Isolation of Intermediate Filaments

Intermediate filaments (IFs) are 8- to 12-nm-diameter filaments that are made up of intermediate filament proteins (IFPs). IFPs constitute a family of proteins that have similarities in structure and are defined by their ability to assemble into IFs (Parry and Steinert, 1995). There are at least 65 distinct human IFPs, and each exhibits a distinct tissue distribution. Therefore, this unit covers the purification of a large and diverse group of related proteins. The conditions used to purify each of these proteins have to be optimized depending on the particular IFP. Nonetheless, all IFs share a basic property of being highly insoluble in conventional extraction buffers. As a result, most of the unwanted soluble proteins can easily be removed by extracting with nondenaturing buffers. IFPs are commonly purified under denaturing conditions using chaotropic reagents such as urea or guanidinium hydrochloride. Purifications are performed by ion-exchange chromatography, and the purified proteins can be reassembled into filaments by dialysis. This reassembly procedure can also be used as an additional purification step. The procedures for purification of IFs are illustrated by the example of purification of neurofilament proteins from bovine spinal cord (see Basic Protocol) as well as the purification of recombinant neurofilament protein from transformed bacteria with a prokaryotic expression system (see Alternate Protocol). Neurofilaments are the predominant IF network in mature neurons and are composed of the light (NFL), medium (NFM), and heavy (NFH) subunits of neurofilament triplet proteins (NFTPs). A discussion of various purification methods for other IF proteins is included in the Commentary.

ISOLATION OF NEUROFILAMENTS FROM BOVINE SPINAL CORD

BASIC PROTOCOL

This protocol describes the purification of neurofilament proteins (NFL, NFM, and NFH subunits) from bovine spinal cord and the procedure for reassembling the purified proteins into neurofilaments in vitro (Liem, 1986).

Materials

Fresh bovine spinal cord (can be obtained from a local slaughterhouse)
Solution A (see recipe), ice cold
Solution A-TSP (see recipe), ice cold
Buffers 1, 2, 3, and 4 (see recipes)
Bio-Gel HTP resin (Bio-Rad) or equivalent hydroxylapatite resin
10 mM sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*), degassed under vacuum
Assembly buffer (see recipe)
7.5% SDS-PAGE gel (*UNIT 6.1*)
DEAE-cellulose resin (Sigma or Whatman)
Buffer 4 (see recipe) containing 1% (v/v) 2-mercaptoethanol
Buffer 4 (see recipe), pH 6.5, containing 55 mM NaCl
Buffer 4 (see recipe), pH 7.0, containing 66 mM NaCl

Dounce homogenizer
Refrigerated centrifuge and centrifuge bottles
1.5 × 10–cm glass barrel chromatography column (Bio-Rad)
Peristaltic pump and fraction collector
0.45-μm syringe filters
Amicon Ultra-15 centrifugal filter units, 30-kDa MWCO (Millipore), or equivalent
Dialysis cassette, 10-kDa MWCO
Ultracentrifuge

Additional reagents and equipment for spectrophotometric determination of protein (*APPENDIX 3B*) and SDS-PAGE (*UNIT 6.1*)

Prepare crude neurofilament proteins

1. Clean up a bovine spinal cord by removing the meningeal sheath and rinsing it with 4 liters of ice-cold solution A. Mince the spinal cord into small (~0.5-cm^3) pieces.

   CAUTION: *In order to minimize the danger of bovine spongiform encephalopathy (BSE), make sure to wear gloves when handling the animal tissues and always purchase the spinal cord from a slaughterhouse accredited for scientific research.*

   One spinal cord ~20 cm in length is sufficient for one neurofilament preparation. The bovine spinal cord can be replaced by bovine brain, rat or mouse brains, or mouse spinal cords. About 50 rat brains will provide the equivalent of one bovine spinal cord.

   The spinal cord should be transported on ice. Some vendors will deliver the spinal cord to the laboratory. If it must be picked up directly from the slaughterhouse, transport it in a styrofoam box with "blue ice."

2. Homogenize the spinal cord (~300 g) in 400 ml solution A in a Dounce homogenizer and centrifuge 30 min at 10,000 × g, 4°C.

   The volume of solution A should be adjusted based on the initial amount of starting material. However, the exact volume is not critical because the neurofilament proteins are insoluble under these conditions.

3. Remove and discard the supernatant and resuspend the pellet in 250 ml ice-cold solution A-TSP.

4. Centrifuge the lysate 1 hr at 10,000 × *g*, 4°C.

5. Discard the supernatant and resuspend the pellet again in 250 ml ice-cold solution A-TSP.

   The supernatant contains myelin and undesirable soluble proteins. Myelin and other membranous material will float to the top of the sucrose.

6. Repeat step 4 and 5 until no more floating material (myelin) is extracted in the supernatant.

7. Dissolve the pellet, which contains the crude neurofilament proteins, in 50 ml room temperature Buffer 1. Centrifuge 30 min at 10,000 × *g*, 4°C, to remove insoluble material, and retain supernatant for purification of neurofilament proteins as described in steps 8 to 15, reserving an aliquot of supernatant for analysis by SDS-PAGE (see step 14).

   The preparation will contain considerable amounts of neurofilament proteins, as well as other cytoskeletal proteins such as glial fibrillary acidic protein (GFAP), vimentin, tubulins, fodrin, and microtubule-associated proteins. It can be stored at −80°C for future use.

Purify neurofilament proteins

8. Rehydrate Bio-Gel HTP with 10 mM NaH_2PO_4, pH 7.4, according to the manufacturer's protocol. Remove the fines by letting the resin settle and decanting several times.

9. Pour the hydrated Bio-Gel HTP into a 1.5 × 10–cm column and allow the resin to pack under gravity. When the bed is stable, attach the column to the peristaltic pump and fraction collector and equilibrate the column with two bed volumes of Buffer 1 at a flow rate of ~1 ml/min.

10. To prevent clogging of the column, filter the solution containing the crude neurofilament preparation (supernatant from step 7) with a 0.45-μm syringe filters.

11. Load a quantity of the filtered preparation containing up to 50 mg of protein onto the HTP column and wash the column with room temperature Buffer 1 at a flow rate of ~1 ml/min until all unbound proteins have been removed, as determined by monitoring the OD_{280} of the eluate (*APPENDIX 3B*).

    Chromatography should be done at room temperature, as the urea in Buffer 1 will precipitate at 4°C.

    The flowthrough and the eluate from the washing step should be saved for later SDS-PAGE analysis (see step 14). The flowthrough will contain GFAP, as well as other contaminants. GFAP can be further purified by a reassembly step, described below.

12. Elute the proteins by washing with Buffer 2 at a flow rate of ~1 ml/min, collecting the eluate in 2-ml fractions and monitoring the OD_{280} (*APPENDIX 3B*) until all protein has been eluted.

13. Elute remaining proteins with Buffer 3 at a flow rate of ~1 ml/min, collecting the eluate in 2-ml fractions and monitoring the OD_{280} (*APPENDIX 3B*) until all the protein has been eluted.

    Chromatography should be performed with a peristaltic pump and a fraction collector.

14. Analyze the fractions with the highest OD_{280} by electrophoresis on a 7.5% SDS-PAGE gel (*UNIT 6.1*).

15. Pool the fractions that contain the neurofilament proteins. If necessary, concentrate the protein to 1mg/ml using an Amicon Ultra-15 centrifugal filter unit (MWCO 30-kDa) according to the manufacturer's instructions.

    Figure 3.23.1A shows a gel of purified neurofilament proteins. The neurofilament proteins are usually eluted in Buffer 3, which contains 300 mM sodium phosphate. The preparation contains all three neurofilament proteins, NFL, NFM, and NFH. Their apparent molecular weights are about 67 kDa, 150 kDa, and 200 kDa, respectively. The three subunits can be purified by additional ion-exchange chromatography, but the bacterial expression systems described below (see Alternate Protocol), have simplified these more difficult steps.

Perform in vitro assembly of neurofilaments

16. Dialyze 10 ml of the purified neurofilament proteins in a 10-kDa MWCO dialysis cassette against 2 liters assembly buffer for 4 hr at 4°C, then change the buffer and continue dialyzing overnight at 4°C to assemble proteins into filaments.

17. Collect the assembled filaments by ultracentrifuging 1 hr at 100,000 × *g*, 4°C, and removing the supernatant.

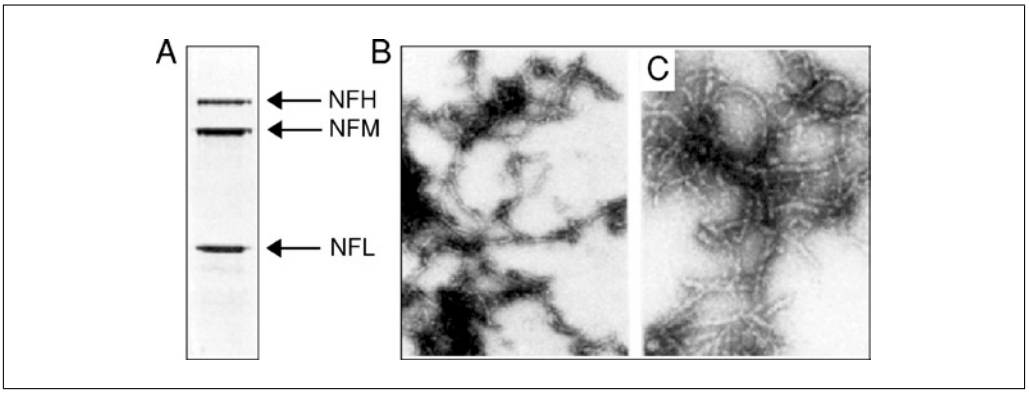

Figure 3.23.1 (**A**) Gel electrophoretic profile of purified neurofilament triplet proteins. (**B** and **C**) Electron micrographs of negatively stained reassembled 10-nm neurofilaments, (B) 37,500× and (C) 60,000×. Reproduced and modified with permission from *Biochemistry* 1982, 21:3221-3226. Copyright 1982 Am. Chem. Soc.

18. *Optional*: Visualize assembled filaments by negative staining under the electron microscope (see Fig. 3.23.1B and C; also see Liem and Hutchison, 1982).

Purify individual neurofilament subunits

After the initial purification and reassembly, the three neurofilament subunits can be further separated from each other by additional ion-exchange chromatography.

19. Prepare DEAE-cellulose resin according to the manufacturer's instructions. Pack a 1.5 × 10–cm column with ~40 ml of resin under gravity.

    The ion-exchange chromatography is performed at room temperature using a peristaltic pump set at a flow rate of 1 ml/min.

20. Connect the column to the peristaltic pump and equilibrate the column with 100 ml of Buffer 4.

21. Dissolve the assembled neurofilaments (pellet from step 17) at a concentration of ~1 mg/ml in Buffer 4 containing 1% (v/v) 2-mercaptoethanol. Apply 20 ml of the neurofilament solution to the column.

22. Wash the column with 80 ml of Buffer 4. Collect the void volume in 2-ml fractions, which will contain NFH.

23. Add 80 ml of 55 mM NaCl/Buffer 4, pH 6.5, and collect the eluate in 2-ml fractions, which will contain NFM.

24. Add 80 ml of 66 mM NaCl/Buffer 4, pH 7, and continue to collect the eluate in 2-ml fractions, which will contain NFH.

25. Analyze the collected fractions by SDS-PAGE (*UNIT 6.1*) and select those that contain the highest amount of the purified protein of interest.

    The purified proteins can be stored up to several months at –80°C.

    NFL obtained from this procedure usually still contains some NFM that has remained on the column. The two can be further separated by additional HTP chromatography. However, as described below (see Alternate Protocol), the use of recombinant proteins obtained from bacterial expression systems has made these further chromatography steps unnecessary. The main advantage of using the material from brain or spinal cord is that the proteins will be post-translationally modified, whereas the recombinant bacterial proteins will not. NFM and NFH are very heavily phosphorylated and NFL and NFM are known to be modified by O-linked N-acetylglucosamine (O-GlcNAc). Purified bovine neurofilament proteins are shown in Figure 3.23.2.

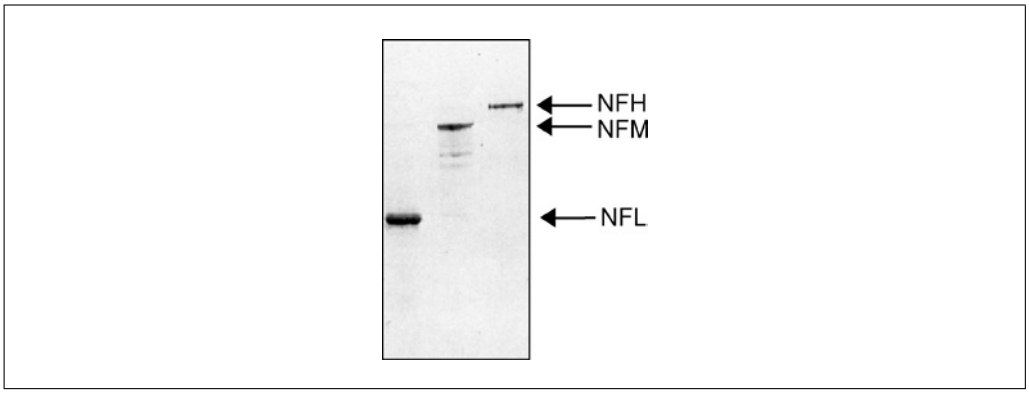

Figure 3.23.2 Gel electrophoretic profile of the separated neurofilament subunits. Reproduced with permission from *Biochemistry* 1982, 21:3221-3226. Copyright 1982 Am. Chem. Soc.

ISOLATION OF RECOMBINANT NEUROFILAMENT LIGHT SUBUNIT (NFL)

ALTERNATE PROTOCOL

This protocol describes the partial purification of NFL protein using a prokaryotic expression system. Crude NFL preparation can be further purified by HTP column chromatography and assembled into homopolymeric filaments by dialysis as described in the Basic Protocol.

Materials

NFL cDNA: generated by reverse-transcription PCR using RNA from brain of mouse (or other species) *or* obtained as EST clone from I.M.A.G.E. Consortium (*http://image.llnl.gov/*)

pET16d vector (Novagen) or equivalent

BL21(DE3) *E. coli* competent cells or equivalent

LB-ampicillin plates and LB-ampicillin liquid medium (*APPENDIX 2A*; see *APPENDIX 3A* for cross-references to selection methods)

100 mM isopropyl-β-D-thiogalactopyranoside (IPTG; see *APPENDIX 3A* for cross-references to protein expression methods)

2× SDS sample buffer (*APPENDIX 2A*)

20 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)

Buffer, 1, 2, and 3 (see recipes)

Refrigerated centrifuge

Probe sonicator

Additional reagents and equipment for molecular biology techniques (cloning, restriction digestion, transformation of *E. coli*, selection of transformants and growth in LB-ampicillin media, induction of expression with IPTG; see *APPENDIX 3A*), and SDS-PAGE (*UNIT 6.1*)

Establish a bacterial culture that expresses NFL

APPENDIX 3A provides cross-references for the molecular biology techniques used in the following steps.

1. Clone NFL cDNA into the pET16d vector. Utilize the *Nco*I site of the vector for cloning so that the N-terminal His_6-Tag will be removed.

   One should avoid introducing a tag onto the protein because it may affect the ability of the IFPs to assemble into filaments.

2. Transform the pET-NFL construct into BL21(DE3) *E. coli* competent cells by heat shock or electroporation (*UNIT 20.5*) and incubate the transformants on LB-ampicillin plates overnight (*APPENDIX 3A*).

3. The following morning, pick 12 colonies with a loop and grow each of them in a 2-ml LB-ampicillin liquid culture to an OD_{600} of 0.4 (which usually takes ∼6 hr). When culture has reached that density, add 8 µl of 100 mM IPTG to induce expression.

4. Incubate cultures an additional 4 hr, then harvest 1.5 ml of each of the 12 cultures by centrifuging 3 min at 5000 × *g*, 4°C. Save the remaining 0.5 ml of each culture at 4°C.

5. Resuspend each cell pellet in 50 µl of 20 mM Tris·Cl, pH 7.5, then add 50 µl of 2× SDS sample buffer to lyse the cells. Heat lysates 5 min in a boiling water bath, then chill on ice and analyze 10 µl of each lysate by SDS-PAGE (*UNIT 6.1*) to evaluate expression levels of NFL.

6. Identify the bacterial colony that expresses the highest amount of NFL, streak out the remaining culture from that colony (see step 4) on an LB-ampicillin plate, and incubate overnight at 37°C to obtain new colonies.

7. Select a colony from the plate and grow overnight in a 2-ml LB-ampicillin liquid culture. The following day, mix 0.2 ml glycerol with 1 ml of that culture and freeze at –80°C to provide a frozen stock for future use.

A detailed protocol to evaluate protein expression in bacteria can be found in the pET system manual (Novagen, http://www.emdbiosciences.com/docs/docs/PROT/TB055.pdf). The authors have used this system to express a number of IFPs, including NFM, NFH, α-internexin, peripherin, and vimentin, and found that all of them are expressed very well in bacteria.

Express proteins

8. Inoculate a 2-ml LB-ampicillin liquid culture with the bacterial colony that has the highest level of NFL expression. Incubate overnight at 37°C.
9. The following day, collect the bacteria by centrifuging 2 min at 5000 × *g*, 4°C. Discard supernatant.
10. Resuspend the bacterial pellet in a small volume of LB-ampicillin medium and transfer the bacteria into 500 ml of LB-ampicillin medium. Grow the cultures at 37°C.
11. After the culture reaches OD_{600} ~0.6 (usually after ~4 hr), add 2 ml of 100 mM IPTG to induce NFL expression. Incubate 4 hr at 37°C.

Harvest and purify proteins

12. After 4 hr, harvest the cells by centrifuging 5 min at 5000 × *g*, 4°C. Proceed to the purification steps or store the bacterial pellet at −80°C for future use.
13. Resuspend the bacterial pellet in 20 ml of 20 mM Tris·Cl, pH 7.5. Lyse the cells by sonication on ice using a probe sonicator with the power level set between 4 and 5, at 40% to 50% duty cycle for 15 to 20 bursts.
14. Centrifuge the lysate 10 min at 14,000 × *g*, 4°C, and discard the supernatant.

The bulk of the NFL, as well as other IFPs are always found in the insoluble fraction.

15. Resuspend the insoluble protein pellet in 20 ml Buffer 1. Perform hydroxylapatite (HTP) column chromatography and SDS-PAGE analysis as described in the Basic Protocol, steps 8 to 14. Store purified NFL up to 3 months at –80°C.

NFL and other neurofilament proteins (NFM, NFH and α-internexin) will elute with Buffer 3. GFAP and vimentin usually elute in the flowthrough with Buffer 1.

NFL can be reassembled by dialysis as described in the Basic Protocol; the dialysis functions as an additional purification step. This reassembly step is not possible for the purification of NFM and NFH or other IFPs, such as the keratins, that are obligate heteropolymers, because they require a partner for coassembly. Many other IFPs (such as GFAP and vimentin) can also be reassembled.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Assembly buffer

0.1 M KCl
10 mM sodium phosphate buffer, pH 6.8 (*APPENDIX 2A*)
1 mM EGTA
1 mM $MgCl_2$
Store with above components up to 6 months at room temperature
Immediately before use, add:

continued

1 mM ATP
1× protease inhibitors (see recipe for protease inhibitor stock solutions)
Adjust pH to 7.4

Buffer 1

8 M urea, deionized and filtered (see recipe)
10 mM sodium phosphate buffer, pH 7.4
0.1% (v/v) 2-mercaptoethanol
1× protease inhibitors (see recipe for protease inhibitor stock solutions)
Prepare fresh

Buffer 2

8 M urea, deionized and filtered (see recipe)
100 mM sodium phosphate buffer, pH 7.0
0.1% (v/v) 2-mercaptoethanol
1× protease inhibitors (see recipe for protease inhibitor stock solutions)
Prepare fresh

Buffer 3

8 M urea, deionized and filtered (see recipe)
300 mM sodium phosphate buffer, pH 7.0
0.1% (v/v) 2-mercaptoethanol
1× protease inhibitors (see recipe for protease inhibitor stock solutions)
Prepare fresh

Buffer 4

8 M urea, deionized and filtered (see recipe)
300 mM sodium phosphate buffer, pH 6.5 or 7.0 (depending on use in protocol; see Basic Protocol materials list)
1× protease inhibitors (see recipe for protease inhibitor stock solutions)
Prepare fresh

Protease inhibitor stock solutions

500× phenylmethylsulfonyl fluoride (PMSF) stock: Prepare 250 mM PMSF in ethanol; store in aliquots at room temperature.

5000× leupeptin stock: Prepare 5 mg/ml leupeptin in water; store in aliquots at –20°C.

5000× aprotinin stock: Prepare 5 mg/ml aprotinin in water; store in aliquots at –20°C.

Alternatively, complete Protease Inhibitor Cocktail Tablets (Roche) may be used.

Solution A

0.1 M NaCl
1 mM EDTA
10 mM NaH_2PO_4
Adjust pH to 6.8 using NaOH
Store up to 6 months at room temperature

Solution A-TSP

Solution A (see recipe) containing:
1% (v/v) Triton X-100
0.85 M sucrose
1× protease inhibitors (see recipe for protease inhibitor stock solutions)
Prepare fresh

Urea, 8 M, deionized and filtered

Prepare an 8 M solution of urea in water. Deionize by stirring with a mixed-bed ion exchanger resin (TMD 8, Sigma or equivalent) for at least 3 hr at room temperature (until the color of the resin changes from greenish blue to yellowish brown). Remove the resin by filtering through Whatman filter paper in a funnel. Store up to 3 months at room temperature. Filter through a 0.45-μm filter immediately before use in the preparation of other solutions.

COMMENTARY

Background Information

IFs are composed of a diverse family of proteins that are expressed in a highly cell-type-specific manner, e.g., keratins in epithelial cells, neurofilaments in neurons, and vimentin in mesenchymal cells. Hence, different types of IFs can be isolated from different kinds of tissues or cultured cells. As illustrated in the Basic Protocol, neurofilament proteins can be purified from bovine spinal cord, although they can also be readily purified from spinal cord or brain from other species (Liem and Hutchison, 1982; Liem, 1986). Spinal cords are a more abundant source for the neurofilament proteins. Microtubule proteins and other cytoskeletal components are for the most part removed by the early cold extraction steps, as are most other soluble proteins. Myelin and other membrane proteins are removed by the sucrose-flotation step. After the repeated extractions and flotations, the major proteins left will be IFPs, i.e., GFAP and neurofilament proteins. NFTPs can be readily separated from GFAP by hydroxylapatite (HTP) chromatography. Advances in molecular biology have made the use of transformed bacteria that produce the IFP of interest the preferred method for isolating IFs (see Alternate Protocol). Subsequently, the purified recombinant proteins are assembled back into filaments in vitro. The advantage of this method is that it is relatively simple to perform and easy to scale up, and the assembled IFs are entirely composed of the desired IFPs. However, the method also has inherent disadvantages. First, it may be difficult to express some of the mammalian proteins in bacteria. Although many IFPs have been successfully purified from transformed bacteria, some others may be toxic to the bacteria and make it difficult for them to be expressed. For example, Heitlinger et al., (1991) experienced difficulty in expressing chicken lamin B_2 in the bacteria strain BL21 (DE3). Second, purified IFPs are not post-translationally modified in bacteria. Lack of post-translational modification does not seem to affect the polymerization process in vitro; however, in vivo, modifications such as phosphorylation have long been known to play regulatory roles in IF assembly. For example, phosphorylation of vimentin has been shown to inhibit filament formation (Eriksson et al., 2004). Furthermore, if the objective is to study IF-associated proteins, the target protein might only bind to post-translationally modified native IFs. Therefore, in some situations, it is important to execute the downstream experiments using both native and recombinant IFs.

IFPs have been divided into six major groups on the basis of their gene structure. Keratins belong to the type I and type II groups. There are at least 50 keratin genes, including the epithelial keratins (also designated "cytokeratin" or "soft" keratins) and the hair keratins (also known as the "hard keratins"). The keratin filaments in epithelial cells are obligate heteropolymers composed of at least one type I and one type II keratin protein. Isolation of epithelial keratins is quite similar to the isolation of neurofilament proteins, except epithelial cells or tissues are used as the starting materials. For crude keratin preparations, one can use the high-salt extraction protocol described by Chou et al. (1993); a step-by-step protocol can be found in Omary and Coulombe (2004). To further purify keratins, ion-exchange chromatography with Q-Sepharose columns has been commonly used; the bound proteins are eluted by a linear salt gradient (Coulombe and Fuchs, 1990; Fradette et al., 1998; Herrmann et al., 1999). To assemble keratin proteins into filaments in vitro, one needs to combine the matching keratin pair and dialyze them together in a Tris-based buffer (10 mM Tris·Cl, pH 7.4/0.2% 2-mercaptoethanol, with protease inhibitors).

Type III IFPs include vimentin, desmin, glial fibrillary acidic protein (GFAP), and peripherin; Type IV includes α-internexin and the neurofilament proteins. These IFPs were originally isolated from different sources: vimentin from BHK21 cells (Steinert et al., 1981), lens tissue (Geisler and Weber, 1981), and mastocytoma cells (Inagaki et al., 1987); desmin from chicken gizzard, porcine stomach, and skeletal muscle (Geisler and Weber,

1980; O'Shea et al., 1981); peripherin from PC12 cells (Parysek and Goldman, 1987); GFAP from bovine brain (Rueger et al., 1979); α-internexin from rat spinal cord (Pachter and Liem, 1985); and neurofilament proteins from bovine spinal cords (Liem and Hutchison, 1982). All of these IFPs have also been successfully purified as recombinant proteins from transformed bacteria. The purification procedures are similar to the protocols described above. With the exception of the neurofilament proteins, all of the type III and IV IFPs are able to self-polymerize in vitro into homopolymeric filaments. NFL can self-assemble into homopolymeric filaments in vitro, but NFM and NFH require NFL to form filaments.

Type V IFPs are nuclear lamins. Unlike other IFPs that form filamentous networks in the cytoplasm, lamins are the major structural constituents of the nuclear lamina. Hence, purification of nuclei should precede the isolation of lamins. Detailed protocols for isolating nuclear lamins from liver, transformed bacteria, and baculovirus expression systems can be found in Omary and Coulombe (2004).

Type VI IFPs include nestin, synemin, and paranemin. Paranemin is probably the avian ortholog of mammalian nestin. Nestin has been successfully purified from BHK-21 cells (Steinert et al., 1999), while synemin and paranemin were originally isolated from avian muscles (Sandoval et al., 1983; Bilak et al., 1998; Hemken et al., 1997). Detailed protocols for isolating these IFPs are described in Omary and Coulombe (2004). Recently, a muscle protein that shows sequence homology to IFPs has been isolated in a two-hybrid screen (Newey et al., 2001). The protein was named syncoilin and was found to be able to bind to desmin. However, desmin and syncoilin do not coassemble into heterofilaments, and syncoilin does not appear to participate in filament formation with any IFPs (Poon et al., 2002). Hence, syncoilin should not be considered as an IFP, and its isolation may be very different from isolating IFPs as described above.

In addition to these six general types of IFPs, lens fiber cells express two specific IFPs, filensin (also called CP115) and phakinin (also called CP49). Filensin and phakinin form a distinct filament network called beaded filaments in lens fiber cells and they can coassemble into 10-nm filaments in vitro. As expected, filensin and phakinin are purified from lens. Hydroxylapatite columns have been used successfully for purifying filensin (Quinlan et al., 1992), while DEAE-cellulose columns have been used for isolating phakinin (Goulielmos et al., 1996).

There are two common reasons for isolating IFs: (1) to study their in vitro assembly properties; and (2) to study their interaction partners (Omary and Coulombe, 2004). The assembly properties can be studied by electron microscopy, cross-linking analysis, and ultracentrifugation. To investigate potential interactions of associated proteins with IFs, one can perform overlay binding assays or centrifugation-based pull-down experiments.

Critical Parameters

The insolubility of IFs simplifies the purification procedures. In general, soluble proteins can be extracted with nondenaturing buffers before starting the purification of the IFPs. The IFPs are generally dissolved in chaotropic reagents such as urea or guanidium hydrochloride. Ionic detergents such as SDS are not recommended, because this will make it more difficult to reassemble the proteins. Reassembly of IFPs into filaments is accomplished rather easily by dialyzing against assembly buffer. The dialysis can also serve as an important purification step and can also remove some degraded proteins. However, this step is not possible for those proteins that cannot self-assemble, such as NFM and NFH, or for the keratins, which are obligate heteropolymers.

Troubleshooting

If protein degradation is observed: (1) make sure the bacterial lysate is not overheated during sonication, and/or (2) increase the concentration of protease inhibitors. Phenylmethylsulfonyl fluoride (PMSF; see *APPENDIX 1B*) is conventionally used at 0.1 mM; it may be necessary to increase its concentration up to 3 mM (Pytela and Wiche, 1980). Be cautious when handling PMSF; it is very toxic.

If impurities are detected: (1) perform a couple more rounds of extractions with solution A-TSP before loading onto the HTP columns; (2) further purify the IFPs by performing another round of ion-exchange chromatography with a different type of column such as the DEAE-cellulose column; or (3) conduct a couple of cycles of assembly-disassembly.

If there is no recombinant protein expression in the transformed BL21(DE3) bacteria: (1) try using other bacterial derivatives such as the Rosetta (Novagen) or BL-21-Codon Plus (Stratagene) *E. coli* strains, which are designed to alleviate codon bias when expressing heterologous proteins; (2) try using another

prokaryotic expression system, such as the pMAL system (New England Biolabs); or (3) consider using eukaryotic expression systems such as baculovirus or yeast.

If the IFP does not pellet well after centrifugation, this is probably due to contamination with genomic DNA. Add DNase I to the extraction buffer at 5 μg/ml or sonicate the crude cell lysate.

If the columns get clogged: (1) be sure to filter the crude IFP lysate before loading onto the column, and (2) degas all the chromatography solutions.

Anticipated Results

The yield of crude neurofilament proteins is about 14 mg per g bovine spinal cord. The yield from HTP chromatography is about 90 mg purified proteins per gram of crude neurofilament proteins. Hence, for a 300-g spinal cord, the total yield of neurofilament proteins is about 375 mg.

Time Considerations

Using a bovine spinal cord as the starting material, the entire purification procedure should take ~5 working days. The first day involves isolation of the crude neurofilament proteins. At the end of the day, crude neurofilament extracts can be stored in Buffer 1 at −80°C up to 3 months. The second day should be used for preparation of the HTP column, and chromatography should be done on day 3. The eluted material can also be stored in Buffer 2 or 3 at −80°C up to 3 months. Analysis of the eluted fractions by SDS-PAGE should be done on day 4. To prevent degradation, one should not assemble the filaments until one is ready to conduct the downstream experiments. It takes ~1 day to dialyze and assemble the filaments. To prepare recombinant proteins from bacteria, it will take ~1 week for cloning the cDNA into the bacterial expression vector and another week to test the optimal conditions for expressing the proteins. After identifying the bacterial colony that expresses the highest amounts of the desired IFP, one should prepare bacterial stocks with glycerol (15% final concentration) for long-term storage at −80°C.

Isolation of T-Tubules from Skeletal Muscle

The transverse tubule (T-tubule) system of a skeletal and cardiac muscle cell is a network of tubular invaginations of the sarcolemma that forms specifically functional associations with the sarcoplasmic reticulum, and they are responsible for conducting the action potential to the interior of the muscle fiber (Fig. 3.24.1). Thus, the signal for excitation-contraction coupling is transferred across the triad junction from T-tubules to the terminal cisternae of the sarcoplasmic reticulum to trigger Ca^{2+} release and muscle contraction.

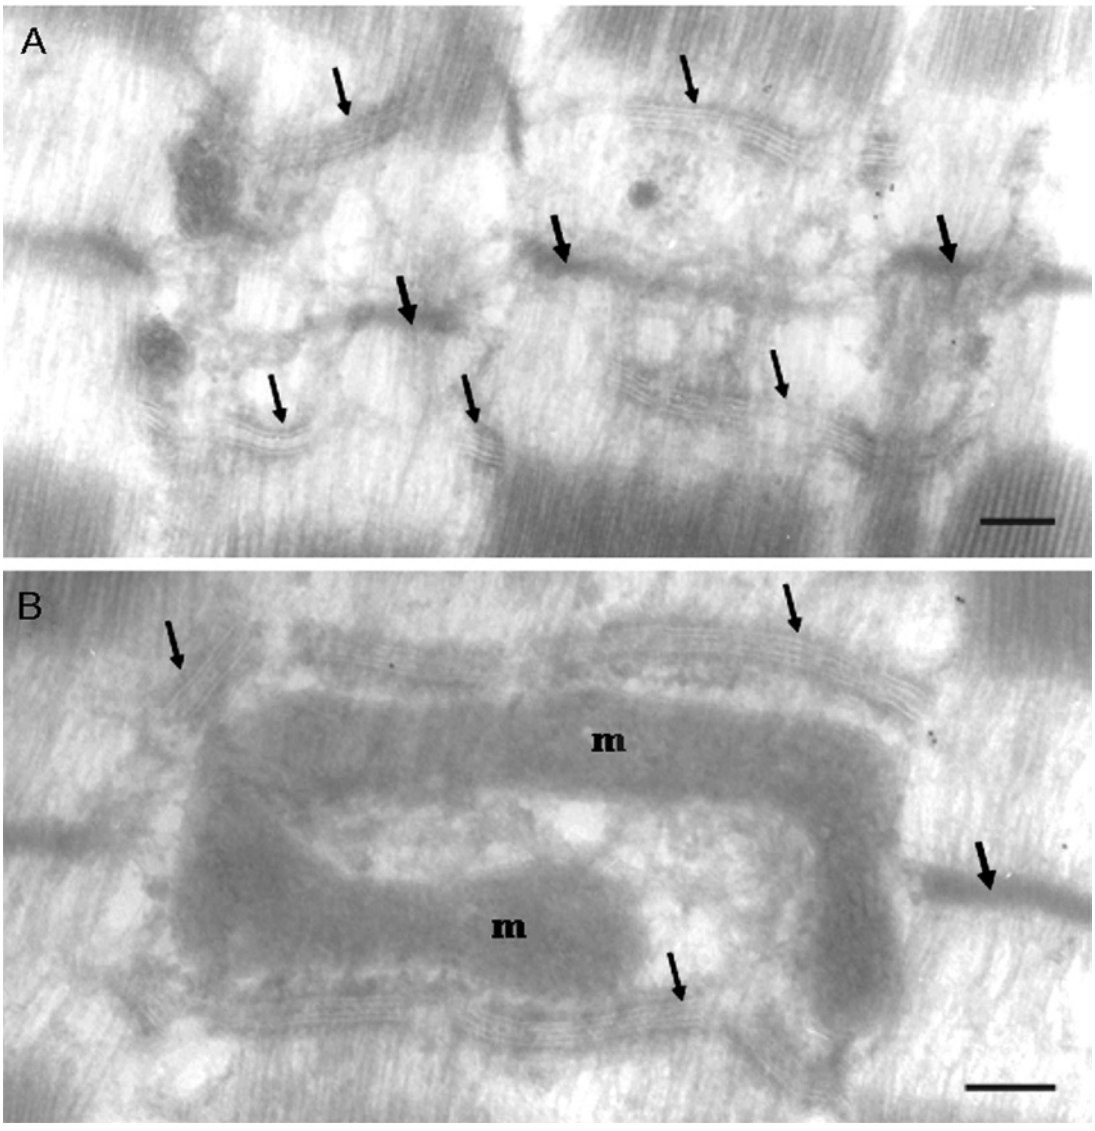

Figure 3.24.1 Electron micrograph of transverse tubules in rat skeletal muscle. Extensor digitorum longus muscle cryo-ultrasections were obtained from overnight-fasted rats and processed for electron microscopy. (**A**) Long sections of transverse tubules (T-tubules), indicated by arrows, run parallel to the Z-line. (**B**) Long stretches of T-tubules are close to mitochondria (m). Scale bars, 250 nm.

Current Protocols in Cell Biology (2006) 3.24.1-3.24.14

Two types of surfaces are distinguished in T-tubule membranes. A portion of T-tubule membranes faces into the junctional area with the sarcoplasmic reticulum, and that portion is called the junctional T membrane. The rest of the T-tubule membrane is in fragments of the network that do not participate in junction formation or that, if they are a junctional portion, face away from the junction itself.

T-tubules contain proteins relevant in the handling of Ca^{2+}, such as L-type Ca^{2+} channels (Carl et al., 1995; Brette and Orchard, 2003) and in the handling of Na^{+}, such as Na^{+}-K^{+}-ATPase or Na^{+} channels (Petrecca et al., 1999). In addition, T-tubules are sites for the initiation of certain signaling pathways that might be connected with the role of T-tubules in the transmission of membrane depolarization. T-tubules contain enzymes and other components important for the phosphoinositide pathway, which includes phospholipase C activity, G proteins, protein kinase C, phosphatidylinositol 4,5 bisphosphate, and inositol 1,4,5-trisphosphate (Di Virgilio et al., 1986; Toutant et al., 1990; Angelica et al., 1993; Hidalgo et al., 1993; Luise et al., 1993; Salvatori et al., 1993; Milting et al., 1994; Petrecca et al., 1999). T-tubules contain β-adrenergic receptors (Caswell et al., 1978). Colocalization of protein kinase A and calcineurin has also been detected in this compartment (Gao et al., 1997; Laflamme and Becker, 1999). T-tubules also contain abundant levels of insulin receptors and GLUT4 glucose transporters; therefore, insulin increases the abundance of GLUT4 in T-tubules (Marette et al., 1992; Munoz et al., 1995a; Wang et al., 1996). These data indicate that T-tubules participate in a large number of biological processes.

This unit focuses on the biochemical methods that permit one to obtain highly purified T-tubule membranes. Basic Protocol 1 focuses on the subcellular fractionation of rat skeletal muscle membranes to obtain membranes enriched in T-tubule markers. Two different methods for further purification of T-tubules are also described: wheat germ agglutination (Basic Protocol 2) and vesicle immunoisolation (Alternate Protocol).

BASIC PROTOCOL 1

SUBCELLULAR FRACTIONATION OF RAT SKELETAL MUSCLE MEMBRANES

This protocol is based in the sequential preparation of two crude membrane fractions, accomplished by a two-step homogenization from a single sample of rat skeletal muscle. These two different crude membrane fractions (F1 and F2) are washed with KCl, loaded with Ca^{2+}, and centrifuged on a sucrose gradient to obtain a variety of cell surface and intracellular membranes and, specifically, a fraction highly enriched in T-tubules (Figure 3.24.2). Of note, Ca^{2+} loading of sarcoplasmic reticulum membranes by incubation of fractions with ATP and $CaCl_2$ (Rosemblatt et al., 1981; Hidalgo et al., 1983) results in a T-tubule-enriched fraction that is free from sarcoplasmic reticulum membranes.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Rats (Wistar, male, ~250 g)
Homogenization buffer (see recipe), ice cold
4 M KCl
Ca^{2+}-loading buffer 1 (see recipe)
1 M ATP
150 mM $CaCl_2$
Ca^{2+}-loading buffer 2 (see recipe).
50 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)

Solution C (see recipe)
35%, 29%, 26%, and 23% (w/v) sucrose in sucrose gradient buffer (see recipe for buffer)
Tris-sucrose buffer (see recipe)
HEPES-sucrose buffer (see recipe)
Liquid nitrogen

Petri dish
Dissecting instruments
Polytron homogenizer with 1-cm-diameter probe
Sorvall refrigerated centrifuge with SA-600 rotor (or equivalent fixed-angle rotor)
Sorvall refrigerated high-speed centrifuge with T-647.5 rotor (or equivalent fixed-angle rotor)
Orbital shaker
Sorvall refrigerated high-speed centrifuge with TA-641 rotor (or equivalent swinging-bucket rotor) and 13-ml ultracentrifuge tubes

Additional reagents and equipment for Bradford protein assay (*APPENDIX 3H*)

Homogenize skeletal muscle

1. Excise 12 g of skeletal muscle tissue from the gastrocnemius and quadriceps muscles of three rats and place in a petri dish on ice. Trim muscles of fat and tendons, and mince into 2- to 4-mm^2 pieces.

2. Prepare six separate samples, each by homogenizing 2 g of minced skeletal muscle in 8 ml of ice-cold homogenization buffer using two 5-sec bursts of a Polytron homogenizer at low speed (setting 4; 6100 rpm) on ice.

