laboratory's resources. If a highly purified product is required, an assay for antibody activity and a reliable means of assessing the degree of protein contamination are essential. The method of choice for determining purity is SDS-PAGE (*UNIT 6.1*). The antibody assay must be rapid and accurate to monitor activity throughout the purification. Some preferred assays are: (1) labeling of cell-surface antigens with the antibody, followed by incubation with a fluorescent anti-Ig of the correct specificity and microscopic (*UNIT 4.3*) or flow cytometry analysis of the sample; (2) ELISA; (3) complement-mediated lysis of the appropriate cells; (4) immunodiffusion; (5) radioimmunoassay (RIA; Cooper and Paterson, 1993); and (6) inhibition of purified fluorescent or radiolabeled antibody binding to its appropriate ligand. Assays will generally not provide a measure of contaminating proteins that remain in the preparation at different stages of the purification. These can be detected by SDS-PAGE.

Several companies produce kits for the purification and fragmentation of antibodies derived from all common animal species. These kits are primarily designed for IgG and IgM classes of antibody, but there is also a kit for purification of egg yolk–derived IgY. The kits mentioned here are the most reliable in the opinion of the authors, but they may not be the least expensive option, so classical methods of purification and fragmentation are described in these units.

IgG can be purified by ammonium sulfate precipitation followed by size-exclusion (SE) chromatography (see Basic Protocol 1). This is the least expensive option available for purification of antibodies. Protein A– and protein G–affinity chromatography (see Basic Protocol 2 and Alternate Protocol 1) are the fastest methods for purifying antibodies, but they are not effective for all subclasses of rat antibody. Affinity chromatography using anti-rat antibody can be used to purify rat antibodies (see Alternate Protocol 2). Ion-exchange (IEX) chromatography (see Basic Protocol 3) can also be used to purify intact monoclonal and polyclonal antibodies and antibody fragments. All these methods give a product with a high degree of purity. Ammonium sulfate precipitation followed by IEX chromatography can be applied to any type of antibody. However, affinity chromatography, either as described in Basic Protocol 2 and Alternate Protocol 1 or carried out using a commercially produced kit, is much more efficient and less tiresome to carry out. There are many commercial kits available for purifying IgG (see Table 16.3.1). The T-Gel purification kit (thiophilic gel; Pierce) produces results similar to those of ammonium

Current Protocols in Cell Biology (2000) 16.3.1-16.3.12

Table 16.3.1 Commercial Kits for Purifying Antibody

Kit	Supplier[a]	Features
HiTrap protein A and protein G columns[b]	Amersham Pharmacia Biotech, Sigma	Ready-packed columns in a variety of sizes for use with syringe loading or a peristatic pump
Immunopure (A) and Immunopure (G) IgG[c]	Pierce	Protein A and protein G purification
Immunopure mouse IgG_1[c]	Pierce	Mild elution buffer kit for purification of mouse IgG_1 on protein A
Immunopure and Immunopure *Plus* (A/G) IgG	Pierce	Binds all IgGs that bind to both protein A and protein G; contains sufficient gel to purify 6 or 16 mg, respectively
MAb Trap GII[b]	Amersham Pharmacia Biotech	A complete protein G kit with buffers, column, and syringe
Protein A and Protein G Superose columns[b]	Amersham Pharmacia Biotech	Ready-made, reusable columns for use with the Pharmacia FPLC system; good for purifying large amounts of antibodies
Antibodies of other types/classes or general kits		
T-Gel[c]	Pierce	One-step purification by adsorption to a thiophilic gel; the gel has broad specificity for immunoglobulins of any type or subclass derived from various animal species; used to purify antibodies from serum, ascites fluid, or culture supernatant
HiTrap IgY[b]	Amersham Pharmacia Biotech	Concentrates IgY antibodies from egg yolk by centrifugation in a liquid linear polymer
HiTrap IgM Purification Column	Amersham Pharmacia Biotech	Prepacked column containing thiophilic adsorption medium coupled to Sepharose High Performance. Interacts with IgM in hydrophilic-hydrophobic interaction. Kit of buffers provided.

[a]See *SUPPLIERS APPENDIX*.

[b]These kits may require specialized equipment or preparation of additional reagents.

[c]These kits come complete or reagents may be purchased separately.

sulfate precipitation because it has a broad specificity toward immunoglobulins derived from various animal species, irrespective of the type or subclass. The E-Z-SEP system (Pharmacia Biotech) consists of a group of kits with applications for all types of antibodies—e.g., ascites IgG, ascites IgM, bioreactor medium IgM, serum-free tissue culture IgG, serum polyclonal antibodies.

BASIC PROTOCOL 1

AMMONIUM SULFATE PRECIPITATION AND SIZE-EXCLUSION CHROMATOGRAPHY

Ammonium sulfate precipitation coupled with size-exclusion (SE) chromatography is a method for purifying proteins of all types and may be the procedure of choice for purifying certain antibodies. Ammonium sulfate precipitation can be used to purify all subclasses of mouse antibodies as well as antibodies of other species. This method can be used to purify IgM, IgG, and IgA of all species. Although more time-consuming than affinity chromatography (see Basic Protocol 2), it has a wider range of applications.

After removing cell debris from ascites fluid or a monoclonal antibody supernatant, ammonium sulfate is added to precipitate the proteins. The precipitate is recovered by centrifugation and dissolved in PBS or borate buffer, then dialyzed and concentrated. It is purified by SE chromatography and the pure IgG is analyzed.

Materials

Ascites fluid or MAb supernatant
PBS (see recipe)
Saturated ammonium sulfate (SAS; *APPENDIX 2A*)
Borate-buffered saline (optional; see recipe)
Sephacryl S-200 Superfine (Amersham Pharmacia Biotech)
PBS containing 0.02% sodium azide (optional)

Glass wool (Polysciences)
Sorvall centrifuge and SS-34 rotor (or equivalent)
26 × 900–mm column (Amersham Pharmacia Biotech)

Additional reagents and equipment for protein dialysis (*APPENDIX 3C*), column chromatography (*APPENDIX 3*), concentrating proteins (*APPENDIX 3C*), and reducing and nonreducing PAGE (*UNIT 6.1 & APPENDIX 3*)

1a. *For ascites:* Remove lipid from (5 to 12 ml) ascites fluid by placing enough glass wool into a funnel to cover the opening, pouring ascites through, rinsing glass wool with PBS, and squeezing glass wool gently with gloved fingers to obtain all the sample. Centrifuge filtered ascites 30 min at 20,000 × *g* (13,000 rpm in SS-34 rotor) either 4°C or room temperature. Decant and save the supernatant and discard membranous material and cell debris remaining in the pellet.

Wear gloves when handling glass wool.

1b. *For MAb supernatant:* Centrifuge (~100 ml) MAb supernatant 30 min at 20,000 × *g*, either 4°C or room temperature. Decant and save the supernatant.

2. Add SAS slowly with stirring to the ascites or tissue culture supernatant to 45% (v/v). Leave 1 to 2 hr or overnight at 4°C to ensure precipitation of all the protein.

3. Centrifuge 1 hr at 20,000 × *g*, either 4°C or room temperature, and save precipitate to use in step 4. Save the supernatant to check for antibody activity.

4. Dissolve precipitate in a minimum volume of PBS or borate buffer (10 to 20 ml is usually suitable).

5. Place the dissolved precipitate in dialysis tubing. Dialyze against ≥20 vol PBS or borate buffer for 24 to 48 hr total at 4°C. Change the dialysis buffer four to six times during dialysis.

Generally, accurate molecular weight cutoffs are not required and it is not necessary to boil the tubing; merely soak for a few minutes in distilled water to soften.

The solution in the dialysis tubing will turn from a yellowish liquid to a cloudy or clear solution.

6. Concentrate the protein solution to ≤5 ml (*APPENDIX 3C*).

7. Prepare a 26 × 900–mm Sephacryl S-200 Superfine column and load the concentrated protein solution onto it. Elute protein with PBS, PBS containing 0.02% sodium azide, or borate buffer, and collect 100 fractions (1% of the column volume).

Monitor the protein fractions with a UV spectrophotometer at 280 nm. Alternatively, a precalibrated column can be used.

8. Check the purity of the fractions with A_{280} values >0.5 on nonreducing and reducing 10% polyacrylamide gels (*APPENDIX 3 & UNIT 6.1*).

In nonreducing PAGE, a band at ~150 kDa indicates IgG; in reducing PAGE, two bands at ~55 kDa (heavy chain) and ~25 kDa (light chain) indicate IgG. IgG_{2b} has asymmetric

Table 16.3.2 Extinction Coefficients and Molecular Size of Immunoglobulins and Their Fragments

Molecule	A_{280} (1 mg/ml solution)	Molecular weight (kDa)	
		Nonreduced	Reduced[a]
IgG	1.43	150	50, 25
IgM	1.18	900	78, 25
IgM subset	1.18	180	78, 25
Fab	1.53	50	25[b]
F(ab′)$_2$	1.48	100-110	25[b]
F(ab′)$_2$μ	1.38	135	44, 25
F(ab′)μ	1.38	65	44, 25

[a]Numbers to the left of the comma represent molecular weights of the heavy chain of immunoglobulins, and numbers to the right are weights of the light chain of immunoglobulins.

[b]May appear as a doublet on SDS-PAGE.

glycosylation of the heavy chains and will therefore appear as a doublet on the gel (Table 16.3.2). If the fractions are not sufficiently concentrated for detection by SDS-PAGE, concentrate as described in APPENDIX 3C).

9. Assess IgG concentration spectrophotometrically at A_{280} (Table 16.3.2). Pool the eluates containing pure IgG.

   Antibodies purified by ammonium sulfate precipitation followed by SE chromatography are of sufficient purity for any manipulation. They may be used for fragmentation after dialysis to the desired buffer (APPENDIX 3C), for ELISA, or for labeling with fluorescein isothiocyanate (FITC) or biotinylation.

10. Adjust IgG concentration to 0.1 to 30 mg/ml in borate buffer or PBS with 0.02% (w/v) sodium azide and store at 4°C up to several years. For back-up frozen stocks, freeze IgG at −70°C.

    Thawing and freezing once from −70°C is usually fine, although as a general rule this should be avoided. Do not store antibodies at −20°C for >1 month. Do not repeatedly freeze/thaw from −20°C.

BASIC PROTOCOL 2

AFFINITY CHROMATOGRAPHY USING PROTEIN A–SEPHAROSE

This protocol describes the purification of antibody using protein A–Sepharose affinity chromatography. Protein A can be used to isolate monoclonal and polyclonal IgG from ascites, serum, and tissue culture and bioreactor supernatants. Protein A purification is recommended for human (except IgG3; mouse IgG_1 may bind only weakly), rabbit, guinea pig, and pig antibodies (see Table 7.2.1). The protocol requires addition of the antibody to a protein A–Sepharose column at pH 8.0, followed by elution at a lower pH. The antibody is then dialyzed back against PBS.

Materials

Ascites fluid or MAb supernatant
PBS, pH 8.0 and pH 7.3 (see recipe)
1 M NaOH
Protein A–Sepharose CL-4B, hydrated (Amersham Pharmacia Biotech or Sigma)
0.1 M citric acid at pH appropriate for subclass of antibody (see step 5)
Borate-buffered saline (optional; see recipe)
3 M potassium thiocyanate, filtered

continued

Sorvall centrifuge and SS-34 rotor (or equivalent)
0.45-µm filter
1.5 × 10–cm column
HiTrap protein A column (Amersham Pharmacia Biotech or Sigma; optional)

Additional reagents and equipment for dialysis (*APPENDIX 3C*) and column chromatography (*APPENDIX 3*)

For ascites fluid

1a. Clarify ascites fluid and remove lipids (see Basic Protocol 1, step 1a).

2a. Dilute ascites fluid 10-fold with PBS, pH 8.0.

For MAb supernatant

1b. Centrifuge MAb supernatant at 20,000 × *g* (13,000 rpm in SS-34 rotor), 4°C, and filter through a 0.45-µm filter.

2b. Adjust MAb supernatant to pH 8.0 by dialysis against PBS, pH 8.0, or by adding 1 M NaOH.

It is important to have the protein sample at pH 8.0 if IgG1 is to be purified. Other subclasses should bind to protein A at pH 7.4.

3. Prepare protein A–Sepharose column and attach to fraction collector. Equilibrate column with PBS, pH 8.0, at either 4°C or room temperature. Layer antibody solution onto resin bed.

Volumes of 1 ml to several liters can be loaded onto a protein A–Sepharose column. Use a peristaltic pump or gravity to assist in loading large volumes.

There is a limit to the binding capacity for immunoglobulin (~5 mg mouse IgG, and 8 mg human IgG, per milliliter resin). The expected concentrations can be assessed from the yields (see Anticipated Results). The antibody activity of the unbound fraction can be tested to check for overloading. Use a flow cytometry assay or ELISA for assessing activity of the eluate.

The HiTrap protein A column is ready-to-use. Alternatively, a column can be prepared in a 10-ml syringe. Add glass wool to the syringe before adding hydrated protein A–Sepharose CL-4B.

4. Wash column with several volumes PBS, pH 8.0.

Eluate should have an A_{280} at baseline before proceeding to the next step.

5. Elute with 0.1 M citric acid at suitable pH (bring to appropriate pH with 1 M NaOH): for mouse IgG_1 use pH 6.5, for IgG_{2a} use pH 4.5, and for IgG_{2b} and IgG_3 use pH 3.0.

It is thought that standing in low pH may damage the antibody; therefore, 50 µl of 2 M Tris base buffer (Boehringer-Mannheim)/ml of eluate may be placed in the fraction collector tubes prior to elution. Reverse elution is undertaken by reversing the leads of the column so that the pump is pushing buffer up the column in the opposite direction to that in which the column was loaded. Samples that do not occupy the entire capacity of the column can be eluted at a higher concentration by this method. Reverse elution can concentrate the antibody if the protein A–Sepharose column is underloaded.

6. Pool protein-containing fractions, place eluates in dialysis tubing, and dialyze eluates against 1 liter PBS, pH 7.3, with or without 0.02% (w/v) sodium azide, at 4°C. Change the dialysis buffer twice. Store samples in PBS or borate-buffered saline at 4°C.

If desired, check purity by SDS-PAGE (UNIT 6.1).

7. Clean column with 1 column volume of filtered 3 M potassium thiocyanate before reequilibrating it in PBS, pH 7.3. Store at 4°C.

   Wash the column with several volumes of PBS, pH 7.3, to remove residual potassium thiocyanate, which absorbs at 280 nm and could interfere in later purifications.

   Antibodies purified by protein A–Sepharose affinity chromatography will be of similar purity to those obtained by ammonium sulfate precipitation and can be used for the same purposes (see Basic Protocol 1).

ALTERNATE PROTOCOL 1

AFFINITY CHROMATOGRAPHY USING PROTEIN G–SEPHAROSE

Affinity chromatography using protein G-Sepharose is useful for purifying antibody from serum, ascites fluid, tissue culture supernatant, and bioreactor supernatant. Protein G (Akerstrom and Bjorck, 1986) has a binding profile opposite to that of protein A with respect to pH: antibodies bind better at a low pH and badly at high pH. However, some antibodies (mouse IgG_1, and rabbit and human antibodies) do remain bound to protein G at high pH (8 to 10), so it is best to bind the antibody at pH 5 and elute at pH 2.8. This method is useful for mouse IgG_1, rat (most subclasses bind weakly although IgG_{2b} may not), monkey, rabbit, cow, goat, horse, and sheep antibodies (see Table 7.2.1). As with protein A purification, there is the possibility of some loss of antibody binding ability due to low-pH elution.

Additional Materials *(also see Basic Protocol 2)*

0.1 M sodium acetate, pH 5.0
0.1 M glycine·HCl, pH 2.8
HiTrap protein G column (Amersham Pharmacia Biotech or Sigma)

1. Prepare ascites fluid or MAb supernatant (see Basic Protocol 2, step 1a or 1b).
2. Dilute with 0.1 M sodium acetate, pH 5.0.

   Dilute >2-fold for tissue culture supernatant or 10-fold for ascites fluid and bioreactor supernatant.

3. Equilibrate HiTrap protein G column in 0.1 M sodium acetate, pH 5.0. Layer antibody solution onto protein G gel.

   Protein G has a higher capacity for IgG than protein A: ~10 mg protein/ml of gel with some species variation.

4. Wash column with several column volumes of 0.1 M sodium acetate, pH 5.0.
5. Elute bound antibody with 0.1 M glycine·HCl, pH 2.8.

   To minimize exposure to low pH, add 50 µl Tris-based buffer (Boehringer-Mannheim) per milliliter of eluate to each tube of the fraction collector..

6. Pool protein-containing fractions and dialyze (*APPENDIX 3C*).
7. Recycle the column by washing it with 0.1 M glycine·HCl, pH 2.8, then reequilibrating it to pH 5.0 with 0.1 M sodium acetate, pH 5.0.

AFFINITY CHROMATOGRAPHY USING ANTI–RAT κ CHAIN MONOCLONAL ANTIBODY COUPLED TO SEPHAROSE

ALTERNATE PROTOCOL 2

Occasionally, a monoclonal antibody (particularly one derived from the rat) cannot be purified by either protein A– or protein G–Sepharose chromatography, either because the antibody fails to bind the protein A or protein G, or because the elution conditions are too harsh for the retention of activity. In such a case, a column consisting of an anti-rat-Ig light-chain monoclonal antibody coupled to Sepharose can be used to bind the rat monoclonal antibody from a tissue culture supernatant or from ascites fluid. A series of buffers of decreasing pH can be used to assess the mildest conditions for elution of the rat antibody from the anti-Ig column. This protocol describes the production of such a column and the conditions for binding and elution from it.

Additional Materials *(also see Basic Protocol 2)*

Mouse anti-rat κ MAb: MAR 18.5 (ATCC TIB 216) purified using protein A–Sepharose (see Basic Protocol 2)
CNBr–Sepharose CL-4B (Amersham Pharmacia Biotech)
Binding buffer: 0.05 M Tris·Cl/0.15 M NaCl/0.02% (w/v) NaN_3, pH 8.6
Crude rat antibody solution to be purified (MAb supernatant or ascites fluid)
pH 7.0 elution buffer: 0.05 M sodium phosphate/0.15 M NaCl/0.02% (w/v) NaN_3, pH 7.0
pH 5.5 elution buffer: 0.05 M sodium citrate/0.15 M NaCl/0.02% (w/v) NaN_3, pH 5.5
pH 4.3 elution buffer: 0.5 M sodium acetate/0.15 M NaCl/0.02% (w/v) NaN_3, pH 4.3
pH 2.3 elution buffer: 0.5 M glycine/0.15 M NaCl/0.02% (w/v) NaN_3, pH 2.3
Additional reagents and equipment for preparation of antibody-Sepharose (*APPENDIX 3*)

Prepare column

1. Covalently couple ≥10 mg purified MAR 18.5 antibody to the CNBr–Sepharose 4B.

   Coupling ratio should be ~10 mg MAR 18.5/ml wet gel. Such a column will have a capacity to bind ~1 mg of protein.

2. Prepare the column and wash extensively with the binding buffer at 4°C or room temperature.

Purify antibody

3. Clarify ascites fluid or MAb supernatant (see Basic Protocol 2).
4. Load the column with ~10 ml ascites or ~100 ml MAb supernatant of crude rat antibody solution.
5. Wash the column extensively with 10 to 15 column volumes of binding buffer. Monitor the A_{280} to be certain the absorbance returns to baseline. Set up a fraction collector to collect all fractions from steps 6 to 9.
6. Elute with 5 column volumes of pH 7.0 elution buffer, watching the UV monitor.

   For most antibodies, this does not elute the bound antibody and serves as a preliminary wash step. Be sure A_{280} has returned to baseline before beginning the next step.

7. Elute with 5 column volumes of pH 5.5 elution buffer, watching the UV monitor.

   Some antibodies will elute under these mild conditions. Be sure A_{280} has returned to baseline before beginning the next step.

8. Elute with 5 column volumes of pH 4.3 elution buffer, watching the UV monitor.

   Most antibodies will elute under these conditions. Be sure A_{280} has returned to baseline before beginning the next step.

9. Elute with 5 column volumes of pH 2.3 elution buffer, watching the UV monitor.

   All antibodies will elute at pH 2.3. This also serves as a final wash step. Be sure A_{280} has returned to baseline before beginning the next step.

10. Equilibrate column with binding buffer by washing with ≥10 column volumes. Store column wrapped in Parafilm at 4°C.

11. Identify eluted protein peaks (including the unbound initial fractions), pool, assay for antibody activity, and concentrate if necessary (see Basic Protocol 1, step 9).

BASIC PROTOCOL 3

DE52 ION-EXCHANGE CHROMATOGRAPHY WITH TRIS·Cl

DE52 ion-exchange (IEX) chromatography can be used to purify antibodies from a tissue culture supernatant, ascites fluid, and serum or ammonium sulfate precipitates derived from any of these antibody-containing fluids. The protocol may also be used as a second step following purification by size exclusion (SE) chromatography (see Basic Protocol 1 and Alternate Protocols 1 and 2). The major contaminant protein in all these preparations is albumin, which binds DE52 tightly under conditions of low-to-moderate ionic strength. Antibody either fails to bind to DE52, in which case it elutes in the void volume as the column is loaded, or it binds loosely, and can be eluted with a gentle salt or pH gradient. Fractions eluted are assayed first by A_{280} and then by either ELISA (*APPENDIX 3*) or SDS-PAGE (*UNIT 6.1*).

Caution should be exercised in that different monoclonal antibodies as well as antibody fractions from different immunized animals' sera elute from DE52 under different conditions. In this protocol, antibody in 0.01 M Tris·Cl at pH 8.6 is passed over the DE52 column and bound antibody is eluted with a gradient in the same buffer approaching 0.5 M NaCl.

Materials

DE52 powder (Whatman)
0.01 M Tris·Cl, pH 8.6 (*APPENDIX 2A*)
0.5 M NaCl/0.01 M Tris·Cl, pH 8.6 (see recipe)
Antibody sample (ascites fluid, tissue culture supernatant, immune serum, or ammonium sulfate precipitate)
1.5 × 50–cm column

Additional reagents and equipment for column chromatography (*APPENDIX 3*), dialysis (*APPENDIX 3C*), and ELISA (*APPENDIX 3*) or SDS-PAGE (*UNIT 6.1*)

1. Swell DE52 powder in 0.01 M Tris·Cl, pH 8.6, and remove fine particles.

   It is very important to adjust the pH prior to pouring the DE52 gel into the column.

2. Pour a 1.5 × 50–cm DE52 column and equilibrate with 0.01 M Tris·Cl, pH 8.6.

   The size of the column is dependent upon the total amount of protein in the crude antibody sample. The capacity of DE52 is ≥100 mg total protein/ml hydrated gel, so a column of 1 to 5 ml is commonly sufficient.

3. Place antibody sample in dialysis tubing. Dialyze twice against ≥20 times the sample volume of 0.01 M Tris·Cl, pH 8.6, overnight at 4°C.

4. Load the dialyzed antibody sample onto the column.
5. Elute column with 0.01 M Tris·Cl, pH 8.6, until all of the protein that does not bind to DE52 at this pH comes through the column (detected by monitoring A_{280} with a UV monitor). Collect the first ten fractions (~12 ml each).

   Some antibodies elute at this stage (i.e., they do not bind DE52 in 0.01 M Tris·Cl, pH 8.6). They will thus be free of the major contaminant, albumin, which remains on the column. However, the great majority of antibodies will adsorb to the column under these conditions.
6. Elute the remaining material using a 200- to 250-ml linear gradient of 0.01 M Tris·Cl, pH 8.6, to an equal volume of 0.5 M NaCl/0.01 M Tris·Cl, pH 8.6. Collect 2-ml fractions.
7. Monitor column fractionation as follows: (1) A_{280}, to measure protein concentration; (2) conductivity, as an indication of the progress of the gradient as the concentration changes; (3) activity of the antibody by ELISA (*APPENDIX 3*); and (4) protein structure by SDS-PAGE (*UNIT 6.1*).

   A typical example of the elution profile of a mouse MAb is shown in Figure 16.3.1. The first peak that comes off as the ionic strength is increased is the IgG. This is confirmed by SDS-PAGE or ELISA.

   IEX chromatography is also useful for separating Fab fragments. Following size-exclusion chromatography of the digestion mixture to remove intact IgG (APPENDIX 3), the 50-kDa fraction is dialyzed (APPENDIX 3C) exhaustively against 0.01 M Tris·Cl, pH 8.6, and separated as described in this protocol using DE52. Elution profiles can vary greatly

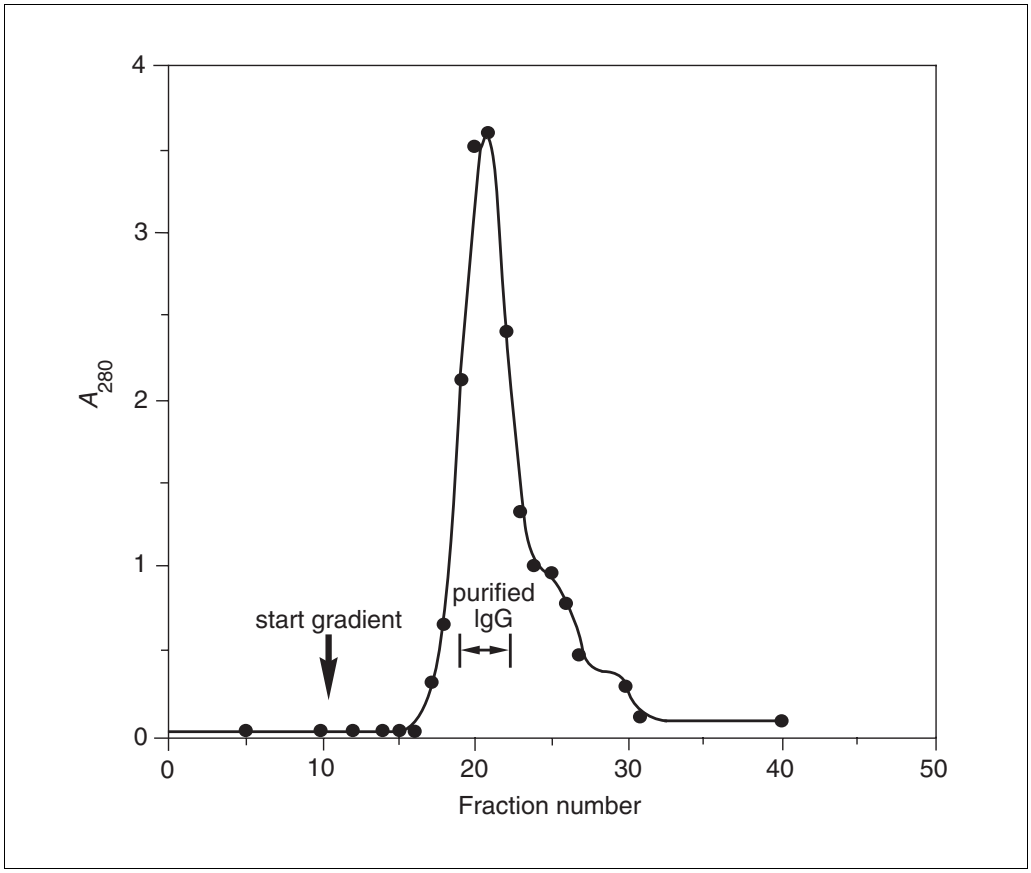

Figure 16.3.1 IEX chromatography elution profile from a DE52 column (1.5 × 50 cm). The IgG fractions from an ACA-34 column were dialyzed against 0.01 M Tris·Cl, pH 8.6, and applied to the column. Ten fractions (12 ml) were collected using the starting buffer, then a linear gradient of 0 to 0.5 M NaCl in Tris·Cl, pH 8.6, was started. Fractions 19 to 22 contained pure IgG as determined by SDS-PAGE (*UNIT 6.1*).

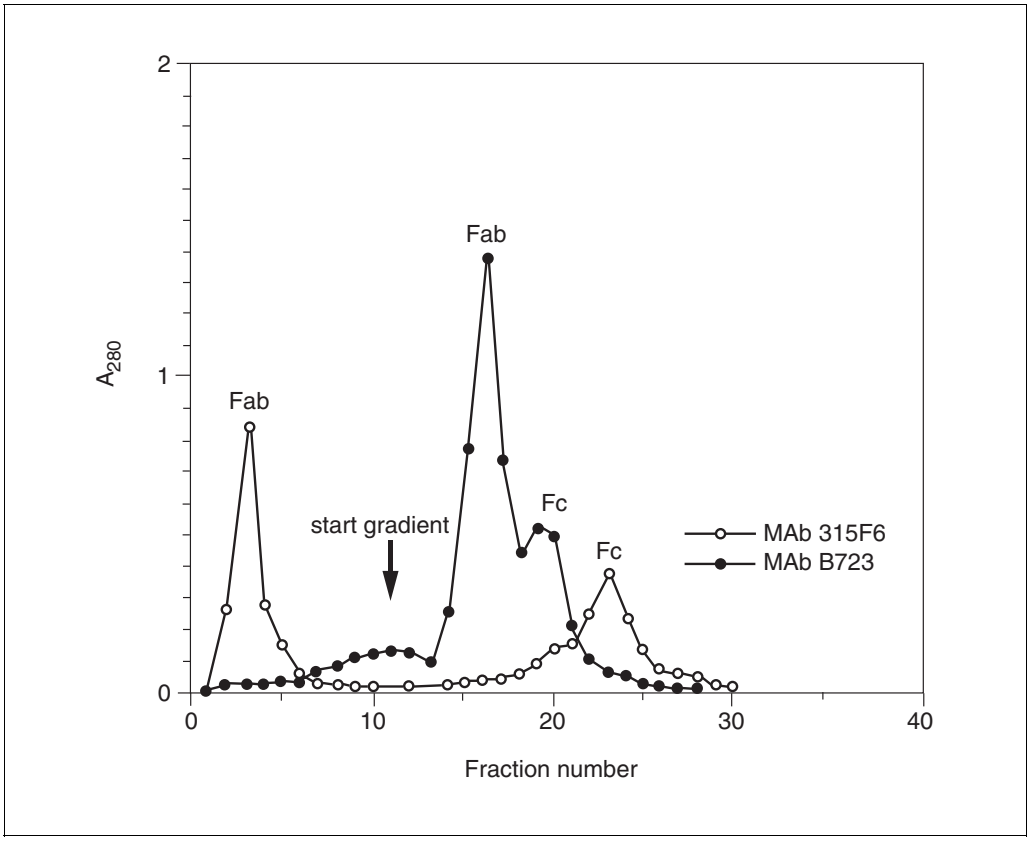

Figure 16.3.2 IEX chromatography elution profile of Fab from two different antibodies using a DE52 column (1.5 × 50 cm). Elution conditions and gradient were the same as for the example in Figure 16.3.1. For MAb 315F6 (open circles), the Fab fragment eluted in the starting buffer and the Fc portion much later in the gradient. Fab fragments from MAb B72.3 (closed circles) eluted at the beginning of the gradient.

between antibodies as shown in Figure 16.3.2. For one of the antibodies (open circles), the Fab elutes at 0.01 M Tris·Cl, pH 8.6. In contrast, the Fab from the other antibody (closed circles) elutes 40 ml after the salt gradient is started. These examples reinforce the need to monitor the location of the protein during the purification process.

REAGENTS AND SOLUTIONS

*Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2D**; for suppliers, see **SUPPLIERS APPENDIX**.*

Borate-buffered saline

0.015 M sodium borate
0.15 M NaCl
Adjust to pH 8.5 with 1 M NaOH and filter sterilize
Store indefinitely at room temperature

0.5 M NaCl/0.01 M Tris·Cl, pH 8.6

1.21 g Tris base
29 g NaCl
800 ml H_2O
Adjust pH to 8.6 with HCl and add H_2O to 1 liter

Phosphate-buffered saline (PBS)

0.23 g NaH_2PO_4 (anhydrous, 1.9 mM final)
1.15 g Na_2HPO_4 (anhydrous, 8.1 mM final)

continued

9 g NaCl (154 mM final)
Add H_2O to 900 ml
Adjust desired pH using 1 M NaOH or 1 M HCl
Add H_2O to 1 liter
Store indefinitely at room temperature

COMMENTARY

Background Information

Before purifying antibody from any preparation, consideration should be given to the potential use of the final product. If the antibody is to be used in an assay with internal controls or to saturate cell-surface antigen, then impure ascites fluid or a dialyzed ammonium sulfate precipitate will usually suffice. At the other extreme, biochemical modifications such as conjugation to drugs or certain fluorochromes (e.g., phicobiliproteins) may require an extremely pure product. In this case ion-exchange (IEX) chromatography (see Basic Protocol 3) should be used in addition to ammonium sulfate precipitation and affinity chromatography. For uses such as conjugation to fluorescein isothiocyanate (FITC), biotin or radioisotopes, antibody that has been purified by protein A or G is perfectly adequate.

Protein A is a cell wall component produced by several strains of *Staphylococcus aureus*; it is a single polypetide chain with a molecular weight of 42,000 Da. Protein A binds specifically to the Fc region of immunoglobulin molecules, especially IgG for which it has four high-affinity binding sites. It is heat stable and retains its native conformation even after exposure to denaturing reagents such as 3 M thiocyanate, or in acidic conditions. Thus antibody can be stripped from protein A and the reagent used again for purification. Not all IgG molecules bind to protein A; rat IgGs bind particularly weakly, and many mouse IgG_1 subclass antibodies will not bind. Some of these antibodies can be affinity purified with the similar reagent, protein G.

Protein G is a bacterial cell wall protein isolated from group G streptococci. Protein G also binds IgG molecules through their Fc portions. There are two binding sites for IgG in native protein G; it also has binding sites for Fab regions of antibody, albumin, and cell membranes. Sigma sells a recombinant form of protein G which has been truncated so the sites for Fc binding remain, but the Fab-, albumin-, and membrane-binding sites have been removed. Protein G is particularly useful for purification of human IgG3 and rat IgG_{2b}; although protein G can be used for other rat IgG molecules, the binding is frequently weak, especially in the case of IgG_1. Protein G is usually better than protein A for purification of mouse IgG_1.

Rat antibody can be problematic to purify, and an anti-rat affinity column (Alternate Protocol 2) may be required. The authors have had little success with protein G purification for rat monoclonal antibodies.

Elution profiles for IEX chromatography are different for each antibody or antibody fragment. The activity of eluted antibodies should be monitored using an ELISA (*APPENDIX 3*) in addition to the absorbance (A_{280}) profile.

Table 16.3.1 describes kits available for antibody purification. On first inspection, these may not seem to be the least expensive option, but it is important to remember that the reliability of kits and their excellent performance in terms of yield usually make them quite economic in the long term. It is a false economy to spend many hours of staff time obtaining a decreased percentage yield for the sake of saving a few dollars at the outset.

Critical Parameters

Because activity of the purified product is of prime importance, this should be evaluated for the impure antibody before purification is started and throughout the steps of purification. Some investigators report that the acid conditions required to elute from protein A can damage the antibody. Care should be taken to avoid excessively long periods of incubation at low pH. Elution from protein A– or protein G–Sepharose can also be accomplished using 3 M potassium thiocyanate, high ionic strength, or high pH. For particular antibodies these conditions may be more gentle, but in the authors' experience the best results are obtained with the methods described here.

Ammonium sulfate precipitation is a more gentle procedure than protein A purification, but it is more time-consuming. It can sometimes be difficult to remove samples from protein G. Use lower pH and increased salt concentration if problems are encountered.

Protein A columns can be used at flow rates of ~1 ml/min, while SE columns should be limited to ≤0.5 ml/min. Optimal results for SE are obtained using samples containing 5 to 100 mg of antibody. Protein A should be loaded within the limits given.

The antibody-binding capacity of protein A is variable between species. For mouse IgG, 1 ml of hydrated protein A will bind ~5 mg of antibody; for human IgG, 1 ml of hydrated protein A will bind ~8 mg of antibody.

For IEX (DE52) chromatography, the pH is very important and buffers should be checked on a pH meter immediately before starting. All column fractions should be retained until SDS-PAGE and antibody activity assays have been performed. In some cases, antibody may elute from the IEX column in the same fractions as serum albumin, in which case SE chromatography should be used.

DE52 has an enormous capacity for binding protein, as estimated by the manufacturer at 130 mg/ml bed volume. Thus, dilute antibody preparations can be concentrated effectively by this method.

Anticipated Results

Different batches of ascites fluid and monoclonal antibody supernatant can vary widely in the amount of antibody they contain. Generally, 1 ml of ascites should yield 1 to 4 mg of purified antibody and 1 ml of MAb supernatant should yield 0.5 to 50 μg of purified product. If cells are grown in automated culture systems that recycle the medium (bioreactors), yields equivalent to those of ascites fluid can be obtained. The lowest yields are usually from ammonium sulfate precipitation and the highest yields are usually from IEX or affinity methods.

Yields significantly lower than these should be a warning that the antibody-producing hybridomas are being overgrown by nonproducers. This can be remedied by returning to an earlier freeze of cells, or by recloning (and rescreening) the hybridoma.

Time Considerations

Procedures such as dialysis and running columns can be lengthy, but large amounts of antibody can be purified in 2 to 3 days. FPLC (fast peptide, protein, and polynucleotide liquid chromatography) systems are expensive, but can reduce the time taken to obtain purified antibody.

Quickest results can be obtained when culture supernatant or ascites is purified by one of the affinity methods described here (Basic Protocol 2): pure antibody can be obtained in <1 day. The ammonium sulfate, size-exclusion, or ion-exchange methods will take longer.

Fragmentation of Immunoglobulin G

To study the distinct regions of an immunoglobulin, it is useful to cleave them with proteolytic enzymes into various fragments (see Fig. 16.4.1 for a schematic of the structure of antibody molecules and their proteolytic fragments). The Fc portion of the antibody molecule is responsible for certain biological effects of antibodies, such as binding to Fc receptors on cells, mediating antibody-dependent cellular cytotoxicity, and complement fixation. It is also thought to be the more immunogenic portion of the molecule in vivo. For experiments concerning effects mediated by specific binding of antibody to cells in vitro or localization of antibodies to certain organs in vivo, it may be necessary to eliminate the nonspecific effects of Fc-receptor binding. The affinity of antibody for an antigen on the surface of viable cells can only be measured accurately using monovalent antigen-binding fragments (Fab).

Classically, fragmentation to the monovalent Fab fragment is carried out using papain digestion (see Basic Protocols 1 and 2), and the bivalent $F(ab')_2$ fragment is obtained by pepsin digestion (see Basic Protocols 3 and 4). Although papain digestion produces Fab fragments from IgG of all subclasses from all species, pepsin is not so universally useful. Alternative methods of fragmentation to $F(ab')_2$ include use of papain that is preactivated with cysteine (see Alternate Protocol 1) and use of the enzyme ficin (see Alternate Protocol 2). These alternate methods are particularly useful for mouse IgG_1 antibodies. When using pepsin and papain for the first time on an antibody, pilot experiments are performed to determine the correct reaction conditions; with preactivated papain and ficin these pilot experiments are unnecessary.

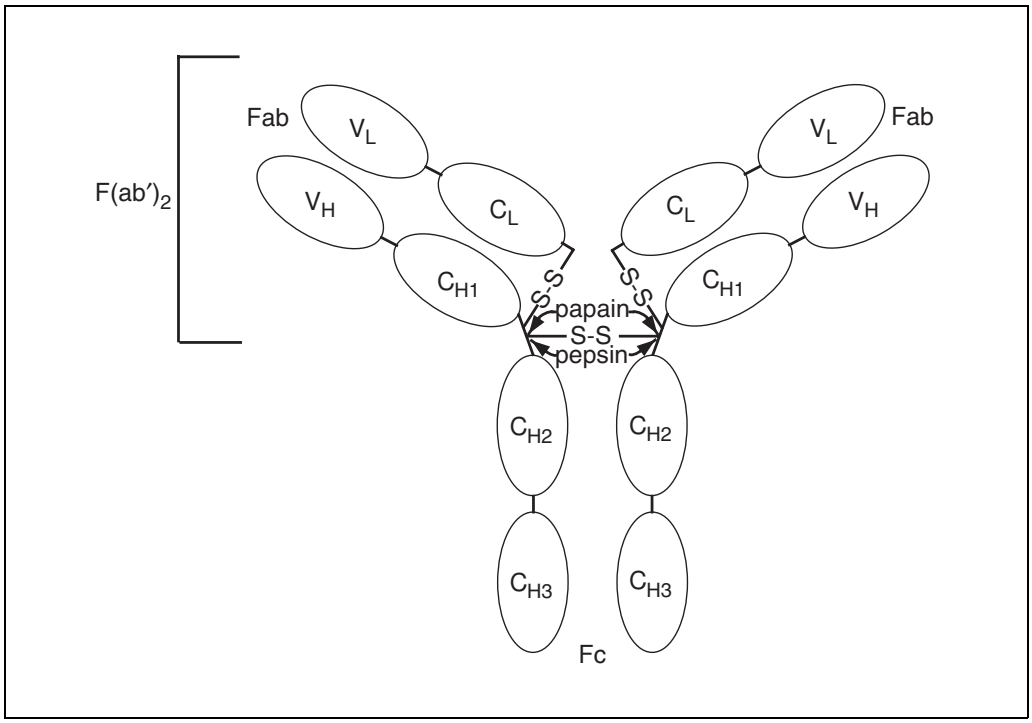

Figure 16.4.1 Proteolytic digestion fragments of immunoglobulins. Structural domains of the variable and constant regions of the light chain (V_L, C_L) and heavy chain (V_H, C_{H1}, C_{H2}, C_{H3}), as well as interchain disulfide bonds (S-S), are indicated. Monovalent fragments of IgG produced by papain digestion are known as Fab, while bivalent papain fragments are $F(ab)_2$. $F(ab')_2$ refers to the bivalent fragments of IgG produced by pepsin digestion; those derived from IgM are called $F(ab')_2\mu$. Bivalent subunits of IgM with both Fab and Fc are known as IgMs (subunit), and fragments of IgG containing a single antibody-binding site and an intact Fc portion are Fab/c.

Current Protocols in Cell Biology (2000) 16.4.1-16.4.10

PILOT FRAGMENTATION OF IgG TO Fab USING PAPAIN

Papain digestion of IgG produces Fab fragments. This protocol is designed to determine conditions for large-scale fragmentation, and can be used for IgG from mouse (all subclasses), rat, human, goat, sheep, horse, chicken, guinea pig, and cow. Once the method for a particular antibody is established, it will be reproducible for each fragmentation.

Purified monoclonal antibody is digested with papain in the presence of the reducing agent cysteine. To determine the optimal conditions, both the concentration of papain and the time of digestion are varied. After terminating the digestions, the fragments are dialyzed and analyzed by SDS-PAGE. By assessing the gel results, optimal conditions are chosen. These conditions are used in the large-scale fragmentation of IgG to Fab (see Basic Protocol 2).

Materials

2 mg/ml purified IgG (*UNIT 16.3*) in PBS (*UNIT 16.3*)
Papain (2× crystallized suspension; Sigma)
Digestion buffer (see recipe)
0.3 M iodoacetamide (prepare fresh from crystalline material; Sigma) in PBS
PBS (*UNIT 16.3*)

Additional reagents and equipment for nonreducing gel electrophoresis (*UNIT 6.5*) and dialysis of proteins (*APPENDIX 3C*)

1. Pipet 100 µl of 2 mg/ml purified IgG in PBS into each of 24 numbered microcentrifuge tubes.

2. Prepare two papain solutions in 5 ml digestion buffer—one at 0.1 mg/ml papain and the other at 0.02 mg/ml.

   Because papain is a suspension, mix well without vortexing before pipetting.

3. Add 100 µl of 0.1 mg/ml papain to eight of the IgG tubes. Add 100 µl of 0.02 mg/ml papain to a second group of eight IgG tubes. Finally, add 100 µl digestion buffer *without* papain to the remaining eight tubes. Close the lids on all of the tubes.

   Thus, reactions have been set up with enzyme/antibody (E/A) ratios of 1:20 and 1:100, and control tubes with no enzyme.

4. Prepare a digestion time curve by incubating tubes in a 37°C water bath and removing them at different times in groups of three—one tube each of E/A at 1:20 and 1:100, and one control tube. Remove the first group after 1 hr, and the subsequent groups at 2, 4, 6, 12, 18, 24, and 48 hr. As each group of three tubes is removed from the water bath, terminate the reaction by adding 20 µl of 0.3 M iodoacetamide in PBS and then vortexing.

   The final concentration of iodoacetamide (0.03 M) irreversibly inactivates papain.

5. Dialyze the reaction mixture (*APPENDIX 3C*).

   Dialysis can be performed using a homemade microdialysis chamber or commercial microdialysis cassettes (e.g., Slide-A-Lyzer Dialysis Cassettes, Pierce).

6. Analyze digestion products by loading an 80-µl aliquot of the dialyzed mixture from each tube onto a 10% nonreducing polyacrylamide gel (*UNIT 6.5*).

   Antibodies that have been digested with papain in the presence of cysteine to produce Fab fragments show a major protein band on a nonreducing polyacrylamide gel at a molecular weight of ~50 kDa, and a second band at 27 kDa which is the remaining Fc portion. There are usually a couple of smaller bands at 24 and 15 kDa which are other unimportant products of digestion. Obviously, undigested antibody will appear as a band at 150 kDa. Frequently, effects of cysteine alone are seen in antibody which has not been treated with papain, causing a protein band on the gel at 120 kDa. This 120-kDa band is also seen in

papain, causing a protein band on the gel at 120 kDa. This 120-kDa band is also seen in the digestion mix at short incubation times (up to 4 hr). The digestion is complete when no protein bands of 150 kDa or 120 kDa are seen in the gel lanes containing the digestion mixture. The time of complete digestion will vary between antibodies.

The effect of incubation with cysteine alone will be seen in the control lanes, probably because cysteine causes some unfolding of the antibody molecule, thus altering its electrophoretic mobility. Fab fragments have a molecular weight of 50 kDa (see Table 16.3.2). At early time points some intact antibody is expected on the gel, with the reaction moving towards completion as incubation times increase.

The amounts of antibody used in this method are suitable for analysis by SDS-PAGE using standard 150 × 1.5–mm gels. If a minigel apparatus is available (e.g., the Phast system from Pharmacia), modify the amounts accordingly and use less antibody.

7. Choose the optimal conditions to obtain Fab from the IgG by assessing the gel results and use these conditions for Basic Protocol 2.

LARGE-SCALE FRAGMENTATION OF IgG TO Fab USING PAPAIN

BASIC PROTOCOL 2

Exact conditions for optimum yield of Fab from each antibody should be assessed from the pilot experiment (see Basic Protocol 1); those conditions are then scaled up in this procedure. The procedure is similar to Basic Protocol 1 where papain is used to digest the antibody and the digested antibody is dialyzed. The dialyzed antibody fragment is then purified by protein A–Sepharose affinity chromatography (*UNIT 16.3*) and can be further purified by size-exclusion chromatography (*APPENDIX 3*). The purity of the product is assessed by nonreducing gel electrophoresis (*UNIT 6.5*).

Materials

Papain (2× recrystallized suspension; Sigma)
Digestion buffer (see recipe)
≥1 mg/ml IgG (≥5 mg total; *UNIT 16.3*) in PBS
Iodoacetamide crystals
PBS, pH 8.0 (*UNIT 16.3*)
Protein A–Sepharose CL-4B
Sephacryl S-200 Superfine (Pharmacia Biotech)

5 × 100–mm column (Bio-Rad)
26 × 900–mm column (Pharmacia Biotech)

Additional reagents and equipment for protein dialysis (*APPENDIX 3C*), column chromatography (*UNIT 16.3 & APPENDIX 3*), concentrating protein solutions (*APPENDIX 3C*), and nonreducing gel electrophoresis (*UNIT 6.5*)

1. Dissolve the required amount of papain in a volume of digestion buffer equal to the volume of antibody solution to be digested; use optimum amounts of enzyme and antibody as well as incubation times from the results of the pilot fragmentation in Basic Protocol 1.

   Digestion buffer is made at twice the required final strength so that when added to the antibody solution in equal volume, the mixture will be at the correct molarity with respect to EDTA and cysteine. Because papain is a suspension, mix well without vortexing before pipetting.

2. Add the papain buffer solution to the ≥1 mg/ml IgG in PBS, mix, and incubate for the required time (determined from Basic Protocol 1) in a 37°C water bath.

3. Stop the reaction by adding crystalline iodoacetamide to 0.03 M final. Mix carefully to ensure that the iodoacetamide dissolves completely.

4. Transfer to dialysis tubing and dialyze the mixture against 2 liters PBS, pH 8.0, for 12 to 20 hr at 4°C.

   More detailed procedures for large-volume dialysis, and selection and preparation of dialysis membranes can be found in APPENDIX 3C.

5. Prepare a 5 × 100–mm protein A–Sepharose CL-4B column (*UNIT 16.3 & APPENDIX 3*) and load dialyzed mixture onto it. Collect unbound fraction containing the Fab fragment and enzyme. If necessary, wash column with PBS to completely recover Fab fragments.

   The remaining intact antibody will bind to the column.

6. Concentrate the mixture containing the Fab fragments to ≤5 ml (*APPENDIX 3C*).

7. Prepare a 26 × 900–mm Sephacryl S-200 Superfine size-exclusion column (*APPENDIX 3*) and load concentrated mixture onto it. Collect fractions corresponding to a molecular weight of 50 kDa.

   Fractions can be collected and their molecular weight assessed by SDS-PAGE or a precalibrated size-exclusion column.

8. Check the purity of the final product (1 to 80 µl) on a 10% nonreducing polyacrylamide gel (*UNIT 6.5*).

9. Assess the concentration of the Fab fragments at A_{280} (Table 16.3.2). Store fragments in borate buffer (*UNIT 16.3*) at 4°C or in PBS containing 0.02% NaN_3 at −70°C.

BASIC PROTOCOL 3

PILOT FRAGMENTATION OF IgG TO F(ab′)$_2$ USING PEPSIN

Pepsin fragmentation of IgG to produce F(ab′)$_2$ is similar to the pilot fragmentation with papain (see Basic Protocol 1) except that the pH and time of digestion are varied. The optimum pH for pepsin digestion is ~2; however, this low pH may damage the antibody, so a pH of ~4 is the minimum recommended. Two different pH values are tested in this pilot experiment, as some antibodies will fragment to Fab or smaller fragments at lower pH values. Because pepsin treatment can be slightly harsher than papain, an enzyme/antibody (E/A) ratio of no higher than 1:20 is recommended, as it is possible that pepsin could damage the binding site of the antibody molecule.

NOTE: F(ab′)$_2$ fragments cannot be obtained from IgG_{2b}. Treatment of IgG_{2b} with pepsin will result in fragments of about the correct molecular weight (120 kDa), but these will be Fab/c fragments (consisting of one Fab fragment and the Fc portion; Fig. 16.4.1).

Materials

3 mg/ml purified IgG (*UNIT 16.3*)
Acetate buffer, pH 4.0 and 4.5 (see recipe)
0.1 mg/ml pepsin (Sigma) in pH 4.0 and pH 4.5 acetate buffers
2 M Tris base
PBS (*UNIT 16.3*)

Additional reagents and equipment for protein dialysis (*APPENDIX 3C*) and nonreducing gel electrophoresis (*UNIT 6.5*)

1. Dialyze 2 ml of 3 mg/ml purified IgG against 200 ml acetate buffer, pH 4.0, and another 2 ml of 3 mg/ml purified IgG against 200 ml acetate buffer, pH 4.5, both for 4 hr at 4°C.

2. Determine the concentrations of both dialyzed IgG solutions by A_{280} readings using the acetate buffer of corresponding pH as the blank (Table 16.3.2).

3. Adjust each dialyzed antibody solution to a concentration of 2 mg/ml in the acetate buffer of corresponding pH.

4. Pipet 100 µl of the 2 mg/ml IgG, pH 4.0, into each of 16 numbered microcentrifuge tubes. Into another 16 numbered microcentrifuge tubes, pipet 100 µl of the 2 mg/ml IgG, pH 4.5.

   Thus, there are two groups of 16 tubes—one group at pH 4.0 and the other at pH 4.5.

5. Add 100 µl of 0.1 mg/ml pepsin in acetate buffer, pH 4.0, to eight tubes in the IgG, pH 4.0 group. To the other eight tubes in this group, add 100 µl of acetate buffer, pH 4.0. Add 100 µl of 0.1 mg/ml pepsin in acetate buffer, pH 4.5, to eight tubes in the IgG, pH 4.5 group. To the other eight tubes in this group, add 100 µl of acetate buffer, pH 4.5.

   Thus, there are two groups of 16 tubes with pepsin at an E/A ratio of 1:20 at two different pH values, and control tubes without enzyme.

6. Incubate the 32 tubes in a 37°C water bath, removing one tube from each group of eight tubes after 1, 2, 4, 6, 12, 24, and 48 hr. As each tube is removed, stop the reaction by adding 40 µl of 2 M Tris base.

7. Transfer to dialysis tubing and prepare microdialysis chamber (*APPENDIX 3C*). Dialyze the samples against 1 liter PBS for 4 hr at 4°C.

8. Analyze 80-µl aliquots of the fragmentation products on a 10% nonreducing polyacrylamide gel (*UNIT 6.5*).

   $F(ab')_2$ has a molecular weight of 110 kDa. Bands of this molecular weight should be seen in the fractions treated with pepsin. Lower-molecular-weight bands (~50 kDa) are probably the Fab′ fragment of the antibody, a further degradation product from pepsin. Amounts of $F(ab')_2$ and Fab′ produced will vary among antibodies, depending on the fragmentation conditions and individual susceptibilities.

9. Choose the best conditions to obtain maximum yield of $F(ab')_2$ by assessing the gel results and use these conditions in the following basic protocol.

LARGE-SCALE FRAGMENTATION OF IgG TO $F(ab')_2$ USING PEPSIN

BASIC PROTOCOL 4

As with the papain large-scale protocol, optimal fragmentation conditions should be assessed for each antibody from the pilot fragmentation (Basic Protocol 3). Purification is by protein A–Sepharose affinity chromatography (Basic Protocol 2). It is important to remember that IgG_{2b} generally cannot be fragmented to $F(ab')_2$.

Materials

≥1 mg/ml purified IgG (*UNIT 16.3*)
Acetate buffer at appropriate pH (see Basic Protocol 3 and recipe)
0.1 mg/ml pepsin in acetate buffer at appropriate pH (see Basic Protocol 3)
2 M Tris base
PBS, pH 8.0 (*UNIT 16.3*)
Protein A–Sepharose CL-4B
Sephacryl S-200 Superfine (Pharmacia Biotech)

5 × 100–mm column (Bio-Rad)
26 × 900–mm column (Pharmacia Biotech)

Additional reagents and equipment for protein dialysis (*APPENDIX 3C*), concentrating protein solutions (*APPENDIX 3C*), column chromatography (*UNIT 16.3 & APPENDIX 3*), and reducing and nonreducing gel electrophoresis (*UNIT 6.5*)

Digest IgG

1. Dialyze ≥1 mg/ml IgG against acetate buffer at the appropriate pH.
2. Determine the concentration at A_{280}.
3. Add 0.1 mg/ml pepsin dissolved in acetate buffer at appropriate pH to give an E/A ratio of 1:20 (see Basic Protocol 3, step 5). Incubate the reaction mixture for the required time (see Basic Protocol 3, step 6) in a 37°C water bath.
4. Stop the reaction by adding ~50 µl of 2 M Tris base/ml reaction. Check with pH paper that pH = 8.0 and add more Tris base if necessary.
5. Transfer the mixture to dialysis tubing and dialyze against 1 liter PBS, pH 8.0, at 4°C (*APPENDIX 3C*).

Purify F(ab′)$_2$

6. Prepare a 5 × 100–mm protein A–Sepharose CL-4B column (*UNIT 16.3 & APPENDIX 3*) and load dialyzed mixture onto it. Collect the unbound fraction.

   At this stage, the F(ab′)$_2$ fragment can be reduced to Fab′ if desired. Add cysteine to a concentration of 0.01 M, mix well and incubate 2 hr at 37°C. Cysteine should reduce and alkylate the inter–heavy chain disulfide bonds. If further alkylation is thought necessary, make the mixture 0.15 M with respect to iodoacetamide. Purify the Fab′ using the steps below.

7. Concentrate the mixture to ≤5 ml.
8. Prepare a 26 × 900–mm Sephacryl S-200 Superfine size-exclusion column (*APPENDIX 3*) and load concentrated mixture onto it. Collect fractions corresponding to a molecular weight of 110 kDa.

   Measure the protein eluting from the column with a UV monitor or spectrophotometer. Assess their contents by SDS-PAGE or use of a precalibrated column.

9. Check the purity of the final product (1 to 20 µl) on a 10% SDS–polyacrylamide gel under reducing and nonreducing conditions (*UNIT 6.5*).

   F(ab′)$_2$ will give a single band at 110 kDa on a nonreducing gel and a single band or a doublet at 25 kDa on a reducing gel.

10. Assess the concentration of the F(ab′)$_2$ fragments at A_{280} (Table 16.3.2). Store fragments in borate buffer (*UNIT 16.3*) at 4°C or in PBS containing 0.02% NaN_3 at –70°C.

ALTERNATE PROTOCOL 1

FRAGMENTATION OF IgG USING PREACTIVATED PAPAIN

Mouse IgG_1 has shown significant resistance to pepsin digestion. The antibody is missing a leucine at residue 234; this restricts the hinge region and causes pepsin resistance. This method can be used to obtain F(ab)$_2$ fragments from IgG_1. Additionally, Fab fragments can be obtained from mouse IgG_{2a} and IgG_{2b} by this cleavage. It is a gentler procedure and can give a more stable fragmentation and a high yield of fragments. The procedure is time-consuming but incubation periods are usually less critical. The conditions used here are typical of large-scale fragmentation and purification. It is not necessary to carry out a pilot fragmentation experiment to assess conditions when using this procedure, although the type of fragment obtained varies between subclasses.

***Additional Materials** (also see Basic Protocol 4)*

10 mg IgG (*UNIT 16.3*) in 2 to 5 ml PBS
Acetate/EDTA buffer (see recipe)
2 mg/ml papain in acetate/EDTA buffer
0.05 M cysteine (free base, crystalline; Sigma)
Iodoacetamide crystals

PD-10 column (Pharmacia Biotech)
26 × 900–mm column

Additional reagents and equipment for protein dialysis and concentration (*APPENDIX 3C*), column chromatography (*UNIT 16.3 & APPENDIX 3*), and SDS-PAGE (*UNIT 6.1*)

Prepare papain

1. Dialyze 10 mg IgG in 2 to 5 ml PBS in acetate/EDTA buffer (*APPENDIX 3C*).
2. Determine the concentration at A_{280} with the acetate/EDTA buffer as a blank.
3. Incubate 2 mg/ml papain and 0.05 M cysteine for 30 min in a 37°C water bath.

   Papain requires a free sulfhydryl group for its catalytic activity. In the native crystalline form, this group is blocked and the enzyme exhibits extremely low proteolytic activity. Cysteine activates the group and activation is optimal in the presence of a heavy-metal binding agent such as EDTA.

4. Equilibrate a PD-10 column with 20 ml of acetate/EDTA buffer (*APPENDIX 3*).
5. Apply papain/cysteine (from step 3) to the PD-10 column. Collect ten 1-ml fractions, eluting with acetate/EDTA buffer.

   This process removes the cysteine from preactivated papain. Use preactivated papain within 2 hr of preparation and keep on ice until use.

6. Assay the fractions at A_{280} and pool the two or three fractions containing papain. Calculate the preactivated papain concentration using the following formula:

   $A_{280}/2.5$ = mg preactivated papain/ml.

Digest IgG

7. Add 0.5 mg preactivated papain to dialyzed, 10-mg IgG solution (from step 2) and vortex. Incubate 6 to 12 hr in a 37°C water bath.
8. Stop reaction by adding crystalline iodoacetamide to a final concentration of 0.03 M.
9. Dialyze against 1 liter PBS, pH 8.0, at 4°C for 6 to 12 hr (*APPENDIX 3*).

Purify fragments

10. Prepare a protein A–Sepharose column equilibrated in PBS, pH 8.0 (*UNIT 16.3*), and apply reaction mixture. Collect unbound 2-ml protein fractions and pool those represented by the first peak.

    The antibody fragments will elute in the first protein peak. Assess this using a UV monitor or spectrophotometer.

11. Concentrate the unbound fractions to ≤5 ml (*APPENDIX 3C*).
12. Prepare a size-exclusion (SE) column (*APPENDIX 3*) and load the sample. Collect 100 fractions (1% of the column volume). Assess the fractions containing the appropriate molecular weight by SDS-PAGE (*UNIT 6.1*) or on a precalibrated column. Store in borate buffer (*UNIT 16.3*) at 4°C or in PBS containing 0.02% NaN_3 at −70°C.

    Monitor the fractions with a UV spectrophotometer at A_{280} nm. The fragments obtained from this procedure are Fab from IgG_{2a} and IgG_{2b}, and $F(ab)_2$ from IgG_1.

ALTERNATE PROTOCOL 2

FRAGMENTATION OF MOUSE IgG_1 TO $F(ab')_2$ USING FICIN

IgG_1 can also be fragmented to $F(ab')_2$ by treatment with ficin in the presence of cysteine. Ficin is a thiol protease isolated from fig latex.

Additional Materials *(also see Basic Protocol 4)*

10 mg mouse monoclonal IgG_1 (*UNIT 16.3*) in 2 to 5 ml PBS
50 mM Tris/2 mM EDTA, pH 7
Ficin solution: 1 mg/ml ficin (Sigma) in 50 mM Tris/2 mM EDTA, pH 7
Cysteine
100 mM *N*-ethylmaleimide (Sigma)
PBS (*UNIT 16.3*)

Additional reagents and equipment for protein dialysis (*APPENDIX 3C)* and column chromatography (*UNIT 16.3 & APPENDIX 3*)

1. Dialyze 10 mg mouse monoclonal IgG_1 in PBS against 1 liter of 50 mM Tris/2 mM EDTA, pH 7, for 6 hr at 4°C.
2. Determine the concentration of the antibody by reading the A_{280} with the dialysis buffer as a blank.
3. Add ficin solution to give a 1:30 enzyme/immunoglobulin ratio.
4. Add solid cysteine to the mixture to give a final cysteine concentration of 1 mM.

   Cysteine is required to activate the enzyme.
5. Incubate 4 to 5 hr in a 37°C water bath with gentle shaking.

   The incubation time is not critical.
6. Stop reaction by adding 1/10 vol of 100 mM *N*-ethylmaleimide.
7. Dialyze the mixture against PBS, then purify the fragments by protein A–Sepharose and size-exclusion (SE) chromatography (see Alternate Protocol 1, steps 10 to 12 and *UNIT 16.3 & APPENDIX 3*).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acetate buffer, pH 4.0 and 4.5

Bring 0.2 M sodium acetate to pH 4.0 and 4.5 (as required) with glacial acetic acid.

Acetate/EDTA buffer, pH 5.5

Bring 0.1 M sodium acetate to pH 5.5 with glacial acetic acid and add EDTA to 0.003 M.

Digestion buffer

PBS (UNIT 16.3) containing:
0.02 M EDTA (disodium salt)
0.02 M cysteine
Prepare fresh; store <10 hr on ice

COMMENTARY

Background Information

Immunoglobulins can be cleaved by proteolytic enzymes into functionally distinct subunits (Fig. 16.4.1). Generally, fragments that bind antigens are of interest. Fab and $F(ab')_2$ fragments contain the antibody-binding portion of the molecule; the Fc fragment is generally only of interest if studying the crystal structure of antibodies. The Fab or $F(ab')_2$ portion of the antibody may be required in certain experiments. For instance, in mixed lymphocyte response (MLR) and cytolytic T lymphocyte (CTL) assays, the Fc portion may cause artifacts because it binds to cells bearing the Fc receptor. It has also been suggested that the Fc portion of the antibody may be more immunogenic in vivo (Hellstrom and Hellstrom, 1985). The Fc portion of IgG_{2a} and Ig_{G3} can invoke antibody-dependent cell-mediated cytotoxicity responses in vivo and in vitro.

The monoclonal antibodies routinely used for in vitro and in vivo experiments are from the mouse, and the protocols of this unit are designed for use with mouse antibodies. Fragmentation of antibodies from other species can be evaluated and optimized using the pilot protocol provided. Fragmentation with papain is similar for many species.

Subclass-dependent susceptibility of mouse antibodies to proteolytic cleavage has been widely reported (Parham, 1986). The order of sensitivity to proteolytic enzymes has been found to be IgG_{2b}>Ig_{G3}>IgG_{2a}>IgG_1. Not all antibodies, however, fall into this ranking; IgG_{2a} can be extremely sensitive to the action of papain in the presence of cysteine. If such sensitivities are found, then the method in which cysteine is removed from the enzyme following preactivation is recommended (see Alternate Protocol 1; Parham et al., 1982).

It must be stressed that all monoclonal antibodies are different and, for this reason, standard conditions for fragmentation are not given for papain and pepsin digestion. A pilot experiment should always be performed to assess optimal conditions before carrying out a large-scale fragmentation. The pilot experiment is very similar to the large-scale procedure. Microdialysis (Overall, 1987) is recommended so that the conditions from small- to large-scale are identical.

IgG can be fragmented to yield monovalent Fab fragments using the proteolytic enzyme papain in the presence of the reducing agent cysteine. IgG subclasses (e.g., IgG_1 and IgG_2) have different susceptibilities to papain digestion. IgG_1, IgG_{2a}, and IgG_3 can be digested to bivalent $F(ab')_2$ fragments using pepsin. Although IgG_1 may be sensitive to pepsin degradation, a more stable digestion is achieved using papain in the absence of cysteine. Ficin is also useful for digestion of IgG_1 to $F(ab')_2$ (Mariani et al., 1991). It is a thiol protease purified from fig latex. It requires activation with cysteine; the concentration of cysteine determines the extent of digestion. Generally, IgG_{2b} cannot be fragmented to $F(ab')_2$. Prior to fragmentation, a pilot experiment should be undertaken to determine individual conditions for fragmentation of each antibody. Separation of fragments can be carried out very efficiently by ion-exchange (IEX) chromatography on DE52 (*UNIT 16.3 & APPENDIX 3*); other methods for separation have been described in the protocols.

Pepsin cleavage of mouse IgG subclasses results in two sites of proteolytic sensitivity, one on either side of the inter–heavy chain disulfide bonds as suggested by Parham (1983). Primary cleavage may occur at a site on the COOH-terminal side of the bridges, giving $F(ab')_2$, followed by secondary cleavage on the NH_2-terminal side, giving Fab′. In the case of IgG_{2b}, the relative sensitivities of these two sites is reversed. Because the heavy chains of IgG_{2b} are asymmetrically glycosylated and the products of pepsin digestion of this subclass are Fab and Fab/c, $F(ab')_2$ has a molecular weight close to that of Fab/c. $F(ab')_2$, however, has rarely been reported to be obtained from IgG_{2b}, and therefore is not a feasible product of this subclass.

Pierce produces several kits for production of Fab and $F(ab')_2$ fragments from mouse (and other species) antibodies. These kits have been used with great success by the authors. Such kits are strongly recommended to those with the funds to purchase them. Each kit comes complete with all buffers and instructions.

Critical Parameters

Because each monoclonal IgG is different, if one antibody of a particular subclass is cleaved under a certain set of conditions, it cannot be expected that all other antibodies of that subclass will behave in the same manner. A pilot experiment should always be carried out when a new antibody is to be fragmented. It is probably better to choose a reaction time that will leave some antibody unfragmented rather than risk damaging the antibody-binding site by excessive exposure to proteolytic en-

zymes. Intact antibody can be easily removed from the fragmentation mixture by passage through a protein A–Sepharose column. For those antibodies that do not bind well to protein A, protein G–Sepharose (*UNIT 16.3*) or ion-exchange chromatography (*APPENDIX 3*) are reasonable alternatives.

Troubleshooting

Optimum reaction conditions may vary after scaling up from the pilot fragmentation. Occasionally the incubation times appear shorter in the small-scale procedure, so it may be necessary to increase the incubation time a little when scaling up.

Another possible difficulty is that the fragmentation does not proceed at all. Probably, this is related to the enzyme. Ascertain that there are no enzyme inhibitors, such as azide, present in the antibody solution (*UNIT 16.3*) before ordering new enzyme.

Anticipated Results

Yields are frequently subclass-dependent. A 100% yield of Fab fragment would be twice the number of moles of intact antibody in the starting mixture, and a 100% yield of $F(ab')_2$ would be equal to the number of moles of antibody in the starting mixture. Typically, yields of 45% to 55% are achieved, although some investigators report yields as high as 70% to 80%.

Time Considerations

Dialysis is usually carried out overnight, although 4 hr is sufficient for samples up to 100 ml. Running a protein A–Sepharose column takes ~4 hr, and running a size-exclusion column takes overnight.

Dialysis and running of columns are time-consuming procedures. The total time required to obtain fragments from a new antibody—beginning with the pilot experiment to the end of the large-scale production—is 4 to 5 days for Fab fragments and 6 to 8 days for $F(ab')_2$ fragments.

Antibody Conjugates for Cell Biology

Antibody conjugates are extremely useful reagents for probing many biologically and chemically important molecules in vitro or in vivo. This unit presents some basic protocols for conjugating antibodies with fluorescent dyes, with biotin (see Basic Protocol 1), and with enzymes (see Basic Protocol 2). These protocols have been selected because they are relatively easy to perform and have high rates of success. The basic approach for conjugating antibodies is to derivatize amino groups on the antibody with the dye or biotin derivative of choice. Conjugation at amine sites is simple to perform, and, with a fluorescent dye, it generally yields brightly fluorescent conjugates. The conjugates retain high levels of biological activity, notwithstanding the fact that the labels react with random amines on the antibody molecule, and they may even react near or at the antigen-binding site. Labeling of the amines is the most widely used commercial method to tag antibodies. In this unit, suggestions are presented for variations on these basic protocols that are useful when quantities of available antibody are limited. Methods for estimating antibody concentration are also included (see Support Protocol).

Alternate protocols for attaching label at the carbohydrate site of the Fc portion or at the sulfhydryl groups of the hinge region, which join the two heavy chains of the antibody molecule (Fig. 16.5.1), are also possible (see Alternate Protocol 1). These alternate protocols, which entail more steps, are more complex and require more meticulous optimization. Furthermore, they are difficult to perform when <1 mg of antibody is available. Among these alternate protocols, a general procedure is described for conjugating antibodies (see Alternate Protocol 2) or enzyme (see Alternate Protocol 3) at the carbohydrate site. Although this alternate protocol is presented for antibody-enzyme conjugates only, the basic principles can easily be adapted for conjugation of antibodies with fluorophores or biotin, as detailed in the Background section. Background Information also includes references for labeling antibodies at the hinge region.

CONJUGATING ANTIBODIES TO FLUOROPHORES OR BIOTIN

BASIC PROTOCOL 1

The procedural steps for antibody-fluorophore conjugation and for antibody-biotin conjugation are quite similar. These steps consist of mixing the dye or the biotin-derived reagent at an appropriate molar ratio and pH with the antibody solution and, after incubation, purifying the conjugate from the reaction mixture by size-exclusion chromatography (*UNIT 5.5*) or dialysis (*APPENDIX 3C*). The antibody-dye or antibody-biotin conjugate can then be analyzed to determine the degree of labeling, i.e., the number of moles of dye or biotin per mole of antibody. See Critical Parameters for helpful hints.

Materials

Antibody to label
1.0 M sodium bicarbonate (see recipe)
Phosphate-buffered saline (PBS; see recipe)
Probe (fluorophore or biotin)
Anhydrous dimethylformamide (DMF) or dimethylsulfoxide (DMSO; see recipe)
1.5 M hydroxylamine, pH 8.0 (see recipe)
Size-exclusion chromatography matrix: MATREX Cellufine GH25 (Amicon/Millipore), BioGel P30 (BioRad Laboratories) or equivalent matrix
ToyoPearl HW-40F (TosoHaas)
Reaction buffer, pH 7.5 (see recipe)
Appropriate TLC solvent (see Table 16.5.1, optional)

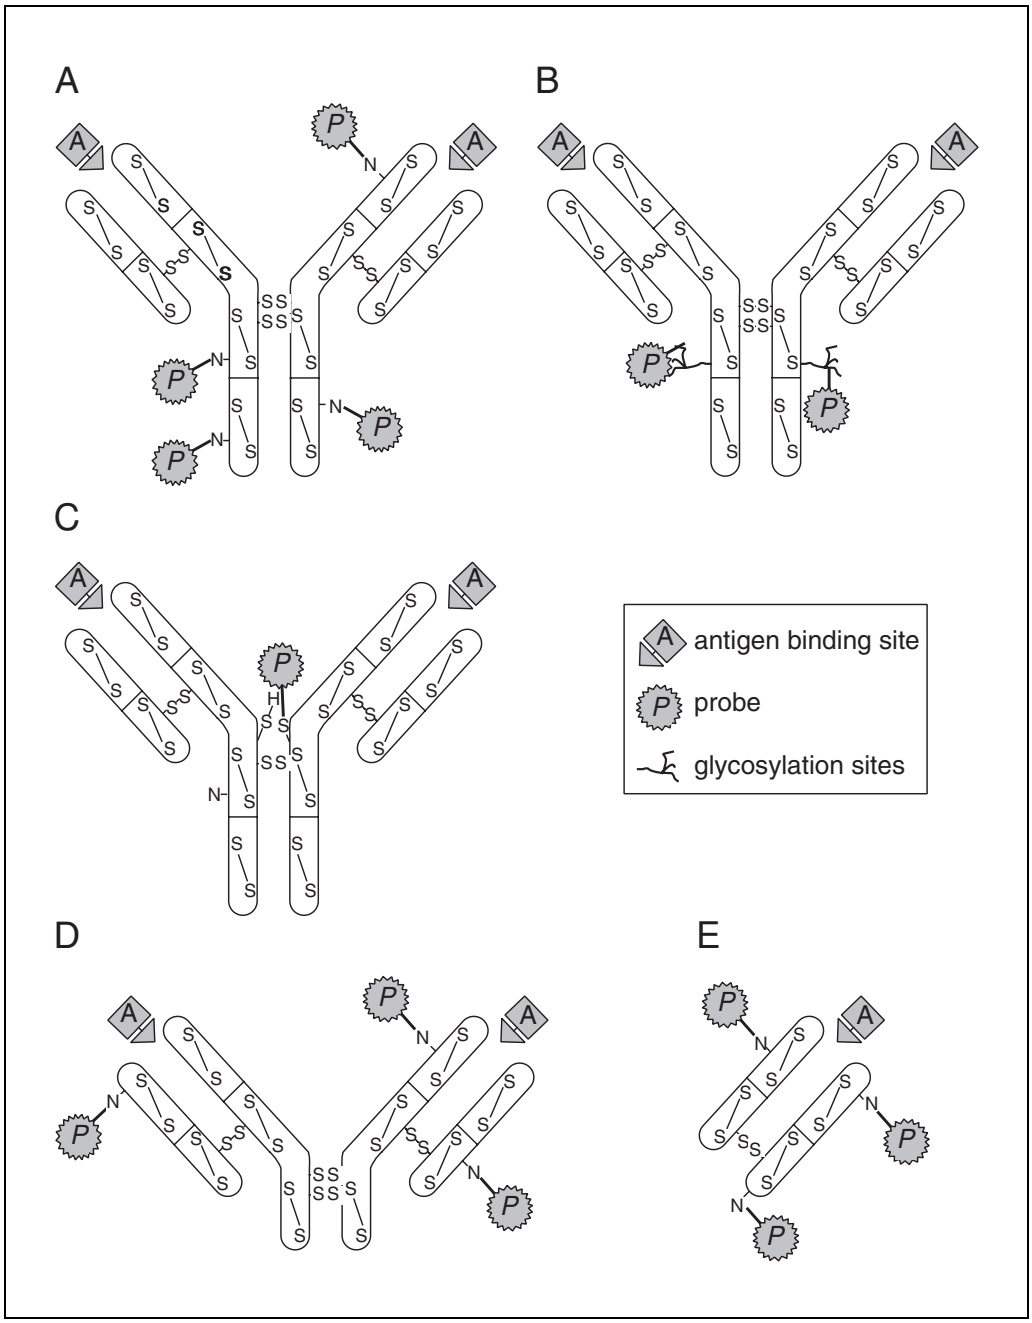

Figure 16.5.1 Schematic representation of possible modes of conjugation of antibodies or their fragments to probes. An antibody or Fab fragment is shown conjugated to one or more probe molecules. The probe symbol indicates a fluorophore, biotin, or an enzyme. (**A**) An antibody conjugated to a probe at several amine groups; (**B**) antibody conjugated at carbohydrate groups in the Fc regions; (**C**) antibody conjugated at thiol group in hinge region; (**D**) Fab fragment conjugated at amine groups; (**E**) $F(ab')_2$ fragment conjugated at amine groups. The molecular weight of intact IgG molecules (with all four subunits) is 140 to 160 kDa; where heavy chains are 50 to 75 kDa, and light chains are each ~25 kDa (A-C). Papain digestion of intact IgG yields Fab fragments of ~50 kDa, consisting of one light chain and a slightly larger fragment of the heavy chain, still attached by a disulfide bond (E). Cleavage of intact IgG antibodies with pepsin yields bivalent $F(ab')_2$ fragments of ~105 kDa (D); and subsequent reduction of the disulfides in the hinge region of $F(ab')_2$ yields two Fab' fragments (not shown), each ~53 kDa.

Table 16.5.1 TLC Solvents and Suggested Incubation Molar Ratios of Probe to Antibody for Several Commonly Used Fluorophores[a]

[a]MR = Incubation molar ratio of fluorophore to antibody, when antibody is at 1 to 3 mg/ml (column 2) or at 4-10 mg/ml (column 3); SE = succinimidyl ester. Solvents: C = chloroform; M = methanol; A = acetic acid; D = dioxane; P = isopropyl alcohol; NH_4 = ammonia; AcCN = acetonitrile.

10 mM 4′-hydroxyazobenzene-2-carboxylic acid (HABA) in 10 mM NaOH (for biotinylation)
Assay buffer: 50 mM sodium phosphate/150 mM NaCl, pH 6.0 (for biotinylation)
0.5 mg/ml avidin in assay buffer (for biotinylation)
0.25 mM biotin in assay buffer (for biotinylation)

Thin layer chromatography (TLC) silica gel/aluminum plates (EM Science; optional)
TLC chamber (optional)
Dialysis tubing
Chromatography column of appropriate size (see step 7)
Ultrafrel centrifugal filter devices, Biomax-50K or-100K (Amicon/Millipore; optional)

Additional reagents and equipment for size exclusion chromatography (*UNIT 5.5*) and dialysis (*APPENDIX 3C*)

Prepare the antibody for conjugation

1. Dissolve the antibody, if lyophilized, at 5 to 10 mg/ml or as concentrated as possible, in 0.1 M sodium bicarbonate (obtained by 10-fold dilution of a 1 M stock). If conjugating with isothiocyanates or sulfonyl chlorides of fluorophores, adjust the pH

of the bicarbonate solution to 9.0. If the antibody to be conjugated is already in solution in 10 to 20 mM phosphate, 0.15 M NaCl (PBS) to obtain the appropriate pH by simply adding 1/10 of the volume of 1 M bicarbonate, with pH unmodified, or pH 9.0 as needed. If the antibody is in a buffer containing Tris, glycine or other amines, dialyze the antibody against PBS or 0.1 M bicarbonate to "exhaustion," because the probes will react with any available free amine.

There is no need to modify the pH when reacting with succinimidyl esters.

Prepare probe solution

2. Calculate the volume of 10 mg/ml solution of probe (fluorophore or biotin) required to react with the antibody to be labeled, as follows:

   ml of 10 mg/ml probe = {[(mg of Ab) / (10 mg/ml of probe)] / (MW of Ab)} × (MR × MW of probe)

   where Ab = antibody; MW = molecular weight; and MR = incubation molar ratio of probe to antibody.

   For example, for labeling 5 mg of antibody with a 1:10 incubation molar ratio of carboxytetramethylrhodamine succinimidyl ester (TAMRA, SE; MW 430.5):

   volume of TAMRA, SE at 10 mg/ml = [(5/10)/(145,000)] × (10 × 430.5) = 0.0148 ml.

3. Immediately prior to starting the reaction, prepare a 10 mg/ml solution of the probe by weighing an amount of probe appropriate for the precision of the balance, for example, 3 mg, and dissolve it in 0.3 ml of DMF or DMSO.