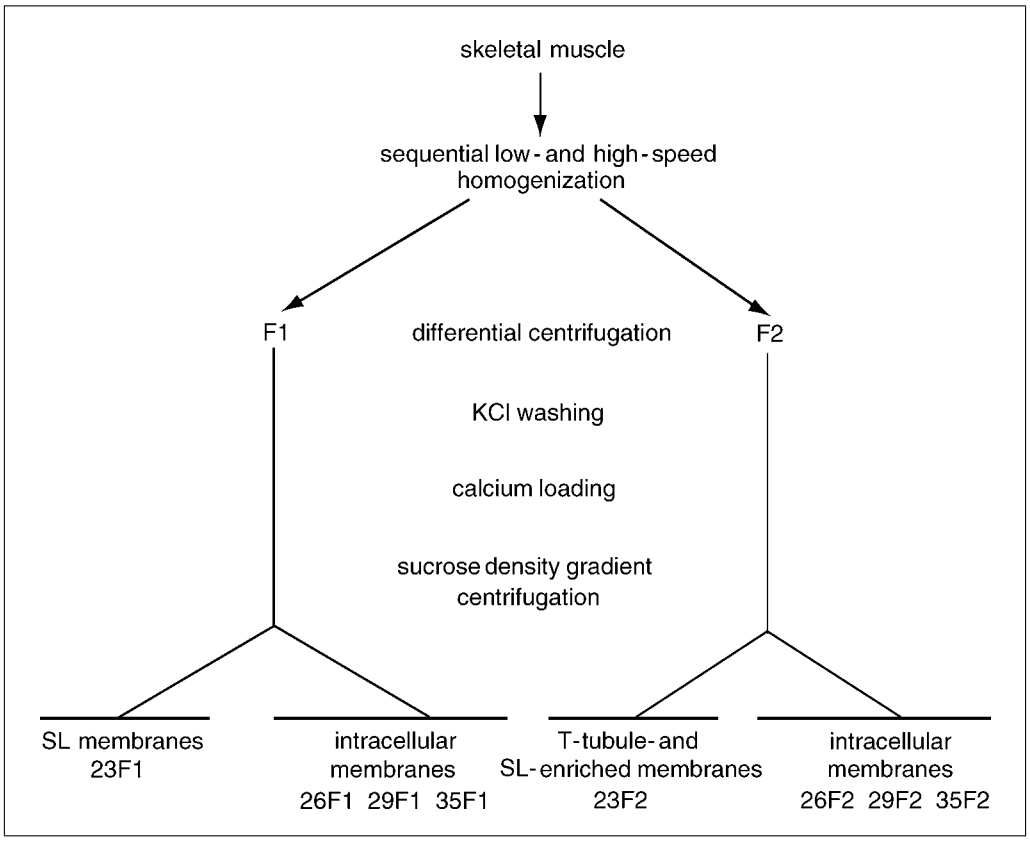

Figure 3.24.2 Flow chart of procedure used to isolate different membrane fractions from rat skeletal muscle. SL, sarcolemma.

Better control over homogenization can be achieved by splitting the sample into 2-g portions and homogenizing separately.

The speed of the homogenizer can be measured by a speed regulator (RECO-60) from Kinematica (http://www.kinematica.ch).

3. Centrifuge the homogenates separately for 20 min at 12,000 × *g* in a fixed-angle rotor, 4°C.

4. Collect the supernatants and store on ice.

5. Resuspend each pellet in 8 ml of homogenization buffer and centrifuge again for 20 min at 12,000 × *g*, 4°C.

6. Collect the supernatants of the second centrifugation and pool them with the supernatants from step 4.

   This pool is referred to as the F1 fraction (~100 ml).

7. Resuspend each of the six pellets in 8 ml ice-cold homogenization buffer and homogenize using two 30-sec bursts of the Polytron homogenizer at high speed (setting 6; 15,100 rpm) on ice.

   This second homogenization further disrupts muscle structures that may have resisted the initial homogenization step.

8. Centrifuge the homogenates 20 min at 12,000 × *g*, 4°C. Collect the supernatants and pool them together. Discard the pellets.

   This pool is referred to as the F2 fraction (~50 ml).

   The process described in steps 7 and 8 eliminates most of nuclei and mitochondria in the discarded pellet.

Solubilize myofibrils

9. Add 4 M KCl to F1 and F2 fractions for a final concentration of 0.6 M KCl. Incubate 1 hr at 4°C on an orbital shaker.

   This process solubilizes the myofibrils present in the membrane fractions.

10. Centrifuge each fraction 1 hr at 150,000 × *g* in fixed-angle rotor, 4°C.

11. Discard supernatants, which contain soluble myofibrillar proteins. Separately resuspend the pellets of F1 and F2 membrane fractions in ~2 ml Ca^{2+}-loading buffer 1.

12. Determine the protein concentration of each of the KCl-washed fractions using the Bradford method (*APPENDIX 3H*).

    Usually 25 mg and 35 mg of protein are recovered in F1 and F2 fractions, respectively.

13. Dilute the F1 and F2 fractions each to a concentration of 2 mg protein/ml with Ca^{2+}-loading buffer 1.

Load sarcoplasmic reticulum vesicles

14. To the KCl-washed F1 and F2 fractions, add 1 M ATP for a final concentration of 2 mM and 150 mM $CaCl_2$ for a final concentration of 0.3 mM.

15. Incubate membrane fractions for 20 min at room temperature on an orbital shaker. Every 5 min (i.e., at time points of 5, 10, and 15 min), add additional 1 M ATP and 150 mM $CaCl_2$ at volumes equivalent to 2 mM ATP and 0.3 mM $CaCl_2$.

    The process described in steps 14 and 15 loads the sarcoplasmic reticulum vesicles with calcium, thereby increasing their density.

Obtain membrane fractions

16. After the 20-min incubation, place the F1 and F2 fractions on ice and bring each solution to 60 ml with Ca^{2+}-loading buffer 2.
17. Centrifuge fractions 60 min at 150,000 × *g* in a fixed-angle rotor, 4°C.
18. Discard supernatants and resuspend each pellet in 1.5 ml of 50 mM Tris·Cl, pH, 7.2.
19. Determine the protein concentration of the resuspended membrane fraction by the Bradford method (*APPENDIX 3H*). Keep one 50-µl aliquot frozen for future analysis.

    Usually 15 and 25 mg of protein are recovered in F1 and F2 fractions, respectively.

20. Add 1.8 ml of solution C to each of the resuspended membrane fractions (F1 and F2).

Separate membranes

21. Prepare two discontinuous density gradients (designated for F1 and F2, respectively) in 13-ml ultracentrifuge tubes by carefully layering 3 ml of 35% sucrose at the bottom of the tube, then layering 2 ml of 29% sucrose over that, followed by 2 ml of 26% sucrose, and finally 2 ml of 23% sucrose as the upper layer. Keep gradients on ice.
22. Carefully layer the resuspended membrane fraction (F1 or F2) on top of its designated gradient. Centrifuge the gradients 12 hr at 77,000 × *g* in a swinging-bucket rotor, 4°C.
23. After centrifugation collect four protein fractions from each gradient:

    Fraction 23 on top of the 23% layer
    Fraction 26 from the 23%/26% interface
    Fraction 29 from the 26%/29% interface
    Fraction 35 from the 29%/35% interface.

    Also collect the pellets (pellet F1 and pellet F2).

24. Dilute all the collected fractions up to 60 ml with Tris-sucrose buffer. Centrifuge the diluted fractions 60 min at 150,000 × *g* in a fixed-angle rotor, 4°C, and remove the supernatants.
25. Resuspend pellets in HEPES-sucrose buffer at the following (typical) volumes:
    a. Add 0.3 ml to pellets obtained from the F1 and F2 fractions 23 and 35.
    b. Add 0.2 ml to pellets obtained from the F1 and F2 fractions 26 and 29.
    c. Add 0.6 ml to pellet F1 and pellet F2 (collected at the bottom of the original gradient; see step 23).
26. Determine the protein concentrations of each of the fractions by the Bradford method (*APPENDIX 3H*).

    F2 fraction 23 is highly enriched in T-tubule membranes and its protein yield is ~0.5 mg.

27. Divide fractions into 30- to 50-µl aliquots in microcentrifuge tubes and freeze in liquid nitrogen. Store at −80°C.

BASIC PROTOCOL 2

SEPARATION OF T-TUBULES FROM SARCOLEMMAL VESICLES BY WHEAT GERM AGGLUTINATION

This protocol is based on previously reported methods used in T-tubule preparations from heart and skeletal muscle (Charuk et al., 1989; Ohlendieck et al., 1991). The method consists of the separation of cell surface membranes that are susceptible to agglutination by wheat germ agglutinin (WGA), a lectin with high affinity for N-acetyl-D-glucosamine and sialic acid, which are components of membrane glycoproteins.

WGA-induced agglutination requires that the cell surface membrane vesicles be right-side-out so the carbohydrates are exposed to the incubation medium. Whereas most sarcolemmal vesicles are right-side-out, vesicles originating from T-tubule membranes show an inverse orientation such that the cytosolic side of the membranes are localized in the lumen of the vesicle (inside-out vesicles). As a consequence, T-tubule vesicles cannot be agglutinated by WGA, because the carbohydrates are located in the vesicular lumen. This protocol leads to efficient separation of T-tubule membranes from sarcolemmal membranes which, otherwise, share similar biophysical properties.

Materials

F2 fraction 23 (Basic Protocol 1)
50 mM potassium phosphate buffer, pH 7.4 (*APPENDIX 2A*), containing 160 mM NaCl
1 mg/ml wheat germ agglutinin (WGA; lectin from *Triticum vulgaris*, lyophilized powder, Sigma) in 50 mM phosphate buffer (pH 7.4)/160 mM NaCl
Tris-sucrose buffer (see recipe)
Deagglutination buffer (see recipe)
Liquid nitrogen

Beckman ultracentrifuge with TLS-55 rotor (or equivalent)
10-ml ultracentrifuge tubes for TLS-55 rotor

Expose T-tubule-enriched fractions to WGA

1. Thaw 300 μg of protein from F2 fraction 23 (enriched in T-tubules) by warming the tube at 37°C.
2. Dilute samples to 1 mg protein/ml with 50 mM phosphate buffer (pH 7.4)/160 mM NaCl.
3. Add 0.3 ml of 1 mg/ml WGA. Shake gently and incubate 10 min on ice.
4. Microcentrifuge 1.5 min at 15,000 × *g*, room temperature. Transfer the supernatant (WGA^- fraction, enriched in T-tubules) to a separate microcentrifuge tube on ice.
5. Resuspend the pellet containing the lectin-agglutinated vesicles (WGA^+ fractions) in 1 ml of 20 mM Tris-sucrose buffer and microcentrifuge 1.5 min at 15,000 × *g*, room temperature, and discard the supernatant. Repeat twice more for a total of three washes.

Harvest WGA^+ fraction (sarcolemmal vesicles)

6. Resuspend the WGA^+ pellet in 0.5 ml of deagglutination buffer. Incubate 20 min on ice.
7. Microcentrifuge the deagglutinated suspension 1.5 min at 15,000 × *g*, 4°C. Collect the supernatant, transfer to a 10-ml ultracentrifuge tube, and ultracentrifuge 60 min at 150,000 × *g*, 4°C.
8. *Optional:* Resuspend the WGA^+ pellet (sarcolemmal vesicles) in 50 μl Tris-sucrose buffer and freeze in liquid nitrogen. Store at −80°C.

   This fraction is harvested if a comparative analysis of sarcolemmal and T-tubule proteins is to be done.

Harvest WGA⁻ fraction (T-tubule vesicles)

9. Ultracentrifuge the nonagglutinated vesicles (supernatant from step 4) 60 min at 150,000 × *g*, 4°C. Remove the supernatant.

10. Resuspend the WGA⁻ pellet in 50 µl Tris-sucrose buffer and freeze in liquid nitrogen. Store at −80°C.

PURIFICATION OF T-TUBULES BY VESICLE IMMUNOISOLATION

ALTERNATE PROTOCOL

An alternative to the purification of T-tubules by WGA agglutination is the use of vesicle immunoisolation techniques. Central to these techniques is the use of antibodies that specifically recognize intracellular domains of membrane proteins selectively localized in T-tubules. This protocol makes use of an antibody raised against protein tt28, a major component of the transverse tubular membrane vesicles (Rosemblatt et al., 1981; Horgan and Kuypers, 1987). Antibodies can be coupled to different type of beads such as agarose or acrylamine (Zorzano et al., 1989, 1996; Munoz et al., 1995a,b; Munoz et al., 1996; Fischer et al., 1997). This protocol leads to efficient separation of T-tubule membranes from sarcolemmal membranes and, in addition, permits the separation of T-tubule membranes from intracellular membranes that also contaminate those membrane fractions.

Materials

Goat anti–mouse IgG coupled to agarose beads, saline suspension (5 to 10 mg antibody/ml bead suspension; Sigma)

Phosphate-buffered saline (PBS; *APPENDIX 2A*), pH 7.4

Anti-tt28 antibody, monoclonal (Rosemblatt and Scales, 1989), or other antibody directed against tt-28 or against other proteins such as DHPR (Morton and Froehner, 1987, 1989; Flucher et al., 1991)

Blocking solution: 1% (w/v) bovine serum albumin (BSA) in PBS, pH 7.4 (prepare fresh)

T-tubule-enriched fraction (typically fraction 23 from F2; see Basic Protocol 1)

2× immunoadsorption solution (see recipe)

3× Laemmli sample buffer (see recipe)

Orbital shaker

95°C water bath or heat block

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*)

Couple anti-tt28 antibody to anti-IgG-coupled agarose beads

1. Pipet 75 µl of the suspension of goat anti-mouse IgG coupled to agarose beads into a microcentrifuge tube. Wash the beads by adding 1 ml PBS, shaking gently, and microcentrifuging 6 sec at maximum speed, room temperature. Discard supernatant and repeat washing step a second time.

2. Add 5 µg anti-tt28 antibody to the bead pellet, then bring to a final volume of 50 µl with PBS. Incubate overnight at 4°C with constant shaking on an orbital shaker.

3. Microcentrifuge 6 sec at maximum speed. Discard the supernatant (containing free anti-tt28 antibody) and wash the pellet twice with 1 ml of PBS using the technique described in step 1.

4. Wash the coupled beads by adding 1 ml blocking solution to the pellet, incubating 15 min at room temperature with sporadic shaking, then microcentrifuging 6 sec at maximum speed, room temperature, and discarding the supernatant. Repeat this wash procedure twice with blocking solution, then once with PBS using the same technique.

Immunoadsorb and collect vesicles

5. Add to 25 μg of protein from T-tubule-enriched fraction in 200 μl of 1× immunoadsorption solution to the coupled beads. Incubate beads overnight at 4°C with shaking on an orbital shaker.

6. Collect the agarose beads and the vesicles bound to them by microcentrifuging 6 sec at maximum speed, room temperature. Transfer the supernatant, which contains the unadsorbed membrane vesicles, to a new microcentrifuge tube. Also save the pellet, which contains the T-tubule vesicles.

7. Add 3× Laemmli sample buffer to the supernatant for a final concentration of 1×, incubate 5 min at 95°C, then microcentrifuge 10 sec at maximum speed. Collect the supernatant and analyze by SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*).

   Analysis of the unadsorbed membranes in the supernatant by SDS-PAGE and subsequent immunoblotting will allow the efficacy of immunoadsorption to be determined.

8. Wash the pellet from step 6 (which contains the vesicles that are bound to the immobilized antibody) twice, each time by adding 1 ml PBS, microcentrifuging 6 sec at maximum speed, room temperature, and discarding the supernatant.

9. Add 0.5 ml PBS to the pellet and incubate for 30 min at room temperature. Microcentrifuge 6 sec at maximum speed, room temperature, and discard the supernatant.

10. Elute the adsorbed material from the beads by adding 0.1 ml of 1× Laemmli sample buffer. Incubate 5 min at 95°C.

11. Microcentrifuge 6 sec at maximum speed, room temperature. Collect the supernatant (eluted material from the beads, containing the proteins that were bound as well as the eluted anti-tt20 antibody) and analyze by SDS-PAGE (*UNIT 6.1*).

    This fraction contains protein tt28 (28 kDa), the α_2 subunit of DHPR (170 kDa), GLUT4 (45 kDa), or the β subunit of insulin receptors (95 kDa).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ca^{2+}-loading buffer 1

50 mM potassium phosphate buffer, pH 7.5 (APPENDIX 2A), containing:
5 mM $MgCl_2$
150 mM KCl
Store up to 1 month at 4°C

Ca^{2+}-loading buffer 2

50 mM potassium phosphate buffer, pH 7.5 (APPENDIX 2A), containing:
5 mM $MgCl_2$
150 mM KCl
0.3 mM $CaCl_2$
Prepare fresh just before use

This buffer can be prepared immediately before use from Ca^{2+}-loading buffer 1 (see recipe) by adding 150 mM $CaCl_2$ to a final concentration of 0.3 mM $CaCl_2$.

Deagglutination buffer

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
250 mM sucrose
300 mM N-acetyl-D-glucosamine
Prepare fresh just before use

HEPES-sucrose buffer

30 mM HEPES, pH 7.4
250 mM sucrose
Prepare just before use and store on ice

Homogenization buffer

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
250 mM sucrose
1 mM EDTA
1 μM pepstatin
1 μM leupeptin
Prepare fresh just before use and store on ice

Immunoadsorption solution, 2×

Phosphate-buffered saline (PBS), pH 7.4 (APPENDIX 2A) containing:
0.2% (w/v) BSA
2 mM EDTA
Prepare fresh just before use

Laemmli sample buffer, 3×

0.3 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
60% (v/v) glycerol
6% (w/v) SDS
Pinch of bromphenol blue
Store in aliquots at –20°C

Solution C

90 mM $Na_4P_2O_7$
540 mM KCl
Store with above ingredients at 4°C
Just before use add 450 mM sucrose
pH should be 7.2 (determined by the 90 mM pyrophosphate)

Sucrose gradient buffer

20 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)
50 mM $Na_4P_2O_7$
300 mM KCl
Store at 4°C

Tris-sucrose buffer

20 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
250 mM sucrose
Prepare just before use and store on ice

COMMENTARY

Background Information

It has been reported that gentle homogenization of skeletal muscle favors the isolation of sarcolemmal membranes, which do not contain T-tubules (Burdett et al., 1987), whereas a more energetic homogenization of skeletal muscle favors the isolation of T-tubule membranes (Lau et al., 1977; Dunn, 1989). Based on these observations, a protocol involving two sequential homogenization steps differing in the speed at which the Polytron operates seems best suited for obtaining T-tubules that are less contaminated with sarcolemmal membranes. However, this procedure is not sufficient to bypass all of the problems associated with the purification of membranes from skeletal muscle. One difficulty is related to the high abundance of myofibrillar proteins in this tissue. In fact, myofibrillar proteins interact with many other cellular proteins and membranes, and

this is particularly the case after tissue homogenization. In order to prevent this nonspecific sequestering of membranes by myofibrillar proteins, homogenates are treated with high concentrations of KCl at 4°C, which destabilizes myofibrillar proteins and reduces their binding to membranes (Barchi et al., 1979). Another technical problem is the extremely high abundance of sarcoplasmic reticulum membranes in skeletal muscle; these contaminate most membrane fractions obtained from this tissue. To minimize this problem, the density of the sarcoplasmic reticulum vesicles is increased in vitro by loading them with Ca^{2+} in a process catalyzed by the high Ca^{2+}-ATPase activity.

The procedure explained in Basic Protocol 1 permits the generation of a membrane fraction highly enriched in T-tubules (named 23F2, referring to fraction 23 of F2; see Basic Protocol 1); this membrane fraction is characterized by the high abundance of the α_2

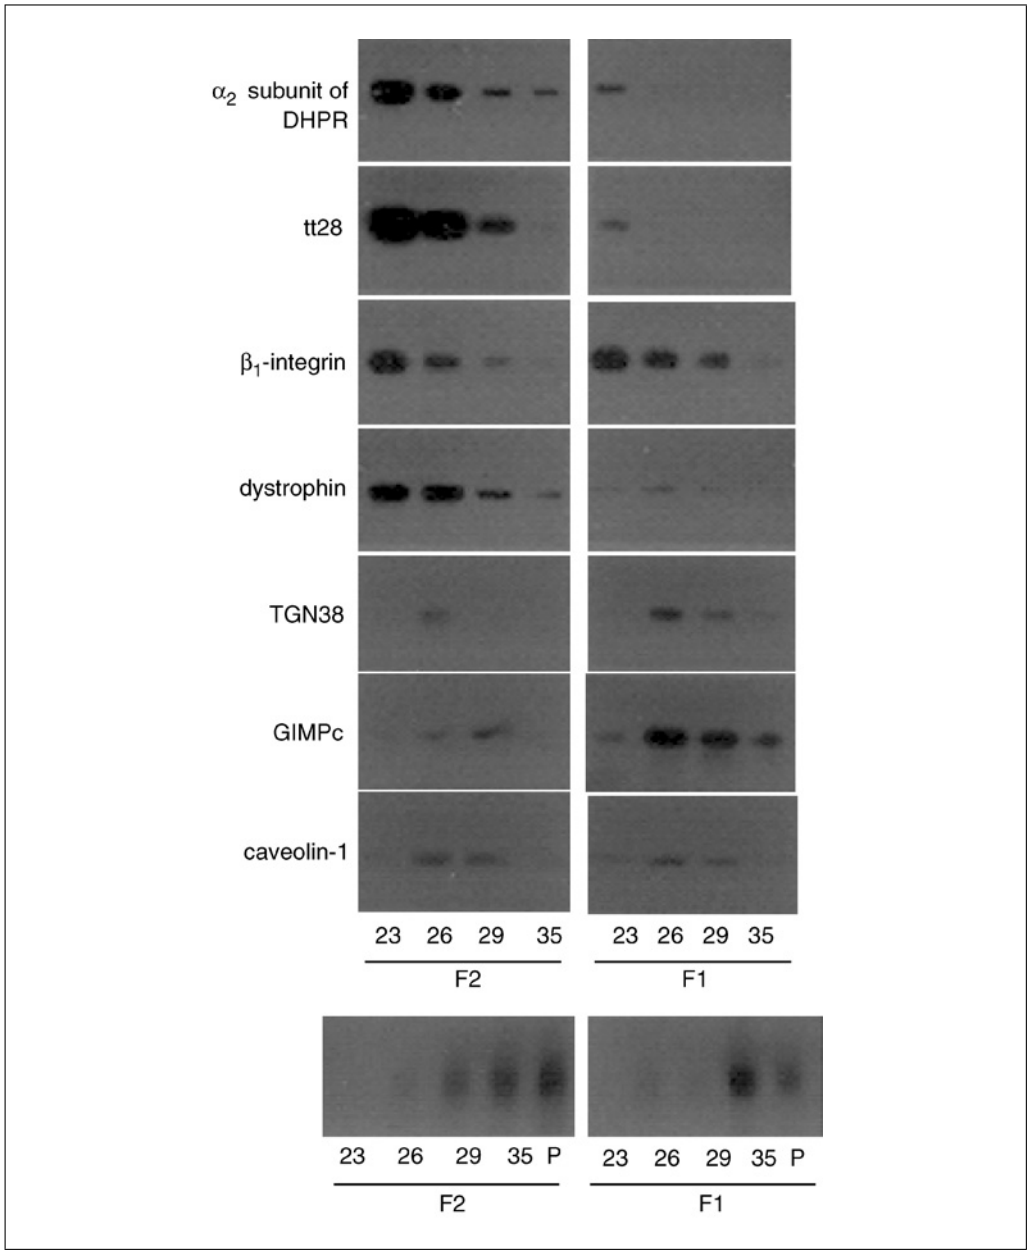

Figure 3.24.3 Demonstration that the fraction 23F2 is highly enriched in T-tubule markers and is essentially free from sarcoplasmic reticulum. The abundance of T-tubule markers (α_2 subunit of dihydropyridine receptors, DHPR, and protein tt28), sarcolemmal markers (β_1-integrin and dystrophin), trans-Golgi network (TGN38), cis-Golgi (GIMPc), sarcoplasmic reticulum (Ca^{2+}-ATPase), and endothelial cells (caveolin-1) is assayed in different membrane fractions obtained from rat skeletal muscle. The distribution of the different proteins is studied by immunoblot assays.

subunit of the dihydropyridine receptor and of the protein tt28, both of which are known markers of transverse tubules (Fig. 3.24.3). This membrane fraction is free from intracellular membrane components or sarcoplasmic reticulum, as indicated (see Fig. 3.24.3) by the absence of Ca^{2+}-ATPase or TGN38 (marker of the *trans*-Golgi network) or GIMPc (marker of the *cis*-Golgi). However, this fraction also contains proteins that are markers of sarcolemmal membranes, such as β_1-integrin or dystrophin (Fig. 3.24.3). In addition, a membrane protein that is only detected in endothelial cells in skeletal muscle, caveolin-1, is detected in very low levels in the membrane fraction 23F2 (Fig. 3.24.3). These data indicate that the membrane fraction highly enriched in T-tubules is also contaminated with sarcolemmal vesicles, and that it contains very low levels of endothelial cell–derived membranes. These characteristics are not specific to preparations obtained via the procedure explained in Basic Protocol 1, but are general properties of methods that permit the isolation of T-tubule membranes.

Purification of T-tubules from sarcolemmal membranes can be achieved through two different methods: separation of T-tubules in a nonagglutinable fraction (WGA^-) after treatment with wheat germ agglutinin (Basic Protocol 2) or immunoisolation of T-tubule vesicles using immobilized antibodies directed against proteins specific of the T-tubules (Alternate Protocol).

Treatment of fraction 23F2 (Basic Protocol 1) with WGA renders two fractions, an agglutinable fraction (WGA^+) and a nonagglutinable fraction (WGA^-). Usually these two fractions account for 74% and 26%, respectively, of the total protein recovered after WGA treatment. Most importantly, the WGA^- fraction is markedly enriched in the T-tubule protein markers tt28 and dihydropyridine receptors and shows no sarcolemmal protein markers such as β_1-integrin, dystrophin, or GLUT1 glucose transporters (Fig. 3.24.4). Thus, the WGA^- fraction constitutes a highly purified T-tubule fraction that is essentially devoid of sarcolemmal markers. It is also likely that this fraction shows low contamination with membranes from endothelial origin, as assessed by the presence of caveolin-1 (Fig. 3.24.4).

Immunoisolation of T-tubule vesicles has been accomplished by using monoclonal antibodies directed against protein tt28 or a cytosolic domain of GLUT4 glucose transporters (Munoz et al., 1995a,b). Immobilized anti-tt28 antibody immunoprecipitates vesicles that are characterized by high tt28 protein, dihydropyridine receptors, and GLUT4 content

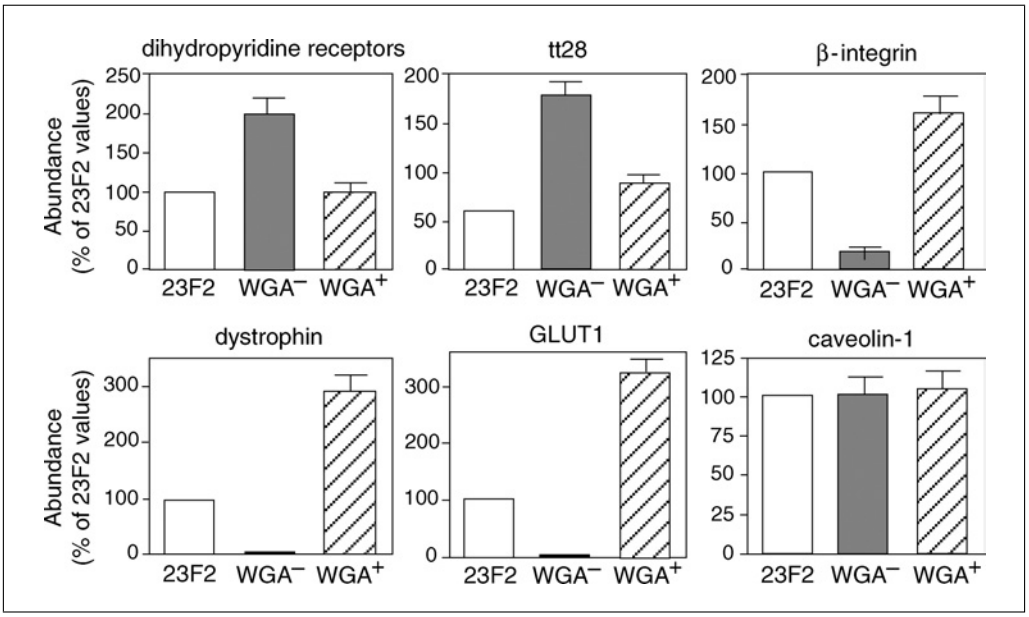

Figure 3.24.4 Purification of T-tubule membrane vesicles by WGA agglutination. Dihydropyridine receptors, protein tt28, β_1-integrin, dystrophin, GLUT1, and caveolin-1 were assayed before and after agglutination with WGA lectin. 23F2 fractions were incubated with WGA, and subsequently the nonagglutinated fraction (WGA^-) was separated from the agglutinated vesicles (WGA^+). The distribution of surface markers was studied by immunoblot assays. Equal amounts of membrane protein from the different fractions were loaded on the gels. The results are mean ±SEM of six experiments and are expressed as percentage of levels detected in fraction 23F2.

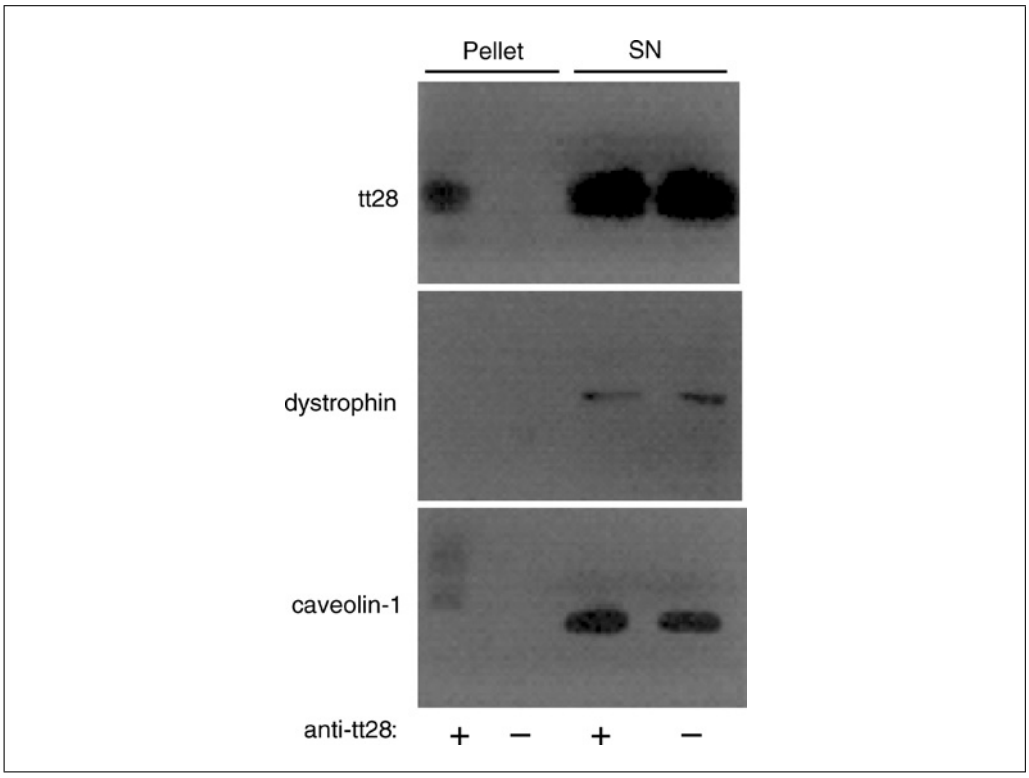

Figure 3.24.5 Purification of T-tubule membranes by vesicle immunoisolation. Membrane vesicles 23F2 highly enriched in T-tubules were incubated with or without immobilized antibody against protein tt28. After incubation, the immunoadsorbed fractions (pellet) and the nonadsorbed fraction (SN) were electrophoresed and immunoblotted to determine the abundance of proteins tt28, dystrophin, and caveolin-1.

(Fig. 3.24.5 and data not shown) and that lack caveolin-1 and dystrophin (Fig. 3.24.5). These data indicate that the purification of T-tubule vesicles by vesicle immunoisolation renders a fraction that is free from contamination by sarcolemmal or endothelial membranes vesicles.

Critical Parameters and Troubleshooting

The methods explained above require substantial training on the part of the researcher, and there are a number of critical parameters that should be kept in mind. The method explained in Basic Protocol 1 has been set up using rat skeletal muscle; therefore, changes in the species being used may lead to different results. More specific concerns relate to three key parameters: (1) the intensity of the homogenization, (2) the effectiveness of the myofibril solubilization, and (3) the increase in the density of the sarcoplasmic reticulum achieved by calcium loading.

In Basic Protocol 1, the yield of membrane protein and the quality of the membrane protein extract critically depend on the Polytron speed and homogenization time. In this regard, an increase in the Polytron speed or duration in the first homogenization may release T-tubules and lower the yield of T-tubule membrane proteins in fraction 23F2. Special attention should be paid to calibration of the speed of the Polytron. Similarly, poor myofibril solubilization or destabilization will reduce the yield of all membrane proteins, including T-tubule membranes. Finally, poor calcium loading of sarcoplasmic reticulum vesicles will markedly reduce the purity of T-tubule membranes.

Based on these considerations, changes in protein yield and in the purity of the different membrane fractions may indicate the existence of a problem at any of these steps. In this regard, membrane yields using Basic Protocol 1 have been reported in the literature (Munoz et al., 1995b).

Anticipated Results

Starting with 12 g of rat muscle, a crude preparation of T-tubules (23F2) equivalent to 0.5 mg protein will be obtained. Wheat germ agglutination starting with 0.3 mg of 23F2 will yield ~0.08 mg of highly purified T-tubules. Immunoadsorption permits a high level of purification of membrane T-tubules, but the preparation will also contain the antibody against the T-tubule protein tt28.

Time Considerations

The amount of time required to perform Basic Protocol 1 is rather long. Performance of the whole procedure takes 1.5 days of continuous work. In contrast, Basic Protocol 2 takes ~3 hr. The Alternate Protocol takes 3 days if both steps, coupling of antibodies to agarose beads and immunoadsorption, are done overnight.

Isolation of Myelin

The methods used to prepare myelin involve homogenization of the tissue in isotonic sucrose solution, followed by the isolation of myelin membranes by a series of steps that include density gradient centrifugation and differential centrifugation. Homogenization of nervous tissue in isotonic sucrose causes the myelin sheath to peel from the axon and form myelin vesicles relatively large in size. The large size of the myelin vesicles, together with the fact that myelin has a lower density than other biological membranes, make differential centrifugation and density gradient centrifugation the main tools for the isolation of this membrane. Three protocols are outlined in this unit. The Basic Protocol describes the isolation of a highly-purified myelin fraction from the central nervous system (CNS). Alternate Protocol 1 outlines the separation of a highly-purified CNS myelin fraction into subfractions of different densities. Alternate Protocol 2 describes the isolation of myelin from the peripheral nervous system (PNS).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

ISOLATION OF CENTRAL NERVOUS SYSTEM MYELIN

BASIC PROTOCOL

This protocol is based on the Norton and Poduslo method (Norton and Poduslo, 1973). Two modifications to the original Norton and Poduslo protocol are incorporated. One is the inclusion of 20 mM Tris·Cl buffer (pH 7.45 at 25°C), 1 mM dithiothreitol (DTT), and a mixture of protease inhibitors (Larocca et al., 1987, 1991; *UNIT 3.4*) in all solutions. The other is the inclusion of an extra density gradient centrifugation (Haley et al., 1981). These two modifications result in better conservation of the enzymatic activities present in myelin and increased purity of the myelin fraction. In particular, the degree of axolemma contamination is reduced (Haley et al., 1981).

This protocol can be used for the isolation of myelin from different sources including developing and adult whole brain, spinal cord, and white matter from animals of different species including rodent, bovine, and human. This protocol can be used to isolate myelin from fresh or frozen tissue. The following describes the isolation of myelin from fresh adult rat whole brain. The brain is homogenized in 0.3 M sucrose solution containing 20 mM Tris·Cl buffer (pH 7.45), 1 mM EDTA, 1 mM DTT, 100 μM phenylmethylsulfonyl fluoride (PMSF), 10 μg/ml leupeptin, and 10 μg/ml antipain (these compounds are present in all steps of the procedure). The homogenate is layered over 0.83 M sucrose and centrifuged 35 min at high speed (75,000 × *g*). The band of crude myelin membranes formed at the 0.3 M /0.83 M sucrose interface is collected, and after washing out the sucrose with hypotonic buffer, this myelin fraction is subjected two times to a cycle of hypoosmotic shock and low-speed centrifugation (15 min at 12,000 × *g*) to remove cytoplasmic and microsomal contaminants. Then myelin is further purified by subjecting the crude myelin fraction to a repetition of the first density gradient centrifugation, and the cycle of hypoosmotic shock and low-speed centrifugation. Finally, a highly-purified myelin fraction is prepared by a third density gradient centrifugation, but in this step, myelin is resuspended in 0.83 M sucrose, and the 0.83 M sucrose solution overlaid with 0.30 M sucrose. During centrifugation, myelin floats upward to band at the 0.30/0.83 M sucrose interface.

Current Protocols in Cell Biology (2006) 3.25.1-3.25.19

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature.

Materials

200- to 300-g Sprague-Dawley rats (30 to 60 days old)
Anesthesia
0.30 M and 0.83 M sucrose solutions (see recipe)
Tris·Cl buffer solution (see recipe)

Glass plate
Dissecting tools including: scissors, razor blades, spatulas, and forceps
50- and 100-ml beakers
Razor blades
40-ml Dounce homogenizer (Kontes) with both loose (clearance 0.0030 to 0.0060 in.) and tight (clearance 0.0010 to 0.0030 in.) pestles
100- and 250-ml graduated cylinder
38.5-ml thick-walled ultracentrifuge tubes
Ultracentrifuge with swinging-bucket rotor (Beckman SW 28, or equivalent)
Pasteur pipets
Glass rod

Additional reagents and equipment for determining protein concentration (*APPENDIX 3H*)

Dissect brains

1. Place a glass plate on a bed of ice in an ice bucket. Ensure that the glass plate will fit flat inside the ice bucket.
2. Anesthetize three animals and then euthanize by decapitation.

   This must be supervised or carried out by an experienced animal technician according to an approved animal protocol.

3. Open the cranial cavity using scissors and forceps, and remove the brain (with the use of a spatula) to a chilled beaker containing 20 ml of 0.30 M sucrose solution, which has been weighed.
4. Reweigh the beaker. Record weight of the brains.
5. Transfer the brains to the glass plate, use a razor blade to quickly remove the meninges and then mince the brains into cubes of ~0.25 × 0.25 × 0.25–cm.

   Mincing the brains is not strictly necessary, but facilitates homogenization.

Homogenize the tissue

6. Place the minced brains in a cold beaker containing 60 ml of 0.30 M sucrose solution.
7. Pour ~30 ml of the minced brain suspenson into the cold vessel of the Dounce homogenizer.
8. Homogenize the tissue suspension by using five strokes of the loose pestle and five to seven strokes of the tight pestle, on ice.
9. Transfer the tissue homogenate to a 100-ml graduated cylinder and proceed to homogenize the rest of the tissue suspension.
10. Combine both homogenates and bring the suspension to a final volume of 72 ml with 0.30 M sucrose solution.

    The suspension should not contain more than 5 g of wet tissue per 100 ml.

Carry out density gradient centrifugation

11. Layer 18 ml of homogenate over 18 ml of 0.83 M sucrose solution in each of four 38.5-ml ultracentrifuge tubes, and ultracentrifuge 30 min at 75,000 × *g*, 4°C.

    When thin-walled tubes are used, be sure that the tubes are filled to within 2 to 3 mm from the top (~2 ml more of 0.30 M sucrose solution should be added).

12. Collect the layers of crude myelin, which form at the interface of the two sucrose solutions, with a Pasteur pipet and transfer to the cold homogenizer vessel. Discard the rest of the gradient.

    To facilitate the harvesting of the crude myelin fraction, first discard the 0.30 M sucrose solution and then collect the crude myelin preparation.

Subject the myelin fraction to osmotic shock

13. Resuspend the combined myelin layers in 20 ml of Tris·Cl buffer by homogenization using five to seven strokes of the tight pestle.

    Osmotic shock and differential centrifugation remove small microsomal membrane fragments and cytoplasmic contaminants.

14. Transfer myelin membranes to a 250-ml graduated cylinder, and bring the suspension to a final volume of 228 ml with Tris·Cl buffer solution.

15. Transfer the suspension to six 38.5-ml ultracentrifuge tubes and centrifuge the suspension 15 min at 75,000 × *g*, 4°C.

16. Discard the supernatant and resuspend the pellet in Tris·Cl buffer solution. To facilitate pellet resuspension, add 2 ml of Tris·Cl buffer solution to the ultracentrifuge tubes and use a glass rod to gently stir the pellet. Using a Pasteur pipet, transfer the resuspended membrane to a 40-ml homogenizer.

    Alternatively, the pellet can be resuspended by pipeting up and down using a Pasteur pipet.

17. Disperse the myelin membranes in 20 ml Tris·Cl buffer solution by homogenization using five to seven strokes of the tight pestle.

18. Transfer myelin membranes to a 250-ml graduated cylinder, and bring the suspension to a final volume of 228 ml with Tris·Cl buffer solution.

19. Transfer the suspension to six 38.5-ml ultracentrifuge tubes and ultracentrifuge the suspension 15 min at 12,000 × *g*, 4°C.

20. Discard the cloudy supernatant, then resuspend and disperse the loosely packed pellets in 228 ml Tris·Cl buffer solution as described in steps 16 to 18.

21. Centrifuge the crude myelin suspension 10 min at 12,000 × *g*, 4°C.

Purify myelin from a crude myelin preparation

22. Combine the crude myelin pellets and suspend them in 72 ml of 0.30 M sucrose solution. Layer 18 ml of this suspension over 18 ml of 0.83 M sucrose solution in four 38.5-ml ultracentrifuge tubes and ultracentrifuge 30 min at 75,000 × *g*, 4°C.

23. Harvest the purified myelin from the interface with a Pasteur pipet and suspend the combined myelin layers in 228 ml Tris·Cl buffer solution.

24. Wash out the sucrose solution and subject the myelin preparation to further purification by hypoosmotic shock and differential centrifugation as described in steps 13 to 21.

A third discontinuous gradient followed by a cycle of hypoosmotic shock and differential centrifugation results in a slight increase in myelin purity. Therefore, consider the possibility of using the myelin fraction obtained in step 24 as purified myelin.

Perform further myelin purification

25. Resuspend the myelin pellet in 72 ml of 0.83 M sucrose solution.
26. Transfer 18 ml of the myelin suspension to 38.5-ml centrifuge tubes, overlay the myelin suspension with 18 ml 0.30 M sucrose and centrifuge 30 min at 75,000 × *g*, 4°C.
27. Harvest the myelin fraction at the interface and subject the myelin fraction to hypoosmotic shock as described in steps 13 to 21.
28. Determine protein concentration (*APPENDIX 3H*) and resuspend pellet in Tris·Cl buffer solution to 1 to 5 mg protein/ml.

Metabolic assays should be carried out as soon as possible upon preparation; some marker enzyme assays can be carried out after storage for 1 to 16 hr at 4°C. Many assays can be carried out on material frozen at −20°C or −80°C. Measurements that are made with frozen material should be compared with those made on fresh material to confirm that they are relatively unaffected by storage conditions. For determination of myelin dry weight, carry out steps 27 and 28 using water instead of buffer. Then lyophilize and weigh the myelin preparation and store up to 1 year at −80°C.

ALTERNATE PROTOCOL 1

SEPARATION OF HIGHLY PURIFIED CNS MYELIN FRACTION INTO SUBFRACTIONS OF DIFFERENT DENSITIES

Highly-purified myelin (see Basic Protocol, step 28) contains a heterogeneous population of membranes that have different morphologies and chemical compositions (Norton and Cammer, 1984). Purified myelin can be subfractionated either by continuous or discontinuous densitygradient centrifugation. This protocol outlines the myelin subfractionation by discontinuous density gradient centrifugation and is based in the method described by Cammer et al. (1977). Isolated CNS myelin is suspended in 0.30 M sucrose solution and layered on a discontinuous gradient. After centrifugation, the myelin subfractions contained at the interfaces and in the pellet are collected, resuspended in Tris·Cl buffer solution, and pelleted. The light myelin subfractions contain mainly multilamellar fragments; the dense subfractions are enriched in single membrane vesicles and fragments with only two or three membrane layers (Norton and Cammer, 1984).

NOTE: All solutions contain 20 mM Tris·Cl buffer (pH 7.45), 1 mM EDTA, 1 mM DTT, 100 μM PMSF, 10 μg/ml leupeptin, and 10 μg/ml antipain.

Additional Materials *(also see Basic Protocol)*

Highly-purified myelin fraction (see Basic Protocol, step 28)
0.30, 0.62, and 0.70 M sucrose solutions (see recipe)

1. Prepare a highly-purified myelin fraction as described in Basic Protocol, step 28.
2. Resuspend the highly-purified myelin in 25 ml of 0.30 M sucrose solution.
3. Prepare two discontinuous gradients using two 38.5-ml ultracentrifuge tubes. In each tube, layer 12.5 ml each of 0.62 M sucrose solution, 0.70 M sucrose solution, and sample.
4. Ultracentrifuge the gradients 35 min at 75,000 × *g*, 4°C.

5. Collect the myelin subfractions, which form at the interfaces of the sucrose solutions (i.e., between 0.30 M/0.62 M and 0.62 M/0.70 M) and in the pellet, with a Pasteur pipet.

   This step will generate three different subfractions: (1) low-density myelin (L), myelin collected from the 0.30 M/0.62 M sucrose interface, (2) medium-density myelin (M), myelin collected from the 0.62 M/0.70 M sucrose interface, and (3) high-density myelin (H), myelin collected from the pellet.

6. Resuspend each myelin fraction in 38 ml Tris·Cl buffer solution.

7. Transfer each myelin suspension to two 38.5-ml ultracentrifuge tubes and ultracentrifuge 35 min at 75,000 × *g*, 4°C.

8. Resuspend pellets, separately, in 2 ml Tris·Cl buffer solution, stir with a glass rod, and store the membrane suspensions as in Basic Protocol, step 28.

ISOLATION OF PNS MYELIN

ALTERNATE PROTOCOL 2

The methods used to isolate PNS myelin are based on protocols designed to isolate CNS myelin. However, isolation of myelin from PNS is more difficult than isolation of myelin from CNS. The presence of a large amount of collagen and connective tissue in PNS makes it necessary to use a more drastic method of tissue homogenization using a Polytron homogenizer, which leads to the formation of smaller myelin vesicles. Because PNS myelin has a lower density than CNS myelin, the concentration of sucrose in the density gradient solutions is modified to avoid the loss of myelin during the isolation. Substantial amounts of small myelin vesicles are lost through the isolation process, in particular during the hypoosmotic shock.

This protocol is based on the methods of Cammer et al. (1981), Wiggins and Fuller, (1981), and Wiggins et al. (1975). The sciatic nerve is cut into pieces with a razor blade on a cold glass plate, the small nerve segments are suspended in 0.27 M sucrose solution containing 20 mM Tris·Cl buffer (pH 7.45), and they are homogenized with a Polytron homogenizer. Then connective tissue is eliminated by passing the homogenate through layers of cheese cloth. The tissue suspension is layered over 0.83 M sucrose solution and centrifuged. Myelin forms a layer at the interface. To prevent loss of myelin in the upper phase of the gradient, the concentration of sucrose used in this protocol is lower than that used in the Basic Protocol. The crude myelin fraction is subjected to hypoosmotic shock and centrifuged to remove microsomal contamination. The crude preparation of myelin obtained after the first cycle of hypoosmotic shock and differential centrifugation is a reasonably pure myelin fraction. Thus, depending on the degree of purity required, it may be possible to consider this myelin fraction as purified myelin. A second discontinuous gradient followed by a second cycle hypoosmotic shock and differential centrifugation results in a slightly increase in the myelin purity; however, a large amount of myelin is lost during this procedure.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0°C to 4°C and kept on ice throughout. Centrifuge rotors should be precooled to the same temperature. All solutions contain 20 mM Tris·Cl buffer (pH 7.45), 1 mM EDTA, 1 mM DTT, 100 μM PMSF, 10 μg/ml leupeptin, and 10 μg/ml antipain.

Additional Materials *(also see Basic Protocol and Alternate Protocol 1)*

25- and 50-ml beaker
50-ml Pyrex tube
Polytron homogenizer (Brinkmann Instruments)
Cheesecloth
Funnel

Dissect sciatic nerve

1. Place a glass plate on a bed of ice in an ice bucket. Ensure that the glass plate will fit flat inside the ice bucket.
2. Anesthetize the rat and euthanize by decapitation. Repeat for a total of four rats.

   This must be supervised or carried out by an experienced animal technician according to an approved animal protocol.

3. Dissect the sciatic nerves using scalpel and forceps, and remove sciatic nerves to a chilled 25-ml beaker containing 10 ml of 0.27 M sucrose solution.
4. Record weight of the sciatic nerves (~28 to 35 mg each).
5. Transfer the four pairs of sciatic nerves to the glass plate, and cut the nerves in segments of 2 to 3 mm using a razor blade or scissors.

Homogenize the neural tissue

6. Place the minced sciatic nerves in a cold 50-ml beaker containing 18 ml of 0.27 M sucrose solution.
7. Pour the minced sciatic nerve suspension into the cold 50-ml Pyrex tube and homogenize the tissue with a Polytron homogenizer, using four 15-sec pulses.
8. To eliminate connective tissue, pour the sciatic nerve homogenate through four layers of cheese cloth placed inside a funnel resting in a 100-ml graduated cylinder surrounded by ice.
9. Pour 18 ml of 0.27 M sucrose solution through the four layers of cheese cloth to recover any tissue suspension that may have been trapped in the cheese cloth, and add the filtrate to the tissue homogenate (total volume 36 ml)
10. Overlay 18 ml of the homogenate over 18 ml of 0.83 M sucrose solution in each of two 38.5-ml ultracentrifuge tubes and ultracentrifuge 45 min at 82,000 $\times$ g, 4°C.
11. With a Pasteur pipet, harvest the crude myelin fraction, which forms at the 0.27M/083M sucrose interface.

Carry out osmotic shock

12. Resuspend the combined myelin layers in 20 ml Tris·Cl buffer solution using a Dounce homogenizer using five to seven strokes with the tight pestle.
13. Transfer myelin membranes to a 100-ml graduated cylinder, and bring the suspension to a final volume of 76 ml with Tris·Cl buffer solution.
14. Transfer the suspension to two 38.5-ml ultracentrifuge tubes and ultracentrifuge the suspension 15 min at 82,000 $\times$ g, 4°C.
15. Discard the supernatant and resuspend the pellet in Tris·Cl buffer solution. To facilitate pellet resuspension, add 2 ml Tris·Cl buffer solution and gently stir the pellet with a glass rod.

    Alternatively, the pellet can be resuspended by pipeting up and down repeatedly using a Pasteur pipet.

16. Transfer the resuspended membrane using a Pasteur pipet to a 100-ml graduated cylinder and bring the suspension to a final volume of 76 ml with Tris·Cl buffer solution.
17. Transfer the suspension to 38.5-ml centrifuge tubes and centrifuge the suspension 10 min at 17,000 $\times$ g, 4°C.

18. Discard the cloudy supernatant and disperse the two crude myelin pellets in a total volume of 76 ml Tris·Cl buffer solution.

19. Transfer the suspension to 38.5-ml centrifuge tubes and centrifuge the suspension 10 min at 17,000 × *g*, 4°C.

    A second discontinuous gradient followed by a cycle of hypoosmotic shock and differential centrifugation results in a slight increase in myelin purity. However, a large amount of myelin is lost during this procedure. Therefore, consider the possibility of using the myelin fraction obtained in step 18 as purified myelin.

    To avoid loss of myelin membranes, it is recommended that the two myelin pellets be combined and purified using only one discontinuous sucrose gradient.

Isolate myelin from a crude preparation

20. Resuspend the combined myelin pellet in 18 ml of 0.27 M sucrose solution by homogenization using five to seven strokes of the tight pestle

21. Layer 18 ml of this suspension over 18 ml of 0.83 M sucrose in one 38.5-ml ultracentrifuge tube and ultracentrifuge exactly as described in step 10.

    The tube containing the myelin fraction has to be balanced with a tube containing just the sucrose gradient.

22. Harvest the purified myelin from the interface with a Pasteur pipet and wash out the sucrose as described in steps 12 to 14.

23. Subject the myelin fraction to further purification by hypoosmotic shock and differential centrifugation as described in steps 15 to 18.

24. Determine protein concentration (*APPENDIX 3H*).

    Metabolic assays should be carried out as soon as possible after preparation; some marker enzyme assays can be carried out after storage for ~16 hr at 4°C. Many assays can be carried out on material frozen at –20°C or –80°C. Measurements that are made with frozen material should be compared with those made on fresh material to confirm that they are relatively unaffected by storage conditions.

ASSAY FOR 2′,3′-CYCLIC NUCLEOTIDE 3′-PHOSPHODIESTERASE ACTIVITY

SUPPORT PROTOCOL

Two enzymes, and a cholesterol ester hydrolase (Eto and Suzuki, 1973), have been shown to be enriched in CNS myelin. The neutral cholesterol ester hydrolase specific activity in myelin is approximately ten times higher than in total homogenate.

The enzyme 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNPase; Kurihara and Tsukada, 1967) has been extensively used as a marker during isolation of CNS myelin, or to estimate myelin contamination of other subcellular fractions (Norton and Cammer, 1984). CNPase catalyzes the hydrolysis of several 2′,3′-cyclic nucleoside monophosphates to their respective 2′-nucleoside monophosphates. These include the 2′,3′-cyclic monophosphates of adenosine, cytidine, and uridine as well as certain oligonucleotides containing a 2′,3′-cyclic nucleotide terminus. Although studies are made with 2′,3′-cyclic AMP, the physiological substrate(s) remains unknown, and the physiological role of CNP has not been established. Several methods have been used to determine CNPase activity (Prohaska et al., 1973), which the authors recommend. In this method the samples are first treated with deoxycholate, and CNPase activity is measured as an inorganic phosphate released from the product, 2′-AMP, by *E. coli* alkaline phosphatase. Measurements are carried out under optimal conditions of temperature (30°C) and pH (6.2). CNPase specific activity in isolated myelin is between three to six times higher than the CNPase specific activity present in the total brain homogenate.

Materials

Myelin sample with 0.2 to 1 mg/ml protein
0.2 M Tris·Cl buffer, pH 7.5 (see recipe)
1% (w/v) sodium deoxycholate solution (see recipe)
CNPase reaction solution (see recipe)
0.3 M Tris·Cl, pH 9.00, containing 21 mM $MgCl_2$
E. coli alkaline phosphatase solution (see recipe)
1:1 (v/v) isobutanol/benzene
1.5% (w/v) ammonium molybdate solution (see recipe)

5-ml Dounce homogenizer (Kontes) with tight (clearance 0.0010 to 0.0030 in.) pestle
Pyrex test tubes (10 × 75–mm)
30° and 100°C water baths

Prepare the samples

1. Dilute 0.2 ml of the myelin sample (containing 0.2 mg to 1 mg of myelin protein) with 0.1 ml of 0.2 M Tris·Cl, pH 7.5.
2. Add 0.2 ml of 1% sodium deoxycholate solution to the mix, and incubate the tube 10 min at 4°C.
3. Add 2 ml of water to the sample treated with deoxycholate, and transfer the mix to the vessel of a 5-ml Dounce homogenizer.
4. Disperse the membranes by homogenization using five to seven strokes of the tight pestle.

Perform the assay

5. Add 20 µl of the dispersed sample membranes (1.5 to 8 µg of myelin protein) to 10 × 75–mm Pyrex test tubes containing 180 µl CNPase reaction solution.
6. Incubate the reaction mix 10 min at 30°C.
7. Terminate the reaction by placing the Pyrex tubes 30 sec in a boiling water bath.
8. Return the tubes to the 30°C water bath, and add 0.1 ml of 0.3 M Tris·Cl (pH 9.00) containing 21 mM $MgCl_2$ and 0.72 U *E. coli* alkaline phosphatase (30 to 60 U/mg), and maintain the tubes 20 to 30 min in the 30°C water bath.
9. Add 1.2 ml of 1:1 isobutanol/benzene and 1.2 ml of 1.5% ammonium molybdate solution.

   This part of the protocol should be carried out under a chemical hood. Because the reagent solution contains O.5 N H_2SO_4 take extra precaution in the handling of the tubes.

10. Vigorously vortex the tubes for 20 sec.
11. Centrifuge tubes 5 min at 800 × *g*, 4°C.

Measure absorbance

12. Collect the upper phase with a syringe, and measure the absorbance at 410 nm against an isobutanol/benzene blank.
13. Determine the amount of phosphate liberated by comparing the value of absorbance obtained with values of absorbance obtained using phosphate standards.

    To construct a phosphate standard curve, add 0.3-ml aliquots of: 5, 3.4, 2.5, 1.5, 1, 0.5, 0.25, and 0.125 mM Na_2PO_4H solutions to 10 × 75–mm Pyrex test tubes. This results in a standard curve of eight points containing 1.5, 1, 0.75, 0.45, 0.3, 0.150, 0.075, and 0.0375 µmol of phosphate, respectively. To prepare the Na_2PO_4H solutions, dilute 10 mM Na_2PO_4H solution with water, as needed.

REAGENTS AND SOLUTIONS

Use distilled and deionized water in all recipes and protocols steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alkaline phosphatase buffer

To 20 ml of H_2O, add:
30 ml 1 M Tris·Cl, pH 9.00 (0.3 M final)
0.427 g $MgCl·6H_2O$ (21 mM final)
Adjust to pH 9.00 with 1 M Tris·Cl or 1 M HCl if required
Add H_2O to 100 ml

Ammonium molybdate solution

To 100 ml of H_2O add:
3 g $(NH_4)6Mo_7O_{24}·4H_2O$ (1.5%, w/v final)
2.81 ml concentrated (35.64 N) H_2SO_4 (0.5 N final)
Add H_2O to 200 ml

CAUTION: *Take extra precaution when preparing this reagent, H_2SO_4 is highly corrosive. Concentrated acid must be slowly added to water. Never add water to concentrated acid because the heat generates a violent reaction that leads to spattering.*

CNPase reaction solution

To 5 ml of Tris-maleate buffer (see recipe) add:
0.035 g of adenosine 2′,3′-cyclic monophosphate sodium salt (10 mM final)
Add Tris-maleate buffer (see recipe) to 10 ml
Prepare fresh

E. coli alkaline phosphatase solution

For ten reactions:
To 0.5 ml of alkaline phosphatase buffer (see recipe), add:
7.2 U *E. coli* alkaline phosphatase (~220 μg)
Add alkaline phosphatase buffer (see recipe) to 1 ml
Prepare fresh

Sodium deoxycholate solution, 1% (w/v)

To 50 ml of H_2O, add:
1 g deoxycholate
Add H_2O to 100 ml

Sucrose solution, 1 M

To 100 ml of H_2O, add:
68.46 g sucrose (1 M final)
4 ml 1 M Tris·Cl, pH 7.45, at 25°C (20 mM final)
4 ml 100 mM Na_2EDTA (2 mM final)
0.031 g dithiothreitol (1 mM final)
Adjust to pH 7.45 with 1 M Tris·Cl or 1 M HCl if required
Add H_2O to 200 ml
Add protease inhibitors according to *UNIT 3.4*
Store up to 1 to 2 days at 4°C

Sucrose solutions for CNS myelin isolation:
To prepare 0.30 M and 0.83 M sucrose solutions, dilute 1 M sucrose solution with Tris·Cl buffer solution (see recipe), as needed. For 0.83 M sucrose, dilute 0.83:0.27 (v/v) 1 M sucrose solution/Tris·Cl buffer solution; for 0.30 M sucrose, dilute 0.30:0.70 (v/v) 1 M sucrose solution/Tris·Cl buffer solution.

Sucrose solutions for PNS myelin isolation:
To prepare 0.27 M and 0.83 M sucrose solutions, dilute 1 M sucrose solution with Tris·Cl buffer solution (see recipe), as needed. For 0.83 M sucrose, dilute 0.83:0.27 (v/v) 1 M sucrose solution/Tris·Cl buffer solution (see recipe); for 0.27 M sucrose, dilute 0.27:0.73 (v/v) 1 M sucrose solution/Tris·Cl buffer solution (see recipe).

Sucrose solutions for subfractionation of CNS myelin:
To prepare 0.30 M, 0.62 M, and 0.70 M sucrose solutions, dilute 1 M sucrose solution with Tris·Cl buffer solution, as needed. For 0.70 M sucrose, dilute 0.70:0.30 (v/v) 1 M sucrose solution/Tris·Cl buffer solution (see recipe); for 0.62 M sucrose, dilute 0.62:0.38 (v/v) 1 M sucrose solution/Tris·Cl buffer solution (see recipe), and for 0.30 M, dilute 0.30:0.70 (v/v) 1 M sucrose solution/Tris·Cl buffer solution (see recipe).

Tris·Cl buffer, 0.2 M (pH 7.5)

To 50 ml of H_2O, add:
20 ml 1 M Tris·Cl, pH 7.50 (0.2 M final)
Add H_2O to 100 ml

Tris·Cl buffer solution

To 100 ml of H_2O, add:
4 ml 1 M Tris·Cl, pH 7.45, at 25°C (20 mM final)
4 ml 100 mM Na_2EDTA (2 mM final)
0.031 g dithiothreitol (1 mM final)
Adjust to pH 7.45 with 1 M Tris·Cl or 1 M HCl if required
Add H_2O to 200 ml
Add protease inhibitors according to *UNIT 3.4*
Store up to 1 to 2 days at 4°C

Tris-maleate buffer

To 100 ml of H_2O, add:
1.16 g maleic acid (50 mM final)
Adjust to pH 6.20 with Tris base solution
Add H_2O to 200 ml
Store up to 30 days at 4°C

COMMENTARY

Background Information

Methods of myelin isolation

Myelin is a highly specialized multilamellar structure that surrounds, in a spiral fashion, segments of axons of the central and peripheral nervous systems of vertebrates (Fig. 3.25.1). In the CNS, myelin is produced by oligodendrocytes, while in the PNS, myelin is generated by Schwann cells (Norton and Cammer, 1984; Morell and Quarles, 1999). Although myelin is present all through the CNS, this membrane is particularly enriched in the brain white matter and spinal cord. PNS contains a high amount of myelin as well. Myelin may account for 75% of the dry weight of some peripheral nerves.

CNS and PNS myelin are morphologically and biochemically different (for detailed analyses of myelin composition, see Norton and Cammer, 1984 and Morell and Quarles, 1999). The protein composition of CNS myelin is more simple than other brain membranes, with the proteolipid protein (PLP) and myelin basic proteins (MBP) making up 60% to 80%. Other proteins include myelin-associated glycoprotein (MAGs) and 2′,3′-cyclic-nucleotide 3′-phosphodiesterase (CNPase). PNS myelin does not contain PLP and the amount of MBP present is low. A single protein, Po, accounts for >50% of the PNS myelin proteins. PNS myelin contains a 170-kDa glycoprotein that constitutes 5% of the total protein. MAG is also present in PNS myelin but to a lesser extent than in CNS myelin. Additionally, both CNS and PNS

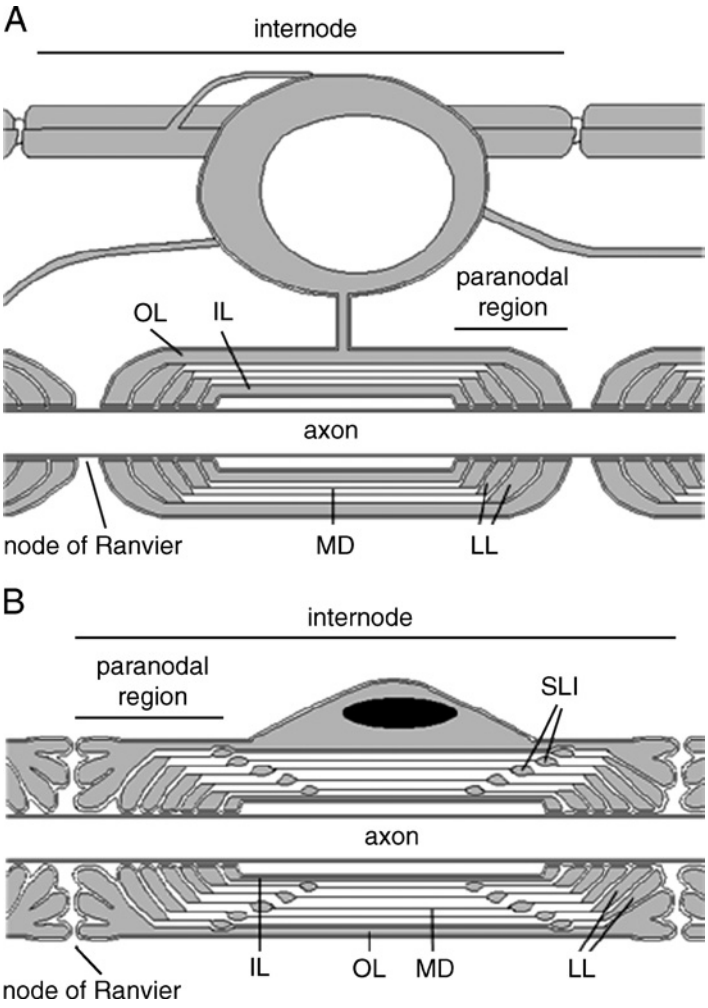

Figure 3.25.1 Composite diagrams showing the morphological characteristics of CNS and PNS myelins. (**A**) CNS. As shown, the myelin sheath is connected to an oligodendrocyte by a process. The longitudinal cross section shows a myelin sheath covering an internode. The paranodal region of the myelin sheath is in close contact with the axon. Apposition of the inner faces of the myelin membranes (cytoplasmatic faces) form the major dense line (MD). Apposition of the outer faces (extracellular faces) form the intraperiod line (not drawn for clarity). Cytoplasm is present in the lateral (LL), inner (IL), and outer (OL) loops. An oligodendrocyte can produce several myelin sheaths and wrap several axon segments. (**B**) PNS. Diagram showing a longitudinal cross section through a Schwann cell and its myelin wrapping around an axon segment. PNS and CNS myelins have similar morphologic characteristics, mainly a multilayer of compact membranes and cytoplasm in the lateral (LL), inner (IL), and outer (OL) loops. Cytoplasm is also present in the Schmidt-Laterman incisures (SLI). The Schmidt-Laterman cleft has islands of cytoplasm appearing between openings in the major dense line (MD). Note that in the CNS, Schmidt-Laterman incisures are absent from brain myelin, and in spinal cord myelin are present only in very small numbers. A Schwann cell only produces one myelin sheath.

myelin contain numerous quantitatively minor proteins (Fig. 3.25.2). Both CNS and PNS myelin have a large ratio of lipids to proteins (lipids amount to 70% to 85% of the myelin weight, while proteins represent 15% to 30%), and both PNS and CNS myelin have the lowest density of any nervous systems membrane.

The abundance of myelin in the mammalian nervous systems, together with its particular physical properties, makes it feasible to purify large quantities of myelin in high yield and purity by standard techniques of subcellular fractionation.

All the methods for isolating myelin require homogenization of the tissue in sucrose solution of low ionic strength. Homogenization of nervous tissue in sucrose solution leads to the swelling of the myelin sheath, disruption of the

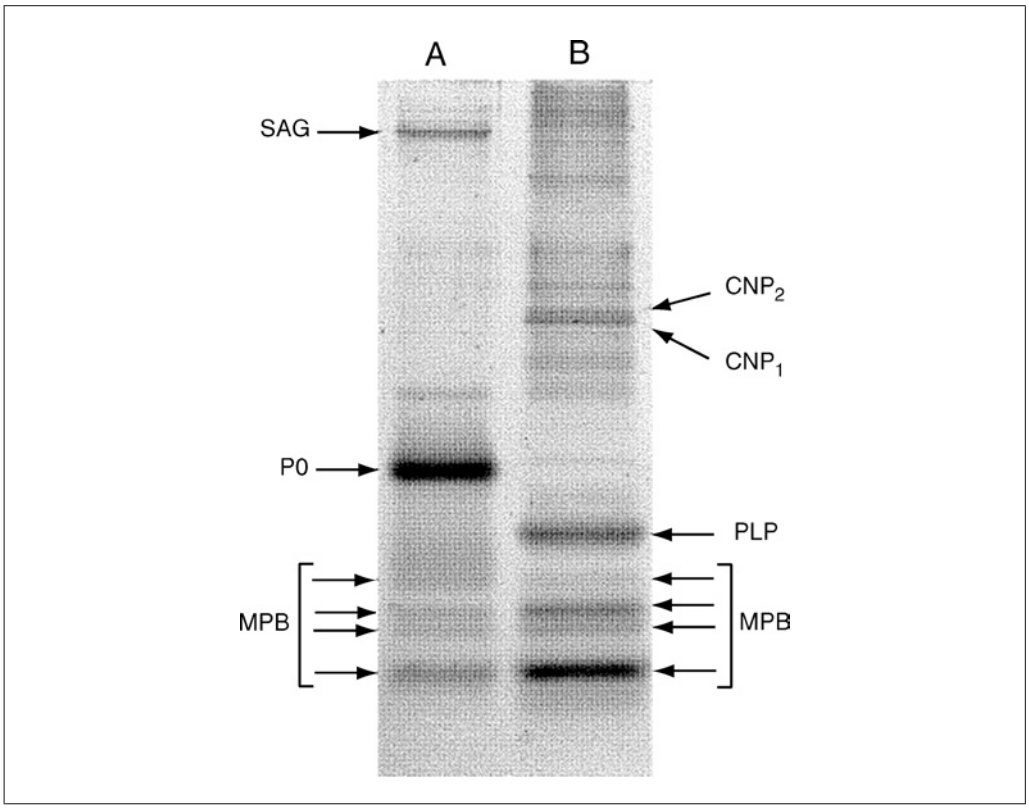

Figure 3.25.2 Protein patterns of rat PNS myelin (**A**) and rat CNS myelin (**B**). Samples of isolated myelin containing 20 μg of proteins were solubilized with SDS, electrophoresed on a 12.5% polyacrylamide gel, and stained with Coomassie brilliant blue. Myelin basic protein (MBP), proteolipid protein (PLP), 2:3-cyclic nucleotide-3′-phosphodiesterase (CNPase), protein zero (Po), and Schwann cell membrane glycoprotein (SAG) are shown. Four MBP isoforms (14.0-, 17.0-, 18.5-, and 21.5-kDa) are present in both CNS and PNS myelins. The PLP band is seen only in CNS myelin. PLP of ~30-kDa migrates anomalously fast on SDS gels. Po (30-KDa) is present only in PNS. Two isoforms of CNPase, CNP1 (~46 kDa) and CNP2 (~48 kDa), are present in CNS myelin, and to a lesser extent in PNS myelin. SAG (170-kDa) is present only in PNS. Several minor bands on the gel are probably myelin components, but are not identifiable solely from their position. Myelin protein patterns may differ depending on species and age of the animal. The four MBP isoforms are generated by alternative splicing of mRNA. The 18.5-kDa MBP in CNS is called P_1 in PNS. Small amounts of PLP are synthesized in PNS but not incorporated into myelin in appreciable amounts. CNP1 and CNP2 are generated by alternative splicing of mRNA. Both CNS and PNS myelin contain numerous minor proteins that are not seen on gels stained with Coomassie blue.

axon myelin interaction, and the formation of relatively large myelin vesicles (up to 20 μm in diameter).

The methods to isolate myelin rely on two properties of the myelin vesicles, their large size and their low density (Norton and Cammer, 1984; Morell and Quarles, 1999). There are mainly two groups of methods of CNS myelin isolation. One group takes advantage of vesicle size to obtain a crude myelin preparation by differential centrifugation of the tissue homogenate (De Robertis et al., 1962; Eichberg et al., 1964). The other group takes advantage of myelin density to obtain an initial enrichment by density gradient centrifugation of the tissue homogenate (Norton and Poduslo, 1973).

In the first group of protocols, a fraction enriched in myelin membranes is obtained by carrying out two differential centrifugations. First, total brain homogenate is centrifuged for 10 min at low speed ($900 \times g$), which results in a supernatant that contains the majority of the myelin membranes, microsomes, and mitochondria, and a pellet containing nuclei. However, a fraction of myelin is also recovered in the nuclear fraction. The amount of myelin recovered in the supernatant or in the nuclear fraction depends on the size of the myelin vesicles, a physical property that depends on the strength of the homogenization and the age of the animal. Second, a fraction enriched in myelin and mitochondria is obtained by centrifugation of the low-speed supernatant for

15 min at 13,500 × *g*. Myelin and mitochondria co-purify in the pellet, while microsomes remain in the supernatant.

Finally, myelin is isolated by centrifugation of the crude mitochondrial fraction for 2 hr at 50,000 × *g* on a sucrose gradient, usually having concentrations of 0.32, 0.8 M, and 1.2 M sucrose. Myelin will layer out at the 0.32 M sucrose/0.8 M sucrose interface.

These protocols permit the simultaneous separation of all the brain fractions. Additionally, the possibility of contamination by microsomes is reduced by the early elimination of the microsomal membranes in the second differential centrifugation. However, they present the disadvantage that to recover all the myelin, the mitochondria and nuclear fractions have to both be processed, and if only myelin is wanted, some of the centrifugation steps are unnecessary.

The protocols outlined in this unit belong to the second group of myelin-isolation methods, in which a crude myelin fraction is isolated in the first step by density gradient centrifugation. These methods take advantage of the low density of myelin. In a sucrose gradient, myelin has a density of ∼1.08 g/ml, and the minimal sucrose concentration required to float all the myelin is 0.8 M (density 1.103 g/ml). A crude myelin fraction is prepared from brain homogenate in 0.32 M sucrose by density gradient centrifugation on a step of 0.85 M sucrose. Myelin will layer out at the 0.32 M/0.85 M sucrose interface, while nuclei, mitochondria and synaptosomes will move through the 0.85 M sucrose phase and form a pellet. Similarly, microsomal membranes will form a pellet or remain resuspended on 0.85 M sucrose. However, after centrifugation, particulate material remains in the 0.32 M sucrose phase and contaminants are trapped in the myelin layer. The amount of contaminants trapped in the myelin layer depends on the tissue from which the myelin is isolated. Tissues such as white matter that are enriched in myelin yield a relatively pure crude myelin fraction. In contrast, tissues containing low amounts of myelin, such as whole brain from animals in the early period of myelination, yield an impure crude myelin fraction. The major contaminant might be glial membranes, endoplasmic reticulum, and axoplasm. Because of their large size, myelin vesicles move through the 0.32 M sucrose ahead of other membrane fractions, and form a layer on the 0.32M/0.85 M sucrose interface. Therefore, it is possible that part of the microsomal fraction has to pass through a layer of myelin membranes, which may result in the retention of some microsomal membranes in the myelin layer. Myelin vesicles formed during the tissue homogenization might also trap microsomal membranes. Moreover, the paranodal areas of the myelin sheath have pockets of cytoplasm containing intracellular organelles such as polyribosomes, mitochondria, and endoplasmic reticulum. Reduction of such contaminants is carried out by osmotically shocking the myelin in hypotonic buffer. The trapped contaminants are released, and the larger myelin particles are separated from the smaller membranous material by low-speed centrifugation. In most methods, the final purification of myelin is carried out by repetitions of both the first density gradient centrifugation on a discontinuous gradient of 0.32 M to 0.85 M sucrose, and of the cycle of hypoosmotic shock and low-speed centrifugation. These protocols yield a reasonably pure myelin fraction that contains no more than 5% contamination. The fact that there are axon-glial intercellular junctions connecting the myelin lateral loops to the axolemma leads to the possibility that fragments of axolemma could also be present in the fraction of purified myelin (Haley et al., 1981). The level of axolemmal contamination can be reduced significantly (0.6% to 1.2 % of the myelin protein) by the addition of a third centrifugation on a discontinuous gradient, in which myelin is resuspended in 0.85 M sucrose. In this case, myelin rises and layers out in the interface (Haley et al., 1981). The level of axolemmal contamination can also be reduced by treatment of the myelin fraction with EGTA (Haley et al., 1981; Norton and Cammer, 1984).

Most of the published protocols for myelin isolation do not include protease inhibitors. Analyses of the myelin proteins by SDS-PAGE gel electrophoresis indicate that significant protein degradation does not occur during myelin isolation. Also, a large number of enzymatic activities have been found in myelin preparations isolated using sucrose solutions (Norton and Cammer, 1984; Morell and Quarles, 1999). However, the inclusion of dithiothreitol and of a mixture of protease inhibitors in all the solutions used during the isolation of myelin is essential for the recovery of some intrinsic proteins, including muscarinic receptors and GTP-binding proteins (Larocca et al., 1987; 1991).

Most of the methods used to isolate CNS myelin can be used to isolate PNS myelin once the problem of homogenization of the nerve tissue is solved. The presence of connective

tissue and collagen in PNS makes the homogenization of the PNS tissue difficult. Two different approaches have been used to overcome this difficulty. One approach is that the tissue is pulverized in liquid nitrogen before homogenization (Greenfield et al., 1973). In another approach, the tissue is homogenized using a high-speed motor-driven homogenizer (Polytron; Wiggins and Fuller, 1981). After homogenization, connective tissue can be removed by low-speed centrifugation or by filtration of the homogenate through gauze.

The protocols used to isolate PNS myelin derive from Norton and Poduslo's method (Norton and Poduslo, 1973). However, because PNS myelin has lower density than CNS myelin, the concentration of sucrose used to homogenize PNS tissue is lower than that used by Norton and Poduslo. Wiggins and Fuller homogenized sciatic nerve in 0.29 M sucrose and overlaid the tissue suspension on 0.80 M sucrose (Wiggins and Fuller, 1981). Roomi et al. (1978) homogenized sciatic nerve in 0.17 M sucrose, and the tissue homogenate was overlaid on 0.65 M sucrose.

The PNS myelin preparation obtained by a first discontinuous-density gradient followed by several washes has been found sufficient to yield myelin with relatively little contamination. Although a second density gradient seems to increase the purity of the myelin fraction (Wiggins et al., 1975), it is important to note that a significant amount of myelin membranes are recovered with the membrane contaminant (Wiggins and Fuller, 1981). Similarly, during hypoosmotic shock and differential centrifugation, it seems that the material discarded contains as much myelin as contaminant (Wiggins and Fuller, 1981).

PNS myelin has also been isolated using a continuous gradient of sucrose (Matthieu et al., 1979). In this protocol, the sciatic nerve is homogenized in water and the tissue suspension is centrifuged at high speed. The supernatant containing the cytoplasmic material is discarded, and the pellet containing a total membrane fraction is resuspended in water and layered on a continuous gradient of sucrose (0.1 M to 1.2 M sucrose, using 1.4 M sucrose as a cushion). Centrifugation is carried out for 4 hr at 31,000 $\times$ *g*. Most of the PNS tissue membranes localizes between 0.32 M and 0.85 M sucrose. Three peaks are obtained: peak A (located at 0.1 M sucrose) contained mostly contaminating adipose material, peak B (located at 0.30 M sucrose) containing mainly membrane fragments with occasional large multilamellar structures, and peak C (located at 0.57 M sucrose) containing large multilamellar myelin fragments and smaller myelin fragments. Biochemical analysis of the gradient fractions confirms that the majority of the myelin is present in peak C. It also indicates that some of the fragments of membranes present in the peak B originate from myelin.

Heterogeneity of the myelin fraction

Highly purified CNS myelin fractions can be separated into subfractions by continuous or discontinuous density gradient centrifugation. The less-dense fractions are enriched in multilamellar fragments, whereas the heavy fractions have a large proportion of single-membrane vesicles and fragments with two or three membrane layers (Norton and Cammer, 1984; Morell and Quarles, 1999).

These fractions have different lipid-to-protein ratios but the lipid compositions are similar. Their protein compositions are different; myelin basic proteins are present in higher amounts in the lighter fractions than in the heavy fractions. The heavier fractions contain more CNPase and carbonic anhydrase enzymatic activities than lighter fractions, while the amount of PLP remains relatively constant among the different fractions. The fact that the different membrane fractions contain myelin components, but in different proportions, points to true heterogeneity, and that heterogeneity in the population of isolated myelin membranes is not just a reflection of contaminant membranes (Norton and Cammer, 1984; Morell and Quarles, 1999).

It is not possible to precisely define the origin of the heterogeneity of the myelin preparation. However, various data indicate that heterogeneity of the myelin fractions can be caused by diverse factors.

(1) A number of regional specializations are present in the myelin sheath. The internodal region consists mainly of a multilayer of condensed membranes. However, internodal clefts are present in which the membranes are not compacted and contain pockets of cytoplasm. Cytoplasm is present also in the lateral loops, regions close to the nodes of Ranvier, and in the outer and inner loops of the myelin sheath (Fig. 3.25.1). Intracellular organelles and elements of the cytoskeleton are present in these uncompacted areas of myelin. Similarly, immunocytochemistry shows that the proteins that form myelin have distinct localizations in the myelin sheath. For example, PLP/DM20 and MBP are localized in the compacted internodal region, CNPase is localized periaxonally and in the outer loops. MAG is

in the periaxonal loop, and MOG (myelin oligodendrocytes glycoprotein) in the outer loop (Norton and Cammer, 1984; Morell and Quarles, 1999).

(2) Different oligodendrocytes might produce myelin sheath of different composition, or depending on the diameter of the axon, an oligodendrocyte might produce myelin of different composition. In particular areas of the brain, some very large fibers contain more MBP that PLP, while small fibers contain more PLP than MBP (Hartman et al., 1982). Moreover, oligodendrocytes of different areas of the CNS produce myelin of different composition. Spinal cord myelin has different composition than cerebral myelin (Lees and Paxman, 1974).