   Sulfonyl chlorides, such as Texas Red sulfonyl chloride and Lissamine rhodamine B sulfonyl chloride, should be dissolved in DMF, because they react with DMSO.

4. Briefly, vortex or sonicate the reactive probe until it dissolves completely.

   In general, reactive probes are very sensitive to hydrolysis; thus, solutions of any reactive probe should not be stored. However, in some cases, the loss of reactivity during storage at ~20°C may be within an acceptable range.

Label antibody

5. While stirring, slowly add the probe solution to the antibody solution, in the amounts determined in step 2. Mix thoroughly.

6. Incubate the reaction mixture 60 to 90 min at room temperature with gentle stirring.

7. (*Optional*) Stop the reaction by adding 1/10 vol of 1.5 M hydroxylamine hydrochloride that has been adjusted to pH 8.0 with NaOH and incubating an additional 20 to 30 min.

   Treatment with hydroxylamine is potentially useful for removing the dye or biotin from unstable conjugates with hydroxyl-containing amino acids (Wong, 1991).

Purify conjugated antibody

8. Purify the antibody from unreacted dye or biotin by size-exclusion chromatography (*UNIT 5.5*) using PBS or reaction buffer.

   The size of the column should be selected based on the amount and concentration of the antibody. A 10 × 400–mm column is adequate for 5 to 10 mg of antibody at 5 to 10 mg/ml, while a 5 × 200– to 250–mm column can be used for 1 to 5 mg of antibody at ≥2 or more mg/ml. For dyes that are relatively hydrophobic, such as rhodamines or Texas Red, it is very useful to layer a small amount of ToyoPearl (a 2- to 3-cm layer) over the matrix used in the column, to help retain the unreacted dye.

If the antibody concentration is <2 mg/ml, purify the conjugate from excess probe by dialysis (APPENDIX 3C) to "exhaustion," i.e., until no free probe is detectable by TLC analysis (see step 9). Although it is more time consuming, dialysis is a very easy method to purify small, diluted amounts of antibody conjugates, avoiding the further dilution inevitable with size-exclusion chromatography performed with free-standing columns.

Alternatively, the solution of the antibody conjugate can be concentrated using a centrifugal spin filter device, with a mwco of 30 to 50 kDa. For amounts of antibody <1 mg, at the concentration of ≥1 mg/ml, separation from unreacted probe can be achieved by centrifuging the antibody, in volumes of ≤0.2 ml, on disposable spin columns, following the manufacturer's directions. Spin columns do not cause appreciable dilution of the sample, and they offer a rapid method to obtain small amounts of purified conjugates. To avoid denaturation, dilute solutions of antibody conjugates (<1 mg/ml) should be stabilized by adding bovine serum albumin (BSA) or gelatin to a final concentration of 1 mg/ml.

9. Identify the fractions from the fluorophore-antibody column chromatography.

For dye conjugates, the antibody conjugate is the first colored fraction to elute from the column, while the unreacted fluorophore is retarded. A clear band should be visible between the conjugate and the unreacted probe. Depending on the type of fluorophore and the type of size-exclusion matrix used, the unreacted dye could appear as a single band or multiple bands, because the succinimidyl ester might be only partially hydrolyzed and/or the dye might consist of isomers. Neither the band of unreacted biotin on the top of the column nor the biotin-antibody conjugate in the eluate from a spin column can be seen directly. Consequently, the biotin conjugate eluting from the column must be identified by measuring the A_{280}.

Analyze conjugates for purity

10. *For fluorescent antibodies only:* Analyze the purity of the eluted antibody conjugate by TLC. Spot 1 to 2 µl of sample on a small strip (~1.5 × ~10 cm) of a silica gel thin layer chromatography sheet and run it in a small, saturated chamber in the appropriate solvent (see Table 16.5.1), in parallel with the dye as a control. Remove the strip when the solvent front reaches ~3/4 of the strip height, and let it dry.

The antibody-conjugate will remain at the origin, while the contaminating unreacted dye will migrate towards the solvent front. The spots can be seen when excited by the long wavelength light of a hand-held UV lamp. If unreacted dye is present, the conjugate can be further purified by dialysis or by spinning it on a new spin column, according to the conjugate volume. This method is not applicable to antibody-biotin conjugates.

Determine the degree of antibody labeling by the probe

For antibody-fluorophore conjugates

11a. Measure the absorbance of the conjugate at the wavelength at which the dye absorbance is maximal (A_{Dye}) and at 280 nm (A_{280}). Then calculate the dye-to-antibody ratio using the following equation:

$$(A_{Dye}/\varepsilon^{M}_{Dye}) \div [(A_{280} - A_{Dye} \times CF)/\varepsilon^{M}A_{280}] = (\text{mol of dye/mol of antibody})$$

where A_{Dye} = dye absorbance at peak wavelength; ε^{M}_{A280} = 203,000 $cm^{-1}M^{-1}$, the approximate molar extinction coefficient of the antibody (IgG) at 280 nm; ε^{M}_{Dye} = molar extinction coefficient of the dye at the same wavelength as A_{Dye}. CF is a correction factor equal to A_{280}(for dye)/A_{Dye}.

Note that, while this formulation applies to fluorophore conjugates with intact IgG molecules, it can approximately apply as well to conjugates with antibody fragments, Fab, Fab′, and F(ab′)$_2$ (see Fig. 16.5.1), when used with the ε^{M}_{A280} appropriate for the antibody fragment. In this case, the ε^{M}_{A280} of the antibody fragment can be calculated from the measured absorbance of antibody solution at 1.0 mg/ml.

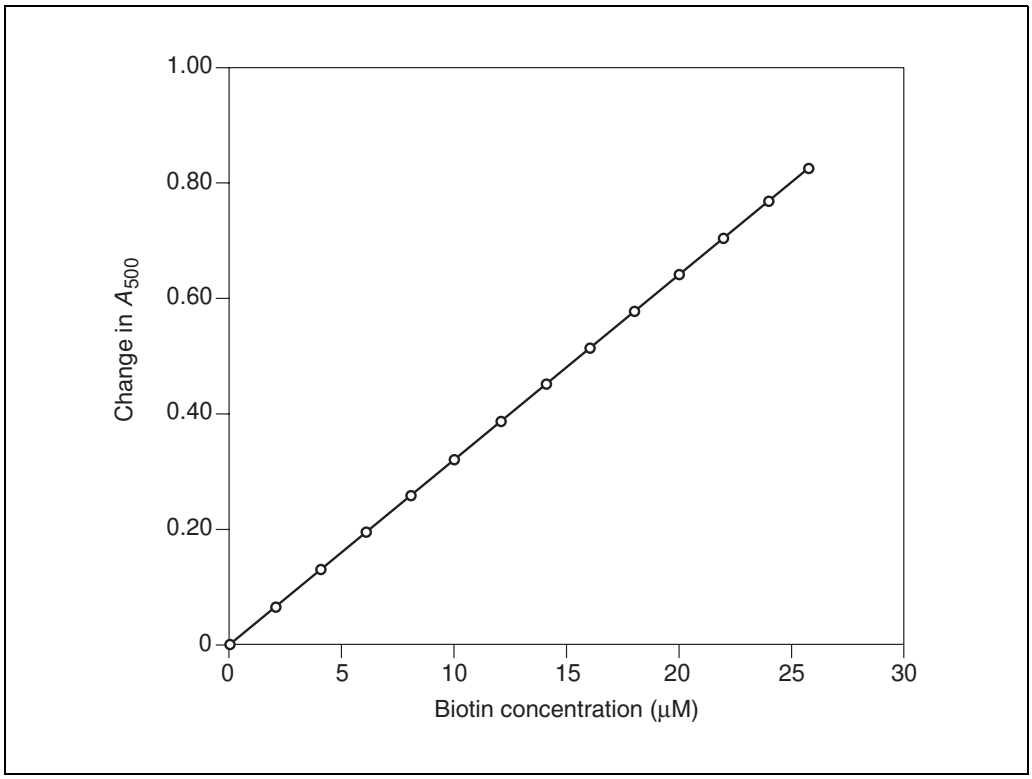

Figure 16.5.2 Standard curve of biotin concentration versus ΔA_{500}. The standard curve for biotin assay with avidin-HABA reagent relates measured difference in absorption at 500 nm to biotin concentration.

For antibody-biotin conjugates

The normal degree of biotinylation of antibodies can be determined by taking advantage of the high affinity of biotin for avidin. The dye, HABA, interacts with avidin, yielding a complex with an absorption maximum at 500 nm. Because of its higher affinity, biotin will displace HABA, decreasing the absorbance at 500 nm (A_{500}) by an amount proportional to the amount of biotin present in the assay. This relation can be quantified in a standard curve.

11b. Prepare the standard curve by adding 0.25 ml of HABA to 10 ml of the 0.5 mg/ml avidin solution. Incubate 10 min at room temperature.

12b. Distribute 0.9 ml of the avidin/HABA solution into each of seven tubes. Add 0.1 ml buffer, pH 6.0, to one tube (reference) and 0.005 to 0.1 ml biotin solution to the other six tubes. Bring the final volume to 1.0 ml (when necessary) with assay buffer, mix well and incubate 10 min at room temperature.

13b. Measure the A_{500} for each concentration point, using assay buffer as a blank, and subtract it from the value obtained from the reference absorption.

14b. Plot a standard curve of the nanomoles of biotin versus the decrease in A_{500}.

An example of such a standard curve is shown in Figure 16.5.2.

15b. To measure the degree of biotinylation of the sample, add an aliquot of biotinylated antibody of known concentration to 0.9 ml avidin-HABA complex. For example, add 0.05 to 0.1 ml of biotinylated antibody at 1 mg/ml to 0.9 ml of avidin-HABA mixture. Bring the volume to 1.0 ml with assay buffer (when necessary), incubate for 10 min, and measure the decrease in A_{500}.

16b. Using the standard curve, determine the nanomoles of biotin corresponding to the observed change in A_{500}.

The ratio between nanomoles of biotin used to displace HABA and nanomoles of antibody represents the degree of biotinylation. For example, the calculation for an IgG conjugate is:

(15 nmol biotin × 145,000 g/mol) ÷ (4.35 mg/ml antibody × 0.1 ml) = 5 mol of biotin per mol of antibody

where 145,000 is the MW of the IgG antibody, and 0.1 ml is the volume of 1 mg/ml of biotinylated antibody sample.

CONJUGATION OF FLUOROPHORES OR BIOTIN WITH F(ab′)$_2$ OR Fab ANTIBODY FRAGMENTS

ALTERNATE PROTOCOL 1

As described in *UNIT 16.4* of this series, antibody fragments that retain antibody binding activity can be generated by selective enzymatic digestion of intact antibodies. Conjugates made with antibody fragments may offer enhanced signals because their smaller size can permit penetration and reaction with the more recessed antigen sites or more extensive binding to closely located binding sites (see Critical Parameters for helpful notes).

Alternative conjugation procedure for fluorophores or biotin. In cases where conjugation with fluorophores or biotin at lysines appears to interfere with antibody binding, labeling can be performed with biotin hydrazides or fluorophore hydrazides at the carbohydrate prosthetic group, located in the Fc portion of the molecule (see Fig. 16.5.1), as described in the protocol for conjugation of antibodies with enzymes (see Basic Protocol 2). The hydrazide of the chosen fluorophore or biotin should be used in place of the enzyme, and purification of the conjugate performed as described (see Basic Protocol 2). As for the succinimidyl ester forms, biotin hydrazides are available with one (X) or two (XX) aminohexanoic acid spacers.

METHODS TO ESTIMATE ANTIBODY CONCENTRATION

SUPPORT PROTOCOL

The antibody concentration can be estimated by three different methods:

Correct the A_{280} of the conjugate for the A_{280} due to the dye, using the correction factor of the specific dye given in Table 16.5.2 and the value, $\varepsilon^{M}_{A280} = 203{,}000\ cm^{-1}\ M^{-1}$, for the IgG antibody. For example, conjugation of a goat anti-guinea pig IgG antibody with Alexa Fluor 488 succinimidyl ester yielded the following data, after 1:10 dilution: $A_{488} = 0.533$; $A_{280} = 0.314$; $\varepsilon^{M}_{Dye} = 71{,}000\ cm^{-1}M^{-1}$ (Table 16.5.2). In this case, the degree of labeling is

$$0.533/71{,}000\ cm^{-1}M^{-1} \div [(0.314 - 0.533 \times 0.11)/203{,}000\ cm^{-1}M^{-1}] =$$
$$5.96 \text{ moles of dye per mole of antibody}$$

where 0.11 is the CF for the Alexa Fluor 488 dye (from Table 16.5.2).

Estimate the protein concentration from the initial amount, assuming a loss of 15% to 20%, or more if some precipitation occurs during purification.

Use a protein assay method (*APPENDIX 3B*) to measure the concentration of the conjugate. This can be problematic, however, because most protein assays suffer from interference by fluorophores.

Table 16.5.2 Optical Properties of Commonly Used Fluorophores for Antibody Labeling

Dye	Abs/Em[a]	ε^{Mb}	CF[c]	Notes
Alexa Fluor 350	347 nm/442 nm	19,000	0.19	Blue-fluorescent labeling dye with higher fluorescence per conjugated dye than AMCA.
AMCA-X	350 nm/448 nm	18,000	0.15	Widely used blue-fluorescent labeling dye. Compact structure
Marina Blue	365 nm/460 nm	20,000	0.20	Blue-fluorescent dye. Compact structure. pH-insensitive at pH >6.
Cascade Blue	400 nm 420 nm	28,000	0.65	Resistant to quenching upon protein conjugation. Exhibits better spectral separation from FITC than does AMCA. Water soluble.
Cascade Yellow	402 nm/545 nm	20,000	0.61	Large Stokes shift. Useful for multicolor analysis in combination with blue-fluorescent dyes.
Pacific Blue	405 nm/455 nm	30,000	0.20	Bright blue fluorescence emission. Longer-wavelength alternative to AMCA and Marina Blue dye.
Lucifer yellow	428 nm/536 nm	11,900	0.30	Water soluble. Available as Lucifer yellow iodoacetamide.
Alexa Fluor 430	431 nm/541 nm	16,000	0.28	Large Stokes shift. One of relatively few dyes that absorb between 400 and 450 nm and have appreciable fluorescence beyond 500 nm.
Fluorescein	494 nm/518 nm	68,000	0.30	Widely used green-fluorescent labeling dye (FITC). Absorption overlaps the 488- nm spectral line of the argon-ion laser. Prone to photobleaching. pH-sensitive from pH 5 to 8.
Alexa Fluor 488	495 nm/519 nm	71,000	0.11	Best fluorescein substitute for immunofluorescence and other labeling applications. Exceptionally photostable and pH-insensitive from pH 4 to 10. Produces brighter conjugates than FITC. Ideal for 488-nm excitation.
Oregon Green 488	496 nm/524 nm	70,000	0.12	Fluorescein substitute. pH-insensitive at pH >6.
BODIPY FL	505 nm/513 nm	68,000	0.04	Insensitive to solvent polarity and pH from pH 4 to 8. Narrow spectral bandwidth. Neutral dye. Succinimidyl ester with a cysteic acid spacer is the preferred reactive form for protein conjugation.
Oregon Green 514	511 nm/530 nm	70,000	0.19	Very photostable. pH-insensitive at pH >6. Absorption matched for 514-nm excitation.

continued

BASIC PROTOCOL 2

CONJUGATION OF ANTIBODIES WITH ENZYMES

Conjugation of antibodies with enzymes involves crosslinking of the two proteins in successive procedural steps. The method involves (1) derivatization of the antibody with a bifunctional reagent that introduces reactive maleimide groups into the molecule and (2) derivatization of the enzyme with a thiol group that can form a stable thioether bond with the maleimide group on the antibody. This approach can be tailored to obtain either heteroconjugates consisting of one molecule of antibody and one molecule of enzyme or conjugates consisting of one antibody labeled with multiple enzyme molecules. The most commonly used enzymes are horseradish peroxidase (HRPO), alkaline phosphatase (APase), β-galactosidase (βGase), and glucose oxidase (GO).

Table 16.5.2 Optical Properties of Commonly Used Fluorophores for Antibody Labeling, continued

Dye	Abs/Em[a]	ε^{M}[b]	CF[c]	Notes
Eosin	524 nm 544 nm	90,000	0.25	Useful photooxidizer of diaminobenzidine (DAB). Phosphorescent (lifetime ~1 msec.) Useful for phosphorescence aniosotropy measurements. Efficient FRET[d] acceptor from fluorescein, BODIPY FL dye, dansyl and coumarin.
Alexa Fluor 532	531 nm/554 nm	81,000	0.09	Bright and photostable dye with spectra intermediate between those of fluorescein and tetramethylrhodamine. Water soluble. Excellent protein-labeling dye.
Tetramethyl-rhodamine (TMR)	555 nm/580 nm	65,000	0.30	Widely used orange-fluorescent labeling dye (TRITC). pH-insensitive. Very photostable. May form nonfluorescent aggregates when attached to proteins.
Cy3	553 nm/570 nm	150,000	0.08	Orange fluorescing, bright and water soluble cyanine dye.
Alexa Fluor 546	556 nm/573 nm	104,000	0.12	Very bright and photostable tetramethylrhodamine (TAMRA or TRITC) and Cy3 dye substitute. Ideal for 546-nm excitation. Water soluble.
Rhodamine Red-X	570 nm/590 nm	120,000	0.17	Rhodamine Red-X succinimidyl ester generally yields higher fluorescence per attached dye than Lissamine rhodamine B sulfonyl chloride and is more stable in water.
Alexa Fluor 568	578 nm/603 nm	91,300	0.46	Bright and photostable Lissamine rhodamine B substitute. Ideal for 568-nm laser excitation. Excellent protein-labeling dye. Water soluble.
Alexa Fluor 594	590 nm/617 nm	73,000	0.56	Bright and photostable Texas Red dye substitute. Ideal for 594-nm laser excitation. Excellent protein-labeling dye. Water soluble.
Texas Red	595 nm/615 nm	80,000	0.20	Good spectral separation from fluorescein. Texas Red-X succinimidyl ester typically yields higher fluorescence per attached dye than Texas Red sulfonyl chloride and is more stable in water.
Cy5	650 nm/667 nm	250,000	0.05	Excitable by 632-nm line of the HeNe laser.
LaserPro	807 nm/812 nm	229,000	0.12	Relatively low quantum yield. Emission is not visible to the eye.

[a]Abs/Em are the absorbance and emission maxima of the dye.
[b]ε^{M} is the molar extinction coefficient of the dye in $cm^{-1}M^{-1}$.
[c]CF is the percentage correction factor determined by the following formula: CF = A_{280} for dye/A_{max} for dye.
[d]FRET, fluorescence resonance energy transfer.

It should be emphasized that βGase contains a large number of free thiols (8 to 12 or more, according to the different preparations of the enzyme) and need not be modified; rather, it can be reacted directly in its native form with the maleimide derivatives of antibodies.

Some protein-to-protein crosslinking kits, adaptable to the conjugation of antibodies with enzymes, are commercially available (Molecular Probes, Pierce, Prozyme).

Materials

HRPO, APase, GO, βGase (Boehringer Mannheim, Sigma)
Reaction buffer, pH 7.5 (see recipe)
TEA buffer (see recipe; for APase only)
Succinimidyl 3-(2-pyridyldithio)propionate (SPDP, MW 312)
Anhydrous dimethylsulfoxide (DMSO) or dimethylformamide (DMF)
BIO-GEL P-30 (Bio-Rad) or Cellufine GH-25 (Amicon/Millipore)
Dithiothreitol (DTT)
Antibody to label
Succinimidyl *trans*-4-(*N*-maleimidylmethyl)cyclohexane-1-carboxylate (SMCC, MW 334)
Tris-(2-carboxyethyl)phosphine, hydrochloride (TCEP, MW 287; Molecular Probes, Pierce Chemical)
50 mM *N*-ethylmaleimide (MW 125.13)
Sephacryl S-200 for HRPO conjugates (Amersham Pharmacia Biotech or Sigma Chemical)
BIO-GEL A-0.5m for APase conjugates (Bio-Rad Laboratories)
BIO-GEL A-1.5m for BGase conjugates (Bio-Rad Laboratories)

Chromatography column of appropriate size (see step 4)
Ultrafrel centrifugal filter devices, Biomax-50K or-100K (Amicon/Millipore)

Additional reagents and equipment for dialysis (*APPENDIX 3C*) and size exclusion chromatography (*UNIT 5.5*)

Prepare the thiolated enzyme

1. Dissolve or dialyze HRPO (or GO) in reaction buffer at a concentration of 10 mg/ml. Dialyze APase in TEA buffer.

2. Weigh 3 mg of SPDP, and dissolve in 0.3 ml DMF to obtain a 10 mg/ml solution. Prepare this solution fresh immediately before using.

3a. *HRPO:* To 10 mg of HRPO (0.25 µmol) in 1 ml reaction buffer, add, while stirring, 40 µl of SPDP solution, to obtain a molar ratio of reagent to HRPO of 5. Incubate 1 hr at room temperature.

3b. *APase:* To 10 mg of APase (0.07 µmol) in 1 ml of pH 7.6 TEA buffer, add 10 µl of the SPDP solution and incubate 1 hr at room temperature.

3c. *GO:* To 10 mg of GO (0.063 µmol) in 1 ml reaction buffer, add 10 µl of the SPDP solution and incubate 1 hr at room temperature.

APase and GO have many more amines available for thiolation compared to HRPO, which has only 4 to 6 amines (Welinder, 1979). Thus the molar ratio of reagent to enzyme is ~5, notwithstanding the disparity in molecular weight between the two proteins.

4. Purify the thiolated enzyme by molecular exclusion column chromatography, using BIO-GEL P-30 or Cellufine GH-25, in reaction buffer for HRPO or TEA buffer, pH 7.6, for APase.

A column bed size of ~10 × 400–mm is required for 10 to 20 mg enzyme.

Determine the degree of thiolation

5. Prepare a 100 mM solution of DTT by dissolving 7.7 mg of DTT in 0.5 ml of distilled water.

6. Transfer 1 ml of 0.5 to 1 mg/ml enzyme solution to a spectrophotometer cuvet. Record the A_{280} and A_{343} of the solution.

7. Add 50 µl of DTT solution. Mix well, incubate 3 to 5 min, and record the A_{280} and A_{343} again.

8. Using an extinction coefficient of 8080 $cm^{-1}M^{-1}$ at 343 nm (Carlsson et al., 1978), calculate the amount of pyridine-2-thione liberated during the reduction.

   The amount of this product is equivalent to the number of thiols introduced in the protein.

9. To determine the enzyme concentration, correct the A_{280} of the enzyme solution for the absorbance contributed by 2-pyridyldithio propionate at this wavelength, according to the following equation:

$$A_{280} \text{ of enzyme} = A_{280} \text{ of conjugate} - (\Delta A_{343} \times 5100 \text{ cm}^{-1}\text{M}^{-1}/8080 \text{ cm}^{-1}\text{M}^{-1})$$

   where $\Delta A_{343} \times 5100 \text{ cm}^{-1}\text{M}^{-1}/8080 \text{ cm}^{-1}\text{M}^{-1}$ reflects the amount of pyridine-2-thione generated during the reaction.

   For HRPO, the enzyme concentration can be determined at 403 nm using the extinction coefficient shown in Table 16.5.2, with no correction. The number of thiols per mole of enzyme can be calculated using the following equation:

   moles of -SH groups per mole of enzyme $= (\Delta A_{343}/8080\ cm^{-1}M^{-1}) \div \{[A_{280} - (\Delta A_{343} \times 5100\ cm^{-1}M^{-1}/8080\ cm^{-1}M^{-1})]/\varepsilon^{M}_{enzyme}$

   or, for HRPO:

   $(\Delta A_{343}/8080\ cm^{-1}M^{-1}) \div (A_{403}/\varepsilon^{M}_{enzyme})$.

10. From the preceding equations, determine the average number of moles of antibody that can be reacted with each mole of enzyme.

    To obtain a 1:1 enzyme-antibody conjugate, the enzyme should be derivatized with 1.2 to 1.5 pyridyldithiol residues per mole. Thiolated enzymes remain stable for a few weeks when stored refrigerated in presence of 2 mM azide or, for HRPO, 0.01% (w/v) thimerosal, because azide inhibits the activity of this enzyme.

Prepare the antibody-maleimide derivative

11. Dissolve or dialyze the antibody in reaction buffer.

    The antibody should be as concentrated as possible to increase both the yield and the efficiency of the conjugation reaction. Ideally, the concentration should be 5 to 10 mg/ml; however, modifications of the labeling procedures can accommodate lower concentrations, especially when labeling small amounts of antibody (0.1 to 1.0 mg). Thus, the antibody concentration may be 2 to 10 mg/ml.

12. Weigh 3 to 5 mg of SMCC and immediately before use dissolve it in DMSO or DMF to obtain a 10 mg/ml solution. Vortex or sonicate to assure complete dissolution.

13. While stirring, add 15 µl of SMCC solution to each 5 mg of antibody to obtain a molar ratio of reagent to antibody of ~15.

    The amount of SMCC should be tailored to the concentration of the antibody. For example: 5 mg of antibody at the concentration of 2 mg/ml would require 15 to 17 µl of the above SMCC solution, while antibody at 10 mg/ml would yield a better conjugate when using a molar ratio of SMCC of 10.

14. Incubate 1 hr at room temperature with gentle stirring.

15. Dialyze 24 hr in the cold with four changes of 1 liter or more reaction buffer.

Deprotect the enzyme thiol groups

NOTE: It is essential that this procedure be carried out simultaneously to the labeling of the antibody with maleimide groups, because both the deprotected thiols of the enzyme and the maleimide groups of the antibody are unstable in water and are best used within a day from their preparation.

Deprotect with DTT

16a. Add 8.0 mg of DTT to each milliliter of the enzyme solution. Incubate 15 to 20 min at room temperature.

17a. Dialyze the thiolated enzyme 24 hr in the cold against 2 liters reaction buffer, with at least four changes of buffer to eliminate as much of the DTT as possible.

Deprotect with TCEP

16b. Calculate the volume of 1 mg/ml TCEP stock solution needed to obtain an incubation molar ratio of 5 moles of TCEP per mole of enzyme

$$\mu l \text{ of TCEP} = (\text{mg of enzyme})/(1 \text{ mg/ml TCEP}) \times 286.7/(\text{MW of enzyme}) \times 5 \times 1000$$

where 286.7 is the MW of TCEP, 5 is the incubation molar ratio, and 1000 is a unit conversion factor. Weigh out 3 to 5 mg of TCEP powder, and dissolve it in 3 to 5 ml reaction buffer to make a 1 mg/ml solution of TCEP.

Alternatively, TCEP can be used in place of DTT to deprotect sulfhydryl groups (Getz et al., 1999). TCEP does not react with maleimides. Thus, one need not eliminate excess TCEP from the reaction mixture, avoiding the need to dialyze to exhaustion. TCEP is very reactive and should be used at an incubation molar ratio of 5 TCEP per mole of enzyme.

17b. Add the appropriate amount of TCEP stock solution to the thiolated enzyme solution, and mix well. Incubate the mixture 10 to 15 min at room temperature.

Synthesize the antibody-enzyme conjugate

18a. *For HRPO, APase, and GO:* Transfer the antibody and the HRPO or APase from the dialysis tubes into two separate test tubes. Slowly drip the antibody solution into the enzyme solution with stirring. Incubate 1 hr at room temperature and overnight at 4°C.

18b. *For βGase:* For each 5 mg of antibody dissolve 15 mg of enzyme in 1.5 ml reaction buffer and proceed as in step 18a.

19. Stop the reaction for HRPO, GO, and APase conjugates with the addition of *N*-ethylmaleimide (NEM) at a final concentration of 50 μM, by diluting the NEM solution 1:1000 in the conjugate reaction mixture. Incubate 30 min at room temperature.

The conjugate is now ready to be purified by column chromatography, immediately or after overnight storage at 4°C.

The reaction of βGase cannot be stopped because of the large number of –SH groups of this enzyme.

Purify the antibody-enzyme conjugate

20. Concentrate the antibody-enzyme conjugate in a centrifugal filter device at the speed recommended by the manufacturer.

21. Pack appropriate size columns (e.g., 1 × 60–cm for 10 mg of protein in the conjugate reaction mixture) with the appropriate matrix.

    For purification of HRPO-antibody conjugate use Sephacryl S-200 in reaction buffer. For GO and APase-antibody conjugates use Bio-Gel A-0.5m in 3 M NaCl/30 mM TEA/1 mM $MgCl_2$, pH 7.6; for BGase Bio-Gel A-1.5m in reaction buffer, with the addition of 3 mM $MgCl_2$ and 2 mM 2-mercaptoethanol.

22. Load the conjugate onto the column, elute with the buffer used to pack the column, collecting 1-ml fractions.

    The first peak to elute, measurable by absorbance at 280 nm, or 403 nm for HRPO conjugates, corresponds to the conjugate. However, each fraction should be checked for antibody binding and enzymatic activity in an ELISA-type (APPENDIX 3) or other appropriate assay.

    An alternative method to purify antibody-enzyme conjugates from the unreacted enzyme relies on the affinity of the Fc portion of the antibody for nickel chelates. An affinity column based on this principle is available from Pierce Chemical. The Fc region complexes with nickel on the column while the unconjugated enzyme passes through. The bound antibody-enzyme conjugate can be eluted by lowering the pH, by increasing the salt concentration, or by simply adding EDTA to the elution buffer. A detailed procedure for using this affinity column accompanies the product. This column cannot be used for $F(ab')_2$ or Fab fragments, as they are devoid of the Fc region (Hermanson, 1996a).

CONJUGATION AT THE CARBOHYDRATE SITE OF THE ANTIBODY

ALTERNATE PROTOCOL 2

The sugar constituents of glycoproteins contain vicinal hydroxyl groups that can be oxidized to dialdehydes by treatment with periodic acid or its salts. The dialdehydes formed easily react with amines, including the hydrazide form of fluorophores, the ε-amino group of lysines, and the amino terminus of proteins. The carbohydrate-containing portion of an antibody molecule is located in the Fc region; thus, the periodate oxidation method of conjugating antibodies allows labeling at a specific location, remote from the antigen binding site.

CAUTION: Some monoclonal antibodies are not glycosylated and cannot, therefore, be conjugated by this procedure.

Materials

Antibody to label in solution (see Basic Protocol 1, step 1)
0.1 M acetate buffer, pH 6.0
20 mM sodium metaperiodate in acetate buffer, pH 6.0, ice cold
Reaction buffer, pH 7.5 (see recipe)
100 mM aqueous sodium cyanoborohydride, freshly prepared
HRPO, APase, βGase, GO
Column chromatography matrices (see Basic Protocol 2)

NOTE: Protect the sample from light during the entire procedure.

1. Dialyze the antibody at 2 to 10 mg/ml in 0.1 M acetate buffer, pH 6.0, at 4°C.
2. Keeping the dialyzed antibody on ice, add an equal volume of ice-cold metaperiodate solution. Incubate 2 hr in the dark at 4°C.
3. Purify the oxidized antibody: If the antibody is dilute (<1 mg/ml), dialyze it against the same buffer, protecting it from light. If the antibody is concentrated, purify it on a desalting column (Bio-Gel P-30 or equivalent) in free-standing or spin-column form (Basic Protocol 1, step 8) to remove the iodate that is produced during the oxidation.

4. Prepare a solution of the enzyme of choice in reaction buffer in the amount needed to obtain an incubation molar ratio of enzyme to antibody of 2 to 10, according to the type of conjugate desired.

   For instance, if a 1:1 ratio of probe to antibody is desired, use an incubation molar ratio of 2; otherwise, the higher the desired enzyme-antibody ratio, the higher will be the necessary incubation molar ratio.

5. Slowly add the antibody to the enzyme solution with stirring and incubate the mixture for 2 hr at room temperature with gentle stirring.

6. (*Optional*) To stabilize the imine bond into a substituted hydrazide, add sodium cyanoborohydride to a final concentration of 10 mM, adding 1/10 vol of a 100 mM stock solution of sodium cyanoborohydride in distilled water. Incubate for 2 hr at 4°C.

   Some researchers consider the imine bond between the sugars on the antibody and the amines on the enzymes to be relatively unstable.

7. Purify the conjugate by any of the chromatography methods (see Basic Protocol 2, step 21).

ALTERNATE PROTOCOL 3

CONJUGATION AT THE CARBOHYDRATE SITE OF THE ENZYME

Since HRPO and GO are glycoproteins, Alternate Protocol 2 can be modified by oxidizing the sugar on the enzyme and, following removal of excess reagent, adding it to the native antibody solution. The steps, molar ratios, and times suggested in Alternate Protocol 2 can be applied to this "reversed" version of the procedure. GO is a flavoenzyme consisting of two 80-kDa subunits that are rich in carbohydrates and joined by a disulphide bond (O'Malley and Weaver, 1972). The conjugation method of choice for GO involves oxidizing the enzyme with periodate at its carbohydrate site. The antibody can then be conjugated to GO through one or more of its amino groups (Rodwell et al., 1986; Husain and Bieniarz, 1994; Hage et al., 1997).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Hydroxylamine, I.5 M, pH 8.0

4.2 g hydroxylamine, hydrochloride
25 ml H_2O
Adjust the pH to 8.0 with 5 M NaOH
Add H_2O to 40 ml
Prepare fresh

Phosphate-buffered saline (PBS)

1.1 g K_2HPO_4
0.43 g KH_2PO_4
9 g NaCl
900 ml H_2O
Adjust the pH to 7.2 or 7.4, if necessary, with 1 M sodium bicarbonate (see recipe)
Add H_2O to 1 liter
Store 1 week at 4°C

The final concentrations are 0.01 M potassium phosphate, 0.15 M NaCl, pH 7.2.

Reaction buffer

11.5 g Na_2HPO_4
2.6 g NaH_2PO_4
5.8 g NaCl
900 ml H_2O
Adjust the pH to 7.5 with 5 M NaOH
Add H_2O to 1 liter
Store 2 weeks at 4°C

For labeling IgM, adjust the pH to 7.2.

Sodium bicarbonate, 1.0 M

8.3 g $NaHCO_3$
100 ml H_2O
Store 2 weeks at 4°C

The resulting pH is generally 8.3 to 8.5

This bicarbonate solution is used to raise the pH of PBS.

TEA buffer

For each liter of buffer, weigh 175 g of NaCl and dissolve it in 750 ml H_2O. Add 4.08 ml of TEA (98%, $\rho = 1.12$ g/ml). Prepare a stock solution of 0.5 M $MgCl_2$ and 0.05 M $ZnCl_2$ by weighing 10.16 g of $MgCl_2$ and 0.68 g of $ZnCl_2$ and dissolving them in distilled water to obtain a final volume of 100 ml. Add 2.0 ml of this stock to the NaCl-TEA solution. Adjust the pH to 7.6 with 3 M HCl, and bring the volume to 1.0 liter with H_2O. Store at 4°C. For prolonged storage (>1 week), add azide to 2 mM final concentration.

This buffer is used for APase only.

Final concentrations are 3.0 M NaCl, 30 mM TEA, 1.0 mM $MgCl_2$, 1.0 mM $ZnCl_2$, pH 7.6.

COMMENTARY

Background Information

Antibodies

The use of antibodies as probes has become widespread in the biosciences. In immunocytochemical applications, the use of labeled secondary antibodies is limited by the number of targets to be detected by different antibodies. This is due to the fact that secondary antibodies, even when purified by immunoadsorption against related species, nonetheless exhibit significant residual cross-reactivity when more than two antibodies are used to stain multiple features of the same sample. Thus, to detect multiple structures or functions simultaneously, direct labeling of primary antibodies with fluorophores, biotin, or enzymes is essential. Biotinylation of antibodies allows detection with fluorescently labeled avidin (or analogous molecules), generally without interference from the secondary antibody or antibodies required in the experimental procedure. Investigators new to the field might refer for general information on the theory of fluorescence and applications of fluorescent probes to the introduction to the topic by Johnson (1996; see also *UNIT 4.2*) and for avidin-biotin technology to the review by Wilchek and Bayer (1990).

For procedures employing fluorescent labeling of primary antibodies, it is important to select probes with the highest quantum yield, because signals from these antibodies lack the amplification obtained with the secondary antibodies. Signal amplification can be achieved by conjugating antibodies with enzymes that use fluorogenic or colorimetric substrates. These substrates should be of the precipitating type for histological preparations or soluble for ELISA and other microplate assays.

Very useful antibody labeling kits, containing detailed instructions, premeasured reactive fluorophores or biotin are now available from a few commercial sources (Amersham Pharmacia Biotech, Molecular Probes, Pierce). These kits generally allow conjugations of 0.2 to 10 mg of an antibody. They are ideal for researchers who need to perform labeling procedures only occasionally or do not have the necessary equipment (e.g., separation columns and solvent for the la-

beling reagent) readily available. They also represent a good starting step for researchers who want to familiarize themselves with the labeling procedure before acquiring larger amounts of the materials and reagents needed for the conjugation.

Fluorophores

The most commonly used amine-labeling reagents belong to three classes of acylating compounds:

1. Isothiocyanates. The isothiocyanate derivatives of fluorophores are relatively stable in aqueous solution. They react with amines at pH 9 to 9.5 to yield thiourea bonds. In this class, fluorescein isothiocyanate (FITC) and tetramethylrhodamine isothiocyanate (TRITC) are the most widely used.

2. Sulfonyl halides. The most commonly used probes in this category are the sulfonyl chloride of Texas Red and that of Lissamine rhodamine B. This reactive form of fluorophores is extremely labile in water. Consequently, in conjugation with proteins the reaction rate is strongly counteracted by the hydrolysis rate of the dye, making reproducibility of the reaction difficult. Also sulfonyl chlorides require relatively basic conditions, pH 9.0 to 9.5, to react with amines.

3. Succinimidyl esters. Reagents of this form react more selectively with aliphatic amines than the isothiocyanates by forming stable carboxamide bonds at pH 7.5 to 8.5 (Haugland, 1996a). Most fluorophores, including fluorescein, rhodamine, Cy3, Cy5, and the new Alexa Fluor dyes, are available as succinimidyl esters (Haugland, 1999). These are highly preferred because of their greater selectivity for amino groups (Wong, 1991), relatively slow hydrolysis rate (Wong, 1991), and high reactivity at lower pH (Hermanson, 1996b), closer to physiological pH. Because of their still high reactivity at pH 7.2, succinimidyl esters can be used efficiently to label IgM antibodies, which tend to denature when the pH is above 7.4.

The author strongly recommends using fluorescein, tetramethylrhodamine, and Texas Red in their succinimidyl ester forms. In the past, fluorescein and tetramethylrhodamine were available only as isothiocyanates, broadly known in their abbreviated forms as FITC and TRITC, respectively. Texas Red was available only as its sulfonyl chloride, which has an extremely rapid rate of hydrolysis in buffer. The new, succinimidyl ester forms of these dyes are preferable, because they will generally yield more reproducible and stable antibody conjugates (Banks and Paquette, 1995; Lefevre et al., 1996).

In determining the degree of antibody labeling in fluorophore conjugates, one should note that the values, both of the extinction coefficients and of the correction factors described in Table 16.5.2, are only approximate. These values are not corrected for the change in extinction coefficients that may occur when the dyes are conjugated to proteins. This change in extinction coefficient can vary from protein to protein, and it can vary with the number of dyes reacted with the protein, due to interference between dye molecules (Ravdin and Axelrod, 1977). Thus, determination of the degree of labeling is relative and approximate. Nonetheless, it is invaluable when comparing different preparations of the same antibody conjugate and for determining the relative optimal number of moles of fluorophores per mole of antibody for particular biological applications.

Phycobiliproteins

This unit does not include protocols for conjugation of antibodies with phycobiliproteins—large, highly fluorescent pigments that are isolated from the photosynthetic apparatus of algae. The conjugation procedure of phycobiliprotein to antibodies is very similar to Basic Protocol 2. Molecular Probes offers a protocol for conjugation with phycobiliproteins, and details are published (Haugland, 1996b). A kit that greatly facilitates phycobiliprotein conjugation is available from Prozyme, although it does not lend itself to optimizing the procedure. The Protein-to-Protein Crosslinking Kit from Molecular Probes could be used for this purpose. However, obtaining the phycobiliprotein of interest, R-phycoerytin (R-PE) or allophycocyanin (APC), already derivatized with 1 to 2 pyridyldisulfide groups per molecule is strongly recommend. This is more economical than preparing and optimizing the activated protein.

Other fluorophores

Fluorophores with enhanced water solubility and fluorescence output have been developed by introducing sulfonic groups in the rings of their molecule. This procedure also confers negative charges that help to decrease interaction between fluorophores and to minimize the loss of probe fluorescence that generally occurs upon conjugation to biological molecules. The excitation wavelengths for these sulfonated fluorophores span the entire spectrum from excitation in the UV range to the 633-nm excitation of the HeNe laser. They include the Alexa Fluor dyes, prepared by sulfonating coumarins or rhodamines (Panchuk-Voloshina et al., 1999), Cy dyes, prepared by sulfonating carbocyanines (Mujumdar et al.,

1989, 1993, 1996), and Cascade Blue, which is a pyrenetrisulfonic acid derivative (Whitaker et al., 1991). Each of these dyes generally offers enhanced signal-to-noise ratios. Many of these dyes form conjugates that tolerate a higher number of moles of dyes per mole of antibody in comparison with the non-sulfonated ones, while avoiding quenching of the fluorescence or precipitation of the antibody (Panchuk-Voloshina et al., 1999). In rare cases the negative charges on these dyes may cause nonspecific interaction with positive charges of the cells under investigation. In these cases, which unfortunately can be determined only experimentally, the nonsulfonated form of the dye (e.g., TAMRA, instead of Alexa Fluor 546, or Texas Red-X, instead of Alexa Fluor 594) should be used. Fluorescein itself carries two negative charges, and in cases of background problems the neutral BODIPY FL can be tried as an alternative.

Biotin

Biotin is a small, ubiquitous molecule that acts as a coenzyme of carboxylases. Due to its strong affinity for avidin and avidin-like molecules (K_d = 1.3×10^{-15} M at pH 5.0), it is broadly used as a label that can be probed with fluorescent or enzyme-linked avidin or streptavidin. Avidin (MW = 66 kDa) and streptavidin (MW = 60 kDa), both tetrameric proteins with ~33% homology in their amino acids composition, can each bind four molecules of biotin (Green, 1975).

Iminobiotin, a modified biotin with lower affinity for avidin, is occasionally used in place of biotin to prepare conjugates that can be separated by affinity chromatography. The succinimidyl ester of iminobiotin can be used to effect labeling of a tag only transiently because the iminobiotin-avidin complex dissociates at low pH (Hoffman et al., 1980; Orr, 1981). Affinity purification of biotinylated conjugates is also possible with monomeric avidin, which has a lower affinity for biotin than the tetrameric form and is now commercially available (Pierce Chemical). Nitroavidin, another form of monovalent avidin with a lower affinity for biotin, can be prepared by selectively nitrating three of the tyrosines, each located at the active site of avidin or streptavidin subunits, leaving just one site available for biotin binding (Morag et al., 1996). Another commercially available form of reactive biotin is the DNP biocytin succinimidyl ester, which carries the colorimetric properties of dinitrophenyl (DNP) and the avidin-binding properties of biotin (Briggs and Panfili, 1991; Haugland, 1996c). With this reagent, direct spectrophotometric measurement of the number of moles of biotin per mole of antibody can be achieved by using the molar extinction coefficient of DNP (15,000 $cm^{-1}M^{-1}$ at 364 nm). This reagent (MW = 862 Da) is larger than most common fluorophores and the reactive biotins described above. Thus, more reagent is necessary to obtain an efficient incubation molar ratio of reagent to antibody during the reaction, because larger molecules react more easily with surface groups and have difficulty reaching internal lysines. However, the presence of the DNP group on the conjugate offers a second tag on the target and the conjugate can be further probed with an anti-DNP antibody (Haugland, 1996c).

Enzymes

Antibody-enzyme conjugates are probably the most widely prepared antibody-based reagents because they are broadly used in diagnostic clinical tests. HRPO conjugates represent ~70% to 80% of the antibody-enzyme conjugates in common use, while APase makes up for most of the remainder; βGase and GO represent ~2%, and they are used primarily in research. The major applications of enzyme-conjugated antibodies lie in immunocytochemical studies of cells or tissue slices and in enzyme-linked immunosorbent assays (ELISA) for quantifying and detecting a wide variety of analytes. The activity of the conjugated enzyme causes the accumulation of measurable enzyme product in the test system, offering amplification of the signal and high assay sensitivity.

It is important to consider the experimental application for which the antibodies are to be conjugated with the enzymes. For cytological or histological studies, conjugates comprised of one enzyme and one antibody molecule are preferable, because, in general, larger conjugates are accompanied by higher background signals. The MW of IgG is ~150 kDa, and IgM is often >850 kDa. Enzymes can also be rather large (e.g., glucose oxidase (GO, MW = 160 kDa), alkaline phosphatase (APase, MW = 140 kDa), β-galactosidase (βGase, MW = 540 kDa)). Consequently, the mass of the antibody-enzyme conjugate can be considerable, especially when multiple enzyme molecules are bound to one antibody molecule. In contrast, for ELISA-based tests, in which only the total signal is essential, larger enzyme-antibody aggregates often increase the sensitivity of the assay.

The simplest method (and one of the oldest) to prepare enzyme-antibody conjugates involves mixing the two conjugate components and adding a "condensation" reagent, generally glutaralde-

hyde, to crosslink the two proteins at random amines. This method presents problems, however. Although conditions can be determined for obtaining an optimal yield of the enzyme-antibody conjugate, nonetheless, unwanted homopolymers of enzyme or of antibody are invariably obtained. Furthermore, this method is impractical for obtaining antibodies labeled with only one enzyme molecule.

Another commonly used method relies on the reaction of a maleimide-labeled enzyme (such as with SMCC, as described in Basic Protocol 2 for derivatizing the antibody) with an antibody or $F(ab')_2$ fragment. The maleimide groups interact with sulfhydryl groups in the hinge region after the disulfide bonds have been reduced by 2-mercaptoethylamine, in the presence of EDTA. Optimizing this procedure involves minimizing the disruption of other disulfide bridges within the antibody molecule and at the same time reducing a sufficient fraction of the hinge disulfides to give an optimal yield of conjugate. 2-Mercaptoethylamine is chosen for this reduction because it is more controllable than dithiothreitol. Details for this method can be found in Hermanson (1996c).

The basic approach described in this unit for preparing antibody-enzyme conjugates is based on forming thioether bonds between a maleimide group on the antibody and a free thiol on the enzyme. These two reactive groups are obtained by derivatizing the conjugate components with the heterobifunctional crosslinking reagents, SMCC and SPDP. This approach is "controllable" and easier to optimize than are other methods. Similar methods that involve reaction of the maleimide crosslinking reagent to the enzyme and conjugation of the sulfhydryl crosslinking reagent to the antibody have been also reported. This "reverse" method, however, is recommended only when *S*-acetylthioglycolic acid *N*-hydroxysuccinimide ester (SATA) is used as the thiolating reagent, because iminothiolane yields very unstable free thiol groups, and SPDP entails reduction with DTT or TCEP, which might disrupt the disulfide groups of the antibody. Furthermore, because deprotection of the thiol in SATA requires only exposure to hydroxylamine (Duncan et al., 1983), the antibody molecule is less likely to be altered. However, one should also consider that assaying for the free thiols generated with either iminothiolane or SATA requires a relatively large amount of antibody. In contrast, the release of pyridyl-2-thione from SPDP reduction permits one to promptly determine the number of free thiols obtained per molecule of enzyme by measuring absorption (Carlsson et al., 1978), yielding the precise number of reactive sites. This offers two advantages: (1) the enzyme can be derivatized with only 1 to 2 sulfhydryl groups in order to obtain mostly heteroconjugates of one enzyme per antibody molecule, and (2) the activity of the enzyme can be disrupted to a lesser degree when only 1 or 2 amines are derivatized.

The protocols presented in this unit for linking enzymes to antibodies can be tailored to the antibody-specific application by modulating the number of reactive crosslinking groups with which the antibody or the enzyme is modified. When free thiols are available, as with βGase, no chemical modification of the enzyme is necessary. Enzymes derivatized with only 1 to 1.5 thiol and antibodies carrying only a few maleimide groups generally yield heteroconjugates, most of which have one enzyme and one antibody. By introducing a larger number of thiols on the enzyme or a larger number of maleimide groups on the antibody, it is possible to obtain small aggregates consisting of one or more antibody molecule conjugated to two or more enzyme molecules.

Critical Parameters

Preparation of the antibody for conjugation

Before being conjugated to a probe, antibodies should be as free as possible of other proteins. Association with extraneous proteins can arise from inadequate purification of the antibody or from stabilizers added to diluted antibody preparation such as bovine serum albumin (BSA) or gelatin. The proper buffer and pH for the antibody conjugation can be obtained by dialysis or by adding 1 M bicarbonate when the antibody is dissolved in PBS. When antibodies are in PBS solution, the pH can be easily changed by adding 1/10 volume of 1 M sodium bicarbonate at pH 8.3 or 9.0, depending on which probe is used. This obviates the need for dialysis, accompanied by losses of material during manipulation of the antibody solution. One should note, however, that the buffer in which the antibody is dissolved should contain no primary amines (e.g., TRIS, glycine, or traces of ammonium sulfate), because they will react with the amine-reactive probe.

Solubility, storage, and stability

Most dyes, biotin, and cross-linking reagents are poorly soluble in buffers, and they require solubilization in an organic solvent such as dimethylformamide (DMF) or dimethylsulfoxide (DMSO). Some of the most recently introduced dyes that exhibit greater fluorescence output and photostability (Cy and Alexa Fluor series) have

improved or good solubility in water, because of the sulfonic groups introduced in the ring of their molecule (Panchuk-Voloshina et al., 1999). Some labeling reagents are available as sulfosuccinimidyl esters, with a sulfonic acid as part of the reactive group, which increases water solubility but may decrease the overall conjugation efficiency. However, in the author's experience, dissolving the labeling reagent as a concentrated solution in DMF or DMSO (10 to 20 mg/ml) and then adding it to the antibody solution in amounts such that the solvent does not exceed 10% of the reaction mixture, does not generally decrease the antibody binding activity. The presence of the solvent, in fact, helps to maintain the labeling reagent in solution and favors the efficiency of the conjugation reaction.

All labeling reagents should be stored desiccated at −20°C. Antibody conjugates of fluorophores, biotin, or enzymes can be stored frozen in small aliquots, avoiding repeated freezing and thawing. The defrosted aliquots should be stable at 4°C for ≥1 week. Labeled antibodies generally maintain the storage requirements of their native form. However, introduction of dyes or biotin to the molecule, with concomitant loss of the positive charges of the tagged lysines or addition of enzyme molecules, may favor aggregation. Therefore, it is good practice to centrifuge antibodies and particularly antibody conjugates briefly in a microcentrifuge before use. Antibodies at concentrations <1 mg/ml are often unstable and should be stored in presence of 1 to 10 mg/ml BSA to avoid denaturation.

Appropriate degree of labeling

The appropriate number of labels per antibody molecule depends on the probe. In general, the number of labels that a protein tolerates before losing its biological activity is proportional to its molecular weight. In the author's experience, a 10- to 20-kDa protein preserves its activity when only one probe molecule per protein molecule is conjugated to the ε-amino group of a lysine. Thus 4 to 8 moles of probe per mole of an IgG antibody are possible in the case of relatively small or hydrophilic molecules (such as fluorescein, biotin, or sulfonated dyes) or 2 to 4 moles, in the case of hydrophobic probes, such as rhodamines. Excessive labeling may present problems: the antibody conjugate might aggregate or precipitate, lose binding activity to the protein, exhibit low fluorescence output due to quenching, or exhibit high background fluorescence in biological applications. The latter phenomenon can arise from a loss of specificity due to structural changes in the antibody caused by the high number of fluorophores substituting the positive charged amines. The Fab fragment (Fig. 16.5.1E), tolerates two or three fluorescein or Alexa Fluor 488 molecules well, but only one Texas Red or rhodamine. $F(ab')_2$ fragments (Fig. 16.5.1D) can be labeled with three to four fluorescein molecules or one to two Texas Red molecules. Consequently, when using Fab fragments, one should use smaller molar ratios of reactive probe to antibody than those recommended in Table 16.5.1 for native antibodies. Precipitated antibodies generally cannot be recovered.

Choosing the appropriate fluorophore

The choice of fluorophore for a particular application should be based on the following considerations. When the fluorescence microscope is the detection instrument, for single-color experiments the choice should be dictated by the spectral properties of the dye relative to the excitation source, the brightness of the probe, and its photostability. Photostability is less essential in flow cytometry experiments. For multiple-color experiments, minimal spectral overlap among the chosen fluorophores is essential. For samples with pronounced autofluorescence, longer wavelength emission dyes are better than the green fluorescence–emitting ones because the autofluorescence background will be lower. Table 16.5.2 describes the optical properties of the most commonly used fluorophores for the labeling of antibodies (also see *APPENDIX 1E*).

Choosing the appropriate incubation molar ratio of fluorophore or biotin to antibody

The factors that determine the number of moles of probe per mole of antibody (degree of labeling) that will be present in the purified conjugate are:

(1) Reactivity of the dye. This varies from dye to dye; it is pH and temperature dependent, and it must be taken into consideration when planning the reaction molar ratio of reagent to protein to use. (2) Concentration of the antibody. As in any chemical reaction, the reagent concentrations determine the rate and efficiency of the reaction and will generate higher yields of conjugate at higher concentrations. (3) Structure of the antibody. Although the Fc portion of the antibody molecule is relatively preserved, the amino acid composition of the remaining regions is quite varied and contains lysine residues in different numbers and positions. Consequently, the reactivity of each antibody is different. When possible, three or more molar incubation ratios of dye, biotin, or crosslinking reagent to antibody should be tried

Table 16.5.3 Performance of Commercially Available Anti-Photobleaching Reagents[a,b]

[b]Abbreviations: nt: not tested; PBS: phosphate-buffered saline.

[c]Notes: In addition to testing anti-photobleaching reagents listed in the table, the authors tested the performance of the following anti-photobleaching reagents when used with the dyes in the Alexa Fluor series: Crystal Mount, Gel Mount, Immu-Mount, Fluor-Save, Clarion, Aqua-Poly Mount, Mowiol. Aqua-Poly Mount and Mowiol worked well with Alexa Fluor 546.

to obtain a degree of labeling of the probe-antibody conjugate that will work best in the specific application. Table 16.5.1 gives guidelines of suggested incubation molar ratios of probe to antibody for different concentrations of antibody. The guidelines are very general and individual antibodies may require customized variations. As previously mentioned, it is desirable to try three different degrees of labeling or, if that is not possible, aim for a moderate degree of labeling of three to four fluorophore moles per mole of antibody. Also note that it is possible to label an antibody for the second time, but it is not possible to reduce the moles of dye per antibody following a conjugation because they are covalently attached.

Choosing the appropriate biotin-binding protein

Avidin is a highly positively charged glycoprotein, rich in mannose and glucosamine. Thus, it may interact nonspecifically with negatively charged molecules within the cell or with sugar receptors of the cell membrane. For this reason, a chemically modified avidin, deglycosylated, and with a lower isoelectric point has been developed. It is commercially available in both unconjugated and conjugated forms under the trademark, NeutrAvidin (Haugland, 1999). Streptavidin is not glycosylated, and it generally yields less nonspecific binding than avidin. However, streptavidin contains the amino acid sequence Arg-Gly-Asp (RYD) that mimics the binding peptide of fibronectin (RGD), a universally recognized domain of the extracellular matrix. Thus, although it is rare, nonspecific interaction is possible also with streptavidin (Alon et al., 1990), in which cases, avidin or its NeutrAvidin form may be preferable.

Choosing the appropriate biotinylation reagent

As described for conjugations with fluorophores, the most broadly used reactive biotin for conjugation with antibodies is the succinimidyl ester form. Three types of succinimidyl esters are available: either biotin derivatized directly at the carboxyl with the reactive group or with a 7- or

14-atom spacer between the carboxyl and the reactive group (called biotin-X and biotin-XX, respectively). The addition of a spacer favors the efficiency of formation of the complex between avidin and the biotinylated antibody, possibly by facilitating the interaction of the biotin group with the hydrophobic crevice of the avidin binding site (Gretch et al., 1987; Hnatowich et al., 1987). Biotin-X and biotin-XX can be used interchangeably, although in this laboratory the authors have found that biotin-XX gives a somewhat higher signal in ELISA (Haugland and You, 1998). Sulfosuccinimidyl esters of biotin, which are highly water soluble are also commercially available. However, this form is generally less reactive and requires a higher molar incubation ratio of reagent to antibody.

Fluorescence intensity in histological preparations

For detection by microscopy, either conventional or confocal, the resistance of the fluorophores to photobleaching is a critical concern. It is very frustrating to see an image disappear as soon as it is in focus. There is considerable variation in the performance of anti-photobleaching products with different fluorophores. The author has tried many of the commercially available anti-photobleaching reagents in cellular preparations stained with the most commonly used fluorophores. The results from this study are reported in Table 16.5.3.

Anticipated Results

The protocols in this unit are established and have a high probability of success. The exact degree of labeling depends on the antibody to be labeled and the application for which it is used. The reactions may be scaled up or down.

Time Considerations

Fluorophore or biotin conjugation and purification of the conjugated antibody will take ~3 hr. Checking the degree of labeling will take 30 to 60 min. Longer times (~2 days) are required when working with very dilute antibodies that require dialysis for purification. Conjugation with enzymes and purification of the conjugated antibody will take ~5 days.

Production of Antibodies That Recognize Specific Tyrosine-Phosphorylated Peptides

It is possible to produce anti-phosphopeptide antibodies (i.e., antibodies recognizing phosphorylated peptides) that recognize a protein only in its phosphorylated state, and that do not cross-react with either the cognate unphosphorylated protein or other phosphoproteins. Because the state of phosphorylation is often indicative of a protein's functional state or activity, such antibodies provide a convenient probe of the functional state of a protein. Thus, unlike conventional antibodies, anti-phosphopeptide antibodies provide information regarding not only the abundance of a protein but also its activity. Unlike general anti–phosphoamino acid (e.g., anti-phosphotyrosine) antibodies, which have broad reactivity, anti-phosphopeptide antibodies may have unique specificity toward the cognate proteins. Such reagents not only facilitate conventional in vitro analysis of phosphoproteins, but also allow heretofore impossible applications—e.g., differential isolation of species of a particular protein that have been phosphorylated at individual phosphorylation sites, as well as analysis of the functional state of a protein in situ by immunohistochemical techniques.

Basic Protocol 1 describes the production of polyclonal anti-phosphopeptide antibodies and Basic Protocol 2 describes the production of monoclonal anti-phosphopeptide antibodies. Both of these procedures are based upon immunizing animals with oligopeptides that have been synthesized containing phosphorylated tyrosine; hence, a knowledge of the sequence and phosphorylation site of the protein of interest is a prerequisite for either protocol. Such an immunization will generate an immune response with at least four components: (1) anti–carrier protein reactivity, (2) general anti-phosphotyrosine reactivity, (3) phosphorylation-independent anti-peptide reactivity, and (4) phosphorylation-dependent anti-peptide reactivity. For the production of polyclonal antibodies (see Basic Protocol 1), a multiple-step affinity chromatographic purification with several negative-selection steps is carried out to produce a final antibody preparation having the desired reactivity. For production of monoclonal antibodies (see Basic Protocol 2), ELISAs are performed to screen candidate hybridoma supernatants against the cognate phosphopeptide, as well as against related phosphorylated and nonphosphorylated peptides, until one is found with the desired reactivity and specificity. Although monoclonal antibodies have a number of advantages, production of polyclonal antibodies is likely to be more predictable, as in the authors' experience a monoclonal hybridoma clone of stringent specificity may occur with very low frequency (see Critical Parameters). Production of monoclonal antibodies is also generally more time-consuming and expensive. The relative merits of monoclonal and polyclonal antibodies are discussed in the Chapter 16 introduction and in general antibody guides (see Key References). Support Protocols are provided for the coupling of peptides (see Support Protocol 2) and phosphotyrosine (see Support Protocol 3) to the affinity matrix (Affi-Gel 10); BSA-agarose affinity matrix is commercially available.

This unit describes production of antibodies against tyrosine-phosphorylated peptides, with which the authors have the most expertise, but the principles discussed here also apply to peptides phosphorylated on serine and threonine (see Key References).

PRODUCTION OF POLYCLONAL ANTI-PHOSPHOPEPTIDE ANTIBODIES

Strategic Planning

The first step of the planning phase is design and synthesis of the required peptides (see Support Protocol 1 and Background Information). The authors employ a peptide containing fifteen amino acids with the phosphorylation site Tyr in the center (residue 8). This peptide consists of fourteen amino acids from the actual sequence of the protein plus an N-terminal Lys to enhance coupling of the peptide to a carrier protein (BSA is used as a carrier in this protocol). The peptide, coupled to BSA, is then used to immunize rabbits. The cognate phosphopeptide is also immobilized on an affinity-chromatography column support (see Support Protocol 2); this affinity matrix will ultimately be used to purify the antibody from the rabbit serum. In addition, a series of negative-selection affinity-chromatography columns are used to adsorb antibodies from the serum that cross-react with epitopes other than the cognate phosphopeptide. These columns are composed of matrix coupled to various synthetic peptides—principally the cognate nonphosphorylated peptide (to remove phosphorylation-independent antibodies) and phosphotyrosine itself (to remove indiscriminant anti-phosphotyrosine reactivity; see Support Protocol 3 for preparation of phosphotyrosine affinity columns). Additional negative-selection steps may be used if needed, depending upon the particular target chosen, to remove antibodies that cross-react with phosphorylation sites of other proteins having known homology to the target site. This cross-reactivity occurs particularly when the target protein is a member of a family of homologous proteins—e.g., a subgroup of related receptor tyrosine protein kinases. If such cross-reactivity is anticipated, it is possible to synthesize not only the cognate phosphorylated and nonphosphorylated peptides, but also phosphopeptides based upon the related homologous sequences, to be used for negative selection. The authors also pass the serum over a column consisting of immobilized carrier protein (commercially available BSA-agarose) to remove the majority of the antibodies generated against the much larger carrier protein. Thus, a typical purification scheme might consist of the following:

Negative-selection affinity-purification columns

- BSA (carrier)
- phosphotyrosine
- cognate nonphosphopeptide
- homologous phosphopeptides (if desired)

Positive-selection affinity-purification column

- cognate phosphopeptide.

The second step in planning is to raise and test antisera in rabbits. To prepare the phosphopeptide-carrier conjugate for immunization of rabbits, the authors couple a 30-fold molar excess of phosphopeptide (14.4 mg dissolved in water and neutralized with 1 N NaOH) to BSA (20 mg dissolved in 0.4 M sodium phosphate buffer, pH 7.5), using glutaraldehyde as the cross-linking reagent as described in Doolittle (1986). The reaction is allowed to proceed 30 min at room temperature; the development of a yellow color in the coupling solution is an indication that the glutaraldehyde has reacted. Conjugation can be confirmed by performing an anti-phosphotyrosine immunoblot on a small test aliquot of the conjugate (although a smear should be expected on the blot, resulting from variation in the amount of peptide coupled per BSA molecule as well as from possible multimers of BSA). Guidelines for immunization of rabbits are provided in *UNIT 16.2*, and many institutions have core facilities for the immunization of rabbits and production of antisera. The authors immunize with 1 mg immunogen (the peptide-BSA conjugate

prepared above, dissolved in PBS) in 1 ml of a 50% emulsion with complete Freunds adjuvant. This is administered subcutaneously at multiple sites, followed by four boosts at 2-week intervals using the same quantity of immunogen in incomplete Freunds adjuvant. An adequate immune response can be seen as early as week 6.

The specificity of the final antibody is demonstrated most simply by immunoblot analysis (*UNIT 6.2*) using a panel of relevant phosphorylated and nonphosphorylated proteins. Electrophoresis is carried out with purified cognate protein in both its phosphorylated and unphosphorylated states, as well as with any proteins toward which there could conceivably be cross-reactivity. These are most easily isolated by immunoprecipitation using conventional antibodies. The blot is probed with the purified anti-phosphopeptide antibody to demonstrate appropriate reactivity. This immunoblot assay may also be used after each chromatographic step to monitor the success of the purification.

An assay also must be devised for estimating the titer of the immune response in the sera of the immunized rabbits. Convenient screening assays for this purpose include tests for the ability of crude sera to immunoprecipitate the target phosphoprotein from a cell lysate known to contain it, as well as immunoblotting of purified phosphorylated target protein with the crude serum.

The relationship among the above procedures is illustrated by the flow chart in Figure 16.6.1.

Purification Method

The purification of polyclonal antibodies consists of multiple affinity-chromatography steps for the negative and positive selection of antibodies of the appropriate reactivity (see Fig. 16.6.1). All of the following chromatographic steps may be carried out at room temperature, with the solutions applied to the columns by gravity.

Materials

BSA-agarose affinity matrix (Sigma) packed (see Support Protocol 2) in a 10-ml bed volume column

Phosphotyrosine affinity matrix column (10-ml bed volume; see Support Protocol 3)

Crude serum from rabbit immunized with phosphopeptide-BSA conjugate (refer to Strategic Planning, above)

PBS/azide: PBS (*APPENDIX 2A*) containing 0.02% (w/v) sodium azide (store indefinitely at 4°C or room temperature)

Cognate nonphosphopeptide affinity matrix column (3-ml bed volume; see Support Protocols 1 and 2 and Strategic Planning)

3 M NaSCN

Homologous phosphopeptide affinity matrix columns (optional; 3-ml bed volume; see Support Protocols 1 and 2 and Strategic Planning)

Positive-selection phosphopeptide affinity matrix column (3-ml bed volume; see Support Protocols 1 and 2 and Strategic Planning)

3.5 M and 4.5 M $MgCl_2$ (optional; see Critical Parameters)

Spectrophotometer (optional)

Dialysis tubing (MWCO 12,000 to 14,000; 10 mm width, 6.4 mm diameter; e.g., Spectra/Por 4 from Spectrum)

Additional reagents and equipment for dialysis (*APPENDIX 3C*), protein quantitation (*APPENDIX 3B*), and analysis of antibodies by ELISA (*APPENDIX 3A*) or immunoblotting (*UNIT 6.2*)

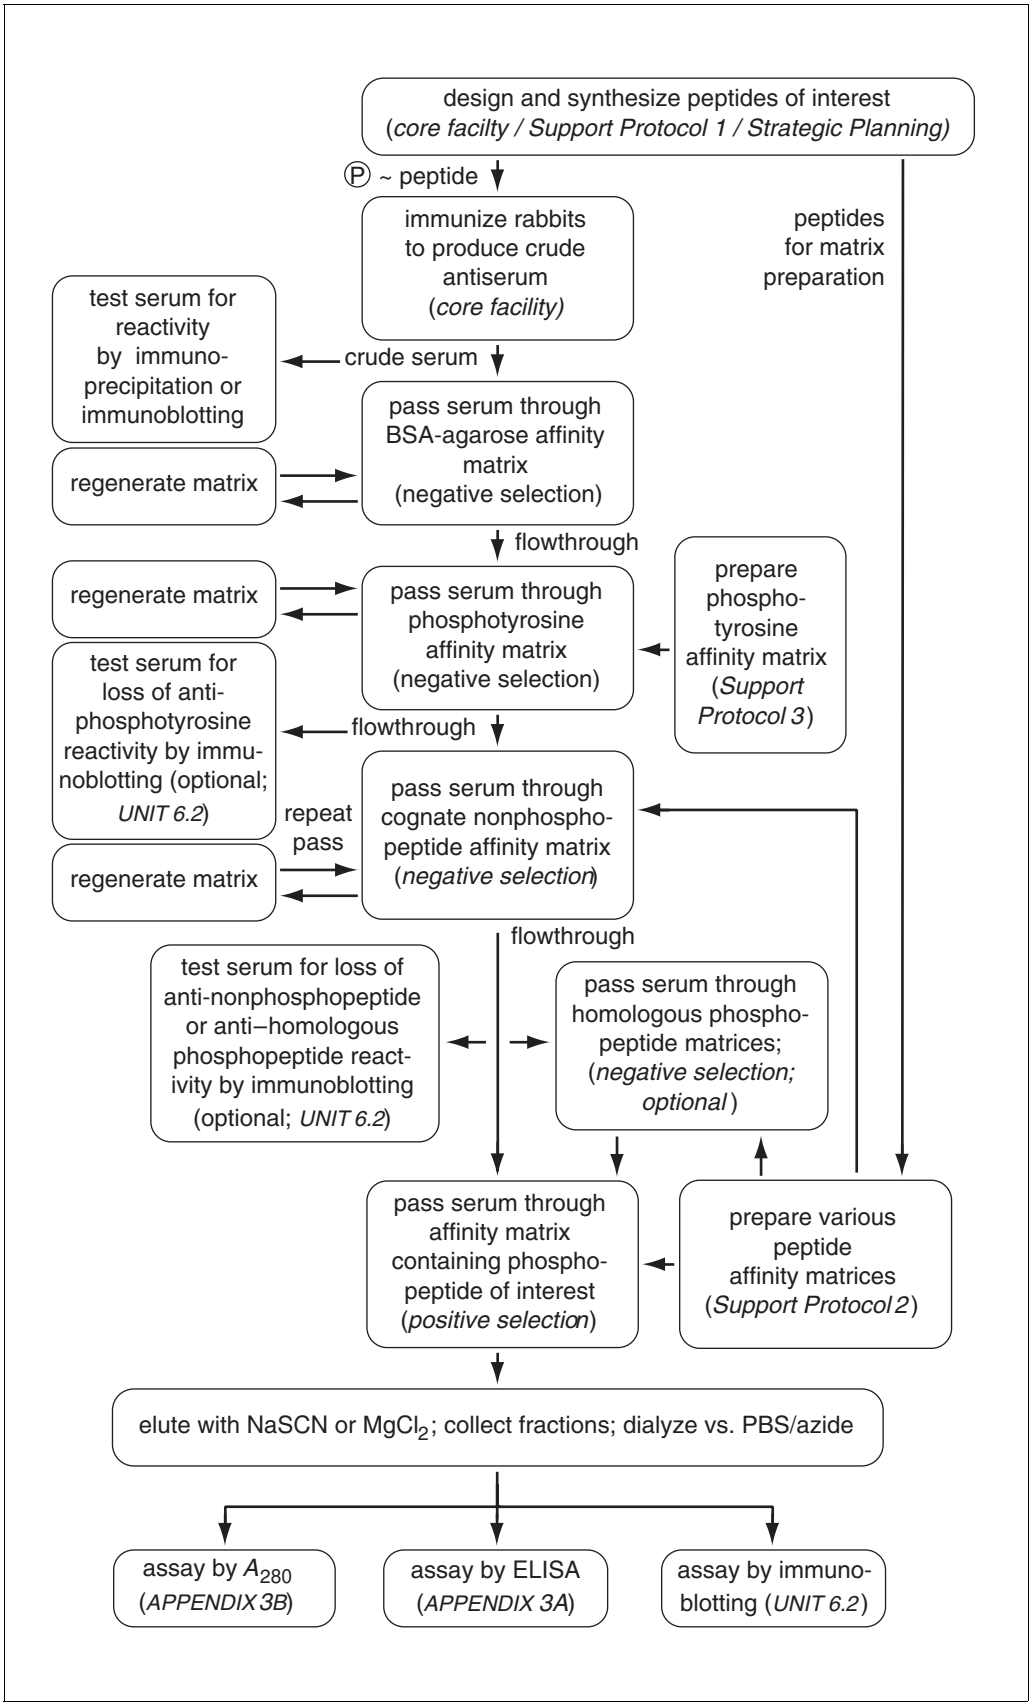

Figure 16.6.1 Flow chart for production of polyclonal anti-phosphopeptide antibodies.

Deplete reactivity of serum toward phosphotyrosine and carrier protein

1. Connect the washed BSA-agarose and phosphotyrosine affinity matrix columns in series.

2. Pass ~15 ml crude serum through the two columns, allowing it to flow through by gravity. Wash with PBS/azide until all of the yellow color of the serum has passed through the columns (or monitor the A_{280} of the column effluent spectrophotometrically until baseline absorbance is reached), then wash with an additional 5 to 10 ml PBS/azide, collecting all washings in the flowthrough fraction, which will contain the antibody of interest.

   Aliquots of the crude serum as well as this first flowthrough may be saved for subsequent analysis and comparison of individual purification fractions. The serum may be analyzed at this time for elimination of anti-phosphotyrosine reactivity by performing immunoblotting (UNIT 6.2) of samples containing a variety of phosphotyrosyl proteins; alternatively, it is possible to save an aliquot for analysis and proceed to the next step (see Troubleshooting).

   Expect that with each passage through a column, the volume of the serum will increase, which will prolong the amount of time needed for subsequent columns. Note that if flowthrough is monitored by the passage of the yellow color of the serum, this will become more difficult as the serum becomes more dilute.

   After the serum passes through, regenerate the columns by washing with 10 bed volumes of 3 M NaSCN followed by 10 bed volumes of PBS/azide, and store at 4°C in PBS/azide for future use.

Deplete reactivity of serum toward cognate nonphosphopeptide

3. Pass the flowthrough serum through the cognate nonphosphopeptide affinity matrix column by gravity as many times as necessary to deplete cross-reactivity, regenerating the column between passes by washing with 10 bed volumes of 3 M NaSCN followed by 10 bed volumes PBS/azide.

   A 15-ml starting serum sample may have to be passed over this column several times to quantitatively deplete cross-reactivity (see Critical Parameters). The serum may be analyzed after each or several passes, or an aliquot can be saved for analysis at a later time.

4. If cross-reactivity with homologous phosphoprotein(s) is anticipated, pass the flowthrough serum through the homologous phosphopeptide affinity matrix column(s) using the methodology described in step 3.

   Refer to Strategic Planning, above, for discussion of cross-reactivity with homologous phosphoproteins.

Purify antibodies by positive-selection affinity chromatography and dialysis

5. Hydrate and wash ~25-cm strips of dialysis tubing in advance for collection of fractions from the positive-selection affinity purification. Secure one end of each length of tubing with a dialysis clamp and check for leaks (APPENDIX 3C). Also prepare 6 liters PBS/azide and cool to 4°C in advance to use as the dialysis solution.

   To minimize the time that the antibodies are exposed to the elution solution, fractions (~3 ml each) from the positive-selection affinity column will be collected directly into preprepared dialysis tubing.

6. Pass the flowthrough serum from the previous chromatography step through the positive-selection phosphopeptide affinity column three times, without washing between passes.

   Three passes are performed to maximize the interaction of the antibody with the affinity matrix.

7. Collect the flowthrough serum from the final pass, then wash the column with 5 to 20 ml PBS/azide (depending upon the precolumn volume and column bed volume) and combine the washings with the flowthrough serum. Wash with an additional 20 ml PBS/azide, and collect the washings separately as the "wash" fraction.

8. Elute with chaotropic agent of choice: either 20 ml of 3 M NaSCN, or 10 ml of 3.5 M $MgCl_2$ followed by 10 ml of 4.5 M $MgCl_2$. Upon starting the elution, immediately begin collecting ~3-ml fractions directly into the dialysis bags prepared in step 5, securing the proximal end of the tubing with dialysis clamps and dropping the bag immediately into the PBS/azide dialysis solution. Collect at least six fractions.

   Alternatively, ~3-ml fractions can be collected in tubes and the liquid immediately placed into dialysis tubing upon completion of each fraction. Most of the antibody will elute in the first three fractions from a column of 2- to 3-ml bed volume. Regenerate the column as in step 3.

   See Critical Parameters for a discussion of the relative merits of NaSCN versus $MgCl_2$ as eluants.

9. Dialyze all fractions collected in step 8 exhaustively against PBS/azide at 4°C (*APPENDIX 3C*).

Analyze and store purified antibody

10. Determine protein concentration of dialyzed fractions by measuring absorbance at 280 nm or by a colorimetric protein assay (*APPENDIX 3B*) and calculate yield.

    The authors have generally recovered ≥1 mg of purified antibody from a 15-ml serum sample.

11. Store the antibody in aliquots at −70°C; store working aliquot at 4°C.

12. Assay the reactivity and cross-reactivity of the final samples, as well as any aliquots saved from previous steps, using ELISA (*APPENDIX 3A*) or immunoblotting (*UNIT 6.2*).

BASIC PROTOCOL 2

PRODUCTION OF MONOCLONAL ANTI-PHOSPHOPEPTIDE ANTIBODIES

Strategic Planning

As in the production of polyclonal anti-phosphopeptide antibodies (see Basic Protocol 1), the first step of the planning phase for anti-phosphopeptide monoclonal antibodies is the design and synthesis of the required peptides (see Support Protocol 1 and Background Information). Here too, the authors employ a peptide containing fifteen amino acids with the phosphorylation site Tyr in the center (residue 8), consisting of fourteen amino acids from the actual sequence of the protein plus an N-terminal Lys to enhance coupling to a carrier protein. A different carrier protein must be employed for immunization than will be used as substrate for the ELISA screen, to avoid detection of anti-carrier antibodies in the ELISA (see Purification Method, below). The authors use keyhole limpet hemocyanin (KLH) as the carrier for immunization and BSA as the carrier for the ELISA substrate. The cognate phosphopeptide can also be immobilized to an affinity-chromatographic column support (see Support Protocol 2) and used ultimately to affinity-purify the antibody produced by the desired hybridoma clone. A number of additional peptides must be produced for use in ELISA screening of candidate hybridoma supernatants, to screen both for the presence of the desired reactivity and the absence of undesired cross-reactivity. For ELISA screening, the peptides are coupled to a carrier protein different from the one used for immunization. Bovine serum albumin (BSA) is used for screening, because many of the clones are likely to react against the carrier used in the immunization of the

mice (KLH) and because unconjugated peptides have not been found to function well as ELISA substrates (Doolittle, 1986). In addition, because antibodies may be generated against the cross-linking reagent, the method used for coupling the phosphopeptide to the BSA to produce the substrate for ELISAs should be different from that used to link peptides to the KLH carrier for immunization (Doolittle, 1986; Czernik et al., 1991).

The second step of planning is to raise antibodies in mice. General guidelines for the immunization of mice and the production of monoclonal antibodies are described in *UNIT 16.1*, and many institutions have core facilities that will perform that task. The authors have immunized BALB/c mice by intraperitoneal injection with 1 mg/ml of immunogen (dissolved in PBS) in a 50% emulsion with complete Freunds adjuvant on day 1 and boosted intraperitoneally on days 15 and 37 with immunogen in incomplete Freunds adjuvant. Test bleeds from day 47 were analyzed by ELISA. On day 57 the mouse with the best titer was boosted intravenously, and its spleen was harvested on day 60. Freshly harvested spleen cells were prepared for cell fusion to generate hybridoma lines, which were subsequently screened by ELISA (*APPENDIX 3A*). The purpose of the ELISA screening is to identify clones that react with the cognate phosphopeptide and to eliminate clones that cross-react with other epitopes in addition to the cognate phosphopeptide. Epitopes screened by ELISA generally consist of the cognate nonphosphorylated peptide (to eliminate clones with phosphorylation-independent reactivities) and at least one unrelated phosphopeptide (to eliminate clones with indiscriminant anti-phosphotyrosine reactivity). In addition, depending upon the particular target chosen, it may be necessary to screen for reactivity with phosphopeptides from proteins of known homology. This occurs particularly when the target protein is a member of a family of homologous proteins—e.g., the subgroups of related receptor tyrosine protein kinases. If such cross-reactivity is anticipated, it is essential to synthesize not only the cognate phosphorylated and nonphosphorylated peptides and at least one unrelated phosphopeptide, but also phosphopeptides based upon the related homologous sequences. Thus, a typical ELISA screening scheme might consist of the following steps.

1. Screen for clones that exhibit reactivity against the cognate phosphopeptide. These clones, which will likely be <10% of all the clones, are potential candidates for the desired clones.
2. Screen for clones with reactivity against the cognate nonphosphopeptide. These clones, which are phosphorylation state–independent, are then eliminated.
3. Screen for clones with reactivity against at least one unrelated phosphopeptide. These clones, which are likely to represent indiscriminant anti-phosphotyrosine reactivity, are also eliminated.
4. Screen for and eliminate clones with reactivity against potential cross-reacting homologous peptides, if any are anticipated.

In the ELISAs performed in the authors' laboratory, 96-well polyvinyl chloride assay plates are generally used and bound monoclonal antibody is detected using biotinylated horse anti-mouse secondary antibody followed by horseradish peroxidase (HRP)–conjugated Avidin D (Vector Labs) and 4-aminoantipyrine (Sigma)/H_2O_2 as the substrate. This gives a deep red color in positive wells and absence of color in negative wells, allowing easy visual scoring without the need for quantitative measurements. The clones that pass all the screening steps are candidates for desirable hybridoma cell lines. These are expanded, frozen down as a pool, subcloned by limiting dilution, then rescreened against cognate phosphopeptide to ensure continued production of antibody through the early passages. Those continuing to produce are expanded further and a larger quantity of either culture supernatant or ascites fluid is screened in further immunoassays. Reactivity is

demonstrated most simply by immunoblot analysis using a panel of relevant phosphorylated and nonphosphorylated proteins. Electrophoresis is carried out with purified (generally by immunoprecipitation using conventional antibodies; *UNIT 7.2*) cognate protein in both its phosphorylated and unphosphorylated states, as well as with any proteins toward which there could conceivably be cross-reactivity. The blot is probed with the monoclonal antibody preparation to demonstrate appropriate reactivity. The antibody preparation can ultimately be purified on a cognate phosphopeptide affinity column.

The relationship among the above procedures is illustrated by the flow chart in Figure 16.6.2.

Purification Method

This protocol presents procedures for isolating hybridoma clones of the desired reactivity, starting from the point at which candidate hybridoma clones have been seeded in 96-well culture plates (see Fig. 16.6.2). Candidate hybridoma supernatants are screened in ELISA assays against a series of peptides (as described in Strategic Planning). Identified clones are expanded, subcloned by limiting dilution, and further purified.

Materials

Candidate hybridoma cell lines from fusion (refer to Strategic Planning and *UNIT 16.1*)
HT medium; prepare as for HAT medium (*UNIT 1.2*) except omit aminopterin
Screening diluent (see recipe)
BSA-conjugated cognate phosphopeptide (for use as ELISA antigen; refer to Strategic Planning and Support Protocol 1
Preimmune serum from mouse used to produce hybridoma line (negative control)
Immune serum from mouse used to produce hybridoma line (positive control)
BSA-conjugated cognate nonphosphopeptide (for use as ELISA antigen; refer to Strategic Planning and Support Protocol 1
BSA-conjugated noncognate phosphotyrosyl peptide (for use as ELISA antigen; refer to Strategic Planning and Support Protocol 1
BSA-conjugated homologous phosphopeptides (optional, for use as ELISA antigens; refer to Strategic Planning and Support Protocol 1

96-well polystyrene tissue culture plates
96-grid note sheets

Additional reagents and equipment for cloning by limiting dilution, ELISA, and freezing and recovery of hybridoma cell lines (*APPENDIX 3A*)

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and proper asceptic technique should be used accordingly.

Identify and sample conditioned media from candidate hybridomas

1. Seed hybridoma cells from fusion at a low density (aiming for one cell per three wells) in multiple 96-well polystyrene tissue culture plates using HT medium. Examine at ~2 weeks and identify all single-colony hybridoma culture wells as potential candidates by recording the number of colonies per well on a 96-grid note sheet. Mark the underside of each well containing one colony for easy identification.

   The supernatant fluid from wells possessing a single colony will be screened for reactivity.

2. Using sterile technique, remove an aliquot of supernatant (e.g., 100 µl from a 200-µl culture) from each potential candidate well and transfer to a separate 96-well polystyrene plate (the "screen plate"). Record the original plate number and well position and the corresponding plate number and well position for the screen plate (e.g., on a grid sheet representing the screen plate, record the original plate number

and well position from which the supernatant in each well was transferred). Replace the aliquot removed from each original well with 100 µl 37°C fresh HT medium.

A brightly colored dot sticker the size of one well, attached to the tissue culture hood surface, will help to keep the plate in register, as the plate may be moved one well at a time along the sticker. If the supernatants are not to be tested immediately, store the screen plates at 4°C, wrapped in plastic wrap.

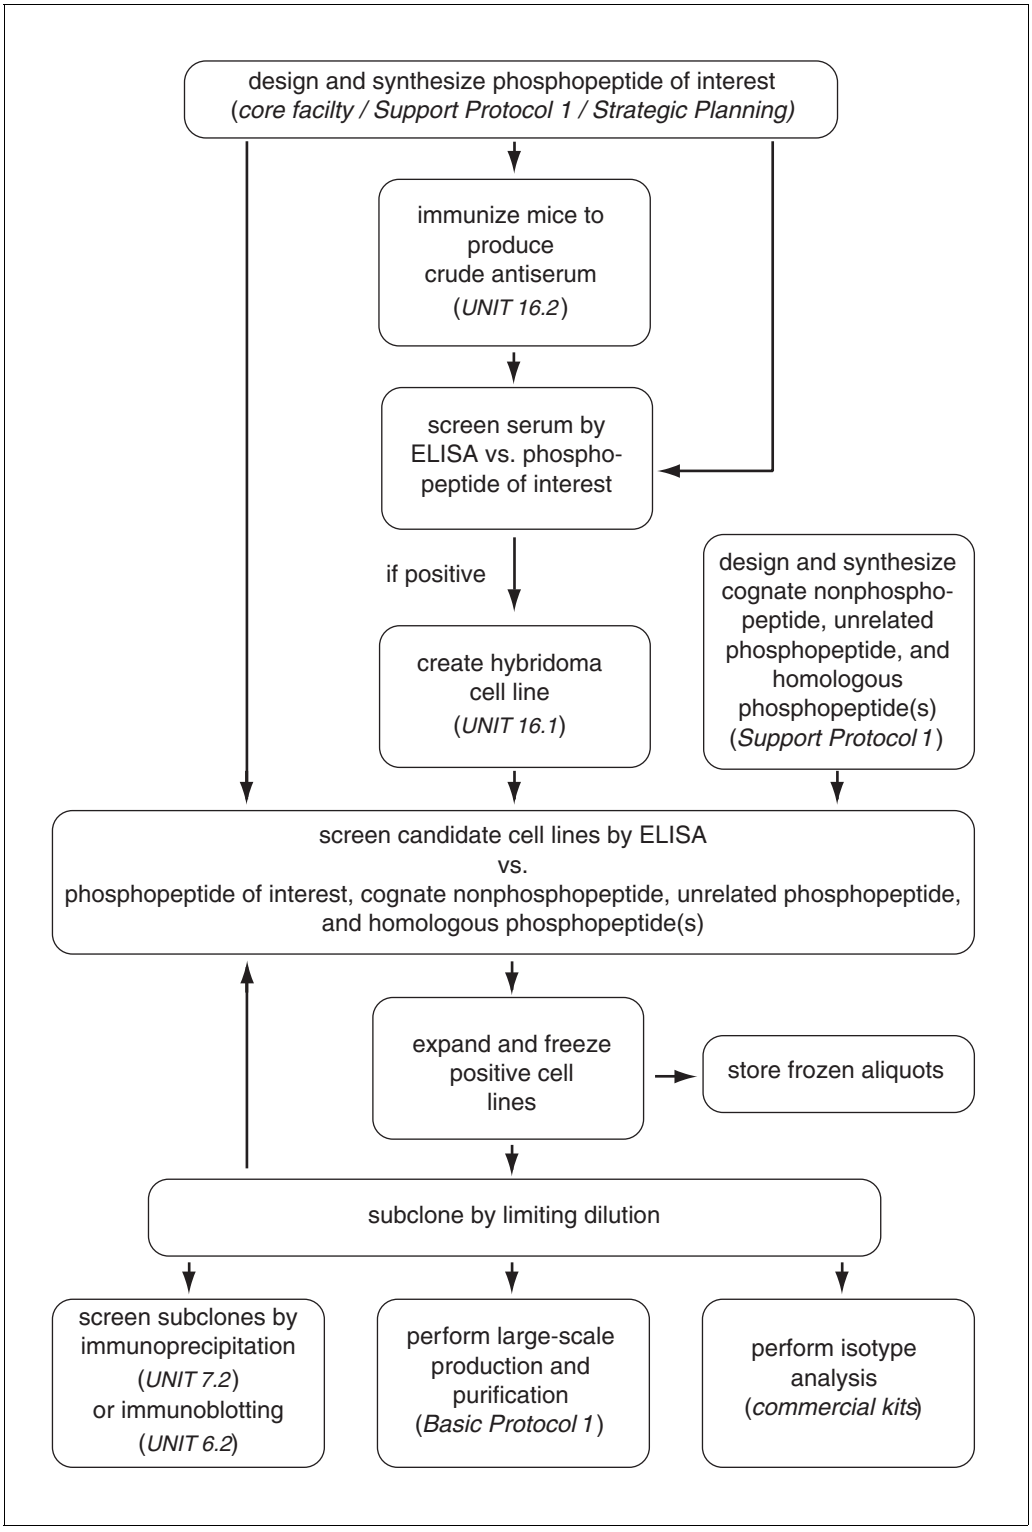

Figure 16.6.2 Flow chart for production of monoclonal anti-phosphopeptide antibodies.

3. To each supernatant in the screen plates, add 150 µl screening diluent

   The components of the screening diluent prevent microbial contamination; this reagent also serves to expand the volume should multiple rounds of screening be required.

Screen candidate hybridomas by ELISA

4. Screen an aliquot (e.g., 50 µl) of each candidate hybridoma supernatant from the screen plate in an ELISA using the BSA-conjugated cognate phosphopeptide as antigen. Record the screen-plate number and well position and corresponding to original culture plate number and well position for each positive sample. Also assay preimmune serum from the mouse used for fusion (negative control) and immune serum from the same mouse (positive control), each at a 1:100 dilution in a 1:1 mixture of HT medium and screening diluent. Include an ELISA with screening diluent only (additional negative control).

   It is important to use a different carrier protein in the ELISAs (BSA) than that used for the immunizations (KLH), to avoid detecting reactivity against the carrier (refer to Strategic Planning, above).

5. Screen an aliquot of each positive sample from step 4 in an ELISA against the BSA-conjugated cognate nonphosphopeptide to eliminate clones with phosphorylation-independent reactivity, against the unrelated BSA-conjugated phosphotyrosylpeptide to eliminate clones with indiscriminant phosphotyrosine reactivity, and, if cross-reactivity with homologous phosphoprotein(s) is anticipated, against phosphopeptide-BSA conjugates corresponding to any potentially cross-reacting homologous phosphoproteins.

   These screens may be done sequentially or, if the number of candidate hybridomas has diminished sufficiently, simultaneously. Isolation of clones with phosphorylation-independent cognate peptide specificity may also be useful.

6. Expand clones that satisfy all screening requirements and freeze aliquots as backup; use remainder for subcloning by limiting dilution.

7. Screen culture supernatants from subclones as in steps 4 and 5 to check for continued production and specificity of the antibody.

   Keep representative independent subclones from each original parental colony, as it cannot be predicted whether each parental monoclonal antibody will recognize the cognate holophosphoprotein or function in all types of immunoassays desired in the future. Candidate subclones should then also be expanded and frozen. It is a good idea to continue to check for production of the appropritate antibody after several rounds of serial passaging and after freezing, thawing, and reexpansion.

8. To characterize the subclones further and identify the most useful clones, assay the culture supernatants for reactivity with cognate holophosphoprotein in individual immunoassays (e.g., immunoprecipitations, as described in *UNIT 7.2*, or immunoblot analyses, as described in *UNIT 6.2*).

   Antibody from the desired clones can be produced on a large scale by harvesting large volumes of culture supernatant and performing affinity purification (see Basic Protocol 1), or by producing ascites fluid, which can be purified by ammonium sulfate precipitation followed by affinity purification. Isotype analysis can be performed by using commercially available kits (Pierce or Sigma).

SYNTHESIS OF PEPTIDES

SUPPORT PROTOCOL 1

Many institutions have core facilities for synthesis of peptides using automated solid-phase peptide synthesizers. For phosphotyrosine-containing peptides, the authors originally used standard Merrifield solid-phase procedures with *t*-butyloxycarbonyl (Boc) amino acids and Boc-*O*-(dibenzylphosphono)-L-tyrosine as the phosphorylated residue (Barany and Merrifield, 1979). For cleavage of phosphopeptide from the resin, 1 g phosphopeptide resin was stirred 10 min at 0°C with 2 ml dimethyl sulfide; then an ice-cold mixture of 4 ml trifluoromethanesulfonic acid (TFMSA) and 10 ml trifluoroacetic acid was added slowly with stirring. The resulting reaction mixture was stirred under a nitrogen atmosphere 4 hr at 0°C and the cleaved phosphopeptide precipitated with methyl *t*-butyl ether at −30°C. The precipitate was dissolved in 40% acetic acid and lyophilized several times from water. This original method suffers from low yields. Currently, most phosphotyrosyl-containing peptides are synthesized with 9-fluorenylmethyloxycarbonyl (Fmoc) phosphotyrosine. The lack of a side chain protecting group on the phosphotyrosine (Kitas et al., 1994) allows standard Fmoc synthesis and cleavage procedures to be employed (Chang and Meienhofer, 1978). However, a higher molar excess of activated Fmoc amino acids than that used in standard procedures may be required for efficient coupling of amino acids after unprotected phosphotyrosine has been added. In some circumstances, a double coupling procedure may be employed to add the few amino acids following phosphotyrosine to the growing peptide chain. This alternative requires the sequential, repeated addition of the next particular amino acid to be added to the peptide. A support protocol for the coupling of peptides to an affinity matrix is provided (see Support Protocol 2).

COUPLING OF PEPTIDES TO AFFI-GEL 10 AFFINITY MATRIX

SUPPORT PROTOCOL 2

This protocol describes coupling of phosphopeptides or nonphosphopeptides to Affi-Gel 10 affinity matrix for use in affinity column chromatographic purification of antibodies. Anhydrous coupling, detailed here, is the most efficient coupling method for peptides. The steps here result in production of 3 ml final bed volume of affinity resin; 3 mmol of peptide is coupled per milliliter Affi-Gel 10. According to the manufacturer's specifications, Affi-Gel 10 resin contains ~15 µmol of active ester per milliliter of gel, and the gel has a capacity for 35 mg of protein or 15 to 20 µmol of a low-molecular-weight ligand per milliliter of gel. Note that these capacities are dependent upon the molecular weight and nature of the protein. After coupling, the matrix may be poured into columns of the appropriate size.

Materials

Synthetic oligopeptide for coupling (see Support Protocol 1)
Dimethyl sulfoxide (DMSO)
N-methylmorpholine (99% purity; Acros Organics)
Affi-Gel 10 (Bio-Rad) or equivalent activated support matrix
Ethanolamine
0.1 M ethanolamine·HCl, pH 8.0
High-salt/high-pH solution: 0.5 M NaCl/0.4% (w/v) sodium bicarbonate
High-salt/low-pH solution: 0.5 M NaCl/100 mM sodium acetate, pH 4.2
PBS/azide: PBS (*APPENDIX 2A*) containing 0.02% (w/v) sodium azide
0.5 M NaCl
3 M NaSCN

Polypropylene screw-cap centrifuge tubes (do not use polystyrene tubes with DMSO)
End-over-end rotator
IEC Clinical centrifuge (or equivalent)
Vacuum aspirator
Glass chromatography columns, ≥5-ml capacity

Prepare peptide solution

1. Dissolve oligopeptide in DMSO at a volume ~0.5 to 4 times the desired bed volume.

   For a 3-ml bed volume, dissolve a total of 9 μmol peptide, which for an average 15-mer peptide of mol. wt. ~1700 would be 15.3 mg.

2. Neutralize the peptide solution by titration as follows: add peptide synthesis–grade *N*-methylmorpholine (full-strength or diluted to 1:1 to 1:9 in DMSO) in 1 to 2 μl increments, remove a 2- to 3-μl aliquot after each addition, dilute this with 50 μl water, then spot it onto a strip of pH paper. Repeat this process until a pH in the range of 7 to 8 is reached.

   Titrate carefully, as it is very easy to overshoot the desired pH. Typically 7 to 8 μl of N-methylmorpholine is required per 3 μmol peptide, although the precise amount will depend greatly upon the particular amino acid sequence. The aliquots must be mixed with water because pH is a measure of hydrogen ion concentration, and hence the pH of a nonaqueous solution cannot be measured.

Add peptide to Affi-Gel 10

3. Mix contents of the bottle of Affi-Gel 10 matrix well to resuspend the resin, then transfer the required amount of resin to a screw-cap polypropylene centrifuge tube and wash three times in DMSO, each time by centrifuging 5 min at 700 × *g* (2000 rpm in an IEC Clinical centrifuge, setting 5), room temperature, aspirating the supernatant by vacuum, resuspending the resin in 5 vol DMSO, then centrifuging again at 700 × *g*.

   Be sure to take at least twice as much Affi-Gel 10 as ultimately will be needed, as the volume will shrink. The resin is supplied as a 50% slurry; therefore, it is necessary to take at least four times the required bed volume. Avoid centrifugation at higher than recommended speed as this may result in collapse of the resin.

4. Aspirate the excess DMSO from the resin and add the peptide solution prepared in step 2. Incubate overnight at room temperature with end-over-end rotation.

Quench and wash the resin

5. Add 2 μl pure ethanolamine per milliliter resin and incubate 2 hr at room temperature with end-over-end rotation.

   Ethanolamine is added directly to the coupling reaction to quench unreacted ester groups.

6. Wash twice in DMSO as in step 3.

7. Wash twice in 0.1 M ethanolamine·HCl, pH 8.0, as in step 3 (performing the first wash on ice as a great deal of heat will be generated). Remove the 0.1 M ethanolamine·HCl from the second wash and replace with fresh, incubate tube overnight at 4°C with end-over-end rotation, then centrifuge at low speed and aspirate the supernatant.

8. Wash three times with high-salt/high-pH solution using the technique described in step 3.

9. Wash three times with high-salt/low-pH solution using the technique described in step 3.

10. Wash three times with PBS/azide using the technique described in step 3 and store washed resin at 4°C until ready to pack in column.

11. Mix matrix into a slurry with 0.5 M NaCl and pour into glass chromatography columns.

Commercially available glass chromatography columns can be used; alternatively, 5-ml plastic syringes with 1-cc plugs of silanized glass wool (UNIT 5.6) in the bottom may function as columns.

12. Wash each column with 10 column volumes 3 M NaSCN followed by 10 column volumes PBS/azide.

COUPLING OF PHOSPHOTYROSINE TO AFFI-GEL 10 AFFINITY MATRIX

SUPPORT PROTOCOL 3

This protocol describes coupling of phosphotyrosine to Affi-Gel 10 affinity matrix for use in affinity column chromatographic purification of antibodies. Phosphotyrosine is insoluble under the anhydrous conditions used for coupling peptides (see Support Protocol 2); therefore, coupling is done under aqueous conditions. The steps here result in production of 10 ml final bed volume of affinity resin, as for peptides, 3 μmol phosphotyrosine is coupled per milliliter of Affi-Gel 10. According to the manufacturer's specifications, Affi-Gel 10 resin contains ~15 μmol active ester per milliliter gel, and the gel has a capacity for 35 mg of protein per milliliter gel or 15 to 20 μmol of a low-molecular-weight ligand per milliliter gel. Note that these capacities may vary depending upon the molecular weight and nature of the protein. Phosphotyrosine-agarose affinity matrix is now also available commercially from Sigma.

Additional materials *(also see Support Protocol 2)*

Phosphotyrosine
0.4% (w/v) sodium bicarbonate
1 M NaOH (optional)

Fritted-glass funnel and vacuum aspirator
Glass chromatography column, ≥14-ml capacity

Additional reagents and equipment for coupling peptides to Affi-Gel 10 affinity matrix (see Support Protocol 2)

Prepare phosphotyrosine solution

1. Dissolve phosphotyrosine in 0.4% sodium bicarbonate at a volume ~0.5 to 4 times the desired bed volume.

   For a 10-ml bed volume, dissolve a total of 30 μmol phosphotyrosine. Based on its molecular weight of 261, this amounts to 7.8 mg, although it is acceptable (and may be easier) to use an excess, as phosphotyrosine is relatively inexpensive.

2. Check that the pH is in the range of 7 to 8 using pH paper. If adjustment is necessary, neutralize the solution by titration—i.e., adding small amounts of 1 M NaOH, removing a 2- to 3-μl aliquot after each addition, then spotting the aliquots onto a strip of pH paper. Repeat this process until a pH in the range of 7 to 8 is reached.

Add phosphotyrosine to Affi-Gel 10

3. Mix contents of the bottle of Affi-Gel 10 matrix well to resuspend resin, then transfer the required amount of resin to a fritted-glass funnel attached to a vacuum aspirator. Wash three times, each time pouring cold distilled water over the resin in the funnel and aspirating, then perform one final wash in the same manner using ice-cold 0.4% sodium bicarbonate.

   Be sure to take at least twice as much Affi-Gel 10 as ultimately will be needed, as the volume will shrink. The resin is supplied as a 50% slurry; therefore, it is necessary to take at least four times the required bed volume. Do not allow >20 min to elapse from the time the resin is removed from the bottle to the time it is mixed with the phosphotyrosine solution.

4. Remove most of the excess liquid from the gel by vacuum aspiration without letting it dry completely, transfer it to a screw-cap centrifuge tube, and add the phosphotyrosine solution from step 2.

5. Incubate overnight at 4°C with end-over-end rotation.

Quench and wash resin

6. Add 2 µl pure ethanolamine per milliliter resin and incubate 2 hr at room temperature with end-over-end rotation.

   Ethanolamine is added directly to the coupling reaction to quench unreacted ester groups.

7. Wash resin twice, each time by centrifuging at low speed (see Support Protocol 2, step 3), aspirating the supernatant, resuspending the resin in 5 vol of 0.4% sodium bicarbonate, then centrifuging again at low speed.

8. Wash resin twice with 0.1 M ethanolamine·HCl, pH 8.0, as in step 7. Remove the 0.1 M ethanolamine from the second wash and replace with fresh. Incubate tube overnight at 4°C with end-over-end rotation, then centrifuge at low speed and aspirate the supernatant.

9. Wash, store, and pack resin in columns (see Support Protocol 2, steps 8 to 12).

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Screening diluent

6.18 g boric acid (100 mM final)
9.54 g sodium borate (47 mM final)
4.38 g NaCl (75 mM final)
10 g bovine serum albumin (BSA; 1% w/v final)
1 g sodium azide (1% w/v final)
H_2O to 1 liter

The pH of the solution will be 8.4 to 8.5.

COMMENTARY

Background Information

Conventional antibodies have proven to be invaluable tools in numerous techniques for the biochemical analysis of proteins. In the past antibodies with specificity toward the phosphorylated forms of proteins were produced serendipitously. Using techniques such as those described in this unit, such antibodies may now be produced by design. Whereas phosphorylated holoproteins might in general be poor candidates for immunogens in the production of such antibodies as a result of their susceptibility to dephosphorylation, it has been suggested that short phosphopeptides are relatively resistant to phosphatases (Czernik et al., 1991), thereby providing a better chance of success.

A dramatic advance in the analysis of protein tyrosine phosphorylation and the regulation of signal transduction pathways by such phosphorylation occurred with the production of polyclonal and monoclonal anti-phosphotyrosine antibodies (Frackelton et al., 1983; Ross et al., 1981; reviewed in Stern, 1991). These antibodies proved capable of recognizing phosphorylated tyrosine residues in the context of virtually any flanking peptide sequence, and were shown to be exquisitely specific in the requirement for a phosphorylated tyrosine yet at the same time remarkably promiscuous in their acceptance of any peptide sequence. Techniques using polyclonal and monoclonal anti-phosphotyrosine antibodies have supplanted the standard methodology of metabolically labeling proteins with $^{32}P_i$, which was cumbersome, time-consuming, hazardous, and of relatively lower sensitivity.

Antibodies that recognize a specific tyrosyl-phosphorylated peptide as described in this unit represent a marriage of anti-phosphotyrosine technology with the stringent sequence-dependent specificity of conventional antibodies (Roussel, 1990; Bangalore et al., 1992; Epstein et al., 1992; DiGiovanna and Stern, 1995). Conceptually, they may be thought of either as anti-phosphotyrosine antibodies that have strict sequence specificity, or as conventional antibodies possessing the additional specificity of phosphorylation dependence.

Anti-phosphotyrosine antibodies have been most useful in the analysis of tyrosine phosphorylation of proteins in a technique using a combination of immunoprecipitation and immunoblotting (known as the "IP-western" method). In this procedure, a protein typically is immunoprecipitated either with conventional anti-protein antibody or with anti-phosphotyrosine antibody, then immunoblotted with whichever of these two antibodies was not used for the immunoprecipitation. Because anti-phosphopeptide antibodies recognize the cognate protein, but only when it is phosphorylated, they are capable of performing both functions in a single step—i.e., either an immunoprecipitation alone or an immunoblot alone is sufficient to supply the desired information.

The most useful functions for such antibodies are likely to be those that in fact are not possible using traditional reagents. For example, using anti-phosphopeptide antibodies, it is possible to identify and isolate distinct phosphorylated species of a phosphoprotein containing multiple phosphorylation sites. Thus, phosphorylation at each site can be examined independently, and a preparative separation of individual phosphospecies of a holoprotein can be achieved. Another unique application is analysis of the abundance and phosphorylation state of individual proteins in situ in preparations of cells or tissues. Because phosphorylation is a major mode of regulation of protein function, the phosphorylation state is often an indicator of the functional status of a protein. The mere identification of a protein in a cell or tissue specimen gives no indication of its functional status. The ability of anti-phosphopeptide antibodies to demonstrate the phosphorylation state, and by extrapolation the functional state, of a single protein with high specificity places these reagents in a unique class. Hence, identity and functional status may be probed simultaneously using one simple assay. In tissue sections, one may probe to determine whether a particular protein is present, and, if present, in what functional state it is found. The authors have employed this strategy in immunohistochemical staining of formalin-fixed, paraffin-embedded human breast tumors using antibody to the phosphorylated form of the receptor tyrosine kinase Neu (DiGiovanna and Stern, 1995), and were able to demonstrate that Neu is phosphorylated, and therefore functionally active, in only a subset of the tumors that overexpress this protein.

Anti-phosphopeptide antibodies possess unique properties that render them capable of performing functions not possible with conventional reagents. From the technical considerations regarding their production, it would follow that antibodies with specificity for the non-phosphorylated state should also be achievable, and the production of such antibodies has also been reported (Nairn et al., 1982; Roussel, 1990; Czernik et al., 1991; Epstein, 1995; Tzartos et al., 1995; Kawakatsu et al., 1996).

Critical Parameters

In the production of polyclonal anti-phosphopeptide antibodies, a major challenge is the depletion of cross-reactivity. The first consideration in achieving this is the anticipation of potential cross-reacting proteins in the planning phase of the procedure. Cross-reactivity is most likely to occur when the target protein is a member of a family of closely related homologous proteins—e.g., of the subfamilies of tyrosine protein kinases. The authors have produced a monoclonal anti-phosphopeptide antibody with specificity for the Tyr-1248 autophosphorylation site of Neu (DiGiovanna and Stern, 1995). A homologous site exists in the epidermal growth factor receptor (EGFR). The antibody produced in the authors' laboratory does not cross-react with the homologous EGFR site in spite of having identical residues in seven of the 14 amino acids of the peptide sequence (five of which are N-terminal to the phosphotyrosine, one C-terminal, and the phosphotyrosine itself). Thus, specificity is achievable even with at least up to 50% identity. Nevertheless, such a close relationship among the phosphorylation sites of different proteins highlights the importance of considering all known related proteins.

The second consideration in depleting cross-reactivity is the quantity of cross-reactive antibodies in a given aliquot to be purified relative to the capacity of the peptide columns used for the negative selection. Because of the expense of the peptides, the authors have gen-

erally prepared small columns (with 2- to 3-ml bed volumes) and passed the sera over the columns multiple times, empirically determining the number of passes necessary to quantitatively deplete cross-reacting material. In these columns, 3 μmol of ligand is coupled per milliliter of Affi-Gel 10. The manufacturer states that the resin contains ~15 μmol active ester per milliliter gel, and that the gel has a capacity for 35 mg of protein or 15 to 20 μmol of a low-molecular-weight ligand per milliliter gel. The BSA and phosphotyrosine columns are relatively inexpensive to produce; thus, a single large column of each is practical and sufficient.

Because the authors elute the antibodies from the positive-selection affinity column in strongly chaotropic solutions that are potentially deleterious to the stability of the antibody (3 M NaSCN or 3.5 M followed by 4.5 M $MgCl_2$), care is taken to collect the fractions in preprepared dialysis tubing so that they may be immediately placed into the PBS dialysate, thus minimizing the time that the antibodies are exposed to the eluting solutions. Although $MgCl_2$ is thought to be "gentler," the authors have found that gravity-driven flow rates from phosphopeptide columns eluted with this salt quickly become extremely slow, possibly because of precipitation of the salt in the column or an interaction of the Mg^{2+} ion with the phosphate groups. Thus use of NaSCN is preferred, and this salt appears to permit recovery of comparable activity.

In the production of monoclonal anti-phosphotyrosyl peptide antibody, which the authors have carried out once, a major technical hurdle was the low frequency with which clones of the desired specificity were produced (DiGiovanna and Stern, 1995). In that work, in which antibody was produced to the phosphorylated form of the receptor tyrosine kinase Neu, >1200 hybridomas (obtained from a single fusion) were screened to obtain a single clone that satisfied all requirements. The authors found 68 candidate clones that recognized the cognate phosphopeptide, of which only 20 were unreactive toward the cognate nonphosphopeptide. Of those, seven cross-reacted with an unrelated phosphopeptide (i.e, exhibited indiscriminant phosphotyrosine activity), and of the remainder three cross-reacted with the homologous EGFR. The remaining ten were subcloned by limiting dilution, after which only five continued to produce antibody. Of these five, only one reliably detected the phosphorylated holoprotein in immunoblots and immunoprecipitations. Thus, the "hit rate" for an antibody that satisfied all requirements was <1 in 1000 clones. As this is the only monoclonal anti-phosphotyrosyl peptide antibody produced by the authors to date, it is impossible be sure whether this low frequency will be a general phenomenon. It is crucial to devise a convenient and reliable ELISA assay for such extensive screening. Other assays may require extensive optimization. For example, the monoclonal antibody produced in the above project performed poorly in immunoblotting when any detection system other than a very sensitive chemiluminescence-based assay was used. This was possibly due to a low affinity of the antibody for the cognate protein. In addition, extensive optimization, particularly aimed toward enhancing the strength of the signal, was required for use of the antibody in immunohistochemistry. Finally, it is important to use different carrier proteins for the immunizing conjugate and the ELISA conjugate, so that antibodies to the carrier used for the immunization will not give positive reactions in the ELISA. Some authorities also advocate using different cross-linking agents, as antibodies against the cross-linker itself could theoretically be generated as well (Doolittle, 1986; Czernik et al., 1991).

Troubleshooting

In the production of polyclonal anti-phosphopeptide antibodies, the most common unfavorable outcomes are persistence of cross-reactivity, loss of specific reactivity, and poor yield. Although it may be tempting, in the interest of saving time, to perform the entire purification and postpone all analyses until the end (a reasonable course of action once a scheme is known to work), it may be prudent, especially with a new protocol, to analyze the serum at each step. For example, the authors have produced antibody to phosphorylated EGFR (M. Digiovanna, M.A. Lerman, and D. Stern, unpub. observ.). The crude antiserum cross-reacted with the related receptors Neu and HER-4, which had been anticipated. The purification was monitored by probing, after each column, an immunoblot consisting of four lanes containing lysates from cells overexpressing (1) phosphorylated EGFR, (2) nonphosphorylated EGFR, (3) phosphorylated Neu, and (4) phosphorylated HER-4. In following the depletion of cross-reactivity, such stepwise analysis demonstrates whether undesired cross-reactivity has been eliminated or whether further passes through a particular negative-selection column are necessary.

If loss of specific reactivity is also a problem, stepwise analyses can also demonstrate where the loss is occurring. Loss of specific reactivity can occur for three major reasons. The first possible reason is that the antibody is not stable over the course of the purification, which may be the case if the procedure is very prolonged. If this is suspected, the pace of the purification may be hastened or the procedure may be carried out at 4°C instead of room temperature. With prolonged purifications, it is especially important to include sodium azide in the PBS used to dilute the serum, to prevent microbial growth. Activity may also be lost nonspecifically as a result of the multiple manipulations in a protocol requiring multiple columns and/or multiple passes through each column. In this case, fraction analysis may indicate which columns are absolutely essential, and also indicate the minimum necessary number of passes through each column. Also, creating larger columns with greater capacity should reduce the number of times the serum will need to be passed over each to deplete cross-reactivity. Finally, specific activity may be lost as a result of the presence in one of the negative-selection columns of a cross-reacting peptide that is so similar to the peptide of interest that essentially any antibody that recognizes the cognate phosphopeptide will recognize this phosphopeptide as well. In this last theoretical scenario, ultimate unique specificity may not be achievable.

The columns used in the purifications can be regenerated and used repeatedly if stored at 4°C in sodium azide–containing buffer to prevent microbial contamination and consequent damage to the matrix. A theoretical consideration is that with repeated use, phosphatases in serum may eventually cleave enough phosphate groups from the peptide moieties on the column to render it ineffective as a phosphopeptide column. Thus, it may be prudent to periodically prepare fresh columns. An alternative would be to add phosphatase inhibitors to the serum prior to purification. Similarly, proteases in serum may eventually cleave peptides from the resin, and this may be prevented by adding protease inhibitors to the serum.

As discussed in Critical Parameters, the main technical hurdle in the production of monoclonal antibodies appears to be the large number of clones that it may be necessary to screen to find one with the desired reactivity. Here, time and persistance are the primary defenses. Another obstacle may be the failure of hybridoma cells to continue to produce antibody upon subcloning, which is likely due to the continuing genetic instability of hybridomas at early passage. If the parental hybridoma colony has been expanded and frozen prior to subcloning, this will serve as a potential source for additional subclones, although it is possible that these additional daughter clones may also be nonproducing. The use of the final monoclonal antibody in a variety of immunoassays is more likely to require potentially extensive optimization of protocols and higher concentrations (because of lower affinities) than the use of polyclonal antibodies.

Anticipated Results

In the production of polyclonal antibodies, the authors have obtained yields of ~1 mg of purified anti-phosphopeptide antibody from a single 15-ml serum sample (M. Digiovanna, M.A. Lerman, and D. Stern, unpub. observ.). These antibodies have been used in the immunoprecipitation of phosphoproteins from both denaturing and nondenaturing solutions. They have also been used in immunoblotting, in immunofluorescence on fixed cultured cells, and in immunohistochemistry on formalin-fixed, paraffin-embedded tissue sections. Specificity can be demonstrated when such assays are inhibited by cognate phosphopeptide but not by cognate nonphosphopeptide or unrelated phosphopeptides.

Through the production of monoclonal antibodies a permanent supply of a uniform reagent is ensured. Many milligrams can be obtained from the ascites produced by a single mouse. The authors have used such an antibody in all of the same assays as described above for polyclonal antibodies. More extensive optimization of protocols is likely to be required with monoclonal antibodies, and these may be expected to have a lower affinity than typical polyclonal antibodies. Isotype analysis can easily be performed by use of commercially available kits (Pierce or Sigma).

Time Considerations

For both protocols, the principal time-consuming step is the production of an immune response in the immunized animals. For the production of polyclonal antibodies, the authors have obtained high titers of reactive sera as early as 6 to 8 weeks in animals that have been boosted every 2 weeks. Later bleeds with continued boosts have yielded even higher titers. Once adequate bleeds have been obtained and the necessary affinity columns prepared, purification can generally be carried out within 1 week, with the exact length of time depending

upon the number of columns and the necessity of analyzing the product after each step.

In the production of monoclonal antibodies, the authors have harvested splenocytes at ~2 months from the initial immunization, with several boosts in between. The screening of hybridoma supernatants can take 1 to 2 weeks, and their expansion and subcloning several weeks more.

CHAPTER 17
Macromolecular Interactions in Cells

INTRODUCTION

The capacity of proteins to perform different functions within cells is essentially conferred by information provided within the proteins themselves. That is, the function of the protein is determined by the one-dimensional sequence of amino acids encoded within the mRNA from which the protein is translated. However, in order for proteins to accomplish the complex tasks required for cell viability, this information must direct not only the three-dimensional folding and post-translational processing of the protein itself, but also the interaction of the protein with other molecules of the cell. These interactions may include binding to small ligands, enzyme substrates, nucleic acids, or other proteins. It is therefore not surprising that elucidating the interactions of proteins with other cellular components has become a major task in transforming molecular biological knowledge of protein sequences into full understanding of protein functions within cells.

Many traditional methods for detecting protein-protein interactions have relied upon biochemical co-purification of tightly associated protein complexes. In addition to conventional column chromatography, rapid affinity methods for co-purification have been developed (*UNIT 17.5*). These methods typically rely upon purification using engineered expression constructs producing proteins with tags that allow retention on an affinity matrix or upon purification by immunoprecipitation (*UNIT 7.2*). After isolation of the protein of interest through these methods, associated proteins can be detected by protein staining (*UNIT 6.6*) of the purified fraction. Alternatively, the interaction of known proteins can be assayed through Western blotting (*UNIT 6.2*), and novel interactions can be documented through methods based on mass spectrometry and bioinformatics (*UNIT 17.5*). These methods can be further extended through the use of chemical cross-linkers, particularly for analysis of multiprotein complexes (*UNIT 17.10*). Cross-linking strategies are particularly valuable when interactions between complex components are relatively transient or lose specificity outside of their native contexts. Moreover, because cross-linkers act at very close proximity, they provide information about the relative spatial distribution of complex subunits with respect to each other.

Alternative methods to identify protein-protein interactions through modified ligand blotting protocols have also been developed (*UNIT 17.2*). In such far-western blotting methods, a protein of interest is immobilized on a membrane support and probed with another non-antibody protein. This method has been particularly useful in examining the interaction between proteins within complex mixtures and in examining proteins whose insolubility or biochemical behavior make them ill-suited for traditional approaches.

A number of methods have been developed for broad-based genetic screening to find novel interactions. The two-hybrid system or interaction trap screening (*UNIT 17.3*) allows evaluation of peptides encoded within large cDNA libraries for interactions with a protein of interest. Interactions between the protein of interest and peptides encoded within the library result in transcriptional activation that can be assayed using simple selection criteria. Moreover, these protocols can also be adapted to test specific association between two proteins for which there is a prior reason to expect an interaction,

Current Protocols in Cell Biology (2006) 17.0.1-17.0.3

again by measuring the extent of transcriptional activation. Smaller epitopes involved in protein-protein interactions can be found using phage-display combinatorial peptide libraries (*UNIT 17.4*). In this method, peptides are fused to the capsid proteins of the filamentous M13 bacteriophage, such that they remain exposed after the assembly of viable phage particles. Peptides are selected by affinity of the phage particles to immobilized proteins of interest. Through multiple rounds of affinity selection, it is possible to isolate phage expressing fused peptides that are characteristic of optimal ligand preferences or protein interaction modules. Peptides found through this method either can be utilized directly for study of the protein of interest or they can be used to search databases in order to identify potential protein-protein interaction partners.

Once interaction partners have been identified, a number of biophysical methods offer the capacity for detailed characterization of binding affinities and kinetics. One attractive method that has become increasingly valuable during the past decade is the use of optical biosensors (*UNIT 17.6*). Optical sensors provide precise measurement of the refractive index near the surface of a sensor. When a protein of interest is immobilized on the sensor, its interactions with partners in the solution above can be monitored. Analysis of steady-state interactions using biosensors can provide equilibrium binding constants over a wide range of affinities. If set up appropriately, optical biosensors can also provide accurate real-time measurements of association, from which chemical on- and off-rates can be deduced.

Precise information about the thermodynamics of a broad variety of macromolecular interactions can be obtained through isothermal titration calorimetry (ITC; *UNIT 17.8*). Changes in macromolecular interactions, for instance the binding of two proteins, are accompanied by the release (exothermic reaction) or absorption (endothermic reaction) of heat. The heat thus produced or consumed is monitored in ITC using a heat-flux calorimeter, which measures the amount of power required to maintain a constant temperature difference between the reaction cell and a reference cell. This measurement can be used to calculate the Gibbs energy, enthalpy, entropy, and heat capacity of the reaction under study.

The obvious limitation of the methods discussed above is that they assay protein interactions outside of the normal context of intact cells. The absence of a cellular context frequently causes a loss of spatial or temporal resolution regarding how macromolecular interactions occur in vivo. Chromatin immunoprecipitation (*UNIT 17.7*) is frequently used to monitor the association between proteins and DNA within intact cells. In this method, native interactions are preserved by formaldehyde cross-linking of protein-DNA and protein-protein complexes. After the DNA is fragmented into shorter pieces, complexes are precipitated with antibodies against proteins of interest, resulting in co-precipitation of the DNA sequences that are directly or indirectly associated with individual proteins. The cross-links can then be chemically reversed, allowing analysis of the DNA sequences by direct methods such as PCR. Recently, methods have also been developed to assay protein-protein interactions directly within cells via the use of fluorescence resonance energy transfer (FRET; *UNIT 17.1*). FRET is a process through which a donor fluorophore transfers energy to an acceptor fluorophore through dipole-dipole coupling. Protein-protein interactions can be detected through this photophysical process by covalently coupling donor and acceptor fluorophores with appropriate excitation and emission spectra to two proteins of interest. Due to the sixth-order distance dependence of the FRET process, efficient FRET occurs only when the fluorophores are in immediate proximity. FRET can be measured effectively by donor quenching through acceptor photobleaching. These powerful new techniques will complement more traditional biochemical methods and extend the study of interactions between molecules in their true biological context.

In an era of rapidly expanding databases of nucleic acid and protein sequences, a true appreciation of how macromolecules function within cells will require not only data about the expression of these molecules, but also knowledge about their localization and relationship to other cellular components. Thus, techniques for determining how macromolecules recognize and interact with each other will provide a key element of cell biological studies, essential for opening the door between genomic information and a deeper understanding of biology.

Imaging Protein-Protein Interactions by Fluorescence Resonance Energy Transfer (FRET) Microscopy

Specific protein-protein interactions, whether induced by covalent protein modifications or not, are generally considered to mediate cellular signaling and function. Detection of these processes has long been restricted to bulk biochemical methods such as immunoprecipitation (*UNIT 7.2*) and immunoblotting (*UNIT 6.2*). These approaches have proven invaluable, e.g., in uncovering the major signal transduction pathways by delineating the hierarchy of protein-protein interactions and kinase-substrate relationships in the different phosphorylation cascades. However, immunoblotting techniques lack spatial information and the interactions that are detected depend on the stability of the complex during the experimental conditions that exist outside the cell in homogenates. Detection of proteins using immunofluorescence provides spatial information on the micrometer scale, and it is therefore not possible to infer protein-protein interactions.

Limited information on the phosphorylation status of proteins can be obtained by the application of phospho-specific antibodies against specific phosphorylated residues in a given protein (see *UNIT 14.2*). The use of these antibodies is, however, restricted by availability and specificity. Only a small number of antibodies against phosphoproteins exist and phosphotyrosine residues have proven to produce the most specific antibodies thus far, leaving a large number of modifications undetectable by microscopy.

This unit describes the preparation and execution of a typical fluorescence resonance energy transfer (FRET) experiment. The following procedures will specifically refer to the use of a GFP-tagged protein as donor and Cy3-labeled antibodies as acceptor. As an example, covalent modification by tyrosine phosphorylation of the epidermal growth factor receptor (EGFR) is determined by FRET between C-terminal GFP-tagged EGFR and Cy3-labeled anti-phosphotyrosine antibodies (Wouters and Bastiaens, 1999). FRET is measured by release of donor quenching through acceptor photobleaching. An advantage of this method is the convenient setup; it does not require specialized equipment but can be performed using common microscopy equipment, preferably a confocal laser scanning microscope (Bastiaens and Jovin, 1996; Bastiaens et al., 1996; Wouters et al., 1998). The method is quantitative, and by simple relationships, a FRET efficiency is obtained. The sample preparation described in this unit is identical for other FRET microscopy techniques or other donor-acceptor pairs. As an illustration, the result of a more advanced FRET measurement using fluorescence lifetime imaging microscopy (FLIM), which is based on the change in GFP fluorescence lifetime (see Background Information), is also included (Bastiaens and Squire, 1999; Ng et al., 1999; Wouters and Bastiaens, 1999).

This unit describes FRET microscopy based on release of quenched donor fluorescence after acceptor photobleaching (see Basic Protocol), microinjection of reagents into the nucleus or cytosol (see Support Protocol 1), and labeling antibodies with Cy3 (see Support Protocol 2).

FRET MICROSCOPY OF FIXED CELLS

BASIC PROTOCOL

A number of quantitative FRET microscopy techniques are available at this time. A technique based on the release of quenched donor fluorescence after acceptor photobleaching will be described in this unit. This technique requires a pixel-by-pixel reference image to be created by photobleaching of the acceptor through continuous illumination at the absorption maximum of the acceptor. The time scale of the pho-

Contributed by Fred S. Wouters and Philippe I.H. Bastiaens
Current Protocols in Cell Biology (2000) 17.1.1-17.1.15

tobleaching process is on the order of minutes. In a lifetime-based FRET approach, the photobleaching step is used at the end of a time-lapse sequence of measurements to introduce an intracellular reference in live cells. In the donor intensity approach (unquenching), described here in detail, the time scale of photobleaching restricts the technique to fixed cells but has the advantages of being relatively simple and quantitative.

Materials

Cells of interest
Plasmid for GFP-tagged protein
Transfection reagent (e.g., Fugene 5 from Boehringer Mannheim, Lipofectin from Life Technologies, Effectene from Qiagen, or Superfect from Qiagen)
Serum-free medium
Low-background fluorescence CO_2-independent medium (Life Technologies, or see recipe)
Phosphate-buffered saline (PBS; see recipe), pH 7.4
4% (w/v) formaldehyde fixative solution (see recipe)
Quench solution: 50 mM Tris·Cl (pH 8.0)/100 mM NaCl (*APPENDIX 2A*)
0.1% (v/v) Triton X-100 in PBS
Antibody (e.g., PY72 monoclonal anti-phosphotyrosine antibody) labeled with Cy3 (see Support Protocol 2)
1% (w/v) bovine serum albumin (BSA, fraction V) in PBS
Mowiol mounting medium (see recipe)

6- and 12-well tissue culture plates
Coverslips
Microscope slides
Confocal laser scanning microscope (e.g., Zeiss LSM 510), equipped with argon (488 nm) and He/Ne (543 nm) lasers selected by the HFT 488/543 double dichroic filter, GFP fluorescence selected by the NFT 545 dichroic and BP 505-530 emission filter, and Cy3 fluorescence selected by the LP560 emission filter
Imaging software package (e.g., NIH-image or IPLab Spectrum from Scanalytics)

Additional reagents and equipment for transfection of mammalian cells (*APPENDIX 3A*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Prepare cells

1. Seed the cells onto culture dishes containing coverslips.

   For live-cell FRET experiments, seed the cells onto glass-bottom MatTek culture dishes.

   The cells should be adherent and grow in a monolayer.

2. Transfect cells with the plasmid for GFP-tagged protein of interest using calcium phosphate precipitation, lipofection, or the activated dendrimer reagent, Superfect.

   For cells that are difficult to transfect, due to resistance to transfection (e.g., primary cell lines), or due to cytotoxicity of the transfection reagent, the DNA for the GFP-tagged protein can be introduced by nuclear microinjection (see Support Protocol 1). The latter method is also particularly useful when the expression levels of the protein of interest have to be controlled accurately.

3. Grow the cells, typically 1 to 2 days post transfection, until expression levels of the GFP-tagged protein are high enough to detect with fluorescence microscopy. When needed, starve the cells overnight with serum-free medium to make them semi-quiescent.

   For cells that undergo apoptosis upon serum deprivation, lower the serum concentration in the medium to 0.5%.

4. On the day of the experiment, transfer the coverslips to a 12-well tissue culture plate.

   Subject the cells to the desired experimental conditions (e.g., growth factor/hormone stimulation, or incubation with drugs or inhibitors).

Fix cells

5. Wash the cells with ice-cold PBS, aspirate, and add 1 ml 4% formaldehyde fixative solution. Allow cells to fix at room temperature for 10 min.

   The common alternative fixation protocol, where cells are incubated in −20°C methanol for 5 min, is not advised. Strictly speaking, this treatment does not fix the tissue, but precipitates the cellular proteins. Protein-protein interactions are therefore likely to be affected.

6. Quench excess fixative with quench solution by briefly washing the cells, then changing to fresh quench solution and incubating 5 min at room temperature.

   In a first short wash, the excess fixative is removed. In a second 5-min incubation, the remaining aldehyde groups are allowed to react with the primary amino group on the Tris molecule. Alternative, equally effective, quench solutions are 0.1 M hydroxylamine or 0.1 M glycine.

7. Permeabilize cellular membranes by incubating 5 min with 0.1% Triton X-100 to allow penetration of acceptor-labeled molecules into fixed cells.

   In this treatment, a compromise is made between optimal morphology and permeabilization. A milder detergent treatment with 0.1% saponin in PBS or a harsher permeabilization with −20°C methanol for 5 min can be considered if morphology or permeabilization, respectively, is compromised.

8. Wash the cells with PBS to remove the permeabilization solution.

Add antibody

9. Dilute Cy3-labeled antibodies appropriately in 1% BSA/PBS. Incubate the coverslips with appropriately diluted Cy3-labeled antibodies for 1 hr, at room temperature.

   Typical concentrations are 0.1 to 10 μg/ml, but it is advised that a titration series be performed to determine the antibody concentration where epitope binding saturates.

   To minimize the amount of antibody needed, press a sheet of Parafilm to the bench with some water, place 25-μl drops of antibody solution on the Parafilm, place the coverslips cells-down on these drops, and incubate 1 hr. To facilitate handling of the coverslips at the end of the 1-hr incubation, place a pipet to the edge of a coverslip and add ~100 μl PBS underneath it. This will lift the coverslip so that it can be easily picked up with jeweler's forceps.

10. Transfer the coverslips to 6-well tissue culture plates and wash four times, each time with 3 ml PBS, to remove excess antibody.

11. Blot off excess PBS with tissue and mount the coverslips on slides with ~10 μl Mowiol mounting solution. Allow Mowiol to harden overnight at 4°C before imaging.

If necessary, cells can be imaged after a short drying period of 1 hr if the coverslip is attached to the slide by painting the edge of the coverslip with molten agarose or rubber cement at four points. Do not use nail polish since this has been shown to quench GFP fluorescence.

Examine cells and calculate results

12. View the specimen on a confocal microscope using a 63× or 100× oil-immersion objective. Acquire an image in the GFP channel (excitation, 488 nm; emission, NFT 545, BP505-530). Either take an image of the entire field of vision or select a region of interest containing the cell that is to be imaged.

    GFP fluorescence is selected by the NFT 545 dichroic and BP 505-530 emission filter.

    Do not use the full dynamic range of the detector, since unquenching will result in added fluorescence. Depending on the make of the confocal microscope, make sure that a second image can be made at exactly the same location. Do not adjust the settings (i.e., pinhole size, contrast, brightness, laser power, or averaging) for the GFP channel.

    This acquisition provides the FRET-quenched donor image (F_{DA}), since the acceptor is present throughout the cell, causing FRET with the GFP donor.

    Minimize GFP photobleaching at this point by limiting the illumination.

13. Change to the Cy3 channel (excitation, 543 nm; emission, LP560) and take an image of the cell, minimizing Cy3 photobleaching. Select a portion of the cell in which the FRET efficiency is to be determined.

    Cy3 fluorescence is selected by the LP560 emission filter.

    This region is where the acceptor will be photobleached, thereby revealing the unquenched donor intensities enabling FRET calculation.

    Consequently, any portion of the cell where the acceptor is not photobleached serves as control [i.e., $1 - F_{DA}/F_{DA} = 0$]. This area in the same cell will provide an essential control to judge the effects of photobleaching GFP, lateral movement, or focal mismatch between the two consecutive donor images.

14. Photobleach the selected acceptor region by repeated scanning with the 543-nm He/Ne laser line at full power. Follow the progress of photobleaching by monitoring the intensities of the respective images (emission: NFT 545, BP505-530). Continue until there is no more discernible Cy3 intensity.

    Depending on the staining intensity and the area that is bleached, this will typically take 1 to 20 min.

    When selecting the photobleaching region on the Zeiss LSM 510 confocal microscope, crop the acceptor image to this region (and note the zoom settings to return to the original image after bleaching) instead of selecting a region of interest (ROI). In the latter option, the entire area will be scanned but the laser will only switch on in the ROI. Consequently, the duty cycle is low and bleaching will take considerably longer.

15. Return to the GFP channel and make the second acquisition, using identical settings and location of the prebleached image.

    This provides the F_D reference in the region where the acceptor was photobleached.

16. To calculate the FRET efficiency in the bleached area, use an appropriate imaging software package. Subtract the prebleach donor image from the post-bleach donor image (i.e., $F_D - F_{DA}$). Divide this image by the postbleach donor image: $(F_D - F_{DA})/F_D$; this is identical to $1 - (F_{DA}/F_D) = E$, the image of FRET efficiencies.

    A software package capable of performing the abovementioned image processing is NIH Image. This package is freely available from http://rsb.info.nih.gov/nih-image/ and ver-

sions are available for Apple Macintosh, Windows (Scion image) and even a Java version is available that runs on any platform (Image J). A more versatile commercial package is IPLab Spectrum.

Image arithmetic for calculating the FRET efficiency should be performed on a region of interest obtained by thresholding the images in order to prevent the amplification of background noise. Therefore, thresholds should be chosen in such a way that the background is omitted in the calculation. Accuracy can be improved by subtracting the average background intensity from the images before calculating the FRET efficiency.

NUCLEAR AND CYTOSOLIC MICROINJECTION

SUPPORT PROTOCOL 1

The following is a generic protocol for introduction of DNA or labeled proteins into a cell. DNA is microinjected directly into the nucleus to achieve controlled and high expression of the protein of interest. Labeled proteins are injected into the cytosolic region next to the nucleus since the cell is at its highest here, facilitating injection.

Materials

Cells of interest, cultured in MatTek glass-bottom 35-mm dishes (MatTek)
DNA (e.g., human EGFR cDNA in the Clontech pEGFP-N1 expression vector; *APPENDIX 3A*)
HPLC-grade water

Millex-GV4 0.22-μm filtration unit
GELloader tips (Eppendorf)
Needles for microinjection (e.g., Femtotip from Eppendorf)
Microinjector (e.g., Eppendorf model 5244)
Micromanipulator (e.g., Eppendorf model 5170)
Inverted microscope with 10× and 40× air objectives

Additional reagents and equipment for preparation of DNA (*APPENDIX 3A*)

1. Prepare DNA, to be microinjected, of the highest possible quality.

   In the authors' experience, double cesiumchloride–banded DNA and DNA purified by Qiagen ion-exchange resin (Qiaprep midi/maxiprep columns) perform equally well.

   Cy3-labeled protein (e.g., antibody against protein of interest; see Support Protocol 2) may also be microinjected.

2a. *For optimal expression a few hours after microinjection:* Dilute DNA in HPLC-grade water to 100 μg/ml.

2b. *For expression overnight:* Dilute DNA in HPLC-grade water to 1 μg/ml.

3. Clear the DNA solution to prevent blocking of the glass needle during microinjection as follows. Place a 0.22 μm Millex filtration unit in a 0.5-ml microcentrifuge tube and place the entire unit in a 1.5-ml microcentrifugation tube to enable centrifugation. Filter 10 μl of the DNA solution by microcentrifugating 1 min at maximum speed, room temperature.

   Since these membranes have low-protein-binding characteristics, they can also be used for clearing Cy3-labeled proteins (see Support Protocol 2).

   The recovery of Cy3-labeled antibodies when cleared this way is also generally very high. Alternatively, microcentrifuge the Cy3-labeled protein for 20 min at maximum speed. Sacrifice a small amount of solution to prevent disturbing the pellet of aggregated protein.

4. Load 2 µl of DNA solution (or Cy3-protein solution) using GELloader tips into the capillary glass needle of the microinjector.

   Commercially available needles (Femtotip from Eppendorf) can be used. These needles fit directly into the needle holder of the Eppendorf microinjection device. Carefully remove the pipet tip that protects the needle. In the authors' experience, this is most easily performed by holding the needle pointing downwards and loosening the tip by rotation until it falls to the ground. If access is available to a needle-pulling device, make sure that the diameter of the needle opening is ~0.25 µm. The diameter of the needle opening can be estimated using a simple syringe-operated micropipet bubble meter (Clark Electronic Instruments) by measuring the air pressure required to expel air bubbles from the pipet into a liquid (Mittman et al., 1987).

5. On an inverted microscope, microinject the DNA solution (or Cy3-protein solution) into the nucleus (or perinuclear cytosol) of cells grown in MatTek culture dishes.

   Typical settings are: 0.3 sec, 150 to 400 hPa injection pressure with 20-hPa back-pressure to prevent medium from entering the needle.

   The injection pressure may be varied according to the needle opening and cell type.

   No major movement of the nucleus (or cell organelles) should be observed. A visual indication for excessive pressure is the separation of the nucleus from the surrounding cellular material (i.e., light ring around the nucleus) and leakage into the cytosol, visible by movement of the cellular organelles.

   Restrict the microinjection procedure to a maximum of 10 min. In the authors' laboratory, microinjection is performed at room temperature in normal CO_2-dependent medium. After 10 min, the medium starts to acidify significantly (i.e., purple medium). CO_2-independent (or HEPES-buffered) media can be used for longer periods.

SUPPORT PROTOCOL 2

PROTEIN LABELING WITH Cy3

Proteins are labeled on unprotonated free amino groups (i.e., α-amino terminus or ε-amino groups on lysine side chains) by the succinimide esters of the fluorescent sulfoindocyanine (Cy) dyes (also see *UNIT 16.5*). Alkaline labeling conditions ensure deprotonation of amino groups. Cy-dyes are water soluble and have high extinction coefficients, making them particularly useful for sensitive detection of proteins with minimal disturbance of protein function. The following protocol describes the labeling of antibodies with Cy3, a suitable donor for GFP in a FRET experiment, and also explains how to remove stabilizing compounds (e.g., gelatin, BSA), which are often added to prolong shelf life, as these contain amino groups that would compete with the labeling reaction.

Materials

Antibody (PY72 monoclonal anti-phosphotyrosine antibody)
1 M Tris·Cl, pH 8.0 (*APPENDIX 2A*)
10 mM and 100 mM Bicine/NaOH, pH 8.0
100 ml citric acid/NaOH, pH 2.8
1 M Bicine/NaOH, pH 9.0
1 M NaCl (*APPENDIX 2A*)
Labeling buffer: 100 mM Bicine/NaOH (pH 8.0)/100 mM NaCl
Cy3.29–OSu monofunctional sulfoindocyanine succinimide ester (Amersham Pharmacia Biotech)
Dimethylformamide (DMF) dried by addition of 10 to 20 mesh 3-Å pore diameter molecular sieve dehydrate (Fluka)
1-ml Protein G HiTrap columns (Amersham Pharmacia Biotech)
Centricon YM30 concentrators (Amicon)

Biogel P6DG Econopac prepacked size-exclusion columns (5.5 × 1.5–cm, ~10 ml; Bio-Rad)

1-ml and 10-ml syringes with HPLC Luer-Lok fitted tubing

Additional reagents and equipment for spectrophotometric protein determination (*APPENDIX 3B*)

Prepare antibody solution

1. Resuspend antibody to 1 mg/ml in PBS.

   Excess stabilizing agents containing free amino groups (e.g., BSA and gelatin) in commercially available antibody preparations compete for the labeling reagent and have to be removed by Protein A or Protein G affinity chromatography (UNIT 16.3). If the protein solution to be labeled is free of additional amino groups, proceed directly to step 10. A number of suppliers of antibodies, e.g., Transduction Laboratories and New England Biolabs, can provide their products free of these compounds. Request that the antibodies be provided at 1 mg/ml concentration in PBS.

2. Prepare a syringe-operated 1-ml protein G HiTrap column. Equilibrate column with 10 ml PBS at a maximum flow of 4 ml/min.

   All fluid handling is performed manually using appropriately sized syringes. These columns are easy to use and result in minimal loss of protein.

   A number of subclasses of IgG molecules do not bind to protein A. When using protein G or A chromatography, make sure that the antibodies are compatible (see Table 7.2.1).

3. Add 0.1 vol 1 M Tris·Cl, pH 8.0, to the antibody solution.

   Commercial antibody solution is typically 0.5 ml at 0.1 mg/ml IgG.

4. Load antibody solution onto the column and wash column with 10 ml of 100 mM Bicine/NaOH, pH 8.0. Collect run-through.

5. Wash column with 10 ml of 10 mM Bicine/NaOH, pH 8.0. Collect run-through.

6. Elute column with 5 ml of 100 mM citric acid/NaOH, pH 2.8, and collect 0.5-ml fractions (i.e., 8 drops) in 1.5-ml microcentrifuge tubes containing 100 µl of 1 M Bicine/NaOH, pH 9.0, to neutralize the pH. Mix immediately and store on ice.

7. Determine the A_{280} of the eluted fractions using a spectrophotometer (*APPENDIX 3B*) and pool the fractions that contain protein.

   Under the given conditions, the protein will typically elute in the first four fractions.

8. Add 0.1 vol of 1 M NaCl. Concentrate the solution in a YM30 Centricon to ~200 µl by centrifuging at 5000 × *g*, 4°C.

9. Redilute to 2 ml with labeling buffer and repeat the concentration and redilution steps (steps 8 and 9).

10. Concentrate to ~50 to 100 µl as in step 8 and collect the concentrated protein solution.

    When labeling proteins from solutions containing relatively high concentrations (i.e., millimolar) of compounds that contain free amino groups (e.g., Tris, glycine, gluthathione), repeat the concentration-redilution cycle more often. Each cycle dilutes the compound ~10 fold. Allow a maximum of 10% of contaminating primary amino groups, compared to the protein to be labeled.

    For example, the protein concentration in a 0.5 mg/ml antibody solution is 3.3 µM, assuming a molecular mass of 150 kDa. If this solution contains 50 mM Tris buffer (a 1.5 × 10^4 fold excess of free amino groups), a 1.5 × 10^5-fold dilution, corresponding to 5.2 concentration cycles, is needed to reach the 10% contamination level.

When labeling proteins other than antibodies, a Bicine concentration of 50 mM is recommended in the labeling buffer. Additional compounds that are needed to maintain the function of the protein to be labeled should be included. At this point, no compounds containing free amino groups should be added. High concentrations of reducing agents are also known to inhibit the labeling reaction. It is recommended that these be included in the chromatography step following labeling to prevent these compounds from interfering with the labeling reaction. Choose the cut-off value of the Centricon carefully to ensure retention of the protein of interest.

Prepare dye

11. Reconstitute Cy3.29–OSu in 20 µl dry DMF to give a ~10 mM Cy3 solution. Determine the exact concentration by measuring the absorption of a 10^4-fold diluted solution in PBS. From the ε_{550} of 150 $mM^{-1}cm^{-1}$, calculate the concentration.

    Cy3.29–OSu is supplied as a desiccated pellet in microcentrifuge tubes.

    DMF is dried by addition of hygroscopic beads to the container.

    The ε_{650} of Cy5 is 250 $mM^{-1}cm^{-1}$.

Perform labeling reaction

12. Determine the protein concentration of the antibody (or protein) solution to be labeled based on A_{280} reading (*APPENDIX 3B*).

    Antibody concentration at A_{280} = 1.0 is typically 1 mg/ml. At low protein concentrations (i.e., <0.1 mg/ml), or for smaller proteins (where the A_{280} = 1.0 = 1 mg/ml protein relation does not hold true), the protein concentration can be determined using the Bio-Rad Coomassie-based protein determination assay.

    Antibodies are known to give a lower apparent concentration when BSA is used as a standard in this assay. Multiply the concentration found by a factor of two or use an IgG standard.

13. Slowly add a 10- to 20-fold molar excess of dye to the protein solution while simultaneously stirring the solution with the pipet tip.

    The added volume of Cy3/DMF should not exceed 10% of the total volume, to prevent protein denaturation by DMF.

14. Incubate 30 min at room temperature, shaking the tube gently every 10 min.

Remove unconjugated dye

15. Remove the unconjugated dye by size-exclusion chromatography on a Bio-Rad P6DG Econopac (6-kDa exclusion size) column. Equilibrate the column with 30 ml PBS (or a buffer that is specifically formulated for the protein to be labeled).

16. Load the labeling reaction mixture onto the column and wash with a small amount (i.e., ~200 µl) of PBS (or equilibration buffer). Discard the first 2.5 ml (void volume ~3.3 ml).

17. Collect the colored protein fraction (or 2 ml of eluate if the staining is too weak to be visible) in a YM30 Centricon concentrator and concentrate to approximately the volume of the labeling reaction.

Determine labeling ratio

18. Estimate the labeling ratio by either of the following formulas:

$A_{554} \times M/[A_{280} - (0.05 \times A_{554}) \times 150]$ for Cy3

$A_{650} \times M/[A_{280} - (0.05 \times A_{650}) \times 250]$ for Cy5

where A_x is the absorption at wavelength x and M is the molecular weight of the protein in kDa.

The extinction coefficients (in units of $mM^{-1}cm^{-1}$) 150 and 250 are for Cy3 and Cy5, respectively. These formulas assume the A_{280} = 1.0 = 1 mg/ml relationship as found for larger proteins (i.e., >50 kDa) and correct for the 5% absorption of Cy3 at 280 nm. For smaller proteins or lower protein concentrations (i.e., <0.1 mg/ml) that cannot be reliably estimated from the A_{280}, determine the protein concentration by the Bio-Rad protein assay and estimate the labeling ratio from:

$A_{554} \times M/(P \times 150)$ for Cy3

$A_{650} \times M/(P \times 250)$ for Cy5

where P is the protein concentration in mg/ml as determined by Bio-Rad assay.

As previously mentioned, IgG concentration obtained with BSA as standard has to be multiplied by 2.

Using mass spectrometry, the authors have observed that ~50% of the Cy3 molecules in the preparation provided by Amersham are reactive. The molar excess is thus 7.5-fold for a 15-fold excess and, the typical labeling ratio of 2 to 3 that is reached under these conditions is therefore reasonably efficient.

19. Verify covalent labeling of the antibody by SDS-PAGE of the labeled product (*UNIT 6.1*). Use transillumination with a UV source (302 nm) to visualize labeled protein.

Ensure that there is no fluorescence at the running front of the gel; this indicates contamination with unconjugated dye. Where applicable, verify the specific activity of the protein and compare to the specific activity before labeling to ensure that labeling did not interfere with the biological function of the protein.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Formaldehyde fixative, 4% (w/v)

Dissolve 4 g of paraformaldehyde (Sigma) in 50 ml water. Add 1 ml 1 M NaOH solution and stir gently on a heating block (>60°C) until the paraformaldehyde is dissolved. Add 10 ml of 10× PBS (see recipe) and allow to cool to room temperature. Adjust the pH to 7.4 using 1 M HCl (~1 ml). Adjust to 100 ml with water and filter through a Millipore 0.45-µM filter using a syringe to remove traces of undissolved paraformaldehyde. Store up to several months at −20°C.

Low-background-fluorescence CO_2-independent medium

Adjust the formulation of the standard medium by omitting the pH indicator phenol red, the antibiotics penicillin and streptomycin, folic acid, and riboflavin. Before use, supplement the medium with 50 mM HEPES/NaOH, pH 7.4. Store 1 to 2 months at 4°C.

Mowiol mounting medium

Mix 6 ml glycerol, 2.4 g Mowiol 4-88 (Calbiochem), and 6 ml water. Shake for 2 hr. Add 12 ml of 200 mM Tris·Cl, pH 8.5 (*APPENDIX 2A*), and incubate at 50°C with occasional mixing until the Mowiol dissolves (i.e., ~3 hr). Filter through 0.45-µM Millipore filtration unit and store in aliquots up to several weeks at 4°C or up to several months at −20°C.

Phosphate-buffered saline, 10×

68 g NaCl
18.8 g Na_2HPO_4
2 g KH_2PO_4
H_2O to 1 liter

COMMENTARY

Background Information

Fluorescence resonance energy transfer (FRET) is a photophysical process that can be exploited to obtain information on protein-protein interactions and protein modification in addition to location (Clegg, 1996). Its usefulness lies in the ability to sense the presence of acceptor fluorophores in the extreme vicinity of a donor fluorophore with a maximum separation distance that is in the order of magnitude of single protein molecules. FRET is a radiationless process whereby an excited donor fluorophore transfers energy to an acceptor by dipole-dipole coupling (Förster, 1948). Due to the 6th-order distance dependence of the FRET efficiency, two discrete states of the fluorophores can be discriminated: exhibition of efficient FRET when donor and acceptor are in close proximity or no occurrence of FRET due to distance.

The transfer of energy (FRET) from an excited donor fluorophore to a nearby acceptor fluorophore has a number of consequences with respect to the fluorescent properties of both fluorophores and this can be exploited to measure the efficiency of this process.

In the methods presented in this unit, FRET is determined by measuring the donor fluorescence emission exclusively (Bastiaens and Squire, 1999). The acceptor fluorophore is excluded from the measurement by the choice of optical filters. As a consequence, a large excess of acceptor can be used and, when using antibodies, specificity can be sacrificed to gain higher occupancy.

In photophysical terms, FRET provides an extra channel of nonradiative decay by which the excited state of the donor fluorophore is depopulated. This results in a reduced quantum yield (Q), the ratio of emitted photons over absorbed photons. The reduction in quantum yield can be determined in two ways: (1) by the decrease in steady-state fluorescence emission; or (2) the decrease in fluorescence lifetime (τ), which characterizes the duration of the excited state of the fluorophore. The measurement of the change in quantum yield by steady-state emission has to be calibrated due to its dependence on concentration and light path. In contrast, the fluorescence lifetime is proportional to Q and is independent of concentration and light path. Fluorescence lifetimes are measured by fluorescence lifetime imaging microscopy (FLIM; Lakowicz and Berndt, 1991; Gadella et al., 1993; Gadella and Jovin, 1995) and can be performed sufficiently fast to enable real-time live cell experiments. FLIM requires a specialized microscopy setup enabling high-frequency modulation of the excitation light and the gain on the detector. This technique can be combined with acceptor photobleaching to provide an internal lifetime reference, e.g., at the end of a live-cell time-lapse sequence. A detailed description of a frequency domain FLIM set-up is given by Squire and Bastiaens (1999). This type of imaging system is gradually being made commercially available by companies such as LaVision or Lambert Instruments (see *SUPPLIERS APPENDIX*).

Calibration in the intensity-based FRET method is achieved by photobleaching the acceptor to provide the unquenched donor (Bastiaens et al., 1996; Bastiaens and Jovin, 1998; Wouters et al., 1998). In this method, an exposure of the donor fluorescence emission is made (F_{DA}, fluorescence emission of donor in presence of the acceptor). Removal of the acceptor fluorophore from the sample by photobleaching enables the acquisition of an unquenched donor emission image when the exposure is taken with settings identical to those used for the original image (F_D, fluorescence emission of the donor in absence of the acceptor). This essentially recovers that part of the fluorescence intensity that is lost to FRET. A pixel-by-pixel FRET efficiency map is obtained by simple image arithmetic: $E = 1 - (F_{DA}/F_D)$. The specificity of the acceptor photobleaching techniques lies in the steep edge at the long-wavelength (i.e., red edge) of the absorption spectrum of the donor, enabling exclusive photobleaching of the acceptor. Essential to the success of this technique is that the photoproduct of the acceptor does not exhibit residual absorption and does not fluoresce at donor emission wavelengths. Cy3 meets both

criteria to act as a proper acceptor for GFP; the same is the case for Cy5 acting as acceptor for Cy3. Since photobleaching of the acceptor occurs on a minute time scale, this type of FRET determination is restricted to fixed cells.

FRET microscopy can be used to detect protein-protein interactions in single cells as if one were performing an immunoprecipitation experiment. There is, however, no need to isolate the complex or remove it from its physiological environment prior to investigation, and the experiment can be performed in living cells. A number of approaches can be followed: (1) the donor molecule can be purified, labeled with Cy3, and introduced into cells by microinjection (Bastiaens and Jovin, 1996); (2) the donor molecule can be detected by a Cy3-labeled antibody or Fab fragment (provided the antibody is highly specific) on fixed cells (Ng et al., 1999); (3) the donor protein can be fused to one of the mutants of the intrinsically fluorescent green fluorescent protein (GFP) from the jellyfish *Aequoria victoria* (Tsien, 1998), genetically encoded, and expressed; (4) acceptor proteins (mostly antibodies or Fab fragments) can be labeled with Cy5 (for Cy3 donors), or labeled with Cy3 (for GFP donors) and introduced by microinjection or incubation in the case of antibodies; and (5) the recently discovered and commercial available red fluorescent protein from the *Anthozoa* sp. (Matz et al., 1999) can be employed. The latter opens up a wide array of possibilities since an ideal acceptor for GFP can be coexpressed in the same cell, obviating the need for exogenous labeling and microinjection.

Alternative methods for measuring FRET on the basis of fluorescence intensities are available. In these methods FRET is not determined from the donor fluorescence exclusively, but also from the sensitized emission of the acceptor, excited by receiving energy from the donor. These approaches fall into two categories (1) those based on changes in donor/acceptor emission ratio (Adams et al., 1991; Miyawaki et al., 1997); and (2) those based on acceptor sensitized emission (Day, 1998; Gordon et al., 1998; Mahajan et al., 1998). These approaches are attractively simple to perform but may suffer from a number of drawbacks that cannot always be corrected for.

In the ratiometric approach, the decrease in donor emission and concomitant increase in acceptor emission are imaged by calculating the ratio of these intensities at each pixel. Since this is a relative measure, a change in FRET can only be observed in live cells where the ratio changes over time. A decrease in the donor/acceptor emission ratio can be taken as an indication for the occurrence of FRET. However, this ratio is also dependent on the local concentrations of the donor and acceptor molecules measured in each pixel, which can complicate the interpretation by differential translocation of the biomolecules conjugated to donor and/or acceptor fluorophores. This problem does not occur when the donor and acceptor fluorophores are present on the same molecule (e.g., the "chameleon" Ca^{2+} biosensors; Miyawaki et al., 1997), since the relative concentrations are identical at each location in the cell.

Measuring FRET from the sensitized emission intensity alone (by using a "FRET filter set") is the most widely used method. Emission from the acceptor would be an exclusive readout for FRET when contamination with donor fluorescence (i.e., donor bleed-through) and direct excitation of the acceptor did not complicate the approach. Correction for these effects by extensive control measurements, some of which have to be performed in different samples where the acceptor is absent, is described in Gordon et al. (1998). Here, both donor-quenching and acceptor-emission information are used to derive the sensitized emission contribution, which is proportional to the FRET efficiency. However, sensitized emission is also proportional to the concentration of the acceptor. Therefore, relative populations of associated molecules cannot be determined. Molecules that are not participating in FRET are not detected. In contrast to donor-based measurements, no estimation can be made of the bound/unbound fractions from the sensitized emission alone. Since excitation spectra generally exhibit an extensive tail at the lower wavelength (blue-edge) the acceptor can easily be excited at the wavelength used for excitation of the donor. Direct excitation will be especially problematic when the recently discovered red fluorescent protein from the *Anthozoa* sp. is used as an acceptor, since its absorption spectrum shows multiple absorption peaks at the excitation optima for the green and yellow fluorescent protein.

Critical Parameters and Troubleshooting

FRET measurements are prone to false negative results. While the finding of FRET by unquenched fluorescence is highly unlikely to be caused by artifactual processes or nonspecific proximity of donor and acceptor, the absence of FRET does not provide proof for the

absence of an interaction for a number of reasons.

The presence of a GFP moiety on the protein of interest might interfere with its function or targeting, thus affecting the interaction with the target protein. Cloning vectors for the construction of GFP fusion proteins routinely contain a multiple cloning site that has been optimized for a maximum number of restriction sites to facilitate cloning. As a consequence, the random amino acid residues that they translate into can adopt an unfortunate secondary structure that hinders the proper behavior of the fused protein. In the case of the EGFR-GFP, the amino acid residues encoded by the cloning site were replaced by a flexible six-glycine linker between the GFP moiety and the EGFR to prevent the GFP from affecting EGFR function (Wouters and Bastiaens, 1999). Another problem might arise when the separation distance between the GFP moiety on the donor protein and the Cy3 groups on the antibody is too large (i.e., >10 nm) for energy to be transferred efficiently. This might be overcome by using antibodies raised against a different epitope, or the entire protein, thus increasing the chance of a favorable orientation of the antibody to the donor fluorophore.

The labeling ratio of the antibodies is a common reason for failure to detect FRET. The labeling ratio should exceed 1 to prevent unlabeled antibody from competing with the labeled antibodies. A higher labeling ratio is beneficial for FRET detection since the R_0 distance (i.e., characteristic value for a given donor-acceptor pair, the distance at which 50% of the excited state energy is transferred by FRET) is effectively increased by a larger number of acceptor molecules per donor molecule. In the authors' experience, labeling ratios up to 5 do not significantly affect the specificity of the antibody. However, this should be verified by using the Cy3-labeled antibody in an immunofluorescence experiment and judging the staining pattern as compared to unlabeled antibody. Remember that absolute specificity is not a requirement in the FRET assay, because only the donor photophysical properties are used. However, in extreme cases, the highly labeled antibody could become nonspecific to a point where significant amounts bind to the donor.

It is essential that the donor images before and after acceptor photobleaching be taken under identical conditions. Any change in parameters that influence the collection efficiency of donor fluorescence (i.e., brightness, contrast, laser power, and averaging) will influence the calculation of the FRET efficiency. This will affect the entire image, and the control region in the *E* map will no longer be distributed around 0 but will be uniformly shifted. This also occurs with donor photobleaching. When the laser is used at high intensity, or when too many scans are made for averaging, a substantial amount of the GFP becomes photobleached. This will lead to a shift to negative *E* values in the control region. Furthermore, it is essential to verify that the sample has not moved and that the same focal plane is imaged in both donor images. Movement causes structures in the control region in the *E* map with positive values at the leading edge and negative values at trailing edges. Movement is most often caused by temperature differences between the slide and the objective but can also be caused by drift in the slide holder. To correct for translation of the image after acceptor photobleaching, the maximum in the correlation function between pre- and post-bleaching images gives the shift between the two images (Bastiaens and Jovin, 1998). The correlation function of the two images is obtained by Fourier transformation on both images, followed by multiplication of the conjugate of the Fourier transform of one image by the Fourier transform of the other, and performing an inverse Fourier transform on the resulting image. Another source of structured contrast in the control region in the *E* map can be caused by focal mismatch between the two images, originating from the apparent appearance (positive *E*) or disappearance (negative *E*) of structures. This problem can be prevented by observing the *z* position of the stage between exposures. A larger pinhole can reduce these problems by decreasing the depth of focus but at the cost of *z* resolution. When using pre- and post-*z* sections rather than single-focus plane images, the maximum in a three-dimensional correlation function can be used for registration of the two data sets and a correct three-dimensional *E* map can be obtained (Bastiaens et al., 1996).