(3) In developing animals, the myelin heterogeneity can be caused by differences in the stage of myelin maturation. The degree of myelin compaction and the myelin composition change during maturation (Danks and Matthieu, 1979).

Critical Parameters and Troubleshooting

Homogenization

The use of a homogenization medium containing low concentration of salt is essential for disruption of the structure of the myelin sheath and the subsequent formation of myelin vesicles. Inclusion of 0.1 M NaCl and 0.05 M potassium phosphate in isotonic sucrose solution preserved the axon-myelin relation, leading to a significant contamination of the myelin preparation with axolemma.

Homogenization of central nervous tissues does not present any difficulty. However, it may be beneficial to chop the tissue into smaller pieces on an ice-cold plate, and the tissue should be kept wet by adding homogenization medium. The ratio of tissue to homogenization buffer should be ~5% (1 g of wet tissue/20 ml of homogenization medium). An increase of this ratio may cause an increase in the levels of contaminant of the isolated myelin, especially when myelin is isolated from brains of animals in development.

On the contrary, homogenization of the PNS tissue is difficult and requires more extreme methods. In this case, homogenization can be performed using a Polytron homogenizer. However, excessive mechanical stress of the tissue leads to the rupture of intracellular organelles and generates small myelin vesicles, which leads to a higher level of contamination and the loss of significant amounts of myelin, in particular, during the hypoosmotic shock and low-speed centrifugation.

Homogenization can be facilitated by grinding the tissue in liquid nitrogen before homogenization (Greenfield et al., 1973). It is important to note that fresh tissue should be used when it is possible. Po, the major protein of PNS myelin, is rapidly degraded by endogenous proteases during dissection and thawing of frozen tissue (Cammer et al., 1981). Therefore, it is important to carry out the tissue dissection quickly and submerge the tissue sample in medium containing protease inhibitors. Similarly, if frozen tissue is used, it is recommended that the frozen tissue be allowed to thaw in sucrose solution containing a mixture of protease inhibitors.

Density gradient centrifugation

The use of swinging-bucket rotors with tube volumes other than those recommended in the protocols is permissible, as long as the volume ratios of sample and gradient are maintained and the rotors are capable of similar relative centrifugal forces.

Discontinuous sucrose density gradient methods, similar to those described here, have been used to isolate myelin from fish nervous systems. In such protocols, changes in the sucrose concentration and centrifugation time were performed to improve myelin yield (Morris et al., 2004).

The large majority of laboratories use discontinuous sucrose gradients as the method of choice for the isolation of myelin. However, special precaution should be taken when myelin is isolated from brains of animals with conditions that affect myelin. Alteration in the myelin composition might lead to both changes in the density of the myelin membranes and changes in the size of the myelin vesicles formed during the homogenization of the tissue (Bourre et al., 1980; Jurevics et al., 2003). Modification of the density and size of myelin vesicles can lead to a reduction of the amount of myelin recovered. Therefore, it may be necessary to modify the concentrations of the sucrose solutions used to make the discontinuous gradient, and the time and speed of centrifugation. In this case, it might be convenient to use a continuous sucrose density gradient to determine changes in the density of the myelin fraction and avoid losing part of the myelin. Myelin membranes can be separated from other CNS membranes using continuous sucrose density gradient zonal centrifugation (Bourre et al., 1980). Total CNS membranes can be separated by zonal centrifugation on

a continuous gradient of 0.1 M to 1.2 M of sucrose. Four peaks of membranes are obtained, two minor (at 0.12 M and at 0.35 M sucrose), and two major (at 0.68 M and at 1.1 M sucrose). The myelin fraction is present mainly in the peak of the 0.68 M region. The degree of contamination of the myelin fractions seems to be higher than the myelin isolated by the methods of Norton and Poduslo. The level of contamination can be reduced significantly by preparing the total membrane fraction by homogenizing the CNS tissue in water instead of isotonic sucrose solutions. In particular, the level of axolemmal contamination is greatly reduced by this hypoosmotic treatment (Bourre et al., 1980).

CsCl continuous density gradients have been used to isolate myelin (Greenfield et al., 1971). In this procedure, myelin forms a band at 0.85 M CsCl, equal to a density of 1.11 g/ml. The fact that myelin has a different density in sucrose than in CsCl might be the result of several factors, including packing of the membranes, degree of hydration, the amount of bound ions, changes in the myelin composition, or extraction of proteins at high ionic strength. Therefore, the authors do not recommend the use of CsCl gradient.

Enzyme and other assays

CNS myelin contains high activity of both CNPase and cholesterol ester hydrolase (Kurihara and Tsukada, 1967; Eto and Suzuki, 1973). In particular, CNPase has been used as a myelin marker and to follow myelin purification (Prohaska et al., 1973).

Nevertheless, the assessment of the degree of purity of isolated myelin is a conceptually difficult task. In part, this problem is generated by the ambiguity of the criteria used to define myelin. The best criterion to define myelin is morphological, not chemical or operational. As shown by electron microscopy, the myelin sheath is a morphologically heterogeneous structure derived from the plasma membrane of the oligodendrocytes that cover discontinuous segments of the axons.

However, the morphologic criteria cannot be applied to assess the purity of the myelin fraction isolated. The methods to isolate myelin involve procedures that disrupt the structures of the myelin sheath and eliminate the cytoplasm and organelles present in the non-compact areas of the myelin sheath. Electron microscopic analysis of the myelin fraction shows the presence of multilamellar membrane fragments, fragments with only

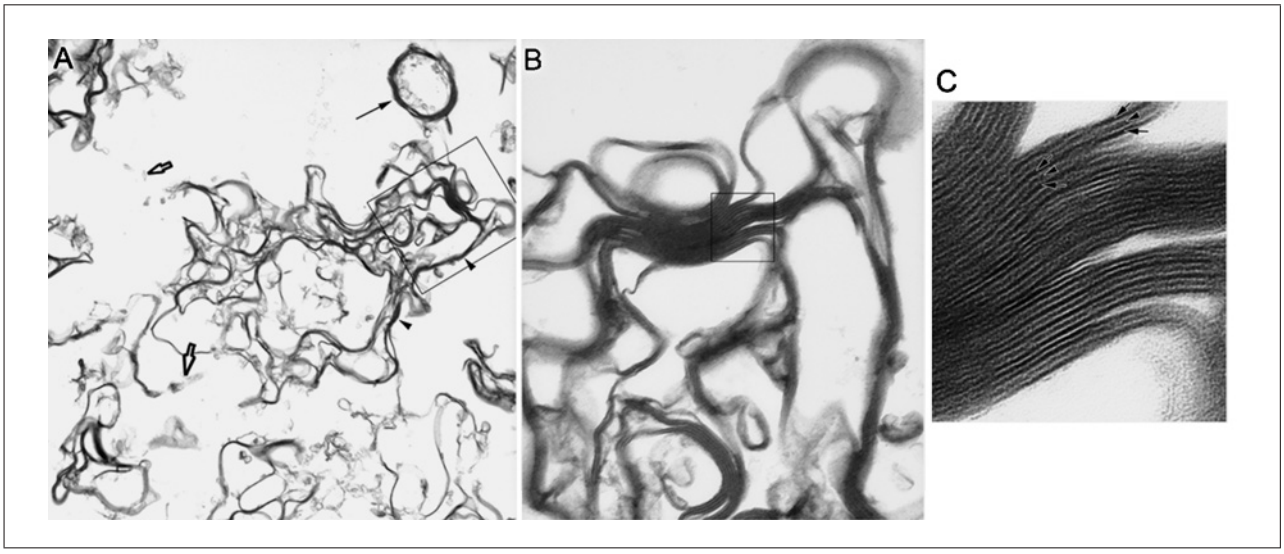

Figure 3.25.3 Electron microscopic analysis of isolated CNS myelin. A pellet of myelin membranes isolated from adult rat brain according to the Basic Protocol was fixed with 2.5% glutaraldehyde in phosphate buffer (pH 7.4), post-fixed with 1% osmic acid, dehydrated through a graded series of ethyl alcohol, cleared in propylene oxide, and embedded in epoxy resin. (**A**) Electron micrograph showing myelin membranes broken up into rings (black arrow) and bands (black arrowheads), which split and rejoin irregularly to form a random net. Small units of membrane fragments (white arrows), appear to originate from split myelin layers (box marks the area shown in **B**). Magnification at 13,000×. (**B**) High-magnification electron micrograph showing the multilamellar nature of myelin fragments (box marks the area shown in **C**). Magnification at 50,000×. (**C**) Electron micrograph showing structural details of an isolated multilamellar myelin membrane. Major dense lines (arrows), intraperiod lines (arrowheads). Magnification at 227,000×. Courtesy of Dr. Cedric Raine.

two or three membrane layers, and single membrane vesicles (Fig. 3.25.3). Morphologic analysis could not determine whether all of these organelles are part of the myelin sheath. However, biochemical analysis supports the fact that these small vesicles are derived from the myelin sheath. Lastly, it is an insoluble problem to define where the oligodendrocyte plasma membrane finishes and the myelin sheath begins.

The best approach to determine myelin purity is to assess the presence in the isolated fraction of myelin of potential contaminant, including membrane fragments from cellular organelles as well as absorbed cytosolic proteins. Several markers can be used to determine contaminants including, nuclei (DNA), mitochondria (succinate dehydrogenase, *UNIT 3.4*), lysosomes (beta glucosidase), endoplasmic reticulum (NADH cytochrome *c* reductase, *UNIT 3.5*), neuronal membranes (acetylcholinesterase), and cytosolic proteins (lactate dehydrogenase, *UNIT 11.18*). Enzyme markers should be used with caution, because markers of plasma membranes, such as Na-K ATPase and 5′-nucleotidase enzymes, have been reported to be present in myelin (Norton and Cammer, 1984).

To determine the yield of the myelin isolation and specific activities of measured enzymes, it is necessary to estimate the protein content of the myelin fractions. The Markwell's method is widely used to determine the amount of proteins present in myelin preparations (Markwell et al., 1978). This method is a modification of the Lowry method; an increase in the cooper tartrate reagent allows assay of samples containing a substantial amount of sucrose or EDTA. Sodium dodecyl sulfate is added to the reagent to alleviate possible lipid interference and to promote rapid solubilization of the myelin proteins. However, because this method does not eliminate the interference of DTT, it is recommended to first precipitate the samples using the deoxycholate-trichloroacetic acid (DOC-TCA) protein precipitation technique (Peterson, 1979), and then solubilize the pellet using Markwell's reagent (2%, w/v, CO_3Na_2, 0.4%, w/v, NaOH, 0.16%, w/v, sodium tartrate, 1%, w/v, SDS, and 0.04% $CuSO_4 \cdot 5\ H_2O$).

Myelin samples can be directly subjected to SDS polyacrylamide gel electrophoresis (*UNIT 6.1*). However, myelin samples containing >25 μg of protein should be delipidated to avoid artifacts produced by the presence of high concentrations of lipids during electrophoresis. In this case, samples are treated with 10 vol of cold acetone and centrifuged; the pellet is washed once with an equal volume of cold acetone, and then resuspended in 2 to 3 ml of ethyl ether/ethanol (2:3 v/v). The insoluble material is recovered by centrifugation and the pellet is washed with 2 ml of ethyl ether and then dried under nitrogen. The delipidated sample can be directly dissolved with SDS in sample buffer.

Anticipated Results

Basic Protocol

Approximately 50% to 55% of the myelin present in the CNS tissue homogenate is recovered when isolation of myelin is carried out according to the Basic Protocol. The amount of myelin obtained depends on both the area of the nervous systems from which the myelin is isolated and the age of the animals from which the tissues are obtained.

Myelin is present throughout the nervous system, but is largely concentrated in areas containing mostly fiber tracts including the white matter of the brain and spinal cord. Myelination is a developmentally regulated process; it begins in the PNS, then the spinal cord, and lastly the brain. Myelination in different areas of the brain does not start and finish at the same time. The myelination pattern is similar for all mammals, but the time of birth in relation to the myelination progression is different in different species. Some animals, such as horses, cows, and sheep have a high degree of myelination at birth. Myelination in animals such as mice and rats starts at ∼9 to 10 days after birth.

Having delineated all the factors that influence the amount of myelin recovered, the Basic Protocol yields ∼3.75 mg of myelin (0.55 to 1.13 mg of myelin proteins per brain) from a brain of a 15-day-old rat, and 60 mg of myelin (9 to 18 mg of myelin protein per brain) from the brain of a 6-month-old rat. From bovine white matter, it is possible to obtain 100 mg of total myelin (15 to 30 mg of myelin protein) per gram of fresh tissue.

Isolated CNS myelin should contain high CNPase specific activity, relative specific activity (RSA) = 2 to 3 (enzymatic specific activity in myelin divided by the enzymatic specific activity in the unfractionated homogenate). In contrast, none or very low activity (RSA <0.04 to 0.06) of other membrane enzyme markers should be detected in the isolated myelin fraction.

Alternate Protocol 1

A very small amount of myelin membranes is lost during this procedure, probably <5%.

Alternate Protocol 2

The percentage of PNS myelin recovered with this protocol is low. Approximately 16% of the myelin present in the PNS homogenate is recovered when the entire protocol is carried out. However, when the isolation is carried out using only one discontinuous gradient, rather than two, 32% of the sciatic nerve myelin is recovered.

The amount of myelin obtained depends on the age of the animal. Myelination in rat sciatic nerve begins early in the first postnatal week, the amount of myelin formed increases 100 fold between birth and day 16, and continuously increases beyond the third month after birth.

One can expect to recover 0.8 to 1.8 mg of myelin protein per pair of rat (30 to 60 days old) sciatic nerves, or ~4 to 9 mg of total myelin.

PNS myelin contains some CNPase enzymatic activity. However, CNPase RSA in rat PNS myelin is ~0.5 to 0.8; a large amount of CNPase in sciatic nerve is present in the plasma membrane of the Schwann cell. CNPase activity in PNS myelin is approximately ten-fold lower than in CNS myelin. No or very low activity (<0.04 to 0.06 RSA) of other membrane enzyme marker should be detected in the isolated myelin fraction.

Time Considerations

The Basic Protocol involves twelve centrifugation steps with a combined time of 3.25 hr; allowing more than two times that time for acceleration, deceleration, and other manipulations, it is possible to obtain purified myelin in ~6.50 hr. It is not recommended, but if a preparation must be interrupted, it should be done after the second sucrose density gradient (after Basic Protocol, step 25). Preparations that have been left overnight at 0°C after this step and then continued on the next day, show no obvious differences in chemical composition, but no studies have been made of the enzymes activities of such preparations. Therefore, it is strongly recommended that the validity of results on myelin obtained by interrupted isolation be checked by comparison with those made on myelin obtained without interrupted isolation. Alternate Protocol 1 should take ~2 hr. Discontinuous sucrose gradients should be prepared immediately before use. Alternate Protocol 2 can be performed in ~5 hr, and if it is decided to purify PNS myelin using only one sucrose density gradient, it should take ~2.5 hr.

Assay of CNPase activity should be completed in <1 hr. Enzyme assays can be carried out in freshly obtained myelin. Alternatively isolated myelin fractions can be stored at 0°C to 4°C for 16 hr without significant loss of activity. Enzymatic assays and compositional measurements may also be carried out on material frozen at −20°C or −80°C. There are, however, no general rules regarding the suitability of a particular storage regime, and it is strongly recommended that the validity of results on stored material be checked by comparison with measurements made on a fresh membrane preparation.

All the solutions can be kept for 1 to 2 days at 4°C or frozen for longer periods at –20°C. However, note that any enzymes, PMSF, or other protease inhibitors, should be added immediately prior to use.

Isolation of Renal Brush Borders

The renal brush border has a prominent role in determining the specificity and rate of reabsorption from the glomular filtrate. Thus, the availability of isolated fractions of renal brush border has been instrumental in elucidating the molecular mechanisms that underlie tubular reabsorption (Murer and Kinne, 1980; Murer and Gmaj, 1986; Cutillas, 2005).

Historically, the first methods described for the isolation of brush border fragments were based mainly on the relative rigidity of the brush border and its resistance to homogenization as contrasted to the lability of the basal-lateral membranes (Murer and Kinne, 1980). With a higher sedimentation rate and greater density, differential centrifugation and simple density gradients were sufficient to obtain preparations enriched in large brush border fragments separated from the bulk of the remainder of the epithelial cell homogenates.

The early methods have gradually been supplanted by methods based on the use of divalent ions, chiefly magnesium or calcium to precipitate extra brush border membranes that are then discarded in an initial centrifugation. The brush border membranes, which do not precipitate due to high negative charges, are then collected by a second centrifugation. Homogenization on ice in 20 volumes of 150 mM KCI and 25 mM MES, pH 7.4, containing 0.01 M $MgCl_2$ is accomplished by four passes through a tight-fitting Teflon pestle in ground glass, followed by three 30-sec bursts with a Polytron homogenizer. The pellet obtained by centrifugation for 10 min at 2000 $\times$ *g* is discarded, and the brush borders are collected by centrifugation of the 2000 $\times$ *g* supernatant for 20 min at 35,000 $\times$ *g*. Then, 1 ml of 150 mM KCl and 25 mM MES is added to the resultant pellet and the membranes are resuspended using a Dounce hand homogenizer.

The selection of the method of membrane isolation is usually dictated by the aim of the study. For reconstitution of transport systems, a fast isolation method providing high yield of sealed vesicles containing the transport system as intact as possible is of primary importance. Often, small amounts of cross contaminating membranes are of little consequence so that purity is sacrificed for the sake of speed and yield. For analytical studies, where integrity of transport systems may be of secondary importance, additional purification steps are included based on different physical criteria.

To isolate brush borders from renal absorptive cells, a number of approaches are available: zonal sucrose gradients (see Basic Protocol), bivalent metal ion precipitation (see Alternate Protocol 1), isolation for dye/buffer uptake (see Alternate Protocol 2), aqueous two-phase preparations (see Alternate Protocol 3), and incremental two-phase isolation for separation of brush border and endosomes (see Alternate Protocol 4). These can be started from fresh or frozen materials. Protocols for assessment of brush border purity include flow cytometry (see Support Protocol 1), enzyme analysis (see Support Protocol 2), and electron microscopy (see Support Protocol 3).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and conform to governmental regulations regarding the care and use of laboratory animals.

Current Protocols in Cell Biology (2007) 3.26.1-3.26.14

BASIC PROTOCOL

ISOLATION OF RENAL BRUSH BORDER BY RATE ZONAL SUCROSE GRADIENTS

Of the many methods to isolate renal brush borders, the simplest are the traditional methods employing rate-zonal sucrose gradients (Berger and Sacktor, 1970). This protocol is popular because it is simple and highly reproducible. A major advantage of brush border membrane vesicles is that if they are not kept strictly ice cold during preparation, they entrap in their lumen the buffer in which they are homogenized, making it easy to deliver dyes and experimentally desirable solutions. These advantages are offset by the disadvantage that there is a tradeoff between yield and purity during membrane isolation.

Materials

New Zealand white male rabbits (2 to 3 kg)
0.5, 1.4, and 1.7 M sucrose solutions in distilled or deionized water

Forceps
Scalpel blade or scissors
Ground glass homogenizers (hand-held and motor-driven e.g., 15-ml Dounce homogenizer and Potter-Elvehjem with Teflon pestle, respectively)
Polytron homogenizer
Phase-contrast microscope
35-ml polyallomer ultracentrifuge tubes
Refrigerated centrifuge (90,000 × *g*) with a swinging-bucket rotor

Dissect the kidney cortices

1. Quickly remove kidneys from an anesthetized (IACUC-approved method) New Zealand white male rabbits weighing 2 to 3 kg, and place in sufficient cold 0.5 M sucrose to cover the kidneys.

2. Decapsulate and defat the kidneys by simple blunt dissection tearing the fascia between forceps.

   The vessels can be removed by cutting a wedge out of the hilum of the kidney. Bisection of the kidney along the long axis then allows clean removal of the papilla and much of the medulla, leaving behind highly enriched renal cortex.

3. Keeping the materials cold throughout this and the following steps, dissect out cortices. Weigh the cortices.

4. Finely slice the cortices with scalpel blade or scissors until the consistency of minced meat is reached.

Homogenize the tissue

5. Homogenize the tissue by hand at a ratio of 1 g tissue to 6 ml cold 0.5 M sucrose with a 15-ml Dounce homogenizer.

   Homogenization by hand is done by stroking up and down until the pestle reaches the bottom of the homogenizer. An extremely gentle homogenization is necessary to obtain large, intact brush borders. Over homogenization results in breaking the brush borders into fragments, which then enter the microsomal fraction.

6. Homogenize the suspension further with three complete strokes of a motor-driven 15-ml Potter-Elvehjem homogenizer with a tight-fitting Teflon pestle at 1000 rpm. Monitor the extent of the homogenization by examining the homogenate by phase-contrast microscopy.

   The objective is to preserve intact, generally rounded brush borders in good yield and fraction purity.

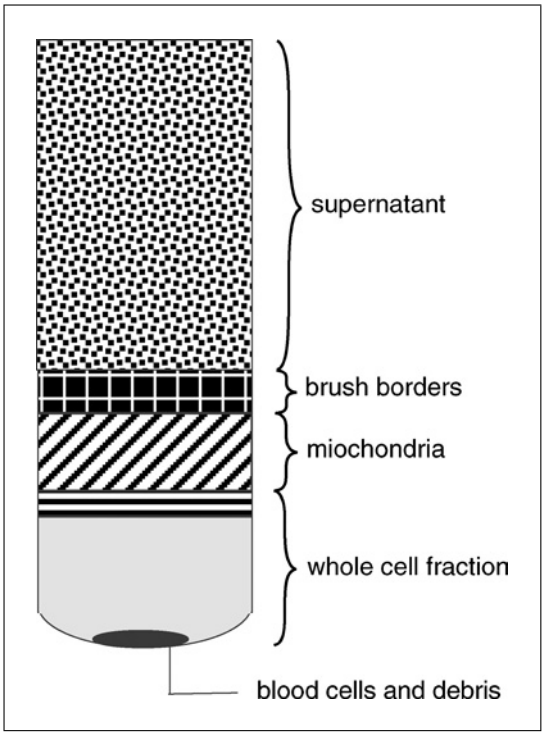

Figure 3.26.1 Schematic of sucrose gradient for separation of the brush border fraction from rabbit renal cortex homogenates. From Berger and Saktor (1970).

7. Layer the homogenate (~6 to 12 ml in 0.5 M sucrose) on a discontinuous gradient comprising 8 ml each of 1.7 and 1.4 M sucrose in 35-ml polyallomer ultracentrifuge tubes.

8. Centrifuge the tubes 60 min at 90,000 × *g*, 4°C.

   The bands resolved are shown in Figure 3.26.1. A thin layer of dense cells is sedimented at the bottom of the tube, and a thicker band of predominantly whole cells is distributed in the 1.7 M sucrose zone. The brownish, mitochondrial-enriched fraction is localized in the 1.4 M sucrose band, with large cell fragments plus many nuclei at the interface of the 1.7 and 1.4 M sucrose zones. The pinkish fluffy layer containing the brush borders is distributed at the interface of the 1.4 M and 0.5 M sucrose zones. A supernatant with increasing turbidity toward the brush border layer remains in the 0.5 M sucrose zone.

Remove the mitochondria

9. Carefully aspirate the brush border–enriched fraction (the entire 0.5 M layer and 0.5/1.4 M interface) from the top.

10. Centrifuge the brush border–enriched fraction from the sucrose gradient 30 min at 4000 × *g*, 4°C.

    This separates the brush borders from the microsomal fraction, yet effectively prevents the loss of small brush borders to the supernatant.

11. To separate brush borders from mitochondrial contamination, centrifuge 5 min at 32,000 × *g*, 4°C, to yield a small, tightly packed pellet containing contaminating mitochondria.

12. Remove the light pink layer containing the brush borders by gentle agitation and careful aspiration without disturbing the mitochondrial pellet.

Prepare brush borders

13. Further separate the intact brush borders from membranous material and disrupted brush borders by approximately six low-speed centrifugations for 10 min at 15,000 to 30,000 × *g*, 4°C.

At each step in the procedure, trace contamination by mitochondrial fragments collecting at the bottom of the centrifuge tube may be discarded as described above.

The final washed fraction is essentially a pure preparation of intact brush borders. Approximately 11 mg of protein (range of 10 to 13 mg) may be obtained from ~1 g renal cortex protein.

Preparations should be held at ice-bath temperatures or, if appropriate, frozen prior to use in an experiment (i.e., an experiment run at room temperature or 37°C, as required).

ALTERNATE PROTOCOL 1

ISOLATION OF KIDNEY BRUSH BORDERS BY BIVALENT METAL PRECIPITATION

Most methods to isolate brush border membrane vesicles from kidney cortex are modifications of the method originally introduced by Booth and Kenny (1974), reproduced in Figure 3.26.2, which is based on differential centrifugation following the addition of 10 to 20 mM $CaCl_2$ or $MgCl_2$ to the initial homogenate.

***Additional Materials** (also see Basic Protocol)*

1 M $MgCl_2$
Homogenate of rabbit kidney cortex (prepared from frozen rabbit kidney, see Basic Protocol, steps 1 to 6)
300 mM mannitol/12 mM HEPES, pH 7.4 (adjusted with Tris)

1. Add solid or 1 M $MgCl_2$ to a homogenate of cortical tissue prepared from frozen rabbit kidneys to a final concentration of 10 mM. Incubate 15 min with stirring in an ice bath.

   The method depends on the preferential aggregation of other subcellular structures by bivalent metal ions.

2. Remove the aggregated material by a low-speed centrifugation of the supernatant 20 min at 1500 × *g*, 4°C, and discard pellet.
3. Centrifuge the supernatant 12 min at 15,000 × *g*, 4°C.
4. Remove supernatant and resuspend pellet in 100 µl of 300 mM mannitol/12 mM Tris·Cl, pH 7.4, with $MgCl_2$ (10 mM final concentration).
5. Centrifuge 12 min at 2200 × *g*, 4°C, and discard pellet.
6. Centrifuge the supernatant 12 min at 15,000 × *g*, 4°C.
7. Resuspend pellet in 10 ml of 300 mM mannitol/12 mM HEPES, pH 7.4.

   Two treatments with Mg^{2+} and four short centrifugations give a product by sucrose gradient centrifugation comparable with brush-border preparations in enrichment and yield of marker enzymes (Hammond and Verroust, 1994; Fig. 3.26.4).

ALTERNATE PROTOCOL 2

ISOLATION OF RENAL BRUSH BORDER FOR DYE/BUFFER UPTAKE

Many investigators have modified the brush border membrane vesicle preparation by using much more vigorous homogenizations (Hammond, 1990; Hammond et al., 1993; Karniski, 2002), which facilitate the uptake of dyes, buffers, or other substances. Follow the Basic Protocol with the following modifications. This is the most commonly utilized brush border membrane vesicles methodology for renal membranes and is described stepwise in Figure 3.26.2. The disadvantage of this more vigorous protocol is that it compromises purity to some extent, which has led to attempts to further purify brush border membrane vesicles by an aqueous two-phase partition or flow cytometry (see Alternate Protocol 3).

For materials, see Basic Protocol.

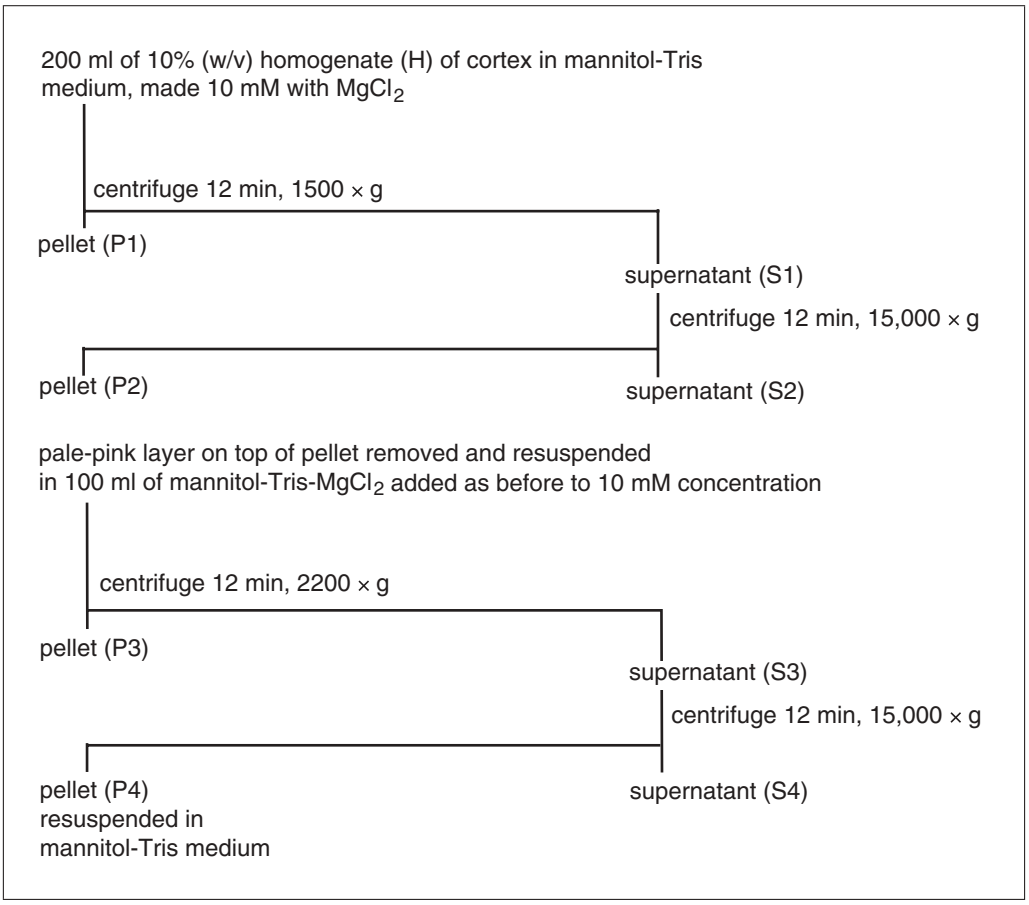

Figure 3.26.2 Preparation of brush border membranes by the divalent ion precipitation method with Mg^{2+} according to the original protocol of Booth and Kenny (1974).

1. Mince the initial kidney cortex with scissors to give the consistency of paté. Add the minced renal cortex to 6 vol of buffer that contains the dye or electrolyte solution intended to be encapsulated.

   Unlike cell isolation, mechanical grinding techniques such as Waring blenders can be substituted for hand mincing, but care must be taken to control the volume of buffer to about six times the volume of the packed tissue to facilitate the subsequent isolation steps.

2. Following motorized glass-Teflon homogenization (see Basic Protocol, step 6), homogenize each ~10-ml aliquot on ice using a Polytron for three bursts of 30 sec at top speed with 30 sec between bursts.

   This creates smaller brush border fragments, but facilitates uptake of the homogenization buffer into the core to the brush borders, which spontaneously vesiculate below a certain membrane size. This allows for controlled delivery of buffers and dyes to the core of the final product, which is critical for diverse studies such as transport properties, and use of indirect dye reporter molecules (Hammond et al., 1993; Karniski, 2002).

ISOLATION OF RENAL CORTICAL MEMBRANES USING AN AQUEOUS TWO-PHASE PARTITION TECHNIQUE

ALTERNATE PROTOCOL 3

Aqueous two-phase partition techniques have been applied to isolation of renal brush border membrane vesicles in an attempt to correct for the increased mitochondrial contamination inherent in protocols using vigorous homogenization, as these protocols are valued for the facile delivery of homogenization buffer to the core of the isolated membrane vesicles. The disadvantage of aqueous two-phase partition is the necessity to validate that the exposure to polyethylene glycols and dextran inherent to the isolation method does not affect the properties of the membranes to be studied.

***Additional Materials** (also see Basic Protocol)*

Kidneys harvested from one or more (depending on requirements) pentobarbital-anaesthetized male Sprague-Dawley rats, 200 to 250 g
20% (w/v) dextran T-500 (Pharmacia)
40% (w/v) polyethylene glycol 3350 (PEG; Union Carbide or Fisher)
0.2 M potassium phosphate, pH 7.2

30-ml Pyrex tube
Parafilm
Pasteur pipets
50-ml polyallomer tubes

Homogenize kidney cortices

1. Place harvested rat kidneys into ice-cold 300 mM mannitol/12 mM HEPES, pH 7.4.
2. Decapsulate each kidney and dissect the cortexes free from the medulla and hilum as described above.
3. Mince the cortex with scissors to give the consistency of paté.

Homogenize tissue

4. Homogenize the tissue as in Basic Protocol, step 6.
5. Continue homogenization using three 30-sec bursts of a Polytron homogenizer at top speed separated by 30 sec. Keep the homogenate on ice throughout.
6. Add 100 µl of 1 M $MgCl_2$/10 ml of homogenate.
7. Centrifuge the resulting cortical homogenate 10 min at 1700 × *g*, 4°C.

Isolate brush border vesicles

8. Remove the supernatant to a 50-ml polyallomer tube and centrifuge 20 min at 14,500 × *g*, 4°C. Discard the supernatant.
9. Resuspend the pellet of brush border membrane vesicles in <2 ml of buffer.
10. Repeat steps 8 and 9.

Perform aqueous two-phase partition fractionation

11. Prepare stock solutions of 20% (w/w) dextran T-500 and 40% (w/w) PEG in double-distilled water.
12. Prepare a 6.4% (w/w) two-phase systems by adding 5.1 g of 20% dextran to 2.56 g of 40% PEG in a tared 30-ml Pyrex tube on ice. Then, add 0.32 ml of 0.2 M potassium phosphate at pH 7.1.
13. Make the total weight of the contents up to 14 g with distilled water or the medium used for homogenate preparation (Table 3.26.1).

    Other weight ratios are prepared by varying the amounts of dextran and PEG added to the system as described (Morré and Morré, 1989).

14. Resuspend the membranes to be separated in a minimum volume (e.g., <2 ml) of the medium used for homogenate preparation, e.g., 300 mM mannitol/12 mM HEPES, pH 7.4.
15. Adjust the final weight of the two-phase system to 16 g with medium after adding the membranes (total volume <2 ml).
16. Cover the Pyrex tube with Parafilm and invert vigorously 40 times in the cold (9°C).

Table 3.26.1 Composition of a 16 g (6.0%) Two-phase System

Reagent	Amount
20% (w/v) dextran T-500 (Pharmacia)[a]	4.80 g
40% (w/v) polyethylene glycol 3350 (PEG; Union Carbide)	2.40 g
0.2 M potassium phosphate buffer, pH 7.2	0.32 ml
Sufficient distilled water or isolation buffer to bring the weight of the mixture to 14 g	
Brush border membranes (~250 mg) resuspended in isolation buffer	2 g

[a]It is practical to prepare stock solutions of the phase system and store them frozen as aliquots. The stock solutions of dextran and polyethylene glycol are prepared on a weight basis, while sucrose, buffer and salt stock solutions are prepared on a molar basis.

17. Centrifuge the resultant mixture 5 min at 750 × *g*, 4°C, to separate the phases.
18. Remove the upper phase using a Pasteur pipet to a 50-ml tube.
19. Dilute the upper phase ten-fold with 300 mM mannitol/12 mM HEPES, pH 7.4.
20. Collect the membranes from the upper phase by centrifuging 30 min at 20,000 × *g*, 4°C.

The yield of brush border protein is ~10 mg per gram of kidney. The brush borders can be used in many ways according to the investigator's interests. Popular examples include immediate use for function studies such as electrolyte uptake studies using fluorophores or radioactive electrolytes, labeling with antibodies, or SDS-PAGE analysis. The brush borders can be frozen at –80°C for later use, but this lyses the vesicles, which encapsulate the surrounding buffer when thawed.

INCREMENTAL AQUEOUS TWO-PHASE PARTITION FRACTIONATION OF RAT KIDNEY TO YIELD BOTH BRUSH BORDER AND ENDOSOMES

ALTERNATE PROTOCOL 4

In studies where endosome contamination is to be minimized or where brush border microvilli-endosome comparisons are a study objective, the brush border microvilli may be preferentially collected from the upper dextran-rich phase by aqueous two-phase partition. Other membranes, including basolateral plasma membranes and endosomes remain in the polyethylene glycol–rich lower phase and are subsequently extracted from the lower phase by employing less concentrated dextran-PEG phase systems.

For materials, see Alternate Protocol 3.

1. For incremental aqueous two-phase partitioning, prepare a 6.0% (w/w) two-phase system containing 4.80 g of 20% dextran and 2.40 g of 40% PEG in a tared 30-ml Pyrex tube on ice.
2. Add 0.32 ml of 0.2 M potassium phosphate at pH 7.2.
3. Adjust the total mass of the contents to 14 g with distilled water.

Other mass ratios are prepared by varying the amounts of dextran and PEG added to the system as described (Morré and Morré, 1989).

4. Resuspend membranes to be separated in 300 mM mannitol/12 mM HEPES, pH 7.4, buffer (total volume <2 ml).
5. Add the membranes to the two-phase system, and adjust the final mass of the contents to 16 g with 12 mM HEPES, pH 7.4, buffer.
6. Cover the Pyrex tube with Parafilm, and invert vigorously 40 times in the cold (9°C).

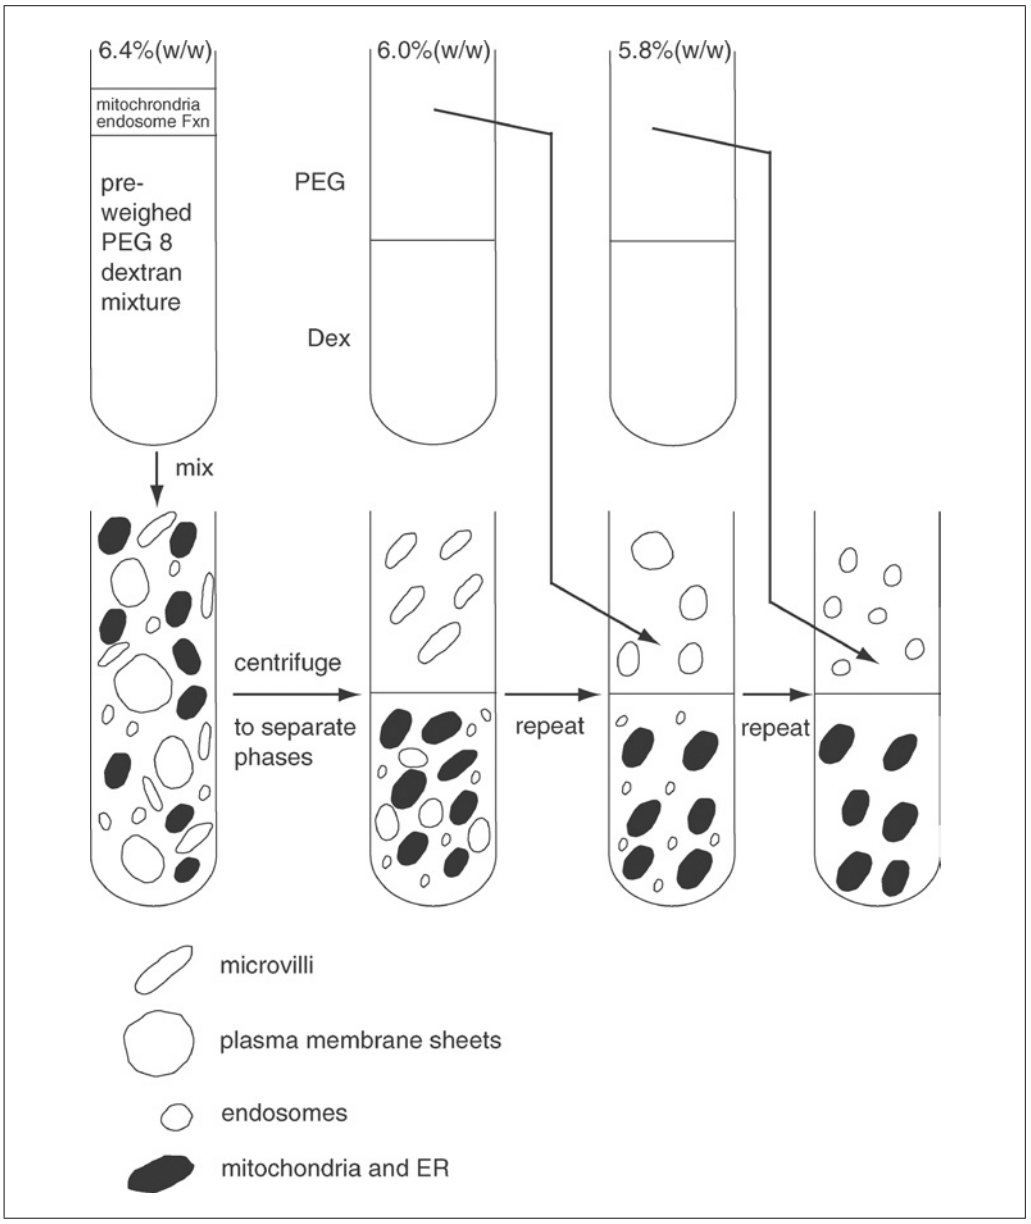

Figure 3.26.3 The incremental two-phase partition for the resolution of different plasma membrane domains and a partially purified endosome fraction from a rat kidney particulate fraction (Morré et al., 1994). The initial partition used a 6.4% PEG-dextran phase system. Brush border membranes partitioned into the upper phase. A 6.0% phase system was equilibrated in parallel and the upper phase of this phase system replaced the brush border-containing upper phase of the 6.4% system. After mixing and resolution of the two new phases, the upper phase now contained the remainder of the plasma membrane including basolateral-derived vesicles. A 5.8% phase system also was equilibrated in parallel and the upper phase replaced the plasma membrane–containing upper phase of the second partition. After mixing and resolution into two phases, a third upper phase enriched in endosomes and depleted in plasma membrane was obtained. The fraction, however, was still contaminated by mitochondrial fragments. The bulk of the mitochondria, endoplasmic reticulum, and nuclei remained in the lower phase after the last partitioning step. Fxn, fraction.