Anticipated Results

After photobleaching of the acceptor, an increase in donor emission intensity can be observed when substantial FRET is present. Image arithmetic should produce FRET efficiencies that are closely distributed around zero in the portion of the cell that was not photobleached. Deviations from this condition indicate donor bleaching, lateral movement, or focal mismatch. With the occurrence of FRET, a separate efficiency distribution is expected in

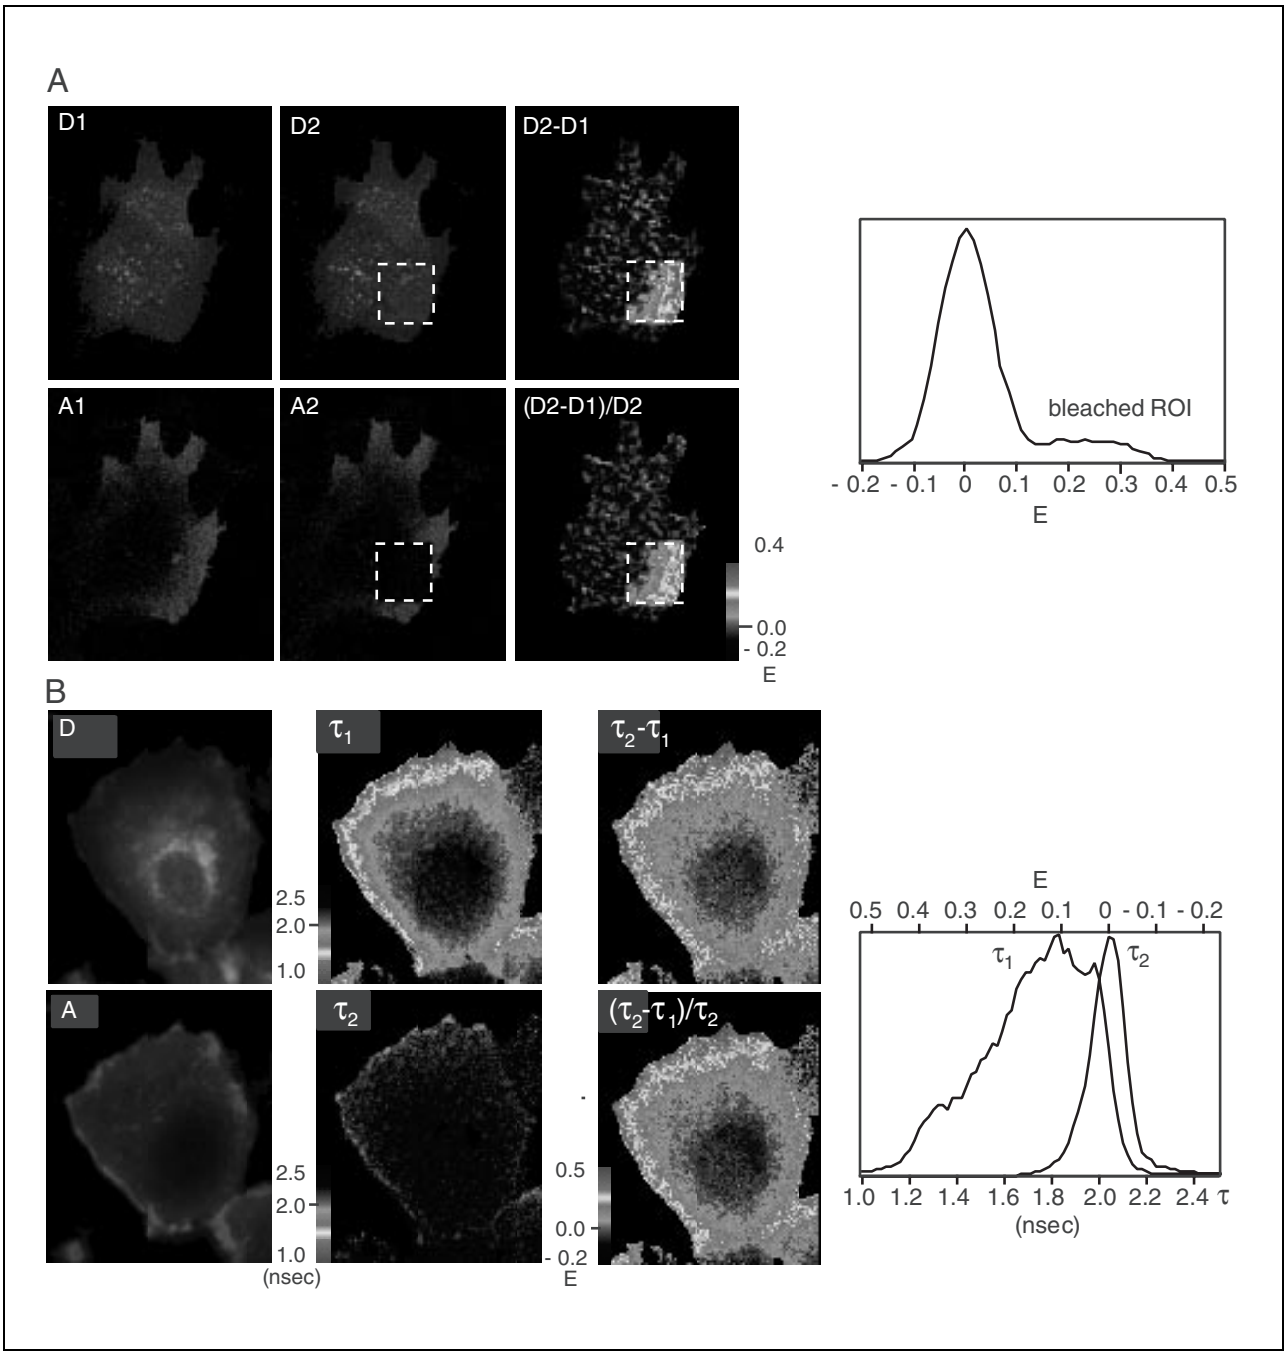

Figure 17.1.1 (**A**) Cy3-PY72 photobleaching releases FRET-quenched EGFR-GFP emission. The histogram shows the distribution of calculated FRET efficiencies in the cell. (**B**) FRET measured by fluorescence lifetime imaging microscopy. The histogram shows the distribution of measured lifetime (nsec) and corresponding calculated FRET efficiencies prior and after photobleaching of the acceptor. **See color figure**.

the photobleached area. The heterogeneity in this distribution contains information about variability in the formation of complexes of the proteins carrying the donor and acceptor fluorophores.

Figure 17.1.1 shows an MCF-7 mammary carcinoma cell expressing EGFR-GFP that was stimulated with 100 ng/ml EGF for 5 min. This cell was incubated with Cy3-labeled anti-phosphotyrosine antibodies (e.g., 10 µg/ml PY72 monoclonal) and EGFR-GFP tyrosine phosphorylation was measured by FRET using the unquenching of GFP fluorescence by acceptor photobleaching (Fig. 17.1.1A) and FLIM (Fig. 17.1.1B). The EGFR-GFP distribution is shown in the D1 image. Most EGFR-GFP is localized at the plasma membrane in addition to internalized (punctate) EGFR-GFP. The cor-

responding antibody-staining A1 shows phosphorylation at the plasma membrane. A rectangular region was subjected to acceptor photobleaching (white box). The GFP fluorescence in this region increased after photobleaching as shown in the difference image (D2 − D1), demonstrating positive FRET efficiencies [(D2 − D1)/D2]. Highest FRET efficiencies can be observed in the plasma membrane corresponding to fully phosphorylated receptor at this location. The large peak in the energy-transfer efficiency histogram that is distributed around zero originates from the area outside the photobleached region and indicates proper image registration. The additional population, ranging from 15% to 35% efficiency, corresponds to the photobleached region. Figure 17.1.1B shows the analogous result of a fluorescence lifetime measurement. The steady-state fluorescence distribution of EGFR-GFP is shown in (D) and the corresponding lifetime map in (τ_1). The anti-phosphotyrosine Cy3 immunofluorescence (A) is photobleached to obtain an intracellular reference lifetime in absence of acceptor (τ_2). As can be seen in the fluorescence-lifetime histogram, these values are homogeneously distributed around an average of ~2.0 nsec. The decrease in lifetime due to FRET is shown in the difference image ($\tau_2 - \tau_1$). The energy-transfer efficiency is given by the normalization of this difference to the reference EGFR-GFP lifetime [$E = (\tau_2 - \tau_1)/\tau_2$] and again shows highly phosphorylated receptor in the plasma membrane.

Time Considerations

From cell seeding, the entire procedure can be performed in 3 to 4 days. This period includes 1 to 2 days for expression of the GFP construct after transfection or microinjection; 1/2 day for treatment, fixation, and antibody incubation of cells; 1/2 day of data acquisition; and 1/2 day for data analysis. Removal of gelatin/BSA from commercial antibody takes ~3 hr. The most time-consuming step in the procedure for labeling antibodies is the buffer exchange using a Microcon concentration device. Depending on the amount of contaminating free amino groups in the original buffer, this can take between 2 and 5 hr. The labeling reaction and subsequent gel filtration chromatography takes ~1 hr.

There are a number of points where the procedure can be interrupted: (1) optimal expression after overnight incubation rather than a 3- to 4-hr incubation post microinjection can be achieved by lowering the concentration of DNA; (2) after fixation and permeabilization, the cells can be stored overnight in PBS at 4°C before antibody incubation; (3) after mounting, the cells can be viewed immediately rather than the following day, by application of rubber cement instead of Mowiol; and (4) the samples can be stored at −20°C for weeks without appreciable loss of antibody staining or FRET.

Identification of Protein Interactions by Far Western Analysis

This unit describes far western blotting, a method of identifying protein-protein interactions. In a far western blot, one protein of interest is immobilized on a solid support membrane, then probed with a non-antibody protein. Far western blots can be used to identify specific interacting proteins in a complex mixture of proteins (see Basic Protocol). They are particularly useful for examining interactions between proteins that are difficult to analyze by other methods due to solubility problems or because they are difficult to express in cells. This method is performed totally in vitro, and the proteins of interest can be prepared in a variety of ways. Peptides can be used to determine the effects of specific residues or post-translational modifications on protein-protein interactions (see Alternate Protocol 2). In addition, many different detection techniques, either radioactive or nonradioactive, can be used. For example, the protein probe may be detected indirectly with an antibody, rather than being labeled radioactively (see Alternate Protocol 1). Thus, techniques and reagents already in hand can frequently be adapted for use with this assay.

CAUTION: Appropriate safety precautions must be taken when working with radioactive materials. Information on proper handling and disposal of radioactive compounds can be found in *APPENDIX 1D* and may be obtained from local radiation safety officials. Specific information on handling ^{35}S-labeled compounds can be found in *UNIT 7.1* and in *APPENDIX 1D*.

FAR WESTERN ANALYSIS OF A PROTEIN MIXTURE

BASIC PROTOCOL

The following is a basic method for detecting protein-protein interactions by far western blotting when one protein is contained within a simple or complex mixture of proteins. First, the protein sample is fractionated on an SDS-PAGE gel (*UNIT 6.1*). After electrophoresis, the proteins are transferred from the gels onto a solid support membrane by electroblotting (*UNIT 6.2*). Transferred membranes may be stained with Ponceau S to facilitate location and identification of specific proteins. Nonspecific sites on the membranes are blocked with standard blocking reagents, and the membranes are then incubated with a radiolabeled non-antibody protein probe. After washing, proteins that bind to the probe are detected by autoradiography (*UNIT 6.3*).

Materials

Samples to be analyzed
1× SDS sample buffer (*APPENDIX 2A*)
Ponceau S staining solution (see recipe)
Blocking buffer I: 0.05% (w/v) Tween 20 in 1× PBS (see recipe for PBS); prepare fresh
Blocking buffer II: dissolve 1 g bovine serum albumin (BSA; fraction V) in 100 ml 1× PBS (see recipe for PBS); prepare fresh
Phosphate-buffered saline (PBS; see recipe), pH 7.9
cDNA encoding protein of interest cloned into an in vitro expression vector
In vitro transcription/translation kit (Promega)
10 mCi/ml ^{35}S-methionine (1000 Ci/mmol)
Probe purification buffer (see recipe)
Probe dilution buffer (see recipe)

Current Protocols in Cell Biology (2000) 17.2.1-17.2.10

Polyvinyldifluoridine (PVDF) or nitrocellulose membrane for protein transfer

Microfiltration centrifuge columns (e.g., Gelman Nanosep, Pall Filtron, or Millipore Microcon)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), electrophoretic transfer of proteins to a support membrane (*UNIT 6.2*), in vitro translation (*UNIT 11.2*), and autoradiography (*UNIT 6.3*)

NOTE: Always handle support membranes with gloves or membrane forceps.

Prepare protein blot

1. Prepare the protein sample to be analyzed by resuspending it in 1× SDS sample buffer.

   UNIT 6.1 gives instructions on preparation of samples and amount of samples to load. In general, ~50 to 100 µg can be loaded in each lane for a complex mixture of proteins. A smaller amount, i.e., 10 to 20 µg, is loaded for less complex protein samples. The amount loaded may also need to be adjusted for the size of gel. (Usually 30 µg/mm^2 loading surface can be resolved without smearing.)

2. Separate the samples on an SDS-polyacrylamide gel (*UNIT 6.1*).

3. Transfer the proteins from the gel to a solid support membrane (e.g., PVDF or nitrocellulose) by semidry electroblotting (*UNIT 6.2*).

   Either nitrocellulose or PVDF membranes can be used with good results. PVDF membranes are easier to handle and tend to give a slightly higher signal-to-noise ratio, probably due to increased protein retention by the membrane.

Stain with Ponceau S

4. After transfer, stain the membrane for 5 min in ~100 ml freshly diluted 1× Ponceau S staining solution. Stain the membrane in a plastic container large enough to hold the blot and use sufficient Ponceau S to cover the membrane completely.

   This step is optional. When the protein samples consist of a few proteins, or when there are clearly visible bands that facilitate orientation of the blot, staining with Ponceau S can provide helpful landmarks. One can unequivocally identify interacting bands, mark the position of molecular weight standards, and trim away excess membrane more exactly.

5. Destain the membrane washing in several changes of deionized water until the proteins are clearly visible. Place light pencil marks adjacent to important protein bands to mark them for future reference. Trim away excess membrane.

   The stain fades quickly so the marks must be placed immediately.

6. Destain an additional 5 min in water until the red staining fades.

Block membrane

7. Block blot for 2 hr in 200 ml blocking buffer I at room temperature with gentle agitation.

8. Decant and add 200 ml blocking buffer II. Incubate as in step 7.

9. Decant blocking buffer II and rinse the membrane briefly in 100 ml of 1× PBS.

   At this point, the blot may be probed immediately or may be wrapped in plastic wrap and stored for up to 2 weeks at 4°C.

Prepare the probe

10. Following manufacturer's procedures, prepare a radiolabeled in vitro–translated probe of the protein of interest using ^{35}S methionine (also see *UNIT 11.2*).

    The probe can be conveniently prepared during the blocking steps.

    The authors routinely use the Promega TnT quick-coupled transcription/translation system for producing probes. For a small blot (e.g., ≤9 × 9–cm), one half of a standard in vitro transcription/translation reaction (i.e., 25 µl) is sufficient for the probe. For larger blots, an entire 50-µl reaction may be used. In the authors' laboratory it is considered essential that the transcription/translation lysate not be repeatedly frozen and thawed.

11. After translation, dilute the probe with 500 µl probe purification buffer, and purify by microcentrifuging 15 to 30 min at 10,000 × *g,* room temperature, in a microfiltration column. Save aliquots of the purified probe for analysis by SDS-PAGE (i.e., 2 µl), and for scintillation counting (i.e., 2 to 5 µl).

    Check microfiltration column manufacturer's procedure for exact centrifugation times required by different columns. In practice, it is not always necessary to purify the probe through a microfiltration column; many probes give good signals without purification. However, if signal-to-noise ratio is low, probe purification may improve results. In addition, it is possible to quantitate the proportion of probe bound if the probe has been purified.

Bind probe

12. Preincubate blot for 10 min in 50 ml of 1× probe dilution buffer (without probe) by gently agitating at room temperature.

13. Dilute the translated probe with 1× probe dilution buffer in a volume sufficient to cover the membrane to be probed (typically 3 ml).

    For small blots, i.e., ≤9 × 9–cm, a 50-ml conical tube makes a convenient incubation chamber. A volume of 3 ml is enough solution to cover the blot and tubes can be rotated on a mechanical rotator. In addition, the conical tube makes the radiolabeled probe easy to contain and dispose of. Larger blots can be incubated on a Nutator or orbital shaker in a heat-sealable bag, or rotated in a hybridization oven adjusted to room temperature.

14. Add the probe to the membrane and incubate 2 hr at room temperature. Rotate the tubes or agitate bags throughout the binding reaction.

Wash the membrane

15. Transfer the membrane to a plastic dish and wash the membrane with 200 ml 1× PBS for 5 min, room temperature. Repeat for a total of four washes.

    Background is generally quite low and extended washing does not substantially reduce background.

16. Air dry the membrane and expose to X-ray film (autoradiography) or phosphor imager screen (see *UNIT 6.3* for both techniques).

    Do not cover the blots with plastic wrap as this will quench the ^{35}S signal. Overnight exposure to X-ray film is usually sufficient to detect positive interactions.

DETECTING INTERACTING PROTEINS BY IMMUNOBLOTTING

ALTERNATE PROTOCOL 1

In vitro–translated probes have the advantages of being quickly produced, easily detected, and quantitated to give an estimate of relative binding. In addition, mutations in the protein probe can be generated by simple cloning procedures and can provide information on binding domains and their critical residues. A disadvantage of in vitro–translated probes is the need for multiple methionine or cysteine residues to obtain a well labeled probe. For the same reasons, small peptide fragments are often not suitable for use as in

vitro–translated probes. [^{14}C]leucine and [^{3}H]leucine can also be used for in vitro translation of proteins; however, in the authors' laboratory [^{14}C]leucine has not yielded probes suitable for use as far western probes.

There are many other ways to generate probes for far western blots. The protein probe may be labeled in vitro with ^{125}I (Schumacher and Tsomides, 1995) or enzymatically with ^{32}P (Kimball, 1998). Biotin-labeled probes may be detected with strepavidin-biotin detection schemes (Luna, 1996; Grulich-Henn et al., 1998; Kimball et al., 1998). Protein binding may be detected indirectly as well. If an antibody to the interacting protein is available, then an unlabeled protein probe can be bound to the blots as usual and then detected by western (immunoblot) analysis. This is especially useful when a tagged recombinant protein and antibody to the tag are available. The following procedure describes detection of an unlabeled protein probe with specific antibody. Many variations of immunoblotting exist; additional information and procedures may be found in *UNIT 6.2*.

Additional Materials *(also see Basic Protocol)*

Recombinant protein or unlabeled in vitro translated–protein for probe
5% (w/v) non-fat instant dry milk in 1× TBST (see recipe for TBST)
Primary antibody specific for protein probe
TBST (see recipe)
Alkaline phosphatase (AP)–conjugated secondary antibody against Ig of species from which specific antibody was obtained
Alkaline phosphatase buffer (see recipe)
Developing solution (see recipe)
100 mM EDTA, pH 8.0 (*APPENDIX 2A*)

Prepare blot and probe

1. Prepare and block the blot (see Basic Protocol, steps 1 to 9).
2. Prepare the probe protein by diluting in vitro–translated or recombinant protein in 3 ml of 1× probe dilution buffer.

   The amount of recombinant protein must be empirically determined for each protein. Various researchers have used from 0.5 to 20 μg recombinant protein/ml of probe dilution buffer.

Expose blot to probe

3. Bind the probe to blot and wash (see Basic Protocol, steps 12 and 14 to 15). Do not dry the membrane after washing.
4. Incubate blot in 200 ml of 5% non-fat milk in 1× TBST for 1 hr, room temperature, with gentle rotation on an orbital shaker.

Expose to antibodies

5. Dilute the primary antibody in 5% milk in 1× TBST. Incubate blot in 5 to 10 ml diluted antibody at room temperature with gentle agitation to ensure blot is evenly covered with the antibody solution.

   Incubations are usually carried out in heat-sealed plastic bags or hybridization bottles to minimize the volume necessary to completely cover the blot. A volume of 5 to 10 ml of diluted antibody is sufficient to cover most blots. Appropriate antibody concentrations vary for each antibody and must be determined empirically.

6. Wash for 10 min in ≥200 ml 1× TBST by agitating on an orbital shaker. Repeat an additional two times.

7. Dilute the AP-conjugated secondary antibody in 5 to 10 ml of 5% milk in 1× TBST and incubate blot for 1 hr as in step 4.

   Suppliers generally provide an estimate of appropriate dilution for the secondary antibody.

8. Wash blot six times for 5 min each in ≥200 ml TBST, with agitation.

Detect antibodies

9. Briefly, rinse blot in 50 ml alkaline phosphatase buffer.

10. Incubate blot in 20 ml developing solution for 1 to 15 min and rinse blot with 100 ml water.

11. Wash blot for 5 min with 100 ml of 100 mM EDTA, pH 8.0, to stop the development reaction. Rinse with 100 ml water, dry, and photograph.

    An example of a far western blot of proteins is shown in Figure 17.2.1. Lane 1 shows a Coomassie blue stain of a protein sample enriched for histone proteins separated on a 22% SDS-PAGE gel. Lane 2 shows a far western autoradiogram of a parallel lane probed with the yeast Tup1 protein according to this protocol. Lane 3 shows a parallel lane probed with an unlabeled Tup1 protein and detected with antibody specific to Tup1 as in Alternate Protocol 2. Both protocols yield the same result—Tup1p interacts with H3 and H4 but not with H2A or H2B. Lanes 4 and 5 show immunoblots of parallel lanes using anti-H3 and anti-H4 antibodies to identify histories H3 and H4 unequivocally.

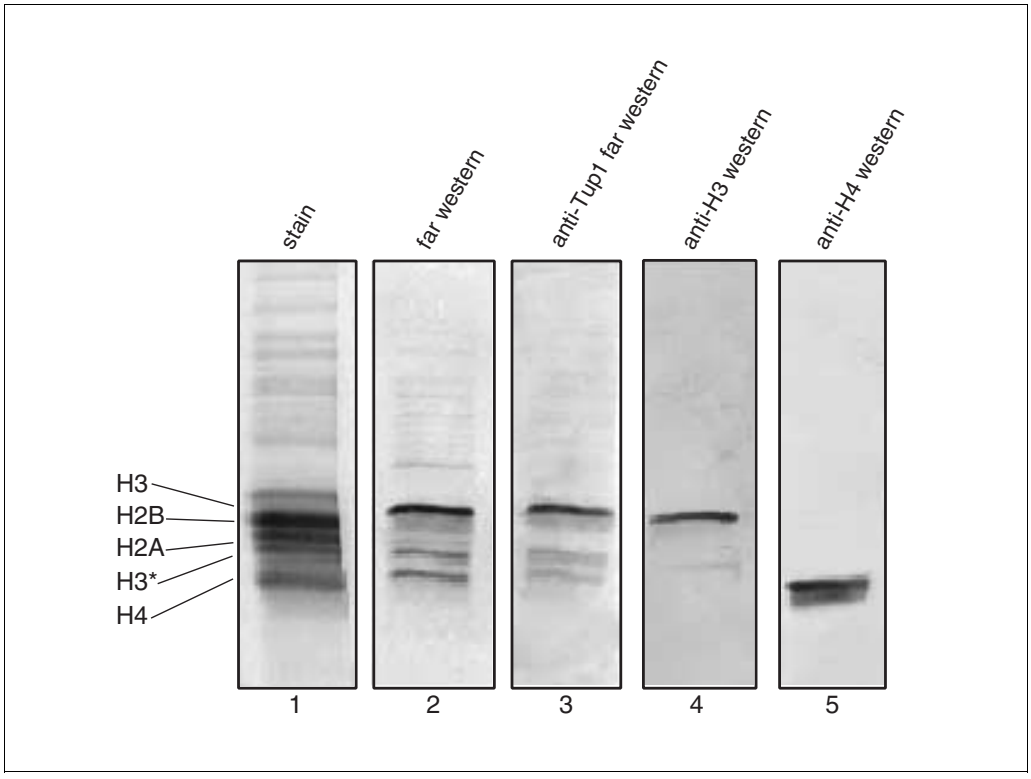

Figure 17.2.1 Far western of blotted SDS-PAGE gel. Lane 1, Coomassie blue–stained gel showing locations of histone bands. Lane 2, far western of a parallel lane using radiolabeled in vitro–translated probe. Lane 3, far western using unlabeled probe detected with probe-specific antibody. Lane 4, western blot using anti-histone H3 specific antibody. Lane 5, western blot using anti-histone H4 specific antibody.

ALTERNATE PROTOCOL 2

USING PEPTIDES TO IDENTIFY SPECIFIC INTERACTING SEQUENCES IN A FAR WESTERN BLOT

Synthetic peptides can also be used in far western analyses. The use of peptides enables the identification of specific interacting sequences. Specific post-translational modifications can be examined for their effect on protein-protein interactions. Peptides as small as 11 amino acids have been used successfully as far western targets.

Peptide far westerns differ from other far westerns only in the preparation of the blots. Peptide dilutions are prepared, then dot or slot blotted onto the support membrane. Blocking and probing of peptide blots are identical to procedures used for traditional far westerns. Duplicate blots are stained to verify that comparable quantities of different peptides have been loaded. Because Ponceau S staining is temporary, staining of duplicate blots with India ink is used to provide a permanent record for peptide blots.

In the authors' experience, only peptides that have been synthesized on MAP resins have worked well for peptide blots. MAP resins consist of branched lysine chains whose chemically active groups have been blocked. Although peptides prepared in other ways do give reproducible results, the peptide concentrations required are several orders of magnitude higher than those required for MAP peptides, making these blots very costly to perform. The reason why increased peptide is needed is unclear, but perhaps the MAP resin "presents" the peptide in such a way that it is more accessible for interaction.

Additional Materials *(also see Basic Protocol)*

Peptides
0.4% Tween 20/PBS (see recipe)
India ink solution (see recipe)
Slot or dot blot apparatus (e.g., Bio-Rad Bio-Dot SF or Schleicher & Schuell Minifold II)

1. Make dilutions of peptides between 5 ng and 5 µg in a final volume of 100 to 200 µl of distilled water.
2. Prepare slot or dot blotter and support membrane (PVDF or nitrocellulose) as described by the manufacturer. Load the peptide dilutions into wells. Prepare duplicate blots, one for far western and one for India ink staining. After all samples are loaded, apply vacuum to draw the peptide samples through the manifold device and onto the support membrane.
3. Block, bind, wash, and autoradiograph one blot for far western (see Basic Protocol, steps 7 to 16).
4. Incubate the second blot in 100 ml of 0.4% Tween 20/PBS for 5 min at room temperature with gentle agitation. Repeat incubation.
5. Stain blot by incubating 15 min to overnight with 100 ml India ink solution at room temperature.
6. Wash the filter for 2 hr in 4 changes of 1× PBS. Dry and store the membrane.

This stain is permanent.

Figure 17.2.2 shows an example of results from this alternate protocol, using peptides as a substrate for a far western. The right-hand panel is a blot stained with India ink verifying that comparable quantities of peptide were loaded on the blot. The left-hand panel is a far western of a duplicate blot demonstrating the effect of acetylation of lysine residues of histone peptides on Tup1p/histone interaction.

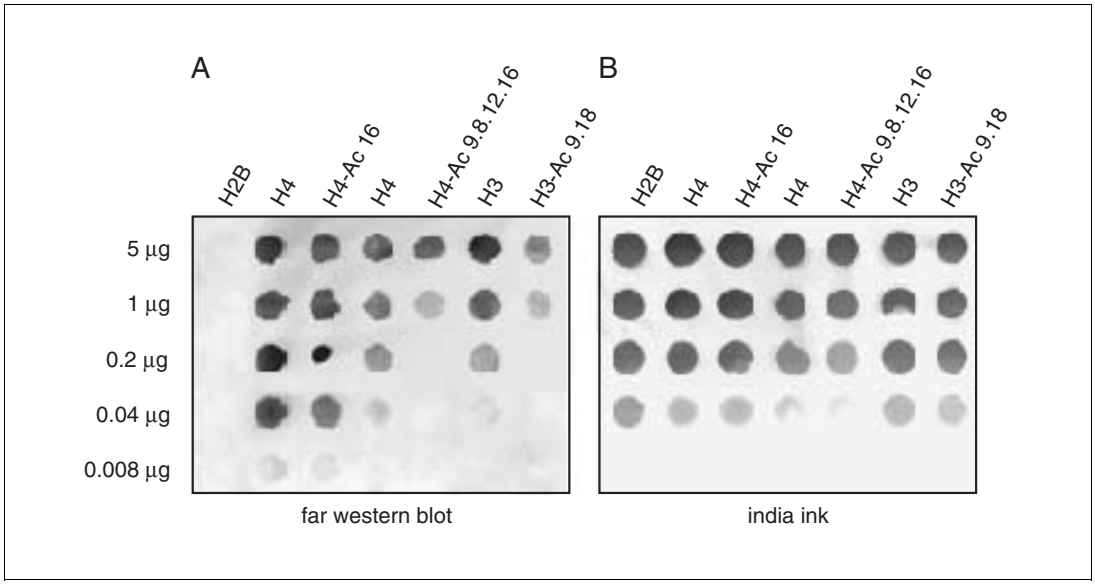

Figure 17.2.2 Far western blot of peptides (**A**) dot blotted onto PVDF membrane and (**B**) stained with India ink. Figure reproduced with permission of Cold Spring Harbor Laboratory Press.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Alkaline phosphatase buffer

100 ml 1 M Tris·Cl, pH 9.5 (*APPENDIX 2A*)
20 ml 5 M NaCl (*APPENDIX 2A*)
5 ml 1 M $MgCl_2$ (*APPENDIX 2A*)
Add H_2O to 1 liter
Store up to 1 year at room temperature

5-Bromo-4-chloro-3-indolyl phosphate (BCIP) stock solution

Dissolve 0.5 g of BCIP in 10 ml of 100% dimethylformamide. Store at 4°C or in small aliquots at −20°C. Discard when solution turns color.

Developing solution

Add 66 µl of NBT stock (see recipe) to 10 ml of alkaline phosphatase buffer (see recipe). Mix well. Add 33 µl of BCIP stock solution (see recipe) and mix again. Prepare fresh.

India ink solution

Add 100 µl India ink (Pelikan or Higgans) to 100 ml 0.4% Tween 20/PBS (see recipe). Prepare fresh.

Nitroblue tetrazolium chloride (NBT) stock solution

Dissolve 0.5 g of NBT in 10 ml of 70% dimethylformamide. Store at 4°C or in small aliquots up to 6 months at −20°C.

Phosphate-buffered saline (PBS), 10×

80 g NaCl
2.2 g KCl
9.9 g Na_2HPO_4
2.0 g K_2HPO_4
Add H_2O to 1 liter

continued

Adjust pH to 7.4
Store indefinitely at room temperature
Prior to use, dilute to 1× by mixing 1 part 10× PBS with 9 parts water

Leftover 1× PBS should be stored at 4°C to discourage bacterial growth.

Ponceau S staining solution, 10×

2 g Ponceau S
30 g trichloroacetic acid
30 g sulfosalicylic acid
Add H_2O to 100 ml
Store indefinitely at room temperature
Just prior to use dilute to 1× by mixing 1 part 10× Ponceau S with 9 parts water

Probe dilution buffer, 10×

3.0 g bovine serum albumin (BSA)
10 ml normal goat serum
10 ml 10× PBS (see recipe)
H_2O to 100 ml
Store indefinitely at −20°C
Just prior to use, dilute to 1× by mixing 1 part 10× stock with 9 parts 1× PBS

Probe purification buffer

400 µl 1 M HEPES, pH 7.4,
400 µl 1 M dithiothreitol (DTT)
9.2 ml H_2O
Prepare fresh

TBST, 10×

90 g NaCl
100 ml 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 g Tween 20
Add H_2O to 1 liter
For 1× TBST dilute 1 part 10× TBST with 9 parts water prior to use
Store indefinitely at room temperature

Tween 20/PBS, 0.4% (w/v)

Dissolve 0.4 g Tween 20 in 100 ml 1× PBS (see recipe). Store up to 1 week at room temperature.

COMMENTARY

Background Information

The far western blot (also called a west western and a ligand blot) has been widely used to examine the interactions of many diverse proteins. For example, it has been used to examine the interactions between the subunits of eukaryotic initiation factors (Kimball et al., 1998), to look at interactions between basic helix-loop-helix DNA-binding proteins (Chaudhary et al., 1997), and to examine the interactions of keratin intermediate filaments with desmosomal proteins (Kouklis et al., 1994). Far westerns have been particularly useful in examining interactions of histones with regulatory proteins. Far westerns have been used to look at interactions of WD repeat proteins with histones (Edmondson et al., 1996; Palaparti et al., 1997), the interaction of Epstein-Barr virus nuclear antigen 2 with histone H1 (Grasser et al., 1993), and the interaction of histones with the *Xenopus* oocyte protein N1 (Kleinschmidt and Seiter, 1988). In addition, far westerns have been used to study receptor-ligand interactions and to screen libraries for interacting proteins (Grulich-Henn et al., 1998; Hsiao and Chang, 1999).

Sometimes, the nature of the proteins being examined is such that standard methods of studying protein-protein interactions are not possible. For example, some proteins are diffi-

cult to solubilize or to extract from cells except under conditions that disrupt protein-protein interactions and therefore, are difficult to assay by immunoprecipitation. Other proteins cannot be expressed in bacteria or yeast due to toxicity problems, thus making the production of recombinant proteins or the use of two-hybrid assays impossible. Far westerns are particularly useful in such cases. Since far westerns are performed totally in vitro, they circumvent these types of problems.

Another advantage of the far western blot is its flexibility. Proteins prepared in a variety of ways can be used for the assay. Cell extracts, recombinant proteins, and peptides can all be used as both probe and target proteins. For example, Palaparti et al. (1997) used cell extracts to probe a semipurified histone sample and detected bound proteins of interest with antibodies. Hsiao and Chang (1999) used phage-expressed proteins immobilized on filter lifts for a far western library screen. Unpurified *E. coli* extracts containing recombinant protein have been successfully used as probes (Fischer et al., 1997).

In addition, many different detection techniques, either radioactive or nonradioactive, can be used. Kimball and co-workers used recombinant protein probes that were labeled radioactively with kinases and recombinant proteins labeled with biotin and subsequently detected with a strepavidin-biotin detection scheme (Grulich-Henn et al., 1998; Kimball et al., 1998). Thus, techniques and reagents already in hand can frequently be adapted for use with this assay.

Finally, the far western can be modified to define the protein domains and amino acid residues that are important in protein-protein interactions. Mutagenized clones can be used to produce variants of protein probes. A single SDS-PAGE gel can be run with identical lanes and cut into strips, and a different in vitro–translated probe can be used for each strip. In this way, multiple variants of a protein can be tested simultaneously for their ability to interact with a target protein.

Non-SDS polyacrylamide gels can also be used to separate proteins for far westerns. For example, acid urea gels, which separate on the basis of both size and charge, have been successfully employed. Finally, peptides corresponding to specific interacting sequences can be synthesized with specific post-translational modifications to test their effects on protein-protein interactions.

Critical Parameters

Blocking nonspecific binding sites on the membranes is critical to achieving good results with far westerns. Too little blocking results in high background, while extended time in blocking solutions results in weakened or lost signal. The reason for the diminished signal is unclear, but protein renaturation apparently takes place during the blocking step, so an optimal renaturation may require limited blocking. The best time may well be different for each protein and require empirical optimization. In addition, different lots of BSA appear to result in diminished signal. Therefore, it is important to purchase high-quality BSA from a reputable manufacturer.

An important consideration is the inclusion of appropriate controls to rule out nonspecific interactions that might result in false positives. Suitable controls should be furnished for both the target proteins and the protein probe. When using a complex mixture of proteins, such as cell extracts, as target, "negative" control proteins are already present. However, when using a mixture of only a few proteins, it is important to provide a protein that does not interact to serve as a negative control for nonspecific binding. The ideal negative control should be similar to the protein of interest in charge and size. Appropriate controls should be subjected to SDS-PAGE and blotted in parallel with the samples of interest. Another important control is the use of an unprogrammed translation lysate as a probe. Translation of an unrelated protein as a control probe is also often helpful.

Troubleshooting

Precise conditions for far westerns vary from procedure to procedure and probably reflect the nature of the individual proteins being examined. Optimal conditions for each protein may need to be determined empirically. If background staining is too high, there are several possible remedies. The probe may be diluted or the sample concentration lowered. Other "blocking" reagents may be tested.The blocking reagent, nonfat dry milk, ranging in concentration from 1% to 5%, has been used successfully. Other detergents such as NP-40 and Triton X-100 are commonly employed for this procedure and may help to decrease background. Also, increasing the length of the blocking step may aid in background reduction. Most procedures that call for extended blocking times suggest incubation at 4°C.

If no specific staining is observed, confirm the quality of the radiolabeled probe by SDS-

PAGE and autoradiography. Make sure the reticulocyte lysate has not been repeatedly frozen and thawed. If using a recombinant protein/antibody scheme, confirm the affinity of that interaction by immunoblotting.

Sometimes a decrease in blocking time or use of a different blocking reagent will increase signal. Some proteins may interact more readily following a denatuation/renaturation cycle. In this case, the membrane is incubated for 1 hr in PBS-buffered 7 M guanidine or 8 M urea and renatured overnight. Renature in blocking buffer I (see Basic Protocol) without agitation at 4°C with several changes of buffer. Finally, the length of the binding reaction can be increased.

Anticipated Results

Sensitivity of the far western blot is dependent on the affinity of the protein-protein interactions being investigated and on the quality of the probe. Thus, extra attention given to the preparation of a high-quality probe is almost invariably worthwhile. When using a radiolabeled probe, a positive interaction can typically be visualized after overnight exposure to X-ray film.

Time Considerations

The basic protocol can be performed in 2 days. An SDS-PAGE gel can be set up and run in 4 to 6 hr. The rest of the procedure can be performed in 8 to 10 hr. It is often convenient to set up the SDS-PAGE gels on one day and run them slowly overnight. The rest of the basic protocol can then be performed the next day. Semidry transfer requires ~2 hr, the blocking steps take ~4 hr, binding of the probe takes ~2 hr, washing, drying, and setting up the autoradiography cassette takes ~1 hr. Detection of interactions using antibodies to detect the probe protein requires an additional day. Peptide blots can be performed in one day.

It is possible to store the blots after the blocking steps for up to 2 weeks at 4°C. The blots should be stored in airtight containers or wrappings so they do not dry out. In addition, in vitro–translated probes may be produced ahead of time and stored unpurified at –20°C, although the efficiency may be reduced for some probes.

Interaction Trap/Two-Hybrid System to Identify Interacting Proteins

To understand the function of a particular protein, it is often useful to identify other proteins with which it associates. This can be done by a selection or screen in which novel proteins that specifically interact with a target protein of interest are isolated from a library. One particularly useful approach to detect novel interacting proteins—the two-hybrid system or interaction trap (see Figs. 17.3.1 and 17.3.2)—uses yeast as a "test tube" and transcriptional activation of a reporter system to identify associating proteins (see Background Information). This approach can also be used specifically to test complex formation between two proteins for which there is a prior reason to expect an interaction.

In the basic version of this method (see Fig. 17.3.2), the plasmid pEG202 or a related vector (see Fig. 17.3.3 and Table 17.3.1) is used to express the probe or "bait" protein as a fusion to the heterologous DNA-binding protein LexA. Many proteins, including transcription factors, kinases, and phosphatases, have been successfully used as bait proteins. The major requirements for the bait protein are that it should not be actively excluded from the yeast nucleus, and it should not possess an intrinsic ability to strongly activate transcription. The plasmid expressing the LexA-fused bait protein (see Table 17.3.1) is used to transform yeast possessing a dual reporter system responsive to transcriptional activation through the *LexA* operator. In one such example, the yeast strain EGY48 (see Table 17.3.2) contains the reporter plasmid pSH18-34. In this case, binding sites for LexA are located upstream of two reporter genes. In the EGY48 strain, the upstream activating sequences of the chromosomal *LEU2* gene—required in the biosynthetic pathway for leucine (Leu)—are replaced with *LexA* operators (DNA binding sites). pSH18-34 contains a *LexA* operator–*lacZ* fusion gene. These two reporters allow selection for transcriptional activation by permitting selection for viability when cells are plated on medium lacking Leu, and discrimination based on color when the yeast is grown on medium containing Xgal.

In Basic Protocol 1, EGY48/pSH18-34 transformed with a bait is characterized for its ability to express protein (Support Protocol 1), growth on medium lacking Leu, and for the level of transcriptional activation of *lacZ* (see Fig. 17.3.2A). A number of alternative strains, plasmids, and strategies are presented which can be employed if a bait proves to have an unacceptably high level of background transcriptional activation.

In an interactor hunt (Basic Protocol 2), the strain EGY48/pSH18-34 containing the bait expression plasmid is transformed (along with carrier DNA made as described in Support Protocol 2) with a conditionally expressed library made in the vector pJG4-5 (see Fig. 17.3.6 and Table 17.3.3). This library uses the inducible yeast *GAL1* promoter to express proteins as fusions to an acidic domain ("acid blob") that functions as a portable transcriptional activation motif (act) and to other useful moieties. Expression of library-encoded proteins is induced by plating transformants on medium containing galactose (Gal), so yeast cells containing library proteins that do not interact specifically with the bait protein will fail to grow in the absence of Leu (see Fig. 17.3.2B). Yeast cells containing library proteins that interact with the bait protein will form colonies within 2 to 5 days, and the colonies will turn blue when the cells are streaked on medium containing Xgal (see Fig. 17.3.2C). The DNA from interaction trap positive colonies can be analyzed by polymerase chain reaction (PCR) to streamline screening and detect redundant clones in cases where many positives are obtained in screening (see Alternate Protocol 1). The plasmids are isolated and characterized by a series of tests to confirm specificity of the interaction with the initial bait protein (Support Protocols 3 to 5). Those found to be specific are ready for further analysis (e.g., sequencing).

Current Protocols in Cell Biology (2000) 17.3.1-17.3.42

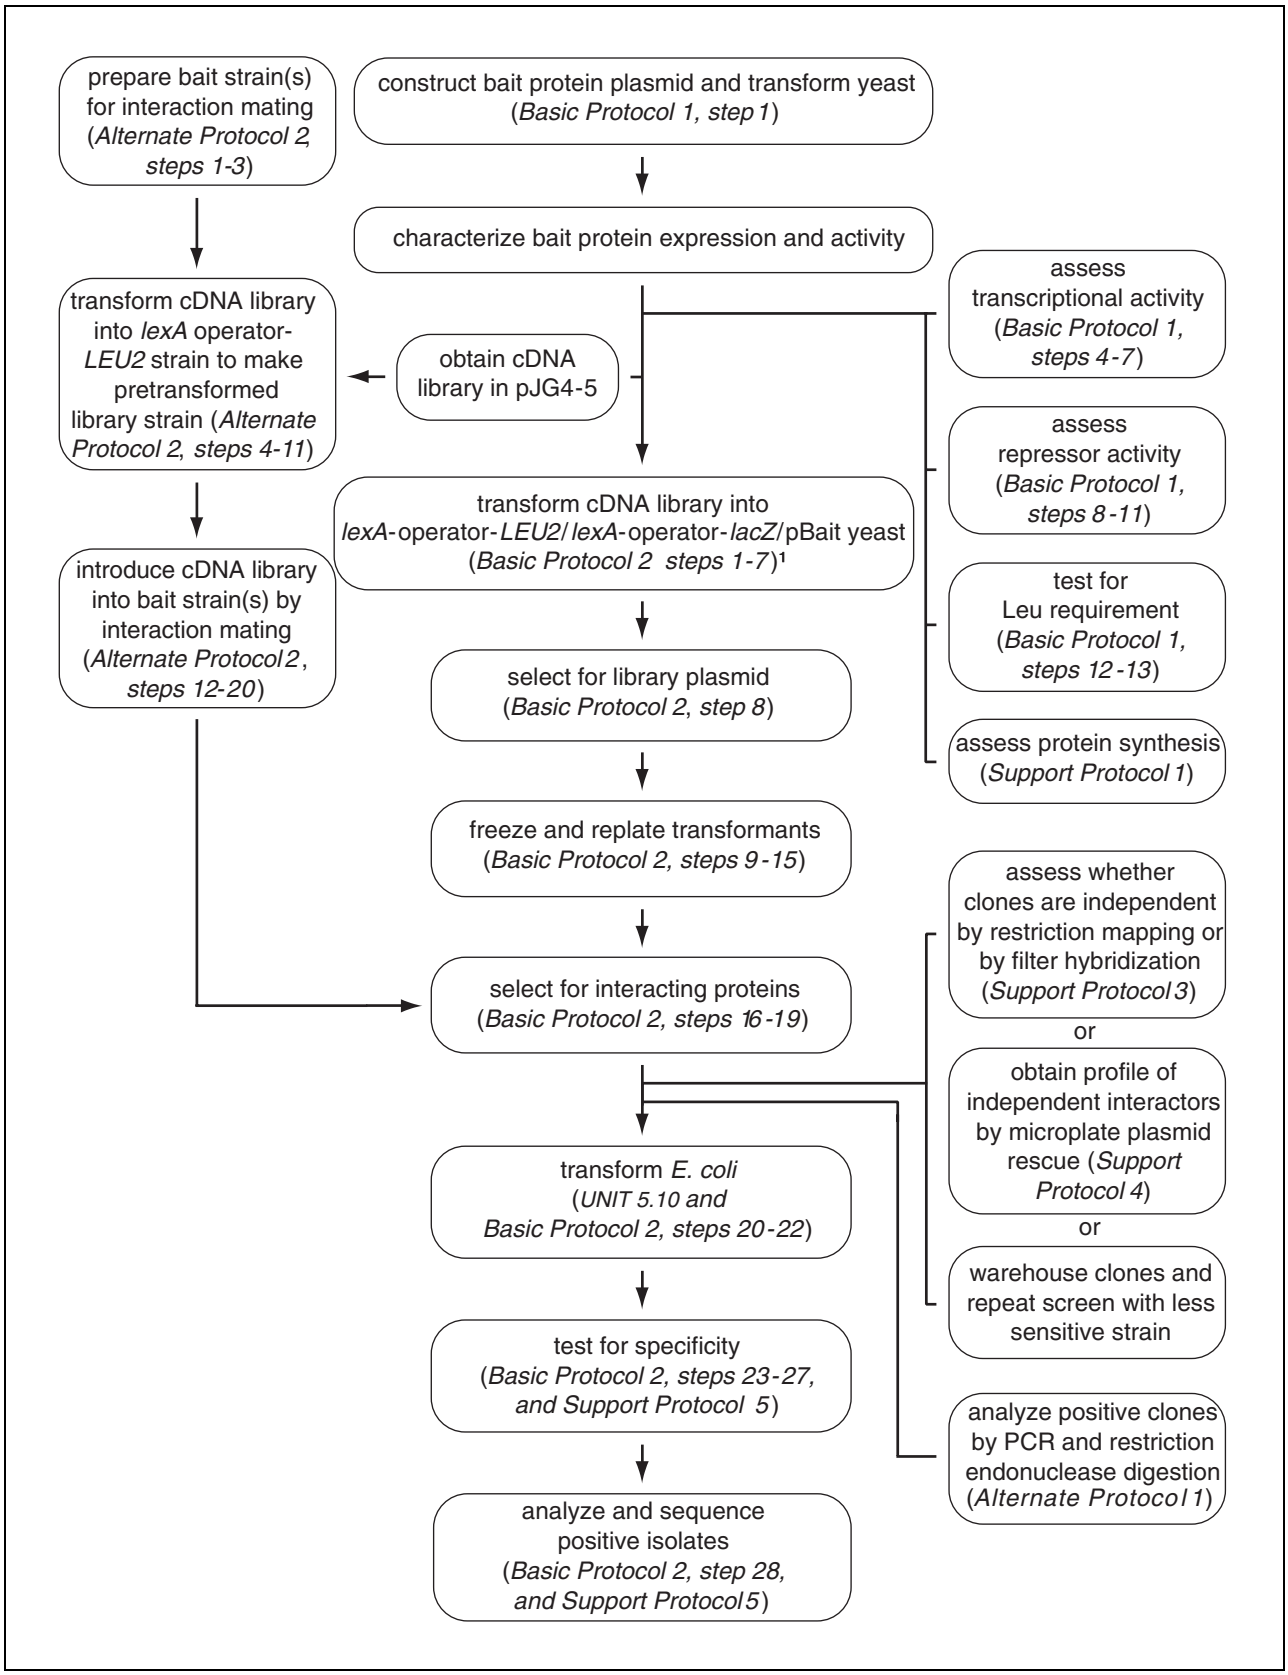

Figure 17.3.1 Flow chart for performing an interaction trap.

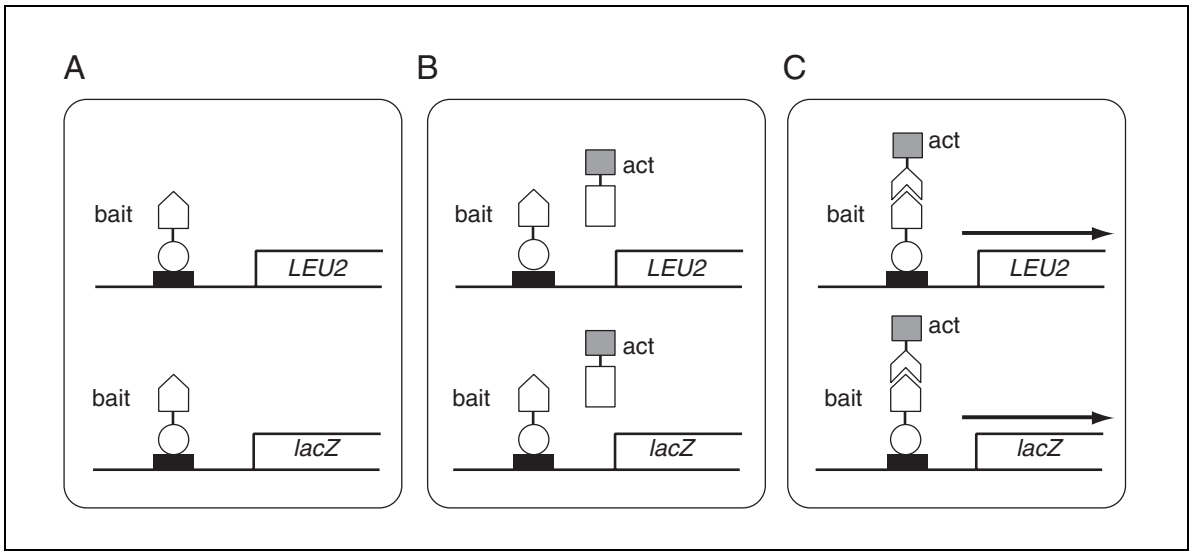

Figure 17.3.2 The interaction trap. (**A**) An EGY48 yeast cell containing two *LexA* operator–responsive reporters, one a chromosomally integrated copy of the *LEU2* gene (required for growth on –Leu medium), the second a plasmid bearing a *GAL1* promoter–*lacZ* fusion gene (causing yeast to turn blue on medium containing Xgal). The cell also contains a constitutively expressed chimeric protein, consisting of the DNA-binding domain of LexA fused to the probe or bait protein, shown as being unable to activate either of the two reporters. (**B**) and (**C**), EGY48/pSH18-34/pbait-containing yeast have been additionally transformed with an activation domain (act)–fused cDNA library in pJG4-5, and the library has been induced. In (B), the encoded protein does not interact specifically with the bait protein and the two reporters are not activated. In (C), a positive interaction is shown in which the library-encoded protein interacts with bait protein, resulting in activation of the two reporters (arrow), thus causing growth on medium lacking Leu and blue color on medium containing Xgal. Symbols: black rectangle, *LexA* operator sequence; open circle, LexA protein; open pentagon, bait protein; open rectangle, library protein; shaded box, activator protein (acid blob).

When more than one bait will be used to screen a single library, significant time and resources can be saved by performing the interactor hunt by interaction mating (see Alternate Protocol 2). In this protocol, EGY48 is transformed with library DNA and the transformants are collected and frozen in aliquots. For each interactor hunt, an aliquot of the pretransformed EGY48/library strain is thawed and mixed with an aliquot of a bait strain transformed with the bait expression plasmid and pSH18-34. Overnight incubation of the mixture on a YPD plate results in fusion of the two strains to form diploids. The diploids are then exposed to galactose to induce expression of the library-encoded proteins, and interactors are selected in the same manner as in Basic Protocol 2. The advantage to this approach is that it requires only one high-efficiency library transformation for multiple hunts with different baits. It is also useful for bait proteins that are somewhat toxic to yeast; yeast expressing toxic baits can be difficult to transform with the library DNA.

CHARACTERIZING A BAIT PROTEIN

BASIC PROTOCOL 1

The first step in an interactor hunt is to construct a plasmid that expresses LexA fused to the protein of interest. This construct is transformed into reporter yeast strains containing *LEU2* and *lacZ* reporter genes, and a series of control experiments is performed to establish whether the construct is suitable as is or must be modified, and whether alternative yeast reporter conditions should be used. These controls establish that the bait protein is made as a stable protein in yeast, that it is capable of entering the nucleus and binding *LexA* operator sites, and that it does not appreciably activate transcription of the *LexA* operator–based reporter genes. This last is the most important constraint on use of this system. The LexA-fused bait protein must not activate transcription of either re-

Table 17.3.1 Interaction Trap Components[a,b]

Plasmid name/source[c]	Selection		Comment/description
	In yeast	In *E. coli*	
LexA fusion plasmids			
pEG202[d,e]	*HIS3*	Ap^r	Contains an *ADH* promoter that expresses LexA followed by polylinker
pJK202[e]	*HIS3*	Ap^r	Like pEG202, but incorporates nuclear localization sequences between LexA and polylinker; used to enhance translocation of bait to nucleus
pNLexA[e]	*HIS3*	Ap^r	Contains an *ADH* promoter that expresses polylinker followed by LexA; for use with baits where amino-terminal residues must remain unblocked
pGilda[d,e]	*HIS3*	Ap^r	Contains a *GAL1* promoter that expresses same LexA and polylinker cassette as pEG202; for use with baits whose continuous presence is toxic to yeast
pEE202I	*HIS3*	Ap^r	An integrating form of pEG202 that can be targeted into *HIS3* following digestion with *Kpn*I; for use where physiological screen requires lower levels of bait to be expressed
pRFHM1[e,f] (control)	*HIS3*	Ap^r	Contains an *ADH* promoter that expresses LexA fused to the homeodomain of bicoid to produce nonactivating fusion; used as positive control for repression assay, negative control for activation and interaction assays
pSH17-4[e,f] (control)	*HIS3*	Ap^r	*ADH* promoter expresses LexA fused to GAL4 activation domain; used as a positive control for transcriptional activation
pMW101[f]	*HIS3*	Cm^r	Same as pEG202, but with altered antibiotic resistance markers; basic plasmid used for cloning bait
pMW103[f]	*HIS3*	Km^r	Same as pEG202, but with altered antibiotic resistance markers; basic plasmid used for cloning bait
pHybLex/Zeo[f,g]	Zeo^r	Zeo^r	Bait cloning vector compatible with interaction trap and all other two-hybrid systems; minimal ADH promotor expresses LexA followed by extended polylinker
Activation domain fusion plasmids			
pJG4-5[c,d,e,f]	TRP1	Ap^r	Contains a *GAL1* promoter that expresses nuclear localization domain, transcriptional activation domain, HA epitope tag, cloning sites; used to express cDNA libraries
pJG4-5I	*TRP1*	Ap^r	An integrating form of pJG4-5 that can be targeted into *TRP1* by digestion with *Bsu*36I (New England Biolabs); to be used with pEE202I to study interactions that occur physiologically at low protein concentrations
pYESTrp[g]	*TRP1*	Ap^r	Contains a *GAL1* promoter that expresses nuclear localization domain, transcriptional activation domain, V5 epitope tag, multiple cloning sites; contains f1 ori and T7 promoter/flanking site; used to express cDNA libraries (Invitrogen)
pMW102[f]	*TRP1*	Km^r	Same as pJG4-5, but with altered antibiotic resistance markers; no libraries yet available
pMW104[f]	*TRP1*	Cm^r	Same as pJG4-5, but with altered antibiotic resistance markers; no libraries yet available
LacZ reporter plasmids			
pSH18-34[d,e,f]	*URA3*	Ap^r	Contains 8 *LexA* operators that direct transcription of the *lacZ* gene; one of the most sensitive indicator plasmids for transcriptional activation
pJK103[e]	*URA3*	Ap^r	Contains two *LexA* operators that direct transcription of the *lacZ* gene; an intermediate reporter plasmid for transcriptional activation
pRB1840[e]	*URA3*	Ap^r	Contains 1 *LexA* operator that directs transcription of the *lacZ* gene; one of the most stringent reporters for transcriptional activation
pMW112[f]	*URA3*	Km^r	Same as pSH18-34, but with altered antibiotic resistance marker
pMW109[f]	*URA3*	Km^r	Same as pJK103, but with altered antibiotic resistance marker

Plasmid name/source[c]	Selection		Comment/description
	In yeast	In *E. coli*	
pMW111[f]	*URA3*	Km^r	Same as pRB1840, but with altered antibiotic resistance marker
pMW107[f]	*URA3*	Cm^r	Same as pSH18-34, but with altered antibiotic resistance marker
pMW108[f]	*URA3*	Cm^r	Same as pJK103, but with altered antibiotic resistance marker
pMW110[f]	*URA3*	Cm^r	Same as pRB1840, but with altered antibiotic resistance marker
pJK101[e,f] (control)	*URA3*	Ap^r	Contains a *GAL1* upstream activating sequence followed by two *lexA* operators followed by *lacZ* gene; used in repression assay to assess bait binding to operator sequences

[a]All plasmids contain a 2µm origin for maintenance in yeast, as well as a bacterial origin of replication, except where noted (pEE202I, pJG4.5I).

[b]Interaction Trap reagents represent the work of many contributors: the original basic reagents were developed in the Brent laboratory (Gyuris et al., 1993). Plasmids with altered antibiotic resistance markers (all pMW plasmids) were constructed at Glaxo in Research Triangle Park, N.C. (Watson et al., 1996). Plasmids and strains for specialized applications have been developed by the following individuals: E. Golemis, Fox Chase Cancer Center, Philadelphia, Pa. (pEG202); J. Kamens, BASF, Worcester, Mass. (pJK202); cumulative efforts of I. York, Dana-Farber Cancer Center, Boston, Mass. and M. Sainz and S. Nottwehr, U. Oregon (pNLexA); D.A. Shaywitz, MIT Center for Cancer Research, Cambridge, Mass. (pGilda); R. Buckholz, Glaxo, Research Triangle Park, N.C. (pEE2021, pJG4-51); J. Gyuris, Mitotix, Cambridge, Mass. (pJG4-5); S. Hanes, Wadsworth Institute, Albany, N.Y. (pSH17-4); R.L. Finley, Wayne State University School of Medicine, Detroit, Mich. (pRFHM1); S. Hanes, Wadsworth Institute, Albany, N.Y. (pSH18-34); J. Kamens, BASF, Worcester, Mass. (pJK101, pJK103); R. Brent, The Molecular Sciences Institute, Berkeley, Calif. (pRB1840). Specialized plasmids not yet commercially available can be obtained by contacting the Brent laboratory at (510) 647-0690 or *brent@molsci.org*, or the Golemis laboratory, (215) 728-2860 or *EA_Golemis@fccc.edu*.

[c]Maps, sequences, and links for some of the plasmids are available at *http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html*.

[d]Plasmids commercially available from Clontech and OriGene; for Clontech pEG202 is listed as pLexA, pJG4-5 as pB42AD, and pSH18-34 as p8op-LacZ.

[e]Plasmids and strains available from OriGene.

[f]In pMW plasmids the ampicillin resistance gene (Ap^r) is replaced with the chloramphenicol resistance gene (Cm^r) and the kanamycin resistance gene (Km^r) from pBC SK(+) and pBK-CMV (Stratagene), respectively. The choice between Km^r and Cm^r or Ap^r plasmids is a matter of personal taste; use of basic Ap^r plasmids is described in the basic protocols. Use of the more recently developed reagents would facilitate the purification of library plasmid in later steps by eliminating the need for passage through KC8 bacteria, with substantial saving of time and effort. Ap^r has been maintained as marker of choice for the library plasmid because of the existence of multiple libraries already possessing this marker. These plasmids are the basic set of plasmids recommended for use.

[g]Plasmids commercially available from Invitrogen as components of a Hybrid Hunter kit; this kit also includes all necessary positive and negative controls (not listed in this table). See Background Information for further details on commercially available reagents.

porter—the EGY48 strain (or related strain EGY191) that expresses the LexA fusion protein should not grow on medium lacking Leu, and the colonies should be white on medium containing Xgal. The characterized bait protein plasmid is used for Basic Protocol 2 to screen a library for interacting proteins.

Materials

DNA encoding the protein of interest

Plasmids (see Table 17.3.1): pEG202 (see Fig. 17.3.3), pSH18-34 (see Fig. 17.3.4), pSH17-4, pRFHM1, and pJK101 for basic characterization; other plasmids for specific circumstances as described (Clontech, Invitrogen, OriGene, or R. Brent)

Yeast strain EGY48 (*ura3 trp1 his3 3LexA*-operator-*LEU2*), or EGY191 (*ura3 trp1 his3 1LexA*-operator-*LEU2*; Table 17.3.2)

- Glu/CM, −Ura, −His
- Gal/CM, −Ura, −His
- Gal/CM, −Ura, −His, −Leu

Z buffer (see recipe) with 1 mg/ml 5-bromo-4-chloro-3-indolyl-β-D-galactosidase (Xgal)

Gal/CM dropout liquid medium (see recipe) supplemented with 2% Gal

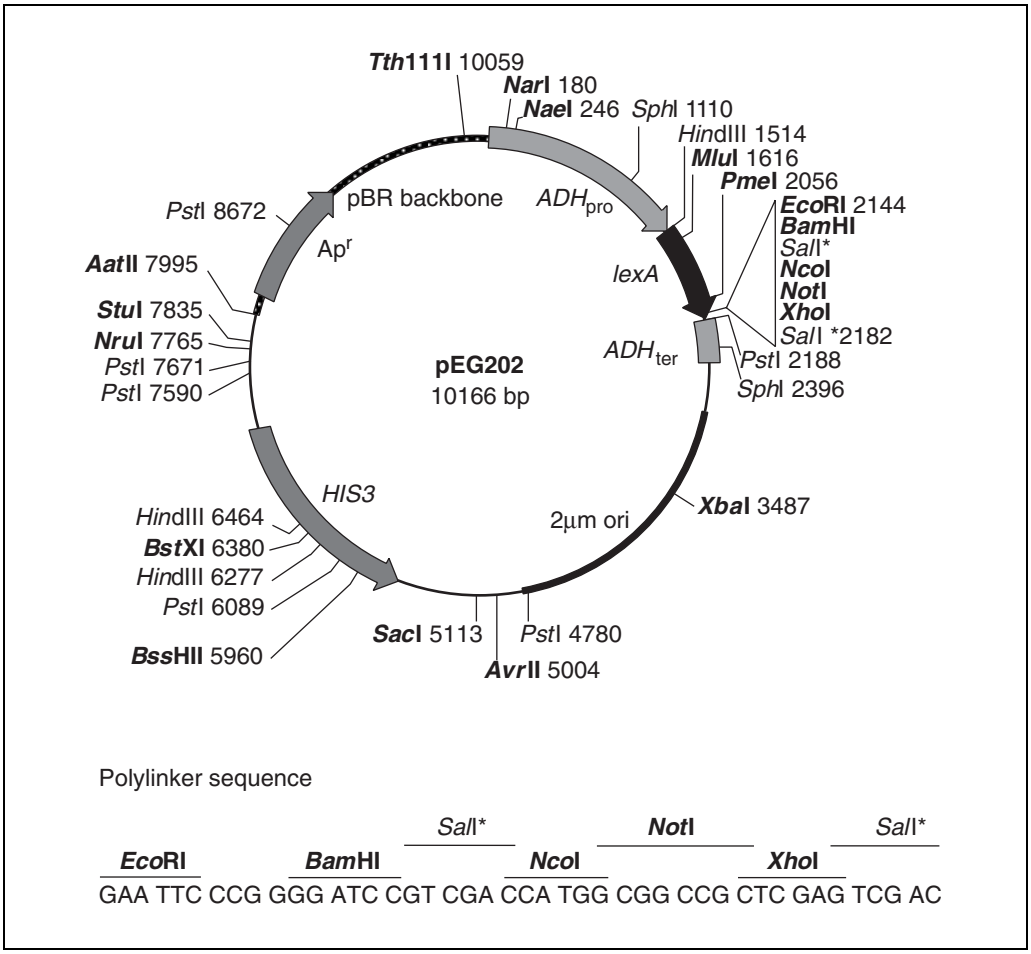

Figure 17.3.3 LexA-fusion plasmids: pEG202 (sequence: accession number U89960). The strong constitutive *ADH* promoter is used to express bait proteins as fusions to the DNA-binding protein LexA. Restriction sites shown in this map are based on recently compiled pEG202 sequence data and include selected sites suitable for diagnostic restriction endonuclease digests. A number of restriction sites are available for insertion of coding sequences to produce protein fusions with LexA; the polylinker sequence and reading frame relative to LexA are shown below the map with unique sites marked in bold type. The sequence 5′-CGT CAG CAG AGC TTC ACC ATT G-3′ can be used to design a primer to confirm correct reading frame for LexA fusions. Plasmids contain the *HIS3* selectable marker and the 2μm origin of replication to allow propagation in yeast, and the Ap^r antibiotic resistance gene and the pBR origin of replication to allow propagation in *E. coli*. In the recently developed LexA-expression plasmids pMW101 and pMW103, the ampicillin resistance gene (Ap^r) has been replaced with the chloramphenicol resistance gene (Cm^r) and the kanamycin resistance gene (Km^r), respectively. Alternative bait plasmids are listed in Table 17.3.1, and maps, sequences, and links for some of them are available at *http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html*.

Antibody to LexA or fusion domain: monoclonal antibody to LexA (Clontech, Invitrogen) or polyclonal antibody to LexA (available by request from R. Brent or E. Golemis)

H_2O, sterile

30°C incubator

Nylon membrane

Whatman 3MM filter paper

Additional reagents and equipment for subcloning DNA fragments, lithium acetate transformation of yeast, liquid assay for β-galactosidase (*APPENDIX 3*), preparation of protein extracts for immunoblot analysis (see Support Protocol 1), and immunoblotting and immunodetection (*UNIT 6.2*)

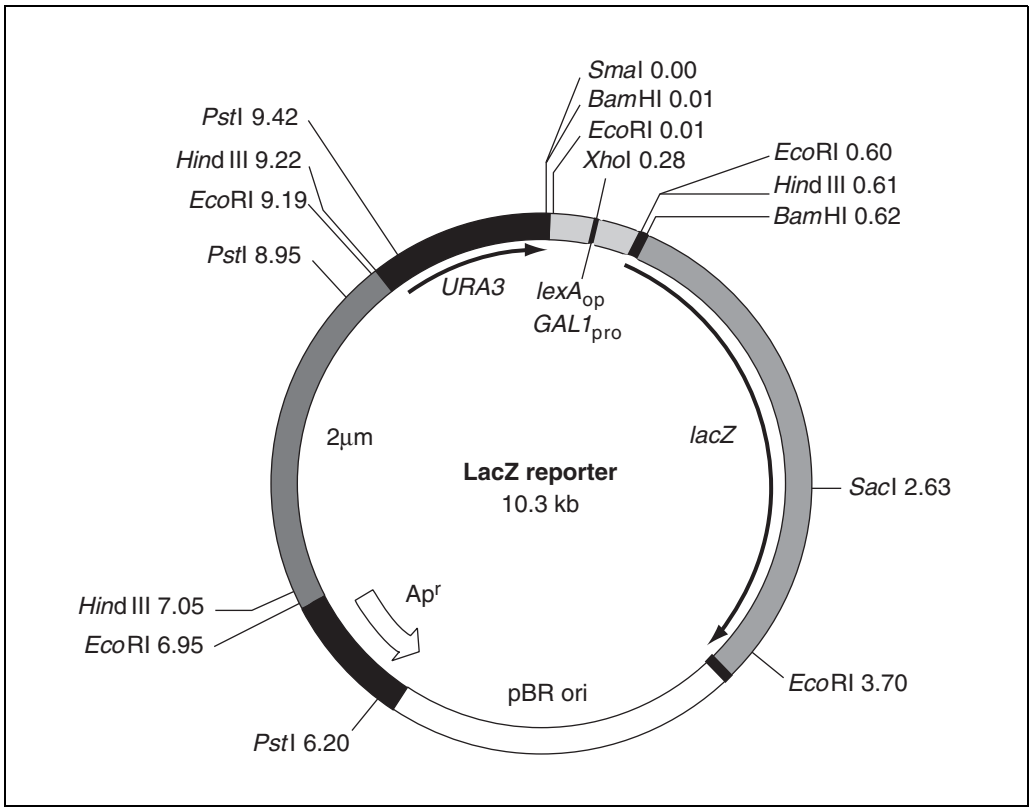

Figure 17.3.4 LacZ reporter plasmid. pRB1840, pJK103, and pSH18-34 are all derivatives of LR1Δ1 (West et al., 1984) containing eight, two, or one operator for LexA (*LexA*$_{op}$) binding inserted into the unique *Xho*I site located in the minimal *GAL1* promoter (*GAL1*$_{pro}$; 0.28 on map). The plasmid contains the *URA3* selectable marker, the 2μm origin to allow propagation in yeast, the ampicillin resistance (Ap^r) gene, and the pBR322 origin (ori) to allow propagation in *E. coli*. Numbers indicate relative map positions. In the recently developed derivatives, the ampicillin resistance gene (Ap^r) has been replaced with the chloramphenicol or kanamycin resistance genes.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

Transform yeast with the bait protein plasmid

1. Using standard subcloning techniques (*APPENDIX 3*), insert the DNA encoding the protein of interest into the polylinker of pEG202 (see Fig. 17.3.3) or other LexA fusion plasmid to make an in-frame protein fusion.

   The LexA fusion protein is expressed from the strong alcohol dehydrogenase (ADH) promoter. pEG202 also contains a HIS3 selectable marker and a 2μm origin for propagation in yeast. pEG202 with the DNA encoding the protein of interest inserted is designated pBait. Uses of alternative LexA fusion plasmids are described in Background Information.

2. Perform three separate lithium acetate transformations (*APPENDIX 3*) of EGY48 using the following combinations of plasmids:

   pBait + pSH18-34 (test)
   pSH17-4 + pSH18-34 (positive control for activation)
   pRFHM1 + pSH18-34 (negative control for activation).

   Use of the two LexA fusions as positive and negative controls allows a rough assessment of the transcriptional activation profile of LexA bait proteins. pEG202 itself is not a good negative control because the peptide encoded by the uninterrupted polylinker sequences is itself capable of very weakly activating transcription.

Table 17.3.2 Interaction Trap Yeast Selection Strains[a]

Strain	Relevant genotype	Number of operators	Comments/description
EGY48[b,c,d]	*MAT*α *trp1*, *his3*, *ura3*, lexAops-LEU2	6	*lexA* operators direct transcription from the *LEU2* gene; EGY48 is a basic strain used to select for interacting clones from a cDNA library
EGY191[c]	*MAT*α *trp1*, *his3*, *ura3*, lexAops-LEU2	2	EGY191 provides a more stringent selection than EGY48, producing lower background with baits with instrinsic ability to activate transcription
L40[c]	MATα *trpl*, *leu*2, *ade*2, GAL4, *lexAops-HIS3*	4	Expression driven from *GAL1* promoter is constitutive in L40 (inducible in EGY strains); selection is for *HIS* prototrophy.
	MATα *trpl*, *leu*2, *ade*2, GAL4, *lexAops-lacZ*	8	Integrated *lacZ* reporter is considerably less sensitive than pSH18-34 maintained in EGY strains

[a]Interaction Trap reagents represent the work of many contributors: the original basic reagents were developed in the Brent laboratory (Gyuris et al., 1993). Strains for specialized applications have been developed by the following individuals: E. Golemis, Fox Chase Cancer Center, Philadelphia, Pa. (EGY48, EGY191); A.B. Vojtek and S.M. Hollenberg, Fred Hutchinson Cancer Research Center, Seattle, Wash. (L40).

[b]Strains commercially available from Clontech.

[c]Strains commercially available from Invitrogen as components of a Hybrid Hunter kit; the kit also includes all necessary positive and negative controls (not listed in this table). See Background Information for further details on commercially available reagents.

[d]Strains commercially available from OriGene.

pSH18-34 contains a 2μm origin and a URA3 selectable marker for maintenance in yeast, as well as a bacterial origin of replication and ampicillin-resistance gene. It is the most sensitive lacZ reporter available and will detect any potential ability to activate lacZ transcription. pSH17-4 is a HIS3 2μm plasmid encoding LexA fused to the activation domain of the yeast activator protein GAL4. This fusion protein strongly activates transcription. pRFHM1 is a HIS3 2μm plasmid encoding LexA fused to the N-terminus of the Drosophila protein bicoid. This fusion protein has no ability to activate transcription.

3. Plate each transformation mixture on Glu/CM −Ura, −His dropout plates. Incubate 2 days at 30°C to select for yeast that contain both plasmids.

   Colonies obtained can be used simultaneously in tests for the activation of lacZ (steps 4 to 7) and LEU2 (steps 12 to 13) reporters.

Assay lacZ gene activation by β-galactosidase assay

4. Streak a Glu/CM −Ura, −His master dropout plate with at least five or six independent colonies obtained from each of the three transformations in step 3 (test, positive control, and negative control) and incubate overnight at 30°C.

   The filter assay described in Steps 5a to 7a (based on Breeden and Nasmyth, 1985) provides a rapid assay for β-galactosidase transcription. Alternatively, a liquid assay (APPENDIX 3) or a plate assay (described in Steps 5b to 7b) may be used. More information on β-galactosidase assays is available on http://www.fccc.edu/research/labs/golemis/betagal.html.

Perform filter assay for β-galactosidase activity:

5a. Lift colonies by gently placing a nylon membrane on the yeast plate and allowing it to become wet through. Remove the membrane and air dry 5 min. Chill the membrane, colony side up, 10 min at −70°C.

   Whatman 3MM filters can be cut to the size of the yeast plate as a more economical alternative to nylon membranes for performing lifts. In addition, two or three 5-min temperature cycles (−70°C to room temperature) can be used instead of a single cycle to promote better lysis; this may be worth doing if there is difficulty visualizing blue color.

6a. Cut a piece of Whatman 3MM filter paper slightly larger than the colony membrane and soak it in Z buffer containing 1 mg/ml Xgal. Place colony membrane, colony side up, on Whatman 3MM paper, or float it in the lid of a petri dish containing ~2 ml Z buffer with 1 mg/ml Xgal.

Acceptable results may be obtained using as little as 300 μg/ml Xgal.

7a. Incubate at 30°C and monitor for color changes.

It is generally useful to check the membrane after 20 min, and again after 2 to 3 hr. Strong activators will produce a blue color in 5 to 10 min, and a bait protein (LexA fusion protein) that does so is unsuitable for use in an interactor hunt using this lacZ reporter plasmid. Weak activators will produce a blue color in 1 to 6 hr (compare versus negative control pRFHMI which will itself produce a faint blue color with time) and may or may not be suitable. Weak activators should be tested using the repressor assay described in steps 8 to 11.

Perform Xgal plate assay for lacZ activation:

5b. Prepare Z buffer Xgal plates.

For activation assays, plates should be prepared with glucose as a sugar source. For repression assays (steps 8 to 11), galactose should be used as a sugar source. In our experience, when patching from a master plate to Xgal plates, sufficient yeast are transferred that plasmid loss is not a major problem even in the absence of selection; this is balanced by the desire to assay sets of constructs on the same plate to eliminate batch variation in Xgal potency. Hence, plates should be made either with complete minimal amino acid mix, or by dropping out only uracil (–Ura), to make the plates universally useful.

6b. Streak yeast from master plate to Xgal plate and incubate at 30°C.

7b. Examine plates for color development at intervals over the next 2 to 3 days.

Strongly activating fusions should be visibly blue on the plate within 12 to 24 hr; moderate activators will be visibly blue after ~2 days.

When a bait protein appreciably activates transcription under these conditions, there are several recourses. The first and simplest is to switch to a less sensitive lacZ reporter plasmid; use of pJK103 and pRB1840 may be sufficient to reduce background to manageable levels. If this fails to work, it is frequently possible to generate a truncated LexA fusion that does not activate transcription.

Confirm fusion-protein synthesis by repression assay

For LexA fusions that do not activate transcription, confirm by performing a repression assay (Brent and Ptashne, 1984) that the LexA fusion protein is being synthesized in yeast (some proteins are not) and that it is capable of binding *LexA* operator sequences (Fig. 17.3.5). The following steps can be performed concurrently with the activation assay.

8. Transform EGY48 yeast with the following combinations of plasmids (three transformations):

   pBait + pJK101 (test)
   pRFHM1 + pJK101 (positive control for repression)
   pJK101 alone (negative control for repression).

9. Plate each transformation mix on Glu/CM –Ura, –His dropout plates or Glu/CM –Ura dropout plates as appropriate to select yeast cells that contain the indicated plasmids. Incubate 2 to 3 days at 30°C until colonies appear.

10. Streak colonies to a Glu/CM –Ura, –His or Glu/CM –Ura dropout master plate and incubate overnight at 30°C.

11. Assay β-galactosidase activity of the three transformed strains (test, positive control, and negative control) by liquid assay (using Gal/CM dropout liquid medium), filter

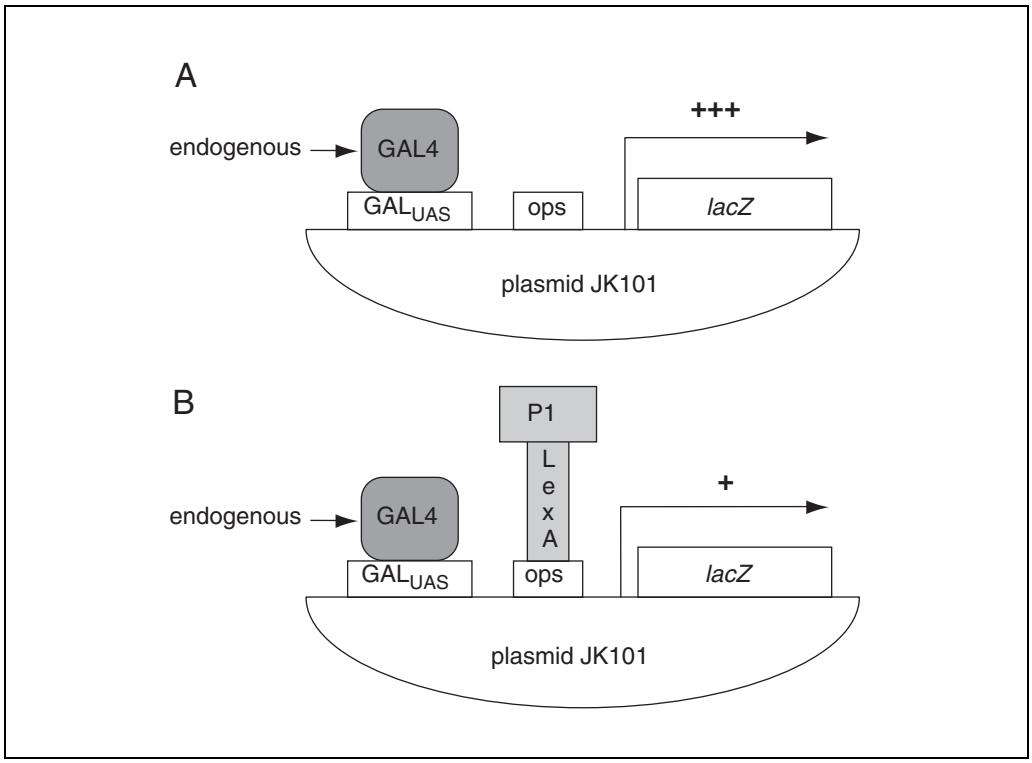

Figure 17.3.5 Repression assay for DNA binding. (**A**) The plasmid JK101 contains the upstream activating sequence (UAS) from the *GAL1* gene followed by *LexA* operators upstream of the *lacZ* coding sequence. Thus, yeast containing pJK101 will have significant β-galactosidase activity when grown on medium in which galactose is the sole carbon source because of binding of endogenous yeast GAL4 to the GAL_{UAS} (**B**). LexA-fused proteins (P1-LexA) that are made, enter the nucleus, and bind the *LexA* operator sequences (ops) will block activation from the GAL_{UAS}, repressing β-galactosidase activity (+) 3- to 5-fold. On glucose/Xgal medium, yeast containing pJK101 should be white because GAL_{UAS} transcription is repressed.

assay (steps 5a to 7a, first restreaking to Gal/CM plates to grow overnight), or plate assay (steps 5b to 7b, using Gal/CM −Ura XGal plates).

This assay should not be run for more than 1 to 2 hr for membranes, or 36 hr for Xgal plates, as the high basal lacZ activity will make differential activation of pJK101 impossible to see with longer incubations. Use of Xgal plates, and inspection 12 to 24 hr after streaking, is generally most effective.

The plasmid pJK101 contains the galactose upstream activating sequence (UAS) followed by LexA operators upstream of the lacZ coding sequence. Thus, yeast containing pJK101 will have significant β-galactosidase activity when grown on medium in which galactose is the sole carbon source because of binding of endogenous yeast GAL4 to the GAL_{UAS}. LexA-fused proteins that are made, enter the nucleus, and bind the LexA operator sequences block activation from the GAL_{UAS}, repressing β-galactosidase activity 3- to 20-fold. Note that on Glu/Xgal medium, yeast containing pJK101 should be white, because GAL_{UAS} transcription is repressed.