7. Centrifuge the resultant mixture 5 min at 1000 × *g*, 4°C, to separate the phases.
8. Collect the upper phase using a Pasteur pipet and dilute it ten-fold with 300 mM mannitol/12 mM HEPES, pH 7.4.
9. Collect membranes from the upper phase by centrifuging 30 min at 20,000 × *g*, 4°C.

Brush border membranes are concentrated in the upper phase of the initial 6.4% dextran-PEG phase separation (Fig. 3.26.3A). The lower phase still contains basolateral plasma membranes, endosomes, mitochondria, and endoplasmic reticulum (ER). An upper phase equilibrated from a 6.0% dextran-PEG phase system extracts the basolateral plasma membranes (Fig. 3.26.3B). An upper phase equilibrated from a 5.8% dextran-PEG phase system extracts the endosomes for further purification in a third partitioning step (Fig. 3.26.3C). The bulk of the mitochondria, endoplasmic reticulum, nuclei, and other internal membranes are retained in the lower phase (Fig. 3.26.3D).

Density gradient centrifugation (Boffeli et al., 1997; Yoshioka et al., 1997), density gradient centrifugation phase partitioning (Hammond et al., 1993; Gingras et al., 1994), differential centrifugation (Biber et al., 1981; Yusufi et al., 1994), flow cytometry (Hammond, 1990), and free-flow electrophoresis (Mircheff et al., 1984) all have been employed to separate brush border membranes and basolateral membranes, which exhibit subtle differences in density and net surface charge.

STUDY OF BRUSH BORDER MEMBRANE VESICLES BY FLOW CYTOMETRY

SUPPORT PROTOCOL 1

Membranes isolated by the vigorous homogenization techniques and divalent ion precipitation have been further imaged and isolated by flow cytometry (Hammond, 1990). Using the technique of fluorescence-activated cell sorting, direct comparison can be made of enzymatic marker purity of rat renal cortical brush border membrane vesicles prepared by divalent ion precipitation, with and without flow sorting based on enzymatic or antibody probes to detect the brush border membrane enzyme marker gamma-glutamyl-transferase. Flow-sorted membrane vesicles are characterized by larger amounts of brush border membrane markers, no detectable mitochondrial or basolateral markers, and greatly reduced Golgi and lysosomal markers. The flow-sorted membrane vesicles are functional for transport studies as they take up at least as much ^{3}H-proline and ^{3}H-glucose per milligram protein as divalent ion–precipitated membrane vesicles. Preparation of membrane vesicles from superficial and deep cortex allows imaging of the different distributions of gamma-glutamyl transferase in membrane vesicles from these areas. Hence, membrane vesicle populations of exceptional purity can be separated according to fluorescent markers using flow cytometry. High-speed observations on large numbers of individual vesicles allow identification of subpopulations, and statistical comparison within a single heterogeneous sample. Unlike today when flow cytometry has become a standard, a near-fully automated analytical tool in biological laboratories, at the time these techniques were reported, there were only a few flow cytometers in use, and they were complex and expensive to run. The isolation and study of membrane vesicles by flow cytometry has had only a few dedicated followers, mostly for highly specific renal or intestinal biological applications (Gorvel et al., 1984; Hammond et al., 1993; Hammond and Verroust, 1994).

ANALYSIS OF MARKER ENZYMES FOR RENAL BRUSH BORDER

SUPPORT PROTOCOL 2

1. Measure protein by using the biocinchoninic acid method (*APPENDIX 3H;* Smith et al., 1985).
2. Determine the activity of K^+-stimulated, ouabain-inhibited, nitrophenyl phosphatase, a basolateral marker enzyme that co-localizes with Na^+/K^+-ATPase, by measuring cleavage of *p*-nitrophenylphosphate (Kashiwamata et al., 1979; Colas and Marous, 1980).
3. Measure the activity of γ-glutamyltranspeptidase by the cleavage of glutamyl *p*-nitroanilide (Tsao and Curthoys, 1980) or L-leucyl-nitroanilide (Ferracci and Maroux, 1980).

4. Measure alkaline phosphatase by cleavage of *p*-nitrophenyl phosphate at pH 9.0 (Shirazi et al., 1980).
5. Assay succinyl dehydrogenase, a mitochondrial marker, based on succinate 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyltetrazolum reductase (Pennington, 1961).
6. Measure mannosidase activity according to the method of Tulsiani et al. (1977).
7. Assay glucose-6-phosphatase in fresh membrane preparations (Nordlie and Arion, 1966) using Leon's reagent for secondary phosphate analysis.

SUPPORT PROTOCOL 3

ANALYSIS OF RENAL BRUSH BORDER PREPARATIONS BY ELECTRON MICROSCOPY

In addition to evaluation by phase-contrast microscopy, the purity and integrity of the brush borders may be evaluated by electron microscopy (Fig. 3.26.4). Samples of membrane vesicles are fixed for electron microscopy with 2% (v/v) glutaraldehyde in

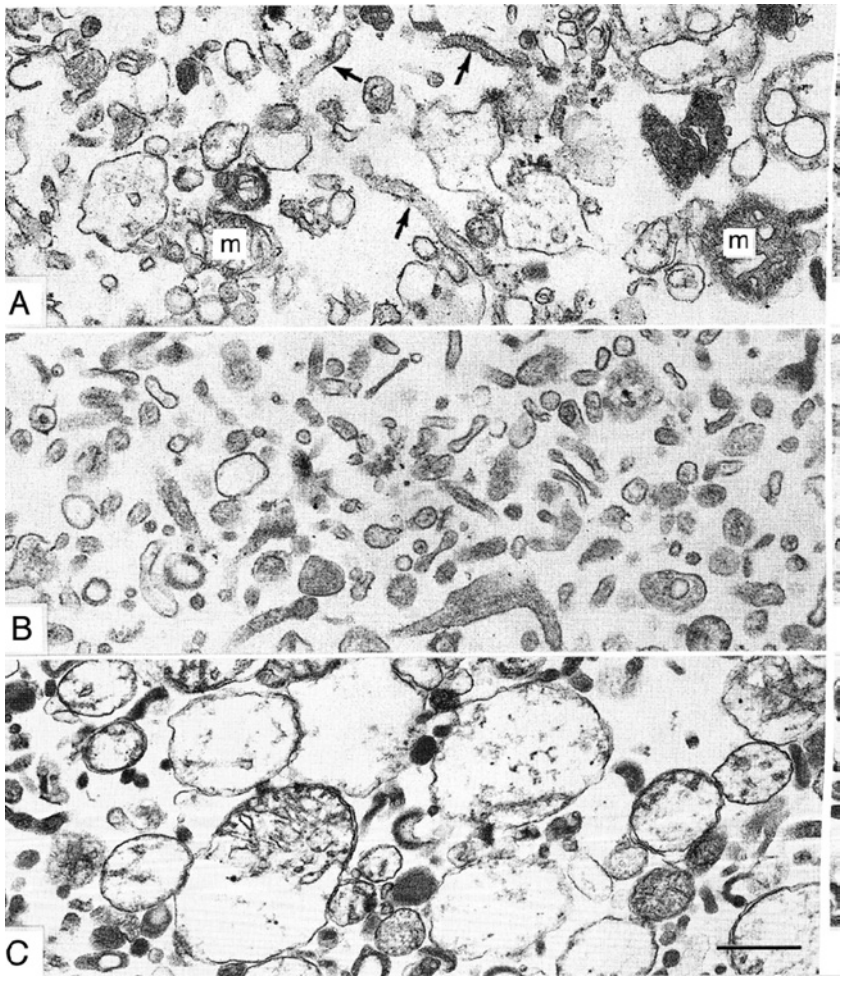

Figure 3.26.4 Electron micrographs of brush-border membrane vesicles following aqueous two-phase partition fractionation. (**A**) Total starting brush-border membrane vesicles fraction prior to aqueous two-phase partition. M = mitochondria. Arrows denote microvilli. (**B**) A 6.8% upper phase enriched in microvilli. (**C**) 5.8% lower phase consisting of mitochondria and membrane contaminants. Scale bar = 0.5 μm. Modified from Hammond et al. (1993).

phosphate-buffered saline. The samples are transferred to 1% (w/v) osmium tetroxide in 0.05 M sodium phosphate, pH 7.2, for 1 hr to overnight at 4°C. Dehydrate the samples in an acetone series and embed in Epon. Lead-stained thin sections are examined and photographed.

COMMENTARY

Background Information

Brush borders are cell-surface structures facing the lumens of the small intestine and kidney cortex specialized for the absorption of nutrients. The name derives from the characteristic folds in the plasma membranes that delineate a large number of fingerlike projections called microvilli. These microvilli greatly increase the surface area of absorptive cells to enhance their absorption rates. In addition to carrying out transport functions, the plasma membrane of the brush border contains many enzymes that assist in the degradation of sucrose into glucose and fructose and of proteins into amino acids. As part of their transport functions, the brush border membrane also contains specific permeases that allow the epithelial cells to absorb these nutrients from the kidney or intestinal lumen.

Absorptive microvilli from epithelial cells represent one of the few nonmuscle systems in which actin microfilaments occur in well-ordered patterns. Each microvillus contains a bundle of 20 to 30 actin microfilaments anchored in the plasma membrane at the tip of the microvillus.

Just under the microvilli are two additional networks also rich in actin and actin-binding proteins. The terminal web is a layer of filaments that crisscrosses the cytosol just under the microvilli. Another is the belt desmosome, which contains a set of actin filaments that encircles the plasma membrane and is linked to the plasma membrane at the level of the terminal web. Study of these networks in brush borders has led to an understanding of how actin filaments cause rigid fingerlike extensions of the plasma membrane and has provided valuable information on the roles of various actin-binding proteins in non-muscle cells.

The bundle of specialized actin filaments at the core of each microvillus lacks myosin, tropomyosin, and α-actinin. The actin bundles presumably play a structural role, one in which the shapes of the microvilli are maintained. The (+) ends of these microfilaments point toward the site of membrane insertion at the tip of the microvillus. In addition to these actin microfilaments, microvilli contain several major proteins that contribute to generating their rigid structure. For the most part, the presence and location of these proteins is similar for brush borders of kidney and intestine (Coudrier et al., 1988). Thus, brush borders are complex cellular structures consisting not only of a plasma membrane but underlying cytoplasmic and cytoskeletal elements. Normally, the objective is to isolate brush borders with microvilli intact for use primarily in structural and in transport studies.

The initial impression that the isolation and application of renal brush border membrane vesicles is straightforward stands in marked contrast to the frustrations of many investigators utilizing the techniques. A lot of the confusion can be explained in two false assumptions. First, the kidney has a highly specialized endosomal pathway characterized by intramicrovillar clefts arising at the base of the brush borders, and delivering membrane elements into small endosomal vesicles and larger endosmal vacuoles, before selectively delivering membrane elements back to the apical membrane surface or to lysosomes (Maunsback, 1976; Christensen and Nielsen, 1990; Verroust et al., 1996). This system of endosomal vesicles and vacuoles is a highly specialized reabsorptive system shared only with cells in the inner ear, and the placenta (Maunsback, 1976; Christensen and Nileson, 1990; Verroust et al., 1996). This phenomenon leads to confusion because when renal brush borders are directly compared with brush border membrane elements from the gastrointestinal tract, or cultured cell systems, the renal membranes have unexpected properties. Second, there is an assumption that compartmental markers such as enzymes and transporters heavily concentrated in the brush border should not traffic into other membrane compartments. In reality, many proteins that are concentrated in the brush border are transported, albeit at lower levels, through the specialized renal endosomal pathway (Maunsbach, 1976; Christensen and Nielsen, 1990; Verroust et al., 1996). Hence, using enzyme enrichment as the sole source of indices of membrane purity can lead to disappointment and uncertainty (Hammond and Verroust, 1994). Several lines of evidence

suggest that fractions very heavily enriched in renal brush border membrane vesicles (Hammond, 1990), intermicrovilar clefts (Hammond et al., 1994), clathrin-coated vesicles (Hammond and Verroust, 1994), endosomal vesicles and vacuoles (Hammond et al., 1994), and lysosomes (Piqueras et al., 1994) can be isolated from the kidney, but their properties are uniquely organ specific for the kidney cortex, and the distribution of compartmental markers is far from absolute (Verroust et al., 1996).

Critical Parameters and Troubleshooting

Assuming all solutions are correctly prepared, low yield, poor morphology, and/or reduced function is most often traced to loss of function in the kidney cortex prior to homogenization, usually attributed to untimely delays between animal sacrifice and transfer of the chopped cortex into the cold homogenization buffer. Further delays in homogenization or over homogenization may also be a factor. Surprisingly, once the homogenate is prepared, further changes are minimal as the initial centrifugation steps are completed. However, even when working in the cold, speed is an essential condition of successful membrane isolation.

Incomplete homogenization as determined visually or by microscopic examination of debris fraction is usually a result of not dicing the tissue finely enough prior to homogenization or the use of an overly loose-fitting homogenizer.

The brush border region of epithelial cells is relatively resistant to homogenization. This permits initial isolation of large fragments of the apical cell structures. These may be disrupted further to form smaller brush border membrane vesicles. However, even under aggressive Polytron homogenization, structures filled with electron-dense material resembling intact microvilli are still present.

For analytical separations based on two-phase partition, it is important to completely resuspend the initial pellet to be applied to the two-phase system. A poorly fitting homogenizer or insufficient homogenization will result in large pieces of unsuspended pellet. Drive the pestle completely to the bottom of the homogenizer and observe the suspension of large particles between glass and pestle. Confirm homogeneity by light microscopy.

Two-phase systems are extremely sensitive to conditions of pH, temperature, polymer-concentrations, and ionic composition. Directions for preparation must be carefully followed with addition by weight using an accurate top-loading balance with sufficient sensitivity to detect milligram differences.

Care should be taken to not allow the temperature of the two-phase system to change during mixing because two-phase partition is temperature dependent. It is best to work consistently either from an ice bucket or in a cold room. It is essential that the contents of the tubes do mix and that an unmixed cushion of dextran does not remain along the wall of the tube. Subsequent separation into two phases occurs too slowly at unit gravity so that the separation is usually accelerated by centrifugation in a swinging-bucket rotor at 750 $\times$ g, 4°C. The speed can range from 250 to 2500 $\times$ g and the duration can range from 3 to 10 min.

A common initial difficulty in phase separation may involve inaccurate preparation of the polymer stocks. If the polymers have picked up excess water in storage, they will be underrepresented and the compositions will not be those required. This can be compensated for by increasing the phase compositions until separation into two equal phases is achieved.

To accurately prepare a stock solution, access to a polarimeter to determine optical rotation is necessary. A detailed description of the procedure for preparation of the dextran stock solution is given by Larsson (1985).

The bulk, $>$90%, of the membranes should remain in the upper phase. If there is nothing or $>$10% of the membranes in the lower phase, the phase composition should be lowered to increase or increased to lower the proportion of membranes entering the lower phase.

Normally, the phases are diluted 1:1 with buffer and the membranes are collected by centrifugation. If the membranes fail to sediment, especially from the lower phase, it is usually the result of incomplete mixing after dilution and prior to centrifugation.

The vesicles are 15- to 20-fold enriched in marker enzymes for the brush border such as alkaline phosphatase with a yield of $\sim$50% (Biber et al., 1981).

Anticipated Results

The anticipated outcome is a preparation of functional isolated kidney brush border membranes suitable for use in transport studies. The yield of purified intact brush borders from rat or rabbit renal cortex is in the range of 10 to 20 mg protein per gram renal cortex protein. Brush border membranes are isolated largely oriented right-side out, and they are extremely resistant to inversion. Protein can be assayed

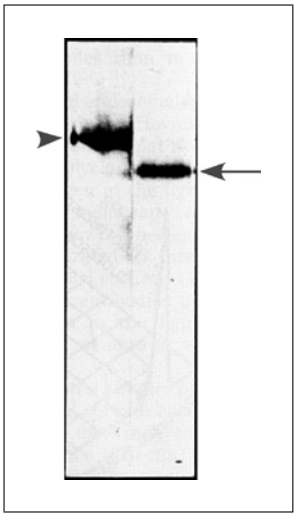

Figure 3.26.5 Immunoblot analysis of glycoprotein content of kidney brush border membrane vesicles and kidney endosomes. (**A**) 330-kDa Heymann antigen (arrowhead) and a 280-kDa protein derived from intermicrovillar clefts (arrow) are present. Modified from Hammond and Verroust (1994).

following isolation of the final brush border fraction using standard biochemical protein assays (Smith et al., 1985).

If specific antibodies are available, analysis of specific proteins can also be undertaken, such as a western blot of renal brush border shown in Figure 3.26.5, which identifies megalin and cubilin that are highly concentrated on the apical brush border of renal cortical cells.

For analytical preparations with reduced contents of mitochondrial and internal and basal-lateral membranes, where more extensive disruption may be required, yield, intactness, and suitability for transport studies will be correspondingly less.

Time Considerations

The key to functional brush borders in high yield is to work fast and not interrupt the procedure. For intact brush borders, the complete protocol from animal sacrifice to resuspension of the final pellet should be completed in 2 to 3 hr. It is essential that all materials, solutions, supplies, and equipment be prepared and at the appropriate temperatures before sacrificing the animal.

ABSTRACT

Increasingly mechanistic virology studies require dependable and sensitive methods for isolating purified organelles containing functional cellular sub-domains. The mitochondrial network is, in part, closely apposed to the endoplasmic reticulum (ER). The mitochondria-associated membrane (MAM) fraction provides direct physical contact between the ER and mitochondria. Characterization of the dual localization and trafficking of human cytomegalovirus (HCMV) UL37 proteins required establishing protocols in which the ER and mitochondria could be reliably separated. Because of its documented role in lipid and ceramide transfer from the ER to mitochondria, a method to purify MAM from infected cells was also developed. Two robust procedures were developed to efficiently isolate mitochondria, ER, and MAM fractions while providing the substantial protein yields from HCMV-infected primary fibroblasts and from transfected HeLa cells. Moreover, this unit includes a protocol that allows visualization of the mitochondria network disruption that occurs in permissively infected cells by their optimal resolution in Percoll gradients. *Curr. Protoc. Cell Biol.* 37:3.27.1-3.27.23. © 2007 by John Wiley & Sons, Inc.

INTRODUCTION

Fractionation, the mechanical separation and purification of subcellular compartments, is an invaluable tool for studying protein localization, trafficking, processing, and functions. Subcellular fractionation is also useful for the concentration of relatively low-abundance proteins, isolation of enzymatic complexes, or proteomic identification of organelle components. Increasingly mechanistic analyses of cellular biology and virology require dependable and sensitive methods for isolating purified organelles from which functional subcellular domains, such as translocation complexes, lipid rafts, and viral envelopment sites, can be studied. Moreover, functional contacts between distinct organelles have been identified and fractionated. For example, the contact sites between endoplasmic reticulum (ER) and mitochondria are being characterized as sites for exchange of calcium (Rizzuto et al., 1998) and lipids (Stone and Vance, 2000) between these organelles. In all, ~5% to 20% of the mitochondrial network surface within a cell is in close apposition to the

DOI: 10.1002/0471143030.cb0327s37

ER (Rizzuto et al., 1998). The mitochondria-associated membrane (MAM) fraction, a subdomain of the ER, which consists of membrane tubules that provide direct physical contact between the ER and mitochondria, has been fractionated to high purity (Vance, 1990). Importantly, the purified MAM fraction is enriched in lipid synthetic enzymes, which produce phosphatidylserine and ceramide, and transport these products from the ER into mitochondria (Stone and Vance, 2000; Ardail et al., 2003; Bionda et al., 2004).

The authors' laboratory investigates human cytomegalovirus (HCMV) UL37 proteins, which dually target the ER and mitochondria of transfected and of HCMV-infected human foreskin fibroblasts (HFFs; Al-Barazi and Colberg-Poley, 1996; Goldmacher et al., 1999; Colberg-Poley et al., 2000; Mavinakere and Colberg-Poley, 2004a,b). The authors recently found that HCMV UL37 proteins traffic sequentially from the ER into the mitochondrial outer membrane (Mavinakere et al., 2006). Characterization of the subcellular localization and trafficking of HCMV UL37 proteins required establishing a protocol in which ER and mitochondria could be reliably separated from one another, despite their prevalent interconnection. Because of the documented role of MAM in lipid and ceramide transfer from the ER to mitochondria, the authors also sought to highly purify the MAM from transfected and from infected cells, adapting an established protocol from Vance (1990). The Vance protocol was originally used for the isolation of microsomes, mitochondria, and MAM from rat liver tissue (Vance, 1990). The following protocols were developed (see Basic Protocol 1) to maximally isolate mitochondria, ER, and MAM fractions while providing the best protein recoveries from HCMV-infected HFFs and from transfected, non-permissive HeLa cells. Basic Protocol 2 has proved especially valuable because it allows visualization of the mitochondria network disruption that occurs in permissively infected cells (McCormick et al., 2003) by their resolution in Percoll gradients.

BASIC PROTOCOL 1

DIFFERENTIAL SUCROSE GRADIENT ISOLATION OF ER AND MITOCHONDRIA

This protocol utilizes discontinuous sucrose gradients to band purified ER and mitochondrial organelles. Initially, cells are lysed mechanically with sonication and, then, a low-speed centrifugation (700 × *g*) is used to remove large cellular debris. Supernatant from this step is collected as a total lysed protein fraction. A subsequent 15,000 × *g* centrifugation crudely pellets mitochondria and separates it from ER and other organelles. The supernatant is loaded onto a three-layered sucrose gradient and purified ER is banded by centrifugation at 152,000 × *g*. Separately, the pellet is washed and loaded onto a two-layer sucrose gradient and purified mitochondria are banded using a 40,000 × *g* centrifugation. The high protein yields and considerable purity of banded organelles makes this fractionation of great utility for studies involving ER- or mitochondrial-resident proteins. The critical steps are shown in Figure 3.27.1.

Materials

Human foreskin fibroblasts (HFFs; Viromed SF cells)
HeLa cells (ATCC CCL-2)
HCMV (strain AD169 or desired strain) or DNA for transfection
2% and 10% (w/v) FBS
Lipofectamine 2000 (Invitrogen; *UNIT 20.6*)
Opti-MEM I (Invitrogen)
1.0, 1.3, 1.5, 1.7, and 2.0 M sucrose solutions (see recipes), sterile
1× PBS, pH 7.4 (*APPENDIX 2A*)
0.25% trypsin/EDTA
1× mannitol/Tris/EDTA (1× MTE) buffer (see recipe)
100 mM PMSF stock (see recipe)
Ultrapure water
70% ethanol

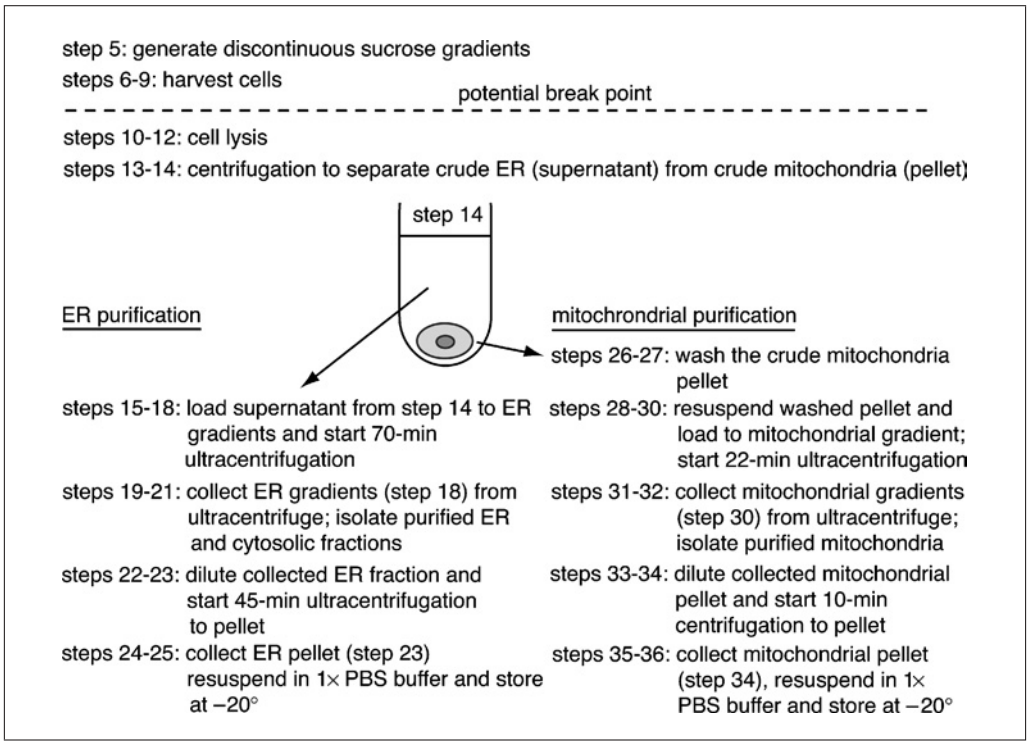

Figure 3.27.1 A flow chart for Basic Protocol 1 is shown. Basic Protocol 1, step 14, separates crude ER (supernatant) from crude mitochondria (pellet). Subsequent steps are grouped by the organelle which is to be purified for clarity and to provide a sense of continuity. To streamline the timing of the procedure and to reduce protein degradation, however, ER and mitochondrial purification steps should be carried out simultaneously.

175-cm^2 flasks (~0.8–2 × 10^7 cells/flask)
37°C incubator
Pre-sterilized (autoclaved) Beckman polyallomer centrifuge tubes: 14 × 89–mm (cat. no. 331372) or 11 × 60–mm (cat. no. 328874)
5-ml serological pipets
Aspirator
Sterile 15-ml conical tubes
Beckman GS-6R centrifuge with GH-3.8 swinging-bucket rotor
Analog sonicator with 1/8-in. microtip (Branson Ultrasonics model 250)
250-ml glass beakers
1.5-ml microcentrifuge tubes
14-ml polypropylene, round-bottom, snap-cap tubes (17 × 100–mm; Falcon cat. no. 2059)
Beckman J2-MI centrifuge with JA20.1 rotor
Beckman XL-90 ultracentrifuge with SW60 Ti and SW41 Ti rotors
1-ml syringes and 20-G needles
Parafilm
Beckman GS-15R centrifuge with F2402 rotor

Culture cells

1. For HCMV infection, seed two 175-cm^2 flasks of 60% to 70% density, actively growing primary HFFs. For transfection, seed two 175-cm^2 flasks of HeLa cells, 25% to 30% density and actively growing cells.

   For best results, use HFFs at or less than passage 18 as primary HFFs undergo senescence following 50 cell doublings or ~25 passages.

Transfer vital DNA to cells

To infect HFF cells with HCMV

2a. Twenty-four hr after seeding, infect permissive HFFs with HCMV (strain AD169 or desired strain), for 1 hr at 37°C in low-serum (2% FBS) medium, at a multiplicity of three plaque forming units (pfu) per cell (Mavinakere and Colberg-Poley, 2004a).

A cell density of ~80% the day of infection is best for maximal virus infectivity, as HCMV grows better in actively growing cells.

3a. After 1 hr, remove virus inocula by suction and overlay cells with complete medium (10% FBS). Proceed to step 4.

To transfect HeLa cells

2b. Transfect HeLa cells with Lipofectamine 2000 (*UNIT 20.6*) according to manufacturer's protocol. For each 175-cm^2 flask, use 20 μg DNA, 35 μl Lipofectamine 2000, and a total of 8.8 ml Opti-MEM I.

3b. Proceed to step 4.

A cell density of 80% to 90% is critical for maximal transfection efficiency using Lipofectamine 2000. If it is necessary to attain the correct cell density, incubate cultures for an extra day after seeding before transfecting.

Lipofectamine 2000 was found to give reliably higher transfection efficiencies in HeLa cells and HFFs than either Oligofectamine or Lipofectamine.

4. Incubate HCMV-infected cells according to the temporal class of examined viral protein. Allow transfected cells to incubate 24 hr at 37°C.

Depending on the abundance of the protein of interest or the kinetics of its movement through the cell, the incubation time may be adjusted to anywhere between 16 to 72 hr.

Prepare discontinuous sucrose gradients

5a. *For mitochondria gradients*. Dispense 1 ml of 1.7 M sucrose into a sterile 11 × 60–mm Beckman polyallomer ultracentrifuge tube. Mark the top of sucrose layer on the outside of the tube with an indelible felt-tip marker. Using a 5-ml serological pipet, carefully overlay with 1.6 ml of 1.0 M sucrose.

Hold the tube at a slight angle and slowly add top layer, to prevent sucrose layers from mixing.

5b. *For ER gradients*. Dispense 2 ml of 2.0 M sucrose to the bottom of a sterile 14 × 89–mm Beckman polyallomer ultracentrifuge tube. Using a 5-ml serological pipet, slowly layer 3 ml of 1.5 M sucrose onto the 2.0 M sucrose. Overlay with 3 ml of 1.3 M sucrose on top of the gradient.

The 14 × 89–mm polyallomer tubes used for ER gradients fit snugly into a polypropylene holder/dryer rack with 102 drying pins (made for 10- to 13-mm tubes).

Use the discontinuous sucrose gradients within 10 hr of preparation, for best results. The fine demarcation between sucrose layers may fade rapidly, but gradients remain stable at room temperature for several hours.

Harvest cells

6. Remove medium from cells by aspiration and wash the monolayers with 10 ml of 1× PBS, pH 7.4. Add 2 ml of 0.25% trypsin/EDTA and incubate 5 min at 37°C.

7. Inactivate the trypsin by adding 8 ml complete medium (10% FBS) to each flask and resuspend cells by vigorous pipetting. Transfer the resuspended cells from each flask into separate, sterile 15-ml conical tubes.

8. Pellet cells by centrifuging 5 min at 200 × *g* (1000 rpm in tabletop Beckman GS-6R centrifuge), 4°C. Aspirate the supernatant and resuspend the cell pellet in 10 ml of 1× PBS, pH 7.4.

9. Centrifuge cell suspension 5 min at 1400 × *g* (2500 rpm in tabletop Beckman GS-6R centrifuge), 4°C. Remove the supernatant by aspiration and store the cell pellet on ice (average pellet size is ~0.145 g).

   Cell pellets are stable on ice for up to 2 hr. Alternatively, the cell pellets can be frozen up to 1 month at –80°C at this stage and saved for later processing.

Lyse cells

10. Dispense 15 ml of 1× MTE and add fresh PMSF to a final concentration of 1 mM. Keep solution on ice. Add 2 ml of this solution to each 15-ml conical tube (step 9), and resuspend cell pellets.

11. Wash the sonicator microtip with ultrapure water and then with 70% ethanol. Blot dry with a Kimwipe before use. Set the sonicator for continuous pulse on a power setting of 3.5.

12. Place the 15-ml conical tube with resuspended cells into a 250-ml glass beaker partially filled with a slurry of ice and cold water. Submerge the cleaned, dry sonicator tip into the cell suspension to just above the bottom of the tube, avoiding touching the bottom. Sonicate the cell suspension on ice three times for 10 sec each, separated by 10-sec rest intervals. Keep the lysed cells on ice.

    Cell pellets from each flask should be kept separately up to this point to maximize the lysis efficiency. In step 14, however, combine the lysed cells from two 175-cm^2 flasks to maximize protein yields during fractionation.

    The 10-sec lysis condition had the best combination of high protein yields and fraction purity. If one wishes to sacrifice protein yield to obtain maximal purity of subcellular fractions, Basic Protocol 2 is recommended using homogenization lysis.

13. Centrifuge the lysed cells in 15-ml conical tubes 10 min at 1400 × *g* (2500 rpm in a tabletop Beckman GS-6R centrifuge), 4°C. Collect 100 µl of supernatant from each 15-ml conical tube, pool together duplicate samples into a single 1.5-ml microcentrifuge tube and label as "total protein." Store immediately at −20°C.

    Depending upon the cell lysis procedure, a pellet may not be seen at this step (corresponding to large cellular debris). A large pellet can be seen after gentle Dounce homogenization, while no pellet is usually visualized after long sonication times (see Table 3.27.1).

14. Decant remaining supernatant into a sterile, pre-chilled 14-ml polypropylene round-bottom snap-cap tube. Combine material from both 175-cm^2 flasks into a common chilled 14-ml tube. Centrifuge tubes without a snap-cap in the inner row of a JA20.1 rotor 10 min at 15,000 × *g*, 4°C.

    Use only polypropylene tubes for this procedure, as polystyrene tubes will crack and leak because of centrifugal stress.

    This centrifugation separates crude ER (supernatant) from crude mitochondria (pellet). Subsequent steps are grouped by the organelle which is to be purified for clarity and to provide a sense of continuity. To streamline the timing of the procedure and to reduce protein degradation, however, ER and mitochondrial purification steps should be carried out simultaneously.

Load ER gradient for ER purification

15. After centrifugation, transfer tubes to ice.

    There should be a large yellowish-brown pellet containing mitochondrial proteins.

Table 3.27.1 Cellular Markers for Verification and Assessment of ER, Mitochondria, and MAM Subcellular Fractions

Subcellular compartment	Marker	Antibody	Vendor	Reference
ER (microsomes)	DPM1	I-20	Santa Cruz Biotechnology cat. no. sc-15836	Maeda et al., 1998
	Calreticulin		Affinity Bioreagents cat. no. PA3-900	Johnson et al., 2001; Gelebart et al., 2005
Mitochondria	Grp75		Stressgen cat. no. SPS-825	Manning-Krieg et al., 1991
	COXII	K-20	Santa Cruz Biotechnology cat. no. sc-23984	Scheffler, 2001
MAM	mEFGP-huPPS-1	B-2 (anti-GFP)	Santa Cruz Biotechnology cat. no. sc-9996	
	FACL4		Abgent cat. no. AP2536b	Simmen et al., 2005

16. Using a micropipet, carefully withdraw 1.7 ml of the supernatant (containing crude ER) and layer it onto the top of the ER sucrose gradient, creating a new layer. Pipet slowly to keep from mixing the top layer of sucrose with the sample. Decant and discard any excess supernatant remaining in the 14-ml tubes containing the protein pellet, and then return the pellets to ice.
17. Transfer an additional 1.3 ml of ice-cold 1× MTE plus PMSF onto the top of the ER gradient.
18. Ultracentrifuge ER gradients 70 min at 152,000 × *g* (35,000 rpm in an SW41 rotor), 4°C. Set acceleration and deceleration profiles to 1 (transition speed of 170 rpm for 2 min).

    It is important to add the extra 1× MTE plus PMSF buffer on top of the samples to keep the polyallomer tubes from collapsing during ultracentrifugation.

Isolate ER fractions

19. Collect the ER gradient tubes from the ultracentrifuge. Withdraw the upper 1 ml of solution from the tube, using a micropipet, and transfer into a sterile 1.5-ml microcentrifuge tube. Label as "cytosol" and store immediately at −20°C.
20. Extract 0.4 to 0.6 ml volume of the large band at the interface of the 1.3 M sucrose gradient layer, using a 20-G needle and 1-ml syringe (Fig. 3.27.2).

    The samples can be stored for 1 to 2 months at –20°C prior to their use for western analysis.

21. Remove the needle from the syringe, and transfer the extracted band to a sterile 11 × 60–mm Beckman polyallomer tube. Add an additional 3.6 to 3.8 ml of ice-cold 1× MTE plus PMSF buffer to dilute out the sucrose.

    It is important to remove the needle from the syringe before dispensing liquid into the new ultracentrifuge tube, to avoid shear forces that would damage the sample.

22. Cover the top of the tube with Parafilm and mix by inversion until the suspension looks homogeneous (until the highly viscous sucrose swirling within the tube is no longer distinguishable).
23. Ultracentrifuge 45 min at 126,000 × *g* (35,000 rpm in an SW60 Ti rotor), 4°C.

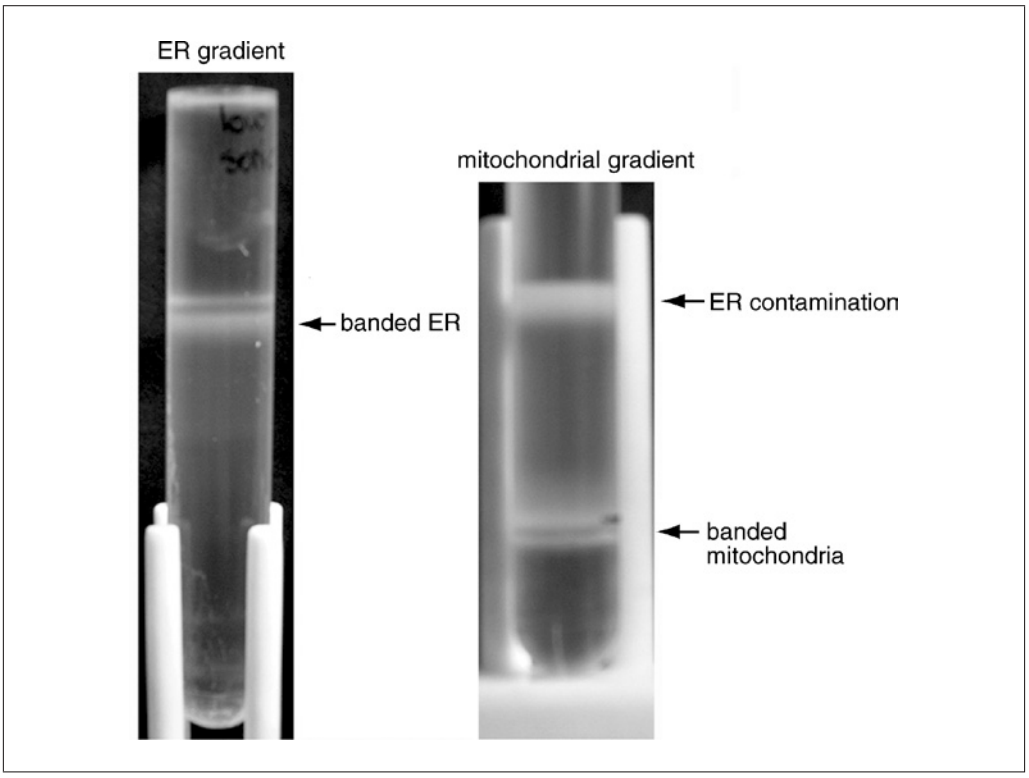

Figure 3.27.2 Representative pictures of visible bands seen upon ultracentrifugation as described in Basic Protocol 1. The ER and mitochondria bands are indicated on their respective gradients following ultracentrifugation.

24. Collect tube from ultracentrifuge. Decant and discard the supernatant.

    There will be a large, translucent pellet at the bottom of the tube.

25. Allow tubes to dry, inverted, for a few minutes. Resuspend the pellet in 100 µl of 1× PBS, pH 7.4, and label as "ER." Store immediately at −20°C.

    The samples can be stored for 1 to 2 months at −20°C prior to their use for western analysis.

Load mitochondria gradient for mitochondrial purification

26. For the mitochondrial pellet wash 1, return to the 14-ml tube on ice containing the protein pellets (step 16). Gently wash the inside sides of the tube with 0.5 ml of ice-cold 1× MTE plus PMSF, being careful not to disrupt the protein pellet. Wash the sides three to five times using the same aliquot of buffer. Decant and discard wash solution.

27. For mitochondrial pellet wash 2, use a fresh aliquot of 0.5 ml of ice-cold 1× MTE plus PMSF buffer to carefully wash the periphery of the protein pellet, which contains ER contaminant proteins. Wash three to five times using the same aliquot of buffer. Decant and discard the wash.

    The ER contaminant proteins make a large, loose ring around the more stable mitochondrial pellet. The mitochondrial pellet will appear more yellow in color, while the surrounding contamination appears whiter in color. A large amount of contaminant protein towards the bottom of the pellet will be seen.

28. Resuspend the washed mitochondrial pellet in 0.8 ml of ice-cold 1× MTE plus PMSF. Load slowly on top of the mitochondrial sucrose gradient so that it forms a new layer.

29. Top off gradient with an additional 0.8 ml of ice-cold 1× MTE plus PMSF buffer.

30. Ultracentrifuge the mitochondrial gradient 22 min at 40,000 × *g* (19,500 rpm in an SW60 Ti rotor), 4°C. Set acceleration and deceleration profiles to 1 (transition speed of 170 rpm for 2 min).