12. If a bait protein neither activates nor represses transcription, perform immunoblot analysis by probing an immunoblot of a crude lysate with antibodies against LexA or the fusion domain to test for protein synthesis (see Support Protocol 1).

Even if a bait protein represses transcription, it is generally a good idea to assay for the production of full-length LexA fusions, as occasionally some fusion proteins will be proteolytically cleaved by endogenous yeast proteases. If the protein is made but does not repress, it may be necessary to clone the sequence into a LexA fusion vector that contains a nuclear localization motif, e.g., pJK202 (see Table 17.3.1), or to modify or truncate the

fusion domain to remove motifs that target it to other cellular compartments (e.g., myristoylation signals).

Test for Leu requirement

These steps can be performed concurrently with the *lacZ* activation and repression assays.

13. Disperse a colony of EGY48 containing pBait and pSH18-34 reporter plasmids into 500 µl sterile water. Dilute 100 µl of suspension into 1 ml sterile water. Make a series of 1/10 dilutions in sterile water to cover a 1000-fold concentration range.

14. Plate 100 µl from each tube (undiluted, 1/10, 1/100, and 1/1000) on Gal/CM −Ura, −His dropout plates and on Gal/CM −Ura, −His, −Leu dropout plates. Incubate overnight at 30°C.

    There will be a total of eight plates. Gal/CM −Ura, −His dropout plates should show a concentration range from 10 to 10,000 colonies and Gal/CM −Ura, −His, −Leu dropout plates should have no colonies.

    Actual selection in the interactor hunt is based on the ability of the bait protein and acid-fusion pair, but not the bait protein alone, to activate transcription of the LexA operator-LEU2 gene and allow growth on medium lacking Leu. Thus, the test for the Leu requirement is the most important test of whether the bait protein is likely to have an unworkably high background. The LEU2 reporter in EGY48 is more sensitive than the pSH18-34 reporter for some baits, so it is possible that a bait protein that gives little or no signal in a β-galactosidase assay would nevertheless permit some level of growth on −Leu medium. If this occurs, there are several options for proceeding, the most immediate of which is to substitute EGY191 (see Table 17.3.2), a less sensitive screening strain, and repeat the assay.

    As outlined in this protocol, the authors recommend the strategy of performing the initial screening using the most sensitive reporters and then, if activation is detected, screening with increasingly less sensitive reporters (see Critical Parameters for further discussion).

PERFORMING AN INTERACTOR HUNT

BASIC PROTOCOL 2

An interactor hunt involves two successive large platings of yeast containing LexA-fused probes and reporters and libraries in pJG4-5 (Fig. 17.3.6, Table 17.3.3) with a cDNA expression cassette under control of the *GAL* promoter. In the first plating, yeast are plated on complete minimal (CM) medium −Ura, −His, −Trp dropout plates with glucose (Glu) as a sugar source to select for the library plasmid. In the second plating, which selects for yeast that contain interacting proteins, a slurry of primary transformants is plated on CM −Ura, −His, −Trp, −Leu dropout plates with galactose/raffinose (Gal/Raff) as the sugar source. This two-step selection is encouraged for two reasons. First, a number of interesting cDNA-encoded proteins may be deleterious to the growth of yeast that bear them; these would be competed out in an initial mass plating. Second, it seems likely that immediately after simultaneous transformation and Gal induction, yeast bearing particular interacting proteins may not be able to initially express sufficient levels of these proteins to support growth on medium lacking Leu. Library plasmids from colonies identified in the second plating are purified by bacterial transformation and used to transform yeast cells for the final specificity screen.

A list of libraries currently available for use with this system is provided in Table 17.3.3. The protocol outlined below describes the steps used to perform a single-step screen that should saturate a library derived from a mammalian cell. For screens with libraries derived from lower eukaryotes with less complex genomes, fewer plates will be required.

Occasionally, baits that seemed well-behaved during preliminary tests produce unworkably high backgrounds of "positives" during an actual screen (see Background Informa-

tion and Critical Parameters). To forestall the waste of time and materials performing a screen with such a bait would entail, an alternative approach is to perform a scaled-back screen when working with a new bait (e.g., 5 rather than 30 plates of primary transformants). The results can be assessed before doing a full screen; it is then possible to switch to lower-sensitivity reporter strains and plasmids, if appropriate. Although individual baits will vary, the authors' current default preference is to use the *lacZ* reporter pJK103 in conjunction with either EGY48 or EGY191. Polymerase chain reaction (PCR) can also be used in a rapid screening approach that may be preferable if a large number of positions are obtained in a library screen (see Alternate Protocol 1).

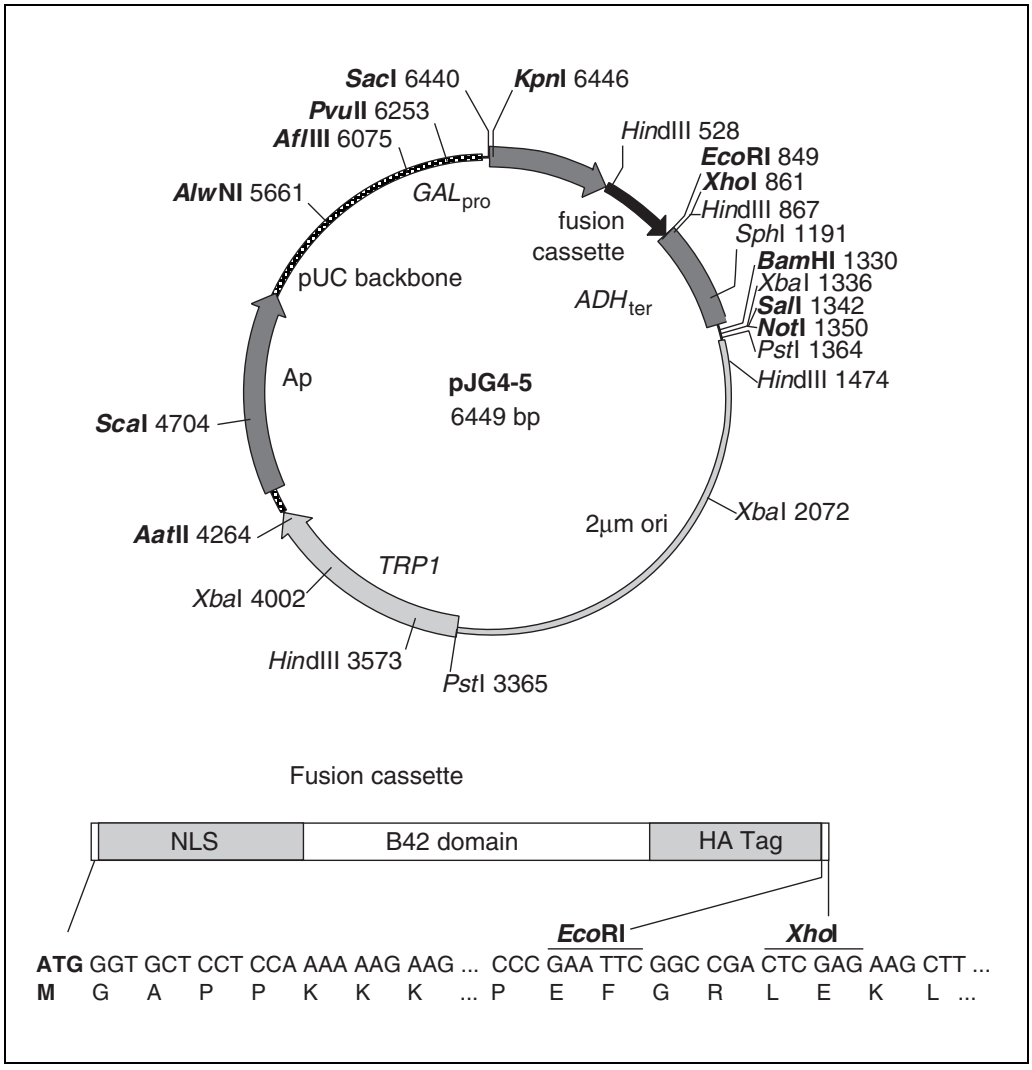

Figure 17.3.6 Library plasmids: pJG4-5 (sequence: accession number U89961). Library plasmids express cDNAs or other coding sequences inserted into unique *Eco*RI and *Xho*I sites as a translational fusion to a cassette consisting of the SV40 nuclear localization sequence (NLS; PPKKKRKVA), the acid blob B42 domain (Ruden et al., 1991), and the hemagglutinin (HA) epitope tag (YPYDVPDYA). Expression of cassette sequences is under the control of the *GAL1* galactose-inducible promoter. This map is based on the sequence data available for pJG4-5, and includes selected sites suitable for diagnostic restriction digests (shown in bold). The sequence 5′-CTG AGT GGA GAT GCC TCC-3′ can be used as a primer to identify inserts or to confirm correct reading frame. The pJG4-5 plasmid contains the *TRP1* selectable marker and the 2µm origin to allow propagation in yeast, and the antibiotic resistance gene and the pUC origin to allow propagation in *E. coli.* Unique sites are marked in bold type. Alternative library plasmids are listed in Table 17.3.1 and maps, sequences, and links for some of them are available at *http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html*.

Materials

Yeast containing appropriate combinations of plasmids (see Table 17.3.1 and Table 17.3.2):
- EGY48 containing *LexA*-operator-*lacZ* reporter and pBait (see Basic Protocol 1)
- EGY48 containing *LexA*-operator-*lacZ* reporter and pRFHM-1
- EGY48 containing *LexA*-operator-*lacZ* reporter and any nonspecific bait

Complete minimal (CM) dropout liquid medium (see recipe) supplemented with sugars (glucose, galactose, and/or raffinose) as indicated [2% (w/v) Glu, or 2% (w/v) Gal + 1% (w/v) Raff]:
- Glu/CM −Ura, −His
- Glu/CM −Trp
- Gal/Raff/CM −Ura, −His, −Trp

H_2O, sterile

TE buffer (pH 7.5; *APPENDIX 2A*)/0.1 M lithium acetate

Library DNA in pJG4-5 (Table 17.3.3 and Fig. 17.3.6)

High-quality sheared salmon sperm DNA (see Support Protocol 2)

40% (w/v) polyethylene glycol 4000 (PEG 4000; filter sterilized)/0.1 M lithium acetate/TE buffer (pH 7.5)

Dimethyl sulfoxide (DMSO)

Complete minimal (CM) medium dropout plates (see recipe) supplemented with sugars and Xgal (20 μg/ml) as indicated [2% (w/v) Glu, and 2% (w/v) Gal + 1% (w/v) Raff]:
- Glu/CM −Ura, −His, −Trp, 24 × 24–cm (Nunc) and 100-mm
- Gal/Raff/CM −Ura, −His, −Trp, 100-mm
- Gal/Raff/CM −Ura, −His, −Trp, −Leu, 100-mm
- Glu/Xgal/CM −Ura, −His, −Trp, 100-mm
- Gal/Raff/Xgal/CM −Ura, −His, −Trp, 100-mm
- Glu/CM −Ura, −His, −Trp, −Leu, 100-mm
- Glu/CM −Ura, −His, 100-mm
- Gal/CM −Ura, −His, −Trp, −Leu, 100-mm

TE buffer (pH 7.5), sterile (optional)

Glycerol solution (see recipe)

E. coli KC8 (*pyrF leuB600 trpC hisB463*; constructed by K. Struhl and available from R. Brent)

LB/ampicillin plates: LB plates (*APPENDIX 2A*) with 50 μg/ml ampicillin

E. coli DH5α or other strain suitable for preparation of DNA for sequencing

Bacterial defined minimal A medium plates: 1× A medium plates containing 0.5 μg/ml vitamin B1 supplemented with 40 μg/ml each Ura, His, and Leu

30°C incubator, with and without shaking

Low-speed centrifuge and rotor

50-ml conical tubes, sterile

1.5-ml microcentrifuge tubes, sterile

42°C heating block

Glass microscope slides, sterile

Additional reagents and equipment for rapid miniprep isolation of yeast DNA, transformation of bacteria by electroporation, miniprep isolation of bacterial DNA, restriction endonuclease digestion (optional), and agarose gel electrophoresis (optional; *APPENDIX 3*)

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper aseptic technique should be used accordingly.

[b]The most updated list of Interaction Trap compatible libraries is available at *http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html*.

[c]Insert size ranges for pJG4-5 based libraries originally constructed in the Brent laboratory, which are now commercially available from Clontech, were reestimated by the company.

Transform the library

1. Grow an ~20-ml culture of EGY48 or EGY191 containing a *LexA*-operator-*lacZ* reporter plasmid and pBait in Glu/CM −Ura, −His liquid dropout medium overnight at 30°C.

   For best results, the pBait and lacZ reporter plasmids should have been transformed into the yeast within ~7 to 10 days of commencing a screen.

2. In the morning, dilute culture into 300 ml Glu/CM −Ura, −His liquid dropout medium to 2×10^6 cell/ml (OD_{600} = ~0.10). Incubate at 30°C until the culture contains ~1×10^7 cells/ml (OD_{600} = ~0.50).

3. Centrifuge 5 min at 1000 to 1500 × *g* in a low-speed centrifuge at room temperature to harvest cells. Resuspend in 30 ml sterile water and transfer to 50-ml conical tube.

4. Centrifuge 5 min at 1000 to 1500 × *g*. Decant supernatant and resuspend cells in 1.5 ml TE buffer/0.1 M lithium acetate.

5. Add 1 µg library DNA in pJG4-5 and 50 µg high-quality sheared salmon sperm carrier DNA to each of 30 sterile 1.5-ml microcentrifuge tubes. Add 50 µl of the resuspended yeast solution from step 4 to each tube.

   The total volume of library and salmon sperm DNA added should be <20 µl and preferably <10 µl.

   A typical library transformation will result in 2 to 3 × 10^6 primary transformants. Assuming a transformation efficiency of 10^5/µg library DNA, this transformation requires a total of 20 to 30 µg library DNA and 1 to 2 mg carrier DNA. Doing transformations in small aliquots helps reduce the likelihood of contamination, and for reasons that are not clear, provides significantly better transformation efficiency than scaled-up versions.

   Do not use excess transforming library DNA per aliquot of competent yeast cells because each competent cell may take up multiple library plasmids, complicating subsequent analysis.

6. Add 300 µl of sterile 40% PEG 4000/0.1 M lithium acetate/TE buffer, pH 7.5, and invert to mix thoroughly. Incubate 30 min at 30°C.

7. Add DMSO to 10% (~40 µl per tube) and invert to mix. Heat shock 10 min in 42°C heating block.

8a. *For 28 tubes:* Plate the complete contents of one tube per 24 × 24–cm Glu/CM −Ura, −His, −Trp dropout plate and incubate at 30°C.

8b. *For two remaining tubes:* Plate 360 µl of each tube on 24 × 24–cm Glu/CM −Ura, −His, −Trp dropout plate. Use the remaining 40 µl from each tube to make a series of 1/10 dilutions in sterile water. Plate dilutions on 100-mm Glu/CM −Ura, −His, −Trp dropout plates. Incubate all plates 2 to 3 days at 30°C until colonies appear.

The dilution series gives an idea of the transformation efficiency and allows an accurate estimation of the number of transformants obtained.

Collect primary transformant cells

Conventional replica plating does not work well in the selection process because so many cells are transferred to new plates that very high background levels inevitably occur. Instead, the procedure described below creates a slurry in which cells derived from $>10^6$ primary transformants are homogeneously dispersed. A precalculated number of these cells is plated for each primary transformant.

9. Cool all of the 24 × 24–cm plates containing transformants for several hours at 4°C to harden agar.

10. Wearing gloves and using a sterile glass microscope slide, gently scrape yeast cells off the plate. Pool cells from the 30 plates into one or two sterile 50-ml conical tubes.

This is the step where contamination is most likely to occur. Be careful.

11. Wash cells by adding a volume of sterile TE buffer or water at least equal to the volume of the transferred cells. Centrifuge ~5 min at 1000 to 1500 × *g*, room temperature, and discard supernatant. Repeat wash.

After the second wash, pellet volume should be ~25 ml cells derived from 1.5×10^6 transformants.

12. Resuspend pellet in 1 vol glycerol solution, mix well, and store up to 1 year in 1-ml aliquots at −70°C.

Determine replating efficiency

13. Remove an aliquot of frozen transformed yeast and dilute 1/10 with Gal/Raff/CM −Ura, −His, −Trp dropout medium. Incubate with shaking 4 hr at 30°C to induce the *GAL* promoter on the library.

Raffinose (Raff) aids in growth without diminishing transcription from the GAL1 promoter.

14. Make serial dilutions of the yeast cells using the Gal/Raff/CM −Ura, −His, −Trp dropout medium. Plate on 100-mm Gal/Raff/CM −Ura, −His, −Trp dropout plates and incubate 2 to 3 days at 30°C until colonies are visible.

15. Count colonies and determine the number of colony-forming units (cfu) per aliquot of transformed yeast.

In calculating yeast concentrations, it is useful to remember that 1 OD_{600} unit = ~2.0×10^7 yeast cells. In general, if the harvest is done carefully, viability will be greater than 90%. Some intrepid investigators perform this step simultaneously with plating out on Leu selective medium (steps 16 and 17).

Screen for interacting proteins

16. Thaw the appropriate quantity of transformed yeast based on the plating efficiency, dilute, and incubate as in step 13. Dilute cultures in Gal/Raff/CM −Ura, −His, −Trp, −Leu medium as necessary to obtain a concentration of 10^7 cells/ml (OD_{600} = ~0.5), and plate 100 µl on each of as many 100-mm Gal/Raff/CM −Ura, −His, −Trp, −Leu dropout plates as are necessary for full representation of transformants. Incubate 2 to 3 days at 30°C until colonies appear.

    Because not all cells that contain interacting proteins plate at 100% efficiency on −Leu medium (Estojak et al., 1995), it is desirable that for actual selection, each primary colony obtained from the transformation be represented on the selection plate by three to ten individual yeast cells. This will in some cases lead to multiple isolations of the same cDNA; however, because the slurry is not perfectly homogenous, it will increase the likelihood that all primary transformants are represented by at least one cell on the selective plate.

    It is easiest to visually scan for Leu^+ colonies using cells plated at ~10^6 cfu per 100-mm plate. Plating at higher density can contribute to cross-feeding between yeast, resulting in spurious background growth. Thus, for a transformation in which 3×10^6 colonies are obtained, plate ~2×10^7 cells on a total of 20 selective plates.

17. Carefully pick appropriate colonies to a new Gal/Raff/CM −Ura, −His, −Trp, −Leu master dropout plate. Incubate 2 to 7 days at 30°C until colonies appear.

    A good strategy is to pick a master plate with colonies obtained on day 2, a second master plate (or set of plates) with colonies obtained on day 3, and a third with colonies obtained on day 4. Colonies from day 2 and 3 master plates should generally be characterized further. If many apparent positives are obtained, it may be worth making master plates of the much larger number of colonies likely to be obtained at day 4 (and after). See Critical Parameters and annotation to step 19 for additional information about appropriate colony selection for the master plate.

    If no colonies appear within a week, those arising at later time points are likely to be artifactual. Contamination that has occurred at an earlier step (e.g., during plate scraping) is generally reflected by the growth of a very large number of colonies (>500/plate) within 24 to 48 hr after plating on selective medium.

    Some investigators omit use of a Gal/Raff/CM −Ura, −His, −Trp, −Leu master plate, restreaking directly to a Glu/CM −Ura, −His, −Trp master plate as in step 19.

Test for Gal dependence

The following steps test for Gal dependence of the Leu^+ insert and lacZ phenotypes to confirm that they are attributable to expression of the library-encoded proteins. The *GAL1* promoter is turned off and −Leu selection eliminated before reinducing.

18. Restreak from the Gal/Raff/CM −Ura, −His, −Trp, −Leu master dropout plate to a 100-mm Glu/CM −Ura, −His, −Trp master dropout plate. Incubate overnight at 30°C until colonies form.

19. Restreak or replica plate from this plate to the following plates:

    Glu/Xgal/CM −Ura, −His, −Trp
    Gal/Raff/Xgal/CM −Ura, −His, −Trp
    Glu/CM −Ura, −His, −Trp, −Leu
    Gal/Raff/CM −Ura, −His, −Trp, −Leu.

    At this juncture, colonies and the library plasmids they contain are tentatively considered positive if they are blue on Gal/Raff/Xgal plates but not blue or only faintly blue on Glu/Xgal plates, and if they grow on Gal/Raff/CM −Leu plates but not on Glu/CM −Leu plates.

    The number of positives obtained will vary drastically from bait to bait. How they are processed subsequently will depend on the number initially obtained and on the preference

of the individual investigator. If none are obtained using EGY48 as reporter strain, it may be worth attempting to screen a library from an additional tissue source. If a relatively small number (≤30) are obtained, proceed to step 20. However, sometimes searches will yield large numbers of colonies (>30 to 300, or more). In this case, there are several options. The first option is to warehouse the majority of the positives and work up the first 30 that arise; those growing fastest are frequently the strongest interactors. These can be checked for specificity, and restriction digests can be used to establish whether they are all independent cDNAs or represent multiple isolates of the same, or a small number, of cDNAs. If the former is true, it may be advisable to repeat the screen in a less sensitive strain background, as obtaining many different interactors can be a sign of low-affinity nonspecific background. Alternatively, if initial indications are that a few cDNAs are dominating the positives obtained, it may be useful to perform a filter hybridization with yeast (see Support Protocol 3) using these cDNAs as a probe to establish the frequency of their identification and exclude future reisolation of these plasmids. The second major option is to work up large numbers of positives to get a complete profile of isolated interactors (see Support Protocol 4). A third option is to temporarily warehouse the entire results of this first screen, and repeat the screen with a less sensitive strain such as EGY191, on the theory that it is most important to get stronger interactors first and a complete profile of interactors later. Finally, some investigators prefer to work up the entire set of positives initially obtained, even if such positives number in the hundreds. Particularly in this latter case, it is most effective to use Alternate Protocol 1 as a means to identify unique versus common positives.

Isolate plasmid from positive colonies by transfer into E. coli

20a. Transfer yeast plasmids directly into *E. coli* by following the protocol for direct electroporation (*APPENDIX 3*, Alternate Protocol 2). Proceed to step 22.

20b. Isolate plasmid DNA from yeast by the rapid miniprep protocol (*APPENDIX 3*) with the following alteration: after obtaining aqueous phase, precipitate by adding sodium acetate to 0.3 M final and 2 vol ethanol, incubate 20 min on ice, microcentrifuge 15 min at maximum speed, wash pellet with 70% ethanol, dry, and resuspend in 5 µl TE buffer.

Cultures can be grown prior to the miniprep using Glu/CM −Trp to select only for the library plasmid; this may increase the proportion of bacterial colonies that contain the desired plasmid.

21. Use 1 µl DNA to electroporate (*APPENDIX 3*) into competent KC8 bacteria, and plate on LB/ampicillin plates. Incubate overnight at 37°C.

Electroporation must be used to obtain transformants with KC8 because the strain is generally refractory to transformation.

22. Restreak or replica plate colonies arising on LB/ampicillin plates to bacterial defined minimal A medium plates containing vitamin B1 and supplemented with Ura, His, and Leu but lacking Trp. Incubate overnight at 37°C.

Colonies that grow under these conditions contain the library plasmid.

The yeast TRP1 gene can successfully complement the bacterial trpC-9830 mutation, allowing the library plasmid to be easily distinguished from the other two plasmids contained in the yeast. It is helpful to first plate transformations on LB/ampicillin plates, which provides a less stringent selection, followed by restreaking to bacterial minimal medium to maximize the number of colonies obtained (E. Golemis, unpub. observ.).

23. Purify library-containing plasmids using a bacterial miniprep procedure (*APPENDIX 3*).

Some investigators are tempted to immediately sequence DNAs obtained at this stage. At this point, it is still possible that none of the isolated clones will express bona fide interactors, and it is suggested that the following specificity tests be completed before committing the effort to sequencing (also see annotation to step 28).

Because multiple 2μm plasmids with the same marker can be simultaneously tolerated in yeast, it sometimes happens that a single yeast will contain two or more different library plasmids, only one of which encodes an interacting protein. The frequency of this occurrence varies in the hands of different investigators and may in some cases account for disappearing positives if the wrong cDNA is picked. When choosing colonies to miniprep, it is generally useful to work up at least two individual bacterial transformants for each yeast positive. These minipreps can then be restriction digested (APPENDIX 3) with EcoRI + XhoI to release cDNA inserts, and the size of inserts determined on an agarose minigel (APPENDIX 3) to confirm that both plasmids contain the same insert. An additional benefit of analyzing insert size is that it may provide some indication as to whether repeated isolation of the same cDNA is occurring, generally a good indication concerning the biological relevance of the interactor. See Background Information for further discussion.

Assess positive colonies with specificity tests

Much spurious background will have been removed by the previous series of controls. Other classes of false positives can be eliminated by retransforming purified plasmids into "virgin" *LexA*-operator-*LEU2*/*LexA*-operator-*lacZ*/pBait–containing strains that have not been subjected to Leu selection and verifying that interaction-dependent phenotypes are still observed. Such false positives could include mutations in the initial EGY48 yeast that favor growth on Gal medium, library-encoded cDNAs that interact with the LexA DNA-binding domain, or proteins that are sticky and interact with multiple biologically unrelated fusion domains.

24. In separate transformations, use purified plasmids from step 23 to transform yeast that already contain the following plasmids and are growing on Glu/CM −Ura, −His plates:

    EGY48 containing pSH18-34 and pBait
    EGY48 containing pSH18-34 and pRFHM-1
    EGY48 containing pSH18-34 and a nonspecific bait (optional).

25. Plate each transformation mix on Glu/CM −Ura, −His, −Trp dropout plates and incubate 2 to 3 days at 30°C until colonies appear.

26. Create a Glu/CM −Ura, −His, −Trp master dropout plate for each library plasmid being tested. Streak adjacently five or six independent colonies derived from each of the transformation plates. Incubate overnight at 30°C.

27. Restreak or replica plate from this master dropout plate to the same series of test plates used for the actual screen:

    Glu/Xgal/CM −Ura, −His, −Trp
    Gal/Raff/Xgal/CM −Ura, −His, −Trp
    Glu/CM −Ura, −His, −Trp, −Leu
    Gal/CM −Ura, −His, −Trp, −Leu.

    True positive cDNAs should make cells blue on Gal/Raff/Xgal but not on Glu/Xgal plates, and should make them grow on Gal/Raff/CM −Leu but not Glu/CM −Leu dropout plates only if the cells contain LexA-bait. cDNAs that meet such criteria are ready to be sequenced (see legend to Fig. 17.3.3 for primer sequence) or otherwise characterized. Those cDNAs that also encode proteins that interact with either RFHM-1 or another nonspecific bait should be discarded.

    It may be helpful to cross-check the isolated cDNAs with a database of cDNAs thought to be false positives. This database is available on the World Wide Web as a work in progress at http://www.fccc.edu/research/labs/golemis/InteractionTrapInWork.html. cDNAs reported to this database are generally those isolated only once in a screen in which obviously true interactive partners were isolated multiple times, cDNAs that may interact with more than one bait, or cDNAs for which the interaction does not appear to make biological sense

in the context of the starting bait. Although some proteins in this database may ultimately turn out in fact to associate with the bait that isolated them, they are by default unlikely to possess a unique and interesting function in the context of that bait if they are well represented in the database.

28. If appropriate, conduct additional specificity tests (see Support Protocol 5). Analyze and sequence positive isolates.

    The primer sequence for use with pJG4-5 is provided in the legend to Figure 17.3.4.

    DNA prepared from KC8 is generally unsuitable for dideoxy or automated sequencing even after use of Qiagen columns and/or cesium chloride gradients. Library plasmids to be sequenced should be retransformed from the KC8 miniprep stock (step 23) to a more amenable strain, such as DH5α, before sequencing is attempted.

RAPID SCREEN FOR INTERACTION TRAP POSITIVES

ALTERNATE PROTOCOL 1

Under some circumstances, it may be desirable to attempt the analysis of a large number of positives resulting from a two-hybrid screen. One such hypothetical example would be a bait with a leucine zipper or coiled coil known to dimerize with partner "A" that is highly expressed. In order to identify the rare novel partner "B", it is necessary to work through the high background of "A" reisolates. This protocol uses the polymerase chain reaction (PCR) in a strategy to sort positives into redundant (multiple isolates) and unique classes prior to plasmid rescue from yeast, thus greatly reducing the number of plasmid isolations that must be performed. An additional benefit is that this protocol preidentifies positive clones containing one or multiple library plasmids; for those containing only one library plasmid, only a single colony needs to be prepared through KC8/DH5α.

Additional Materials *(also see Basic Protocol 2)*

Yeast plated on Glu/CM −Ura, −His, −Trp master plate (see Basic Protocol 2, step 19)
Lysis solution (see recipe)
10 µM forward primer (FP1): 5′-CGT AGT GGA GAT GCC TCC-3′
10 µM reverse primer (FP2): 5′-CTG GCA AGG TAG ACA AGC CG-3′

Toothpicks or bacterial inoculating loops, sterile
96-well microtiter plate
Sealing tape, e.g., wide transparent tape
150- to 212-µm glass beads, acid-washed (*UNIT 3.8*)
Vortexer with flat plate

Additional reagents and equipment for performing an interactor hunt (see Basic Protocol 2), PCR amplification of DNA, agarose gel electrophoresis, restriction endonuclease digestion, electroporation, and miniprep isolation of bacterial DNA (*APPENDIX 3*)

1. Perform an interactor hunt (see Basic Protocol 2, steps 1 to 19).

2. Use a sterile toothpick or bacterial inoculating loop to transfer yeast from the Glu/CM, −Ura, −His, −Trp master plate into 25 µl lysis solution in a 96-well microtiter plate. Seal the wells of the microtiter plate with sealing tape and incubate 1.5 to 3.5 hr at 37°C with shaking.

    The volume of yeast transferred should not exceed ~2 to 3 µl of packed pellet; larger quantities of yeast will reduce quality of the DNA. DNA can be efficiently recovered from master plates that have been stored up to 1 week at 4°C. If yeast have been previously gridded on master plates, transfer to microtiter plates can be facilitated by using a multicolony replicator.

3. Remove tape from the plate, add ~25 µl acid-washed glass beads to each well, and reseal with the same tape. Firmly attach the microtiter plate to a flat-top vortexer, and vortex 5 min at medium-high power.

   The microtiter plate can be attached to the vortexer using 0.25-in (0.64-cm) rubber bands.

4. Remove the tape and add ~100 µl sterile water to each well. Swirl gently to mix, then remove sample for step 5. Press the tape back firmly to seal the microtiter plate and place in the freezer at −20°C for storage.

5. Amplify 0.8 to 2.0 µl of sample by standard PCR (*APPENDIX 3*) in a ~30-µl volume using 3 µl each of the forward primer FP1 and the reverse primer FP2. Perform PCR using the following cycles:

Initial step:	2 min	94°C
31 cycles:	45 sec	94°C
	45 sec	56°C
	45 sec	72°C.

   These conditions have been used successfully to amplify fragments up to 1.8 kb in length; some modifications, such as extension of elongation time, are also effective.

6. Load 20 µl of the PCR reaction product on a 0.7% low melting temperature agarose gel (*APPENDIX 3*) to resolve PCR products. Based on insert sizes, group the obtained interactors in families, i.e., potential multiple independent isolates of identical cDNAs. Reserve gel until results of step 7 are obtained.

   No special precautions are needed for storing the gel. Since HaeIII digests typically yield rather small DNA fragments, running the second gel does not take a lot of time. Usually, the delay does not exceed 45 to 60 min, during which time the first gel may be stored in a gel box at room temperature or wrapped in plastic wrap at 4°C.

7. While the gel is running, use the remaining 10 µl of PCR reaction product for a restriction endonuclease digestion with *Hae*III in a digestion volume of ~20 µl (*APPENDIX 3*). Based on analysis of the sizes of undigested PCR products in the gel (step 6), rearrange the tubes with *Hae*III digest samples so that those thought to represent a family are side by side. Resolve the digests on a 2% to 2.5% agarose gel (*APPENDIX 3*).

   Most restriction fragments will be in the 200-bp to 1.0-kb size range so using a long gel run is advisable. This analysis should produce a distinct fingerprint of insert sizes and allow definition of library cDNAs as unique isolates or related groups.

   A single positive yeast will sometimes contain multiple library plasmids. An advantage of this protocol is the ready detection of multiple library plasmids in PCR reactions; thus, following subsequent bacterial transformations, only a single TRP1 colony would need to be analyzed unless multiple plasmids were already known to be present.

8. Isolate DNA fragments from the low melting temperature agarose gel (step 6).

   If inspection of the banding pattern on the two gels suggests that a great many reisolates of a small number of cDNAs are present, it may be worthwhile to immediately sequence PCR products representative of these clusters, but it is generally still advisable to continue through specificity tests before doing so. If the PCR products are sequenced, the FP1 forward primer works well in automated sequencing of PCR fragments, but the FP2 primer is only effective in sequencing from purified plasmid.

   In general, priming from the AT-rich ADH terminator downstream of the polylinker/cDNA in library plasmid is less efficient than from upstream of the cDNA, and it is hard to design effective primers in this region.

9. Remove the microtiter plate of lysates from the freezer, thaw it, and remove 2 to 4 µl of lysed yeast for each desired positive. Electroporate DNA into either DH5α or KC8 *E. coli* as appropriate, depending on the choice of bait and reporter plasmids (see

Table 17.3.1 and see Background Information for further information). Refreeze the plate as a DNA reserve in case bacteria fail to transform on the first pass.

KC8 E. coli should be used for electroporation when the original reagents pEG202/pJG4-5/pJK101 are used for the interaction trap.

An additional strength of this protocol is that it identifies redundant clones before transfer of plasmids to bacteria, thus reducing the amount of work required in cases where plasmid identity can be unambiguously assigned. However, although restriction endonuclease digestion and PCR analysis are generally highly predictive, they are not 100% certain methods for estimating cDNA identity. Thus, if there is any doubt about whether two cDNAs are the same, investigators are urged to err on the side of caution.

10. Prepare a miniprep of plasmid DNA from the transformed bacteria (*APPENDIX 3*) and perform yeast transformation and specificity assessment (see Basic Protocol 2, steps 24 to 28).

PERFORMING A HUNT BY INTERACTION MATING

ALTERNATE PROTOCOL 2

An alternative way of conducting an interactor hunt is to mate a strain that expresses the bait protein with a strain that has been pretransformed with the library DNA, and screen the resulting diploid cells for interactors (Bendixen et al., 1994; Finley and Brent, 1994). This "interaction mating" approach can be used for any interactor hunt and is particularly useful in three special cases. The first case is when more than one bait will be used to screen a single library. Interaction mating allows several interactor hunts with different baits to be conducted using a single high-efficiency yeast transformation with library DNA. This can be a considerable savings, since the library transformation is one of the most challenging tasks in an interactor hunt. The second case is when a constitutively expressed bait interferes with yeast viability. For such baits, performing a hunt by interaction mating avoids the difficulty associated with achieving a high-efficiency library transformation of a strain expressing a toxic bait. Moreover, the actual selection for interactors will be conducted in diploid yeast, which are more vigorous than haploid yeast and can better tolerate expression of toxic proteins. The third case is when a bait cannot be used in a traditional interactor hunt using haploid yeast strains (see Basic Protocol 2) because it activates transcription of even the least sensitive reporters. In diploids the reporters are less sensitive to transcription activation than they are in haploids. Thus, the interaction mating hunt provides an additional method to reduce background from transactivating baits.

In the protocol described below, the library DNA is used to transform a strain with a *LEU2* reporter (e.g., EGY48). This pretransformed library strain is then frozen in many aliquots, which can be thawed and used for individual interactor hunts. The bait is expressed in a strain of mating type opposite to that of the pretransformed library strain, and also bearing the *lacZ* reporter. A hunt is conducted by mixing the pretransformed library strain with the bait strain and allowing diploids to form on YPD medium overnight. The diploids are then induced for expression of the library-encoded proteins and screened for interactors as in Basic Protocol 2.

NOTE: Strain combinations other than those described below can also be used in an interaction-mating hunt. The key to choosing the strains is to ensure that the bait and prey strains are of opposite mating types and that both have auxotrophies to allow selection for the appropriate plasmids and reporter genes. Also, once the bait plasmid and *lacZ* reporter plasmid have been introduced into the bait strain, and the library plasmids have been introduced into the library strain, the resulting bait strain and library strain must each have auxotrophies that can be complemented by the other, so that diploids can be selected.

Additional Materials *(also see Basic Protocols 1 and 2)*

Yeast strains: either RFY206 (Finley and Brent, 1994), YPH499 (Sikorski and Hieter, 1989; ATCC #6625), or an equivalent *MATa* strain with auxotrophic markers *ura3*, *trp1*, *his3*, and *leu2*

YPD liquid medium (*UNIT 1.6*)

Glu/CM –Trp plates: CM dropout plates –Trp (see recipe) supplemented with 2% glucose

pJG4-5 library vector (Fig. 17.3.6), empty

100-mm YPD plates (*UNIT 1.6*)

Additional reagents and equipment for lithium acetate transformation of yeast (*APPENDIX 3*)

Construct the bait strain

The bait strain will be a *MATa* yeast strain (mating type opposite of EGY48) containing a *lacZ* reporter plasmid like pSH18-34 and the bait-expressing plasmid, pBait.

1. Perform construction of the bait plasmid (pBait; see Basic Protocol 1, step 1).

2. Cotransform the *MATa* yeast strain (e.g., either RFY206 or YPH499) with pBait and pSH18-34 using the lithium acetate method (*APPENDIX 3*). Select transformants on Glu/CM –Ura,–His plates by incubating plates at 30°C for 3 to 4 days until colonies form. Combine 3 colonies for all future tests and for the mating hunt.

   The bait strain (RFY206/pSH18-34/pBait or YPH499/pSH18-34/pBait) can be tested by immunoblotting to ensure that the bait protein is expressed (see Support Protocol 1). Synthesis and nuclear localization of the bait protein can also be tested by the repression assay (see Basic Protocol 1, steps 8 to 12).

3. *Optional:* Assay *lacZ* gene activation in the bait strain (see Basic Protocol 1, steps 4 to 7).

   If the bait activates the lacZ reporter, a less sensitive lacZ reporter plasmid (Table 17.3.1), or an integrated version of the lacZ reporter should be tried. A bait that strongly activates the lacZ reporters usually cannot be used in a hunt based on selection of interactors with the LEU2 reporter, because the LEU2 reporters are more sensitive than the lacZ reporters. However, both reporters are less sensitive to activation by a bait in diploid cells, as compared to haploid cells. Thus, a more important test of the transactivation potential of a bait is to test the leucine requirement of diploid cells expressing it, as described in steps 6 to 20, below.

Prepare the pretransformed library strain (EGY48 + library plasmids)

4. Perform a large-scale transformation of EGY48 with library DNA using the lithium acetate method (see Basic Protocol 2, steps 1 to 8, except start with EGY48 bearing no other plasmids). To prepare for transformation, grow EGY48 in YPD liquid medium. Select library transformants on Glu/CM –Trp plates by incubating 3 days at 30°C.

5. Collect primary transformants by scraping plates, washing yeast, and resuspending in 1 pellet vol glycerol solution (see Basic Protocol 2, steps 9 to 12). Freeze 0.2- to 1.0-ml aliquots at −70° to −80°C.

   The cells will be stable for at least 1 year. Refreezing a thawed aliquot will result in loss of viability. Thus, many frozen aliquots should be made, so that each thawed aliquot can be discarded after use.

Prepare the pretransformed control strain (EGY48 + pJG4-5)

6. Transform EGY48 grown in YPD liquid medium with the empty library vector, pJG4-5, using the lithium acetate method (*APPENDIX 3*). Select transformants on Glu/CM –Trp plates by incubating 3 days at 30°C.

7. Pick and combine three transformant colonies and use them to inoculate 30 ml of Glu/CM –Trp medium. Incubate 15 to 24 hr at 30°C (to OD_{600} >3).

8. Centrifuge 5 min at 1000 to 1500 × *g*, room temperature, and remove supernatant. Resuspend in 10 ml sterile water to wash cells.

9. Centrifuge 5 min at 1000 to 1500 × *g*, room temperature, and remove supernatant. Resuspend in 1 pellet vol glycerol solution and freeze 100-µl aliquots at –70° to –80°C.

Determine plating efficiency of pretransformed library and pretransformed control strains

10. After freezing (at least 1 hr) thaw an aliquot of each pretransformed strain (from step 5 and step 9) at room temperature. Make several serial dilutions in sterile water, including aliquots diluted 10^5-fold, 10^6-fold, and 10^7-fold. Plate 100 µl of each dilution on 100-mm Glu/CM –Trp plates and incubate 2 to 3 days at 30°C.

11. Count the colonies and determine the number of colony-forming units (cfu) per aliquot of transformed yeast.

    The plating efficiency for a typical library transformation and for the control strain will be ~1 × 10^8 cfu per 100 µl.

Mate the bait strain with the pretransformed library strain and the pretransformed control strain

In steps 12 through 20, an interactor hunt is conducted concurrently with testing *LEU2* reporter activation by the bait itself. For most baits, this approach will be the quickest way to isolate interactors. However, for some baits, such as those that have a high transactivation potential, or those that affect yeast mating or growth, steps 12 through 20 will serve as a pilot experiment to determine the optimal parameters for a subsequent hunt.

12. Grow a 30-ml culture of the bait strain in Glu/CM –Ura,–His liquid dropout medium to mid to late log phase (OD_{600} = 1.0 to 2.0, or 2 to 4 × 10^7cells/ml).

    A convenient way to grow the bait strain is to inoculate a 5-ml culture with approximately three colonies from a plate and grow it overnight at 30°C with shaking. In the morning, measure the OD_{600}, dilute into a 30-ml culture to a final OD_{600} = 0.2, and grow at 30°C with shaking. The culture should reach mid to late log phase before the end of the day.

13. Centrifuge the culture 5 min at 1000 to 1500 × *g*, room temperature, to harvest cells. Resuspend the cell pellet in sterile water to make a final volume of 1 ml.

    This should correspond to ~1 × 10^9 cells/ml.

14. Set up two matings. In one sterile microcentrifuge tube mix 200 µl of the bait strain with 200 µl of a thawed aliquot of the pretransformed control strain from step 9. In a second microcentrifuge tube mix 200 µl of the bait strain with ~1 × 10^8 cfu (~0.1 to 1 ml) of the pretransformed library strain from step 5.

    The library mating should be set up so that it contains a ~2-fold excess of bait strain cfu over pretransformed library strain cfu. Because the bait strain was harvested in log phase, most of the cells will be viable (i.e., cells/ml = ~cfu/ml), and the number of cfu can be sufficiently estimated from optical density (1 OD_{600} = ~2 × 10^7 cells/ml). Under these conditions, ~10% of the cfu in the pretransformed library strain will mate with the bait

strain. Thus, a complete screen of 10^7 library transformants will require a single mating with at least 10^8 cfu of the pretransformed library strain and at least 2×10^8 cfu of the bait strain.

To screen more library transformants, set up additional matings. The number of pretransformed library transformants to screen depends on the size of the library and the number of primary transformants obtained in step 5. If the size of the library is larger than the number of transformants obtained in step 5, the goal will be to screen all of the yeast transformants. In this case, complete screening of the library will require additional transformations of EGY48 and additional interactor hunts. If the size of the library is smaller than the number of transformants obtained in step 5, the goal will be to screen at least a number of transformants equivalent to the size of the library.

15. Centrifuge each cell mixture for 5 min at 1000 to 1500 × *g*, pour off medium, and resuspend cells in 200 µl YPD medium. Plate each suspension on a 100-mm YPD plate. Incubate 12 to 15 hr at 30°C.

16. Add ~1 ml of Gal/Raff/CM –Ura, –His, –Trp to the lawns of mated yeast on each plate. Mix the cells into the medium using a sterile applicator stick.

17. Transfer each slurry of mated cells to a 500-ml flask containing 100 ml of Gal/Raff/CM –Ura, –His, –Trp dropout medium. Incubate with shaking 6 hr at room temperature to induce the *GAL1* promoter, which drives expression of the cDNA library.

18. Centrifuge the cell suspensions 5 min at 1000 to 1500 × *g*, room temperature, to harvest the cells. Wash by resuspending in 30 ml of sterile water and centrifuging again. Resuspend each pellet in 5 ml sterile water. Measure OD_{600} and, if necessary, dilute to a final concentration of $\sim 1 \times 10^8$ cells/ml.

    This is a mixture consisting of haploid cells that have not mated and diploid cells. Under a microscope, the two cell types can be distinguished by size (diploids are ~1.7× bigger than haploids) and shape (diploids are slightly oblong and haploids are spherical). Because diploids grow faster than haploids, this mixture will contain ~10% to 50% diploid cells. The actual number of diploids will be determined by plating dilutions on –Ura, –His, –Trp medium, which will not support the growth of the parental haploids.

19. For each mating make a series of $^1/_{10}$ dilutions in sterile water, at least 200 µl each, to cover a 10^6-fold concentration range. Plate 100 µl from each tube (undiluted, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, and 10^{-6} dilution) on 100-mm Gal/Raff/CM –Ura, –His, –Trp, –Leu plates. Plate 100 µl from the 10^{-4}, 10^{-5}, and 10^{-6} tubes on 100-mm Gal/Raff/CM –Ura, –His, –Trp plates. Incubate plates at 30°C. Count the colonies on each plate after 2 to 5 days.

20. For the mating with the pretransformed library, prepare an additional 3 ml of a 10^{-1} dilution. Plate 100 µl of the 10^{-1} dilution on each of 20 100-mm Gal/Raff/CM –Ura, –His, –Trp, –Leu plates. Also plate 100 µl of the undiluted cells on each of 20 100-mm Gal/Raff/CM –Ura, –His, –Trp, –Leu plates. Incubate at 30°C. Pick Leu^+ colonies after 2 to 5 days and characterize them beginning with step 17 of Basic Protocol 2.

    The number of Leu^+ colonies to pick to ensure that all of the pretransformed library has been screened depends on the transactivation potential of the bait protein itself. The transactivation potential is expressed as the number of Leu^+ colonies that grow per cfu (Leu^+/cfu) of the bait strain mated with the control strain, as determined in step 19 of this protocol. It can be calculated as the ratio of the number of colonies that grow on Gal/Raff/CM –Ura,–His, –Trp, –Leu to the number of colonies that grow on Gal/Raff/CM –Ura, –His, –Trp for a given dilution of the mating between the bait strain and the control strain. A bait with essentially no transactivation potential will produce less than 10^{-6} Leu^+/cfu. For a bait to be useful in an interactor hunt it should not transactivate more than 10^{-4} Leu^+/cfu.

To screen all of the pretransformed library, it will be necessary to pick a sufficient number of Leu^+ colonies in addition to background colonies produced by the transactivation potential of the bait itself. Thus, the minimum number of Leu^+ colonies that should be picked in step 20 of this protocol is given by:

(transactivation potential, Leu^+/cfu) × (# library transformants screened).

For example, if 10^7 library transformants were obtained in step 2 (and at least 10^8 cfu of these transformants were mated with the bait strain in step 14, since only ~10% will form diploids), and the transactivation potential of the bait is 10^{-4} Leu^+/cfu, then at least 1000 Leu^+ colonies must be picked and characterized. In other words, if the rarest interactor is present in the pretransformed library at a frequency of 10^{-7}, to find it one needs to screen through at least 10^7 diploids from a mating of the library strain. However, at least 1000 of these 10^7 diploids would be expected to be Leu^+ due to the bait background if the transactivation potential of the bait is 10^{-4}. The true positives will be distinguished from the bait background in the next step by the galactose dependence of their Leu^+ and $lacZ^+$ phenotypes.

PREPARATION OF PROTEIN EXTRACTS FOR IMMUNOBLOT ANALYSIS

SUPPORT PROTOCOL 1

To confirm that the bait fusion protein constructed in Basic Protocol 1 is synthesized properly, a crude lysate is prepared for SDS-PAGE and immunoblot analysis (*UNITS 6.1 & 6.2*). The presence of the target protein is detected by antibody to LexA or the fusion domain.

Materials

Master plates with pBait-containing positive and control yeast on Glu/CM −Ura, −His dropout medium (see Basic Protocol 1, step 4)

Glu/CM −Ura, −His dropout liquid medium: CM dropout plates −Ura, −His (see recipe) supplemented with 2% glucose

2× Laemmli sample buffer (see recipe)

Antibody to fusion domain or LexA: monoclonal antibody to LexA (Clontech, Invitrogen) or polyclonal antibody to LexA (available by request from R. Brent or E. Golemis)

30°C incubator

100°C water bath

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting and immunodetection (*UNIT 6.2*)

1. From the master plates, start a 5-ml culture in Glu/CM −Ura, −His liquid medium for each bait being tested and for a positive control for protein expression (i.e., RFHMI or SH17-4). Incubate overnight at 30°C.

   For each construct assayed, it is a good idea to grow colonies from at least two primary transformants, as levels of bait expression are sometimes heterogenous.

2. From each overnight culture, start a fresh 5-ml culture in Glu/CM −Ura, −His at OD_{600} = ~0.15. Incubate again at 30°C.

3. When the culture has reached OD_{600} = 0.45 to 0.7 (~4 to 6 hr), remove 1.5 ml to a microcentrifuge tube.

   For some LexA fusion proteins, levels of the protein drop off rapidly in cultures approaching stationary phase. This is due to a combination of the diminishing activity of the ADH1 promoter in late growth phases and the relative instability of particular fusion domains. Thus, it is not a good idea to let cultures become saturated in the hopes of obtaining a higher yield of protein.

4. Microcentrifuge cells 3 min at 13,000 × *g*, room temperature. When the pellet is visible, remove the supernatant.

   Inspection of the tube should reveal a pellet ~1 to 3 µl in volume. If the pellet is not visible, microcentrifuge another 3 min.

5. Working rapidly, add 50 µl of 2× Laemmli sample buffer to the visible pellet in the tube, vortex, and place the tube on dry ice.

   Samples may be frozen at −70°C.

6. Transfer frozen sample directly to a boiling water bath or a PCR machine set to cycle at 100°C. Boil 5 min.

7. Microcentrifuge 5 sec at maximum speed to pellet large cellular debris.

8. Perform SDS-PAGE (*UNIT 6.1*) using 20 to 50 µl sample per lane.

9. To detect the protein, immunoblot and analyze (*UNIT 6.2*) using antibody to the fusion domain or LexA.

SUPPORT PROTOCOL 2

PREPARATION OF SHEARED SALMON SPERM CARRIER DNA

This protocol generates high-quality sheared salmon sperm DNA (sssDNA) for use as carrier in transformation (Basic Protocol 2). This DNA is also suitable for other applications where high-quality carrier DNA is needed (e.g., hybridization). This protocol is based on Schiestl and Gietz (1989). For more details of phenol extraction or other DNA purification methods, consult *APPENDIX 3*.

Materials

High-quality salmon sperm DNA (e.g., sodium salt from salmon testes, Sigma or Boehringer Mannheim), desiccated
TE buffer, pH 7.5 (*APPENDIX 2A*), sterile
TE-saturated buffered phenol
1:1 (v/v) buffered phenol/chloroform
Chloroform
3 M sodium acetate, pH 5.2 (*APPENDIX 2A*)
100% and 70% ethanol, ice cold

Magnetic stirring apparatus and stir-bar, 4°C
Sonicator with probe
50-ml conical centrifuge tube
High-speed centrifuge and appropriate tube
100°C and ice-water baths

1. Dissolve desiccated high-quality salmon sperm DNA in TE buffer, pH 7.5, at a concentration of 5 to 10 mg/ml by pipetting up and down in a 10-ml glass pipet. Place in a beaker with a stir-bar and stir overnight at 4°C to obtain a homogenous viscous solution.

   It is important to use high-quality salmon sperm DNA. Sigma Type III sodium salt from salmon testes has worked well, as has a comparable grade from Boehringer Mannheim. Carrier DNA is also commercially available from Clontech. Generally it is convenient to prepare 20- to 40-ml batches at a time.

2. Shear the DNA by sonicating briefly using a large probe inserted into the beaker.

   The goal of this step is to generate sheared salmon sperm DNA (sssDNA) with an average size of 7 kb, but ranging from 2 to 15 kb. Oversonication (such that the average size is closer to 2 kb) drastically decreases the efficacy of carrier in enhancing transformation. The

original version of this protocol (Schiestl and Gietz, 1989) called for two 30-sec pulses at three-quarter power, but optimal conditions vary between sonicators. The first time this protocol is performed, it is worthwhile to sonicate briefly, then test the size of the DNA by running out a small aliquot alongside molecular weight markers on an agarose gel containing ethidium bromide. The DNA can be sonicated further if needed.

3. Once DNA of the appropriate size range has been obtained, extract the sssDNA solution with an equal volume of TE-saturated buffered phenol in a 50-ml conical tube, shaking vigorously to mix.
4. Centrifuge 5 to 10 min at 3000 × *g*, room temperature, or until clear separation of phases is obtained. Transfer the upper phase containing the DNA to a clean tube.
5. Repeat extraction using 1:1 (v/v) buffered phenol/chloroform, then chloroform alone. Transfer the DNA into a tube suitable for high-speed centrifugation.
6. Precipitate the DNA by adding $\frac{1}{10}$ vol of 3 M sodium acetate and 2.5 vol of ice-cold 100% ethanol. Mix by inversion. Centrifuge 15 min at ~12,000 × *g*, room temperature.
7. Wash the pellet with 70% ethanol. Briefly dry either by air drying, or by covering one end of the tube with Parafilm with a few holes poked in and placing the tube under vacuum. Resuspend the DNA in sterile TE buffer at 5 to 10 mg/ml.

   Do not overdry the pellet or it will be very difficult to resuspend.
8. Denature the DNA by boiling 20 min in a 100°C water bath. Then immediately transfer the tube to an ice-water bath.
9. Place aliquots of the DNA in microcentrifuge tubes and store frozen at −20°C. Thaw as needed.

   DNA should be boiled again briefly (5 min) immediately before addition to transformations.

   Before using a new batch of sssDNA in a large-scale library transformation, it is a good idea to perform a small-scale transformation using suitable plasmids to determine the transformation efficiency. Optimally, use of sssDNA prepared in the manner described will yield transformation frequencies of >10^5 colonies/µg input plasmid DNA.

YEAST COLONY HYBRIDIZATION

SUPPORT PROTOCOL 3

This protocol is adapted from a modification of the classic protocol of Grunstein and Hogness (1975; Kaiser et al., 1994). It is primarily useful when a large number of putative interactors has been obtained, and initial minipreps and restriction digests have indicated that many of them derive from a small number of cDNAs; these cDNAs can then be used as probes to screen and eliminate identical cDNAs from the pool.

Materials

Glu/CM −Trp plates: CM dropout plates −Trp (see recipe) supplemental with 2% glucose
Master dropout plate of yeast positive for Gal dependence (see Basic Protocol 2, step 18)
1 M sorbitol/20 mM EDTA/50 mM DTT (prepare fresh)
1 M sorbitol/20 mM EDTA
0.5 M NaOH
0.5 M Tris·Cl (pH 7.5)/6× SSC (*APPENDIX 2A*)
2× SSC (see recipe)
100,000 U/ml β-glucuronidase (type HP-2 crude solution from *Helix pomatia*; Sigma)

82-mm circular nylon membrane, sterile
Whatman 3MM paper
80°C vacuum oven *or* UV cross-linker

Additional reagents and equipment for bacterial filter hybridization (*APPENDIX 3*)

1. Place a sterile nylon membrane onto a Glu/CM −Trp dropout plate. From the master dropout plate of Gal-dependent positives, gently restreak positives to be screened onto the membrane and mark the membrane to facilitate future identification of hybridizing colonies. Grow overnight (~12 hr) at 30°C.

   Growth for extended periods of time (i.e., 24 hr) may result in difficulty in obtaining good lysis. It is a good idea to streak positive and negative controls for the cDNAs to be hybridized on the membrane.

2. Remove membrane from plate. Air dry briefly. Incubate ~30 min on a sheet of Whatman 3MM paper saturated with 1 M sorbitol/20 mM EDTA/50 mM DTT.

   Optionally, before commencing chemical lysis, membranes can be placed at −70°C for 5 min, then thawed at room temperature for one or more cycles to enhance cell wall breakage.

3. Cut a piece of Whatman 3MM paper to fit inside a 100-mm petri dish. Place the paper disc in the dish and saturate with 100,000 U/ml β-glucuronidase diluted 1:500 in 1 M sorbitol/20 mM EDTA (2 µl glucuronidase per ml of sorbitol/EDTA to give 200 U/ml final). Layer nylon membrane on dish, cover dish, and incubate up to 6 hr at 37°C until >80% of the cells lack a cell wall.

   The extent of cell wall removal can be determined by removing a small quantity of cells from the filter to a drop of 1 M sorbitol/20 mM EDTA on a microscope slide and observing directly with a phase-contrast microscope at ≥60× magnification. Cells lacking cell wall are nonrefractile.

4. Place membrane on Whatman 3MM paper saturated with 0.5 M NaOH for ~8 to 10 min.

5. Place membrane on Whatman 3MM paper saturated with 0.5 M Tris·Cl (pH 7.5)/6× SSC for 5 min. Repeat with a second sheet of Whatman 3MM paper.

6. Place membrane on Whatman 3MM paper saturated with 2× SSC for 5 min. Then place membrane on dry Whatman paper to air dry for 10 min.

7. Bake membrane 90 min at 80°C in vacuum oven or UV cross-link.

8. Process as for bacterial filter hybridization (*APPENDIX 3*), hybridizing the membrane with probes complementary to previously isolated cDNAs.

   When selecting probes, either random-primed cDNAs or oligonucleotides complementary to the cDNA sequence may be used. If the cDNA is a member of a protein family, it may be advantageous to use oligonucleotides to avoid inadvertently excluding genes related but not identical to those initially obtained.

SUPPORT PROTOCOL 4

MICROPLATE PLASMID RESCUE

In some cases, it is desirable to isolate plasmids from a large number of positive colonies (Basic Protocol 2, steps 18 and 19). The protocol described below is a batch DNA preparation protocol developed by Steve Kron (University of Chicago, Chicago, Ill.) as a scale-up of a basic method developed by Manuel Claros (Laboratoire de Génétique Moleculaire, Paris, France).

Materials

2× Glu/CM −Trp liquid medium: 2× CM −Trp liquid medium (see recipe) supplemented with 4% glucose
Master plate of Gal-dependent yeast colonies (see Basic Protocol 2, step 18)
Rescue buffer: 50 mM Tris·Cl (pH 7.5)/10 mM EDTA/0.3% (v/v) 2-mercaptoethanol (prepare fresh)
Lysis solution: 2 to 5 mg/ml Zymolyase 100T/rescue buffer *or* 100,000 U/ml β-glucuronidase (type HP-2 crude solution from *Helix pomatia*; Sigma) diluted 1:50 in rescue buffer
10% (w/v) SDS
7.5 M ammonium acetate (*APPENDIX 2A*)
Isopropanol
70% ethanol
TE buffer, pH 8.0 (*APPENDIX 2A*)

24-well microtiter plates
Centrifuge with microplate holders, refrigerated
Repeating micropipettor
37°C rotary shaker

Grow yeast cultures

1. Aliquot 2 ml of 2× Glu/CM −Trp medium into each well of a 24-well microtiter plate. Into each well, pick a putative positive colony. Grow overnight with shaking at 30°C.

   The 2× minimal medium is used to maximize the yield of yeast. Four plates can generally be handled conveniently at once, based on the number that can be centrifuged simultaneously.

2. Centrifuge 5 min at 1500 × *g*, 4°C. Shake off supernatant with a snap and return the plate to upright.
3. Swirl or lightly vortex the plate to resuspend cell pellets in remaining liquid. Add 1 ml water to each well and swirl lightly.

   Cell pellets can most easily be resuspended in residual liquid before adding new solutions. Addition of liquid can be accomplished using a repeating pipettor.

4. Centrifuge 5 min at 1500 × *g*, 4°C. Shake off supernatant and resuspend pellet. Add 1 ml rescue buffer.
5. Centrifuge 5 min at 1500 × *g*, 4°C. Shake off supernatant and resuspend pellet in the small volume of liquid remaining in the plate.

Lyse cells

6. To each well, add 25 µl lysis solution. Swirl or vortex to mix. Incubate (with cover on) on a rotary shaker ~1 hr at 37°C.

   Lysis solution need not be completely dissolved before use. By 1 hr, lysis should be obvious as coagulation of yeast into a white precipitate.

   Susceptibility of yeast strains to lytic enzymes varies. If lysis occurs rapidly, then less lytic enzyme should be used. If the lysis step is allowed to go too far, too much of the partially dissolved cell wall may contaminate the final material. Lysis can be judged by examining cells with a phase-contrast microscope. Living cells are white with a dark halo and dead cells are uniformly gray. Lysis leads to release of granular cell contents into the medium. Once cells are mostly gray and many are disrupted, much of the plasmid should have been released.

7. To each well, add 25 µl of 10% SDS. Mix gently by swirling to completely disperse the precipitates. Allow plates to sit 1 min at room temperature.

   At this point, the wells should contain a clear, somewhat viscous solution.

Purify plasmid

8. To each well, add 100 µl of 7.5 M ammonium acetate. Swirl gently, then incubate 15 min at −70°C or −20°C until frozen.

   Addition of acetate should result in the formation of a massive white precipitate of cell debris and SDS. The freezing step appears to improve removal of inhibitors of E. coli transformation.

9. Remove plate from freezer. Once it begins to thaw, centrifuge 15 min at 3000 × *g*, 4°C. Transfer 100 to 150 µl of the resulting clear supernatants to clean 24-well plates.

   In general, some contamination of the supernatant with pelleted material cannot be avoided. However, it is better to sacrifice yield in order to maintain purity.

10. To each well, add ~0.7 vol isopropanol. Mix by swirling and allow to precipitate 2 min at room temperature.

    A cloudy fine precipitate should form immediately after isopropanol is added.

11. Centrifuge 15 min at 3000 × *g*, 4°C. Shake off supernatant with a snap.

12. To each well, add ~1 ml cold 70% ethanol. Mix by swirling, centrifuge 5 min at 3000 × *g*, 4°C. Shake off supernatant with a snap, invert plates and blot well onto paper towel. Allow plates to air dry.

13. To each well, add 100 µl TE buffer. Swirl well and allow to rest on bench several minutes, until the pellets appear fully dissolved. Transfer preps to microcentrifuge tubes or 96-well plates for storage at −20°C.

    One to five microliters of each of the resulting preparations can be used to transform competent E. coli: for KC8, electroporation should be used (see Basic Protocol 2, step 21). Sometimes, the yield of transformants is low if E. coli carrying plasmids are not permitted time to increase the plasmid copy number above a critical threshold before the cells are placed on selective medium. Allow plenty of time for cells to express antibiotic resistance or the TRP1 gene before plating.

    If insufficient numbers of colonies are obtained by this approach, the final plasmid preparation can be resuspended in 20 µl instead of 100 µl TE buffer to concentrate the DNA stock.

SUPPORT PROTOCOL 5

ADDITIONAL SPECIFICITY SCREENING

The three test plasmids outlined (pSH18-34, pRFHM1, and pEG202; see Basic Protocol 2, step 24) represent a minimal test series. If other LexA-bait proteins that are related to the bait protein used in the initial library screen are available, substantial amounts of information can be gathered by additional specificity tests. For example, if the initial bait protein was LexA fused to the leucine zipper of c-Fos, specificity screening of interactor-hunt positives against the leucine zippers of c-Jun or GCN4 in addition to that of c-Fos might allow discrimination between proteins that are specific for fos versus those that generically associate with leucine zippers.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

A medium

5 g $(NH_4)_2SO_4$
22.5 g KH_2PO_4
52.5 g K_2HPO_4
2.5 g sodium citrate·$2H_2O$

continued

Before they are used, concentrated media should be diluted to 1× with sterile water and the following sterile solutions, per liter:

1 ml 1 M $MgSO_4 \cdot 7H_2O$
10 ml 20% carbon source (sugar or glycerol)
and, if required:
0.1 ml 0.5% vitamin B1 (thiamine)
5 ml L amino acids to 40 µg/ml *or*
DL amino acids to 80 µg/ml
Antibiotic

Complete minimal (CM) dropout medium

1.3 g dropout powder (Table 17.3.4)
1.7 g YNB −AA/AS
5 g $(NH_4)_2SO_4$
20 g dextrose
(Alternatively, replace last three ingredients with 27 g minimal medium premix)

For CM plates, add 20 g agar and a pellet of NaOH per liter.

CM dropout powder, also known as minus or omission powder, lacks one or more nutrients but contains the other nutrients listed in Table 17.3.4. Complete minimal (CM) dropout medium is used to test for genes involved in biosynthetic pathways and to select for gene function in transformation experiments. To test for a gene involved in histidine biosynthesis one would determine if the yeast strain in question can grow on CM minus histidine (−His) or "histidine dropout" plates. It is convenient to make several dropout powders, each lacking a single nutrient, to avoid weighing each component separately for all the different dropout plates required in the laboratory.

It may be preferable to use a 10× solution of dropout powder (i.e., 13 g of dropout powder in 100 ml water) that has been "sterilized" separately (and added to the other ingredients after autoclaving) to improve the growth rate in this medium.

Glycerol solution

65% (v/v) glycerol, sterile
0.1 M $MgSO_4$
25 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
Store up to 1 year at room temperature

Laemmli sample buffer, 2×

10% (v/v) 2-mercaptoethanol (2-ME)
6% (w/v) SDS
20% (v/v) glycerol
0.2 mg/ml bromphenol blue
0.025× Laemmli stacking buffer (see recipe; optional)
Store up to 2 months at room temperature

This reagent can conveniently be prepared 10 ml at a time.

Laemmli stacking buffer, 2.5×

0.3 M Tris·Cl, pH 6.8
0.25% (w/v) SDS
Store up to 1 month at 4°C

Lysis solution

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM EDTA
0.3% (v/v) 2-mercaptoethanol (2-ME), added just before use

continued

Table 17.3.4 Nutrient Concentrations for Dropout Powders[a]

Nutrient[b]	Amount in dropout powder(g)[c]	Final conc. in prepared media (μg/ml)	Liquid stock conc. (mg/100 ml)[d]
Adenine (hemisulfate salt)	2.5	40	500
L-arginine (HCl)	1.2	20	240
L-aspartic acid[e]	6.0	100	1200
L-glutamic acid (monosodium salt)	6.0	100	1200
L-histidine	1.2	20	240
L-leucine[f]	3.6	60	720
L-lysine (mono-HCl)	1.8	30	360
L-methionine	1.2	20	240
L-phenylalanine	3.0	50	600
L-serine	22.5	375	4500
L-threonine[e]	12.0	200	2400
L-tryptophan	2.4	40	480
L-tyrosine	1.8	30	180[f]
L-valine	9.0	150	1800
Uracil	1.2	20	240

[a]CM dropout powder lacks one or more nutrients but contains the other nutrients listed in this table. Nomenclature in this manual refers to, e.g., a preparation that omits histidine as histidine dropout powder. Conditions from Sherman et al., 1979.
[b]Amino acids not listed here can be added to a final concentration of 40 μg/ml (40 mg/liter).
[c]Grind powders into a homogeneous mixture with a clean, dry mortar and pestle. Store in a clean, dry bottle or a covered flask.
[d]Use 8.3 ml/liter of each stock for special nutritional requirements. Store adenine, aspartic acid, glutamic acid, leucine, phenylalanine, tyrosine, and uracil solutions at room temperature. All others should be stored at 4°C.
[e]While these amino acids can be used reliably when included in autoclaved media, they supplement growth better when added after autoclaving.
[f]Use 16.6 ml/liter for L-tyrosine nutritional requirement.

2% (v/v) β-glucuronidase from *Helix pomatia* (Type HP-2; Sigma), added just before use

SSC (sodium chloride/sodium citrate), 20×

3 M NaCl (175 g/liter)
0.3 M Na_3citrate·$2H_2O$ (88 g/liter)
Adjust pH to 7.0 with 1 M HCl (*APPENDIX 2A*)

Z buffer

16.1 g $Na_2HPO_4 \cdot 7H_2O$ (60 mM final)
5.5 g $NaH_2PO_4 \cdot H_2O$ (40 mM final)
0.75 g KC1 (10 mM final)
0.246 g $MgSO_4 \cdot 7H_2O$ (1 mM final)
2.7 ml 2-mercaptoethanol (50 mM final)
Adjust to pH 7.0 and bring to 1 liter with H_2O. Do not autoclave.

COMMENTARY

Background Information

Interaction-based cloning is derived from three experimental observations. In the first, Brent and Ptashne (1985) demonstrated that it was possible to assemble a novel, functional transcriptional activator by fusing the DNA-binding domain from one protein, LexA, to the activation domain from a second protein, GAL4. This allowed the use of a single reporter system containing a single DNA-binding motif, the *LexA* operator, to study transcriptional activation by any protein of interest. In the second, Ma and Ptashne (1988) built on this work to demonstrate that the activation domain could be brought to DNA by interaction with a DNA-binding domain. In the third, Fields and Song

Table 17.3.5 Two-hybrid System Variants[a,b]

System	DNA-binding domain	Activation domain	Selection	Reference
Two-hybrid	*GAL4*	*GAL4*	Activation of *lacZ*, *HIS3*	Chien et al., 1991
Interaction trap	*LexA*	*B42*	Activation of *LEU2*, *lacZ*	Gyuris et al., 1993
"Improved two-hybrid"	*GAL4*	*GAL4*	Activation of *HIS3*, *lacZ*	Durfee at al., 1993
Modified two-hybrid	*LexA*	VP16	Activation of *HIS3*, *lacZ*	Vojtek at al., 1993
KISS	*GAL4*	VP16	Activation of *CAT*, *hyg*^{r}	Fearon et al., 1992
Contingent replication	*GAL4*	VP16	Activation of T-Ag, replication of plasmids	Vasavada et al., 1991

[a]Abbreviations: *CAT*, chloramphenicol transferase gene; *hyg*^{r}, hygromycin resistance gene; T-Ag, viral large T antigen.
[b]An extended version of this table is available on *http://www.fccc.edu/research/labs/golemis/betagal.html*.

(1989), working independently of Ma and Ptashne, used two yeast proteins, SNF1 and SNF4, to make an SNF1 fusion to the DNA-binding domain of GAL4 and an SNF4 fusion to the GAL4 activation domain. They demonstrated that the strength of the SNF1-SNF4 interaction was sufficient to allow activation through a GAL4 DNA-binding site. From this, they suggested the feasibility of selecting interacting proteins by performing screens of cDNA libraries made so that library-encoded proteins carried activating domains.

Several groups have developed cDNA library strategies along these lines, with some systems using LexA and others using GAL4 as the DNA-binding domain (Table 17.3.5). LexA and GAL4 each have different properties that should be considered when selecting a system. LexA is derived from a heterologous organism, has no known effect on the growth of yeast, possesses no residual transcriptional activity, can be used in GAL4$^+$ yeast, and can be used with a Gal-inducible promoter. Because GAL4 is an important yeast transcriptional activator, it has the disadvantage that experiments must be performed in gal4$^-$ yeast strains to avoid background due to activation of the reporter system by endogenous GAL4. Such gal4$^-$ strains are frequently less healthy and more difficult to transform than wild-type strains, and either libraries must be constitutively expressed or alternate inducible systems must be used. By contrast, the GAL4 DNA-binding domain may be more efficiently localized to the nucleus and may be preferred for some proteins (for a review of GAL4-based systems, see Bartel et al., 1993). Whichever system is used, it is important to remember that the bait protein constitutes a novel fusion protein whose properties may not exactly parallel those of the original unfused protein of interest. Although systems using the two-hybrid paradigm have been developed in mammalian cells (see Table 17.3.5), these have not been used effectively in library screens. It seems likely that the organism of choice for two-hybrid identification of novel partner proteins will remain yeast.

cDNAs that pass specificity tests are referred to as positives, or "true positives." In interactor hunts conducted to date, anywhere from zero to practically all isolated plasmids passed the final specificity test. If no positives are obtained, the tissue source for the library originally used may not be appropriate, and a different library may produce better results. However, there are some proteins for which no positives are found. Various explanations for this are provided below. Conversely, some library-encoded proteins are known to be isolated repeatedly using a series of unrelated baits, and these proteins demonstrate at least some specificity. One of these, heat shock protein 70, might be explained by positing that it assists the folding of some LexA-fused bait proteins, or alternatively, that these bait proteins are not normally folded. This example illustrates the point that the physiological relevance of even quite specific interactions may sometimes be obscure.

Because the screen involves plating multiple cells to Gal/CM −Ura, −His, −Trp, −Leu dropout medium for each primary transformant obtained, multiple reisolates of true positive cDNAs are frequently obtained. If a large number of specific positives are obtained, it is generally a good idea to attempt to sort them into classes—for example, digesting minipreps of positives with *Eco*RI, *Xho*I, and *Hae*III will

generate a fingerprint of sufficient resolution to determine whether multiple reisolates of a small number of clones or single isolates of many different clones have been obtained. The former situation is a good indication that the system is working well.

An important issue that arises in an interactor hunt is the question of how biologically relevant interacting proteins that are isolated are likely to be. This leads directly to the question of what K_d of association two molecules must have to be detected by an interactor hunt. In fact, this is not at all a simple issue. For the system described here, most fusion proteins appear to be expressed at levels ranging from 50 nM to 1 μM (Golemis and Brent, 1992). Given the strength of the *GAL* promoter, it is likely that many library-encoded proteins are expressed at similarly high levels, ≥1 μM in the nucleus (Golemis and Brent, 1992). At this concentration, which is in considerable excess over the nuclear concentration of operator-bound bait protein, a cDNA library–encoded protein should half-maximally occupy the DNA-bound bait protein if it possesses a K_d of 10^{-6} M, making it theoretically possible that very-low-affinity interactions could be detected. Such interactions have been observed in some cases. In contrast, some interactions that have been previously established using other methods and are predicted by known K_d to be easily detected by these means, either are not detected or are detected only weakly (Finley and Brent, 1994; Estojak et al., 1995). Because of the conservation of many proteins between lower and higher eukaryotes, one explanation for this observation is that either one or both of the partners being tested is being sequestered from the desired interaction by fortuitous association with an endogenous yeast protein. A reasonably complete investigation of the degree of correlation between in vitro determinations of interaction affinity and apparent strength of interaction in the interaction trap is included in Estojak et al. (1995). The result of this investigation suggests it is important to measure the affinity of detected interactions under different conditions, using a second assay system, rather than to draw conclusions about affinity based on detection in the interaction trap.

A number of different plasmids can be used for conducting an interactor hunt. Their properties are summarized in Tables 17.3.1 and 17.3.2. Because of the generous and open scientific exchange between investigators using the system, the number of available plasmids and other components has greatly expanded since the appearance of the initial two-hybrid reagents, facilitating the study of proteins inaccessible by the original system.

The original parent plasmid for generating LexA fusions, pEG202 is a derivative of 202 + PL (Ruden et al., 1991; see Fig. 17.3.3) that contains an expanded polylinker region. The available cloning sites in pEG202 include *Eco*RI, *Bam*HI, *Sal*I, *Nco*I, *Not*I, and *Xho*I, with the reading frame as described in the legend to Figure 17.3.3. Since the original presentation of this system, a number of groups have developed variants of this plasmid that address specialized research needs. Those currently available, as well as purposes for which they are suited, are listed in Table 17.3.1. pGilda, created by David A. Shaywitz, places the LexA-fusion cassette under the control of the inducible *GAL1* promoter, allowing expression of the bait protein for limited times during library screening, reducing the exposure of yeast to toxic baits. pJK202, created by Joanne Kamens, adds nuclear localization sequences to pEG202, facilitating assay of the function of proteins lacking internal nuclear localization sequences. pNLexA, created by Ian York, places LexA carboxy-terminal in the fusion domain, allowing assay of interactions that require an unblocked amino-terminus on the bait protein. pEE202I, created by Mike Watson and Rich Buckholz, allows chromosomal integration of a pEG202-like bait, thus reducing expression levels so they are more physiological for bait proteins normally present at low levels intracellularly. All of these have been extensively tested by numerous researchers. pGilda, pJK202, and pEE202I work with complete reliability. pNLexA works effectively with ~50% of the fusion domains tried, but synthesizes only very low levels of protein (relative to expression of the same fusion domain as a pEG202 fusion) with the remaining 50%. Attachment of fusion domains amino-terminal either to *LexA* or *GAL4* has been generally problematic in the hands of many investigators; it may be that appending additional protein sequences to the amino termini of these proteins is destabilizing, although the problem has not been rigorously investigated.

A series of *lacZ* reporters of differing sensitivity to transcriptional activation can be used to detect interactions of varying affinity (see Table 17.3.2). These plasmids are *LexA* operator–containing derivatives of the plasmid

LR1Δ1 (West et al., 1984). In LR1Δ1, a minimal *GAL1* promoter lacking the *GAL1* upstream activating sequences (GAL_{UAS}) is located upstream of the bacterial *lacZ* gene. In pSH18-34, eight *LexA* operators have been cloned into an *Xho*I site located 167 bp upstream of the *lacZ* gene (S. Hanes, unpub. observ.). pJK103 and pRB1840 contain two and one operator, respectively.

pJK101 is similar to pSH18-34, except that it contains the *GAL1* upstream activating sequences (GAL_{UAS}) upstream of two *LexA* operator sites. A derivative of del20B (West et al., 1984), it is used in the repression assay (Brent and Ptashne, 1984; see Fig. 17.3.5) to assess LexA fusion binding to operator.

pSH17-4 is a *HIS3* 2μm plasmid that encodes LexA fused to the activation domain of the yeast activator GAL4. EGY48 cells bearing this plasmid will produce colonies in overnight growth on medium lacking Leu, and yeast that additionally contain pSH18-34 will turn deep blue on plates containing Xgal. This plasmid serves as a positive control for the activation of transcription.

pRFHM1 is a *HIS3* 2μm plasmid that encodes LexA fused to the N-terminus of the *Drosophila* protein bicoid. The plasmid has no ability to activate transcription, so EGY48 cells that contain pRFHM1 and pSH18-34 do not grow on –Leu medium and remain white on plates containing Xgal. pRFHM1 is a good control for specificity testing, because it has been demonstrated to be sticky—that is, to associate with a number of library-encoded proteins that are clearly nonphysiological interactors (R. Finley, Wayne State University, Detroit, Mich., unpub. observ.).

This protocol uses interaction libraries (Table 17.3.3) made in pJG4-5 or its derivatives (see Fig. 17.3.6). pJG4-5 was developed to facilitate isolation and characterization of novel proteins in interactor hunts (Gyuris et al., 1993). The pJG4-5 cDNA library expression cassette is under control of the *GAL1* promoter, so library proteins are expressed in the presence of galactose (Gal) but not glucose (Glu). This conditional expression has a number of advantages, the most important of which is that many false-positives obtained in screens can be easily eliminated because they do not demonstrate a Gal-dependent phenotype. The expression cassette consists of an ATG to start translation, a nuclear localization signal to extend the interaction trap's range to include proteins that are normally predominantly localized in the cytoplasm, an activation domain (acid blob; Ma and Ptashne, 1987), the hemagglutinin epitope tag to permit rapid assessment of the size of encoded proteins, *Eco*RI-*Xho*I sites designed to receive directionally synthesized cDNAs, and the alcohol dehydrogenase (*ADH*) termination sequences to enhance the production of high levels of library protein. The plasmid also contains the *TRP1* auxotrophy marker and 2μm origin for propagation in yeast. A derivative plasmid, pJG4-5I, was created by Mike Watson and Richard Buckholz to facilitate chromosomal integration of the activation domain fusion expression plasmid.

A series of recently developed derivatives of pEG202, pJG4-5, and *lacZ* reporter plasmids (MW101 to MW112) alter the antibiotic resistance markers on these plasmids from ampicillin (Ap^r) to either kanamycin (Km^r) or chloramphenicol (Cm^r; Watson et al., 1996). Judiciously mixing and matching these plasmids in conjunction with Ap^r libraries would considerably reduce work subsequent to library screening, because the KC8 transformation, which involves *trpC* complementation in bacteria, could be omitted.

EGY48 and EGY191 (see Table 17.3.2) are both derivatives of the strain U457 (a gift of Rodney Rothstein, Columbia University, New York, N.Y.) in which the endogenous *LEU2* gene has been replaced by homologous recombination with *LEU2* reporters carrying varying numbers of *LexA* operators, using a procedure detailed in Estojak et al. (1995).