Isolate mitochondrial fractions

31. Collect mitochondrial gradients from the ultracentrifuge (step 30). Using a 1-ml syringe with a 20-G needle, extract a volume of 0.4 ml from the band at the interface of the 1.7 M and 1.0 M sucrose layers (Fig. 3.27.2).

    The mitochondrial band can vary in visibility and is often very thin and hard to see, which is why marking the location of the interface with an indelible felt tip marker before centrifugation is important.

32. Remove the needle and dispense the extracted volume into a sterile 1.5-ml microcentrifuge tube.

33. Add 1.1 ml of ice-cold 1× MTE plus PMSF, cap microcentrifuge tube, and mix well by inversion until suspension is homogeneous.

34. Centrifuge 10 min at 15,000 × *g*, 4°C (in tabletop Beckman GS-15R centrifuge).

35. Decant and discard supernatant (a small, stable yellowish-brown pellet should be visible).

36. Allow tube to dry, inverted, for a few minutes. Resuspend pellet in 30 µl of 1× PBS, pH 7.4, and label as "mitochondria." Store immediately at −20°C.

    The samples can be stored for 1 to 2 months at −20°C prior to their use for western analysis.

BASIC PROTOCOL 2

SEPARATION OF MITOCHONDRIA AND MITOCHONDRIA-ASSOCIATED MEMBRANE FRACTION

This procedure combines differential and Percoll gradient centrifugations. Its critical steps are underscored in Figure 3.27.3. During the first steps, the post-nuclear supernatant (PNS) is separated from nuclei and cellular debris by differential centrifugation at low *g* forces. The post-nuclear supernatant is then subjected to centrifugation at 10,300 × *g* during which the crude mitochondrial fraction is separated from the total microsomal fraction. The total microsomal fraction consists mainly of vesicles derived from rough and smooth ER and membranes from the Golgi apparatus and plasma membrane. The microsomal fraction is then recovered as a pellet after centrifugation of the total microsomal fraction at 100,000 × *g*. The post-microsomal (high-speed) supernatant is generally used as "cytosol" in downstream applications. The crude mitochondrial fraction is subjected to a density gradient fractionation through a self-generating Percoll gradient (Pertoft et al., 1978). Because both mitochondria and mitochondria-associated membrane (MAM) have similar densities, a second step of purification that includes a centrifugation at 6300× *g* follows their collection from the gradient. Finally, the supernatant containing MAM is subjected to centrifugation at 100,000 × *g* and the MAM is isolated as a pellet above the tight Percoll pellet.

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be pre-cooled to 0°C to 4°C and kept on ice throughout the procedure.

Materials

Untransfected or transfected HeLa cells (3×10^7 cells, ten 100 × 20–mm tissue culture dishes, 100% confluent) or uninfected or HCMV-infected HFF cells (5×10^7 cells, four 850-cm^2 roller bottles, 90% confluent)

Phosphate-buffered saline (PBS; see recipe)

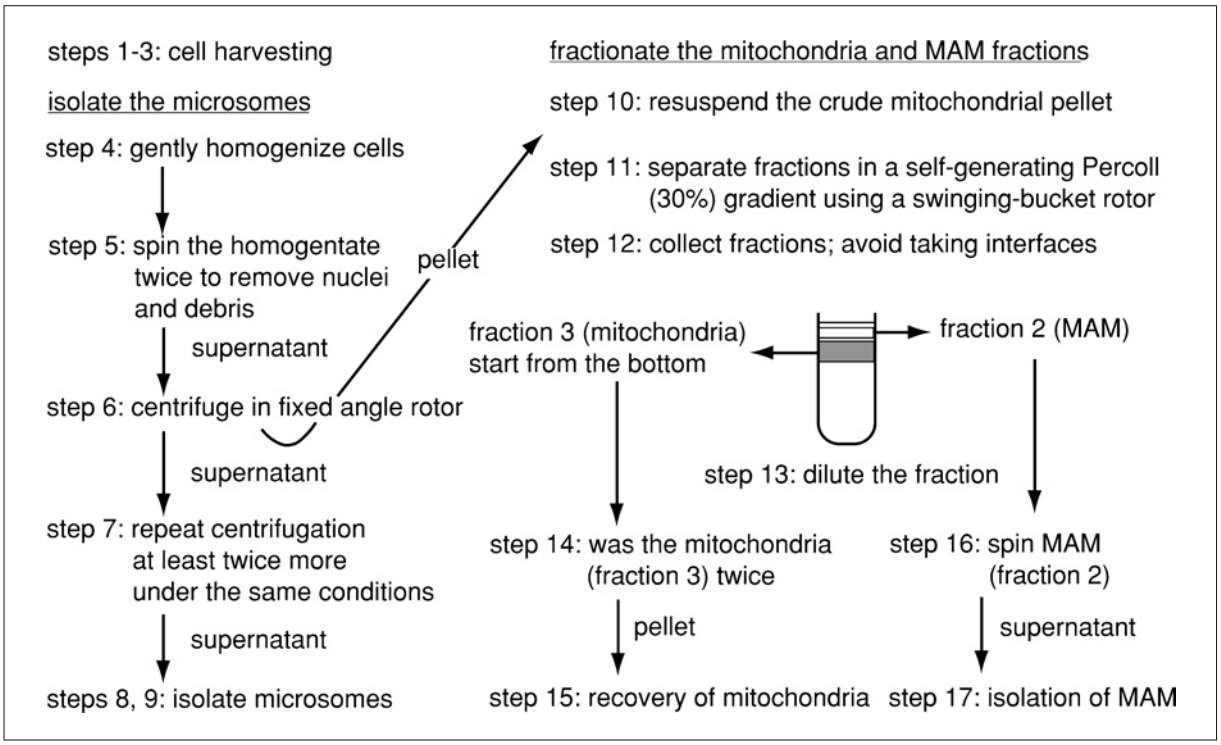

Figure 3.27.3 Schematic representation of Basic Protocol 2. Critical steps in the procedure, which improve purity of the microsomes, mitochondria, and MAM, are emphasized by bold font.

Sucrose homogenization medium (SHM; see recipe), ice cold
Protease inhibitors (optional but recommended, see recipe)
Mannitol buffer A (see recipe), ice cold
30% (v/v) Percoll suspension in mannitol buffer B (see recipe), ice cold
Mannitol buffer B (see recipe), ice cold

Beckman GS-15R tabletop centrifuge with swinging-bucket rotor (e.g., S4180)
14-ml polypropylene round-bottom centrifuge tubes (e.g., Falcon)
Potter-Elvehjem plastic-coated tissue grinder with ball-shaped Teflon pestle (e.g., Wheaton safe-grind type, cat. no. 358003)
Overhead stirrer for tissue grinder (Wheaton, cat no. 903475)
Phase-contrast microscope
1.5-ml microcentrifuge tubes
Beckman GS-15R centrifuge with fixed-angle rotor (e.g., F2402)
Centrifuge tubes, 1.5-ml microcentrifuge tubes
Beckman XL-90 ultracentrifuge with swinging-bucket rotor (e.g., SW 41)
Ultracentrifuge SW41 tubes (ultraclear tubes are highly recommended, e.g., 14 × 89–mm, cat. no. 344059)
1-ml syringes and 20-G needles

Harvest cells

1. Wash the cell monolayers with ~50 ml PBS at room temperature. Remove PBS by suction.
2. Harvest cells (90% to 100% confluent), using a sterile scraper, into 50 ml PBS and pellet cells by centrifuging 10 min at 1000 × *g*, room temperature, using a tabletop centrifuge and four 14-ml centrifuge tubes.
3. Decant the supernatant and resuspend cell pellets in 8 ml ice-cold sucrose homogenization medium containing freshly added protease inhibitors.

Isolate microsomes

4. Attach the pre-cooled pestle of a Potter-Elvehjem homogenizer to an overhead stirrer and gently homogenize the cells by ten up-and-down strokes at 500 rpm. Confirm that ≥90% cell breakage has occurred by examining the homogenate under a phase-contrast microscope.

   It is best to keep the cells on ice throughout the homogenization.

   To check the efficiency of the homogenization, pipet 2 to 3 μl of the homogenized suspension onto a glass slide, overlay with coverslip, and observe using a microscope. A shiny ring around the nuclei indicates that cells are still intact. If >90% of the nuclei do not have the shiny ring, proceed to the next step. Otherwise, repeat the homogenization at 1000 rpm.

5. Transfer homogenates to 1.5-ml microcentrifuge tubes. Pellet the nuclei, cell debris and any unbroken cells by low-speed centrifugation. Centrifuge the homogenates two times in a fixed-angle rotor (e.g., F2402) 5 min at 600 × *g*, 4°C.

   This step is more convenient using a 10-ml centrifuge tube. The centrifugation steps will then be under the same conditions using a different rotor (S4180) but the same centrifuge (Beckman GS-15R). However, it is still recommended that the homogenate should be transferred in 1.5-ml microcentrifuge tubes for the centrifugation that is described in step 6 because of the better separation of the pellet from the supernatant.

6. Transfer the supernatant into new 1.5-ml microcentrifuge tubes and centrifuge 10 min at 10,300 × *g*, 4°C, using the tabletop centrifuge (e.g., Beckman GS-15R) with a fixed-angle rotor (e.g., F2402) and retain the pellet for subsequent steps.

7. Centrifuge supernatant at least two additional times under the same conditions (10 min at 10,300 × *g*, 4°C) until a pellet is no longer visible. Save supernatant on ice for subsequent steps.

   These additional centrifugation steps under the same conditions are needed to ensure that the microsomal fraction will be efficiently separated from any residual mitochondrial membranes and MAM.

8. Pellet the microsomes by ultracentrifuging resultant supernatant 60 min at 100,000 × *g*, 4°C, using a swinging-bucket rotor (e.g., SW41).

9. Resuspend the pellet in 0.5 ml of sucrose homogenization medium.

Fractionate mitochondria and MAM fractions

10. Resuspend the pellet from step 6 in 0.3 ml of mannitol buffer A using two or three strokes in a Potter-Elvehjem homogenizer at 500 rpm, as above in step 4, and carefully layer on top of 10 ml of 30% Percoll suspension in a 14 × 89–mm SW41 ultraclear tube.

11. Centrifuge 65 min at 95,000 × *g*, 4°C, in an ultracentrifuge with a swinging-bucket rotor (e.g., a Beckman SW41).

    The generation of Percoll gradients is an automatic process occurring during centrifugation of the colloid. Therefore, the use of an acceleration program (e.g., 500 rpm for 3 min) in the beginning of the ultracentrifugation is recommended. Although Percoll gradients are considered to be very stable, a similar deceleration program would be the best choice, if such a program is available on the ultracentrifuge.

    A total of 1 to 5 mg of protein (~0.5 ml) on 10 ml of gradient material results in satisfactory separation of banded material without overloading the gradient.

12. Collect the banded organelles in 0.5- to 1-ml fractions (Fig. 3.27.4). To collect the fractions, attach a sterile metallic needle of appropriate diameter (e.g., 20-G) to a sterile 1-ml syringe and carefully puncture the wall of the tube just above fractions

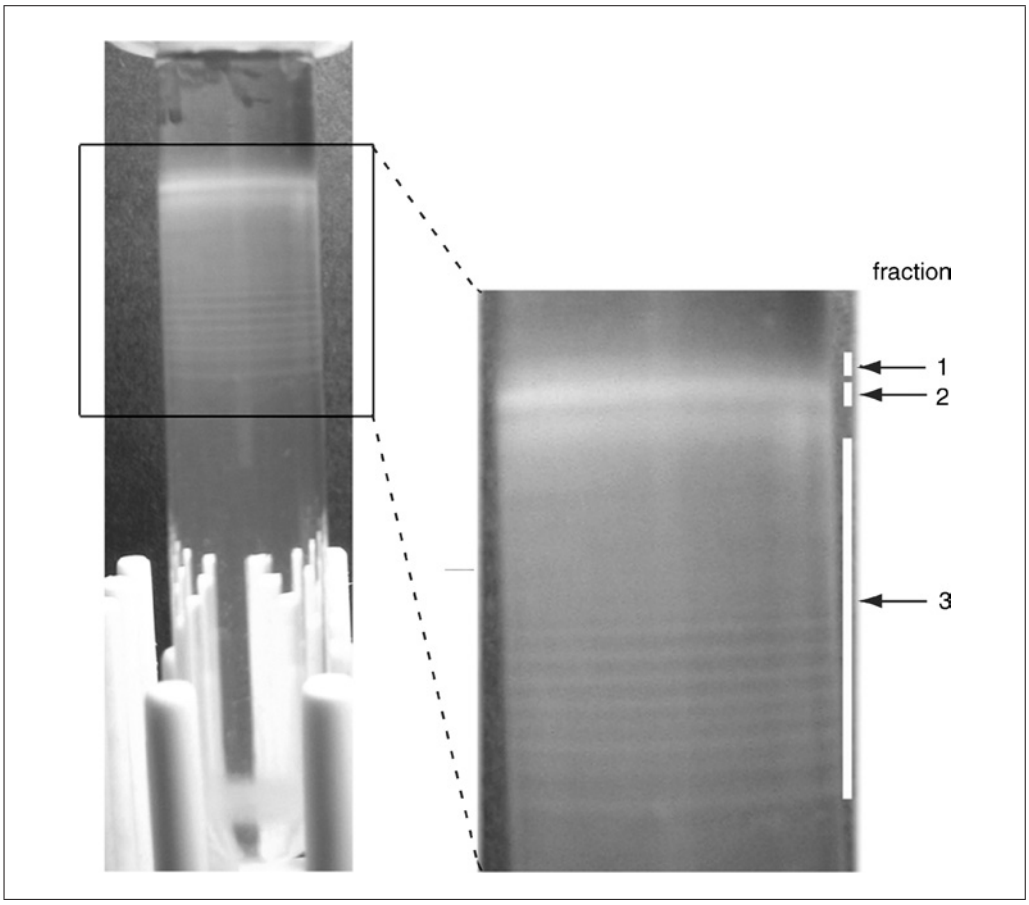

Figure 3.27.4 Separation of MAM and mitochondrial fractions using a self-generating Percoll (30%) gradient. Crude mitochondrial extract from HeLa cells was subjected to ultracentrifugation in a Percoll gradient (see Basic Protocol 2). Three fractions were isolated as indicated on the enlarged section of the gradient. Fraction 2 was identified as the MAM fraction, which is immediately above the top of the mitochondrial fraction (fraction 3). The heterogeneous mitochondrial fraction was conservatively taken.

1 and 2 and below fraction 3 (Fig. 3.27.4). Slowly and conservatively suction the fractions with a fan-like movement, avoiding other bands.

The MAM fraction (fraction 2) is the compact, white band, which is located immediately above the multi-band mitochondrial fraction (fraction 3), ~$^{1}/_{3}$ down the tube.

13. Transfer each sample to a 14 × 89–mm ultraclear SW41 tube. Dilute the fractions with ≥5 vol of ice-cold mannitol buffer B (~10 ml total) to dilute Percoll.

14. Wash the diluted mitochondrial band (fraction 3), at least two times, with 5 ml of ice-cold mannitol buffer B. Pellet mitochondria after each wash by centrifuging 10 min at 6300 × *g* (~6000 rpm using an SW41 rotor), 4°C.

    These washing steps are necessary to remove the Percoll from the fraction, which otherwise will interfere with subsequent analysis.

15. Resuspend the mitochondrial pellet after the last washing step in ice-cold mannitol buffer B at a concentration of 0.5 to 2 mg protein/ml (usually 0.05 to 0.2 ml).

16. Centrifuge the diluted MAM fraction (fraction 2) in SW41 ultraclear tubes 10 min at 6300 × *g* (~6000 rpm), 4°C.

    This step is needed to ensure that the mitochondria-associated membrane fraction will be detectably free from any residual mitochondria.

17. Ultracentrifuge the resulting supernatant 60 min at 100,000 × *g*, 4°C, to pellet the MAM.

    After the ultracentrifugation, the mitochondria-associated membranes form a loose pellet, which is located above the hard pellet of Percoll particles.

18. Resuspend the MAM in ice-cold homogenization buffer at a concentration of 0.5 to 2 mg protein/ml (usually 0.05 to 0.2 ml). Freeze the isolated fractions at −80°C or submit immediately to SDS-PAGE (*UNIT 6.1*) or proteomics analyses.

    The loose MAM pellet is carefully resuspended using a micropipette and transferred to a new 1.5-ml microcentrifuge tube. These fractions may be stored up to 6 months at –80°C.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Mannitol buffer A

To 100 ml ultrapure H_2O, add:
9.13 g mannitol (0.25 M final)
38 mg EGTA (0.5 mM final)
10 ml 100 mM HEPES (5 mM final)
Adjust pH to 7.4 with 1 N NaOH
Add ultrapure H_2O to 200 ml
Sterilize by autoclaving for 20 min using a liquid cycle
Store up to 2 or 3 months at 4°C

Mannitol buffer B

To 100 ml ultrapure H_2O, add:
8.22 g mannitol (0.225 M final)
76 mg EGTA (1 mM final)
50 ml 100 mM HEPES (25 mM final)
Adjust pH to 7.4 with 1 N NaOH
Add ultrapure H_2O to 200 ml
Sterilize by autoclaving for 20 min using a liquid cycle
Store up to 2 or 3 months at 4°C

MTE solution, 1×

In 60 ml ultrapure H_2O, dissolve:
4.914 g D-mannitol (270 mM final)
121.1 mg Tris-base (10 mM final)
3.72 mg EDTA (0.1 mM final)
Adjust pH to 7.4 with 6 M HCl
Add ultrapure H_2O to 100 ml
Sterilize through a 0.22-μm vacuum filter
Store 3 to 6 months at room temperature

Percoll solution, 30% (v/v)

1 vol 90% (v/v) stock isotonic Percoll (see recipe)
2 vol mannitol buffer B (see recipe)
Sterilize by autoclaving for 20 min using a liquid cycle
Store 2 or 3 months at 4°C

Phosphate-buffered saline, pH 7.4

3 liters distilled water
32 g NaCl (140 mM final)
0.8 g KH_2PO_4 (1.5 mM final)
8.7 g $Na_2HPO_4 \cdot 7H_2O$ (8.1 mM final)
0.8 g KCl (2.7 mM final)
Adjust pH to 7.4 with 1 N NaOH
Add H_2O to 4 liters
Sterilize by autoclaving for 20 min using a liquid cycle
Store 2 or 3 months at 4°C

PMSF, 100 mM

In 500 μl absolute ethanol, dissolve:
8.71 mg PMSF
Store up to 1 year at −80°C

Protease inhibitors

PMSF (200 mM final):
0.348 g phenylmethylsulfonyl fluoride
10 ml 2-propanol or ethanol
Store up to 1 year at −20°C

Add to solutions as required so that the final concentrations are 1 mM.

Stock isotonic Percoll, 90% (v/v)

9 vol Percoll (Pharmacia cat. no. P1644)
1 vol 2.5 M sucrose (0.25 M final)
Sterilize by autoclaving for 20 min using a liquid cycle
Store 2 or 3 months at 4°C

Sucrose, 1.0 M

In 60 ml ultrapure H_2O, dissolve:
34.23 g sucrose
121.1 mg Tris-base (10 mM final)
3.72 mg EDTA (0.1 mM final)
Adjust pH to 7.6 with 6 M HCl
Add ultrapure H_2O to 100 ml
Sterilize by autoclaving 20 min using a liquid cycle
Store 3 to 6 months at room temperature
Open only in a laminar flow hood to avoid contamination

Sucrose, 1.3 M

In 60 ml ultrapure H_2O, dissolve:
44.50 g sucrose
121.1 mg Tris-base (10 mM final)
3.72 mg EDTA (0.1 mM final)
Adjust pH to 7.6 with 6 M HCl
Add ultrapure H_2O to 100 ml
Sterilize by autoclaving 20 min using a liquid cycle
Store 3 to 6 months at room temperature

Sucrose, 1.5 M

In 60 ml ultrapure H_2O, dissolve:
51.35 g sucrose
121.1 mg Tris-base (10 mM final)
3.72 mg EDTA (0.1 mM final)
Adjust pH to 7.6 with 6 M HCl
Add ultrapure H_2O to 100 ml
Sterilize by autoclaving 20 min using a liquid cycle
Store 3 to 6 months at room temperature

Sucrose, 1.7 M

In 60 ml ultrapure H_2O, dissolve:
58.19 g sucrose
121.1 mg Tris-base (10 mM final)
3.72 mg EDTA (0.1 mM final)
Adjust pH to 7.6 with HCl
Add ultrapure H_2O to 100 ml
Sterilize by autoclaving 20 min using a liquid cycle
Store 3 to 6 months at room temperature

Sucrose, 2.0 M

In 60 ml ultrapure H_2O, dissolve:
68.46 g sucrose
121.1 mg Tris-base (10 mM final)
3.72 mg EDTA (0.1 mM final)
Adjust pH to 7.6 with HCl
Add ultrapure H_2O to 100 ml
Sterilize by autoclaving 20 min using a liquid cycle
Store 3 to 6 months at room temperature

Sucrose homogenization medium (SHM)

To 100 ml ultrapure H_2O, add:
17.1 g sucrose (0.25 M final)
20 ml 100 mM HEPES (10 mM final)
Adjust pH to 7.4 with 1 N NaOH
Add ultrapure H_2O to 200 ml
Sterilize by autoclaving for 20 min using a liquid cycle
Store 2 or 3 months at 4°C

COMMENTARY

Background Information

Highly purified mitochondria are very difficult to obtain in appreciable amounts. The discontinuous sucrose gradient protocol (see Basic Protocol 1) is valuable for experiments that require higher yields of mitochondrial samples. It is often imperative to use the same pool of purified mitochondria to observe fraction purity, probe for the presence of mitochondrially localized viral proteins, and examine the post-translational modifications of those proteins. Obtaining enough purified mitochondria for all of these experiments by the Percoll protocol (see Basic Protocol 2) presented here would not be feasible. The discontinuous sucrose gradient protocol takes slightly less time, is more user-friendly, requires less starting material (number of cells), and produces higher yields of mitochondrial fractions. These mitochondrial fractions are well-purified and practical for almost any application. Also, the utility of starting with fewer cells is that one can compare more experimental conditions and controls within a single fractionation experiment. However, when one is willing to sacrifice protein yield for even higher purity mitochondrial fractions, or when one needs to isolate MAM fractions to compare to either

ER or mitochondria, then the Percoll protocol (see Basic Protocol 2) is the preferred method.

Points of contact between the ER and mitochondria make up 5% to 20% of the total mitochondrial network (Rizzuto et al., 1998). These connections, as well as the ER and mitochondria organelles themselves, are quite variable and can undergo rapid changes in overall morphology, size, and composition (Bereiter-Hahn and Vöth, 1994; Collins et al., 2002). Factors such as calcium homeostasis, cell metabolism, and perceived stress can have dramatic impacts on both the form and function of these organelles. Thus, it is imperative to monitor fraction purity for each experiment by analyzing total, ER, mitochondria, and MAM pools by utilizing suitable organelle markers (Table 3.27.1). Not only will this ensure that the identity and purity of the fractions are sufficient for unequivocal conclusions, but appropriate controls can provide additional information about cell status at the time of fractionation.

Following lipofection, it is important to check transfected cells often. Lipofectamine 2000 was the least toxic, in the authors' hands, to both HeLa and HFF cells, but cell viability can still change significantly in response to overexpression of a transfected plasmid. When using control plasmids encoding innocuous or beneficial (anti-apoptotic) proteins, Lipofectamine 2000 can be left in the culture medium for up to 24 hr. However, for transfection of most plasmids, it is prudent to change Lipofectamine 2000 transfection medium after 4 hr, replacing it with complete cell medium so as to minimize the stress or apoptotic signals on the cells. Furthermore, overexpression of some plasmids may be more toxic to cells, in which case one must wash out the lipofection medium after 4 hr (as before) and, moreover, may have to decrease the total incubation time before cell harvesting. Prior to harvesting, monitor the cells for viability as cells that are heavily stressed or apoptotic are not reliable for fractionation experiments.

The need to obtain intact and highly purified subcellular fractions, including MAM, imposes the additional use of density gradient centrifugation to remove contamination by broken membranes or organelles of similar size as in Basic Protocol 2. Percoll is considered to be one of the best density gradient medium available for the separation of cells, organelles, viruses, and subcellular particles. Because of its low osmolarity (<25 mOs/kg water), Percoll forms a density gradient without generating an osmolarity gradient (Pertoft et al., 1978). Osmolarity of the gradient medium must be taken into consideration since cellular membrane-bound organelles such as mitochondria and MAM act as osmometers. A high external osmolarity will result in shrinkage of membrane-bound organelles while low osmolarities will result in swelling of organelles, hence altering their buoyant densities. Differences in the osmolarity of the gradient medium can explain differences in the size and apparent buoyant densities of subcellular compartments when different gradient media are used. Buoyant densities of organelles in sucrose rise as water is removed from their enclosed spaces. In contrast, organelles in Percoll gradients in physiological range (280 to 320 mOs/kg) have lower apparent buoyant densities than in sucrose (Pertoft et al., 1978).

Another unique feature of Percoll is that it can form self-generated gradients by centrifugation at moderate *g* forces. Fixed-angle rotors are most commonly used for Percoll gradients. The advantage of using fixed-angle or vertical rotors is that the path-length for formation of the gradient is shorter and the gradient forms more rapidly. Both Vance (1990) and Hovius et al. (1990) used a fixed-angle rotor to isolate purified mitochondria from a self-generated Percoll (30% v/v) gradient. Conversely, the authors used a swinging-bucket rotor for the formation of the Percoll gradient. There are two main reasons for this choice: first, because both fractions (mitochondria and MAM) have similar densities and they are banded within the density range of ~1.039 to 1.051 g/ml (Fig. 3.27.4), a better separation of this density range can be achieved by using a rotor with a longer path-length. Second, a good spatial separation between resolved mitochondria subpopulations, which differ slightly in density and size from one another, can be achieved (Collins et al., 2002). The latter feature is especially desirable in the case of HCMV-infected cells in which disruption of mitochondria networks (McCormick et al., 2003) can be visualized by density banding of mitochondrial species in these Percoll gradients.

Based upon the authors' experience, the transfection protocol does not affect the pertinent physical properties of the organelles and their constituents during fractionation. Thus, no difference should be expected between fractions that are isolated from either untransfected or transfected cells. However, HCMV infection markedly alters the fractionation protocol.

A change in the density of mitochondrial bands after HCMV infection has been observed. This density change in fraction 3 is detected as a significant increase of the mitochondrial markers in the pellet that is formed after the first centrifugation of the diluted MAM fraction at 6300 × *g* (see Basic Protocol 2, step 16). Usually, only background levels of the mitochondrial markers can be detected in this pellet. It appears that HCMV infection causes a shift of mitochondrial densities such that some mitochondria band in the density range of MAM. This is probably related to the documented disruption of mitochondria networks by HCMV. Therefore, it is highly recommended that the study of the MAM should always be based on the more rigorous fraction that is isolated after the final ultracentrifugation step at 100,000 × *g*, as it is described in Basic Protocol 2, step 17. This fraction is consistently devoid of mitochondrial contamination in both uninfected and HCMV-infected cells.

Critical Parameters and Troubleshooting

Sucrose gradient fractionation

Sometimes a mitochondrial band will not be seen after centrifugation, so make sure to mark the gradient interface between the 1.7 M and 1.6 M sucrose layers when preparing the gradients. If a band is not seen after centrifugation, insert the collecting needle into the side of the 11 × 60–mm Beckman tube at the marked gradient interface and carefully withdraw ~0.4 ml of liquid.

When collecting protein fractions with needles, the use of small-bore needles should be avoided as they increase the shear force on the extracted samples. Extract the protein band slowly into the syringe, then remove the needle before dispensing the protein fraction into a microcentrifuge tube for storage. This saves the sample from the shear force of flowing a second time through the needle.

Proteins can be degraded extremely rapidly. Once the cells have been lysed, work as quickly as possible. Also make sure to keep samples on ice at all times. Pre-cooling buffers to 4°C can also help. Furthermore, PMSF is a serine protease inhibitor. It does not inhibit other proteases, and does not even inhibit all serine proteases. If protein degradation appears to be a problem, it may be necessary to add a commercially available protease inhibitor cocktail to the 1× MTE buffer in addition to PMSF. Freeze fractionated samples immediately upon collection to avoid unwarranted degradation.

Differential pelleting by centrifugation

In the initial steps of Basic Protocol 2, we use differential centrifugation to separate the mitochondrial and MAM fractions from the microsomal fractions using a centrifugation at 10,300 × *g*. This centrifugation step proved to be critical. The method of Hovius et al. (1990) uses pelleting at a lower RCF (10,000 × *g*) to reduce the ER content in the resulting crude mitochondrial fraction. This lower centrifugal force will be insufficient to efficiently pellet the MAM with mitochondria and will decrease the subsequent yield of MAM on Percoll gradients. The proposed RCF (10,300 × *g*), however, greatly improves the yields of MAM in subsequent Percoll gradient.

Another critical step of the method involves the centrifugal separation of the mitochondrial-MAM fraction from the microsomal fraction. Care must be taken in this step to remove all traces of unpelleted mitochondrial-MAM. It is therefore recommended to use a fixed-angle rotor and at least two centrifugations under the same conditions (Fig. 3.27.3). In the authors' experience, if the above conditions are not followed, the supernatant microsomal fraction is still contaminated with detectable mitochondrial-MAM fraction.

Percoll density gradients

To generate Percoll gradients, stock isotonic Percoll (SIP) solution is prepared at the desired density in 0.25 M sucrose. To accurately measure buoyant density, samples are premixed with the gradient material. However, if samples are layered onto the top of the Percoll gradient, better resolution of subcellular particles from soluble proteins is attained. Soluble proteins tend to remain above the Percoll gradient and subcellular particles will sediment into the gradient, thus achieving better separation.

Percoll gradients continuously change during high-speed centrifugation. Therefore, depending on the centrifugation conditions (type of rotor, RCF, time of centrifugation), the density profile of the gradient and, consequently, the separation or the organelles will be altered. Thus, using density marker beads (Amersham Biosciences cat. no. 17–0459-01) to monitor densities in a duplicate gradient is recommended. Their use verifies the consistency of density gradient formation and greatly facilitates identification of the desired fractions.

In spite of their many advantages, Percoll particles are difficult to remove from purified fractions. A simple approach is to separate subcellular particles from Percoll-coated silica particles by high-speed centrifugation in a swinging-bucket rotor or fixed-angle rotor (Calaminus et al., 1979). The organelles can be separated from Percoll by centrifugation at 100,000 × *g* for 2 hr (in a swinging-bucket rotor) or 90 min (in a fixed-angle rotor). Percoll is in the tight pellet; whereas, the biological material remains loosely packed and can be gently resuspended.

Anticipated Results

Different lysis methods

The effects of various lysis conditions were evaluated using untransfected HeLa cells fractionated by discontinuous sucrose gradients (Table 3.27.2). Five conditions were surveyed: low sonication (three, 5-sec pulses), medium sonication (three, 10-sec pulses), high sonication (three, 15-sec pulses), homogenization (10 strokes with Dounce homogenizer), or freeze/thaw cycles (three cycles of 1-hr incubation at −80°C followed by a rapid thaw in a 37°C water bath).

Homogenization, the gentlest lysis procedure, had the lowest ER and mitochondrial yields of the lysis protocols tested. The low-speed spin after lysis, to remove large cellular debris, produced large pellets of intact cells after homogenization, which decreased the material available for subsequent banding on ER and mitochondrial gradients.

To determine the purity of the fractionated mitochondria and ER from the various lysis procedures, an examination of the presence of ER (DPM1), MAM (FACL4), and mitochondrial (Grp75, COXII) markers in the banded ER and mitochondria fractions (Fig. 3.27.5) was done. Sonication resulted in good separation of ER and mitochondria although the anti-DPM1 antibody detected mitochondrial DPM (Gasnier et al., 1992) in this experiment. However, the other markers tested (FACL4, Grp75, and COXII) showed good separation of ER and mitochondria. Medium or high sonication disrupted the association between the MAM and mitochondrial compartments, as the MAM marker (FACL4) was detected in the ER fraction and was barely detected in the mitochondrial fraction. Conversely, the freeze/thaw lysis showed an equal distribution of MAM in both ER and mitochondrial fractions. Of the lysis procedures tested, homogenization was the most effective at preserving the association of the MAM with mitochondria. Nonetheless, the highest yields of ER and mitochondrial fractions were obtained from low and medium sonication procedures. Medium sonication was therefore chosen as the preferred lysis condition for discontinuous sucrose gradient fractionation (see Basic Protocol 1). This procedure produces superior yields of well-purified ER and mitochondrial fractions, with MAM membranes predominantly appearing in the ER fraction.

Purification of mitochondria and mitochondria-associated membranes

The ultracentrifugation of the crude mitochondrial extract in a self-generating Percoll (30%) gradient using a swinging-bucket rotor produces three distinct fractions (Fig. 3.27.4). Using density marker beads (Pharmacia), the authors found that MAM and mitochondria from cultured human cells span a range of densities between 1.039 and 1.051 g/ml (data not shown). The higher density beads ($\geq$1.069 g/ml) sediment near the bottom of the Percoll gradient. Because of this broad span of 1.039 to 1.051 g/ml densities, the self-generating 30% Percoll gradient is excellent for effective resolution of MAM from mitochondria.

Fraction 1 appears as a faint, diffuse layer just above fraction 2; whereas, fraction 2 is the more compact white in color band, less dense than mitochondria. Fraction 3 consists of multiple denser mitochondrial bands. Because the borders of the fractions usually are partially overlapping, care must be taken during the collection of the bands to minimize mixing of the samples. If a needle and syringe is used for this purpose, it is recommended that the collection should start from the top in the case of fraction 1 and from the bottom for fraction 3. In every case, the interface between the fractions should be carefully avoided.

The isolated fractions were verified by western blot analysis using known cellular protein markers for cytosol (Hsp70), microsomes (DPM1, calreticulin), MAM (mEGFP-huPSS-1), and mitochondria (COXII, Grp75) (Fig. 3.27.6 and Table 3.27.1). The MAM is physically associated and pelleted with mitochondria. Upon resolution in Percoll gradients, its position is consistent with previously reported relative densities of MAM (Vance, 1990). Most compellingly, the high relative abundance of mEGFP-huPSS-1 fusion protein in fraction 2 as well as the presence of the other ER markers (DPM1, calreticulin) indicate that it is an ER subcompartment, enriched for phosphatidylserine synthetic enzymes as

Table 3.27.2 Mitochondrial and ER Yields and Purity from Differentially Lysed HeLa Cells

		Average						
Lysis method	Yield samples	Initial cell pellet (g)	Total protein fraction (mg)	Mitochondria yield (μg)	ER yield (μg)	Yield	MAM detected in	Purity
Sonication								
Low (3 × 5 sec)	1, 2	0.153	9.87	415.86	842.6	High	ER + mitochondria	Good
Medium (3 × 10 sec)	1, 2	0.148	9.584	350.34	824.4	High	ER	Good
High (3 × 15 sec)	1, 2	0.146	8.778	163.14	820.5	Medium	ER	Good
Freeze/thaw	1, 2		7.634	ND[a]	195.2	Medium	ER + mitochondria	Good
Homogenization	1, 2	0.146	1.484	ND[a]	ND[a]	Low	MAM/ mitochondria	Excellent
	3, 4	0.147	1.392	ND[a]	ND[a]	Requires large scale-up	Mitochondria	

[a]ND, not determined as extract protein concentrations were below detection level of the BCA assay.

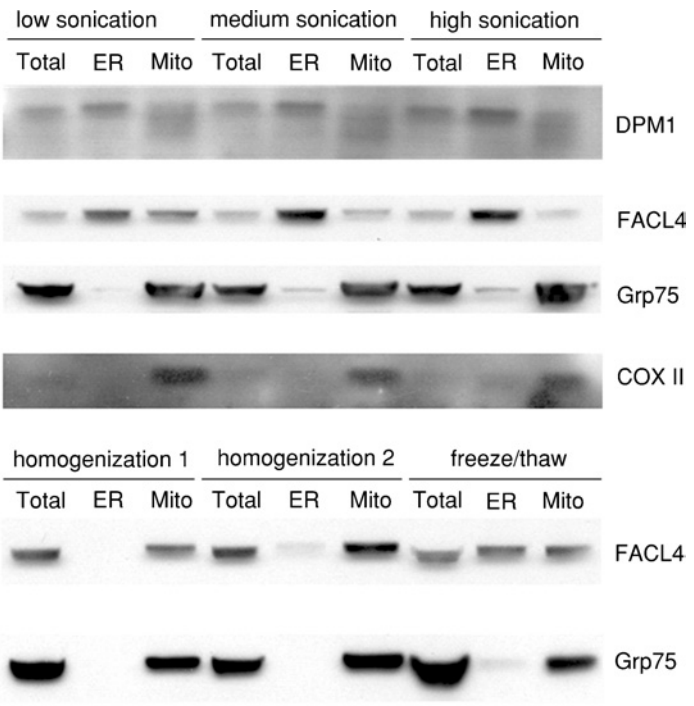

Figure 3.27.5 Western analyses of ER (DPM1), mitochondrial (Grp75, COXII), and MAM (FACL4) markers in HeLa cells lysed by different methods. HeLa cells were fractionated using discontinuous sucrose gradients (see Basic Protocol 1) as detailed in Table 3.27.2. Briefly, cells were lysed using sonication (three times, 5, 10, or 15 sec each), Dounce homogenization (ten strokes), or freeze/thaw cycles (three times 1 hr at –80°C, followed by rapid thawing). Twenty micrograms of total, ER, and mitochondrial protein fractions from each sonication condition were subjected to SDS-PAGE in 10% Bis-Tris NuPage gels (Invitrogen). For homogenization and freeze/thaw lysis conditions, 40 μl of each fraction were used (due to low protein concentrations). Proteins were then transferred to nitrocellulose membranes and probed for DPM1 (1:100 goat anti-DPM1, 1:2000 donkey anti-goat HRP). Membranes were stripped and reprobed for Grp75 (1:2000 mouse anti-Grp75, 1:2500 goat anti-mouse). Similarly, membranes were then stripped and reprobed sequentially for FACL4 (1:250 rabbit anti-FACL4, 1:3000 goat anti-rabbit HRP) then COX II (1:200 goat anti-COXII, 1:2500 donkey anti-goat HRP).

previously documented in rat liver tissue (Stone and Vance, 2000). Therefore, it has been concluded that fraction 2 contains the purified mitochondria-associated membranes from cultured human cells.

Western analyses identified fraction 3 as the purified mitochondria (Fig. 3.27.6). The parallel bands that can be observed within this fraction reflect mitochondria of slightly different sizes and densities. Mitochondria in the cell differ in size and morphology (Bereiter and Vöth, 1994; Collins et al., 2002). It should be noted that the position of the mitochondria in the gradient, exactly below fraction 2, is another indication that fraction 2 represents the mitochondria-associated membranes.

The identity of fraction 1 is less clear. Western analyses clearly indicate that it is ER-related as it shares markers (Fig. 3.27.6, calreticulin) with the ER and MAM. Nonetheless, fraction 1 notably differs in the presence of an alternative DPM species detected by the anti-DPM1 antibody. Moreover, fraction 1 has markedly less mEGFP-huPSS-1 than the MAM fraction. Because of its association with the MAM and mitochondria and the retention of some ER markers, fraction 1 could represent a transition between the rough ER and the MAM or from the ER to another secretory compartment.