Interaction Trap–compatible reagents have recently become commercially available; Clontech and Invitrogen were the first to market such reagents and have recently been joined by OriGene. All suppliers use systems with the most sensitive reporters (EGY48 and pSH18-34), and provide their own positive and negative controls for testing activation or interaction between defined proteins. For expression of bait and library proteins, the Clontech Matchmaker LexA two-hybrid system and the OriGene Duplex-A system use some of the basic set of plasmids described here (see Table 17.3.1 for availability). Forward sequencing primers for bait and library plasmids are included in the Clontech kit, and Insert Screening Amplimer Sets for both plasmids can be acquired separately. Additional related products from Clontech include KC8 competent cells, anti-LexA monoclonal antibodies, a yeast transformation system, a yeast plasmid isolation kit, and an EGY48 partner strain for yeast

mating to facilitate the analysis of interaction specificity. OriGene has a generally similar product line to Clontech. In contrast, Invitrogen has substantially modified the Interaction Trap core reagents to develop its own bait and library plasmids. pHybLex/Zeo, a novel bait plasmid, is ~50% smaller than the original pEG202 (making it easier to clone into), and it has an enriched polylinker. Significantly, it replaces both the *Ap*^{r} and *HIS3* genes with a novel gene that confers resistance to the antibiotic Zeocin (supplied with the kit), which provides selection in both bacteria and yeast. This elimination of auxotrophic selection for the bait plasmid renders the LexA-fusion construct usable with libraries and strains from all existing two-hybrid systems and additionally facilitates the direct selection of library plasmid in strains other than KC8. Some changes, which are designed to make the vector easier to use, have also been introduced in the library vector pYESTrp (e.g., it uses a V5 epitope tag for protein detection). The Invitrogen kit, termed Hybrid Hunter, includes the bait/library/reporter plasmids and EGY48 yeast strain as noted, and additionally includes primer sets for bait and library plasmids and the L40 yeast strain, should an investigator wish to use a *HIS3* auxotrophy selection. Additional related products from Invitrogen include antibodies for detection of bait and prey fusion proteins (anti-LexA and anti-V5), pJG4-5 library vector primers, and a Transformation Kit.

A significant advantage of the entry of commercial entities into the Interaction Trap field is the rapid increase in the number of compatible cDNA libraries. A list of currently available premade libraries available from these companies is presented in Table 17.3.3, and custom-made libraries are also available upon request. Because new libraries and other related reagents are being constantly added to the line of two-hybrid related products, it is advisable to contact the companies or visit their Web sites (*www.clontech.com, www.invitrogen.com,* and *www.origene.com*) for the latest information.

Finally, over the last several years, a number of groups have adapted basic two-hybrid strategies to more specialized applications, and they have devised strategies to broaden their basic functionality. Interaction Mating (Finley and Brent, 1994) has been used to establish extended networks of targeted protein-protein interaction. In this approach, a panel of LexA-fused proteins is transformed into a *MATa* haploid selective strain (such as RFY206), a panel of activation-domain fused proteins is transformed into a suitable MATα haploid (such as EG448), and the two panels are cross-gridded against each other for mating. Selected diploids are then screened by replica plating to selective medium. This approach complements library screening in large-scale applications, such as proposed definition of interaction maps for entire genomes (Bartel et al., 1996).

Interaction mating has also provided the basis for an alternative two-hybrid hunt protocol (see Alternate Protocol 2), useful in cases when a single library will be screened with different baits. In this approach (Bendixen et al., 1994; Finley and Brent, 1994: Kolonin and Finley, 1998), a library is introduced into a single strain, like EGY48, and aliquots are stored frozen. To conduct a hunt, an aliquot is thawed and mated with a strain expressing a bait. This allows one to avoid repeated high-efficiency transformations, since a single library transformation can provide enough pretransformed yeast to conduct dozens of interactor hunts. Moreover, some yeast strains pretransformed with libraries are becoming commercially available, which may eliminate altogether the need to conduct a high-efficiency library transformation for some researchers.

Two-hybrid approaches have been shown to be effective in identifying small peptides with biological activities on selected baits (Yang et al., 1995; Colas et al., 1996), which may prove to be useful as a guide to targeted drug design. Rapid screening protocols have been devised using custom-synthesized libraries expressing sheared plasmid DNA to facilitate rapid mapping of interaction interfaces (Stagljar et al., 1996). Osborne and coworkers have demonstrated the effectiveness of a tribrid (or tri-hybrid) approach, in which an additional plasmid expresses a tyrosine kinase to specifically modify a bait protein, allowing detection of SH2-domain-containing partner proteins that recognize specific phosphotyrosine residues (Osborne et al., 1995). A variety of more elaborate tribrid approaches, in which a DNA-binding domain fused protein is used to present an intermediate nonprotein compound for interaction with a library, have been developed and proven effective. These approaches have allowed the identification of proteins binding specific drug ligands (Chiu et al., 1994; Licitra and Liu, 1996), as well as the identification of proteins binding to RNA sequences (SenGupta et al., 1996; Wang et al., 1996). It is expected that the range of utility of these systems will continue to expand.

Critical Parameters and Troubleshooting

To maximize chances of a successful interactor hunt, a number of parameters should be taken into account. Before attempting a screen, bait proteins should be carefully tested to ensure that they have little or no intrinsic ability to activate transcription. Bait proteins must be expressed at reasonably high levels and must be able to enter the yeast nucleus and bind DNA (as confirmed by the repression assay). Optimally, integrity and levels of bait proteins should be confirmed by immunoblot analysis, using an antibody to either LexA or the fused domain. In particular, at this time, bait proteins that have extensive transmembrane domains or are normally excluded from the nucleus are not likely to be productively used in a library screen. Proteins that are moderate to strong activators will need to be truncated to remove activating domains before they can be used.

If a protein neither activates nor represses, the most likely reason is that it is not being made. This can be determined by immunoblot analysis of a crude lysate protein extract of EGY48 (*UNIT 6.2*; Samson et al., 1989) containing the plasmid, using anti-LexA antibodies as primary antiserum. If the full protein is not made, it may be possible to express truncated derivatives of the protein. If the protein is made, but still does not repress, it may not enter the yeast nucleus effectively, although this appears to be a relatively rare problem. In this case, introducing the coding sequence for the fused moieity into a LexA fusion vector containing a nuclear localization motif (e.g., pJK202; J. Kamens, BASF, Worcester, Mass., unpub. observ.) may solve the problem.

The test for the leucine (Leu) requirement is extremely important to determine whether the bait protein is likely to yield an unworkably high background. The *LEU2* reporter in EGY48 is more sensitive than the pSH18-34 reporter for some baits (Estojak et al., 1995). Therefore, it is possible that a bait protein demonstrating little or no signal in a β-galactosidase assay may nevertheless permit some growth on –Leu medium. If this occurs, there are several options. First, a less sensitive strain can be used, as described in the text. Second, background can sometimes be reduced further by making the EGY strain diploid (e.g., D. Krainc, Harvard Medical School, Boston, Mass.; R. Finley and R. Brent, unpub. observ.) or by performing the hunt by interaction mating as described in Alternate Protocol 2. A third option is to attempt to truncate the bait protein to remove activating function. In general, it is useful to extrapolate from the number of cells that grow on –Leu medium to the number that would be obtained in an actual library screen, and determine if this is a background level that can be tolerated. For example, if two colonies arise from 100,000 plated cells on –Leu medium, 200 to 400 would be expected in an actual screen of 10^6 cDNAs. Although this is a high initial number of positives, the vast majority should be eliminated immediately through easily performed controls. This is a judgment call. Finally, very rarely it happens that a bait that appears to be well behaved and negative for transcriptional activation through all characterization steps will suddenly develop a very high background of transcriptional activation following library transformation. The reason for this is currently obscure, and no means of addressing this problem has as yet been found: such baits are hence inappropriate for use in screens.

The protocols described in this unit use initial screening with the most sensitive reporters followed by substitution with less sensitive reporters if activation is detected. An obvious question is, why not start out working with extremely stringent reporters and know immediately whether the system is workable? In fact, some researchers routinely use a combination of pJK103 or pRB1840 with EGY191, and obtain proteins that to date appear to be biologically relevant partners from library screens. However, extensive comparison studies using interactors of defined in vitro affinity with different combinations of *LacZ* and *LEU2* reporters (Estojak et al., 1995) have indicated that although the most sensitive reporters (pSH18-34) may in some cases be prone to background problems, the most stringent reporters (EGY191, pRB1840) may miss some interactions that certainly are biologically relevant and occur inside cells. In the end, the choice of reporters devolves to the preference of individual investigators: the bias of the authors is to cast a broad net in the early stages of a screen, and hence to use more sensitive reporters when practicable.

It is important to move expeditiously through characterization steps and to handle yeast transformed with bait plasmids with care. In cases where yeasts have been maintained on plates for extended periods (e.g., 4 days at room temperature or >2 to 3 weeks at 4°C), unex-

pected problems may crop up in subsequent library screens.

The transformation protocol is a version of the lithium acetate transformation protocol described by Schiestl and Gietz (1989) and Gietz et al. (1992) that maximizes transformation efficiency in *Saccharomyces cerevisiae* and produces up to 10^5 colonies/μg plasmid DNA. In contrast to *Escherichia coli*, the maximum efficiency of transformation for *S. cerevisiae* is ~10^4 to 10^5/μg input DNA. It is extremely important to optimize transformation conditions before attempting an interactor hunt. Perform small-scale pilot transformations to ensure this efficiency is attained and to avoid having to use prohibitive quantities of library DNA. In addition, as for any effort of this type, it is a good idea to obtain or construct a library from a tissue source in which the bait protein is known to be biologically relevant.

In practice, the majority of proteins isolated by interaction with a LexA fusion turns out to be specific for the fused domain; a smaller number are nonspecifically sticky, and to date there appears to have been only one isolation from a eukaryotic library of a protein specific for LexA. However, it is generally informative to retest positive clones on more than one LexA bait protein; ideally, library-derived clones should be tested against the LexA fusion used for their isolation, several LexA fusions to proteins that are clearly unrelated to the original fusion, and if possible, several LexA fusions that there is reason to believe are related to the initial protein (e.g., if the initial probe was LexA-Fos, a good related set would include LexA-Jun and LexA-GCN4).

Colony selection for master plate production is one of the more variable parts of the procedure. For strong interactors, colonies will grow up in 2 days. However, if plates are left at 30°C, new colonies will continue to appear every day. Those that appear rapidly are most likely to reflect interactors that are biologically relevant to the bait protein. Those that appear later may or may not be relevant. However, many parameters can delay the time of colony formation of cells that contain valid interactions, including the strength of the interaction and the level of expression of the library-encoded protein.

Anticipated Results

Depending on the protein used as bait, anywhere from zero to hundreds of specific interactors will be obtained from 10^6 primary transformants.

Time Considerations

If all goes well, once the required constructions have been made it will take ~1 week to perform yeast transformations, obtain colonies, and determine whether bait proteins are appropriate. It will take a second week to perform library transformations, replate to selective medium, and obtain putative positives. A third week will be required to rescue the plasmid from the yeast, passage it through *E. coli*, transform fresh yeast, and confirm specificity.

Mapping Protein-Protein Interactions with Phage-Displayed Combinatorial Peptide Libraries

This unit describes the process and analysis of affinity selecting bacteriophage M13 from libraries displaying combinatorial peptides fused to either a minor or major capsid protein. The first protocol provided in this unit describes direct affinity selection using target protein bound to a microtiter dish, followed by purification of selected phage by ELISA (see Basic Protocol). A bead-based affinity selection using fusion protein targets is also described (see Alternate Protocol). With either protocol, one can readily isolate peptide ligands that bind to a target protein of interest and use the consensus sequence to search proteome databases for putative interacting proteins.

AFFINITY SELECTION USING PROTEIN TARGETS IN MICROTITER DISHES

BASIC PROTOCOL

In this method, a target protein is immobilized on a microtiter plate and a phage-display combinatorial peptide library is added to the wells to select for phage that bind to the protein target. Selected (bound) phage are then recovered and amplified. The selection is repeated two additional times to enrich for the binding phage and reduce the recovery of nonspecifically bound phage. After the third selection, the binding specificity of individual clones is examined by ELISA using wells containing target protein and a negative control. Binding is detected with an HRP-conjugated anti-phage antibody and a chromogenic substrate. The sequences from specifically bound clones can then be analyzed by DNA sequencing and the predicted peptide ligand can be compared to available databases.

While peptides have been displayed on all six of the capsid proteins of bacteriophage M13, proteins III and VIII are the most popular fusion partners. Protein III (pIII) is a minor capsid protein, present in five copies at one end of the filamentous particle, and functions in infecting bacteria. Fortunately for molecular biologists, display of peptides (or proteins) at the N terminus of the mature protein generally does not interfere with the function of its three globular domains. Protein VIII (pVIII) is the major capsid protein, with ~2500 copies per particle. Due to the crystalline nature of this protein on the virus surface, mature pVIII tolerates only short (i.e., 9-mer) peptides at its N terminus. While pIII and pVIII display libraries are both useful in selecting peptide ligands that can be used to predict protein-protein interactions, peptides isolated from pIII libraries typically have low-micromolar (1 to 10 μM) dissociation constants, whereas peptides isolated from pVIII libraries have mid-micromolar (10 to 100 μM) dissociation constants. This quantitative difference reflects the difference in valency of the displayed peptides as well as the resulting avidity effects that occur when binding microtiter plate wells are densely coated with target. Libraries of phage displaying combinatorial peptide libraries at the N terminus of pIII can be purchased from New England Biolabs. Libraries of phage displaying combinatorial peptide libraries at the N terminus of pVIII can be obtained by request (see Felici et al., 1991).

Materials

Purified protein target(s) to be analyzed
0.2 M sodium bicarbonate buffer (Na_2HCO_3), pH 8.5
Control targets (see Troubleshooting)
Blocking buffer: 1% (w/v) BSA in PBS (see recipe for PBS)
Wash buffer: 0.05% (v/v) Tween 20 in PBS

Contributed by Brian K. Kay and Luisa Castagnoli
Current Protocols in Cell Biology (2003) 17.4.1-17.4.9

Combinatorial phage-display library (New England Biolabs or Felici et al., 1991)
Acid elution buffer: 50 mM glycine·HCl, pH 2
Neutralization buffer: 0.2 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
Bacteria: fresh overnight culture of DH5αF′ (*APPENDIX 3A*)
2× YT culture medium and top and bottom agar (see recipe)
Negative control protein (fusion partner)
Anti–bacteriophage M13 monoclonal antibody coupled to horseradish peroxidase (HRP; Amersham Pharmacia Biotech), diluted 1:5000 (v/v) in wash buffer
Chromogenic substrate (see recipe)

ELISA-ready 96-well microtiter plates (Costar or Immunolon, high capacity)
Aerosol-resistant pipet tips
5-ml sterile tubes
Sterile toothpicks
Spectrophotometer capable of reading microtiter plates

Additional reagents and equipment for DNA purification and sequencing (*APPENDIX 3A*)

Coat microtiter plate wells

1. Dilute 1 to 3 µg of purified protein target into 0.5 ml of 0.2 M sodium bicarbonate, pH 8.5, and add 150 µl to three wells of a 96-well microtiter plate. Repeat for each protein target to be tested and for each control. Incubate without shaking for 2 hr at room temperature or, for less stable proteins, overnight at 4°C.

   To prevent evaporation, keep the wells sealed with tape during all incubations.

2. Add 200 µl blocking buffer to each well and incubate for 30 min at room temperature.
3. Flick the liquid into a sink and slap the plate two times against a paper towel.
4. Add 200 µl wash buffer to each well, flick out the contents, and slap against a clean paper towel. Repeat two additional times.

Select interacting phage

5. Dilute combinatorial phage-display library to 1000 library equivalents per 150 µl wash buffer and then add 150 µl diluted phage particles to each test and control well. Incubate for 2 hr at room temperature.

   To ensure selection of rare peptide sequences, the authors typically use 1000 library equivalents for the first selection step with a target protein. Thus, if a library has a complexity of 10^9 members, 10^{12} particles should be added to 150 µl wash buffer.

   To minimize the contamination of pipettors with phage particles, the authors strongly recommend using aerosol-resistant pipet tips when transferring liquids containing phage.

6. Flick the liquid into a sink and slap the plate two times against a paper towel.
7. Add 200 µl wash buffer to each well, flick out the contents, and slap the plate against a clean paper towel. Repeat two additional times.

Recover bound phage

8. Add 150 µl acid elution buffer to the washed, empty wells and incubate 10 min at room temperature. Pool the liquid from triplicate wells into a single clean 5-ml plastic tube containing 150 µl neutralization buffer.

   Generally, 10^3 to 10^8 phage particles are recovered from each well. Phage can also be eluted from the wells with 0.2 M ethanolamine, pH 12, and neutralized as above.

9. Add 200 µl bacteria (fresh overnight culture) and incubate for 10 min at room temperature.

10. Add 3 ml of 2× YT top agar and pour onto a 100 × 15–mm petri dish containing 2× YT bottom agar (*APPENDIX 3A*). Allow plate to harden 5 min at room temperature, and then leave the plate overnight in a 37°C incubator.

    Instead of plate amplification, it is also possible to amplify the phage in a liquid culture. To do this, transfer the solution containing the infected bacteria to 5 ml of 2× YT broth and incubate in a 50-ml tube, with vigorous aeration, overnight at 37°C.

11. Elute the phage particles from the top agar by covering with 5 ml wash buffer and incubating overnight at 4°C without shaking.

12. Transfer ~500 µl phage suspension to a clean tube and centrifuge 10 min at 16,100 × *g* (13,200 rpm) to pellet the bacteria. Transfer the supernatant to a clean tube.

    If desired, the phage can be concentrated by precipitation. Add 400 µl of 20% (w/v) PEG/2.5 M NaCl to 1.6 ml of the cleared supernatant. Keep on ice for at least 15 min to allow precipitation of phage particles, centrifuge 5 min as above, and resuspend the pellet in 200 µl of wash buffer.

Repeat affinity selection process

13. Perform two additional rounds of screening by repeating steps 1 to 12 two times using the amplified phage supernatant from step 12. As in the first round, set up triplicate wells for selection (step 1) and pool the recovered phage before amplification (step 8).

    The phage mixtures typically have titers of 10^{11} plaque-forming units per milliliter (pfu/ml) after each round of selection and amplification.

14. After the third round of selection, make several serial dilutions at 1:100 in PBS. Then set up several sterile 5-ml tubes for infection (one for each dilution). To each tube add:

    200 µl overnight culture of DH5αF′ bacteria
    1 to 10 µl diluted phage particles
    3 ml 2× YT top agar.

15. Plate out each dilution on 2× YT bottom agar and incubate overnight at 37°C.

16. With sterile toothpicks, transfer phage from 20 well-isolated plaques to separate 5-ml sterile tubes containing 50 µl overnight culture of DH5αF′ bacteria and 1 ml of 2× YT culture medium. Grow overnight at 37°C with vigorous aeration.

    Repeat steps 14 and 15 at different dilutions if there are not twenty well-isolated plaques on one or more of the plates.

Perform ELISA

17. Coat one column of wells in a 96-well microtiter plate with the target protein and another column with a negative control protein (i.e., fusion partner), as described in steps 1 through 4. Set up enough column pairs to test the desired number of clones from step 16.

18. To each pair of wells (target and control), add 100 µl wash buffer and 25 µl of a culture supernatant prepared from a single bacteriophage clone (step 16). Incubate for 2 hr at room temperature.

19. Wash the wells as described in steps 6 and 7.

20. To each well, add 100 µl of anti-phage monoclonal antibody (HRP-conjugated) diluted 1:5000 in wash buffer. Incubate for 1 hr at room temperature.

21. Wash the wells as described in steps 6 and 7.

22. To each well, add 100 µl chromogenic substrate. Incubate ~30 min.

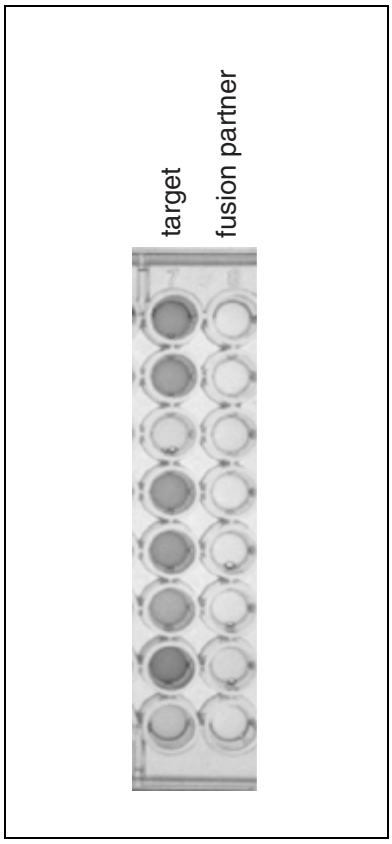

Figure 17.4.1
Photograph of a phage ELISA result. Using eight different clones that were isolated with GST-SrcSH3 domain as the target, 25 μl of culture supernatant were added to pairs of microtiter plate wells containing GST-SrcSH3 or GST. Retention of the phage in the wells was detected with anti-phage antibodies (coupled to HRP) through a colorimetric assay. Six of the clones were verified to bind the SrcSH3 domain specifically.

23. Measure the optical absorbance of the wells at 405 nm with a microtiter plate spectrophotometer.

    Wells with bound phage yield optical density values of >0.6, while wells without bound phage generate optical density values of ≤0.2. See Figure 17.4.1 for typical results.

    Typically, many of the output phage from the third round of selection bind to the target protein under these conditions. If not, one can perform an additional round of selection, perform filter lifts to identify binding clones in the output of the third round of selection (Sparks et al., 1996), or repeat the selection experiment with an alternative method of immobilizing the target (for example, see Alternate Protocol).

Characterize sequence of interacting phage

24. Purify and sequence the DNA inserts of binding phage, using either double-stranded DNA (prepared from the replicative form of DNA) or single-stranded DNA (prepared from secreted virus particles).

    Purification kits for either application are commercially available (e.g., from Qiagen). Also see APPENDIX 3A for purification and sequencing methods.

    Suitable sequencing primers upstream and downstream of the gene III cloning site are 5′-ATT CAC CTC GAA AGC AAG CTG-3′and 5′-CTC ATA GTT AGC GTA ACG-3′, respectively. Suitable sequencing primers upstream and downstream of the gene VIII cloning site are 5′-GTT CCG ATG CTG TCT TTC GCT-3′and 5′-AAC CGA TAT ATT CGG TCG CTG AGG-3′, respectively.

    The authors often sequence from ten to twenty clones. If one sequence predominates, a heteroduplex mobility assay can be used to identify nonsibling clones for sequencing (Fack et al., 2000).

25. Convert the coding sequence to peptide sequence.

In the NNK coding scheme, there are 32 codons that encode one stop codon (TAG), which is suppressed in DH5αF′ with a glutamine, and all 20 amino acids, which are represented one (C, D, E, F, H, I, K, M, N, Q, W, Y), two (A, G, P, V, T), or three times (L, R, S).

AFFINITY SELECTION USING FUSION PROTEIN TARGETS ON BEADS

ALTERNATE PROTOCOL

If a fusion protein is used as a target, phage can be affinity selected with the target protein attached to a resin. In the authors' experience, glutathione-*S*-transferase (GST) fusion proteins can successfully select phage when bound to glutathione-Sepharose resin, which is commercially available. To avoid carry over of contaminant proteins that are bound nonspecifically to the resin, it is best to elute the fusion protein off the column with gluthathione, dialyze the sample, and adsorb it to a fresh batch of glutathione-Sepharose resin. Other types of tags (i.e., maltose-binding protein or six-histidine tags) can be used to link the target protein to an affinity matrix; however, the corresponding affinity resin tends to have a background of nonspecifically adsorbed phage that is five to ten times higher than that obtained with glutathione-Sepharose. In addition, metal-chelating resins used for immobilized metal affinity chromatography tend to select for peptides rich in histidines from the phage-displayed combinatorial peptide libraries.

Additional Materials *(also see Basic Protocol)*

50% (w/v) slurry of glutathione-Sepharose resin 4B (Amersham Pharmacia Biotech, Sigma) in 0.5 M NaCl/20% (v/v) ethanol (capacity 5 mg bound protein/ml resin)
PBS (see recipe) with 0%, 1%, and 3% (w/v) BSA
Glutathione-*S*-transferase (GST) fusion protein of interest (target protein)
TBS (optional): 50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*), with 150 mM NaCl

Bind fusion protein target to resin

1. Microcentrifuge ~40 µl of a 50% glutathione-Sepharose resin 4B slurry for 1 min at 800 × *g*, room temperature. Remove the supernatant.
2. Wash the pelleted resin by adding 200 µl PBS, microcentrifuging as in step 1, and removing the supernatant.
3. Resuspend beads in 200 µl PBS, add 10 µg GST fusion protein (~10^{14} molecules), and allow it to bind for 1 hr at 4°C with gentle mixing.
4. Wash the beads three times with 200 µl ice-cold wash buffer (see step 2).
5. Resuspend the beads in 300 µl PBS containing 3% BSA. Mix gently for at least 4 hr at 4°C to saturate the nonspecific binding sites on the resin.

   Usually, it is convenient to prepare enough target-bound resin for the entire experiment (i.e., through the third round of selection in step 13). Prepared resin should be kept in PBS with 3% (w/v) BSA for no longer than 1 week at 4°C.

Bind phage to resin

6. Microcentrifuge the beads as above and add 100 µl PBS (or TBS) containing 1% BSA and 10^{10} pfu of phage library.

   This amount of phage particles represents 20 library equivalents of a library with a complexity of 5 × 10^8 clones.

7. Incubate for at least 1 hr at 4°C while mixing gently.

   For convenience, overnight is also acceptable.

8. Centrifuge the beads as above and discard the supernatant.

9. Wash the beads five times with 1 ml wash buffer. While the resin beads are in the final wash, transfer the suspension to a fresh tube, centrifuge the beads, and remove the wash buffer.

   The beads are transferred to a fresh tube to avoid carry-over of phage bound to the surface of the plastic tube.

Recover bound phage

10. Elute the bound phage by adding 200 µl acid elution buffer. Let sit for 10 min at room temperature.
11. Microcentrifuge beads 30 sec at 800 × *g* (2500 rpm), transfer the supernatant to a clean tube, and neutralize the solution by adding 50 µl neutralization buffer.
12. Keep 10 µl eluted phage in a sealed tube in the refrigerator (at 4°C) as a stock of affinity-selected phage. Amplify the titer of the remaining 100 µl of bound phage as described above (see Basic Protocol, steps 9 to 12).

    If necessary, the phage supernatant can be kept at 4°C with 0.02% (w/v) NaN_3. Chloroform should not be used as this type of phage is sensitive to chloroform.

Repeat affinity selection

13. Perform two additional rounds of selection by repeating steps 6 to 12. Use 100 µl (~10^{10} pfu) for the second round of selection. Add to a fresh 40-µl aliquot of glutathione-Sepharose beads with the GST fusion protein bound to it.

    To improve the isolation of high-affinity peptide ligands, the target protein can be adsorbed to the affinity resin at a much lower concentration (2 µg total protein) and up to ten washes can be used.

    This titer (10^{11} pfu/ml) is obtained consistently. The titer should only need to be checked when looking for the cause of a failure.

Characterize phage isolates

14. Perform a phage ELISA and sequence inserts of interest as described above (see Basic Protocol, steps 17 to 25).

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Chromogenic substrate

Dissolve 220 mg of 2′,2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS; Sigma) in 50 mM citric acid (10.5 g citrate monohydrate in 1 liter of sterile water), and adjust the pH to 4 with ~6 ml of 10 M NaOH. Filter sterilize the solution and store at 4°C (stable for at least 6 months). Immediately before use, add 30% H_2O_2 to a final concentration of 0.05%.

Phosphate-buffered saline (PBS), 10×

80 g NaCl
2.2 g KCl
9.9 g Na_2HPO_4
2.0 g K_2HPO_4
Add H_2O to 1 liter
Store up to 2 weeks at room temperature
Dilute to 1× before use

YT culture medium and top and bottom agar, 2×

Make up 2× YT medium:
10 g tryptone
10 g yeast extract
5 g NaCl
Bring to 1 liter with H_2O
Autoclave
Store up to 2 weeks at 4°C
For bottom agar: Before autoclaving, add Bacto-agar to a final concentration of 1.5% (w/v)
For top agar: Before autoclaving, add Bacto-agar to a final concentration of 0.8% (w/v)

COMMENTARY

Background Information

In phage display, a protein or peptide library is encoded within a phage genome and is expressed on the surface of the phage as a fusion with the phage coat protein. Phage may then be selected on the basis of the functionality of their surface proteins. This method allows one to screen large numbers of sequences based on protein function. In this unit, phage-displayed peptides are screened based on their ability to bind to a protein of interest (i.e., the target protein). Phage-display combinatorial peptide libraries are typically screened by affinity selection with a particular target protein. In many cases, it is possible to identify, from the affinity-selected peptides, members with a sequence that closely resembles segments (epitopes) of a natural interacting partner of the protein of interest. A practical consequence of the phenomenon known as convergent evolution (Kay et al., 2000) is that one can search whole genome databases for proteins containing segments that match consensus sequences shared by the selected peptides, and then determine experimentally whether or not the identified proteins interact with the target (Smothers and Henikoff, 2001). For example, combinatorial peptide libraries have proven useful in defining the optimal ligand preferences of protein interaction modules, such as EH (Salcini et al., 1997), PDZ (Songyang et al., 1997), SH2 (Songyang et al., 1993), SH3 (Tong et al., 2002), and WW domains (Linn et al., 1997), the heterodimeric G protein βγ subunit (Scott et al., 2001), the catalytic subunit of protein phosphatase 1 (PP1c; Zhao and Lee, 1997), the estrogen receptor (Paige et al., 1999), and the ubiquitin ligase DM2 (Kay et al., 1998). Thus, a fruitful means of mapping protein-protein interactions is to isolate peptide ligands to various prokaryotic proteins and identify candidate interacting proteins in the sequenced genome by computer analysis.

Critical Parameters

The most critical aspect of a successful experiment is to ensure that the protein targets retain their ability to interact with other proteins when immobilized (Stevens, 2001). In the Basic Protocol, the authors recommend immobilizing the protein target on microtiter plate wells. However, because the protein sometimes denatures when affixed to the plastic surface and fails to yield any target-binding phage, one frequently isolates plastic-binding phage instead (Adey et al., 1995). Thus, if the necessary reagents are available, the investigator should always confirm that the immobilized target protein retains its ability to interact with other protein. On the other hand, if the protein target is a GST fusion protein, the Alternate Protocol is recommended.

Troubleshooting

The authors recommend the following targets (with their motif among selected peptides) that are commercially available and can serve as positive controls: FLAG mAb M2 (DYKXXD), streptavidin [HP(Q/M)], Src SH3 domain (RxLPxLP or PxxPxR), and troponin C [(V/L)(D/E)xLKxxLxxLA]. If the suggested positive control targets do not yield binding phage, the titer of selected and amplified phage should be checked. Titers of 10^{11} pfu/ml are expected after amplification. The pH of elution and neutralization solutions should also be checked, as phage titers drop at low pH.

Anticipated Results

The authors have successfully isolated peptide ligands to ~50% of the target proteins tested. The K_d values of peptides recovered by

phage display, when chemically synthesized and tested in solution, range from 10 μM to 500 nM (Grøn and Hyde-DeRuyscher, 2000; Hyde-DeRuyscher et al., 2000), and the peptides bind as surrogates (Pillutla et al., 2001) of interacting protein partners (i.e., the peptides compete off the interacting partner).

By inspecting the sequences of the selected peptides, one often finds a consensus or motif with which one can search sequence databases for potentially interacting proteins. Two Web sites that are useful for searching proteomes with short peptide motifs are *http://www.proteome.com/databases/* and *http://www.arraygenetics.com/about_seqit.php3*. Of course, given the large size of GenBank, a large number of computer matches will generally be found; thus, one must use some judgment in sifting through the best matches to choose the ones that might make biological sense. Such predictions can first be tested by chemically synthesizing peptide segments (i.e., 12-mers) corresponding to the matching segments and testing whether or not they bind in vitro. If antibodies are available to the candidate interacting proteins, positive results can then be followed by co-immunoprecipitation experiments. Thus, much like yeast two-hybrid screening (Fields and Song, 1989; Phizicky and Fields, 1995; *UNIT 12.1*), phage-displayed combinatorial peptide libraries can help in mapping protein-protein interactions (Tong et al., 2002).

Time Considerations

With a single target, it takes 1 to 2 weeks to complete three rounds of selection with a phage-displayed combinatorial peptide library. With a modest investment of time and effort, one can apply these relatively straightforward protocols toward isolating peptide ligands for many different targets. Much more time is spent in analyzing the selected peptides, evaluating their possible biological significance, and testing the hypotheses generated.

Protein-Protein Interactions Identified by Pull-Down Experiments and Mass Spectrometry

The discovery of new interacting partners for a protein of interest can provide significant clues to its functional role. Identification of a binding protein with a defined cellular role can often present immediate new research directions. Several techniques have been developed to identify protein-protein interactions. Generally, these use a "bait" protein of interest to search a pool of cellular proteins for an interacting partner, coupled with some form of detection mechanism. One commonly used technique is the yeast two-hybrid system (*UNIT 17.3*), which utilizes transcriptional activation of a reporter gene in yeast as a readout of protein-protein interaction.

This unit describes the use of glutathione *S*-transferase (GST) fusion protein "pull-down" approaches to isolate interacting proteins and to then identify them by SDS-PAGE and mass spectrometry (MS). For more background on the use of GST fusion proteins and the pull-down technique, see Commentary. Protein-protein interaction partners are identified in a way that involves (and is dependent on) direct protein-protein interaction. The detection mechanism is protein staining of SDS-PAGE gels and is therefore not dependent on any secondary process, such as a cellular event or activation of enzyme activity. MS techniques for protein identification enable sensitive identification of proteins by comparison of spectral data obtained from tryptic protein digests of an unknown protein with theoretical in silico digests of entries within a DNA or protein sequence database.

The methods in this unit can be performed in a number of ways, and the advantages and disadvantages of some of these variations are presented in Strategic Planning, along with the options that are available within the protocols themselves. Some attention is given to long-term planning, after the pull-down experiments, to confirm and further study the protein-protein interactions identified. The first protocol presented (see Basic Protocol 1) details the use of GST fusion proteins coupled to glutathione (GSH)-agarose beads (as a support matrix) for affinity purification of interacting proteins from a tissue or cell lysate. The method involves the binding of GST fusion protein–coupled beads to proteins in a tissue lysate, recovery of the beads, washing away nonspecific proteins, elution of the bound proteins, and analysis by SDS-PAGE. The protocol details the application of spin columns to improve assay speed and reproducibility. A separate protocol (see Basic Protocol 2) describes MS-compatible methods of gel staining after SDS-PAGE, and sample preparation for analysis by MS. Methods of MS analysis are beyond the scope of this unit and are not described here (see Chapter 16 in Coligan et al., 2003, for an in-depth treatment of mass spectrometry; also see *UNIT 5.6* in this manual). However, the samples are prepared to a stage that is suitable for shipping to an in-house or commercial MS service for analysis. One specific application of the pull-down approach (described in the Alternate Protocol) is for the identification of nucleotide-dependent binding partners of small GTPases, critical regulators of cellular signaling and function.

Three support protocols are described that detail preparatory procedures that are necessary before performing the pull-down experiment. Support Protocol 1 describes a method for preparation of GST fusion protein–coupled beads and Support Protocol 2 provides detail on cross-linking procedures to covalently couple the GST fusion protein to the GSH beads. Procedures for large-scale tissue lysate production are provided in Support Protocol 3, with a focus on sheep brain as a large-scale tissue source. Support Protocol 4 describes recycling procedures for the reuse of the large quantities of GSH-agarose beads that are necessary for the pre-clearing steps in tissue lysate preparation.

STRATEGIC PLANNING

This unit comprises several component protocols, some of which have alternative methods. This Strategic Planning section describes the planning steps required to link these together into a cohesive approach for performing pull-down experiments combined with mass spectrometry. A flow chart of the strategic planning and design stages involved, and how these link to the experimental steps, is shown in Figure 17.5.1. The left-hand column (design and analysis) is a representation of this Strategic Planning section; how it is linked to the experimental protocols is illustrated on the right. Some initial consideration must be given to the approach to be taken, based on the protein of interest, its cellular function, enzymatic or other activity, domain structure, and the properties to be investigated.

Achieving Specificity

One of the first considerations should be the question of how specificity can be achieved in the pull-down experiment. The conditions to be compared within the experiment should be carefully considered, as vector construction and mutation may be required well in advance of the experiment. Optimally, a pull-down experiment should encompass the target fusion protein as well as a set of truncations, mutations, deletions, or even a set of related proteins from other genes. For example, such an approach for a new SH3 domain might be to use five different SH3 domains (including the new one) to isolate binding proteins for each and determine which are unique or common. This may reveal which binding proteins are specific to the SH3 domain of interest. Another example might be the use of a set of characterized mutations from a particular disease to analyze differential protein-protein interactions in various pathological states. Another approach might use just one protein but in a number of different activation states. This produces internal controls for specificity and enables a more confident assessment of the significance of the results obtained. An example of the latter approach might be a phosphorylated protein with its phosphorylation site serine or threonine residue mutated to alanine (incapable of being phosphorylated) and/or glutamic acid (pseudophosphorylation). All three would be analyzed simultaneously to isolate potential phosphorylation-dependent binding proteins. Another example might be a GST-tagged small GTPase bound to GDP or GTP (as described in the Alternate Protocol) to isolate activation state–dependent binding proteins (effectors). It is clear from these examples that the choice of constructs required will be dependent on the protein of interest and its properties to be investigated in the pull-down experiment. Using truncations may have the extra advantage of narrowing down the protein-protein interaction site on the protein of interest and simultaneously increasing the specificity in identifying interacting proteins.

Appropriate external controls also need to be established for the constructs that will be used in the pull-down experiment. These will be analyzed by SDS-PAGE in parallel with the eluted proteins from the pull-down. The minimum set of controls includes a separate set of beads containing recombinant GST, as well as a pull-down with GSH beads alone (both to be used concurrently in the pull-down with lysate). The GSH bead pull-down control can be obtained by taking an aliquot of beads from those used to pre-clear the tissue lysates in Support Protocol 3 and Basic Protocol 1. Additionally, it may be necessary to concurrently analyze GST fusion protein beads that have not been combined with lysate—this is an essential control when the GST fusion protein beads have not been cross-linked.

Design of Expression Constructs

It is worth considering how recombinant fusion proteins will be attached to the beads, especially when designing the expression vectors from scratch. The main consideration is how the protein of interest will be fused to the tag. First, it needs to be determined if it will be an amino- or a carboxy-terminal tag. This choice will depend on where the functional regions of the protein of interest are located within the protein, as tagging close

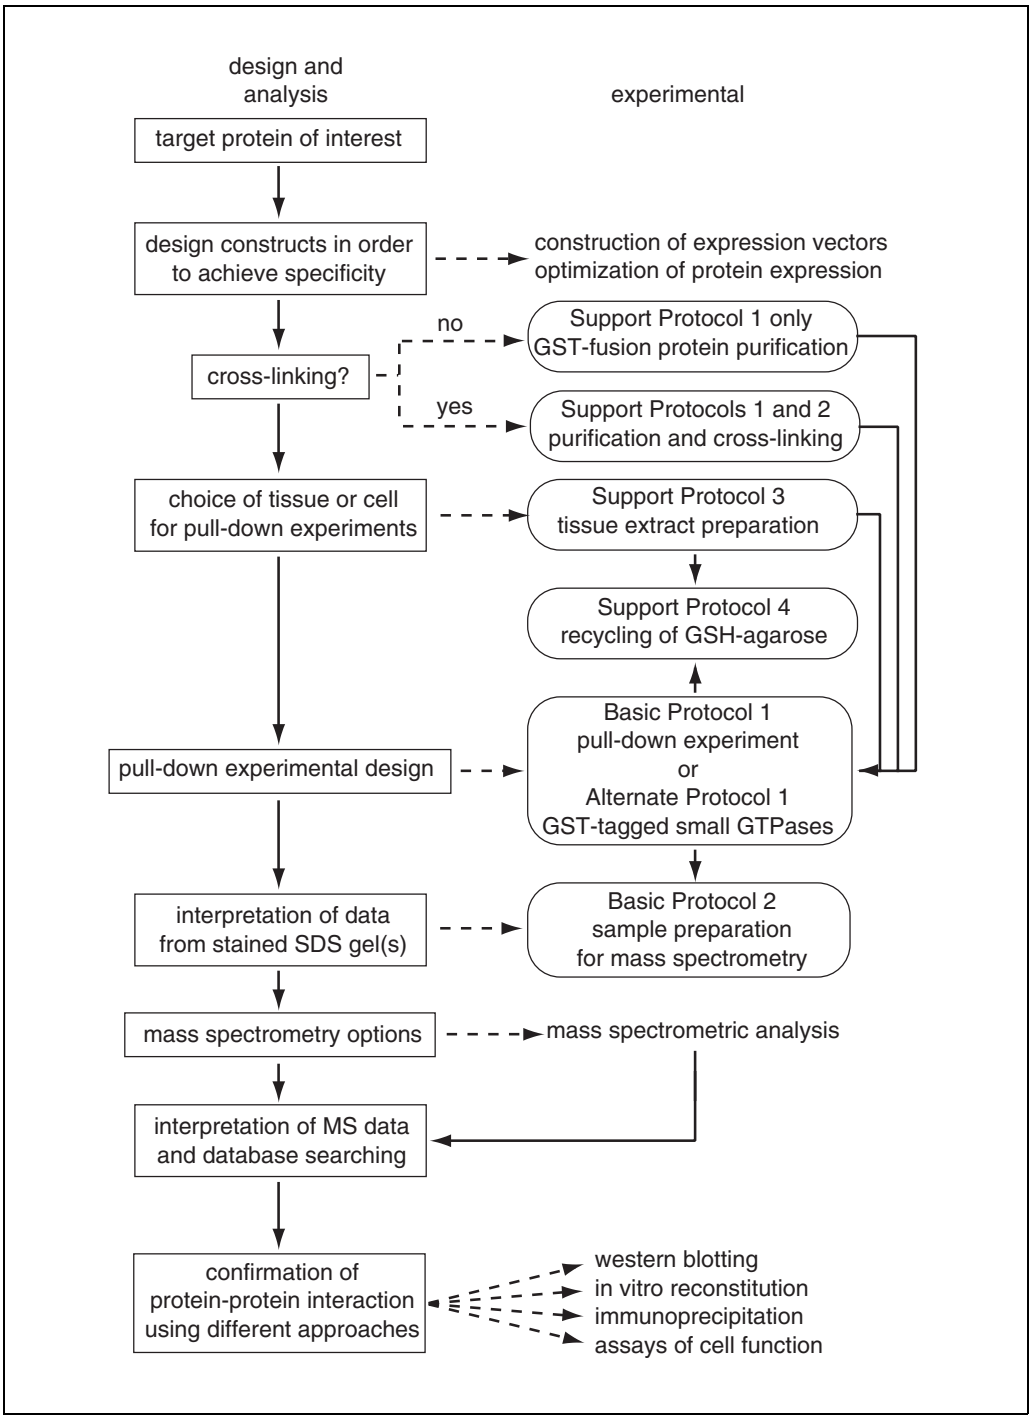

Figure 17.5.1 Flowchart for strategic design and the experimental processes described in this unit, showing how the planning and analysis stages (left-hand side; a summary of the Strategic Planning section) are linked with the experimental protocols (right-hand side). It is also a reference for how the protocols relate to one another.

to such regions could potentially interfere with the protein's function and thus with binding sites for other proteins. Secondly, the linker region between the fusion tag and the protein of interest may be significant. If this region is extensive or hydrophobic, the expressed protein could be insoluble (leading to poor yields in purification), and it may bind many proteins nonspecifically in pull-down experiments.

While this protocol is mainly concerned with GST fusion proteins, alternative tags can be used since the concepts are essentially the same. Alternatives include maltose binding protein (MBP) tags; purification of recombinant protein by whatever means, followed by coupling to a reactive matrix such as Affi-gel (Bio-Rad), may also be used. Some fusion protein tags are particularly unsuitable for use in pull-down experiments, particularly the six-histidine tag that is commonly used for recombinant protein purification as metal-affinity beads are known to bind many proteins nonspecifically. Whether or not cross-linking will be necessary needs to be considered, as recombinant proteins cannot be cross-linked to maltose or metal-affinity columns with DSS (as in Support Protocol 2) because both types of beads lack primary amine groups.

Cross-Linking

Next, consider whether to cross-link the protein of interest to the bead support. GST fusion proteins can be covalently attached to immobilized GSH-agarose beads using cross-linking reagents such as DSS (Support Protocol 2). Cross-linking a fusion protein of interest to the bead support is not essential, and significant results can be achieved without it. The advantage of coupling to the beads is the ability to elute only the interaction partners, leaving the GST fusion protein "bait" covalently attached to the bead. Thus, it will not be present in the subsequent extract or SDS acrylamide gel. The absence of GST fusion protein in the gel can be significant, because the presence of large amounts of fusion protein can make identification of specific binding proteins difficult, simply because of the number and size of the GST fusion protein–related bands that are present on the gel. This problem gets worse as the molecular weight of the fusion protein increases because many of the fusion protein–related bands migrate at smaller molecular weights than the fusion protein itself. Additionally, the presence of large quantities of GST fusion protein bands on the gel can sometimes seriously interfere with the identification of other proteins in the sample by MS peptide mass mapping (see below)—recombinant GST may seem to be present in every band, regardless of molecular weight, making identification of other proteins very difficult. Presumably, the large amount of fusion protein used does not resolve fully, and while the majority of the protein may be present as indicated by protein stain at the appropriate molecular weight, the traces that are present throughout the lane interfere with peptide mass mapping techniques. Other MS techniques of protein identification (e.g., peptide sequencing) may not be as susceptible to interference by the presence of GST fusion protein contamination in protein bands (see below). Non-MS techniques, such as Edman degradation, will also be relatively immune to this effect. While GST fusion protein contamination is common, it often proves to be inconsequential to achieving results, even from peptide mass mapping techniques like MALDI-TOF MS (see Anticipated Results and Brymora et al., 2001b).

While there are distinct advantages to using cross-linking in GST fusion protein pull-down experiments, there are also some caveats to consider. Loss of some or all biological activity of specific proteins (particularly enzymes) may occur as a result of the chemical modification that occurs during cross-linking. This loss of activity may be the consequence of a conformational change in the protein when primary amine groups (i.e., lysine residues) on the surface of the molecule react with an amine-directed cross-linking reagent (such as DSS). Alternatively, loss of activity may occur when specific lysine groups involved in binding a protein interaction partner or substrate (in the case of an enzyme) are modified

by the cross-linker. Therefore, it may be necessary to fully evaluate the influence of cross-linking reagents on any known functions of a protein of interest before using them in the pull-down approaches described herein. Alternatively, a pull-down experiment may be performed both with and without cross-linking of the GST fusion protein beads, particularly if the protein of interest has no known functions that can be tested outside of the pull-down. It may thus be possible to establish if cross-linking has any adverse influence on the protein-binding characteristics of a target protein.

Considerations in Tissue Source for Interacting Proteins

The source of protein for isolation of interacting proteins is often an obvious choice, decided on the basis of the investigator's research interests, but several factors should be kept in mind. Concerning mammalian systems, the tissue where the target protein is predominantly expressed can be an ideal starting point; presumably, if the protein is expressed there, then the interacting partner proteins must also be present. Also, a tissue could be chosen where the target protein is known to have a specific function, with the aim of determining the mechanism of how the protein carries out that function. However, the concentration of interacting partners may be higher in a tissue other than the tissue of interest (thus enabling easier isolation and identification) and yet may still represent a protein-protein interaction that is valid within the tissue of interest. In this way, it may initially be a useful approach to use a panel of different tissue sources (e.g., brain, lung, liver, kidney, and muscle) and establish which interacting proteins are unique to a particular tissue and which are common to all, and in which tissue they are present in the greatest abundance.

Likewise, it is worth considering a rational approach to how a lysate is to be prepared for use in pull-down approaches. This unit provides options for the preparation of whole-tissue lysate, as well as cytosolic, peripheral membrane, and membrane protein extracts (see Support Protocol 3). The whole tissue lysate, while having a higher concentration of potential interaction partners (and therefore being more likely to isolate them), is also more prone to higher levels of nonspecific protein binding. Fractionating proteins into the three described subcellular compartments reduces nonspecific binding but risks dilution of a protein of interest between three times the volume of lysate. It is usually also necessary to analyze the three extracts at once, which may lead to experiments that are too large and impractical (as three times the number of columns would be required). It is, however, possible that extracting proteins specifically from one of the subcellular compartments will concentrate that protein in that fraction and provide a clearer result than the use of a whole-tissue lysate. Given all of these factors, it can be worth considering the initial use of a panel of different tissue extracts to determine which gives the clearest result for isolation of interacting proteins.

Another consideration in the choice of tissue source is the abundance of endogenous GST proteins that can interfere with interpretation of results from pull-down experiments. After purification of recombinant GST fusion protein beads, the GSH beads still have free binding sites for other GSTs, and these can be specifically isolated on GSH beads if they are not fully removed from a tissue lysate. Some lysates contain high levels of endogenous GSTs, particularly cytosolic extracts and lysates from testis and liver. Further pre-clearing may be required for these lysates (see Critical Parameters and Troubleshooting).

The use of cultured cells as a source of interacting proteins has less utility for the procedures described in this unit, due to the limited quantity (and relatively high cost) of protein lysate that can be obtained. However, cells can be particularly of use in situations where a nonmammalian system is used as a source of interacting proteins (e.g., yeast), or when studying particular mammalian cell types (as opposed to whole tissues), provided

that enough lysate can be obtained. Cultured cells (e.g., thirty 7.7-ml flasks) can also be useful for a single pull-down experiment, without stringent control experiments. Any binding proteins identified may then be specifically targeted for more stringent analysis in scale-up experiments from larger tissue lysates. In this case, limited or no subcellular fractionation of cultured cells is recommended. A total cell lysate (using Triton X-100) is used in order to maximize protein recovery. Cultured cells may also be useful for further characterization of a protein-protein interaction detected from a tissue lysate (see below).

The final consideration for mammalian protein studies relates to scaling up tissue lysate size by switching to a physically larger species (e.g., ovine or bovine). The protein products of the same gene usually function similarly within different species including binding to similar proteins. Mass spectrometric methods for protein identification do not have any major difficulty adapting between species, since the vast majority of a particular protein's sequence is often identical between species (Larsen and Roepstorff, 2000). Mass spectrometric methods which rely on peptide mass mapping (see below) are thus usually little affected (except perhaps for small proteins that digest to only a few peptides), since the majority of peptides in a proteolytic digest are of identical molecular weight between species. Methods that directly provide primary sequence data for digested peptides are similarly little affected since amino acid sequence data can be used directly in database searches across species.

Mass Spectrometry Techniques

Modern advances in mass spectrometry (MS) have led to an increasingly complex number of approaches and types of instrumentation that can be utilized for identification of a protein of interest. While the sample preparation techniques are common to all (see Basic Protocol 2), the methods of analysis and the style of data obtained can vary widely between different techniques. The different instruments can also vary considerably in sensitivity, availability, and price, and often the identification of isolated proteins must be achieved using whatever instrument is available to the researcher. Proteins are generally identified by either one of two methods: peptide mass mapping (also known as peptide mass fingerprinting) or peptide sequencing (Coligan et al., 2003, Chapter 16).

Almost all types of MS instrumentation are capable of generating data suitable for analysis by peptide mass mapping. Peptide mass mapping uses a computer program to analyze a peptide mass spectrum for peaks that fit suitability criteria (e.g., of resolution and intensity). The masses of these peaks are then compared against a theoretical proteolytic digest of every protein in a selected database to identify a statistically significant match within a specified mass tolerance range (e.g., ±0.01 Da, or 50 ppm). This whole procedure can be completely automated by software, where the mass spectrum is the input and the protein identification (ranked by some kind of statistical score) is the output. The power of this approach is that it is very fast and can lead to a positive identification even in the face of changes in some peptides (e.g., post-translational modification or species differences). The main disadvantage of this technique is its dependence on the purity of the initial sample—if there is more than one protein in the gel piece being analyzed, it becomes more difficult to reliably match the data to one specific protein. While it is possible to identify one or more proteins out of such a peptide mixture, it is generally more difficult to achieve reliable results from such samples. Thus, gel resolution and dexterity in band cutting become critical to ensure that only a single protein is present in a gel piece (see Basic Protocol 2). The most suitable instrument for peptide mass mapping (despite the fact that most mass spectrometers can be used) is the matrix-assisted laser desorption ionization time-of-flight mass spectrometer (MALDI-TOF MS). This suitability arises from the simplicity, cost, and speed of the MALDI-TOF technique—it is possible to analyze (and thereby identify) hundreds of prepared protein samples each day

using this instrument (with varying success rates). Therefore, the MALDI-TOF mass spectrometer is usually the instrument of first choice for protein identification.

Peptide sequencing is a self-descriptive title that applies to the ability of some of the higher-end mass spectrometers to isolate a specific peptide from a spectrum and fragment it, yielding data that can be interpreted to give a primary amino acid sequence for that selected peptide (often called "tandem MS" or "MS/MS"). This peptide sequence, combined with the peptide mass, is then used to search against a protein sequence database, enabling identification of the protein. These instruments are available in many different combinations of components, providing versatile methods of sample delivery and analysis; one example is electrospray ionization tandem MS (ESI-MS/MS), for liquid samples, perhaps in combination with a liquid chromatography step. This technique can therefore identify a protein or proteins that are present in a sample, irrespective of whether the sample is contaminated with other proteins. It is a very powerful technique and probably the best suited for unequivocal identification of proteins. Generally speaking, however, the technique is slow (a maximum of around five samples per day) and is perhaps more suited to a secondary role as an adjunct to a high-throughput peptide mass mapping technique such as MALDI-TOF MS. Protocols for protein identification by this method, further background, and comparisons of MS techniques can be found in *UNIT 5.6* (also see Coligan et al., 2003).

If it is not possible to perform mass spectrometric analysis in the laboratory (due to lack of access or instrumentation), a commercial service can be used. Alternatively, more traditional protein sequencing techniques can also be used, but they are generally limited to samples of high abundance. Edman sequencing of tryptic peptides (described in Coligan et al., 2003) is one possibility. Sample preparation for this technique is identical to the approach presented in Basic Protocol 2. Sequencing results can be compared directly to a protein sequence database.

Confirmation of Protein-Protein Interactions

After the pull-down experiments have been concluded and the specific protein-protein interaction partners have been identified, it is important to verify the obtained results with other complimentary techniques. These are required to confirm that the discovered interaction is not an artifact of the experimental conditions and that the protein identification is accurate, as well as to determine whether the interaction is direct. The following are all approaches that may be indicated for confirmation of an interaction:

1. Immunoblots (*UNIT 6.2*) may be performed with specific antibodies raised against the new interacting partner to probe smaller-scale pull-down experiments (e.g., from cultured cell lysates) and thus confirm identification. Also, probing with antibodies against known interaction partners of the target protein (if these are available) can show that the system is working as it should.

2. The protein-protein interaction may be reconstituted in vitro with expressed recombinant protein, in pull-down experiments where only the two interacting proteins are used. These experiments demonstrate that the interaction is direct and does not involve some other factor that is present in the original tissue lysate. Thorough controls are necessary, as artifacts arising from nonspecific binding are more common in a reconstituted system using recombinant proteins than in one using proteins from a tissue or cell lysate. This is often due to recombinant protein not being correctly folded or post-translationally modified in the same manner as the tissue-derived protein.

3. Coimmunoprecipitation experiments may be performed to cosediment the two proteins complexed to one another from a cell or tissue lysate. This can also be done from cells that are overexpressing epitope-tagged versions of the two proteins (with different tags on each), enabling immunoprecipitation of the tag. This approach eliminates the need to raise or obtain immunoprecipitating antibodies, particularly if the proteins in question are poorly characterized.

4. Genetic approaches (e.g., reporter gene assays) can also be used, particularly in a nonmammalian system like yeast.

5. Overexpression of mutations or truncations in the protein of interest in cells that are deficient in the protein-protein interaction in question may be exploited in the hope of eliciting a change in cellular response through alterations in the activity of the interacting protein.

BASIC PROTOCOL 1

THE PULL-DOWN EXPERIMENT

The large-scale approach to pull-down experiments described in this protocol uses recombinant GST fusion protein coupled to GSH agarose beads, with or without cross-linking (purified as described in Support Protocols 1 and 2) and tissue lysates (prepared as described in Support Protocol 3). It utilizes small spin columns for some of the steps, as these improve the efficiency. Specifically, improved assay speed, protein recovery, reproducibilty, and decreased elution volumes are achieved when compared to traditional microcentrifuge tube approaches using centrifugation and aspiration of supernatant (Brymora et al., 2001a). There are several sizes of spin columns available that are more or less suitable for this protocol, the best being the MicroSpin columns from Amersham Biosciences. The different types, as well as the advantages and disadvantages of each, are described in Table 17.5.1.

It is possible (and often preferable) to perform the entire pull-down experiment (binding, washing, and elution steps) completely within the spin column (a schematic representation of this is shown in Fig. 17.5.2). This has the advantage of reducing any bead loss caused by repeated transfers between tubes, but it is dependent on the volume of lysate that is intended (as the columns are generally quite small: 0.5- to 1.5-ml) and the probable abundance of any interaction partners in that volume. Alternatively, the binding steps can be performed in larger volumes of tissue lysates (e.g., a 50-ml tube per pull-down), and the beads can later be transferred carefully to the spin columns for washing and elution. This latter approach is described in detail in this protocol, since it is more likely to yield successful results when combined with mass spectrometry. However, for subsequent characterization of protein-protein interactions, particularly for analysis by immunoblotting, smaller-scale pull-down experiments using the former technique are often preferable.

How much of the beads and recombinant GST-protein should be used? It is necessary to have an excess of recombinant protein relative to anything that may be in the lysate, but not so much that it will distort everything in the final analysis on the SDS acrylamide gel (if cross-linking is not used). The optimal amount of GST fusion protein to use needs to be determined empirically for a particular experiment.

For GST fusion proteins not cross-linked to GSH beads, an approximate place to start is 5 µg recombinant protein on beads per 1 g of tissue in a whole tissue lysate.

For GST fusion proteins cross-linked to GSH beads, use 10 to 50 µg recombinant protein on beads per 1 g of tissue in a whole tissue lysate.

Table 17.5.1 Advantages and Disadvantages of Different Types of Spin Columns

Name	Supplier	Maximum vol. (ml)	Advantage (+), Disadvantage (-)
MicroSpin Columns	Amersham Biosciences	0.6	+Minimal dead volume under frit +Reuseable (wash out beads with water and soak in 70% ethanol until needed; centrifuge tubes dry)
Micro Bio-Spin Chromatography Columns	Bio-Rad Laboratories	1	+Larger volume in a small profile that fits most microcentrifuges –Large dead volume in hollow plug (Luer-lok fitting) –Small volumes of elution buffers may need to be manually removed from plug after heating. Minimized by rapidly removing plug (within a few seconds) after removal from water bath. –Single-use only
Bio-Spin Chromatography Columns	Bio-Rad Laboratories	1.5	+Large volumes can be added (e.g., lysates) –Large dead volume in hollow plug (Luer-lok fitting), but this can be alleviated with custom-made plugs that penetrate into Luer fitting –Need to confirm that centrifuge has sufficient clearance above rotor to house spin column when it is sitting in its collection tube –Single-use only

The overall bead volume does not matter greatly, but it needs to be as small as possible (20 to 100 µl). A larger bead volume will wash less efficiently and will bind more nonspecific proteins from the tissue lysate. The beads sometimes have a very high concentration of bound recombinant GST fusion protein; in these cases, dilute the beads with bead storage buffer (see Support Protocol 1), so that the small volumes can be pipetted accurately. Swirl the bead slurry or vortex very gently between each pipetting step to ensure uniform suspension.

When using multiple GST fusion proteins on different beads, the final bead volume used for each pull-down must be normalized or equalized. For example, if using five different GST constructs with 25 µg of each attached to varying amounts of beads (as is normally the case), it is necessary to dilute all the beads with GSH agarose so they all match the same volume. In other words, use the same bead volume as well as the same protein amount in each pull-down that is intended to be used on the same gel. This ensures that any nonspecifically binding proteins are relatively constant between the different conditions and are therefore not mistaken for specific binding proteins.

Materials

Tissue lysate (see Support Protocol 3)
Bead storage buffer: 20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)/50% (v/v) glycerol
GSH-agarose beads (e.g., glutathione-Sepharose 4B; Amersham Biosciences)
Wash buffers 1 *or* 2, and 3 (see recipes)
1× SDS sample buffer (*UNIT 6.1*)

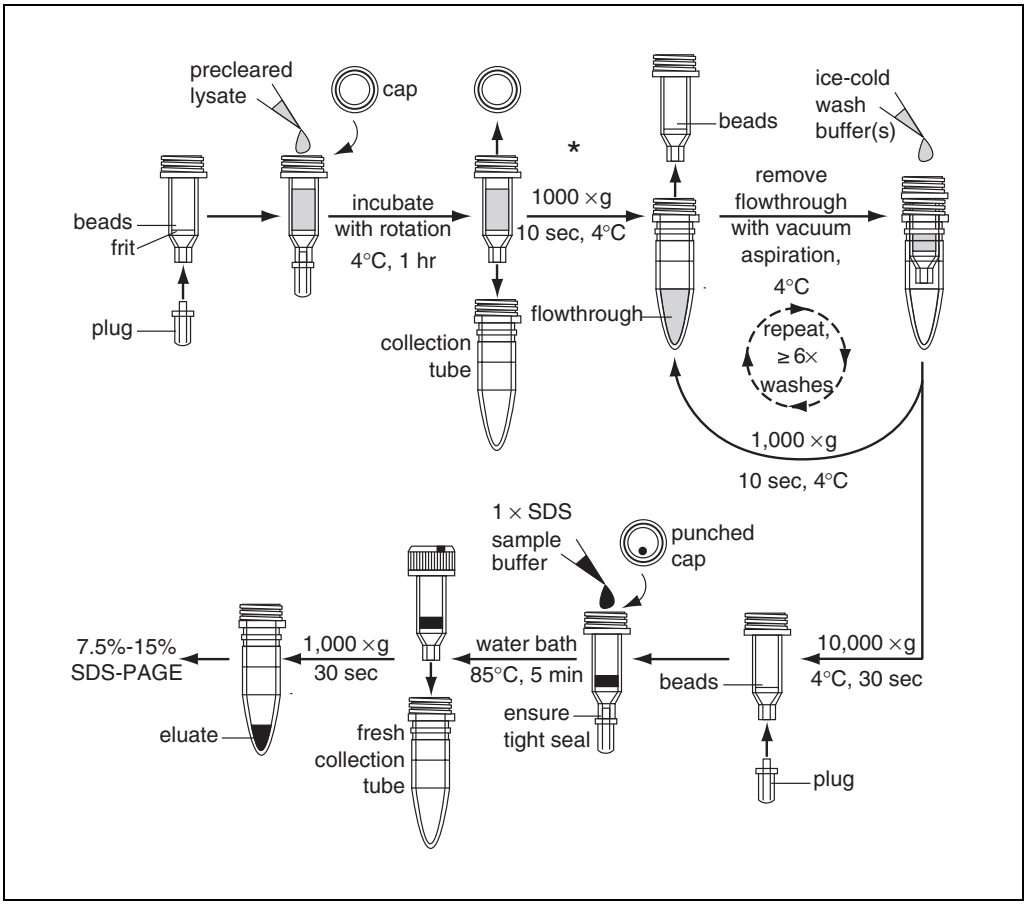

Figure 17.5.2 The spin column–based pull-down experiment. An illustrative description of the approach taken when an entire pull-down experiment is performed within the spin column. This differs from the protocol presented in Basic Protocol 1 and the Alternate Protocol, as it is designed for smaller-scale experiments. The large-scale experiments in the text intersect with this figure at the point marked with an asterisk (*), corresponding to step 12 in Basic Protocol 1 and the Alternate Protocol.

Benchtop centrifuge, 4°C
Appropriately sized tubes that can be centrifuged
End-over-end rotator
Empty plastic column (e.g., Poly-Prep from Bio-Rad; to suit lysate volume) *or* Miracloth (Calbiochem)
MicroSpin columns (Amersham Biosciences), or other spin columns (see Table 17.5.1)
85°C water bath

Additional reagents and equipment for preparing GST fusion proteins attached to GSH-agarose beads (see Support Protocol 1), cross-linking of fusion proteins (optional; see Support Protocol 2), preparing tissue lysate (see Support Protocol 3), and SDS-PAGE (*UNIT 6.1*)

Prepare GST fusion proteins and tissue lysates

1. Prepare recombinant GST fusion proteins attached to GSH-agarose beads (see Support Protocol 1). Cross-link if desired (see Strategic Planning and Support Protocol 2). Store at −20°C in bead storage buffer for up to 6 months.

2. Prepare a tissue lysate (see Support Protocol 3 or use other method).

   Ensure that lysate is free from even small traces of particulate contamination. These will only block the columns later and result in large amounts of nonspecific protein on the gel. If present, it is very important to remove them by centrifugation at high speed (e.g., 18,000 × g) for 30 min, even if this has already been performed earlier.

Pre-clear lysates with GSH beads

If using tissue lysates prepared according to Support Protocol 3, the lysates have already been precleared with GSH-agarose: skip steps 3 to 8 and proceed starting with step 9. If using a different source of lysate, then continue with step 3.

3. Wash a batch of fresh or recycled GSH-agarose beads that have no recombinant protein attached as follows:

   a. For 2 g tissue use 100 µl of beads; for 200 g tissue use about 2 ml GSH beads.

   b. Add 1 ml (for 2 g tissue) or 20 ml (for 200 g tissue) of wash buffer (i.e., the base buffer that was used for tissue lysis in Support Protocol 3, or wash buffer 1) to the beads and centrifuge in a benchtop centrifuge 5 min at 500 × *g*, 4°C. Remove supernatant and collect the beads in a minimal volume of buffer.

   Avoid centrifuging beads (until the elution step) much faster than 2000 × g, or the beads will be crushed.

4. Pre-clear the tissue lysate with the washed GSH beads for removal of endogenous GSTs present in the lysate and nonspecifically binding proteins, by combining the washed GSH beads (from step 3) with the tissue lysate and incubating at 4°C on an end-over-end rotator for 30 min.

   This will remove most of the endogenous cellular GST. The addition of a large volume of GSH-agarose still does not fully remove all endogenous GST proteins from a tissue lysate (~80% are removed with each clearing step).

5. Sediment the beads by centrifuging the mix in a benchtop centrifuge, 5 min at 500 × *g*, 4°C.

6. Carefully pour off the supernatant into fresh, cooled tubes on ice. Keep the supernatant as "precleared tissue lysate" for addition to the GST fusion protein beads at step 10.

   Optionally, keep an aliquot (of an equivalent bead volume to that of the recombinant protein beads to be added to the lysate) of these beads to run in parallel on the gel in the final analysis. The remaining bulk GSH beads can later be recycled (see Support Protocol 4).

7. Repeat this pre-clearing twice more, if required, to remove more endogenous tissue GST proteins.

   This is especially important for tissue lysates that are rich in endogenous GSTs (particularly cytosolic extracts and lysates of specific tissues, e.g., testis or liver).

8. Pass the total precleared tissue lysate through an empty, clean plastic column—e.g., a Bio-Rad Poly-prep column of an appropriate size for the volume of lysate used: use a 10-ml column (10-cm length, 20-mm top diameter) for ≤100 ml lysate—or four layers of Miracloth.

   This will remove traces of beads that may have been missed earlier but which cannot readily be seen. It is essential to prevent even minor contamination of individual samples with even a small number of beads (as they likely have bound large amounts of endogenous GSTs). A larger column (e.g., 40-ml) will be faster than a smaller column; with larger volumes of lysate, the Miracloth is preferable.

Bind tissue lysates to the GST fusion protein beads

9. Divide the precleared tissue lysate into equal portions, depending on the number of conditions to be examined.

10. Add from 0.5 to 50 ml of lysate to 10 to 200 µl of GST fusion protein beads (from step 1) in appropriately sized tubes that can be later centrifuged. Cap the tubes and incubate 1 hr at 4°C on an end-over-end rotator (preferably in a cold room).

    The beads should not be allowed to settle.

    If concerned about adding any of the components of the bead storage buffer to the tissue lysates, then centrifuge the beads 15 to 20 sec at 1000 × g, 4°C, carefully remove the supernatant, and resuspend them in the base buffer of the lysate before adding them to the precleared tissue lysate.

Recover and wash beads

11. Centrifuge the lysate and bead mixture 5 min at 500 × *g*, 4°C, then carefully decant (or remove by vacuum aspiration) most (but not all) of the supernatant, leaving a minimal volume of lysate above the bead pellet, without disturbing the bead bed.

    IMPORTANT NOTE: *Be extremely careful not to disturb the bed of beads. From here on, it is essential to recover as much of the beads as possible, minimizing accidental losses. It is important to inspect the lid and sides of the tube before centrifugation to ensure that the beads are within the liquid. Beads that are trapped on the walls or lid (not in the liquid) are not adequately pelleted by the low-speed centrifugation and will result in bead loss. Ensure that all these beads are collected by thorough washing in step 13 below.*

12. Transfer the beads plus remaining small volume of tissue lysate to a prechilled MicroSpin column and microcentrifuge the remaining tissue lysate into a collection tube for 10 sec at 1000 × *g*, 4°C.

    Try not to centrifuge beads so fast or so long that they totally dry out, as determined by visual inspection of the beads. The beads should be visible, but should not appear to be loose and crystalline.

    Note that Figure 17.5.2 is marked with an asterisk (*) at the point equivalent to step 12, so the remaining steps can be followed diagrammatically.

13. Remove the tissue lysate in the collection tube by vacuum aspiration, replace the MicroSpin column, and add 0.5 ml of ice-cold wash buffer 1 to the tube that had originally contained the lysate. Rinse the tube well to recover any traces of beads. Transfer this wash to the MicroSpin column.

    If the lysate used above was a membrane or whole-tissue lysate, substitute wash buffer 2 for wash buffer 1 in this step and in step 15.

    The aim is to recover any residual beads from the bottom and sides of the tube and pool them with the others that are now in the MicroSpin column. This eliminates variability between the various conditions. Visually inspect the initial tube for beads; if any are present, repeat this step.

14. Spin the wash into the collection tube by microcentrifuging for 10 sec at 1000 × *g*, 4°C. Remove the flowthrough in the collection tube to waste by vacuum aspiration, then replace the column in the collection tube.

    This step is faster if the collection tubes are left in the prechilled rotor.

15. Wash the beads (now containing the target binding proteins) six times, each time by adding 0.5 ml of ice-cold wash buffer 1 (or 2, see annotation to step 13), microcentrifuging 10 sec at 1000 × *g*, 4°C, and removing flowthrough from the collection tube to waste by vacuum aspiration.

16. Wash three additional times with 0.5 ml of wash buffer 3, using the technique described in step 15.

17. For the very last wash, spin the beads dry by microcentrifuging 30 sec at 10,000 × *g*, 4°C.

Elute proteins from MicroSpin columns for SDS-PAGE analysis

18. Plug the bottom of the column thoroughly to ensure a tight seal. Add 1× SDS sample buffer to the beads.

    Use a volume of 1× SDS sample buffer appropriate for the bead volume and analysis by SDS-PAGE, e.g., for 50 µl of bead volume use 50 to 80 µl of sample buffer. Try to keep the volume to a minimum. It is essential to dilute the SDS sample buffer to a final 1× (i.e., 2% SDS) before use; do not use the concentrated SDS sample buffer found in most laboratories until it is diluted.

19. Cap the MicroSpin column with a punched cap and place in an 85°C water bath for 5 min.

    A single hole in the cap, punched with a heavy-gauge needle, is essential to prevent pressure buildup during heating, which would cause the sample to leak out the bottom. Under no circumstances should the tube be heated at 100°C, or the white plastic frit may buckle, causing leakage of sample and beads. If using columns other than the MicroSpin, ensure in advance that they will tolerate heating at 85°C.

20. After heating, dry the outside of the column with a tissue, remove the bottom plug, and centrifuge the 1× SDS sample buffer (now containing the proteins for analysis) into a fresh collection tube by microcentrifuging 30 sec at maximum speed. Store the samples on ice (if loading gels immediately) or in the freezer (if the gel will be run at a later date).

    If small volumes of 1× SDS (relative to the bead volume) are used, the elutions will likely lose some blue color. This is acceptable, as the beads retain bromophenol blue dye. Load gel using the normal technique (UNIT 6.1).

21. Analyze the samples by SDS-PAGE (*UNIT 6.1*) on a long gradient gel run overnight at 10°C.

    For optimal protein resolution (essential for analysis by mass spectrometry) the gels must be long gels (e.g., 20-cm gels; preferably gradient gels of 7.5% to 15% acrylamide), not minigels. Additionally, the gels should be 1 mm in thickness for optimal strength and ease of processing for mass spectrometry. Gels of 1.5-mm thickness are too thick for in-gel digestion (see Basic Protocol 2), and 0.75-mm gels tear far too easily. The controls suggested above (see Strategic Planning) should be run on the same gel.

22. Stain the gel by an appropriate technique suitable for mass spectrometry (see Basic Protocol 2).

Analyze results

23. Compare bands between the lanes of the gel for differential binding between the conditions used and controls. Refer to Anticipated Results for more detail.

ALTERNATE PROTOCOL 1

EFFECTOR ISOLATION WITH GST-TAGGED SMALL GTPASES

This protocol is specifically aimed at the study of nucleotide-dependent binding proteins (e.g., Ras, Rab, or Rho family GTPases). For other GST fusion proteins, such as isolated domains or enzymes, use Basic Protocol 1. Small GTPases bind guanine nucleotides (GTP and GDP) in a nucleotide-binding pocket on their surface. In so doing they undergo changes in conformation which allow them to bind to specific proteins in a GTP- or GDP-dependent manner (Takai et al., 2001). The GTP-bound form of the small GTPase is termed the active state, and GTP-dependent binding proteins are termed effectors since activation of many signaling pathways leads to increased GTP binding of the small GTPase, promoting further signaling. These proteins are particularly significant in cell biology investigations because of their role as regulators of a multitude of cellular processes. In humans there are around 150 small GTPases known to be expressed.

The main differences between this alternate protocol and Basic Protocol 1 are the presence of Mg^{2+} in the buffers (for maintenance of nucleotide binding and stability of the small GTPase) and the additional nucleotide-binding steps; there are also additional small changes in other steps. It is advisable to be familiar with the details of Basic Protocol 1 before following this protocol.

For small GTPases, it is most interesting to isolate specific binding proteins for each of the two states of activation, i.e., to load the GST–small GTPase columns respectively with GDP and GTP. Depending on the intrinsic GTP hydrolysis rate of the small GTPase to be used, it may be necessary to use a GTP analog such as GTPγS [guanosine 5′-*O*-(3-thiotriphosphate)] instead of GTP. For instance, the small GTPase Rac1 has a GTP hydrolysis rate that is 40 times higher than H-Ras (Menard et al., 1992). The authors have used GTP quite successfully for the isolation of effectors for the small GTPase RalA (Brymora et al., 2001b). This is possible because RalA has a relatively low GTPase activity (Frech et al., 1990). It may be preferable to use GTP rather than costly GTPγS for purely economical reasons, but it must be justified according to the criteria above.

Additional Materials *(also see Basic Protocol 1)*

1 M $MgCl_2$ (*APPENDIX 2A*)
Bead storage buffer (20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)/50% (v/v) glycerol) containing 2.5 mM $MgCl_2$ (added from 1 M $MgCl_2$ stock; *APPENDIX 2A*)
Small GTPase loading buffer (see recipe)
100 mM GDP and GTP (or GTPγS) stock solutions (prepare fresh on the day of the experiment and keep cold):
100 mM GDP (mol. wt. 463.2) = 1 mg in 21.6 µl H_2O
100 mM GTP (mol. wt. 567.1) = 1 mg in 17.6 µl H_2O
100 mM GTPγS (mol. wt. 627.2) = 1 mg in 15.9 µl H_2O
Wash buffers 4 *or* 5, and 6 (see recipes)

Prepare GST fusion proteins and tissue lysate

1. Prepare recombinant GST-tagged small GTPase proteins attached to GSH-agarose (Support Protocols 1 and 2) with the following modifications:

   a. Purify small GTPases with 1 to 5 mM Mg^{2+} present in all buffers (added from 1 M $MgCl_2$ stock), including those used in the cross-linking steps.

   b. Omit EDTA from any buffers that come into contact with the small GTPase throughout the protocol (apart from the small GTPase loading buffer) and replace with 2.5 mM $MgCl_2$ (added from 1 M $MgCl_2$ stock).

   c. Store at −20°C in bead storage buffer (including 2.5 mM $MgCl_2$ added from 1 M $MgCl_2$ stock) for up to 4 to 6 months.

2. Prepare tissue lysate (Support Protocol 3) with addition of 2.5 mM $MgCl_2$ (added from 1 M $MgCl_2$ stock) to all buffers. Preclear with GSH-agarose (Basic Protocol 1, steps 3 to 8), if necessary.

   Ensure that the tissue lysate is free from even small traces of particulate contamination.

   If using tissue lysates prepared according to Support Protocol 3, the lysates have already been precleared with GSH-agarose; in this case proceed to nucleotide loading (step 3 of this protocol). If using a different source of lysate, the lysate must be precleared with GSH-agarose beads.

Load GST fusion protein beads with the appropriate nucleotides

If the pre-clearing steps are being performed, the beads may be loaded with nucleotides while the pre-clearing beads are being incubated (see Basic Protocol 1, step 4). The following steps are based on the protocol used by Cantor et al. (1995), which works on the principle that, in the absence of Mg^{2+}, the small GTPases bind nucleotides with low affinity and cannot hydrolyze GTP. Therefore, brief incubation in EDTA (present in the small GTPase loading buffer) promotes nucleotide exchange, and subsequent addition of an excess of Mg^{2+} loads the small GTPase with whichever guanine nucleotide is present. It is essential to load the GST–small GTPase beads with nucleotides as close as possible to the point at which they will be added to the tissue lysate.

3. Pipet the required amount of GST fusion protein beads (as a well suspended slurry) into two MicroSpin columns (or use a microcentrifuge tube if the binding steps are not going to be performed within the spin column): two equal lots for GDP versus GTP.

   It is important to use precisely equal amounts of beads for the different nucleotide loading procedures.

4. Remove the storage buffer (i.e., remove most of the Mg^{2+}) by microcentrifuging the MicroSpin column 10 sec at 1000 × *g* into a collection tube. Plug the base of the column.

5. Add an equal volume (or 50 µl, if the bed volume is <50 µl) of small GTPase loading buffer; ensure that there is an excess of EDTA present, so as to chelate all the Mg^{2+} in the protein beads (i.e., if not using MicroSpin columns, increase the added EDTA to 5 mM, for a final concentration of 2.5 mM).

6. Add the required nucleotide (GDP, GTP, or GTPγS) from a 100 mM stock, to a final concentration of 2 mM.

   GTP stocks must be prepared fresh, as GTP hydrolyzes to GDP in solution.

7. Mix the GST fusion protein beads by gently flicking the tube (avoid vigorous vortexing and try to avoid spreading the beads on the sides of the tube), then incubate at 37°C for 20 min in a water bath to induce nucleotide binding and exchange.

8. Cool the tubes on ice. After ~1 min, add 1 M $MgCl_2$ to achieve a final concentration of 10 mM Mg^{2+} (1.2 µl for a 100-µl reaction), and gently mix.

   The beads are now ready for pull-down experiments. They should be kept on ice and not left too long before use (not more than 30 min). The buffer that is currently in the beads (nucleotide and Mg^{2+}) can remain.

Bind tissue extracts to the GST fusion protein

9. Divide the precleared tissue lysate into precisely equal portions, depending on the controls included (at minimum this is three aliquots: one for GST beads and one each for GDP and GTP). Add GDP or GTP to the appropriate aliquot, from a 100 mM stock, to achieve a final concentration of 0.1 mM.

   There should already be Mg^{2+} present; if not, add a sufficient quantity of 1 M $MgCl_2$ to achieve 2.5 mM.

   The addition of nucleotides to the precleared tissue lysate will reduce competition and exchange with the preloaded nucleotides on the GST-small GTPase beads to be added in the next step.