Cellular markers for verification of subcellular compartment identity and purity

To verify the purity of the isolated microsomal and mitochondria fractions, established organelle-specific markers that were previously used (Colberg-Poley et al., 2000; Mavinakere and Colberg-Poley, 2004a,b; Mavinakere et al., 2006), and others, were used for the same purpose. To unequivocally

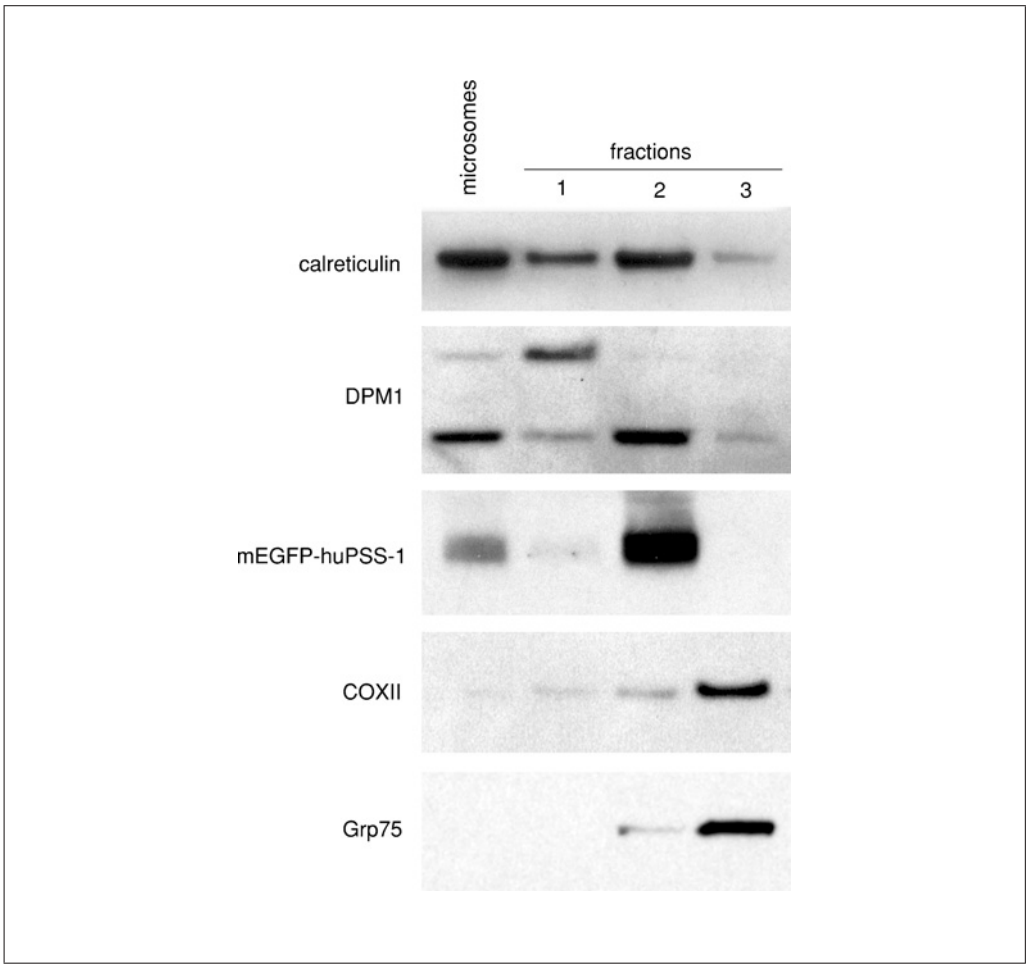

Figure 3.27.6 Western analyses of fractionated HeLa cells that stably express mEGFP-huPSS-1 fusion protein. Stably transfected cells were fractionated according to the procedure described in Basic Protocol 2 and subcellular fractions were isolated. Fractionated proteins (10 μg) were separated by 10% SDS PAGE and transferred onto nitrocellulose membranes using a semi-dry protein transfer apparatus (BioRad). Blotted proteins were probed against markers for microsomes (anti-DPM1, 1:100 or anti-calreticulin, 1:1000), MAM (mEGFP-huPSS-1 using anti-GFP, 1:100), and mitochondria (anti-COX, 1:100 or anti-Grp75, 1:2500) and with the corresponding horseradish peroxidase-conjugated secondary Ab (1:2000). Reactivity was detected using the chemiluminescent method (Amersham, GE Healthcare).

identify the MAM fraction (fraction 2) from Percoll gradients, phosphatidyl-serine synthase 1 (PSS-1), which has been shown to be enriched in the rat liver MAM (Stone and Vance, 2000), was chosen. However, neither commercial antibodies nor human PSS-1 cDNA clones were available. Therefore, the complete human PSS-1 cDNA was cloned from a HeLa cDNA library and its open reading frame was tagged with EGFP (data not shown). The cellular markers, antibodies, commercial sources and original references for ER, mitochondria and MAM are listed in Table 3.27.1. A HeLa cell transfectant stably expresses the fusion protein mEGFP-huPSS-1 fusion protein. The fractionated subcellular compartments from HeLa-PSS-1_{20} cells verified the identity of fraction 2 as the MAM by virtue of the selective presence of PSS-1 in fraction 2 but not in fraction 3 (Fig. 3.27.6).

Microsomes

Dolichol phosphate-mannose synthase 1 (DPM1). DPM synthase 1, a transmembrane protein, which catalyzes mannosyl transfer from GDP-mannose hydrophobic long-chain acceptor dolichol-phosphate, is present in the rough ER (Maeda et al., 1998). In human cells, DPM1, which is located at the cytosolic side of the ER, associates with DPM2 and DPM3 to form the complete multicomponent enzyme of human DPM synthase (Maeda et al., 2000). In addition, a mitochondrial DPM synthase is located on the cytosolic face of

the outer membrane of mitochondria (Gasnier et al., 1992). On occasion, the anti-DPM1 (I-20, Santa Cruz Biotechnology) antibody used detected these different DPM species in the ER or in mitochondrial fractions.

Calreticulin. Calreticulin is a Ca^{2+}-binding chaperone that contains an N-terminal amino acid signal sequence and a C-terminal KDEL ER retrieval sequence, which are responsible for its localization in the ER lumen (Gelebart et al., 2005). However, calreticulin has also been detected in cellular compartments, other than ER and including the cell surface (Johnson et al., 2001). Anti-calreticulin (Affinity Bioreagents) antibody detected calreticulin in the cytosol; whereas, other markers for the ER (anti-DPM1), MAM (anti-mEGFP-PSS-1), or mitochondria (anti-GRP75 and anti-COXII) did not.

Mitochondria

Grp75 (glucose regulated protein 75 kDa). Grp75 is a molecular chaperone that is localized in the mitochondrial matrix, where, in concert with Hsp60, it is thought to participate in the refolding of proteins translocated into this organelle (Manning-Krieg et al., 1991). Very recently, it was shown that Grp75 is also present in a macromolecular complex with VDAC and IP_3Rs at the ER-mitochondria interface (Szabadkai et al., 2006).

COXII (cytochrome c oxidase subunit II). COXII is one of three mitochondrial DNA–encoded subunits (MTCO1–3) of respiratory complex IV. Complex IV localizes to the mitochondrial inner membrane and is the terminal enzyme of the electron transport chain (Scheffler, 2001). Although COXII is mainly localized in the mitochondria, recently, it was shown that the protein is present at extra-mitochondrial sites (Sadacharan et al., 2005).

Mitochondria-associated membranes

mEGFP-huPSS-1 (monomeric-enhanced green fluorescent protein- human phosphatidylserine synthase). Both the PSS-1 and PSS-2 enzymes are involved in phosphatidylserine biosynthesis in mammalian cells. It has been shown that PSS-1 is highly enriched in MAM of rat liver and is largely excluded from the bulk of the ER (Stone and Vance, 2000). The fusion protein mEGFP-huPSS-1 has the same localization like the wild-type protein in human cells.

FACL4 (fatty acid CoA ligase, long chain 4). FACL4 converts long-chain fatty acids into fatty acyl-CoA esters for use in synthesizing complex lipids (Piccini et al., 1998). Similar to PSS-1, it is enriched in MAM compartments and is a marker for MAM fractions in western blot analyses (Simmen et al., 2005).

Time Considerations

Basic Protocol 1 can easily be accomplished within 1 full working day. The time required heavily depends on the number of transfection or infection conditions being tested. It is best to limit the scale of the experiment to ultracentrifuge availability (i.e., each ultracentrifuge rotor can only hold six tubes). For a point of reference, twelve 175-cm^2 flasks (six duplicate sets of experimental conditions) can be processed at once using a single rotor for each ultracentrifugation set, taking a total of ~6 to 7 hr. Preparation and sterilization of buffers is done prior to the day of fractionation. PMSF is added fresh to 1× MTE buffer just before use. Creation of sucrose gradients and harvesting of cell pellets are done first. Cell pellets are stable on ice for up to 2 hr, providing a convenient resting point. Alternatively, cell pellets can be frozen, providing a stopping point in the protocol. After sonication of cells, there are no more stopping points in the protocol, and one should work as quickly as possible. The ultracentrifugation for the ER fraction is relatively long (70 min), and this should be started first. After beginning this ultracentrifugation, go back and perform the pellet washes and load the gradients for the mitochondrial fractions. Both centrifugations will probably finish around the same time. Again, work with the ER fractions first, as they require an additional 45 min ultracentrifugation. Then, go back and collect banded mitochondria from the other tubes.

There are no points at which Basic Protocol 2 can be stopped. All of the fractions that are isolated through this procedure must be stored at −80°C upon recovery. All the solutions can be made ahead of time and stored for 1 to 2 days at 4°C or for longer period (e.g., 2 to 3 months) frozen at −20°C. Note that PMSF or other protease inhibitors should be added immediately prior to use.

Cell preparation and homogenization can be accomplished in 30 min. The separation of crude mitochondrial fraction and total microsomal fraction should take an additional ~30 min. The estimated time of both the isolation of the fractions from the Percoll gradient and the recovery of the pure microsomal pellet is ~2 hr. Another 90 min are needed for the isolation of pure mitochondria and MAM fractions. The total time of this protocol is

estimated to be ~4 hr. Functional assays should be carried out as soon as possible after the preparation, but for simple marker enzyme assay material can be stored up to 16 hr at 0° to 4°C without much loss of activity.

Isolation of Amyloplasts

Kay Denyer[1] and Marilyn Pike[1]

[1]John Innes Centre, Norwich Research Park, Norwich, Norfolk

ABSTRACT

Two different methods for the preparation of starch-rich plastids are described together with protocols for the determination of plastid yield, purity, and intactness. The preparation of amyloplasts from maize endosperm and oilseed rape embryos are given as examples, but the protocols could be adapted for the isolation of starch-rich plastids from other plant organs. A method for the determination of the quantitative distribution of an enzyme between the plastids and cytosol is given. Typical results and references for marker enzymes for a range of subcellular compartments are listed. *Curr. Protoc. Cell Biol.* 38:3.28.1-3.28.15. © 2008 by John Wiley & Sons, Inc.

Keywords: amyloplast • plastid • starch

INTRODUCTION

Amyloplasts are nonphotosynthetic starch-containing plastids. They accumulate starch in the form of insoluble granules. Some amyloplasts, such as those in pea embryos, contain a single large starch granule (see Figure 3.28.1). Other amyloplasts, such as those in rice endosperm, contain numerous separate granules. The starch granule(s) in amyloplasts usually occupy a large proportion of the volume of the plastid. Some plastids, such as those in oilseed rape embryos, contain large amounts of starch only at some developmental stages. When considering plastid isolation protocols, these starch-rich plastids are equivalent to amyloplasts and will be referred to as such in this unit.

All plastids are fragile and therefore difficult to isolate from the plant without breakage. Intact amyloplasts are more difficult to isolate than chloroplasts because of their high

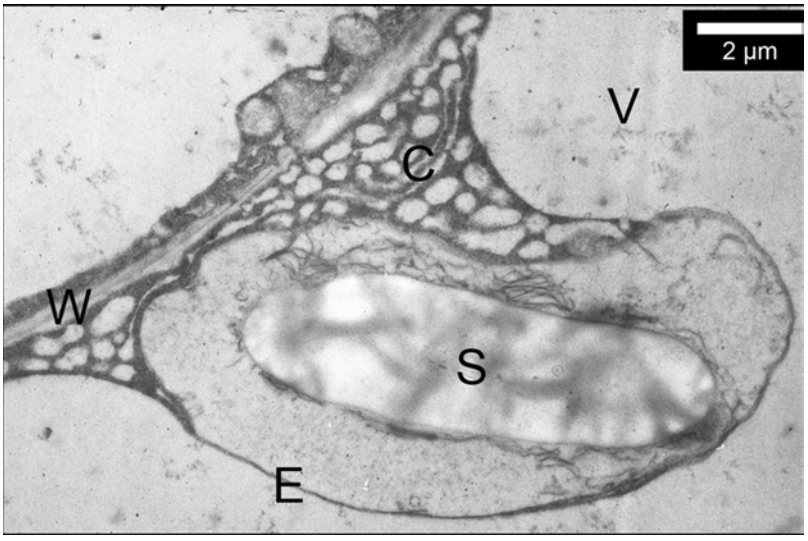

Figure 3.28.1 Ultrastructure of an amyloplast in a developing pea embryo. The figure is an electron micrograph of an amyloplast containing a single starch granule (S). The plastid envelope (E), cytosol (C), cell wall (W), and cell vacuole (V) are indicated.

starch content. Starch granules tend to rupture through the plastid envelope if they are subjected to abrupt changes in gravity or to agitation. Even for chloroplast isolation, leaves with low starch content are favored (Walker, 1971). However, the presence of starch granules can also aid plastid isolation: amyloplasts sediment more readily than other less dense organelles such as mitochondria. Thus, although starch granules make amyloplasts fragile, they also ease their purification from other organelles.

Chloroplast isolation protocols were developed before those for amyloplasts. The standard chloroplast isolation protocols had to be modified to enable the less robust amyloplasts to be isolated without damage (see Background Information). Whereas intact chloroplasts can be isolated from tissue that has been pulverized in a mortar or macerated in an electric blender, many amyloplasts will not survive such violent extraction methods. The first requirement for successful amyloplast isolation, therefore, is to use a method that will release the amyloplasts from the cells without breaking them. Slicing the tissue with a sharp razor blade is the least damaging extraction method. More robust amyloplasts with relatively low starch content, such as those from rape embryos, will survive extraction with a Polytron tissue homogenizer.

To separate the amyloplasts from pieces of tissue, whole cells, and cell debris, the preferred method is filtration through cloth of a mesh size just large enough to allow the passage of the plastids. Cloth is preferred to nylon membrane because it absorbs some of the cell debris. After filtration, the amyloplasts are separated from soluble cellular components, such as cytosolic enzymes, by low-speed centrifugation. The exact centrifugation conditions will be determined by the sedimentation properties of the amyloplasts. Those containing large amounts of starch will require lower centrifugation speeds and times than amyloplasts with relatively less starch. Refrigerated centrifuges with swing-out rotors that are capable of slow acceleration and deceleration are preferred. The purpose for which the amyloplasts are to be used will determine how the plastids are resuspended following centrifugation. If the amyloplasts are to be assayed for enzyme activity, then it is no longer important to maintain plastid integrity after the supernatant has been removed from the plastid pellet. The plastid pellet can be resuspended in a suitable medium, and the plastids deliberately broken by vigorous mixing, passage through a small-bore syringe needle, or addition of detergent. If the isolation of intact amyloplasts is necessary, the plastids must be resuspended very gently to avoid rupture. It will be necessary to resuspend the plastids without breaking them, before they can be purified further. The shape of the centrifuge tube can influence the ease of resuspension. Wide, round-bottom centrifuge tubes will aid resuspension and maximize the yield of intact plastids.

Below, we describe two slightly different amyloplast isolation protocols that we have used for the isolation of amyloplasts from different tissues: maize endosperm (Basic Protocol) and rape embryos (Alternate Protocol). These methods are likely to be applicable to other types of plant organ. Support protocols describe methods for determining the yield, purity (Support Protocol 1), and intactness by latency (Support Protocol 2) and protection (Support Protocol 3) of the amyloplasts. Both require the assay of enzymes known to be located exclusively in particular subcellular compartments (marker enzymes). By quantifying the distribution of the marker enzymes, the contributions of their subcellular compartments to each fraction can be deduced. A selection of suitable marker enzymes and references to protocols for their assay are listed in Table 3.28.1. In Support Protocol 4, we give an example of the methods and calculations required to quantify the subcellular distribution of an enzyme that is present in both plastids and cytosol.

NOTE: The authors recommend that all equipment that will come into contact with the plastids or with solutions used on the plastids be rinsed several times with distilled water to remove all traces of detergent.

Table 3.28.1 Assay Procedures for Marker Enzymes

Enzyme	Compartment	Reference
Phosphoenolpyruvate carboxylase (EC 4.1.1.31)	Cytosol	Wedding and Kline (1994)
Alcohol dehydrogenase (EC 1.1.1.1)	Cytosol	Macdonald and ap Rees (1983); El-Shora and ap Rees (1991)
UDP-glucose pyrophosphorylase (EC 2.7.7.9)	Cytosol	Hansen et al. (1965)
Pyrophosphate:fructose 6-P phosphotransferase (EC 2.7.1.90)	Cytosol	Journet and Douce (1985)
NADP-glyceraldehyde-3-P dehydrogenase (EC 1.2.1.13)	Plastid	Holtum and Winter (1982)
Alkaline pyrophosphatase (EC 3.6.1.1)	Plastid	Gross and ap Rees (1986)
ADP-glucose pyrophosphorylase (EC 2.7.7.27)	Plastid	Entwistle and ap Rees (1988)
Fumarase (EC 4.2.1.2)	Mitochondria	Hatch (1978); El-Shora and ap Rees (1991)
Citrate synthase (EC 4.1.3.7)	Mitochondria	El-Shora and ap Rees (1991)
Succinate dehydrogenase[a] (EC 1.3.99.1)	Mitochondria	Bonner (1953)
Cytochrome *c* oxidase (EC 1.9.3.1)	Mitochondria	Bowles and Kauss (1976); Appelmans et al. (1954)
Cytochrome *c* reductase[b] (EC 1.6.2.1)	ER	Bowles and Kauss (1976)
Hydroxypyruvate reductase (EC 1.1.1.81)	Peroxisomes	El-Shora and ap Rees (1991)

ISOLATION OF AMYLOPLASTS FROM MAIZE ENDOSPERM

BASIC PROTOCOL

This protocol results in a crude preparation of amyloplasts suitable for studies of the subcellular distributions of enzyme activities. This is a gentle and quick procedure designed to maximize yield and minimize loss of enzyme activity. The starting material for this protocol, endosperm dissected from developing maize kernels, is shown in Figure 3.28.2. We have used very similar protocols to that described here to isolate plastids from pea embryos and from wheat and barley endosperm.

Materials

Amyloplast isolation medium 1 (AIM 1; see recipe), ice cold
~10 g of developing endosperm harvested 11 to 22 days after pollination

Pasteur pipets and rubber pipet bulbs
Single-edged razor blades
90-mm petri dish
Filtration cloth (e.g., Miracloth, pore size 22 to 25 μm; Calbiochem, or equivalent)
Small funnel
30-ml glass centrifuge tube
Refrigerated benchtop centrifuge (e.g., Beckman RT 6000D, or equivalent)
Measuring cylinder
Small (1-ml) syringes and fine (23-G) needles

NOTE: Carry out all procedures at 0° to 4°C using solutions and equipment prechilled to that temperature.

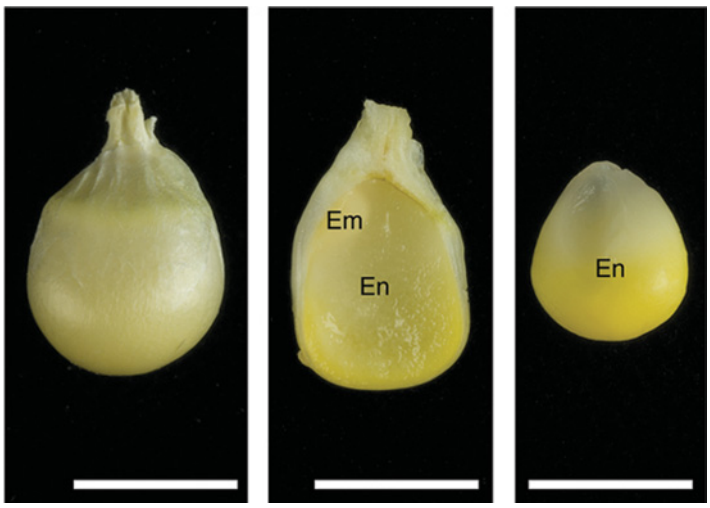

Figure 3.28.2 Developing maize kernels. The panel on the left shows a single developing maize kernel. The panel in the center shows a kernel cut in half to reveal the embryo (Em) and the endosperm (En). The panel on the right shows endosperm dissected from one kernel. The scale bars are 0.5 cm. For the color version of this figure go to *http://www.currentprotocols.com*.

Prepare equipment and plant materials

1. Make a wide-ended glass Pasteur pipet as follows: break off the narrow end of a standard Pasteur pipet by wrapping the end in tissue and applying pressure with a gloved hand. Invert the broken pipet and place the fractured end into a rubber pipet bulb.

   Alternatively, use an automatic pipettor with a wide-ended disposable tip. Widen the tip by cutting off the end with scissors.

2. Place a razor blade and a 90-mm petri dish on ice to cool.

3. Place a small piece of Miracloth in a small funnel and suspend over a 30-ml glass centrifuge tube in ice. Prewet the Miracloth and the tube with ~1 ml AIM 1.

4. Immediately before the experiment, harvest the maize kernels and place on ice. Remove the pericarp (the seed coat surrounding the endosperm and embryo) and embryo from each kernel and discard.

5. Place the endosperm in the 90-mm petri dish on ice. Add sufficient AIM 1 to cover the endosperm and incubate for 20 to 60 min.

Chop endosperm to release intact plastids

6. Replace the AIM 1 with 4 to 5 ml fresh AIM 1 and chop the endosperms repeatedly with a very sharp single-edged razor blade until the endosperms are coarsely diced.

7. Tilt the petri dish slightly and carefully remove the liquid (homogenate) surrounding the pieces of endosperm with the wide-ended Pasteur pipet.

   The homogenate, containing intact plastids, will look pale yellow. Try not to suck up bits of the endosperm. Pipet the homogenate slowly and avoid vortex mixing, which promotes the introduction of air bubbles.

8. To remove pieces of tissue and intact cells, filter the homogenate through the prepared Miracloth and into the 30-ml glass centrifuge tube. Add the homogenate to the funnel slowly, with the pipet in contact with the Miracloth, to avoid the formation of drips. Position the funnel and the tube in the ice so that the plastids glide down the side of the tube (rather than dropping from the funnel and splashing to the bottom of the tube).

9. Add 4 to 5 ml more AIM 1 to the petri dish, chop the endosperm more finely, and transfer the homogenate to the filter/tube as before.

10. Repeat chopping and filtering once or twice more until the endosperm is finely divided and all the homogenate has been transferred to the tube. Remove the funnel and discard the chopped endosperm.

11. Cover the top of the tube with Parafilm, then mix the filtered homogenate in the tube by very slow and gentle inversion. Measure the volume and take a 0.5-ml sample of the homogenate for enzyme analysis.

Prepare the plastid-enriched pellet and the supernatant fractions

12. Centrifuge the homogenate at 100 × *g* for 10 min, 4°C.

    The intact plastids will collect in the pellet. The pellet will also contain other subcellular fractions such as cell walls and perhaps even intact cells.

    The pellet should be pale yellow throughout. If the bottom of the pellet is white, this indicates that some of the plastids have ruptured, releasing their starch granules.

13. Remove the supernatant to a measuring cylinder and note the volume. Take a 0.5-ml sample of the supernatant for enzyme analysis.

    The volume of the supernatant should be only slightly less than the volume of the homogenate. The supernatant will contain most of the enzymes from the cytosol, intact organelles that are less dense than amyloplasts (such as mitochondria), and enzymes from broken plastids.

Resuspend the plastids

14. Carefully layer 1 ml AIM 1 above the plastid-enriched pellet. Gently and slowly resuspend the pellet by rocking and revolving the tube repeatedly. Take a 0.5-ml sample of the resuspended pellet for enzyme analysis and retain the remaining resuspended pellet for use in downstream experiments.

    The resuspended pellet should contain intact plastids. To determine plastid intactness, see Support Protocol 2 or 3.

    It is important to use the intact plastids quickly once they are prepared, so do not try to do too many assays with any one plastid preparation. Also, randomize the order of your replicate assays in case there are changes, e.g., in the integrity of the plastids with time.

Prepare samples for enzyme assays

15. Rupture the plastids in the 0.5-ml samples of homogenate, supernatant, and pellet by squirting 10 times up and down through a fine (23-G) syringe needle attached to a small (1-ml) syringe.

    Alternatively, you could add Triton X-100 to 0.1% (v/v), but you must check that this does not interfere with your enzyme assays.

16. To remove insoluble material such as starch granules, centrifuge the samples 5 min at 14,000 × *g*, 4°C.

17. Assay the resulting supernatant for marker enzymes and other enzymes of interest (Support Protocols 1 and 4).

ISOLATION OF AMYLOPLASTS FROM OILSEED RAPE EMBRYOS

ALTERNATE PROTOCOL

This protocol is similar to Basic Protocol, but it includes, in addition, two alternative methods for the purification of the plastids after the initial low-speed centrifugation. This method is suitable for amyloplasts that are reasonably robust and where purity as well as yield is important. We have used this method to isolate plastids from oilseed

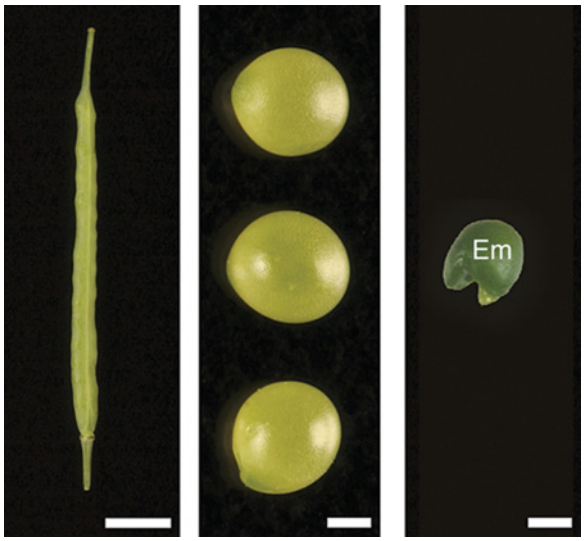

Figure 3.28.3 Developing oilseed rape (mid-developmental stage). The panel on the left shows a single developing silique (scale bar = 1 cm). The panel in the center shows three individual seeds removed from a silique (scale bar = 1 mm). The panel on the right shows an embryo (Em) dissected from a seed (scale bar = 1 mm). For the color version of this figure go to *http://www.currentprotocols.com*.

rape embryos at a number of stages during seed development (Fig. 3.28.3). The plastids contain starch only during mid embryo development. At later stages of development, the starch is degraded and replaced by oil.

Materials

1× and 2× amyloplast isolation medium 2 (AIM 2; see recipe), ice cold
Developing embryos of oil seed rape (*Brassica oleracea* variety Topas)
Percoll

Polytron homogenizer (e.g., model PT 3000, Kinematica, *http://www.kinematica-inc.com/*; or equivalent)
90-mm petri dish
Filtration cloth (e.g., Miracloth, pore size 22 to 25 μm; Calbiochem, or equivalent)
15- and 30-ml glass centrifuge tubes
50-ml plastic graduated cylinder, prechilled
Small funnel
Wide-ended pipet (see Basic Protocol, step 1) or small paintbrush
Refrigerated centrifuge (e.g., Sorvall RC5C with an HB4 rotor, or equivalent)
Small (1-ml) syringes and fine (23-G) needles

NOTE: Carry out all procedures at 0° to 4°C using solutions and equipment prechilled to that temperature.

Prepare equipment and plant materials

1. Place the Polytron probe and a 90-mm petri dish containing 5 to 10 ml 1× AIM 2 on ice to cool.

2. Place a small piece of Miracloth in a small funnel and suspend over a 30-ml glass centrifuge tube in ice. Prewet the Miracloth and tube with approximately 1 ml 1× AIM 2.

3. Immediately before the experiment, harvest developing siliques (Fig. 3.28.3) and place on ice. Choose siliques containing seeds at the mid-stage of development (siliques at this stage have attained their maximum length). Remove 500 to 1000 seeds from the siliques and place in the medium-containing petri dish prepared in step 1, on ice.

4. Using a wide-bore (23-G) syringe needle to hold each seed, remove the testa (seed coat surrounding the embryo) and place the embryo into 5 to 10 ml ice cold 1× AIM 2 in a petri dish on ice.

5. After preparing all the embryos, remove the 1× AIM 2 with a pipet and replace with 5 to 10 ml of fresh 1× AIM 2.

Homogenize embryos to release intact plastids

6. Pour the embryos in 1× AIM 2 into a cold 50-ml plastic measuring cylinder.

7. Using a Polytron, homogenize the embryos for 5 sec at 9,500 to 10,000 rpm on ice.

8. To remove large pieces of tissue and intact cells, filter the homogenate through the prepared Miracloth and into the 30-ml glass centrifuge tube.

9. Remove the material from the filter and suspend in 5 to 10 ml fresh 1× AIM 2. Homogenize and filter as before (steps 7 and 8), combining the first and second filtrates.

   The homogenate, containing intact plastids, will look milky green.

10. Adjust the volume of the filtered homogenate to 50 to 100 ml with 1× AIM 2. Mix gently and take a 0.5-ml sample of homogenate for enzyme analysis.

Prepare the plastid-enriched pellet and the supernatant fractions

11. Divide the homogenate between two to four 30-ml glass centrifuge tubes and centrifuge 5 min at 750 × *g*, 4°C.

    The intact plastids will collect in the pellets.

12. Remove the supernatants and combine in a measuring cylinder. Note the volume and take a 0.5-ml sample for enzyme analysis.

    During this procedure, some plastids will rupture and release starch granules. The starch granules will collect in the pellet and can be seen as a small white pellet below the green plastid pellet.

13. Resuspend the plastid-enriched pellets, carefully layer 1 ml of 1× AIM 2 above each pellet, and gently resuspend them using a wide-ended pipet (see Basic Protocol, step 1) or a small paintbrush.

Purify the plastids

Two alternative plastid purification methods are given below. The second method (steps 14b to 19b) generally gives cleaner plastids, but a lower yield compared to the first method (steps 14a to 19a).

Higher-yield method

14a. Add 20 ml of 1× AIM 2 to each of the resuspended pellets, mix gently, and centrifuge 5 min at 750 × *g*, 4°C.

15a. Discard the supernatants.

16a. Repeat steps 14a and 15a once more.

17a. Carefully layer 0.5 ml of 1× AIM 2 above each of the plastid pellets and gently resuspend the plastids as before.

18a. Combine the purified plastids and take a 0.5-ml sample for enzyme analysis.

19a. Determine plastid intactness (Support Protocol 2 or 3 or use the plastids in downstream experiments).

Cleaner-plastid method

14b. Prepare 5 ml of 35% Percoll in a cold 15-ml centrifuge tube by mixing 1.75 ml Percoll, 2.5 ml of 2× AIM 2, and 0.75 ml H_2O.

15b. Combine the resuspended plastid-enriched pellets and dilute to 5 ml with 1× AIM 2. Mix gently and layer the plastids over the 35% Percoll.

16b. Centrifuge 8 min at 1000 × *g*, 4°C, in a centrifuge with the brakes off to allow slow deceleration. Discard the supernatant (including the interface and the Percoll) and carefully resuspend the plastid pellet in 1 ml AIM 2 as before.

Thylakoid membranes will collect at the interface between the AIM 2 and the Percoll. Intact plastids will collect in the pellet. Both the pellet and the interface should be green.

17b. Add 4 ml 1× AIM 2 to the resuspended pellet, mix gently, and centrifuge 5 min at 750 × *g*, 4°C. Discard the supernatant.

The pellet should contain purified plastids.

18b. Carefully layer 1 ml 1× AIM 2 above the plastid pellet and gently resuspend the plastids as before. Take a 0.5-ml sample for enzyme analysis.

19b. Determine plastid intactness (Support Protocol 2 or 3 or use the plastids in downstream experiments).

Prepare samples for enzyme assays

20. Rupture plastids (and other organelles) in the 0.5-ml samples of homogenate, supernatant, pellet, and purified plastids by squirting these liquids 10 times up and down through a fine (23-G) syringe needle attached to small (1-ml) syringe.

21. To remove insoluble material such as starch granules, centrifuge the samples 5 min at 14,000 × *g*, 4°C.

22. Assay the resulting supernatants for marker enzymes and other enzymes of interest (Support Protocols 1 and 4).

SUPPORT PROTOCOL 1

DETERMINING THE YIELD AND PURITY OF AMYLOPLASTS

The pellets obtained in the amyloplast isolation procedures should be enriched in amyloplasts and depleted in cytosolic enzymes and non-plastid organelles (such as mitochondria) relative to the initial homogenate. The proportion of plastids in the homogenate that are recovered in the plastid-enriched pellet (the yield of plastids) can be determined by measuring the distribution of enzymes known to be confined to the plastids (plastid marker enzymes). Similarly, the purity of the plastids can be assessed by measurement of the activities of other marker enzymes in these fractions. Aliquots of each fraction are reserved during the amyloplast preparation procedure for this purpose (see Basic Protocol and Alternate Protocol). For suitable plastid marker enzymes see Table 3.28.1.

Materials

Aliquots of homogenate, supernatant, and pellet fractions (see Basic Protocol and Alternate Protocol)

Additional reagents and equipment for assays of amyloplast marker enzymes (see references in Table 3.28.1)

NOTE: Carry out all procedures at 0° to 4°C using solutions and equipment prechilled to that temperature unless otherwise stated.

1. Measure the activity of each marker enzyme in the 0.5-ml aliquots of homogenate, supernatant, and pellet.

   The literature references in Table 3.28.1 describe assay procedures for amyloplast marker enzymes.

2. Calculate the activity of each enzyme in the total volumes of these fractions.

3. Check that there have been no significant losses of enzyme activity during plastid isolation by calculating, for each enzyme, the recovery of activity in the supernatant plus pellet as a proportion of that in the homogenate.

   This recovery value should be close to 100%.

4. For each enzyme, calculate the activity in the pellet as a proportion of that in the supernatant plus pellet.

   The proportion of the plastid marker enzyme in the pellet shows the yield. The proportion of the marker enzymes for other subcellular compartments that are in the pellet shows the degree to which the plastids are contaminated with those compartments.

DETERMINATION OF PLASTID INTACTNESS BY LATENCY

SUPPORT PROTOCOL 2

This approach relies on the inability of the substrates of a plastidial marker enzyme to cross the plastid envelope and enter the plastid. This means that assays of intact plastids will give low values compared to assays of ruptured plastids. Only enzymes with substrates that cannot cross the envelope in vitro (e.g., NADP-glyceraldehyde 3-phosphate dehydrogenase) can be used in these latency experiments. The difference between the values found for intact and deliberately ruptured plastid preparations, expressed as a percentage of the activity in the ruptured plastids, is called the latency (Stitt and ap Rees, 1979), and is a measure of the proportion of intact plastids in the preparation. To prevent plastid rupturing during the assay, osmoticum (e.g., sorbitol) is added to the assay mix to the same final concentration as in the plastid preparation, which has been resuspended in sorbitol-containing AIM 1 or AIM 2. The assays must be mixed very carefully to avoid plastid rupture. To deliberately rupture the plastids, the osmoticum is omitted from the assay and the assay and plastids are thoroughly mixed. A high concentration of osmoticum is then added so that the final concentrations of osmoticum in both the intact and ruptured assay mixes are the same.

As an example, the following method is given for a marker enzyme that is normally assayed spectrophotometrically in a 1-ml assay volume (e.g., NADP-glyceraldehyde 3-phosphate dehydrogenase). It is assumed that the plastids used have been resuspended in medium (i.e., AIM 1 or AIM 2; see Reagents and Solutions) containing 0.5 M sorbitol.

Materials

2 M sorbitol
Resuspended, intact plastids (Basic Protocol and Alternate Protocol)
Cuvettes suitable for spectrophotometry

Additional reagents and equipment for assays of amyloplast marker enzymes (see references in Table 3.28.1)

1. Set up two cuvettes by adding all of the components of the assay (except the substrate used to start the reaction and the plastids; see references in Table 3.28.1) in a final volume of 0.70 ml.
2. To one of the cuvettes (intact plastid assay), add 0.25 ml of 2 M sorbitol and mix well.
3. Using a wide-ended pipet, carefully add 0.05 ml plastids, cover the opening of the cuvette with Parafilm, and mix by gentle inversion two to three times.
4. To the second cuvette (ruptured plastid assay), before adding sorbitol, add 0.05 ml plastids, mix vigorously by vortexing, and then, after mixing, add 0.25 ml 2 M sorbitol.
5. Measure the activities in the two cuvettes using a spectrophotometer, ensuring that after adding the starting reagent, the samples are mixed by gentle inversion two to three times.
6. Determine the percentage of intact plastids in the preparation (% latency) using the following equation:

   $[(\text{activity of ruptured} - \text{activity of intact})/(\text{activity of ruptured})] \times 100 = \%\text{latency}$
7. Repeat the estimate of latency for several independently-prepared batches of plastids.

SUPPORT PROTOCOL 3

DETERMINATION OF PLASMID INTACTNESS BY PROTECTION

This method relies on the assumption that enzymes within intact amyloplasts are protected from proteolysis because the added trypsin cannot cross the amyloplast envelope (Stitt et al., 1978). Treatment of intact plastids with trypsin will therefore result in the removal of proteins released from ruptured plastids, but it will not alter the activity of enzymes that are contained within intact plastids. After trypsin treatment, an inhibitor of trypsin is added, plastids are deliberately ruptured, and the activity of a plastidial marker enzyme is measured. To show that the trypsin and inhibitor themselves have no effect on activity of the marker enzyme, they are added together to a parallel sample. To demonstrate that the marker enzyme is sensitive to trypsin when not protected by an intact plastid envelope, deliberately ruptured plastids are also treated with trypsin. Provided these two controls give the expected results, the proportion of the plastid marker enzyme that is protected from trypsin indicates the proportion of intact plastids in the amyloplast preparation.

As an example, the following method is given for a marker enzyme that is normally assayed spectrophotometrically in a 1-ml assay volume (e.g., NADP-glyceraldehyde 3-phosphate dehydrogenase).

Materials

Resuspended, intact plastids (Basic Protocol and Alternate Protocol)
400 mg/ml trypsin (Type IX, 6000 U/mg, from bovine pancreas) stock solution in H_2O (prepare immediately before use)
600 mg/ml trypsin inhibitor (Glycine max, 12,000 U/mg) stock solution in H_2O (prepare immediately before use)

Small (1-ml) syringes and fine (23-G) needles
25°C water bath
Cuvettes suitable for spectrophotometry

Additional reagents and equipment for assays of amyloplast marker enzymes (see references in Table 3.28.1)

1. Deliberately rupture a sample of the plastids by squirting 10 times up and down through a fine (23-G) syringe needle attached to small (1-ml) syringe.
2. Measure the enzyme activity (see references in Table 3.28.1) of the both intact and ruptured plastids (initial activity).
3. To 0.2-ml samples of the intact and ruptured plastids, add trypsin alone (to a final concentration of 4 mg/ml) or trypsin (final concentration, 4 mg/ml) together with trypsin inhibitor (final concentration, 6 mg/ml). Incubate at 25°C for 30 min.
4. Add trypsin inhibitor (6 mg/ml) to the samples that contain trypsin alone.
5. Measure the enzyme activity of each sample (final activity).
6. Provided that the final activity of the samples incubated with trypsin and inhibitor was the same as the initial activity, calculate the percentage of intact plastids in the preparation (% protection) using the following equation:

   $$[(\text{activity after trypsin alone})/(\text{activity after trypsin+inhibitor})] \times 100 = \%\ \text{protection}$$

7. Repeat the estimate of the extent of protection for several independently prepared batches of plastids.

DETERMINATION OF THE DISTRIBUTION OF AN ENZYME BETWEEN THE AMYLOPLASTS AND CYTOSOL

SUPPORT PROTOCOL 4

The amyloplast isolation protocols described in this unit can be used to investigate the subcellular location of an enzyme. This is because a plastidial enzyme will sediment with the plastids and be enriched in the pellet fraction. In contrast, a cytosolic enzyme will not sediment with plastids and will be found mainly in the supernatant. Some enzymes are located in both the cytosolic and plastidial compartments. For example, ADP-glucose pyrophosphorylase in cereal endosperms is both plastidial and cytosolic (Denyer et al., 1996). In such cases, the amyloplast isolation procedures can be used to quantify the distribution of the enzyme between these two compartments. To illustrate the methodology, in this section, we will consider an enzyme X that is located in both the plastids and the cytosol. We will describe how to use an amyloplast isolation protocol to determine the how much of the activity of X is plastidial. In principle, the same method could be used to determine the distribution of an enzyme between the plastids and any other compartment for which marker enzymes distributions can be determined (see Denyer and Smith, 1988).

Using the data for the average distributions of plastidial and cytosolic marker enzymes (Support Protocol 1), the percentage of the total activity of X that is plastidial can be calculated. This calculation relies upon the fact that the distribution of plastidial X between the supernatant and pellet fractions will be the same as that of the plastid markers and the distribution of cytosolic X will be the same as that of the cytosolic markers. Additionally, the total activity of X in the pellet will be the sum of plastidial X in the pellet plus cytosolic X in the pellet. In theory, the calculation is not influenced by the yield of plastids, provided that the distributions of cytosolic and plastidial marker enzymes are significantly different statistically. The accuracy of the calculation depends on there being no loss of enzyme activity during the amyloplast isolation procedure. It is important therefore to establish that the sum of the activity of each enzyme in the pellet plus supernatant fraction equals that in the initial homogenate.