10. Directly add the nucleotide-loaded beads to the precleared tissue lysate, including the buffer in which they are contained (anywhere from 10 to 200 µl of beads are added to 0.5 to 50 ml of lysate in suitably sized capped tubes). Incubate at 4°C for 1 hr on an end-over-end rotator (in a cold room).

Recover and wash beads

11. Centrifuge the lysate and bead mixture 5 min at 500 × *g*, 4°C, then carefully decant (or remove by vacuum aspiration) most (but not all) of the supernatant, leaving a minimal volume of lysate above the bead pellet, without disturbing the bead bed.

    IMPORTANT NOTE: *Be extremely careful not to disturb the bed of beads. From here on, it is essential to recover as much of the beads as possible, minimizing accidental losses. It is important to inspect the lid and sides of the tube before centrifugation to ensure that the beads are within the liquid. Beads that are trapped on the walls or lid (not in the liquid) are not adequately pelleted by the low-speed centrifugation, and will result in bead loss. Ensure that all these beads are collected by thorough washing in step 13 below.*

12. Transfer the beads plus remaining small volume of tissue lysate to a prechilled MicroSpin column and microcentrifuge the remaining tissue lysate into a collection tube for 10 sec at 1000 × *g*, 4°C.

    Try not to centrifuge the beads so fast or so long that they totally dry out, as determined by visual inspection of the beads. The beads should be visible but should not appear to be loose and crystalline.

    Note that Figure 17.5.2 is marked with an asterisk (*) at the point equivalent to step 12, so the remaining steps can be followed diagrammatically.

13. Remove the tissue lysate in the collection tube by vacuum aspiration, replace the MicroSpin column, and add 0.5 ml ice-cold wash buffer 4, to the tube that had originally contained the lysate. Rinse the tube well to recover any traces of beads. Transfer this volume to the MicroSpin column.

    If membrane or whole tissue lysates were used above, substitute wash buffer 5 in this step and step 15.

    The aim is to recover any residual beads and pool them with the others that are now in the MicroSpin column. This eliminates variability between the samples (particularly between GDP- and GTP-loaded samples). Visually inspect the initial tube for beads; if any are present, repeat this step.

14. Spin the wash into the collection tube by microcentrifuging for 10 sec at 1000 × *g*, 4°C. Remove the flowthrough in the collection tube to waste by vacuum aspiration, then replace the column in the collection tube.

    This step is faster if the collection tubes are left in the prechilled rotor.

15. Wash the beads (now containing the target binding proteins) six times, each time by adding 0.5 ml of ice-cold wash buffer 4 (or 5, see annotation to step 13), microcentrifuging 10 sec at 1,000 × *g*, 4°C, and removing the flowthrough from the collection tube to waste by vacuum aspiration.

16. Wash three additional times with 0.5 ml of ice-cold wash buffer 6, using the technique described in step 15.

17. For the very last wash, spin the beads dry by microcentrifuging 30 sec at 10,000 × *g*, 4°C.

Elute proteins from MicroSpin columns for SDS-PAGE analysis

18. Plug the bottom of the column thoroughly to ensure a tight seal. Add 1× SDS sample buffer to the beads.

    Use a volume of 1× SDS sample buffer appropriate for the bead volume and analysis by SDS-PAGE, e.g., for 50 µl of bead volume use 50 to 80 µl of sample buffer. Try to keep the volume to a minimum. It is essential to dilute the SDS sample buffer to a final 1× (i.e., 2% SDS) before use; do not use the concentrated SDS sample buffer found in most laboratories until it is diluted.

19. Cap the MicroSpin column with a punched cap and place in an 85°C water bath for 5 min.

    A single hole in the cap, punched with a heavy-gauge needle, is essential. to prevent pressure buildup during heating, which would cause the sample to leak out the bottom. Under no circumstances should the tube be heated at 100°C, or the white plastic frit may buckle, causing leakage of sample and beads. If using columns other than the MicroSpin, ensure in advance that they will tolerate heating at 85°C.

20. After heating, dry the outside of the columns with a tissue, remove the bottom plug, and centrifuge the 1× SDS sample buffer (now containing the proteins for analysis) into a fresh collection tube by microcentrifuging 30 sec at maximum speed. Store the samples on ice (if loading gels immediately) or in the freezer (if the gel will be run at a later date).

    If small volumes of 1× SDS (relative to the bead volume) are used, the elutions will likely lose some blue color. This is acceptable, as the beads retain bromophenol blue dye. Load gel using the normal technique.

21. Analyze the samples by SDS-PAGE (*UNIT 6.1*) on a long-gradient gel run overnight at 10°C.

    For optimal protein resolution (essential for analysis by mass spectrometry) the gels must be long gels (e.g., 20-cm gels; preferably gradient gels of 7.5% to 15% acrylamide), not minigels. Additionally, the gels should be 1 mm in thickness for optimal strength and ease of processing for mass spectrometry. Gels of 1.5-mm thickness are too thick for in-gel digestion (see Basic Protocol 2), and 0.75-mm gels tear far too easily. The controls suggested above (see Strategic Planning) should be run on the same gel.

22. Stain the gel by an appropriate technique suitable for mass spectrometry (see Basic Protocol 2).

Analyze results

23. Compare the protein stain in both lanes (GDP-loaded versus GTP-loaded) to find the proteins that bind in a nucleotide-dependent manner, and which do not bind to the various controls. See Anticipated Results for more details.

SUPPORT PROTOCOL 1

GST FUSION PROTEIN PURIFICATION

This procedure describes a technique for expression and purification of GST fusion proteins. There are many different protocols available for purification of GST fusion proteins, and the one provided here is a fairly standard protocol that works well for many GST fusion proteins. It is not, however, universally applicable, and modifications may be required to increase yield of functional product. Such modifications are many and varied (there are almost as many different protocols as there are GST fusion proteins), and as such they will not be discussed in this unit, since there are many other suitable references available that specifically cover such optimization procedures (see, e.g., Harper and Speicher, 1997). Some of these are provided by the manufacturers of expression vectors or GSH-agarose beads (e.g., see The Recombinant Protein Handbook form Amersham Biosciences).

Materials

Glycerol stock of *E. coli* cells containing GST fusion protein expression vector (see *APPENDIX 3A* and Coligan et al., 2003)
LB medium and LB agar plates (see *APPENDIX 2A*) containing 100 μg/ml ampicillin (or other appropriate antibiotic selection for GST expression vector used)
100 mM isopropyl-1-thio-β-D-galactoside (IPTG), filter sterilized
Bleach (e.g., Clorox)
Bacterial lysis buffer: 20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)/250 mM NaCl
100 mg/ml lysozyme
100 mM PMSF (*APPENDIX 2A*)
20 mg/ml leupeptin
Liquid nitrogen and appropriate storage canister
1 mg/ml DNase I
10% (v/v) Triton X-100 (*APPENDIX 2A*)
Bacterial lysis buffer (see above) containing 1% (v/v) Triton X-100
1% (w/v) SDS
Wash buffer 1 (see recipe)
Bead storage buffer: 20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)/50% (v/v) glycerol
1× and 3× SDS sample buffer (*UNIT 6.1*)
Bovine serum albumin (BSA; optional)

Shaking bacterial incubator
Culture tubes, sterile
1-liter conical flasks (Pyrex or autoclavable plastic), sterilized by autoclaving or baking
Bugstoppers (Whatman), sterilized by autoclaving, *or* other sterile, gas-permeable flask closures
Probe sonicator (e.g., Branson)
Refrigerated high-speed centrifuge and benchtop centrifuge
15-ml and 50-ml polypropylene screw-cap tubes (e.g., Falcon)
Pipet tip cut to increase opening to >1 mm
85°C water bath
MicroSpin columns (Amersham Biosciences)

Additional reagents and equipment for growing bacterial cells (see *APPENDIX 3A*), SDS-PAGE (*UNIT 6.1*), Coomassie blue staining of gels (*UNIT 6.6*)

Culture bacterial cells and induce protein expression

1. *Day 1 (evening):* Streak out glycerol stock of an *E. coli* strain containing GST fusion protein expression vector on an LB agar plate containing 100 µg/ml ampicillin (or other appropriate antibiotic selection for GST-expression vector), and grow overnight (~16 hr) at 37°C.

   See APPENDIX 3A for references on growing bacterial cells.

2. *Day 2 (morning):* Remove plates from incubator and store inverted at 4°C for up to a month.

3. *Day 2 (evening):* Inoculate an appropriate volume of LB medium containing 100 µg/ml ampicillin (or other appropriate antibiotic) with a single colony from the LB agar plate. Incubate overnight at 37°C with shaking at 200 to 250 rpm.

   Typically, a 1:50 to 1:100 dilution into 0.5 to 2 liters will be required the next day, so ensure that sufficient overnight culture is inoculated.

4. *Day 3 (morning):* Dilute 7.5 ml of the overnight culture into 500 ml of LB medium containing 100 µg/ml ampicillin (or other appropriate antibiotic) in a 1-liter conical flask, and cap flask with an autoclaved Bugstopper (or another suitable gas-permeable closure). Incubate at 37°C with shaking at 200 to 250 rpm for 3 to 4 hr. Measure the optical density (OD) at 600 nm against LB medium (or water) as a blank.

   Induce the bacteria (step 5) when the OD is ~0.8 to 1.2 (up to 2).

5. Remove a 1-ml aliquot of the OD 0.8 to 1.2 bacterial culture to a sterile 1.5-ml microcentrifuge tube and grow in parallel with the remainder of the culture (this is the noninduced control sample, "–IPTG"). To the remainder of the culture, add 100 mM IPTG for a final concentration of 0.1 mM to induce protein expression, and incubate 2 to 6 hr at 25° to 30°C.

   The optimal induction temperature, OD, and duration will vary depending on the fusion protein of interest and may need to be determined systematically on a small scale (e.g., in 5- to 10-ml cultures) prior to large-scale protein production. Lower-temperature induction and shorter induction times at higher OD may increase the yield of folded, soluble protein (also see Coligan et al., 2003).

6. At the end of the incubation, place a 1-ml aliquot of the culture in a microcentrifuge tube (this is the induced sample, +IPTG). Centrifuge the bulk culture for 20 min at 18,000 × *g* (or maximum speed in a high-speed centrifuge), room temperature. Add bleach for a concentration of 2% to 4% (v/v) to the supernatant in the flasks, let stand for a minimum of 2 hr, and discard.

   Some plastic flasks may not be tolerant to bleach; these should be washed well in detergent and disinfected by autoclaving. Do not bleach Bugstoppers, or soak them in detergent; instead, autoclave them.

7. Resuspend bacterial pellet in a volume of bacterial lysis buffer equal to 5% of the total induced culture volume (i.e., 50 ml per liter of culture), and freeze this bacterial suspension at −20°C overnight or until purification. Microcentrifuge the 1-ml −IPTG and +1PTG control samples at maximum speed, carefully remove and discard the supernatant, and freeze these control pellets at −20°C.

   The samples can be stored in this way for up to 6 months.

Purify GST fusion proteins

8. Thaw the bacterial suspension (use cool water if necessary, but do not allow the samples to warm above ~4°C). Once thawed, add a final concentration of 1 mg/ml lysozyme (from 100 mg/ml stock), 1 mM PMSF (from 100 mM stock), and 20 µg/ml leupeptin (from 20 mg/ml stock), and vortex well. Incubate on ice for ~5 min.

9. Pass the bacterial suspension through two freeze/thaw cycles by sequential dropping of the tubes into liquid nitrogen for about 20 to 30 sec (or longer on dry ice if liquid nitrogen is not available), removing with tongs, and thawing in cool water (again ensuring that the samples do not warm much beyond 4°C).

   CAUTION: *When handling liquid nitrogen, ensure adequate eye protection and ventilation. Also, ensure that the tubes can withstand liquid nitrogen without shattering before dropping in any samples. There may be a slight color change (creamy white to a slightly more yellow/brown color) and a viscosity change after the freeze/thaw cycles, indicating that lysis has occurred.*

10. Sonicate on ice for 30 sec with a probe sonicator to further rupture the cells and break up any DNA.

    Do not oversonicate, as this may denature the proteins. This step can be omitted if protein degradation or denaturation occurs.

11. Add 1 mg/ml DNase I stock to a final concentration of 5 µg/ml and 10% Triton X-100 to a final concentration of 1% (v/v). Incubate at 4°C (in a cold room), with slow rotation on an end-over-end rotator for 30 min.

12. Centrifuge samples in a high-speed centrifuge 30 min at 18,000 × *g*, 4°C.

13. While centrifugation is in progress, pipet an appropriate quantity of well-suspended GSH-agarose slurry (as supplied by the manufacturer) into a 50-ml polypropylene screw-cap tube using a pipet tip that has been cut to increase the opening to >1 mm.

    How much of the GSH-agarose beads should be used? The manufacturers of GSH-agarose usually evaluate each batch of beads for binding capacity (and this is usually around 8 mg/ml for GST). Some prior estimation of protein expression level is useful, and an initial small-scale purification can be useful to assess this. For 0.5 to 1 liter of bacterial culture, a 0.5- to 1-ml bed volume of GSH-agarose yields a relatively high incorporation of protein to the beads (~1 to 2 mg/ml bed volume or greater). Some highly expressing soluble proteins may require even more GSH-agarose (e.g., the GST that is used for controls).

14. Centrifuge in a benchtop centrifuge 5 min at 500 × *g*, then remove and discard the supernatant (preferably by vacuum aspiration), being extremely careful not to lose any beads. Add 10 bed volumes of bacterial lysis buffer including 1% Triton X-100, resuspend the beads well and centrifuge 5 min at 500 × *g*, then carefully remove the supernatant and discard.

    Do not centrifuge beads much faster than 2000 × g at any point, or the beads may be crushed. Crushed beads are harder to isolate and bind more nonspecific proteins.

15. When the centrifugation of the bacterial lysate (from step 12) is finished, mark the level of the liquid in the centrifuge tube with a marker (the soluble bacterial fraction is the supernatant). Take a 20-µl sample (for gel; label as soluble), then decant the rest of the supernatant into the 50-ml tube containing the beads (step 14). Incubate at 4°C for 1 hr with rotation on an end-over-end rotator (preferably in a cold room) to bind the GST fusion proteins to the beads.

    The beads should remain suspended at all times during incubation.

16. While the beads are binding, resuspend the pellet from the centrifugation of the bacterial lysate in a volume of 1% SDS solution equivalent to that indicated by the mark on the centrifuge tube. When it is relatively homogenous, take a 20-µl sample (for the gel; label as pellet) and discard the remainder.

    Considerable agitation (vortexing and trituration) will be required to disrupt the pellet. It will likely not fully solubilize, the aim is to homogenize and reduce the particle size. Full solubilization is not required, as it is intended as a control on SDS-PAGE—the heating and additional SDS added will make it homogenous enough for the gel.

17. After the binding step (step 15) is complete, centrifuge the 50-ml tube 5 min at 500 × *g*, 4°C, to pellet the beads. Carefully decant the supernatant from the beads, taking care not to lose any beads. Ideally, leave a small volume of lysate behind at the end to avoid disturbing the bead bed. Take a 20-µl sample of the supernatant (for the gel; label as through).

18. Add 10 to 20 bed volumes of wash buffer 1 to the beads, then centrifuge 5 min at 500 × *g*, 4°C, and carefully remove the supernatant by decanting or vacuum aspiration. Repeat this wash three to four times, and in the process carefully transfer all of the beads to a 15-ml tube for storage, ensuring that all beads are transferred.

    One of the best tubes for storage of beads are 15-ml Falcon 2059 polypropylene tubes, as the beads do not adhere to the walls and resuspend easily from the round base.

19. Wash the beads once by resuspending them in 5 bed volumes of bead storage buffer, centrifuging 5 min at 1000 × *g*, 4°C, and removing the supernatant.

20. Add 2 bed volumes of bead storage buffer to the bead volume to make a 33% (v/v) slurry, and store at −20°C.

    The beads should never be allowed to freeze, which will cause the beads to crack. The presence of 50% glycerol in the bead storage buffer is essential to prevent this.

21. Perform SDS-PAGE (*UNIT 6.1*) and stain with Coomassie blue (*UNIT 6.6*) to analyze purification and quantitate amount of protein bound to GSH beads. Prepare samples and lay out gel as follows:

    a. *Molecular weight standards:* Serially dilute to provide a reference for estimation of protein on beads after gel is stained (see step 22). Alternatively, load four lanes with 2, 5, 10, and 20 µg BSA as a standard.

    b. *−IPTG and +IPTG induction controls:* Resuspend control pellets (step 7) in 80 µl of 1× SDS sample buffer, heat to 85°C for 5 min, and microcentrifuge 1 min at maximum speed. Load 10 µl of the supernatant on the gel.

    c. *Soluble, pellet, and through samples:* Add 10 µl of 3× SDS sample buffer to the 20 µl of sample, vortex, and heat to 85°C for 5 min. Load 10 µl on the gel.

    d. *Beads:* Using a cut-off pipet tip with an opening 1 to 2 mm in diameter, pipet 5, 10, or 20 µl (or all three to quantitate more accurately) of the slurry prepared in step 20 (ensuring the beads are well suspended by swirling or vortexing gently for ~10 sec) into a fresh MicroSpin column. Place in a collection tube and microcentrifuge 30 sec at 10,000 × *g* to remove bead storage buffer. Cap the bottom of the column well, add 30 µl of 1× SDS sample buffer, and cover with a punched cap. Heat at 85°C in a water bath for 5 to 10 min. Dry the outside of the column, and place in a fresh microcentrifuge tube. Microcentrifuge 30 sec at maximum speed to collect sample buffer and eluted protein. Load the entire volume on the gel.

Normalize the protein between different GST fusion proteins

Prior to performing the pull-down experiment (in Basic Protocol 1 or the Alternate Protocol) or the cross-linking (Support Protocol 2) it is necessary to approximate the amount of protein attached to the beads (milligram protein per milliliter beads).

22. Analyze the gel bands from 5, 10, and 20 µl of bead slurry on the gel (see step 21) by visual (or densitometric) comparison with the serially diluted markers to estimate the protein concentration on the beads.

    This is important even for a single GST fusion protein, but it is essential for multiple GST fusion proteins. When comparing a number of different GST fusion proteins in the same pull-down experiment, the same amount of protein must be used for each condition on the same amount of beads (see Basic Protocol 1).

23. Before performing pull-down experiments (Basic Protocol 1 or the Alternate Protocol) or cross-linking (Support Protocol 2), dilute each of the batches of beads to be used in the experiment with GSH beads that have been freshly washed as in step 13, to adjust them all to about the same protein concentration per milliliter of beads. If desired, confirm equal protein concentration by loading an equal small volume of all beads on SDS-PAGE (*UNIT 6.1*).

    The target is around 1 mg/ml, however the range can be rather large. A protein concentration of 0.05 mg/ml (5 µg on 100 µl beads) is about the minimum, while there is probably no maximum concentration; once the bed volume added to a pull-down becomes too small, it can become difficult to recover the beads from a large volume (unless they never leave the column, such as in the spin column–based pull-down experiment in Figure 17.5.2).

SUPPORT PROTOCOL 2

CROSS-LINKING GST FUSION PROTEINS TO GSH-AGAROSE

Perform this protocol only if the intention is to covalently couple a GST fusion protein to GSH beads. Cross-linking has a number of benefits and caveats, and these are discussed in Strategic Planning. The main chemical cross-linking agents used for this purpose are disuccinimidyl suberate (DSS) and bis(sulfosuccinimidyl) suberate (BS3). DSS is a water-insoluble, homobifunctional *N*-hydroxysuccinimide ester (NHS-ester), and BS3 is its water-soluble analog (both are available from Pierce). The main targets for NHS esters are primary amines. For proteins, cross-linking usually involves reaction with the side chains of amino acids. Only the ε-amine of lysine reacts significantly with NHS esters, as the N-terminal α-amine groups on a protein are not available for cross-linking. A covalent amide bond is formed when the NHS ester reacts with the primary amine, releasing N-hydroxysuccinimide. When cross-linking GST fusion proteins to GSH beads, the reaction must be between the primary amine of GSH (the α-amine of the γ-glutamyl residue is the only one available) and lysine residues in either recombinant GST or the attached fusion protein. Due to the length of the DSS molecule (11.4 Å), the former seems more likely, though the latter is not impossible. Due to reactivity with amines, cross-linking reactions should be performed in non-amine buffers such as phosphate, carbonate/bicarbonate, HEPES, or borate buffers to maximize coupling efficiency. Other buffers can also be used provided they do not contain primary amines; Tris buffers contain primary amines and must be avoided. A large excess of Tris at neutral-to-basic pH is added at the end of the reaction to quench it.

Since DSS is insoluble in aqueous solvent, it is first dissolved in an organic solvent (e.g. DMSO), then added to the aqueous reaction mixture. Cross-linkers fall out of aqueous solutions at the concentrations used for cross-linking, and a milky, turbid solution can be observed. Cross-linking will still proceed effectively. Storage of stock solutions for long periods (hours) is not recommended for either class of compounds, because NHS esters hydrolyze rapidly. The solvent DMSO is hygroscopic and absorbs water, which will

promote hydrolysis. BS3 is a more efficient cross-linker than DSS, primarily because it is not insoluble in aqueous solution; however, it is considerably more expensive.

This procedure is designed for the coupling of an ~0.3- to 1.0-ml bed volume of GST fusion protein beads.

Materials

GST fusion protein beads (prepared as in Support Protocol 1, with the protein concentration determined)
PBS (*APPENDIX 2A*)
Disuccinimidyl suberate (DSS), 13.2 mg in screw-cap tube (see recipe)
bis(sulfosuccinimidyl) suberate (BS3; see recipe)
Dimethylsulfoxide (DMSO; H_2O-free, i.e., fresh)
Quenching buffer: 1 M Tris·Cl, pH 8.2 (*APPENDIX 2A*), room temperature
Glutathione wash buffer (see recipe), room temperature
Wash buffer 1 (see recipe), ice-cold
Cross-linking wash buffer: 25 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)/1.5 M NaCl, ice-cold
Bead storage buffer: 20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)/50% (v/v) glycerol
Appropriately sized columns (e.g., Bio-Rad 2-ml Bio-Spin columns or 10-ml Poly-Prep columns)

Cross-link beads

1. Pipet the required volume of GST fusion protein beads to be cross-linked into a suitably sized plastic column (which can also be capped at both ends, e.g., Bio-Rad Bio-Spin 2-ml column), and allow to drain. Keep a 10-µl bed volume aliquot of starting beads for SDS-PAGE analysis of cross-linking efficiency at the end of the protocol (step 14).

   If the beads have been stored in 50% glycerol (i.e., bead storage buffer in Support Protocol 1), the column will not drain, due to the viscosity. It can be assisted by the use of a vacuum line or gentle centrifugation into a collection tube (5 min at 500 to 1000 × g). Make sure that the beads do not dry out.

2. Wash the column with four 2-ml washes of PBS. Let all the solution drain out.

   This is required to thoroughly remove any traces of amines, such as Tris.

3. Plug the bottom of the column and add 0.5 ml PBS. Flick gently to resuspend the beads.

4. Dissolve 13.2 mg of DSS in 1 ml of dry DMSO to make a 35.8 mM solution. Dilute this 1 ml of DSS solution into a clean tube containing 1.5 ml of PBS at room temperature.

   The DSS solution must be made fresh, immediately before use; do not store this reagent.

   The 35.8 mM DSS stock solution is a good place to start in most cases, but it may not always be ideal. Generally, if the exact amount of protein is known, a 20- to 50-fold molar excess of the cross-linker is appropriate. The final cross-linker concentration in the reaction should be between 0.25 and 5 mM.

   BS3 is added to a cross-linking reaction at the same molar concentration as DSS. Due to its aqueous solubility, it can be added directly to a protein solution. If desired, a 35.8 mM stock solution can be prepared by dissolving 20.5 mg of BS3, immediately before use, in 1 ml of 5 mM sodium citrate, buffer pH 5.0. This stock solution should be added in a dropwise fashion to the reaction.

5. Immediately add the diluted DSS solution to the prepared GST fusion protein bound to the column (step 3), at room temperature. Plug both ends of the column and suspend the beads by repeated gentle inversions and by tapping the gel-bed end of the column (alternatively, gently mix with a fine spatula). Incubate 45 min at room temperature, with continuous mixing or inversion.

   When DSS is added to the aqueous buffer it may become very cloudy. This is normal, and cross-linking will still proceed.

6. After the reaction is complete, remove the top cap first, then the bottom cap. Place the column inside a collection tube. Drain the column, but do not allow the beads to run completely dry, then plug the bottom.

Block amine-reactive sites on beads

7. Add 2 ml quenching buffer to the column. Mix it in and gently invert the column for 10 min at room temperature.

   This blocks all amine-reactive sites that may still be present after the cross-linking reaction, preventing any other proteins from being covalently coupled to the beads.

8. Drain the column, but do not allow the gel to run completely dry, then plug the bottom.

9. Wash the column four times, each time by adding 3 ml freshly prepared glutathione wash buffer at room temperature, and allowing it to pass through. Keep an aliquot of the eluate to run on a gel later (step 14).

   This step removes GST fusion protein that is not covalently coupled to the glutathione beads. Keeping the eluate allows the assessment of any eluted GST fusion protein, and thus gives a crude index of the coupling efficiency.

Wash beads

Switch back to 4°C for the washing steps.

10. Wash the column by adding 4 ml of ice-cold wash buffer 1 and allowing it to pass through.

    The column can be on the laboratory bench (at room temperature) for the washing, but keep the buffers ice cold.

11. Wash the column twice, each time with 4 ml of ice-cold cross-linking wash buffer.

12. Wash the column twice, each time with 4 ml of ice-cold wash buffer 1.

13. Add twice the bed volume of bead storage buffer, resuspend the beads by gently flicking the column, and store capped at −20°C up to 4 to 6 months.

14. Analyze 10 µl of starting beads, 20 µl of the GSH elutions (step 9), and 10 µl of the final cross-linked beads on an SDS-PAGE mini-gel.

    Ideally, there should be no or little protein on the gel from the GSH elutions, and no protein from the final cross-linked beads. Practically, there are often faint bands in the elutions and occasionally a trace in the final beads. This level of protein can still be acceptable for use in pull-down experiments, depending on the initial reason for performing the cross-linking. Greater levels of protein in either the elutions or the final beads indicates that the reaction was inefficient and probably insufficient for use.

PREPARATION OF LARGE-SCALE TISSUE LYSATES

This method is for preparation of two liters of sheep brain cytosol, peripheral membrane, and integral membrane lysates for use with GST fusion–protein pull-down experiments. Alternatively, a whole-tissue lysate (Triton X-100 extract) can be prepared. The samples are prepared and frozen as fifty 40-ml aliquots in 50-ml screw-cap tubes, ready to thaw, centrifuge, and then use immediately. The aliquots provide a rapid source of protein that can be stored in the freezer until required. Lysates are stored at −20°C for up to 6 months and could be stored longer at −70°C. Generally, it is best to use the lysates when they are as fresh as possible. For other tissues, this method may need to be adapted or scaled up or down. However the protocol below gives a good indication of the optimal tissue-derived protein amounts required for identification of the major proteins that bind to a particular GST fusion protein. Using less tissue will work, but this amount is optimal for obtaining the largest number of interacting proteins.

Materials

200 g sheep brain (see recipe)
Buffers A, B, C, and D (see recipes; prepare in advance and cool overnight to 4°C)
GSH-agarose beads (e.g., glutathione-Sepharose 4B; Amersham Biosciences)
10% (v/v) Triton X-100

Colander or tea strainer
1-liter plastic beakers
Ultra-Turrax tissue homogenizer (IKA Labortechnik) with 25-mm-diameter blade/tip
Refrigerated centrifuge and 0.5-liter centrifuge bottles
Miracloth (Calbiochem)
50-ml screw-cap plastic tubes

NOTE: Sometimes precipitates accumulate during freeze/thaw of these samples, and this is particularly true for the peripheral membrane extract (see note above). All frozen aliquots must be centrifuged after defrosting at 35,000 × *g* (or maximum speed) for 30 min at 4°C, before incubation with recombinant GST fusion protein beads. It is essential to clear any debris before adding the extract to the beads. It may also be useful to pre-clear the cytosol extracts a third time before use, to remove any remaining traces of endogenous GST (this is optional; see Basic Protocol 1 or the Alternate Protocol). All volumes of beads in this protocol refer to bed volumes.

Extract cytosolic protein

1. Defrost 200 g frozen sheep brain by placing the pieces in 1 liter of buffer A that is being stirred at 10°C**,** (add the brains to the buffer, rather than vice versa) and leaving them until they start to sink (after ~7 min). Strain the brains with a colander or tea strainer and place them in 2 liters of ice-cold buffer B.

   Sheep brain can be replaced with rat brain (one rat brain weights ~1.85 g; 40 rats = 74 g), but at considerable expense.

   Alternatively, for a whole-tissue lysate, add 0.5 liter buffer D (instead of buffer B) and skip directly to step 17. Make sure the homogenate is free of particulate matter by an additional centrifugation in step 17, followed by filtration through Miracloth, before proceeding to step 18.

2. Homogenize brains in four 500-ml lots of buffer B (in 1-liter plastic beakers) with an Ultra-Turrax (i.e., an homogenizer with sharp blades, not a Teflon/glass homogenizer), using a 25-mm diameter blade/tip and a speed setting of 19,000 rpm.

   This should be performed in 1-liter plastic beakers (to minimize risk of breaking glass).

3. Centrifuge homogenate in 0.5-liter centrifuge bottles 30 min at 18,000 × *g*, 4°C.

   If the available centrifuge cannot manage large volumes at 18,000 × g, then use the maximum speed wherever this is indicated in this protocol.

4. Collect the supernatant and filter through Miracloth to remove floating particulate matter.

   Keep the pellet on ice for step 10.

5. Centrifuge the filtrate again as in step 3 and filter through fresh Miracloth again.

6. Wash 8 ml of GSH-agarose beads in a 50-ml screw-cap tube by centrifuging 5 min at 500 × *g*, 4°C, and carefully remove the supernatant. Resuspend the pellet in 50 ml of buffer B and centrifuge again 5 min at 500 × *g*, 4°C. Discard the supernatant, and pre-clear the cytosol extract by incubating 20 min with 2 ml of the prewashed beads at 4°C with continuous stirring. Filter the pre-cleared cytosol extract through clean Miracloth.

   Do not use a stir bar to stir the extract with beads, as the beads may be crushed and will then pass through the Miracloth.

7. Repeat the pre-clearing step with an additional 2 ml of fresh GSH-agarose beads.

   The multiple pre-clearing steps are performed to remove the enormous amounts of endogenous GST protein from the brain (particularly the brain cytosol), which would interfere with the subsequent pull-down experiments.

8. Filter the precleared cytosolic protein extract through clean Miracloth to collect the GSH-beads.

   Pool the GSH beads with the previous volume for later recycling (see Support Protocol 4).

9. Divide the cytosol into fifty 40-ml aliquots in 50-ml plastic tubes with screw-cap lids, freeze on dry ice, and store up to 6 months at −20°C.

Extract peripheral membrane protein

10. *Wash 1:* Rehomogenize the pellet from step 4 in 2 liters of buffer B (see step 2) and centrifuge (see step 3).

    This is simplified by leaving the homogenate in the same centrifuge bottle and rehomogenizing within that bottle.

11. *Wash 2:* Remove and discard the supernatant, then repeat the homogenization and centrifugation.

12. Remove and discard the supernatant. Rehomogenize the pellet in 500 ml of buffer C using the technique described in step 2. Stir in a beaker in the cold room for 20 min, then centrifuge 30 min at 35,000 × *g*, 4°C. Remove the supernatant and centrifuge it again for 30 min at 35,000 × *g*, 4°C.

13. Collect the supernatant as peripheral membrane extract and dilute to 2 liters with buffer B. Add 10% Triton X-100 solution to a final concentration of 0.1%.

    Keep the pellet for step 16.

    Since no extra salt is added beyond that in the buffer C that was added in step 12, the final NaCl concentration is reduced to 125 mM, which is more appropriate for pull-downs than 0.5 M. The addition of Triton X-100 is required to prevent the formation of excessive protein precipitates that occur with this peripheral membrane extract during pre-clearing steps and during pull-down experiment incubations. This precipitation only occurs with this extract and seems to be triggered by freeze/thawing and incubation with beads. It is not removed by prior centrifugation, but it is prevented by addition of trace amounts of Triton X-100 (0.1% v/v final concentration). It is worth keeping in mind that the presence of this detergent may interfere with some protein-protein interactions.

14. *Pre-clearing:* Incubate the peripheral membrane extract with 2 ml prewashed (step 6) GSH-agarose beads for 20 min at 4°C with continuous stirring. Filter the precleared peripheral membrane protein extract through Miracloth.

    For the peripheral membrane, it is not necessary to repeat the pre-clearing, since there is much less endogenous GST in this fraction than there is in the cytosol.

    Pool the GSH beads with the others (from steps 6 to 8) for recycling.

15. Divide the peripheral membrane extract into fifty 40-ml aliquots in 50-ml tubes with screw-cap lids, freeze on dry ice, and store at −20°C for up to 6 months.

Extract membrane protein

16. Wash the pellet from step 13 once with 1 liter buffer C by rehomogenizing (as in step 2) and centrifuging as in step 3. Discard the supernatant.

17. Rehomogenize the pellet in 500 ml of buffer D using the technique described in step 2. Stir in the cold room for 20 min in a beaker, then centrifuge 30 min at 35,000 × *g*, 4°C.

18. Collect the supernatant as membrane extract and immediately dilute to 2 liters with buffer B, to match the volume of the cytosol. Discard the pellet.

    Since no extra Triton X-100 is added beyond that present in the buffer D, the Triton X-100 is diluted to 0.25%.

19. *Pre-clearing:* Incubate the membrane extract with 2 ml pre-washed (step 6) GSH-agarose beads for 20 min at 4°C (keep stirring). Filter the precleared peripheral membrane protein extract through clean Miracloth to collect the beads.

    For the membrane, it is not necessary to repeat the pre-clearing, since there is much less endogenous GST in this fraction than there is in the cytosol.

    Pool the GSH beads with those from the other extracts, and recycle them for reuse as described in Support Protocol 4.

20. Divide the membrane extract into fifty 40-ml aliquots in 50-ml tubes with screw-cap lids, freeze on dry ice, and store up to 6 months at −20°C.

SAMPLE PREPARATION FOR MASS SPECTROMETRY

BASIC PROTOCOL 2

Enzymatic in-gel digestion of SDS-PAGE-separated proteins followed by mass spectrometry (MS) analysis and database searching is now a common approach for identifying unknown proteins from a semipurified system such as a pull-down experiment. The following is a step-by-step protocol to take protein samples from an unstained SDS-PAGE gel through proteolytic digestion to a peptide mixture ready for analysis by MS. First, an SDS-PAGE gel, prepared and run in Basic Protocol 1 or the Alternate Protocol, is stained and analyzed for protein bands that bind specifically to the target protein (see Anticipated Results). The bands of interest are excised and completely destained to remove any stain that might interfere with subsequent proteolysis and MS analysis. Treatment with protease (usually trypsin) digests the protein within the gel piece, and the resulting peptides are extracted, concentrated, and analyzed by MS. Techniques for performing MS analysis are not described here, as they are beyond the scope of this unit (some techniques are described in *UNIT 5.6;* see Chapter 16 in Coligan et al., 2003, for a full treatment). It is envisaged that many researchers would utilize a service (institutional or commercial) for their MS analysis; therefore, suitable methods for shipping SDS acrylamide gels and gel pieces are outlined.

Two different MS-compatible options are presented for staining of SDS acrylamide gels: colloidal Coomassie blue and zinc-imidazole stain. Either staining technique is particularly suitable for routine use in this protocol. There are other MS-compatible stains not described in this protocol. One of these is the silver stain, a highly sensitive stain that enables detection of low nanogram quantities of protein. One must ensure that the chosen silver stain protocol does not contain a glutaraldehyde fixation step, as this interferes heavily with MS analyzes. The most widely used compatible silver stain is that described by Shevchenko et al. (1996). It is important to convert the silver in the excised gel piece to a soluble form and remove it from the gel piece completely for MS analysis. Another staining method utilizes the fluorescent dye SYPRO Ruby, which is highly suitable for MS as it requires no destaining (Berggren et al., 2002; *UNIT 6.6*). This has the disadvantage that it requires specialized imaging equipment to observe the stained bands, but it is a very simple technique that is highly sensitive (comparable with silver stain).

The colloidal Coomassie blue stain (Neuhoff et al., 1988) is a rapid gel staining method that is slightly superior in sensitivity and reliability of quantitation when compared with traditional noncolloidal Coomassie brilliant blue stain (which is usually dissolved in acetic acid/methanol or trichloroacetic acid). The colloidal stain is faster than other stains since there is no need for strong destaining steps. In fact, destaining of the whole gel is not required at all, though it does help to better visualize the lower-intensity protein bands. Destaining is performed only briefly in high-quality water, thus avoiding acids and improving protein identification by mass spectrometric techniques. Acidic residues of proteins can become methylated when SDS-PAGE gels are kept for prolonged periods in acetic acid, making it harder to identify the protein. Additionally, colloidal Coomassie can be easily destained from a small gel piece. Coomassie blue has a distinct appearance in mass spectra, a variable peak of m/z ~800 to 850 Da (often 804 or 832 Da). If this is a strong peak in the spectra, it can significantly interfere with detection of weaker samples, particularly in MALDI-TOF MS. Additionally, the presence of Coomassie in a gel piece can inhibit trypsin's proteolytic activity, so that digestion may not proceed efficiently. Therefore, effective destaining of a Coomassie-stained gel piece is essential for analysis by MS.

The zinc-imidazole negative staining method is fast, simple, sensitive, and highly compatible with MS (Castellanos-Serra and Hardy, 2001). It is also gentle, as there are no acids, dyes or chemical modifiers. The sensitivity of the method (>10 ng protein) is better than Coomassie blue staining (>100 ng protein) and approaches that of silver staining (1 to 10 ng protein/band). Therefore, this negative stain often reveals bands not stained with Coomassie (Fernandez-Patron et al., 1995). It is also completely reversible. The stain is a negative, or reverse stain: it relies on precipitation of a zinc salt in the part of the gel matrix that is not occupied by proteins. Imidazole reacts with Zn^{2+} to produce insoluble zinc imidazolate, which is a deep white. Proteins inhibit the formation of zinc imidazolate and therefore appear clear. Protein bands are visualized by placing the gel above a dark surface, e.g., black paper or plastic. Negative staining techniques do not offer as much contrast as a positively stained gel, and they are therefore not ideal for quantification purposes. Also, it should be noted that the zinc-imidazole stain is not retained when the gel is dried. On the positive side are the great speed of this method and the fact that no stain is attached to protein, which avoids unwanted chemical modifications. Finally, one should note that not all staining methods will detect all proteins, and some may be missed by any of these approaches.

It is also possible to excise and in-gel digest bands from dried gels for analysis by MS (but not from zinc-imidazole negatively stained gels). However, a small reduction in peptide recovery after in-gel tryptic digestion is observed when compared with wet gels

that have not been dried. Therefore, it is recommended that wet gels be used as a first preference for the procedures described in this protocol. If dried gels are to be used, begin from step 10, carefully excising the band with a sharp scalpel blade. The dried gel piece will reswell upon washing with water (step 13a or b). At this point it is important to remove any and all pieces of cellulose membrane (commonly used for gel drying procedures), which will detach from the gel as it swells, then proceed with destaining and in-gel digestion in the protocol as described.

The protocols for in-gel protein digestion are well established, fairly simple, and straightforward. Very often, key handling procedures during the sample preparation steps are overlooked because they seem easy and nonchallenging. Weeks and months of work can easily be jeopardized because the sample was contaminated or wasted in the final steps before MS analysis. Therefore, several general experimental considerations apply to all stages in this protocol. Precautions need to be taken, mainly to avoid contamination of the samples with various substances that will interfere with MS analysis. These precautions are:

1. Lab coats and powder-free gloves must be worn at all times. Use the highest-grade purity chemicals available, including the highest-grade laboratory water.

2. Take particular care to avoid protein contamination from skin, hair, and saliva (one of the most common interfering substances for MS protein identification is keratin) at all steps, including scanning and drying of SDS acrylamide gels and cutting and washing of stained bands. Avoid talking, coughing, sneezing, or breathing directly over the sample.

3. Keep samples covered or capped at all times unless being processed. Use cleaned tools and containers for anything that will come in contact with the samples.

4. Always use high-quality microcentrifuge tubes and pipet tips to avoid polymer contamination and loss of peptide sample through binding to plastic. Either siliconized, hydrophobically coated or highly polished plastics are recommended.

5. Heating gel pieces or peptide samples should be avoided. When using the Speedvac evaporator, the heat setting is not recommended.

6. Check with the mass spectrometry service first, to obtain additional advice on how to prepare, store, and ship the samples for analysis, and strictly follow their instructions.

Two different protocols for staining SDS acrylamide gels are presented, the colloidal Coomassie and zinc-imidazole negative stain. Either protocol is appropriate for the purposes of this unit, so both are described.

Materials

Unstained SDS acrylamide gel (Basic Protocol 1 or Alternate Protocol)
Colloidal Coomassie stain (see recipe)
1% (v/v) acetic acid
Zinc stain solutions I and II (see recipes)
50% (v/v) and 100% acetonitrile
25 and 50 mM ammonium bicarbonate (prepare from 1 M stock; see recipe)
25 mM ammonium bicarbonate in 50% (v/v) acetonitrile (prepare from 1 M ammonium bicarbonate stock; see recipe)
Zinc destain solution (see recipe)
Digestion buffer (see recipe), ice-cold
5% (v/v) formic acid
50% (v/v) acetonitrile containing 0.1% (v/v) trifluoroacetic acid (TFA)

Sealable plastic containers of appropriate size for gel
Platform shaker
Flatbed scanner (preferably with transparency adapter for Coomassie stain)
Computer running graphics software, e.g., Adobe Photoshop
Light box
Scalpel (with new blades) or fine-gauge needles
Siliconized, hydrophobically coated, or highly polished plastic microcentrifuge tubes (e.g., Axygen Maxymum recovery clear 0.6-ml tubes), pipet tips (Axygen Maxymum recovery pipet tips), and gel-loading tips (e.g., Sorenson Multi Miniflex round sterile gel loading pipet tips, 0.1 to 10 µl)
Stainless steel mortar and pestle (e.g., Quantum Scientific)
Heat-sealable plastic sleeves and heat sealer
Pieces of cardboard and large sturdy flat box to accommodate gels
50-ml screw-cap tubes
Heavy-gauge needle
Thermomixer/shaker (to fit microcentrifuge tubes)
Bath sonicator

Stain the gel

For colloidal Coomassie staining

1a. After running the gel, immediately rinse the whole gel with water at room temperature at least three times (each time for 5 min) before proceeding with the stain.

This step is to remove any traces of SDS remaining on the gel, which could lead to high background and reduced protein staining.

2a. In a container with a cover that can be sealed, cover gel with enough colloidal Coomassie stain so that gel can float freely. Seal the container (to avoid methanol evaporation or contamination) and incubate 1 hr to 3 days with gentle shaking or rocking at room temperature.

The gel must float freely, or it may tear during staining.

Most proteins are detectable after ~1 hr, even while still in the stain solution. Weaker bands show up better within a few hours (normally 3 hr). For quantitative staining, the gel should be left in the solution for ~24 hr (up to 3 days), but this is not usually required.

It is not possible to overstain the gel, and over 1 to 3 days the staining increases slightly in sensitivity.

3a. Destain by immersing in two to three changes of Milli-Q purified water for 15 to 30 min each.

Faint bands often become much clearer after destaining. Very little background staining is encountered with this protocol.

4a. If destaining goes too far, or if the gel was not left in the initial stain for >3 hr, restain as in step 2a.

In many cases restaining actually enhances band detection after a second round of staining. Restaining can be done at any time.

5a. Store gels up to 2 weeks in water at 4°C (to prevent bacterial or fungal growth) or for longer periods in 1% (v/v) acetic acid.

It is highly desirable to excise the target protein bands within a few days of gel staining (see step 10) to avoid artifacts arising from storage.

For zinc-imidazole negative staining of SDS gels

1b. After running the gel, immediately rinse it twice in Milli-Q purified water for up to 5 min each time.

Free glycine can bind to zinc and interfere with the staining process.

2b. Cover the gel with zinc stain solution I and leave on a shaker for 15 min.

3b. Pour off the solution and rinse once quickly with distilled water for 10 to 30 sec.

This rinse step must be very brief. Do not leave the gel in the rinse even for a couple of minutes or the stain will wash out.

4b. Cover the gel with in zinc stain solution II for 35 sec.

The gel background will rapidly appear as a milky precipitate. If the gel is left in this solution longer than 35 sec the stain will begin to fade. To prevent overstaining, proceed quickly to the next step. The timing here also depends somewhat on the acrylamide percentage. Thus, at low acrylamide (~7.5%), <35 sec may be slightly better, while for higher acrylamide (~15%), 40 to 45 sec may be better.

5b. Pour off the solution and immediately rinse three times in Milli-Q purified water (each time for ~1 min), then leave the gel in Milli-Q purified water.

A transparent container will enable the bands to be visualized when placed above a dark background like black paper.

Analyze the stained gel

6. Search the gel for bands that appear to be specific for a particular condition and are absent from the controls, as described in Anticipated Results.

Scan the stained gel

7. For documentation purposes, obtain a quality scan (or a photograph) of gels before excising the bands of interest. For Coomassie-stained gels, use a flatbed scanner (preferably with a transparency adaptor, i.e., a light box in the lid) to record the gel stain. For zinc-imidazole negative staining, record an image by placing the gel onto a flatbed scanner and covering it with a black piece of paper or plastic.

For some scanners it is necessary only to simply leave the lid of the scanner open while recording the zinc image.

For large gels, scan at least at 600 dpi, TIFF format, in 8-bit color. Use LZW compression to keep the file size to a minimum.

8. Using graphics software like Photoshop, convert a copy of the TIFF file to the much smaller JPEG format and then insert the JPEG image into a drawing program (e.g., Microsoft Powerpoint, or CorelDraw). Draw rectangular shapes around the bands of interest and place a simple, unique label next to each one. Use exactly the same labels on the microtubes with the samples as in the computer file. Cover the labels with tape so the writing does not rub off during subsequent steps.

This serves as a laboratory record, and a copy can be sent to an MS service as well. If it is intended to send the whole, intact gel to an MS service, skip to step 13a.

Excise bands

9. Inspect the hydrophobically coated or highly polished pipet tips and microcentrifuge tubes for dust prior to use. If unsure, rinse the microcentrifuge tubes with 50% acetonitrile, followed by water, prior to use.

10. Rinse the whole gel with water and (wearing powder-free gloves) place on a cleaned glass plate over a light box.

For band cutting, work in a clean filtered forced-air-flow hood if possible. If not, clean the bench area thoroughly with ethanol or methanol.

11. Excise the band of interest with a clean scalpel or needle, cutting as close to the edge of the band as possible.

Remember to change scalpels and needles between samples to avoid cross-contamination. Alternatively, rinse the scalpel after each band first with ethanol, then with water.

It is important to reduce the volume of the background gel that is excised. Keep the amount of excess acrylamide included around the band to a minimum. For very large or fat bands, a piece from the center or side is often all that is required.

12. Carefully transfer the gel piece to a clean, labeled microcentrifuge tube.

Store and ship intact gels and gel pieces

It is preferable to not store gels or gel pieces for prolonged periods, but the following guidelines are provided to prevent unwanted spoilage if this is necessary. Additionally, if the researcher is using a commercial or institutional MS service, these often require that the intact gels or excised gel pieces are shipped to them for analysis. Therefore, appropriate handling techniques for shipping these are described here, and the remainder of this protocol does not need to be followed. If it is intended to perform in-gel protein digestion and peptide extraction, then continue with step 14.

13a. *For intact gels:* Store intact gels at 4°C submerged in water for no more than 2 weeks, in a covered container to avoid drying out or contamination. Do not store the gels on the bench or they will grow mold. Alternatively, heat seal them in a strong thoroughly rinsed plastic sleeve for storage at 4°C. Ship intact gels in a few milliliters of water in a heat-sealed plastic bag, packaged in such a way as to avoid tearing or having the gel fold over on itself—e.g., place the heat-sealed bag between rigid pieces of cardboard to keep the gel flat, then place the assembly in a large sturdy flat box.

13b. *For excised gel pieces:* Store excised gel pieces (sometimes referred to as gel plugs) in sealed microcentrifuge tubes either at 4°C submerged in a small volume of water or at −20°C without water for months. Ship gel pieces, each in a separately labeled microcentrifuge tube, submerged in a small volume of water (e.g., 50 µl) to prevent the gel slices from drying out; place the microcentrifuge tubes in a 50-ml screw-cap tube to protect them from being crushed in transit.

Wash and destain the excised gel pieces

For destaining colloidal Coomassie–stained gel pieces

14a. Discard the storage solution. Rinse gel pieces three times, each time by adding 100 µl water and incubating 10 min at room temperature with shaking, then removing the liquid.

Coomassie blue interferes with the MS analysis and inhibits tryptic digestion. Therefore it is removed prior to tryptic digestion. The number and the duration of the following washing steps depends on the sample itself. Some bands destain easily and may only need a few rinses with water and a single step with 100% acetonitrile, while others are more stubborn and may need several rounds of ammonium bicarbonate/acetonitrile (CH_3CN). Under no circumstances should one proceed with trypsin digestion until the gel pieces are completely clear and colorless.

The use of a mixer/shaker (suitable for microcentrifuge tubes) or occasional vortexing at room temperature is recommended for all washing and destaining steps. Use gel-loading tips, to prevent aspirating the gel particles when removing and discarding the liquid after each change of solution during the wash steps. Change tips between different samples. A

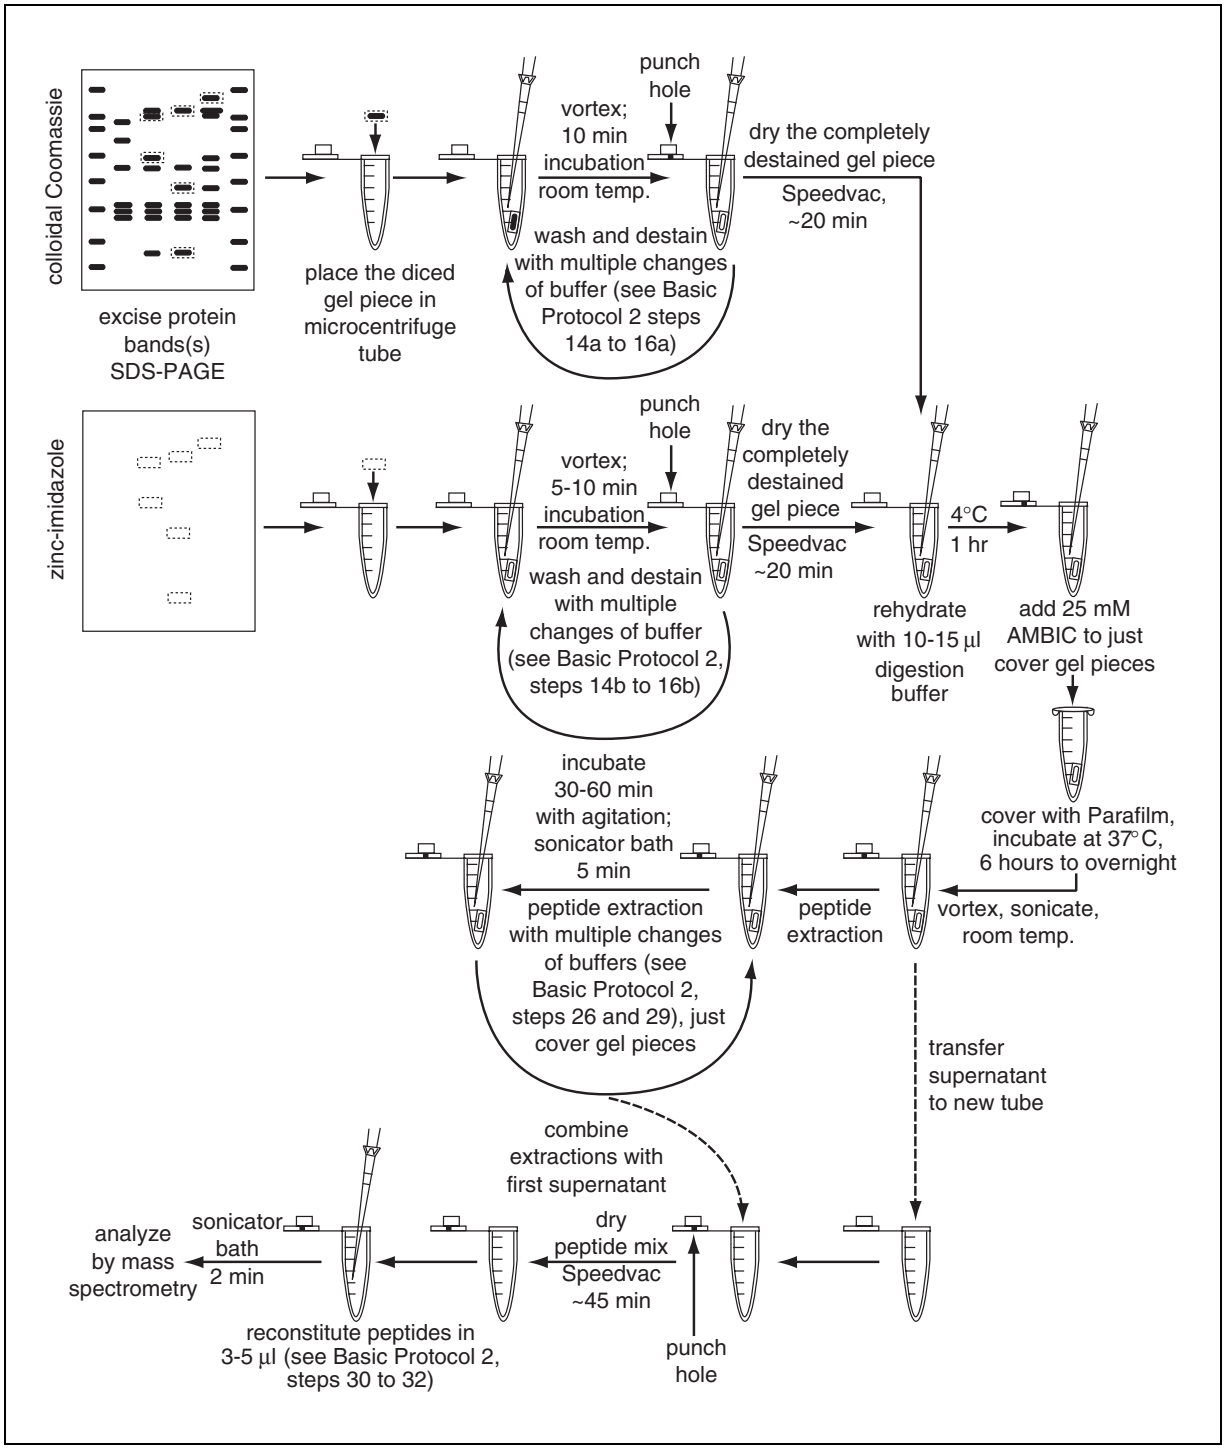

Figure 17.5.3 Schematic of Basic Protocol 2 describing the in-gel digestion technique and peptide extraction steps. For graphical reasons, the gel pieces are depicted as whole (to show the state of the stain), but would in practice be diced. Refer to the main body of the text for more details. Abbreviation: AMBIC, ammonium bicarbonate, pH 8.0.

schematic diagram of the remainder of this protocol can be found in Figure 17.5.3, though it is best to use the figure while paying close attention to the text of the following steps.

15a. Add 100 µl of 25 mM ammonium bicarbonate in water to equilibrate the gel particles. Incubate for 30 min to overnight with shaking. Remove liquid. Wash gel pieces three times, each time by adding 100 µl of 25 mM ammonium bicarbonate in 50% acetonitrile, incubating 10 min at room temperature with shaking, then removing the liquid.

16a. Add enough 100% acetonitrile to just cover the gel particles (which should become white and stick together). Change the acetonitrile once after 5 min. Remove the liquid. Add 100 µl of 50 mM ammonium bicarbonate, leave for 5 min, then add an equal volume of 100% acetonitrile (to make a final concentration of 25 mM ammonium bicarbonate in 50% acetonitrile). Incubate for an additional 5 to 10 min with shaking. Remove liquid.

In this step the gel particles are completely dehydrated with neat acetonitrile to allow the subsequent aqueous solution to better access the center of the gel piece, giving a better chance of removing any stain.

For destaining zinc-imidazole negative stained gel pieces

14b. Discard the storage solution. Rinse gel pieces three times, each time by adding 100 µl water and incubating 10 min at room temperature with shaking, then removing the liquid.

15b. Add 200 µl of zinc destain solution per gel piece, vortex, and incubate with shaking for 5 to 10 min at room temperature until gel piece is completely clear. Remove the liquid.

A zinc chelator is required to destain the gel. Glycine (present in the zinc destain solution) is suitable for this purpose. The pH must be kept in the neutral to basic range to avoid precipitation of the protein in the gel.

16b. Wash gel pieces four times, each time by adding 1 ml water and incubating 10 min at room temperature with shaking, then removing the liquid.

This step is to dilute the glycine, which will interfere with subsequent staining or analysis.

Grind and dehydrate the gel pieces

17. Using a clean stainless steel mortar and pestle, grind each of the excised bands into smaller particles inside the tube. Alternatively, use a long needle to carefully cut it into cubes (~1 mm to a side) inside the tube.

This step is to increase the surface area in contact with buffer and to minimize the volumes of the solutions used in the subsequent in-gel digestion and extraction of the resulting peptide mixture.

18. Add sufficient 100% acetonitrile to just cover the gel particles and leave for 5 min to dehydrate. Remove the liquid.

19. Pierce a hole, if one is not already present, in the lid of the microcentrifuge tube using a heavy-gauge needle to allow for evaporation. Completely dry the gel particles in a Speedvac evaporator (~20 min).

The gel pieces should shrink, become white and stick together. At this point the destained gel pieces can be stored at 4°C for months.

Perform in-gel tryptic digestion

20. Rehydrate the dried gel particles in 10 to 15 µl of freshly prepared ice-cold digestion buffer (use just enough to cover the sample).

Gel pieces should expand and change from white dry pellets back to transparent gel pieces.

21. Incubate the samples at 4°C (sitting on ice) for about 1 hr.

This will allow the trypsin to enter the gel pieces, while it remains inactive at 4°C.

22. After 1 hr, if the initial liquid is fully absorbed, add 10 to 15 µl of 25 mM ammonium bicarbonate in water (without trypsin), or just enough to cover the gel particles.

It is necessary to have a small excess of solution covering the gel piece, so that the gel piece does not dry out during the subsequent 37°C overnight incubation (step 23).

23. Cap the tubes and wrap the tops with Parafilm to seal them. Transfer the tubes to an incubator at 37°C for overnight digestion.

    At 37°C, the trypsin (which had previously entered the gel piece during rehydration) is active and digests the proteins from within the gel piece.

    Most proteins should be completely digested by trypsin after 4 to 6 hr. However samples are usually incubated overnight for convenience. The extraction of the resulting peptide mixture could then take place on the following day.

Extract the peptides

24. Next day, microcentrifuge the tubes briefly at maximum speed to get the condensation to the bottom of the tubes. Vortex the tubes or sonicate (in a mild sonicator bath) for 1 to 5 min.

    This step is to assist the peptides to diffuse from the gel piece into the solution.

25. Microcentrifuge briefly at maximum speed (to force all the sample to the bottom of the tube) and transfer the supernatant to a fresh microcentrifuge tube.

    The supernatant should contain most of the tryptic peptides. If performing MS on-site, then take a small aliquot (0.5 µl) for immediate analysis.

    This first extraction step has a lower extraction efficiency but is quick, and there is less sample loss because the samples are not dried in a Speedvac evaporator. Subsequent extractions in organic phase are needed for recovery of hydrophobic or long peptides.

26. Wash gel pieces by adding ~25 µl (or enough) 25 mM ammonium bicarbonate in water to just cover them, then removing the liquid and combining it with the supernatant from step 25.

27. Add 20 µl of 5% formic acid, incubate 10 min, then add 20 µl of 100% acetonitrile (final concentration of 2.5% v/v formic acid and 50% v/v acetonitrile) to the gel pieces and incubate for 20 to 30 min at room temperature with shaking.

28. Vortex or sonicate the gel particles and supernatant for 1 to 5 min. Microcentrifuge briefly at top speed and collect the supernatant. Pool with the previous extract from step 25.

29. Add 20 µl of 100% acetonitrile for a single extraction of 20 min with shaking. Vortex or sonicate the gel particles and supernatant for 1 to 5 min. Microcentrifuge briefly at maximum speed, collect the supernatant, and pool it with the previous extracts.

30. Concentrate the pooled extracts in an Speedvac evaporator to near-complete dryness (5 µl).

    The aim is to reduce the sample volume and to remove volatile salts (such as ammonium bicarbonate).

31. Subject the samples to MS analysis (see remaining steps) or freeze them and store at −20°C for shipment to an MS facility.

    Alternatively, lyophilize the samples and store them at −80°C for long periods of time.

Reconstitution of tryptic peptides

32a. *For MS analysis by MALDI-TOF MS:* Resuspend the dried peptides in 3 to 5 µl of 50% acetonitrile/0.1% TFA.

32b. *For analysis by ESI-MS:* Resuspend the dried peptides in 0.1% v/v formic acid.

    The choice of reconstitution solvent system depends on the MS method to be used (see Strategic Planning). Some solvents (e.g., TFA) may not be universally compatible between approaches.

33. Sonicate for 2 to 5 min by immersion of the tubes in a bath sonicator, then microcentrifuge the tubes briefly (1 min) at maximum speed.

The optimal resuspension conditions may vary, depending on the chosen method of MS analysis (see Strategic Planning). The above techniques are suitable for general resuspension of dried peptides.

34. Analyze the reconstituted peptides by the MS method of choice (see, e.g., Coligan et al., 2003, Chapter 16).

SUPPORT PROTOCOL 4

RECYCLING OF GSH AGAROSE

GSH-agarose beads can be regenerated and reused, preferably for the same purpose (for example, preclearing of tissue lysates). In this support protocol, a method is described which removes bound endogenous GSTs from the GSH beads. Since large amounts of these beads are used in the preclearing steps (see Basic Protocol 1, the Alternate Protocol, and Support Protocol 3), it can be economical to recycle them for use in the next preparation of tissue lysates. It should be noted, however, that it is not recommended to recycle any beads that have had their bound proteins eluted for analysis by SDS-PAGE.

It is also worth noting that the GSH-agarose regeneration protocol described by the manufacturer (Amersham Biosciences) proved ineffective at removing the large quantities of bound proteins that are present after preclearing tissue lysates. The authors have found that many other treatments will remove bound endogenous GSTs from GSH agarose, including reduced glutathione, acidic glycine, and denaturants (such as SDS or guanidine). All of these treatments will remove an equivalent amount of GST from the beads (~95% after two washes); however, the order in which they are applied influences the ability to remove the remaining bound protein. Specifically, if denaturants are used initially, the protein remaining on the beads is rendered insensitive to removal by glutathione. Therefore, the optimal protocol is described herein—reduced GSH, followed by acidic glycine. After many cycles of reuse, the beads may lose some binding capacity from accumulated protein and hydrophobically bound material, so additional steps are included to remove these substances using detergents.

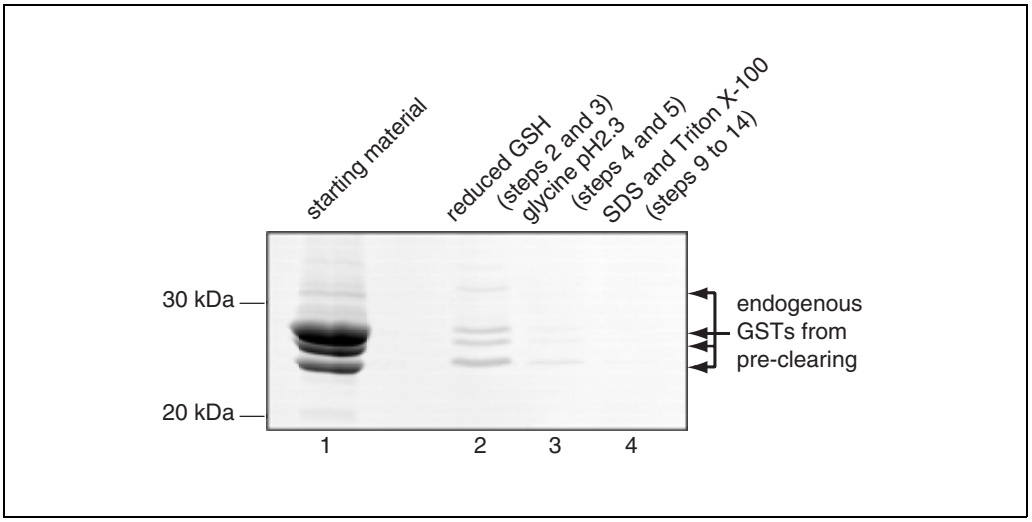

Figure 17.5.4 Regeneration of GSH agarose. The expected results from Support Protocol 4 are shown. Lane 1 shows the stained endogenous GST proteins present bound to a batch of GSH agarose that has been used for preclearing a tissue lysate. Lanes 2 to 4 show the sequential treatments which remove protein from the beads, and enable their reuse for preclearing procedures.

The sequential removal of bound endogenous GSTs that occurs from the utilization of this protocol is illustrated in Figure 17.5.4. After all the washes are performed, almost none of the endogenous GST protein remains bound to the beads.

Materials

Beads for recycling (from pre-clearing steps in Basic Protocol 1, the Alternate Protocol, or Support Protocol 3)
Glutathione wash buffer (see recipe), room temperature
Bead recycling buffer: 100 mM glycine hydrochloride, pH 2.3, room temperature
Phosphate buffered saline (PBS; *APPENDIX 2A*), room temperature
20% (v/v) ethanol
1% (w/v) SDS (see *APPENDIX 2A*)
0.1% (v/v) Triton X-100 (see *APPENDIX 2A*)
End-over-end rotator

1. Estimate or measure the bed volume empirically from the settled mass of beads. Take a small sample of the beads (20 to 40 µl bed volume) before recycling for later analysis by SDS-PAGE.
2. Elute the GST proteins from the GSH beads by adding ten times the bed volume of glutathione wash buffer and incubating 1 hr at room temperature on an end-over-end rotator. Centrifuge 5 min at 500 × *g*, room temperature, in a benchtop centrifuge, then carefully remove the supernatant by vacuum aspiration or decanting.

   This is a competitive elution of GST with glutathione.
3. Repeat step 2, for another 1-hr incubation with glutathione wash buffer.
4. Repeat step 2, but use bead recycling buffer in place of glutathione wash buffer.

   This step uses pH 2.3 glycine to effect greater elution. The authors have noted that bound GSTs are not eluted from GSH beads at pH 2.5, hence attention to pH is essential.
5. Repeat step 4, for another 1-hr incubation with bead recycling buffer.
6. Wash the GSH beads by resuspending them in ten bed volumes of room temperature PBS. Centrifuge 5 min at 500 × *g*, room temperature, in a benchtop centrifuge, then carefully remove the supernatant by vacuum aspiration or decanting. Repeat two additional times.
7. Wash once more as in step 6, but use ten bed volumes of 20% ethanol in place of the PBS.

   The ethanol is included as a preservative.
8. Store at 4°C in 20% ethanol as a 25% to 50% slurry.

   At this point the beads are largely clear of specifically bound endogenous GSTs. However, it is useful to analyze the beads for the absence of bound proteins by taking a small sample (20- to 40-µl bed volume) and analyzing the bound proteins, both before and after recycling by SDS-PAGE and Coomassie staining. If the beads show no protein bands (or very faint bands) after the above steps, they are suitable for reuse. If significant protein remains bound to the beads, continue with step 9.

   After multiple cycles of recycling, the GSH beads may lose some binding capacity and become unable to efficiently extract endogenous GSTs from tissue lysates. This may be due to an accumulation of precipitated, denatured or nonspecifically bound proteins and hydrophobically bound substances. If this is found to be the case, carry out the remaining steps of this protocol to remove these.

9. Incubate the beads twice, for 1 hr each (as in step 2), but with 10 bed volumes of 1% SDS.

   Note that GSH-agarose beads are stable to 1% SDS for up to 14 days at room temperature, without any loss in binding capacity.

10. Wash briefly with ten bed volumes of PBS, centrifuge 5 min at 500 × *g*, room temperature, and remove supernatant.

11. Wash beads as in step 6, but use 0.1% Triton X-100 (in water) in place of PBS.

    The Triton X-100 wash is included to remove more hydrophobic material, and to complex with any residual SDS that is present on or around the beads.

12. Wash the GSH-agarose beads three times with PBS, using the technique described in step 6 except without the 1-hr incubation.

13. Wash once more as in step 6 (without the incubation), but use ten bed volumes of 20% v/v ethanol in place of the PBS.

14. Store at 4°C in 20% ethanol as a 25% to 50% slurry.

    It may be necessary to re-evaluate the amount of protein bound to the beads by taking a sample (20- to 40-µl bed volume) and analyzing by SDS-PAGE.

REAGENTS AND SOLUTIONS

*Use Milli-Q purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Ammonium bicarbonate, 1 M

Prepare a 1 M stock solution, pH 8.0, by dissolving 0.79 g of ammonium bicarbonate in 10 ml water; there is no need to adjust the pH because it should be pH 8.0.

Store at room temperature for up a few weeks.

Bis(sulfosuccinimidyl) suberate (BS3)

Weigh out 20.5-mg aliquots of bis(sulfosuccinimidyl) suberate (B53; Pierce) into screw-capped tubes, flush with N_2 gas, and cap tightly. Store desiccated at −20°C. Immediately before use, dissolve one 20.5-mg aliquot in 1 ml of 5 mM sodium citrate buffer, pH 5.0 (38.5 mM final). Add the solution dropwise to the reaction.

Buffer A

20 mM Tris·Cl, pH 7.5
1 mM EGTA

Prepare 10 liters by dissolving 24.22 g Tris base in 10 liters water and adding 50 ml of 200 mM EGTA stock (see recipe), then adjusting the pH to 7.5 with concentrated HCl. Prepare fresh before use, store at 4°C.

Buffer B

20 mM Tris·Cl, pH 7.5
1 mM EGTA
7 µg/ml leupeptin
1 mM PMSF

To 9 liters buffer A (see recipe), add 3.15 ml of 20 mg/ml leupeptin stock. Prepare fresh and store at 4°C without PMSF. Add 5 ml of 100 mM PMSF stock (*APPENDIX 2A*) per 500-ml volume to each aliquot of buffer immediately before use.

PMSF is added immediately before use because it does not last more than 45 min in solution.

Buffer C

20 mM Tris·Cl, pH 7.5
500 mM NaCl
1 mM EGTA
7 µg/ml leupeptin
1 mM PMSF

To 1.5 liters buffer A (see recipe), add 43.8 g NaCl, 525 µl of 20 mg/ml leupeptin stock. Prepare fresh before use and store at 4°C without PMSF. Add 5 ml of 100 mM PMSF stock (*APPENDIX 2A*) per 500-ml volume to each aliquot of buffer immediately before use.

Buffer D

20 mM Tris·Cl, pH 7.5
1% v/v Triton X-100
1 mM EGTA
7 µg/ml leupeptin
1 mM PMSF

To 500 ml buffer A (see recipe), add 50 ml of 10% (v/v) Triton X-100 (*APPENDIX 2A*) and 175 µl of 20 mg/ml leupeptin stock. Prepare fresh before use and store at 4°C without PMSF. Add 5 ml of 100 mM PMSF stock (*APPENDIX 2A*) immediately before use.

Colloidal Coomassie Blue stain

Mix the following components in the order indicated. Weigh 170 g ammonium sulfate into a beaker. Add 340 ml of methanol, then 36 ml of concentrated phosphoric acid, and bring to 1 liter with water. Dissolve completely using magnetic stirring and heating to 60° to 70°C for 30 min or more (it is essential to fully dissolve the ammonium sulfate before proceeding). Add 1 g of Coomassie G-250 and again stir well to dissolve (to retain the colloidal dye particles this solution must not be filtered). Store up to 6 months at room temperature.

It is extremely helpful to let this stain settle in the bottle (i.e., by leaving the bottle to sit on the bench) for a day or more before use, and then to slowly decant the stain to a clean bottle, leaving the insoluble material behind. This removes/reduces the fine particulate matter which can adhere to the gel during staining. Do not recycle this stain, discard after each use.

Final concentrations: 17% (w/v) $(NH_4)_2SO_4$, 3% (v/v) phosphoric acid, 34% (v/v) methanol, and 0.1% (w/v) Coomassie Brilliant Blue G-250.

Digestion buffer

Reconstitute lyophilized trypsin (sequencing-grade porcine trypsin or Trypsin Gold MS grade, Promega) in 50 mM acetic acid. Divide into aliquots and store reconstituted trypsin at −70°C.

For short periods of time, the reconstituted trypsin may be stored at −20°C, with no more than five freeze/thaw cycles.

Final concentrations: 25 mM ammonium bicarbonate, pH 8.0/12.5 ng/µl trypsin.

Disuccinimidyl suberate (DSS)

Weigh out 13.2-mg aliquots of disuccimidyl suberate (DSS; Pierce) into screw-cap tubes, flush with N_2 gas, and cap tightly. DSS is moisture-sensitive, so store it desiccated at 4°C. Warm vials to room temperature before opening. Once opened, store under nitrogen gas (stable up to 2 years, but only if stored correctly). Dissolve DSS in DMSO (see Support Protocol 2, step 4) immediately before use, and do not keep in solution for more than 1 hr.

EGTA, 200 mM

Combine 76.08 g EGTA (acid form; mol. wt. 380.4) with 1 liter of water (or 15.22 g with 200 ml of water). Adjust pH to 7.4 with ~26 ml saturated Tris base.

The EGTA takes a long time to dissolve and to equilibrate at the correct pH; EGTA will not fully dissolve until pH is increased.

To prepare saturated Tris base, note that maximum Tris solubility at 0°C is 2.4 M, or 290.6 g/liter.

Glutathione wash buffer

Dissolve 184 mg of reduced glutathione (GSH; mol. wt. 307.3) in 8 ml TBS (see recipe for wash buffer 1), adjust to pH 8.0 with ~300 µl saturated Tris base, and make up to 12 ml with TBS (final glutathione concentration, 50 mM). Make fresh before use.

To prepare saturated Tris base, note that maximum Tris solubility at 0°C is 2.4 M, or 290.6 g/liter.

Sheep brain

One sheep brain is ~76 g. The authors normally collect about 12 brains (900 g) on each abattoir visit. At the abattoir, brains must be obtained within 1 min of sacrifice, rinsed very briefly in cold PBS (*APPENDIX 2A*), diced into 2- to 5-g cubes (~1 to 2 cm per side) on a cutting board, and frozen immediately in liquid nitrogen, before returning to the laboratory. Store frozen at –70°C and use as soon as possible (within ~3 months).

Small GTPase loading buffer

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
2 mM EDTA
25 mM NaCl

The small GTPase loading buffer must be made fresh the same day it is to be used. It is not stable whether frozen or kept at room temperature for these experiments, as the EDTA breaks down in solution (Glebska et al., 2002).

Wash buffer 1 (TBS)

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
150 mM NaCl
Store up to 1 year at room temperature

Wash buffer 2

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
150 mM NaCl
0.2% (v/v) Triton X-100
Store up to 1 year at room temperature

Wash buffer 3

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 1 year at room temperature

Wash buffer 4

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
150 mM NaCl
2.5 mM $MgCl_2$
Store up to 1 year at room temperature

Wash buffer 5

20 mM Tris·Cl pH, 7.4 (*APPENDIX 2A*)
150 mM NaCl
0.2% v/v Triton X-100
2.5 mM $MgCl_2$
Store up to 1 year at room temperature

Wash buffer 6

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
2.5 mM $MgCl_2$
Store up to 1 year at room temperature

Zinc destain solution

25 mM Tris·Cl, pH 8.3 (*APPENDIX 2A*)
192 mM glycine

Combine 3.03 g of Tris base and 14.4 g glycine and make up to 1 liter with water. Do not adjust pH, it will be pH 8.3.

Zinc stain solution I

Add 10 ml of 10% (w/v) SDS (*APPENDIX 2A*) to 13.62 g of imidazole, and make up to 1 liter with water. Store up to 1 year at room temperature.

Final concentrations: 0.2 M imidazole, 0.1% (w/v) SDS.

Zinc stain solution II

Bring 57.51 g $ZnSO_4 \cdot 7H_2O$ to 1 liter with water (final concentration, 0.2 M). Store up to 1 year at room temperature.

COMMENTARY

Background Information

Glutathione (γ-glutamyl cysteinyl glycine; GSH) contains a free thiol group that provides protection for cells against oxidative stress by maintaining a reducing intracellular environment. In conjunction with glutathione *S*-transferases (GSTs), glutathione also participates in detoxification of many reactive exogenous chemical substances by forming adducts through the thiol group. Glutathione-agarose (GSH-agarose, or GSH beads) are prepared by immobilizing glutathione through the thiol group (S-linked) onto beaded agarose, using a 12-atom carbon spacer to link the bead to the glutathione. GSTs bind glutathione with high affinity, and this is the basis for the use of *Schistosoma japonicum* GST in recombinant fusion proteins. A simple purification procedure therefore utilizes the GST fusion protein's specific coupling to GSH agarose, isolation of beads, washing, and competition from GSH beads with free glutathione for elution. This is commonly used as a method for purification of GST fusion proteins, but the affinity of GST fusion proteins for GSH agarose has also been employed as a way to couple a protein of interest to a solid support for affinity chromatographic approaches.

Pull-down experiments are based on affinity chromatography. The use of GST fusion proteins for this technique is common. As an affinity chromatography technique, therefore, the pull-down experiment is ideally suited to specifically isolate protein-protein interaction

Table 17.5.2 Troubleshooting Guide for GST Fusion Protein Pull-Down Experiments

Problem	Probable/possible causes	Possible solutions
Many or all bands are identified as glutathione *S*-transferase (*Schistosoma japonicum*)	Very large amount of GST recombinant protein used as bait	Cross-link the GST fusion protein to the GSH beads with DSS or BS3 (see Support Protocol 2). Refer to Strategic Planning for more details. Reduce the amount of GST fusion protein used.
Intense staining of four to five proteins of 20-30 kDa (in all lanes), which interfere with the detection of other proteins	The very large amount of endogenous tissue GST present in tissue lysates, binding to the remaining free glutathione sites of the GSH beads (multiple mammalian isoforms give rise to the band pattern); see Figures 17.5.4 and 17.5.5 for examples of brain GSTs	Rigorously preclear lysates with GSH beads (at least three times). Alternatively, if the GST fusion protein is cross-linked to the beads (Support Protocol 2): wash the beads (after binding to lysate) 2 to 3 times with glutathione wash buffer, followed by three washes of wash buffer 2 to specifically elute the GSTs before elution in SDS sample buffer. *CAUTION:* Washing with GSH may also elute other specifically binding proteins, due to its reducing potential, and should therefore be carefully tested.
No specific binding proteins are observed for the protein of interest relative to control	Bacterially produced GST fusion proteins are not correctly folded or post-translationally modified	Refer to literature on protein of interest and on bacterial expression systems, and change expression system accordingly. Use a nonbacterial expression system (e.g., baculovirus, in vitro translation), as long as sufficient GST fusion protein for pull-downs can be obtained.
	Tissue source for lysate inappropriate for protein of interest	Change tissue source. Use a tissue that is known to express the protein of interest, or screen several tissues and analyze simultanously by SDS-PAGE, to compare binding proteins from different tissues. This has the advantage of revealing binding proteins that are specific to the function of the protein of interest in a particular tissue as contrasted with other tissues. Scale up chosen tissue 10-fold. Try tissues isolated from animals of different developmental stages.
	Washing or binding buffers may be too stringent (salt, detergent concentration interferes with binding)	Dilute out salt or detergent further (for peripheral membrane and membrane extracts). Homogenize pellets in smaller volumes (e.g., 250 ml instead of 500 ml), and then dilute to 2 liters with buffer B. Alternatively, use buffers for tissue extraction that have different properties (e.g., CHAPS, NP-40, or saponin).

continued

Table 17.5.2 Troubleshooting Guide for GST Fusion Protein Pull-Down Experiments, *continued*

Problem	Probable/possible causes	Possible solutions
Spin columns blocked and any added solutions will not flow through	Particulate contamination is present in lysate, which blocks the pores of the column's frit (10-µm pore size)	Ensure that the lysate used is free of particulate contamination. Sometimes the particles cannot be seen with the naked eye, so it is important to thoroughly centrifuge the lysate before use at maximum speed in a high-speed centrifuge, ≥10,000 × *g* for 30 min at 4°C, even if this has already been done. It is possible to obtain temporary flow in the column by the use of a thin, flat spatula to stir the beads within the column. However, such samples do not usually wash efficiently and are not likely to yield useful results.
SDS sample buffer leaks out of MicroSpin columns during heating in the 85°C water bath, resulting in lost samples	A sufficiently tight seal was not obtained when the bottom of the column was plugged	Ensure that: (1) The plug is not loose. It may be necessary to exchange and try different plugs until one is sufficiently tight. It can help to maintain a small collection of washed plugs, in case one cannot be found in the current batch that adequately seals the column. (2) The column is not cracked or unevenly broken at the base. Care must be taken early on when snapping the columns from the plugs that the plastic does not break unevenly or crack the column. It may be necessary, if it is too uneven, to trim the base of the column with a scalpel blade to ensure a flush seal.
	The top cap for the column was not punched with a needle. When heated, pressure built up inside the column, forcing the SDS sample buffer out through the bottom	Punch the top screw caps of the columns with a heavy gauge needle (22-G or wider). Keep a collection of punched caps (they never contact the sample) to avoid having to punch them every time.
Large amounts of nonspecific proteins are eluted from GST fusion protein beads after pull-down (particularly from membrane protein extracts)	Hydrophobic (largely membrane) proteins may adhere to the beads when washed without detergent	After the binding step, wash beads with wash buffer 1 plus 0.1% Triton X-100 for the first round of washing. It is essential to subsequently wash thoroughly (at least three times) with wash buffer 2 (no Triton) to eliminate the chance of SDS-PAGE distortions caused by Triton X-100. This detergent also can interfere with MS analysis if present in the sample loaded onto the gel.
High-molecular-weight bands appear in samples eluted from non-cross-linked GST fusion protein beads after storage (e.g., the bands marked G on Figure 17.5.5)	Many GST fusion proteins (by unknown mechanisms) form polymers upon prolonged storage at −20°C that are resistant to reducing SDS-PAGE	Purify fresh GST fusion–protein beads, and perhaps cross-link beads to prevent recurrence.

continued

Table 17.5.2 Troubleshooting Guide for GST Fusion Protein Pull-Down Experiments, *continued*

Problem	Probable/possible causes	Possible solutions
Beads stick to the walls of the tubes and cannot be easily removed by washing	Agarose beads often stick to walls of tubes, particularly when using small volumes of bead/liquid mix in large tubes	Polypropylene tubes (particularly 15-ml Falcon 2059 tubes) bind fewer beads than equivalent tubes of other plastics. Use tubes which are of a suitable volume for the volume containing the beads, or increase volume to match the tubes. The inclusion of a detergent (e.g., Triton X-100) may prevent beads adhering to the walls of the tubes. With small volumes of bead slurry, avoid vigorous vortexing when resuspending the settled beads.
In the Alternate Protocol: Known GTP-dependent binding proteins (effectors) do not bind, or bind in a fashion that is not GTP-dependent	The GTP used for preloading of GST-small GTPase beads has been hydrolyzed to GDP, or GST-small GTPase beads were inefficiently loaded with nucleotides	Ensure that: (1) GTP stock is sufficiently fresh (sometimes it is hydrolyzed before the expiration date). (2) All the Mg^{2+} was complexed with freshly prepared EDTA in the loading step. Any free Mg^{2+} that is present will promote hydrolysis of GTP at 37°C. Use a nonhydrolyzable analog of GTP, such as GTPγS, instead of GTP.
There is still GST fusion protein eluted from the beads after chemical cross-linking, which interferes with pull-down experiment	The cross-linking reaction was incomplete or inefficient, or cross-linker has degraded	Ensure that sufficient cross-linker is used; requantitate the level of protein bound to GSH beads. Wash more extensively with PBS before cross-linking to ensure absence of amine buffers. Cross-link for longer durations (up to 2 hr). Use freshly purchased DSS (if stored for some time). Switch to the more soluble cross- linker BS3.
	GSH washing to remove small amounts of non-cross-linked fusion protein was inadequate, or inefficient	Wash the column after cross-linking with two 4-ml washes of bead recycling buffer, and allow the solution to pass through. Note that 100 mM glycine at pH 2.3 is relatively harsh, and may damage some proteins. At this pH it elutes GST from GSH, and thus can be a useful adjunct to the GSH wash. Keep the eluate (pH-neutralized) for a gel to see if any protein eluted.
Poor digestion (seen as few peptides in mass spectrum, i.e., poor sequence coverage)	Protein substrate has many oxidized cysteine residues, and/or is internally disulfide-bonded	Reduction and alkylation of the substrate can lead to improved sequence coverage (an example protocol is found in *UNIT 5.6*).
	The protein of interest is not a good trypsin substrate (i.e., too few Lys and Arg residues)	Chose a different protease, such as LysC. This is particularly necessary for highly basic, or particularly small (<15-20-kDa) proteins with few Arg or Lys residues.

continued

Table 17.5.2 Troubleshooting Guide for GST Fusion Protein Pull-Down Experiments, *continued*

Problem	Probable/possible causes	Possible solutions
	Too short or too long incubation	Need to optimize digestion time. Most proteins are completely digested after 4-6 hr. Exhaustive digestion of up to 48 hr, with an addition of a second batch of digestion buffer, could be performed in some cases to achieve a higher sequence coverage.
	Trypsin has been stored or reconstituted inappropriately, has expired, or has lost activity	Check storage conditions and expiration date Wrong reconstitution buffer. Resuspend trypsin according to manufacturer's recommendations. Multiple freeze/thaw will affect enzyme activity. Check pH of digestion buffer. Trypsin works best at pH 7-9. May need different enzyme-to-substrate ratio: add more digestion buffer for larger (more intensely stained) protein bands.
	Coomassie Blue stain interferes with digestion. (In this case it will also appear in the spectra, most likely as the strongest peak, m/z = 800-850 Da.)	More thorough destaining required. Under no circumstances should one proceed with trypsin digestion unless Coomassie-stained gel pieces are completely clear and colorless.
No solution remains around the gel piece after the digestion period	Insufficient rehydration with digestion buffer, before 37°C incubation	Add more (10-20 µl) of 25 mM ammonium bicarbonate, pH 8.0, before 37°C incubation Incubate longer at 4°C before digestion.
	The temperature difference between the bottom of the tube and the lid may result in evaporation of the liquid	Use of a 37°C oven or incubator is better than a heating block or water bath.
Polymers, detergents, and other impurities lead to poor quality MS spectra	Check all stages of experimental and sample preparatory protocols for possible sources of contamination	In general, minimize or completely avoid the use of detergents throughout all protocol steps. Triton X-100 particularly interferes with MS. This detergent may even be present from the gel piece at sufficient levels to interfere with MS analysis. Ensure that Triton X-100 is not present in any samples for SDS-PAGE (it may also originate from an adjacent lane in the same gel). Remake all buffers from scratch.
	Many brands of plastics may leach small amounts of contaminants that interfere with high-sensitivity MS techniques	Use high-quality plastics: siliconized, highly polished, or hydrophobic-coated microcentrifuge tubes and pipet tips. Avoid screw-cap microcentrifuge tubes, as the rubber O-ring may leach plasticizers. Colored tubes and tips may also leak dyes. Pierce holes on the top of the microcentrifuge tube from the inside out to avoid contamination of the sample with plastic fragments from the lid.
	Salt and detergents in sample	Use Millipore Zip-Tips or other microcolumns to concentrate and purify the peptide samples. Follow the manufacturer's protocols.

continued

Table 17.5.2 Troubleshooting Guide for GST Fusion Protein Pull-Down Experiments, *continued*

Problem	Probable/possible causes	Possible solutions
Trypsin autolytic products interfere with and suppress other peaks in mass spectrum (note that peaks at 842 Da and 2211 Da are expected autolytic products of trypsin)	Some autolytic peaks are expected; excessive peaks may be the result of incorrect trypsin use	Sequencing-grade trypsin is modified for maximal specificity. When stored according to instructions, it is highly stable and resistant to autolysis, as the Lys residues have been reduced and methylated. Autolytic products are expected as a result of a autocleavage at Arg residues, which are not protected. Use sequencing-grade trypsin (see recipe for digestion buffer).
	Too much trypsin during digestion. Excessive volume of digestion buffer used (inappropriate for small gel pieces)	Use less: 10-15 µl or just enough to cover gel particles. Change trypsin-to-substrate ratio. 12.5 ng/µl is usually enough for an average-sized protein band that has been diced to pieces and properly destained.
	Trypsin stored inappropriately, or stock freeze/thawed too often	Store according to manufacturer's recommendations. Aliquot trypsin stock and freeze/thaw no more than five times.
	Wrong buffer used to reconstitute the trypsin	Use 50 mM acetic acid, or the optimal buffer recommended by the manufacturer.
MALDI-TOF MS sample spots do not dry well, forming a glossy surface; crystallization is poor	Impurities in the sample, such as detergents or glycine from zinc-imidazole stained gels interferes with crystallization	More extensive gel washing steps are required to thoroughly remove glycine before preparing gel bands for MS analysis. Use Millipore Zip-Tips or other microcolumns to purify the peptides from the impurities. Follow the manufacturer's protocols.
High-intensity peak in mass spectrum of 832 Da suppresses all other peptide signals	The peak is most likely Coomassie blue	Destain gel piece more thoroughly before proceeding to tryptic digestion. Samples can be recovered by micropurification using MilliPore Zip-Tips or other microcolumns. Follow manufacturer's protocols.
Many or all bands are identified by MS as keratin	Common contamination from skin, hair, or dust	Review and follow the recommendations and precautions as described in the introduction to Basic Protocol 2.

Protein-Protein Interactions Identified by Pull-Down Experiments

partners with a GST fusion of a protein of interest. Traditionally, the pull-down experiment has been used as a secondary confirmatory approach to some other protein-protein interaction detection technique, such as a yeast two-hybrid screen. Partly this has been due to the lack of a sufficiently sensitive detection technique for the identification of stained bands on an SDS-PAGE gel. Immunoblots are sensitive enough for this purpose, so once an interaction is discovered, it is relatively simple to confirm it using a pull-down experiment and a specific antibody. Rapid advances in mass spectrometry (MS) techniques have led to it becoming standard institutional or laboratory instrumentation. The sensitivity of these instruments is now sufficient to identify the proteins in a stained gel piece at the sensitivity of the staining technique. Therefore, the pairing of GST fusion protein pull-down experiments with MS creates a new and powerful technique that is readily able to identify protein-protein interaction partners from SDS acrylamide gels (Graves and Haystead, 2002).

Some of the main advantages of the pull-down experiment in combination with MS as a means of identifying protein-protein interactions are:

1. The isolation of a protein-protein interaction partner roughly correlates to the strength of the particular protein-protein interaction. That is, the more intense a stained, identified band on SDS-PAGE, the greater the likely affinity of the interaction. It can therefore give some notion of the major (highest-affinity) interaction in a particular lysate, based on the

intensity of band staining. This is only an approximate correlation, since the intensity of staining may also be influenced by the abundance of the binding protein, or its activation state.

2. Isolation and identification of the protein-protein interaction are not dependent on any third-party detection system (e.g., transcriptional activation of a reporter gene, or selection by cellular viability).

3. The target gene is, by the nature of the approach, cloned into a suitable GST vector, and thus is immediately available for further experiments to map the interaction site using deletion or site-directed mutagenesis.

4. The assay can be internally controlled for specificity, and can simultaneously isolate protein-protein interaction partners dependent on target protein structure and/or function. This is determined by the experimental design (see Strategic Planning for more details).

5. The use of MS techniques draws the identification of a protein-protein interaction partner from an entire sequence database, and it is possible to use protein sequence databases (e.g., nonredundant or Swiss-Prot) or translated DNA sequence databases (nucleotide, EST, or even genomic) for this purpose. Therefore, if one database does not contain a match to the obtained data, other possibilities can be entertained through comparison with other databases, particularly if a binding protein is a novel protein product.

As described in Strategic Planning, MS-based techniques for protein identification are largely species-independent, at least within a group of closely related species (e.g., mammals).

Some of the limitations/disadvantages of the pull-down experiment are:

1. It is dependent on MS analysis (therefore initially expensive and technically demanding); however, results may be achieved collaboratively with MS labs or through the use of a commercial MS service.

2. The entire approach is dependent on recombinant GST fusion proteins and therefore requires optimization of expression, solubility within the bacteria, and achieving appropriate folding. Not all proteins will be compatible for expression of functional product in bacteria.

3. Not all protein-protein interactions are stable enough, or are of sufficient affinity, to be isolated by pull-down experiment. Interference can also arise from detergents, salts, and pre-existing cellular complexes, among other factors.

4. The approach can perform poorly for identification of low-abundance protein-protein interaction partners. This is particularly true for some nuclear proteins (e.g., telomerase), which exist at very low levels in cells. In this case, a good interaction may be achieved, but it may not be detected by stained SDS-PAGE gels.

5. Not all proteins isolated are direct binding partners of the protein of interest. It is common to isolate entire complexes of proteins in the pull-down experiment, where only a subset of the constituent proteins interact directly with the GST fusion protein. An example of this can be observed in Figure 17.5.5, where the entire exocyst complex is isolated with GTP-loaded GST-RalA (see Anticipated Results for more detail). It was later shown that two out of the eight exocyst complex proteins, Sec5 and Exo84, are the binding partners for RalA (Moskalenko et al., 2002; Sugihara et al., 2002; Moskalenko et al., 2003). The authors have observed several other examples where binding proteins of the partners of the target protein are isolated by pull-down experiment. Additional experiments are required to clarify the mode of binding for proteins which are isolated in this way (see Strategic Planning).

Critical Parameters and Troubleshooting

There are many factors that will contribute towards a successful outcome when using the methods in this unit. Most of these are discussed throughout the protocols in the appropriate steps. The pull-down experimental design is heavily dependent on the Support Protocols in this unit, which are the preparatory techniques required for achieving successful outcomes. The commonly encountered problems, their possible cause, and possible solutions are outlined in Table 17.5.2, in the form of a troubleshooting guide. The solutions described are remedies for the major interfering factors in these experiments; however, since this unit contains a relatively complex set of protocols, this list is by no means exhaustive. Considerations that are specific to a particular protein of interest should also be taken into account when troubleshooting any problems that are encountered. Other sources of reference should also be consulted, particularly for troubleshooting GST fusion protein expression and purification, a subject that is better and more comprehensively covered elsewhere (see, e.g., Harper and Speicher, 1997).

Anticipated Results

The intention of this unit is to isolate specific binding proteins that are specific to a protein of interest through the use of GST fusion proteins coupled to GSH-agarose beads and to prepare them for identification by mass spectrometry. An example of the type of results that can be achieved is shown in Figure 17.5.5, which illustrates a sample pull-down experiment using GST-RalA to isolate nucleotide-specific binding proteins, by the approach described in the Alternate Protocol. Pull-down experimental results can often be interpreted in more than one way, so there are several possibilities that should be considered.

Generally speaking, the most important results are those protein bands that bind specifically to the internal controls (e.g., to one mu-

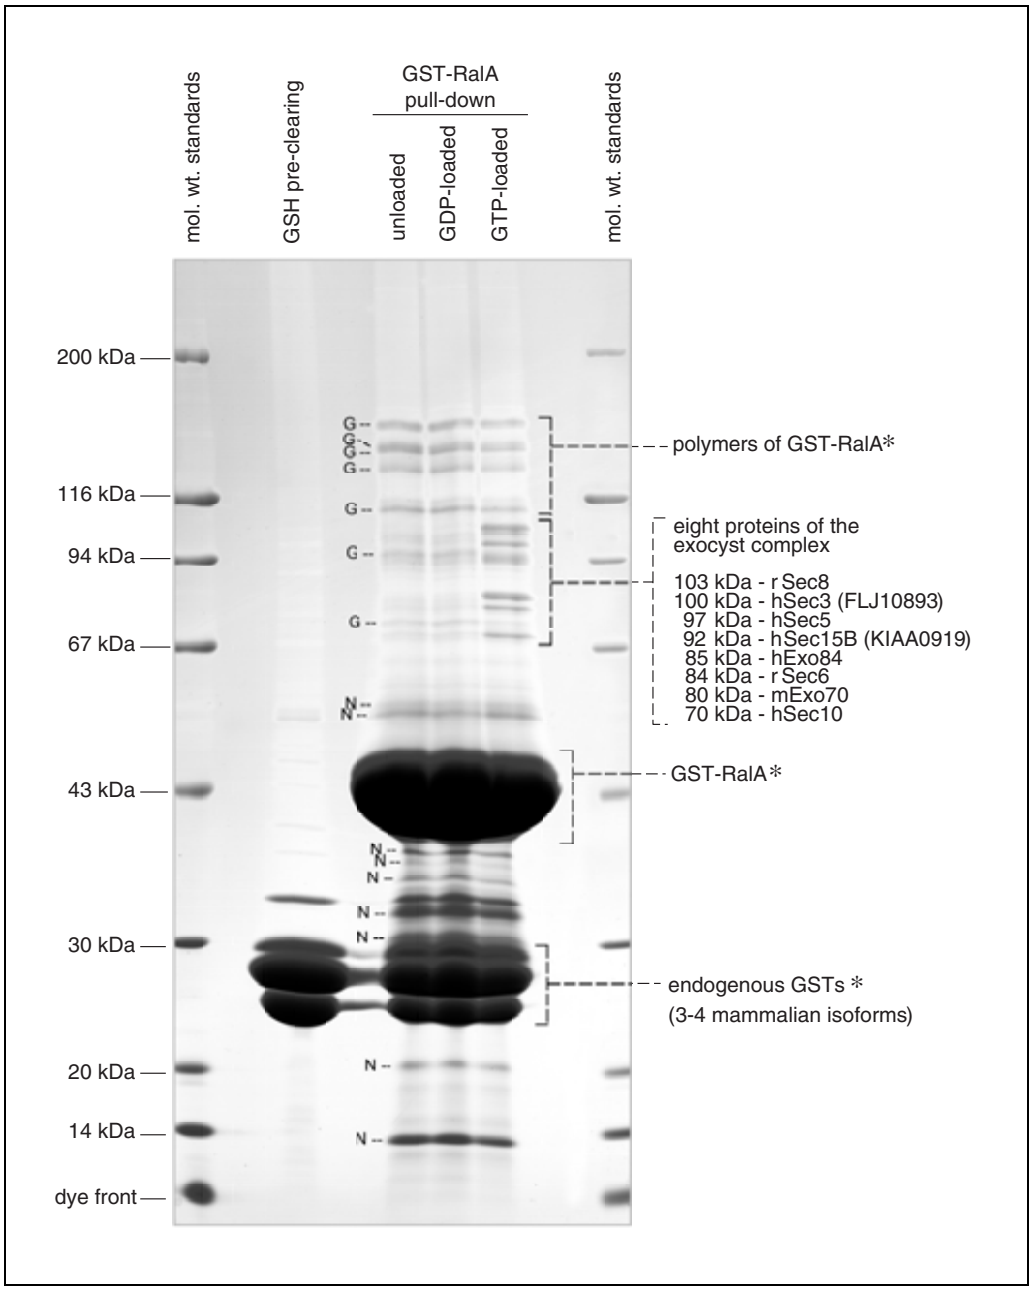

Figure 17.5.5 Sample results from a GST-RalA pull-down experiment. Shown is a Coomassie blue–stained gel of a pull-down from sheep brain cytosol using GST-tagged RalA. For a full discussion, see Anticipated Results. Stained protein bands that have been identified by MALDI-TOF MS are indicated on the right. Features marked with an asterisk (*) are interfering species. Bands that have been identified as erroneously migrating GST-RalA are marked G. The bands marked N are either nonspecific sheep proteins, fragments of GST-RalA, copurified bacterial contaminants, or real nucleotide-independent binding proteins.

Table 17.5.3 Time Considerations for GST Fusion Protein Pull-Down Experiments

Protocol	Step(s)	Action	Total time	Hands-on time
Support Protocol 1	1–2	Streak out glycerol stock	Overnight[a]	20 min
	3	Inoculate overnight culture	Overnight	20 min
	4–7	Dilute bacteria and induce GST- fusion–protein expression	1 day[a]	1–2 hr
	8–21	Purification of recombinant GST fusion proteins	1 day (including SDS-PAGE)	1 day (with breaks)
	22–23	Normalize protein concentration on beads	3–4 hr (including SDS- PAGE)[a]	1–2 hr
Support Protocol 2	All	Cross-linking of beads	5–6 hr (including SDS- PAGE)[a]	3–4 hr (with incubations)
Support Protocol 3	—[b]	Abattoir and tissue collection	1–2 hr	1–2 hr
	1–20	Tissue lysate preparation	1 (long) day, less with help[a]	1 day (with some breaks)
Basic Protocol 1 or Alternate Protocol	All, except gels	Pull-down experiment	1 day[a]	1 day (with breaks)
	21 (Basic Protocol 1 and Alternate Protocol)	Large-format SDS-PAGE	Overnight	1 hr
Basic Protocol 2	1a–5a	Staining gels with colloidal Coomassie stain	1–3 days	20 min
	1b–5b	Staining gels with zinc-imidazole negative stain	1 hr	30 min
	6–12	Gel scanning and band excision	2–4 hr[a]	2–4 hr
13a–19a	12a–18	Coomassie gel piece destaining	2–3 hr[a]	1–2 hr
13b–19b	12b–18	Zinc-imidazole gel piece destaining	1–2 hr[a]	1 hr
	20–23	In-gel digestion	6 hr to overnight	1–2 hr
	24–30	Peptide extraction	2–4 hr[a]	1–3 hr
Support Protocol 4	All	Recycling GSH beads	6–7 hr (including SDS-PAGE)	2–3 hr

[a]Product can be stored for prolonged period of time at conclusion of steps.
[b]See recipe for sheep brains in Reagents and Solutions.

tant/domain/activation state of the protein relative to others), but at the same time do not bind to the external controls (e.g., GSH or GST beads). These proteins are likely to be functionally relevant protein-protein interaction partners, since their interaction is specific to one state of the GST fusion protein under study. In Figure 17.5.5, the most striking results are the eight bands that bind specifically to GTP-loaded GST-RalA beads, between 70 and 103 kDa. These were identified by MALDI-TOF MS as the eight components of the mammalian exocyst complex (Brymora et al., 2001b). The proteins were identified by peptide mass mapping and comparison with the mammalian nonredundant database, and it can be seen that this approach has identified the proteins—regardless of the fact that they are all are from sheep lysate—as being identical to exocyst sequences from human, rat, and mouse sources. Two of the identified proteins were identified as novel human proteins (FLJ10893 and KIAA0919) and subsequently through bioinformatic analysis as new exocyst complex proteins (hSec3 and hSec15B, respectively). It is apparent that the pull-down approach, combined with the power

of mass spectrometric analysis, enabled the identification of a new, GTP-dependent binding complex for the small GTPase RalA. It should also be noted that even though this gel lacks most of the required external controls (e.g., recombinant GST beads, GST-RalA beads alone), it is still possible to assign specificity of binding to the exocyst bands, since they do not bind to the other internal states of GST-RalA (i.e., unloaded and GDP-loaded GST-RalA).

Proteins that bind to all states of the GST fusion protein beads, but not the external controls, may also be relevant binding proteins that are not regulated under the conditions used in the pull-down experiment. Also, the issue may simply be that the protein-protein interaction is a more stable, less dynamic interaction that fulfills a different cellular purpose. This type of interaction requires more characterization to establish its relevance (see Strategic Planning). It is possible that the correct conformational change for an alteration in binding could not be achieved in vitro with the GST fusion protein, but it might be achieved in a different system. It is also possible that they are nonspecifically binding proteins, so it is necessary to run sufficient controls to determine if this is so. In Figure 17.5.5, the protein bands marked "N" are a good example of where insufficient controls limit data interpretation. It is impossible to determine from this experiment (without using MS analysis to identify every protein band) if they represent nonspecific binding of sheep brain proteins to the recombinant GST part of GST-RalA, fragments or polymers of GST-RalA (e.g., the bands marked G), copurified bacterial contaminants, or specifically binding proteins that bind in a nucleotide-independent manner. This experiment could have been strengthened considerably (for the interpretation of these bands) by the addition of a recombinant GST with lysate control (to eliminate recombinant GST–binding proteins), and also by running an equal amount of lysate-untouched GST-RalA (to see which bands originate from GST-RalA or bacterial contamination). After these control conditions have been taken into account, it probably could be determined whether these bands are specific binding proteins.

Proteins that are present throughout all lanes (external controls and pull-down lanes) are not likely to be genuine interactions and are most likely to be nonspecific. In Figure 17.5.5, the bands marked as endogenous GSTs are a prime example of this (the level of endogenous GST in this experiment could have been reduced significantly by repeated preclearing; see Critical Parameters and Troubleshooting). However, if there is a difference in the intensity of staining of these nonspecific bands that is disproportionate with the level of GST fusion protein coupled to the beads, there may also be a specifically binding protein that is comigrating on SDS-PAGE with the nonspecific protein. Identification of such bands requires careful analysis.

Additionally, it should be noted that identification of specific types of proteins should be viewed with caution. Cytoskeletal proteins and chaperones—notably tubulin, actin, myosin heavy chain, and hsc70—are often found in pull-down experiments to some degree. Be careful when ascribing specific binding to any of these proteins, as they are commonly present in pull-down experiments and are mostly bound nonspecifically or trapped in the spin column by filtration.

Time Considerations

An estimation of the time required for each group of steps is described in detail in Table 17.5.3. Several steps have been given a relatively wide time estimate (e.g., 4 to 6 hr), due to the number of samples being processed, experience of the investigator, and other experimental variables. Time taken to perform these experiments may actually be longer than described herein when particularly large numbers of samples need to be processed. Steps that include the time required for performing SDS-PAGE (indicated) can be shortened within 1 day by ~2 hr by freezing the samples in SDS sample buffer at −20°C and running the gels at a later time.

Measuring Protein Interactions by Optical Biosensors

Optical evanescent wave biosensors, such as surface plasmon resonance, resonant mirror, or waveguide biosensors, have been increasingly used during the last several years for the characterization of protein-protein interactions (Margulies et al., 1993, 1996; Malmborg and Borrebaeck, 1995; Garland, 1996; van der Merwe and Barclay, 1996; Schuck, 1997a). This includes both the determination of equilibrium binding constants, which reveal the magnitude of the binding energy, as well as the determination of the bimolecular rate constants describing the kinetics of the interaction.

Studying protein interactions at a surface, as opposed to solution methods, has at least two fundamental advantages. First, the magnitude of the signal involved is independent of the affinity of the interaction over a wide range. Because one binding partner is confined to the surface (in the following referred to as ligand), the number of free binding sites that are under observation in an experiment is determined predominantly by the surface immobilization procedure (requiring usually only very small amounts of material). Therefore, the sensitivity of the method is limited essentially by the availability of the soluble binding partner (the analyte) in a well-defined state, at concentrations in the order of the inverse affinity constant. This allows studies of interactions with affinities spanning a range of at least 10^5 to 10^{10} M^{-1}, and makes this method very attractive, in particular, for high-affinity interactions. Second, the separation of the surface-immobilized sites from the mobile binding partners in solution, if combined with an appropriate fluidic handling system, is virtually ideally suited for the real-time observation of the kinetics of the binding processes. Chemical on-rate constants of up to 10^5/Msec to 10^6/Msec and off-rate constants of between 10^{-5}/sec and 10^{-1}/sec are generally accessible. Information on the chemical on-rate constants, and on the lifetime of the complexes formed, can be of great value, for example, in the study of interactions involved in cellular signaling processes.

However, these fundamental advantages are gained at the expense of additional experimental difficulties intrinsic to surface binding studies. These include the need for immobilization of one reactant at a relatively high local surface density (and the execution of binding studies under these conditions), the problems of nonspecific surface binding, possible multiple attachments to the surface through multivalent interactions, the problem of mass transport in kinetic experiments, and finally the possibility of surface potentials influencing the thermodynamics of the interaction (Leckband et al., 1995; Leckband, 1997).

Although the different commercial instruments for optical biosensing are based on slightly different physical principles, they all exploit surface-confined electromagnetic fields for the precise and real-time measurement of the refractive index of the medium in the immediate vicinity of the sensor surface (Garland, 1996; Knoll, 1998; Lukosz, 1991). When ligands are immobilized to the sensor surface, reversibly interacting analytes will accumulate at the sensor surface when brought into the solution above. By virtue of the difference of the refractive index increments of proteins and most aqueous buffer solutions, an increase of the total refractive index at the surface will then be reported (Fig. 17.6.1). Removal of the analyte from the solution causes dissociation of the reversibly bound molecules from the surface sites, which is accompanied by a decrease in the refractive index at the sensor surface, generating a decrease in the signal. Since the changes in signal are, to a good approximation, proportional to the changes in the mass of surface-bound analyte, the steady-state signals can be analyzed in terms of the law of

Current Protocols in Cell Biology (2004) 17.6.1-17.6.22

mass action and Langmuir isotherms. The time course of the signal can be interpreted in the context of chemical binding kinetics. This basic principle, and consequently the derived strategies for studying protein-protein interactions, as well as most of the experimental procedures and potential complications, are the same in the different commercial instruments. Among the manufacturers are Biacore (*http://www.biacore.com*), Affinity Sensors (*http://www.affinity-sensors.com*), Intersens Instruments (Amersfoort, Netherlands), BioTul (*http://www.biotul.com*), and Artificial Sensing Instruments

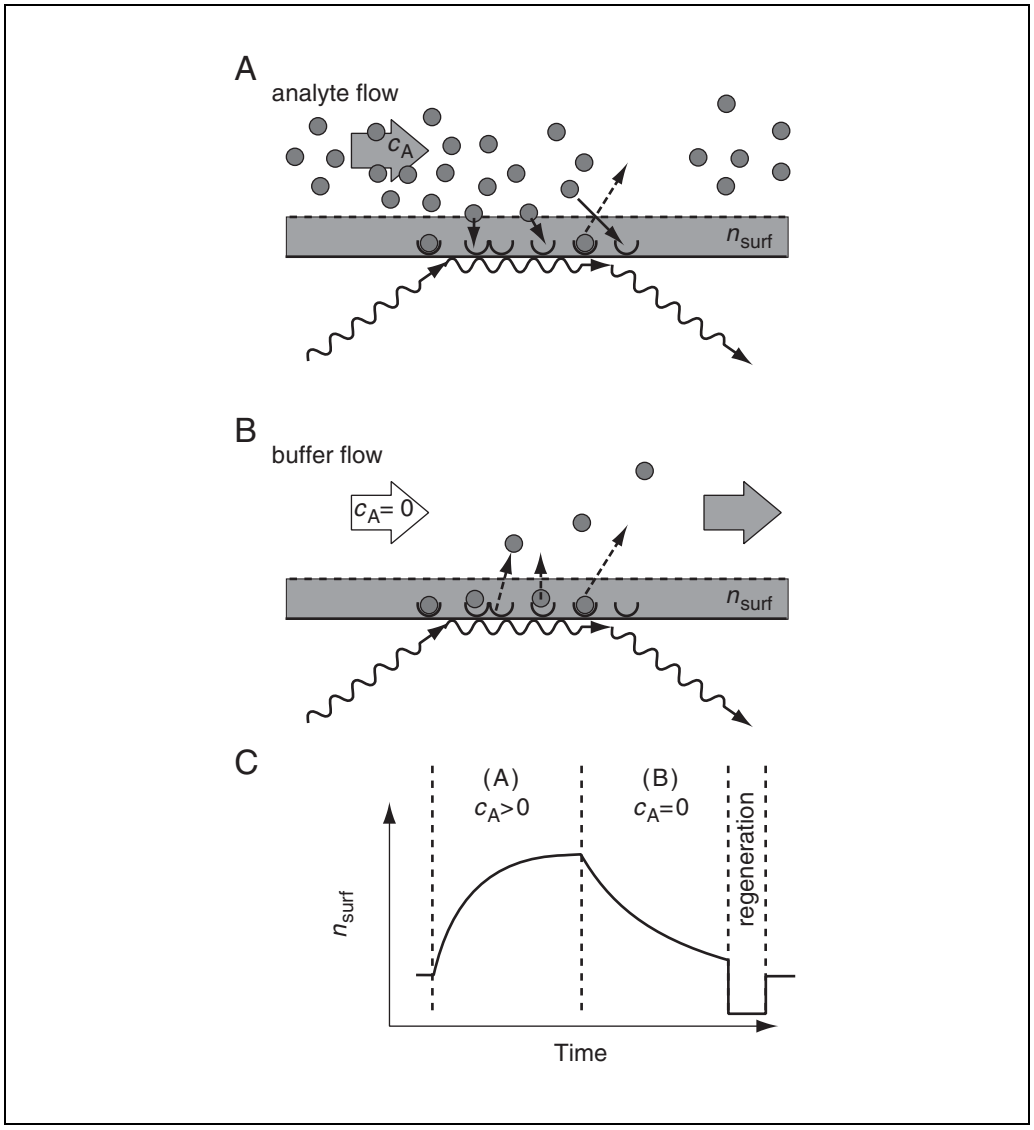

Figure 17.6.1 Schematic presentation of a typical optical biosensor experiment. Light is coupled into a structure that allows generation of surface-confined electromagnetic waves (e.g., surface plasmons in a gold film, or modes of a planar waveguide), which are sensitive to the refractive index of the solution in the range of the evanescent field, n_{surf}. Typical penetration depths of the sensitive volume into the solution are in the order of 100 nm. Ligands are attached to the sensor surface, as indicated by half-circles. (**A**) When analytes (full circles) are introduced into the solution above the surface, reversible interactions with the ligand lead to association events at a rate governed by $k_{on}c_A c_{L,free}$ (solid arrows), and dissociation events at a rate $c_{complex}k_{off}$ (dashed arrows). In the association phase, association events outnumber dissociation events until a steady state is reached. (**B**) When the surface is washed with running buffer in the absence of analyte, only dissociation events take place. (**C**) Signal obtained from probing the refractive index n_{surf} during the sequential application of the configurations depicted in A and B, given in arbitrary units. Following the association phase (A) and the dissociation phase (B), usually a regeneration procedure is applied for removing all remaining analyte from the surface before a new experimental cycle takes place.

(ASI AG, Zürich, Switzerland). The purpose of this unit is to provide a brief introduction to these techniques for the quantitative characterization of biomolecular interactions.

At the time of the introduction of optical biosensors in biomedical research, these instruments were thought to offer a particularly simple technique for the rapid quantitative measurement of equilibrium binding constants as well as binding kinetics. The reader is cautioned that the apparent simplicity and rapidity of the method is deceptive, and that the ease of using some of the commercial data analysis software packages can be highly misleading. The reliability of many of the initially used approaches in this field could not be verified in subsequent critical assessments of the methods. However, the technique has evolved significantly during the last few years. This is mainly due to the refinement and increasing variety of immobilization strategies, the identification of sources of artifacts, the use of control experiments, and the maturation of the analytical techniques (most notably global modeling). Emphasis is given in this unit to introducing the reader to robust approaches that will result in reliable results. Although the technique is frequently presented as being label-free, one of the interacting proteins has to be attached in an active form to the sensor surface. Most frequently, this is accomplished through covalent coupling, which can introduce all the problems well-known in chromophoric labeling and related covalent protein modifications. For all these reasons, the use of this technique requires careful planning and the execution of a number of different experiments, with time and effort more or less comparable to any of the other techniques available for the study of protein-protein interactions.

Optical biosensors are very versatile for the study of protein interactions. However, as described below (see Strategic Planning), the choice of the experimental strategy is usually dictated by the proteins under investigation. Only general guidelines can be given for this stage of the experiment. Detailed procedures for some of the most commonly employed immobilization procedures are described, followed by an introduction to the different strategies for the binding studies, and a brief description of some of the most commonly encountered problems. Next, the need for control experiments is emphasized, and the execution of a variety of such control experiments is described. Finally, some ideas are given for simple troubleshooting. Obviously, this introductory unit cannot be even remotely complete, or cover many of the more advanced techniques such as assembly of protein complexes (Andersen et al., 1999; Schuster et al., 1993). For many of these, the reader will be referred to the specialized literature cited throughout this unit.

STRATEGIC PLANNING

The first step in planning a biosensor experiment for the measurement of the interaction of two proteins requires the choice of the binding partner to be immobilized and the type of binding experiment that will be employed (steady-state, kinetic, or competition experiment, see Binding Experiments and Data Analysis). This involves the consideration of several factors related to size, purity, and chemical properties of the protein, as well as the stoichiometry of the interaction. In general, this will require the protein samples to be well characterized with respect to these properties.

Size, Concentration, and Volume

Optical biosensors detect changes in the refractive index at the sensor surface due to analyte binding. This signal is superimposed by an offset from the bulk refractive index differences of the buffers used). Because the refractive index increment of proteins is very similar in units of weight concentration, the signal obtained from saturation of a given number of surface sites will increase with increasing molar mass of the soluble protein

(or other analyte). In some of the commercial instruments, the binding of an analyte with a molar mass of only 1000 Da can be detected without difficulty, given the commonly achievable surface densities of sites. There is virtually no upper limit for the size of the analyte. Size consideration is important before setting up the experiment if the two binding partners to be studied are of significantly different size. The choice of a larger species as the analyte is generally preferable because this provides a larger signal. However, the immobilization of a very small peptide is usually difficult to control, and in practice frequently leads to unsuitably high density of surface sites, which can introduce problems of steric hindrance and mass transport limitation (see discussion of Mass Transport Limitation). In the absence of any other considerations, it seems advantageous to immobilize the larger binding partner, in order to diminish the probability of steric hindrance problems brought about by binding to surface sites in close vicinity. This will also help to minimize the probability of the immobilization affecting the conformation of the binding epitope. On the other hand, peptide ligands often are far more resistant to the denaturing effects of repeated cycles of binding and regeneration, and can be expected to provide a more stable binding surface than most proteins.

If one of the proteins under study is available only in small quantities, it is advantageous to immobilize this species, because during the course of a study usually only a few functionalized surfaces are needed, each requiring usually only a few micrograms of material. The analytes are used in larger amounts; in one complete set of kinetic experiments volumes of the order of 100 µl at concentrations of ten times the K_D are typically required. In competition experiments, similar quantities of the immobilized species are additionally required. The active concentration of the analyte should be well known, because errors in this value will directly translate into proportional errors of both the binding constant K_D and the chemical on-rate constant k_{on}, resulting from analysis of the experiment (see Binding Experiments and Data Analysis).

Purity

The sample purity requirements in biosensor experiments can be relatively low. In principle, the criterion for sufficient purity is the absence of cross-reaction between the two samples, aside from the interaction of the proteins under study—i.e., that no binding occurs between any contaminating species in the ligand sample and in the analyte sample. In practice, this means that at least either one of the samples should be highly purified. However, very strict requirements have to be met to ensure the absence of contaminating multimeric aggregates of the mobile species (see discussion of Analyte Aggregates, below, and Davis et al., 1998).

Oligomeric Structure, Stoichiometry, and Multivalent Binding

It is important to avoid multiple attachment of a single analyte molecule to two or more surface sites. If this occurs, the lifetime of the surface-bound complex is greatly enhanced. This avidity effect depends strongly on the local density of surface sites (Muller et al., 1998), and the binding data obtained under these conditions are governed to a large extent by the specific properties of the functionalized surface, much more than the surface binding properties of the analyte. (It cannot be assumed that the avidity effect of multivalent binding to the sensor surface is similar to possible avidity effects in binding to cell surface receptors.) Therefore, if the proteins under study are subject to multimeric binding, the multivalent species must be chosen for immobilization. For example, in antibody-antigen interactions, the antibody should be immobilized and the antigen should be the mobile analyte (Fig. 17.6.2). For unknown stoichiometries, appropriate control experiments should be performed that can identify the presence of multivalent species. For the same reason, the presence of even very small amounts of reversibly formed

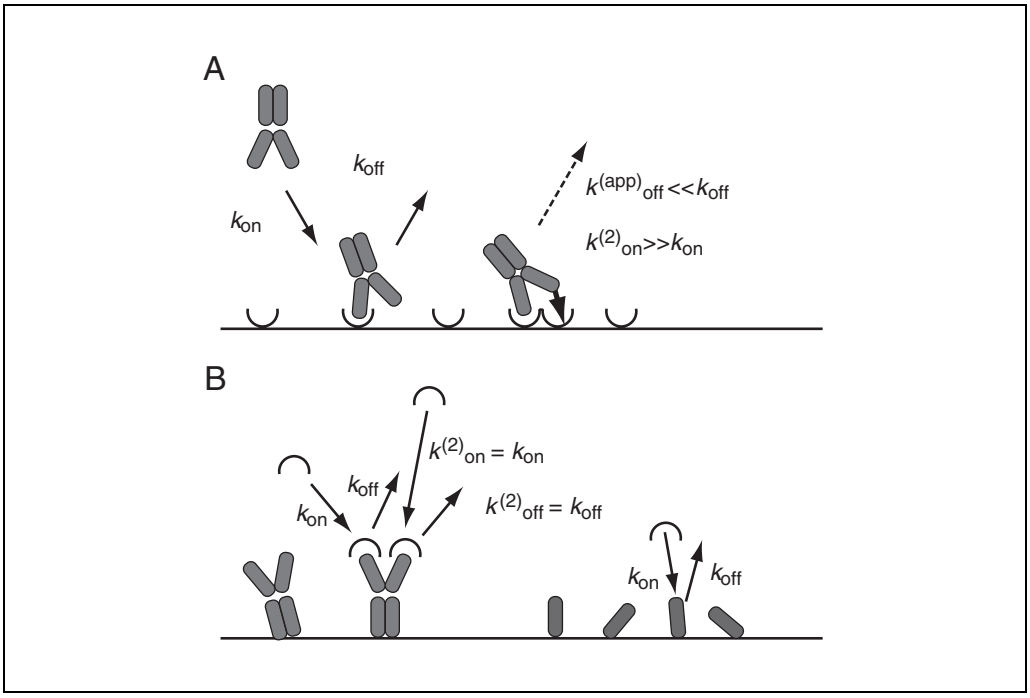

Figure 17.6.2 (**A**) The binding of a bivalent analyte can take place through the interaction with a single ligand molecule (left), or with two ligand molecules (right), depending on the local ligand density. If an unoccupied immobilized ligand molecule is within an accessible distance to an already singly bound analyte molecule, then the on-rate constant of the second interaction is strongly enhanced because of the entropic colocalization constraints. The overall dissociation rate constant of the double attached analyte is substantially reduced (usually by orders of magnitude), because it requires the virtually simultaneous dissociation of both interactions, which is much more improbable than a single dissociation event. The overall binding kinetics obtained from multivalent analytes is highly complex. (**B**) If the configuration is reversed, with the bivalent binding partner immobilized to the sensor surface, then both valencies act independently (left), and (in the absence of cooperativity of the sites) lead to binding kinetics that are identical to that of the monovalent interactions (right).

oligomers (self-association) or irreversibly formed oligomers can significantly interfere with the analysis of surface binding equilibria or kinetics. Because of the difficulties in detecting relatively weak or rapidly reversible oligomerization, solution techniques like analytical ultracentrifugation can be preferable to chromatographic or electrophoretic techniques.

Reactive Properties: Susceptibility to Immobilization, Nonspecific Binding, and Regeneration

The key to successful biosensor experiments is the immobilization of one protein species in an active, and, if possible, uniformly oriented state to the sensor surface. The ease of immobilization can be the major consideration for the choice of the immobilized species. Examples are the presence of biotin, histidine, or other tags on the molecule that allow specific capture, or the presence of a single accessible cysteine suitable for employing specific cross-linking chemistry. If a protein is produced by recombinant methods, appropriate tags can frequently be introduced.

Analogously, the protein that exhibits less nonspecific surface binding is the preferable choice for an analyte. Many sensor surfaces are slightly hydrophobic, and it is highly recommended to measure the extent of binding of both proteins to the nonfunctionalized surface at the maximal concentrations to be used in the binding experiments (e.g., at concentrations equal to 10-fold the expected dissociation equilibrium constant, K_D).

Significant degrees of nonspecific binding can make the analysis of the surface binding kinetics very difficult.

Most analytical strategies require a series of multiple association/dissociation cycles to be executed with the same surface. Therefore, conditions need to be established that allow removal of all surface-bound analyte, without permanently altering the conformation and activity of the immobilized ligand (but tolerating possible destruction of the analyte). Naturally, the choice of the regeneration procedure depends very much on the proteins. Frequently, helpful hints can be obtained from the procedure used to purify the ligand—e.g., conditions employed during ion-exchange or affinity chromatography. Examples of common regeneration procedures include exposure to low-pH glycine or HCl buffer for 1 or 2 min. For some sensitive ligands that interact weakly with their respective analytes, an extended washout with the binding buffer is the gentlest and most reliable regeneration procedure. After selection of a regeneration procedure, control experiments for the integrity of the surface and for the reproducibility of the observed signal should be performed. These should consist of several identical association/dissociation/regeneration cycles. Insufficient regeneration can be identified by residual signal increase after each cycle and/or a negative drift of the baseline. The loss of binding sites through too-harsh regeneration conditions is indicated by a maximal signal during the association phase, which decreases with each cycle. Regeneration is not required for the equilibrium-titration techniques (Myszka et al., 1998; Schuck et al., 1998).

IMMOBILIZATION PROTOCOLS

The goal of immobilization is the stable coupling of the ligand to the sensor surface in an active form. In addition to the obvious functional test of analyte binding during the course of the interaction study, probing the conformation with monoclonal antibodies against ligand epitopes can be highly useful. If possible, it is desirable to reverse the role of ligand and analyte to rule out artifacts of immobilization on the interaction. It is important to note that the immobilization methods differ in their requirement for the exposure of the ligand to relatively harsh conditions, such as pH values below the pI in the commonly employed amine coupling. A related consideration in the choice of the immobilization strategy is the orientation of the surface-immobilized ligand. Random coupling techniques, such as amine coupling, may create different subpopulations of differently reactive ligand molecules at the surface, while specific orientation techniques (e.g., through specific cysteines or through specifically attached biotin moieties) create uniform surfaces. An elegant method for allowing uniform surface attachment is the introduction of specific tags (such as cysteine or histidine) into recombinantly produced or synthetic ligands.

Below are basic descriptions of three of the most commonly used immobilization techniques, which can be applied to the most commonly employed carboxymethylated dextran sensor surfaces. In any of these methods it is very important to control the number of surface sites, since several surface-related artifacts are invoked if the surface density of the proteins under study is too high. The density of immobilized protein can be measured as the difference of the signal before and after immobilization, which can be transformed into the maximal analyte binding capacity by multiplication with the molar mass ratio of the analyte and ligand. For kinetic experiments, generally a relatively low density of immobilized protein should be obtained—i.e., a binding capacity of 50- to 200-fold of the instrumental noise [~50 to 200 units (RU) on a Biacore system]. For competition and for certain control experiments (see Competition Analysis), a larger binding capacity can be desirable. In practice, for initial orientation on the behavior of a particular system of interacting proteins, it is best to prepare several different surfaces of different ligand densities and to compare the analysis of each. This will be helpful for

diagnosing the regimes where mass transport limitations may be present (see Mass Transport Limitations), or where high surface coverage may lead to steric hindrance of analyte binding to neighboring surface sites (leading to biphasic surface binding kinetics).

Instruments that allow the on-line observation of a reference surface can be optimally utilized if the reference surface is treated as similarly as possible to the functionalized surface. This is important predominantly because of possible nonspecific interactions of the analyte with the sensor surface and the possible changes in surface properties due to immobilization. For amine coupling, this can include the application of the activation/deactivation cycle to the reference surface, but without cross-linking of any protein, or with cross-linking of a nonfunctional control protein (for example an unrelated antibody of the same isotype). For the same reason, if using biotin-streptavidin coupling, it is advantageous to immobilize streptavidin to both surfaces.

A variety of additional immobilization techniques are available in addition those described below, such as hydrazide coupling (O'Shannessy et al., 1992), Ni^{2+} chelate coupling (Gershon and Khilko, 1995; O'Shannessy et al., 1995; Sigal et al., 1996), coupling of hydrophobic groups (Stein and Gerisch, 1996), the use of self-assembled monolayers (Sigal et al., 1996) or supported lipid or hybrid bilayers (Plant et al., 1995; Ramsden et al., 1996), and immobilization to aminosilane-derivatized surfaces (Edwards et al., 1995; Buckle et al., 1993). For details on chemical modifications of the proteins, see Hermanson (1996). Additionally, capturing strategies can be used for reversible attachment of the ligand. More specific information on commercially available sensor surfaces, and step-by-step protocols for the corresponding immobilization techniques, can be found in the commercial instrument handbooks, such as the Biacore applications handbook or the IAsys applications notes.

Amine Coupling

Amine coupling is most frequently carried out using a sensor surface that is modified with carboxymethylated dextran. It relies on the electrostatic preconcentration of the ligand to the sensor surface, and therefore requires that the proteins be positively charged. The coupling buffer should be 1 to 2 pH units below the pI of the protein, of low ionic strength (to avoid charge screening), and not contain any primary amines. Effective pre-concentration can be tested before the activation of the surface. It is frequently necessary to test immobilization with several different buffers of slightly different pH; an adjustment by only one half pH unit can be crucial for a successful immobilization.

In a typical protocol, the carboxyl groups of the sensor surface are activated by exposure for 5 to 7 min with 50 mM *N*-hydroxysuccinimide (NHS) and 200 mM *N*-ethyl-*N*′-(dimethylaminopropyl)carbodiimide (EDC). Next, the ligand is injected in 10 mM sodium acetate pH 4.5 buffer. To control the amount of cross-linked ligand, it is usually better to adjust the reaction time as compared to adjustment of the ligand concentration. Repeated injection/wash cycles can be used to differentiate the covalently attached ligand from electrostatically surface-bound ligand. Finally, the surface is deactivated with 1 M ethanolamine·HCl, pH 8.5, for 7 min. Biacore and IAsys provide kits and prepared buffers for this procedure. The NHS and EDC should be kept frozen separately, in aliquots, at −20°C until use.

Avidin- or Streptavidin-Biotin Coupling

Covalent immobilization of avidin or streptavidin allows the capture of biotinylated proteins. This method avoids the need to expose the protein to a pH lower than the pI, and therefore can better preserve activity. Procedures for biotinylating the analyte are found in Hermanson (1996). The affinity of biotin-avidin interaction is very high and leads to a

very stable surface. It should be noted that streptavidin-coated surfaces tend to be more sticky and lead to an increased level of nonspecific binding of the analyte to the surface. Therefore, good blank control surfaces are important.

The amine coupling protocol described above and a carboxymethylated dextran surface can be used for this procedure. The surface is activated with NHS/EDC (see discussion of Amine Coupling), the streptavidin (~100 μg/ml in buffer of pH 4.5 to 5.0) or avidin (~50 μg/ml in pH 4.5 buffer) is immobilized, and the surface is deactivated with ethanolamine. Note that, if commercially prepared streptavidin surfaces are used, this activation step can be omitted. The biotinylated protein is then injected; usually concentrations of 10 to 100 μg/ml and low flow rates are sufficient for efficient capture. Typical times for exposure of the surface are 10 to 30 min.

Thiol-Disulfide Exchange Coupling

This immobilization technique is frequently used for acidic proteins, for small peptides, and for cases when immobilization in a specific orientation is important. It also serves as a highly efficient coupling procedure that can be used if amine coupling or avidin-biotin coupling is unsuccessful. In this method, the immobilization is accomplished either by the introduction of an active disulfide group onto the sensor surface, which can react with thiols on the protein to be immobilized, or, vice versa, by the modification of the sensor surface with a thiol group, which then can react with active disulfides on the protein. The choice between these alternative procedures is dependent on the protein, i.e., the presence of accessible thiol groups, or the potential for introducing activated disulfide groups. The latter procedure may be accomplished, e.g., using 2-(2-pyridinyldithio)ethaneamine (PDEA) to derivatize carboxyl groups or succinimidyloxycarbonyl-α-methyl-α-(2-pyridyldithio)toluene (SMPT) for derivatizing amino groups. It should be noted that, in general, thiol-disulfide exchange coupling cannot be used for studies in the presence of reducing agents. However, the use of covalent thioester coupling—e.g., with succinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (SMCC), sulfo-SMCC, or *N*-(γ-maleimidobutyryloxy)succinimide ester (GMBS)—produces a surface that is stable against reducing agents, and allows one to specifically chose the site of coupling. In addition, the latter technique provides a small spacer between the protein and the surface, which may allow better accessibility (Khilko et al., 1995).

BINDING EXPERIMENTS AND DATA ANALYSIS

Optical biosensors provide data on the time course of analyte binding, and allow for a number of different experimental and analytical strategies for interaction analysis. Most rely on a repeated cycle of association, dissociation, and surface regeneration (Fig. 17.6.1). Among the most important analysis strategies are the kinetic analysis, which takes advantage of the real-time observation to obtain the kinetic rate constants of the reaction; the steady state analysis for measuring the affinity of the reaction; and the competition analysis for measuring the affinity of the interaction in solution. The choice may be constrained by the affinity and kinetics of the proteins under study. If possible, multiple approaches should be taken and the results should be compared for their consistency. Their optimal application requires approximate knowledge of the order of magnitude of the affinity of the interaction. This may make it necessary to perform these studies in several steps.

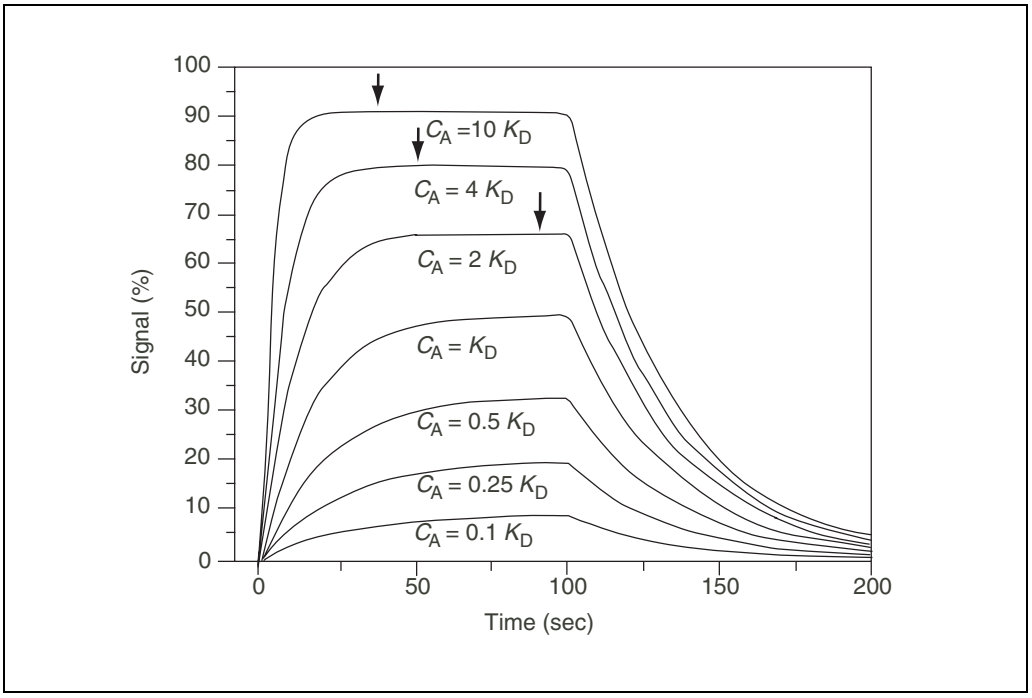

Figure 17.6.3 Schematic presentation of an ideal 1:1 pseudo first-order reaction. Shown is a superposition of the binding progress curves that should be obtained in a series of experiments at different analyte concentrations. The data are given in percent of the signal at maximal binding, but the units of the signal do not affect the results of the data analysis. The arrows on the curves at the higher concentrations indicate that steady-state binding is attained, whereas, for the lower curves, longer association times would be required as part of a steady-state analysis.

Kinetic Analysis

Experimental

The experiment consists of repeated injections of the analyte at different concentrations (Fig. 17.6.3). It should be conducted at relatively low surface density of sites, to avoid kinetic artifacts arising from mass transport limitation. An analyte concentration range as wide as possible should be covered (at least from 1/10 of the K_D to 10 times the K_D), using two-fold or three-fold dilutions. The time allowed for the surface binding phase (injection time) should be long enough for the observation of significant curvature in the binding progress, since it is only the curvature that contains the information about the reaction rate constants. It is highly desirable that steady-state binding be attained, at least for the highest concentrations used. The observation time for the dissociation phase should at least be similar to the injection time.

Data analysis

If the analyte-ligand interaction follows a pseudo first-order reaction, L + A $\Leftrightarrow$ LA then the measured binding progress (proportional to [LA]) is described by:

$$\frac{dR}{dt} = k_{on} c_A (R_{max} - R) - k_{off} R$$

Equation 17.6.1

where c_A denotes the analyte concentration, R denotes the signal (in arbitrary units), and R_{max} denotes the signal at maximum saturation of the surface sites. The goal is the calculation of the chemical on-rate and off-rate constants, k_{on} and k_{off}, which relate to the equilibrium constant as:

$$K_D = \frac{k_{off}}{k_{on}}$$

Equation 17.6.2

While it is possible, in principle, to transform the data as dR/dt versus R in the association phase and as $\log(R)$ versus time in the dissociation phase, where $k_{obs} = (k_{on}c_A + k_{off})$ and k_{off}, respectively, would represent the slopes of the obtained straight lines, this procedure is very unreliable. Instead, it is state-of-the-art procedure to directly fit Equation 17.6.1, or its integrated form:

$$R_{assoc}(t) = \frac{R_{max}}{1 + \frac{k_{off}}{k_{on}c_A}}[1 - \exp(k_{on}c_A + k_{off})t]$$

Equation 17.6.3

$$R_{dissoc}(t) = R_{assoc}(t_d)\exp[-k_{off}(t - t_d)]$$

Equation 17.6.4

directly to the data (with t_d denoting the end of the association and the beginning of the dissociation phase, where $c_A = 0$; O'Shannessy et al., 1993). This should be done without truncation of the data beyond possible regions of artifacts from buffer changes or injections. Global analysis should be employed, which allows one to analyze all experimentally observed curves at all analyte concentrations simultaneously. This results in unambiguous best-parameter estimates for the binding constants, and provides residuals that should be inspected for comparison of the model and the data. Software needed for global analysis can be obtained from the manufacturer or as shareware. It should be noted that exclusion of specific data regions that may be poorly described by the model will introduce a bias into the analysis.

If the global analysis cannot be performed, and separate analyses of the individual binding curves of each experiment according to Equations 17.6.3 and 17.6.4 are applied, then tests for consistency of the results are crucial (Schuck and Minton, 1996a). Important tests are: (1) the estimated extrapolated values of R_{assoc} ($t \rightarrow \infty$) at different concentrations should be consistent with a Langmuir isotherm for the estimated K_D (e.g., approaching half-saturation at $c_A = K_D$; see Figure 17.6.2); and (2) the extrapolated values of ($k_{assoc}c_A + k_{off}$) from the association phases should be consistent with the value of k_{off} as estimated in the dissociation phase. An analysis of the accuracy of the kinetic rate constants can be found in Ober and Ward (1999a).

Possible problems

The data may be only poorly described by Equations 17.6.3 and 17.6.4 (leading to a poor fit and systematically distributed residuals) and instead show multiphasic behavior. Although it is in principle possible to apply global modeling with multiple binding-sites models, this is not recommended, because it is very difficult and can easily lead to very large errors (up to several orders of magnitude). Such modeling is usually not very robust, and many different models may fit the same data equally well (Glaser and Hausdorf, 1996). The reader is also advised to be extremely cautious with some of the implemented models in commercial or shared software, because they may not be valid descriptions of real surface binding processes (for example, mass transport models or models for bivalent analytes). Frequently, the deviations of the data from the single exponential binding

progress predicted in Equations 17.6.3 and 17.6.4 are signatures of experimental artifacts, such as heterogeneity of the ligand (subpopulations of ligand with different binding properties through nonspecific immobilization), steric hindrance of binding to neighboring sites, or the presence of mass transport limitations or multivalent aggregates of the analyte (see discussion of Common Experimental Obstacles).

Steady-State Experiments and Binding Isotherm Analysis

This approach can yield both equilibrium constants and, if appended by a dissociation analysis, kinetic constants. Its main advantage with respect to the previously described technique (see discussion of Kinetic Analysis) is that it is much more robust and reliable because it is less affected by problems of potential multiphasic binding.

Experimental

If in the course of the association experiments a steady-state signal is observed, which is generally possible for interactions with relatively high k_{off}, then a binding isotherm can be constructed (Figs. 17.6.3 and 17.6.4). In an experimental procedure similar to the kinetic analysis, a concentration range as wide as possible should be covered, with two-fold concentration steps starting from both far below (≤1/10) K_D up to almost complete saturation of the surface sites, far above the K_D (≥ 10 times the K_D). The injection times required to attain steady state at the lower concentrations are longer (see Equations 17.6.3 and 17.6.4), and exponential extrapolation may be used, in particular in the Biacore system, since the association times may be limited in the by the limited volume in the injection loop of the microfluidics. Exponential extrapolation is not advised, however, for concentrations above K_D.

For interactions that do not yield steady-state binding within a tolerable time interval for the association phase, or where the ligand does not withstand a regeneration procedure, equilibrium titration represents an experimental variant (Fig. 17.6.4). In this approach, the analyte concentration is increased in two-fold steps, allowing for attainment of steady state in each step, avoiding regeneration between the steps. This can be achieved by addition of a small aliquot of the analyte into a fixed volume of solution above the sensor surface (in cuvette-based sensors; Hall and Winzor, 1997), into a loop of recycling sample (slightly modified Biacore X; Schuck et al., 1998), or into the running buffer reservoir of a standard Biacore (Myszka et al., 1998). The fixed-volume techniques require far less sample volume.

After the highest analyte concentration has been applied, the dissociation phase can be observed and analyzed in terms of Equation 17.6.4. This can give an estimate of k_{off}, which can be used in conjunction with Equation 17.6.2 to calculate k_{on} as k_{off}/K_D.

Data analysis

Although the data analysis could in principle be performed by Scatchard analysis, this is not recommended for statistical reasons. A better method is a plot of $R_{steady\text{-}state}$ versus $\log(c_A)$, in which the K_D can be easily estimated as the inflection point at half saturation of the typical sigmoid isotherm (Fig. 17.6.4). The functional form for modeling is:

$$R_{steady-state}(c_A) = \frac{R_{max}}{1 + K_D/c_A}$$

Equation 17.6.5

Even if the data cannot be fitted well with this expression, the 50% saturation will still represent a good estimate of the order of magnitude of an average K_D. It is important, however, in such an approach, to have enough data points at high analyte concentrations

for a reliable estimate of R_{max} and the 50% saturation level, respectively. Then the robustness will be greater than that of the kinetic analysis of Equations 17.6.3 and 17.6.4.

Competition Analysis

Competition experiments can be performed in different variations, but conceptually all use a calibration of the sensor signal as a function of free analyte concentration, followed by experiments with mixtures of analyte and soluble ligand in different molar ratios. The basic presumption is that the soluble ligand competes with the immobilized ligand for the

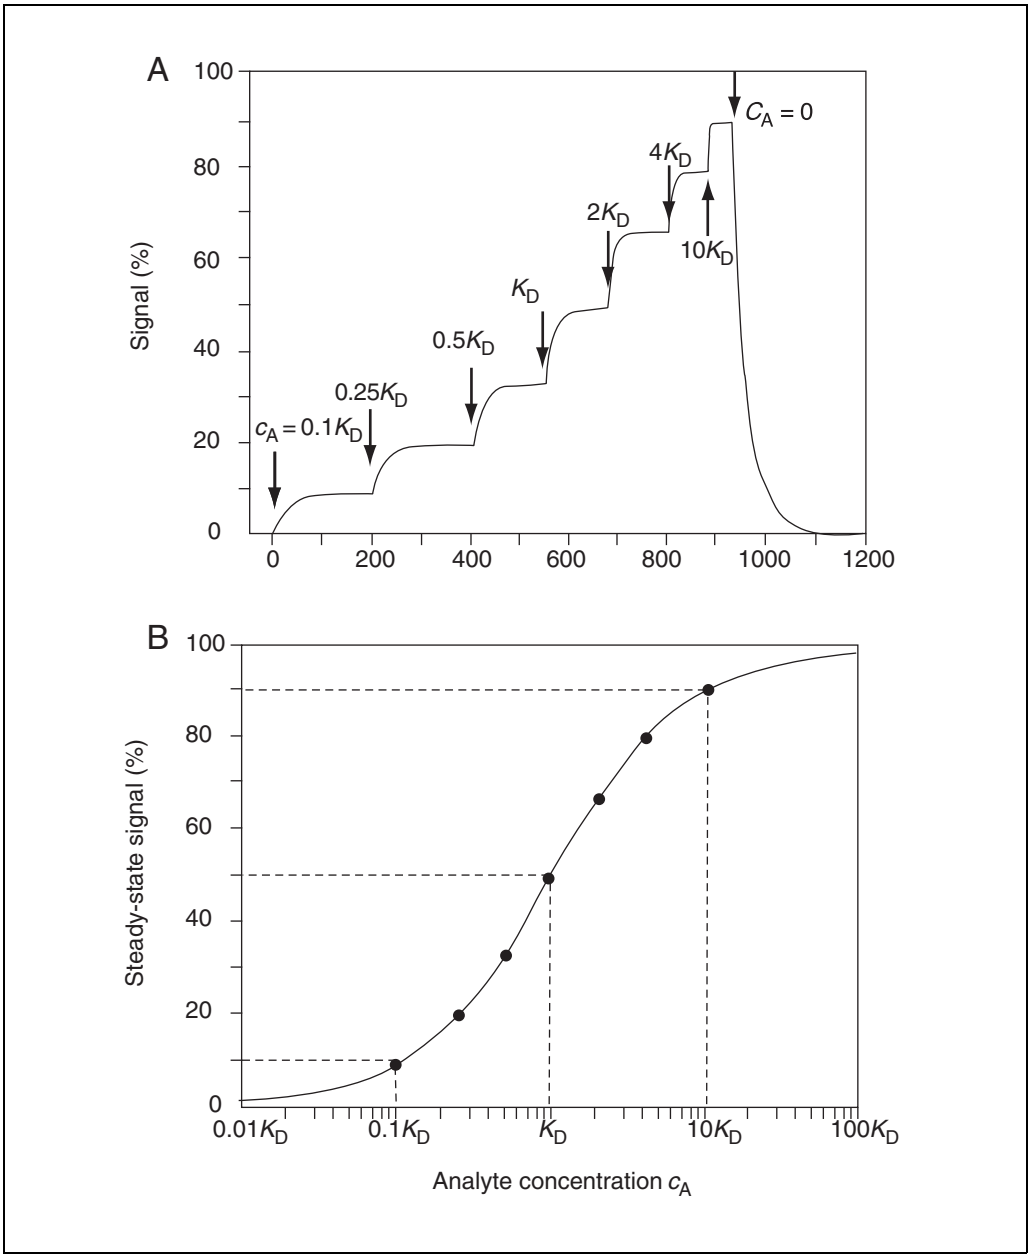

Figure 17.6.4 (**A**) Time course of an equilibrium titration experiment. Arrows indicate the time-points of the step-wise increase in the analyte concentration. (**B**) Steady-state binding analysis according to Equation 17.6.5. In a plot of the steady-state signal versus the base-10 logarithm of the analyte concentration, the binding isotherm exhibits a typical sigmoid shape. The inflection point at 50% saturation determines K_D, and the width of the curve is characterized by ~10% saturation at 1/10 K_D and ~90% saturation at 10 K_D (dotted lines). Visible inspection of the data in this representation already allows a robust parameter estimation.

free analyte, which leads to a reduction of the surface binding. This gives information on the solution affinity of ligand and analyte, while the freedom from the need to explicitly model the surface binding drastically diminishes the influence of potential surface artifacts on the results (Nieba et al., 1996; Schuck et al., 1998). This analysis can be extended to any other competitor that completely inhibits ligand binding of the analyte when bound to the analyte.

Experimental

For low-affinity systems with high chemical off-rate constants, in general, steady-state conditions can be achieved. Accordingly, the binding isotherm can be taken as a "calibration" of the sensor signal as a function of the free analyte concentration. Experiments to derive the surface binding constant can be conducted as described above (see Steady-State Experiments and Binding Isotherm Analysis). In a second variation, for high-affinity systems, mass-transport limited conditions are established by using a large immobilization density. Under these conditions, the initial binding rate constant will be directly proportional to the free analyte concentration ($dR/dt = k_t c_A$). The initial binding rate constant should be measured in equidistant concentration intervals for analyte concentrations up to a few times (two-fold) the K_D. After either one of these sets of calibration experiments, a set of experiments is performed using a constant concentration of analyte, $c_{A,tot}$ (which should be taken in the range of K_D), premixed and equilibrated with different concentrations of the soluble form of the ligand. The ligand concentrations, c_L, should be taken in two-fold steps, spanning the range from far below to far above the K_D. Choice of the fixed analyte concentration is important, since too high a value for $c_{A,tot}$ would show competition only in the range of stoichiometric binding. For systems that do not withstand regeneration, a recycling competitive titration procedure has been developed (Schuck et al., 1998).

Data analysis

For the high-affinity variant of the experiment with a linear initial rate of binding, $dR/dt = k_t c_A$, a plot of dR/dt versus c_A can be used to graphically calculate the amount of free analyte, $c_{A,free}$, during the competition experiment, or $c_{A,free}$ is calculated according to the analytical inversion $c_{A,free}(c_L) = dR/dt(c_L)/k_t$. Similarly, in place of the linear function, an empirical calibration function for $dR/dt(c_A)$ could be used. The obtained concentration of free analyte $c_{A,free}$ in experiments at different soluble ligand concentrations c_L can be plotted as $c_{A,free}$ versus $\log(c_L)$, which gives a competition isotherm with the characteristic sigmoid shape. It can be fitted with Equation 17.6.6, the solution of the quadratic equation of the mass action law combined with mass balance:

$$c_{A,free} = c_{A,tot} - \frac{1}{2}\left(c_{A,tot} + c_L + K_D^{sol} - \sqrt{(c_{A,tot} + c_L + K_D^{sol})^2 - 4c_{A,tot}c_L}\right)$$

Equation 17.6.6

which gives the solution binding constant of analyte and ligand, K_D^{sol}. If the low-affinity variant of the experiment was used, the steady-state analysis of the sensor response in the absence of soluble ligand can be performed according to Equation 17.6.5, giving R_{max} and $K_D^{surface}$. This can be used in a direct analysis of the competition steady-state response using:

$$R(c_L) = \frac{R_{max}}{1 + K_D^{surf} / \left[c_{A,tot} - \frac{1}{2}\left(c_{A,tot} + c_L + K_D^{sol} - \sqrt{(c_{A,tot} + c_L + K_D^{sol})^2 - 4c_{A,tot}c_L}\right)\right]}$$

Equation 17.6.7

Alternatively, both titrations can be analyzed simultaneously in a global fit to both isotherms, assuming the binding constants to the surface sites and in solution to be identical.

COMMON EXPERIMENTAL OBSTACLES

Two of the most important experimental problems are mass transport limitations and the effect of aggregates on the binding kinetics. The first difficulty is found most frequently (but not exclusively) in systems of medium to high affinity with high k_{on}, whereas the second is observed predominantly in systems with lower affinity, where higher analyte concentrations are required. Other obstacles can be steric hindrance effects of binding to adjacent surface sites (O'Shannessy and Winzor, 1996), or the contribution of second-order kinetics to the binding process in cuvette systems (Edwards et al., 1998). Most of these processes scale with the immobilization level of the ligand. For this reason, a low ligand density is generally advantageous in minimizing potential problems. Special considerations for working at very low ligand densities are described in Ober and Ward (1999a,b). The use of control experiments (e.g., comparison of the K_D from solution competition experiments with the K_D obtained from surface binding kinetic measurements) is very useful in verifying the absence of artifacts. The role of mass transport and analyte aggregates will be explained in detail below.

Mass Transport Limitation

If the supply of analyte to the sensor surface is the limiting factor in the surface binding rate, the observed binding kinetics are mass transport limited. This will depend directly on both the density of the immobilized sites, and on the chemical on-rate constant of the interaction. In the association phase, this will produce a zone of depleted analyte concentration in the vicinity of the surface, while in the dissociation phase, this will lead to a zone of nonvanishing free analyte concentration, which is subject to rebinding-retention effect (Silhavy et al., 1975; Fig. 17.6.5). The quantitative influence of this process on the observed surface binding kinetics is governed by a highly complex reaction/diffusion/convection process (Yarmush et al., 1996; Schuck, 1996). Although the processes in the association and dissociation phase are conceptually closely related, it cannot be assumed that the ratio of the "apparent" rate constants still reflects a good estimate of the equilibrium constant. Also, it is strongly recommended that the nonspecialist reader refrain from modeling using mass-transport-corrected kinetic models.

Instead, the primary goal is to identify mass transport limitations, and to establish experimental conditions avoiding transport effects. The following is a list of diagnostic indicators, in the order of reliability, for mass transport limited binding.

1. *Dependence on surface capacity.* This is a very good indicator of mass transport limitation, since the transport limit always directly scales with the density of active surface sites. For this reason, variations of the immobilization density of the ligand are recommended as routine tests demonstrating the absence of transport limitation and other surface-related artifacts. This test can fail in the presence of significant non-specific analyte binding to the surface.
2. *Increased dissociation rate when a soluble form of the ligand is injected (Fig. 17.6.5D).* This always strongly indicates rebinding (mass transport limitation) if detected. Since the ligand by itself should not interact with the surface, its effect is the binding to analyte near the sensor surface, preventing it from rebinding and allowing diffusion and washout from the surface (Fig. 17.6.5C). Unfortunately, this

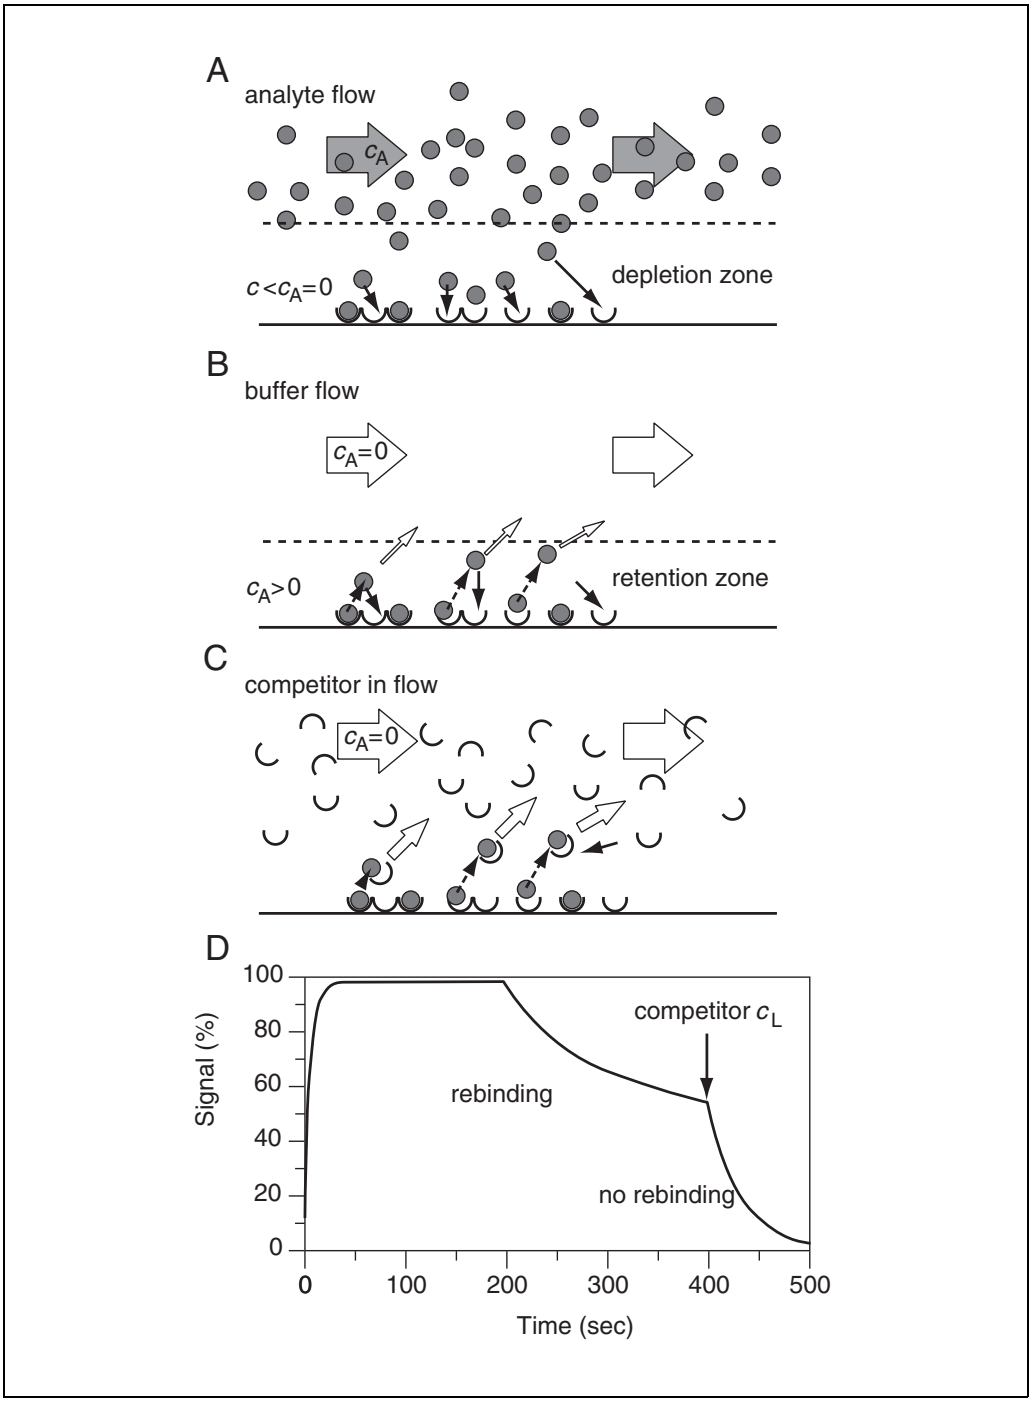

Figure 17.6.5 Mass transport effects on the surface binding process. (**A**) In the association phase, insufficient transport does not fully replenish the free analyte in a zone near the sensor surface (depletion zone). The inability to maintain the concentration c_A in the depletion zone leads to a limited surface binding rate. (**B**) The corresponding effect of mass transport limitation in the dissociation phase is that the surface is insufficiently washed and dissociated analyte is insufficiently removed. This generates a zone near the surface in which free analyte (after dissociation from the ligand) can rebind to empty ligand sites before diffusing into the bulk flow. This zone is indicated as retention zone. (**C**) Introduction of an excess of the soluble form of the ligand as a competitor into the buffer of the dissociation phase helps prevent rebinding to the surface. Soluble ligand can bind to dissociated analyte before rebinding takes place, and the soluble complex can diffuse into the buffer flow. This can allow the measurement of k_{off} free of mass transport effects. (**D**) Time course of dissociation during a mass transport induced rebinding situation (as depicted in panel B), and after introduction of a soluble competitor into the washing buffer (arrow). In the presence of the competitor, the signal reflects the chemical off-rate constant k_{off}, while in the rebinding situation, the apparent rate governing the signal is reduced.

effect may not be present for large ligands or ligands/analytes with high nonspecific binding if they exhibit limited diffusivity.

3. *Double exponential dissociation phase*. This will be seen only after dissociation from more than 50% occupation of all available surface sites.

4. *Weak dependence on the flow rate (stirring speed in cuvette-based systems).* Since the transport parameters only change with the cube root of the flow rate, i.e., generating only a factor of 2 when changing the flow rate by a factor of 10, this flow rate dependency can be difficult to detect. This is particularly true if the flow rate is only varied by a factor of 2, and the reaction is only partially transport influenced. Then, only a ~10% change in the apparent k_{off} would be expected in cases where the true k_{off} is 100% larger than the apparent k_{off}.

5. *Linear association phase*. This effect may not always be present, in particular at substantial transport limitation (Schuck, 1996; Schuck, 1997b; Schuck and Minton, 1996b).