Materials

Aliquots of homogenate, supernatant, and pellet fractions (see Basic and Alternate Protocols)

Assay mix for enzyme X (the enzyme of interest; see Table 3.28.1)

Additional reagents and equipment for determining yield and purity of amyloplasts (Support Protocol 1) and assays of amyloplast marker enzymes (see references in Table 3.28.1)

1. Measure the distributions of plastid and cytosolic marker enzymes and enzyme X in the homogenate, supernatant, and pellet as in Support Protocol 1.
2. Calculate the average distributions of the plastid marker enzymes and the cytosolic marker enzymes.
3. Calculate the activity of enzyme X in the pellet as a percentage of that in the supernatant plus pellet.
4. Solve the following equation:

$$\%X \text{ in plastids} =$$

$$[(\%X \text{ in pellet} - \%CM \text{ in pellet})/(\%PM \text{ in pellet} - \%CM \text{ in pellet})] \times 100$$

where PM = plastidial marker and CM = cytosolic marker.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Amyloplast isolation medium 1 (AIM 1)

50 mM HEPES
0.8 M sorbitol
1 mM disodium EDTA
1 mM KCl
2 mM $MgCl_2$
Adjust to pH 7.5 with NaOH
Store at 4°C for up to 1 week
On the day of use add:
1 g/liter bovine serum albumin (BSA)
2 mM dithiothreitol (DTT)

Amyloplast isolation medium 2 (AIM 2), 2× and 1×

40 mM HEPES
1 M sorbitol
20 mM KCl
2 mM $MgCl_2$
2 mM disodium EDTA
20% (v/v) ethanediol
Adjust to pH 7.4 with NaOH
Store at 4°C for up to 1 week
On the day of use add:
10 g/liter bovine serum albumin (BSA)
5 mM dithiothreitol (DTT)
1× AIM 2:
Dilute 2× AIM 2 1:1 with water before use.

COMMENTARY

Background Information

The first plastids to be isolated successfully were chloroplasts. Some of the techniques developed for chloroplasts were later also used for amyloplast isolation. For example, the use of sorbitol as an osmoticum, which is widespread in amyloplast isolation protocols today, was first used in chloroplast isolation protocols (Walker, 1964). Sorbitol was considered superior to sugars as an osmoticum since there is less chance of it being metabolized (Walker, 1971).

Initial attempts to separate chloroplasts from other cellular organelles used sucrose density gradients. Density gradients were also used subsequently for amyloplast isolation. In the earliest protocols, the extracts containing plastids were loaded onto the gradient and centrifuged until the organelles reached a position where the density of the gradient was equal to their own. For chloroplasts, however, this method was not very successful, since the density of chloroplasts is little different from that of many other organelles. Thus, the chloroplasts prepared by such methods were highly contaminated. An improvement on this technique was made by Miflin and Beevers (1974), and was based on the observation that chloroplasts sedimented in sucrose gradients more rapidly than other organelles (probably because of their starch content). They used much shorter centrifugation times, such that few organelles other than the chloroplasts attained their equilibrium positions in the gradient. Early attempts to isolate amyloplasts involving density gradient centrifugation used high-density reagents such as Urografin (Duffus and Rosie, 1975; Gaynor and Galston, 1983), Nycodenz (Entwistle and ap Rees, 1988), or Ficoll (Echeverria et al., 1985), rather than sucrose.

Few of these early amyloplast isolation experiments used marker enzymes to measure the yield, purity, and intactness of the amyloplasts. Sometimes only qualitative assessment of the plastids by microscopy was used, and plastid-free starch granules, rather than intact amyloplasts, may have been the main product. An exception was the work of MacDonald and ap Rees (1983), who isolated amyloplasts from soybean cultures. These amyloplasts were shown to be substantially free from contamination (using marker enzymes) and intact (as determined by latency and protection experiments). This work set the standard for later attempts to isolate amyloplasts from other tissues.

The isolation of starch-rich amyloplasts from cereal endosperm was achieved using methods based on those developed for soybean plastids (MacDonald and ap Rees, 1983). As with the soybean amyloplasts, the cereal endosperm amyloplast isolations used protoplasts as the starting material (Echeverria et al. 1985, 1988; Entwistle and ap Rees, 1988; Tyson and ap Rees, 1988). Interestingly, ADP-glucose pyrophosphorylase was used as one of the marker enzymes for the cereal endosperm plastids, having been shown earlier to be confined to plastids in soybean (MacDonald and ap Rees, 1983). Later it was discovered that, in cereal endosperm, most of the activity of this enzyme is cytosolic (Denyer et al., 1996), and so now we know that, for cereal endosperm, this is not an appropriate enzyme to use as a plastid marker.

A significant simplification to the plastid isolation procedures was made by Emes and England (1986) for the purification of pea root plastids. Instead of using density gradient centrifugation, they used a brief, low-speed centrifugation step to remove cell debris, followed by centrifugation of the resulting supernatant containing plastids through a layer of Percoll. Unfortunately, this method is not suitable for the isolation of starch-rich amyloplasts, since they would sediment in the first centrifugation step. The pea embryo amyloplast protocol developed by Denyer and Smith (1988) represented a further simplification of the method of Emes and England (1986), and it is suitable for starch-rich amyloplasts. A single centrifugation step is used to sediment the amyloplasts directly from the homogenization medium. This method was later used to isolate amyloplasts from maize endosperm (Denyer et al., 1996), and similar methods, involving the isolation of plastids by sedimentation from the homogenization medium, were used to isolate amyloplasts from potato tuber (Mohabir and John, 1988), wheat endosperm (Tetlow et al., 1993), and oilseed rape embryos (Alternate Protocol; Kang and Rawsthorne, 1994). These one-step methods of amyloplast isolation have the advantage that, as well as being quick and simple, they give high yields of amyloplasts. However, their disadvantage is that the amyloplasts produced are not completely free of contamination from other cellular compartments. They should be regarded as fractions enriched in amyloplasts rather than as purified amyloplasts. Enriched fractions are suitable for many experiments, including

enzyme localization (see Support Protocol 4). If required, preparations of greater purity can be generated by washing the plastids by resuspension and re-centrifugation as in the Alternate Protocol, or by subjecting the plastids to density gradient centrifugation (e.g., Neuhaus et al., 1993). However, the price for greater purity is a decrease in yield, and it is necessary to question whether or not the properties of the few purified plastids obtained are similar to those of the bulk of the plastids in the original tissue.

Critical Parameters

The starch content of plastids has a critical influence on their yield, low starch content favoring higher yields. Thus, the choice of starting material is an important consideration. We have found that the highest yields of amyloplasts from cereal endosperm are obtained from endosperms harvested at an early stage in seed development, before they attain maximum starch content. The accurate analysis of the yield and purity of the amyloplast preparation is also critical. This depends upon the appropriate use of marker enzymes. We recommend using two marker enzymes for each subcellular compartment of interest. The distributions of the two markers should be in close agreement. A list of marker enzymes likely to be suitable for amyloplast isolation from a range of different plant organs is given in Table 3.28.1. The original references describing the methods are given. To adapt these assay methods for your plant extracts, we recommend that you check that the pH and the concentrations of all substrates and effectors are optimal for activity with extracts of your plant material and that the activity is linear with respect to both assay time and the amount of extracted added.

Other important parameters include the following:

1. Minimizing the time taken from harvest of the plant material to completion of the last assay will improve the yield of plastids and minimize loss of enzyme activity.
2. All transfers of intact plastids should be done gently and smoothly to avoid plastid rupture.
3. The osmotic strength of the medium in which the plastids are suspended should be optimized, and abrupt changes in osmotic strength, pH, and temperature should be avoided.
4. Detergent should be avoided—even traces on glassware can lead to plastid rupture.

Anticipated Results

Values for yield, intactness, and contamination of maize endosperm and oilseed rape amyloplast preparations obtained previously using the methods described here are shown in Table 3.28.2. Reported values for plastids made from a range of other plant organs are also shown for comparison.

Time Considerations

The isolation and purification of amyloplasts from maize endosperm requires 1 to 2 hr and from oilseed rape embryos 3 to 4 hr. Analysis of yield, purity, and intactness takes 1 to 2 hr.

Table 3.28.2 Published Values for Yield, Intactness, and Contamination of Amyloplast Preparations[a]

Reference	Plant organ	Yield of plastids	Intactness	Contamination with cytosol
MacDonald and ap Rees (1983)	Suspensions cultures of soybean	23%	44%-74%	0.2%
Denyer and Smith (1988)	Pea cotyledons	43%	65%-67%	3.6%
Neuhaus et al. (1993)	Various heterotrophic plant tissues	ND	89%-96%	0.6%-1.5%
Tetlow et al. (1993)	Wheat endosperm	23%	50%	<0.7%
Kang and Rawsthorne (1994)	Oilseed rape	10%	63%-65%	3.9%
Denyer et al. (1996)	Maize endosperm	24%-47%	ND	0.7%-1.4%

ABSTRACT

This unit describes various protocols for the isolation and purification of the main constituents of microtubules, chiefly α- and β-tubulin, and the most significant microtubule associated proteins (MAPs), specifically MAP1A, MAP1B, MAP2, and tau. We include a classical isolation method for soluble tubulin heterodimer as the first basic purification protocol. In addition, we show how to analyze the tubulin and MAPs obtained after a phosphocellulose chromatography purification procedure. This unit also details a powerful and simple method to determine the native state of the purified tubulin based on one-dimensional electrophoresis under nondenaturing conditions (*UNIT 6.5*). The last protocol describes the application of a new technique that allows visualizing the quality of polymerized microtubules based on atomic force microscopy (AFM). *Curr. Protoc. INTRODUCTION

The different morphologies displayed by cells from different tissues—for example the great diversity of neurons—is the result of the assembly of different cell scaffolds.

There are three different components in the cell scaffold known as the cytoskeleton. These are microtubules (Fig. 3.29.1), microfilaments, and intermediate filaments. Microtubules are particularly abundant in brain tissue and their components represent ∼20% of the total protein content from soluble brain extract, with α- and β-tubulin heterodimers the major components.

Microtubules are tubular cytoplasmic fibers with a diameter of 24 nm (Fig. 3.29.2). In addition to their role in the determination of cell shape they also play fundamental roles in other common cellular functions, such as intracellular transport, chromosome segregation (a specific form of transport), and flagella/cilia-mediated cell motility. In neurons, besides their function in determining neuron shape, microtubules seem to play essential roles in the formation and maturation of the axon and dendrites. The majority, if not all, of the microtubule functions are based on the capacity of these polymers to polymerize/depolymerize. The capacity of microtubules for assembly-disassembly was mimicked in vitro in the pioneer work of Weisenberg (1972), who reproduced conditions for the assembly of these polymers using a brain cell extract. In this work it was established that microtubule polymerization depends on the amount of tubulin and that, at least in vitro, a critical concentration of this protein is needed for polymerization into microtubules. Since there is a large amount of tubulin in a brain cell extract, it is possible

to induce microtubule assembly in vitro. In addition, Weisenberg also found that the presence of GTP and the absence of calcium were both needed to properly carry out microtubule assembly. These observations served as the basis of various methods for microtubule protein purification (Borisy and Olmsted, 1972; Shelanski et al., 1973). At that time it was also found that microtubules are induced to assemble at warm temperatures. In contrast to tubulins from Antarctic fishes that polymerize at low temperatures, mammalian microtubules are not cold-stable and depolymerize very fast at 4°C. The observed temperature dependence seems to reside in differences in the polymerization energetics and kinetics of specific tubulin polypeptides. Thus, warming a cytosolic brain extract promotes microtubule polymerization, and the microtubules can be easily collected by centrifugation. But, because in vitro–polymerized mammalian microtubules depolymerize in the cold, after centrifugation, collected microtubules can be depolymerized using a cold buffer. After depolymerization, the solution can again be centrifuged to remove contaminants and those microtubule fragments that are not competent for depolymerization.

This sequence of warm-polymerization and cold-depolymerization can be repeated two or more times until the desired degree of purity of the microtubules is achieved.

The quality and quantity of tubulins and proteins associated with microtubules (MAPs) obtained can be followed by SDS-PAGE analysis (*UNIT 6.1*). From this analysis it is possible to observe the main microtubule components—two polypeptides or subunits, α- and β-tubulin (for reviews see: Vallee et al., 1986; Matus, 1988; Avila, 1990). MAPs are classified in three major families. The first protein family comprises the MAP1 polypeptides: MAP1A, MAP1B, and MAP1C (or dynein, a motor protein). The second family is composed of four structurally related proteins derived from a single gene: MAP2A, MAP2B, MAP2C, and MAP2D. The third family, present in a lower amount, is composed of several related polypeptides (tau proteins), or isoforms expressed from a unique gene. All these MAPs preferentially bind to the C-terminus of tubulins (Serrano et al., 1984a,b, 1986).

In this unit, we describe protocols for the purification of tubulins (Basic Protocols 1 and 3 and Alternate Protocol 2), MAP1 (Basic Protocol 4), MAP2 (Basic Protocol 5), and tau proteins (Basic Protocol 6), but not for other MAPs or motor proteins (such as dynein). We also describe how to assemble microtubules in vitro in the presence of paclitaxel (Taxol; Basic Protocol 2 and Alternate Protocol 1) and protocols for native gel electrophoresis (Support Protocol 1) and atomic force microscopy (AFM; Support Protocol 2).

ISOLATION OF MICROTUBULE PROTEIN BY CYCLES OF POLYMERIZATION AND DEPOLYMERIZATION

BASIC PROTOCOL 1

Many similar microtubule protein purification methods have been developed, published, and used for the purification of microtubule proteins (Shelanski et al., 1973; Williams and Lee, 1982; Vallee, 1986a). Most of these are based on the reversible assembly capacity of microtubule proteins in the presence or in the absence of assembly-promoting agents, such as glycerol or dimethyl sulfoxide (DMSO). Here we describe the isolation of brain microtubule proteins by temperature-dependent cycles of polymerization-depolymerization using glycerol and DMSO in the first and second polymerization cycles, respectively (Fig. 3.29.3). Figure 3.29.3 illustrates the results of the step-by-step protocol that we follow in our laboratories. This method can be applied to brain tissues from different sources, i.e., porcine, bovine, rat, etc. The protocol is appropriate for a medium-scale preparation (1 to 3 cow or pig brains).

Materials

One to three brains (100 to 500 g total start-up tissue; the weight of a pig brain is ~100 g)
Phosphate-buffered saline, pH 6.7 (PBS; *APPENDIX 2A*), 4°C
Isotonic buffer (see recipe), 4°C
Protease inhibitors (see recipe)
Buffer A (see recipe), 4°C
Glycerol
PMSF
GTP (see recipe)
Dimethyl sulfoxide (DMSO)

Plastic wrap
Ice-water bath
No.10 scalpel blade
500-ml beaker
Potter homogenizer (Teflon-in-glass homogenizer), as large as possible
Centrifuge (if possible two centrifuges, one at 4° to 6°C and the other at 25° to 30°C): Sorvall RC-5B or equivalent Beckman J2, J21 series, or Avanti J-25

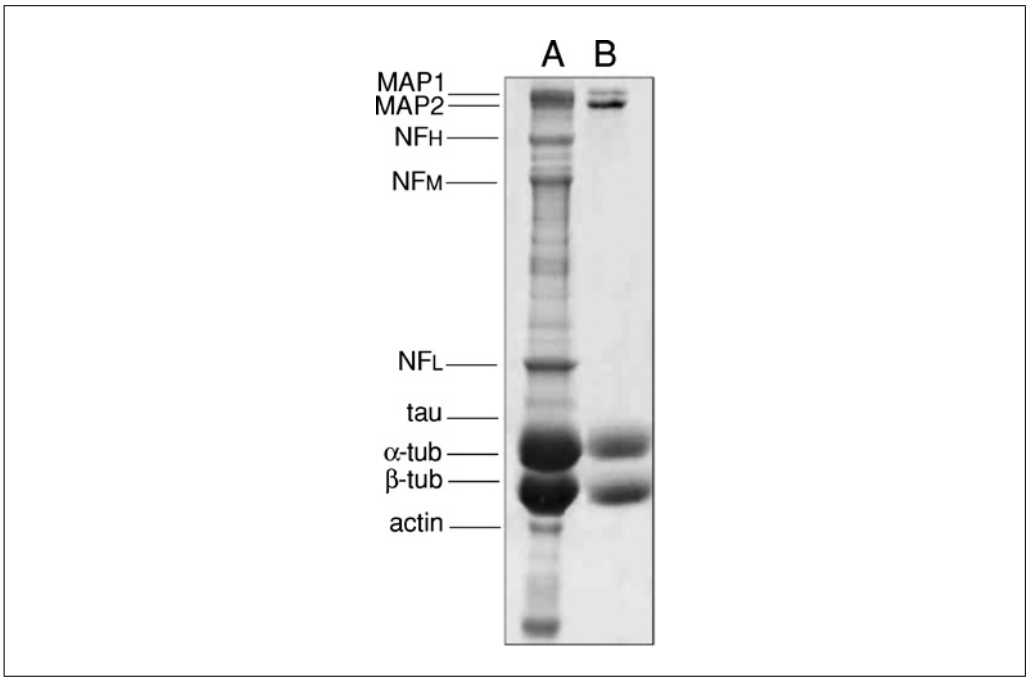

Figure 3.29.3 Characterization of pelleted protein after one (**A**), and three polymerization cycles. (**B**) In (A), the presence of MAP1, MAP2, neurofilament proteins (NF_H, NF_M and NF_L), tau protein, tubulin subunits, and actin are indicated. The gel was stained with Coomassie blue as explained in *UNIT 6.6.*

Centrifuge rotors: GSA or JA-10; type 50.2Ti and 70.1 Ti for the Beckman
Graduated flask
26.3-ml ultracentrifuge tubes
35°C rocking incubator
Ultracentrifuge Beckman L8-70, Optima XL-100 or 120

Additional reagents and equipment for measuring protein concentration (*APPENDIX 3B*)

Obtain the brains

1. Make an appointment with veterinarians at the slaughterhouse and request fresh brains to be picked up immediately after animal slaughter.
2. Wrap brains carefully with plastic before introducing in the ice-water bath. Place brains on ice during transport to the laboratory (<1 hr in our case). After arriving at the laboratory start the preparation of the cytosolic extracts (immediately).

Prepare brains

3. Rinse brains well, three times, each time with 100 ml cold PBS buffer and keep them cold throughout the following steps until the first polymerization cycle.
4. Remove the meninges, the blood clots, and most of the peripheral blood vessels from the brain.
5. Chop the brains into smaller pieces (1- to 2-cm) using a no. 10 scalpel blade.
6. Weigh the tissue in a tared 500-ml cold beaker.

Homogenize the brain tissue

7. Add 0.75 to 1 ml of isotonic buffer per gram of tissue.

   The use of the isotonic buffer for tissue homogenization facilitates the removal of neurofilaments in the following microtubule isolation process.

8. Add PMSF to a final concentration of 1 mM. Add aprotinin, leupeptin, and pepstatin to a final concentration of 1 μM each (see recipe for protease inhibitors in Reagents and Solutions).

9. Disrupt brain tissues at 4°C by using a Potter homogenizer, which allows a fast and reproducible homogenization.

   Use the largest Potter you have and homogenize as many times as required depending on the total volume (see Critical Parameters).

10. Clear the crude brain homogenate by centrifuging 30 min at 25,000 × *g*, 4°C.

    If necessary, since the volume is too high, a rotor type GSA (Dupont-Sorvall) or equivalent JA-10 in a Beckman J2-21, or Avanti J-25 centrifuge can be used.

11. Decant the supernatant in a cold 500-ml beaker and, if necessary for further clarification, centrifuge again for 30 to 45 min at 25,000 × *g*, 4°C.

12. Discard the pellet and take the supernatant. Take a small aliquot for analysis in SDS-PAGE (*UNIT 6.1*), native electrophoresis (Support Protocol 1), and for protein determination (*APPENDIX 3B*).

    From an initial 100 g we usually get 150 ml at 40 mg/ml at this point, and, of this amount, ~20% represents microtubule proteins.

13. Measure the total volume of the cytosolic extract in a graduated flask and make it 1× buffer A by adding for each 90 ml of extract, 10 ml of 10× buffer A. Add glycerol to a final concentration of 25%(v/v) to 30%(v/v) (Krauhs et al., 1981).

    Be aware that some commercial glycerol preparations have a concentration of 87%.

14. Add PMSF to a final concentration of 1 mM to prevent protein degradation by nonspecific proteolysis. Finally, add 1 M GTP (1000×) to a final concentration of 1 mM.

Perform first polymerization

15. Transfer the solution to 26.3-ml ultracentrifuge tubes and balance them to ±0.01 g. Incubate solution for 30 min at 35°C with gentle agitation.

16. Ultracentrifuge the mixture 45 min at 100,000 × *g*, 25°C, using a prewarmed (30°C) rotor.

    We use the 50.2 Ti rotor in a Beckman centrifuge.

17. Discard the supernatant and take the pellet, which should be translucent.

    If necessary, pellets can be frozen at −80°C at this point without much loss of function of the polymerized tubulin. We usually get 300 to 400 mg protein at this point, determined by Lowry's method.

Perform first depolymerization

18. Resuspend the pellet in cold buffer A at 10 to 20 mg/ml. Let the mixture to stand in an ice-water bath for 30 min.

    Intermittent homogenization of the mixture with a Teflon-in-glass homogenizer (10 strokes) will facilitate microtubule depolymerization.

19. Centrifuge 15 to 20 min at 25,000 × *g*, 4°C using a precooled rotor Beckman 50.2 Ti. Discard the pellet and keep the supernatant.

    The pellet at this point is enriched in the so-called cold-resistant microtubule fraction and denatured protein. It is not advisable to centrifuge at very high speed, to avoid loss of "competent" microtubule proteins.

20. Add PMSF and GTP to the supernatant to a final concentration of 1 mM (add 1/1000 volume of 1 M GTP). Add DMSO to a final 10% concentration.

CAUTION: DMSO is hazardous: see APPENDIX 2A for guidelines on handling, storage, and disposal.

Perform second polymerization

21. Transfer the solution to 26.3-ml ultracentrifuge tubes and balance them to within ±0.01 g. Incubate the tubes 30 min at 35°C with gentle agitation.

22. Collect the microtubules polymerized in the second cycle by ultracentrifuging 40 min at 180,000 × *g* (Beckman 70.1 Ti at 50,000 rpm), 25° to 30°C.

If at this point there is only one rotor available, wash the rotor with hot water to rapidly reach the appropriate temperature.

23. Discard the supernatant. To finish the second cycle resuspend the pellet in 6 ml of cold 0.5× buffer A. Let the mixture stand in an ice-water bath for 30 min.

The pelleted protein can be frozen in liquid nitrogen or at −80°C for further use. We usually get 60 to 80 mg protein at this point.

Occasional homogenization of the mixture with a Teflon-in-glass homogenizer (10 strokes) will facilitate depolymerization of microtubules.

24. Centrifuge 20 min at 25,000 × *g*, 4°C, using a precooled rotor. Discard the pellet. Measure protein concentration in the supernatant by using a spectrophotometer absorbance at 280 nm and 260 nm. (*APPENDIX 3B*)

The extinction coefficient of tubulin at 280 nm is 115,000 $M^{-1}cm^{-1}$ [1.15 $(mg/ml)^{-1}$ cm^{-1}]. This extinction coefficient is calculated from tubulin sequences and includes the contribution of the two bound guanine nucleotides to the absorbance at 280 nm. For this reason, we use the formula $A_{280}/1.15$ = mg/ml of the sample. Also, this formula might be improved if we take into account the contribution of nucleotides to the absorbance at 260 nm: $1.45 \times A_{280} - 0.74 \times A_{260}$ = mg/ml of tubulin. The isolated tubulin competent to polymerize can be stored at −80°C for several months or until further steps.

BASIC PROTOCOL 2

ISOLATION OF MICROTUBULE PROTEIN USING PACLITAXEL (TAXOL)

An alternative single-step method to isolate polymerized microtubule proteins is based on the fact that microtubules assemble and remain stable in the presence of paclitaxel (Shiff et al., 1979). This allows one to sediment them and to resuspend them in a cold buffer without depolymerization (Borisy and Olmsted, 1972). Moreover, an advantage of this procedure is the fact that MAPs can be easily dissociated from these stable microtubules by exposing them to an elevated ionic strength. Additionally, the use of paclitaxel permits the purification of tubulin from sources where the amount of this protein is low.

Materials

Bovine or porcine brain tissue (10 g)
Phosphate-buffered saline (*APPENDIX 2A*)
Buffer A (see recipe)
Protease inhibitors (see recipe)
Paclitaxel (Taxol; see recipe)
GTP (see recipe)
PMSF
Sucrose underlayer solution (1 ml per centrifuge tube containing 10% sucrose, 10 μM paclitaxel, and 0.5 mM GTP)
Scalpel blade, No.10
500-ml beaker

Potter homogenizer (Teflon-in-glass homogenizer)
Centrifuge rotors: GSA or JA-10. Type 50.2Ti and 70.1 Ti for the Beckman Ultracentrifuge Beckman L8-70, Optima XL-100 or 120
13.5-ml ultracentrifuge tubes
30°C rocking incubator
Pasteur pipet

Prepare cytosolic extract

1. Obtain fresh brains from the slaughterhouse as described in Basic Protocol 1.
2. Place and keep brains on ice until arrival at the laboratory, as described in Basic Protocol 1.

   Although we use fragments of any region of porcine brain, whole brains from other sources can also be used.

3. Rinse brains well, three times, each time with 100 ml cold PBS buffer and keep them cold throughout the following steps until the first polymerization cycle.
4. Remove the meninges, the blood clots, and most of the peripheral blood vessels from the brain.
5. Chop the brains into smaller pieces (1 to 2 cm) using a scalpel blade, no. 10. Weigh the tissue in a tared 500-ml cold beaker.
6. Add 15 ml buffer A (1.5 ml per g of tissue).
7. Disrupt brain tissues at 4°C by using a Potter homogenizer.

   Follow recommendations in Basic Protocol 1.

8. Add freshly prepared PMSF to a final concentration of 1 mM in DMSO. Also add the following protease inhibitors to a final concentration of 1 μM: aprotinin, leupeptin and pepstatin (see recipe for protease inhibitors in Reagents and Solutions).
9. Clear the crude brain homogenate by ultracentrifuging 40 min at 100,000 × *g*, 4°C. Use a precooled rotor (Beckman 50.2 Ti or similar).

Polymerize microtubules

10. Discard the pellet and add paclitaxel to the supernatant to a final concentration of 20 μM, GTP to a final concentration of 1 mM, and PMSF to a final concentration of 1 mM.
11. Transfer the solution to 13.5-ml ultracentrifuge tubes and balance them to within ±0.01 g. Incubate at 30 min at 30°C with gentle agitation.
12. With a Pasteur pipet introduce 1 ml of a 30°C prewarmed sucrose solution very gently at the bottom of the tube.
13. Collect the assembled microtubules in the polymerization cycle by ultracentrifuging 30 min at 180,000 × *g* (prewarmed rotor Beckman 70.1 Ti), 25° to 30°C.
14. Discard the supernatant and keep the translucent pellet. Resuspend pellet in 3 ml buffer A containing 20 μM paclitaxel and 1 mM GTP.

    These microtubule preparations, containing assembled microtubules, can be used as a source for isolating MAPs, such as MAP1B (see below) or they can be stored in the refrigerator (4°C). You must be aware that storage for >1 week will enrich the preparation in unpolymerized tubulin. To store samples for longer periods keep the preparation at −80°C.

ALTERNATE PROTOCOL 1

MICROTUBULE POLYMERIZATION IN THE PRESENCE OF PACLITAXEL

??

Microtubule proteins (tubulin and MAPs) are prepared by repeated cycles of assembly/disassembly using a temperature-dependent procedure as described in Basic Protocol 1. Purified microtubule heterodimers are incubated 30 to 40 min with 20 to 25 μM paclitaxel (taxol) at 35°C in BRB80 buffer (see recipe) containing 1 mM GTP and 30% glycerol. The pellet corresponding to the polymerized microtubules is obtained by centrifuging 30 min at 45,000 × *g*, 30°C through a 50% sucrose cushion containing 1 mM GTP.

BASIC PROTOCOL 3

ISOLATION OF TUBULIN DIMERS FROM MICROTUBULE PROTEINS

Tubulin contains very acidic regions, mainly in its C-terminal domain (Krauhs et al., 1981), which allows its fractionation from many other proteins by ion-exchange chromatography (anionic or cationic). Two types of resins have been successfully used to purify tubulin: cationic resins such as DEAE-cellulose (or DEAE-Sephadex) and anionic resins like phosphocellulose. However, it is possible to use any other type of ion-exchange resins such as Mono-Q or Mono-S from Pharmacia, or HiTrap columns. Nevertheless, all these chromatographic columns show advantages and disadvantages. For example, while the use of DEAE-cellulose is a slow procedure, the use of phosphocellulose columns might result in a partial inactivation of tubulin due to magnesium ion chelation (Williams and Detrich, 1979). Likewise, highly purified tubulin can be obtained from cationic columns, but the fact that tubulin binds to these resins requires the use of a salt gradient to elute the protein, which might result in tubulin denaturation. Therefore, tubulin elution from these columns requires a further step of salt removal by dialysis or ultrafiltration. In this protocol we describe the classical procedure to purify tubulin using phosphocellulose chromatography. This method has been chosen because it is the fastest and does not need the additional dialysis step that could also result in a partial denaturation of tubulin.

Materials

Resin: Whatman P11 Cellulose Phosphate
0.5 M NaOH
0.5 M HCl
Buffer A (see recipe)
50 mg of porcine brain microtubules stored at −80°C or in liquid nitrogen (Basic Protocol 1)

Buchner funnel
XK50/20 (Length 20 cm, i.d. 50 mm; Pharmacia) column including:
  Thermostat jacket
  Flow adaptor
  Flanged tubing at both ends for direct connection to valves
  Pumps
  UV monitors if using an FPLC or an AKTA system
Teflon-in-glass homogenizer
Ice-water bath
Ultracentrifuge

Additional reagents and equipment for isolating microtubule proteins (Basic Protocol 1), determining protein concentration (*APPENDIX 3B*), SDS-PAGE (*UNIT 6.1*), and nondenaturing gel electrophoresis (Support Protocol 1)

Precycle the ion exchanger

1. Take 100 g of resin and stir into 1.5 liter of 0.5 M NaOH for 30 min at room temperature. Filter the resin in a Buchner funnel and wash with water several times.

   Alternatively, stir the resin in a beaker and let it settle by gravity for a few minutes and decant the supernatant.

2. After the wash, treat the resin with 1.5 liter of 0.5 M HCl as described above. Filter or decant and wash several times with water.
3. Repeat this procedure until a neutral pH is attained.
4. Next, filter and stir the resin in 0.5× buffer A.
5. Add the resin to an XK 50 column (~150 ml) and equilibrate with 0.5× buffer A until the absorbance at 280 nm returns to baseline.

Prepare sample

6. Collect microtubule proteins (10 mg/ml), isolated following Basic Protocol 1, by depolymerization of microtubules preparing a homogenate in cold 0.5× buffer A with the help of a Teflon-in-glass homogenizer.
7. Leave homogenized sample in ice-water for 30 min.

   Intermittent homogenization of the mixture with a Teflon-in-glass homogenizer (10 strokes) will facilitate microtubule depolymerization.

8. Ultracentrifuge the homogenate 15 min at 25,000 × *g*, 4°C, using a precooled rotor. Discard the pellet and keep the supernatant.

   We currently use 50.2 Ti or 70.1 Ti rotors in a Beckman centrifuge in our laboratory.

9. Adjust the final protein concentration of the supernatant to ~10 mg/ml and load it onto a prepacked XK 50 phosphocellulose column (1 ml column/mg protein) equilibrated in 0.5× buffer A.

   The first time you use the resin you must take into account that you will probably lose some tubulin. This is due to the fact that some will irreversibly bind to the phosphocellulose. This could be overcome or minimized by previously loading in the column with 1 g of BSA diluted in the same buffer, followed by several washes with the salt-containing buffer before re-equilibration.

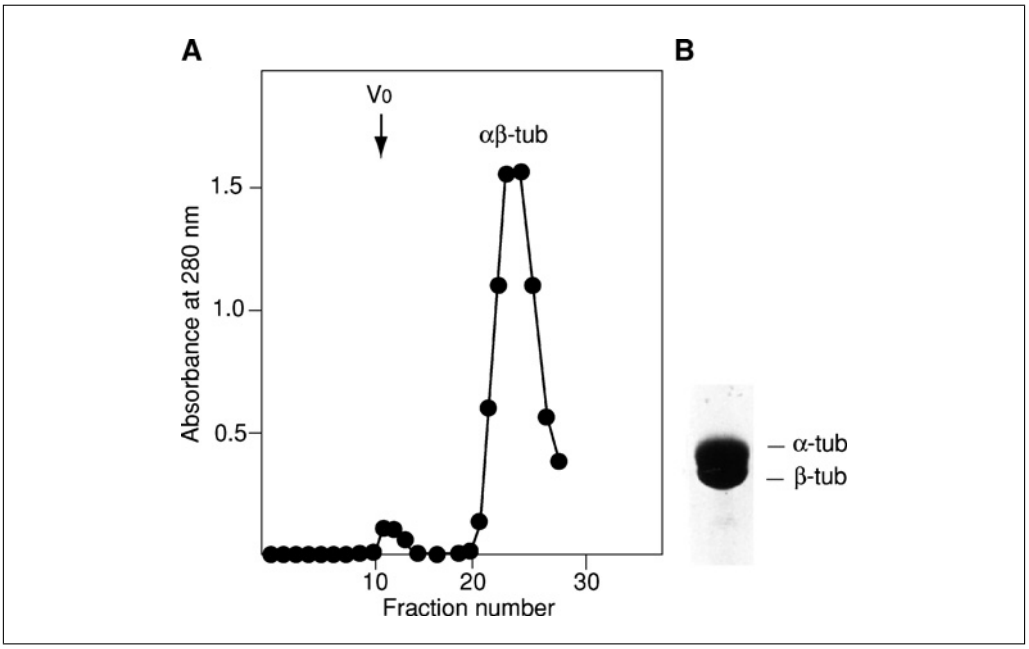

Figure 3.29.4 (**A**) Chromatographic elution profile obtained at 280 nm of absorbance from a gel filtration analysis of phosphocellulose-purified tubulin chromatographed through a Sepharose 4B column. (**B**) Denaturing SDS gel (8.5% polyacrylamide) analysis of the peak corresponding to a molecular mass of 110 kDa eluted from the column. The gel was stained with Coomassie blue as explained in *UNIT 6.6.* Abbreviations: V_o, void volume.

10. Collect 0.5-ml fractions from the column.

    Tubulin, which will be present in the first fractions after the void volume of the column, can be detected by measuring absorbance at 280 nm (Fig. 3.29.4).

11. Determine protein concentration by Bradford, Lowry, or BCA, and measure the absorbance at 280/260 as described in *APPENDIX 3B*.

12. To finish, analyze the quality of purified tubulin by SDS-PAGE (*UNIT 6.1*) and by nondenaturing gel electrophoresis (Support Protocol 1).

13. Add to the tubulin-containing fractions the amount of 10× buffer A to obtain 1× buffer A, and GTP to a final concentration of 1 mM. Freeze fractions immediately in liquid nitrogen or at −80°C.

    Other microtubule associated proteins (MAPs) can be eluted from the column using buffer A containing 2 M NaCl (Basic Protocol 2 and Alternate Protocols 4 and 5).

BASIC PROTOCOL 4

ISOLATION OF MAP1A/1B

Microtubule-associated proteins comprise a heterogeneous group of polypeptides which display different structural characteristics, are differentially expressed during development, and are localized at different sites in neurons. A good example of these differences can be found between proteins termed MAP1A and MAP1B (Bloom et al., 1984; 1985). MAP1B is localized in the developing rat brain (Tucker et al., 1989), decreasing its expression dramatically at the end of the neuronal differentiation. On the other hand, MAP1A is expressed at later developmental stages and its level of expression remains constant through adulthood. MAP1B and the protein tau are mostly axonal proteins, whereas the high-molecular-weight forms of MAP2 are mostly found in dendrites (Matus, 1988).

Different MAPs display different characteristics which have served in developing diverse strategies and schemes to purify them. For instance, MAP2 and tau proteins are heat-resistant proteins, whereas MAP1A/1B denature at high temperature. Yet, since MAP1A/1B preferentially bind to a cluster of acidic amino acids present at the carboxy-terminus of tubulin (Tucker et al., 1989; Cross et al., 1991), molecules like poly-L-aspartic acid can be employed to compete with the interaction of these MAPs with tubulin (Fujii et al., 1990). Moreover, MAP1B can be isolated from the brain of newborn rats, whereas the most appropriate source for other MAPs is the adult brain. Similarly, the differential proportion of axons/somatodendritic tissues between white and gray matters can also be used to differentially purify MAP1 (white matter) and MAP2 (gray matter), minimizing contaminations (Vallee, 1986b), while either of the two matters can be used to purify MAP1A. In the case of tau, the expression pattern of the different isoforms is clearly different between white and gray matter, and there is a dramatic decrease in the amount of two tau isoforms in gray matter (de Ancos and Avila, 1993).

MAP1B/1A are both thermolabile proteins and cannot be isolated through a heat-treatment step. Instead, the addition of poly-L-aspartic to taxol-stabilized microtubules detaches MAP1A/1B proteins from these polymers. This step is performed in a PIPES buffer where the interaction of MAP1 proteins with tubulin is weakened (Pedrotti et al., 1993). MAP1 proteins are next fractionated from taxol-polymerized microtubules by centrifugation, being further purified using an FPLC (fast protein liquid chromatography) or AKTA system (Pazzagli and Avila, 1994). This particular protocol uses adult rat or porcine brains as the source of MAP1A. MAP1B is isolated from whole newborn-rat brains. These sources were chosen taking into consideration the information described above.

Materials

White matter from a cow or ten brains from adults rats (MAP1A)
Twenty brains from newborns rats (MAP1B)

Buffer B (see recipe)
GTP
Paclitaxel (Taxol; see recipe)
Poly-L-aspartic
Buffer C (see recipe)
Buffer D (see recipe)
Buffer A (see recipe)

10.4-ml centrifuge tubes
Ice-water bath
Centrifuge
Centrifuge rotors: GSA or JA-10. Type 50.2Ti and 70.1 Ti for the Beckman
100-ml Erlenmeyer flask
37°C incubator
Ultracentrifuge Beckman L8-70, Optima XL-100 or 120
1-ml Mono-Q column (or another with similar characteristics) connected to a FPLC or AKTA system

Additional reagents and equipment for preparing and homogenizing the brains (Basic Protocol 1), FPLC (Pazzagli and Avila, 1994), and SDS-PAGE (*UNIT 6.1*)

1. Follow steps 1 to 17 of Basic Protocol 1.
2. Resuspend the pelleted protein in buffer B to a final concentration of 4 mg/ml. Transfer to 10.4-ml centrifuge tubes. Let stand 30 min in an ice-water bath.
3. Centrifuge 15 min at 20,000 × *g*, 4°C.
4. Collect the supernatant in a 100-ml Erlenmeyer flask and add GTP, paclitaxel, and poly-L-aspartic acid to final concentrations of 1 mM, 10 μM, and 50 μM, respectively. Incubate for 30 min at 37°C.
5. Ultracentrifuge at 30 min at 100,000 × *g*, 25° to 30°C.

   Prewarm the rotor.

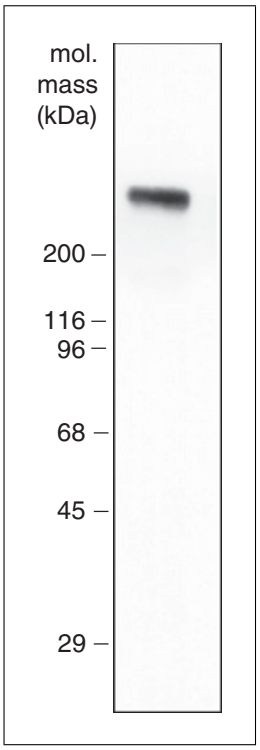

Figure 3.29.5 Characterization of the isolated MAP1A protein (Basic Protocol 4) by denaturing SDS-PAGE (7% polyacrylamide). The gel was stained with Coomassie blue as explained in *UNIT 6.6*.

6. Load the MAP1-containing supernatant (at a concentration of 0.5 mg/ml) onto a 1-ml mono-Q column and fractionate by fast protein liquid chromatography (FPLC; Pazzagli and Avila, 1994). Wash and equilibrate the column with buffer C until the A_{280} of the eluent returns to the baseline.
7. Next, elute using a linear gradient from buffer C to buffer D.
8. Characterize the protein content of the different collected fractions by SDS-PAGE (*UNIT 6.1*).
9. Select only MAP1-containing fractions (Fig. 3.29.5) and dialyze against buffer A. Store samples at −20°C or −70°C.

Be aware that usually MAP1 proteins are eluted in more than one peak.

BASIC PROTOCOL 5

ISOLATION OF HIGH-MOLECULAR-WEIGHT MAP2

The MAP2 gene gives rise to different isoforms that are developmentally regulated. For instance, those showing a higher molecular weight are the major isoforms in adult brain (Matus, 1988). As already mentioned, MAP2 is heat resistant and remains stable and fully functional after a high temperature treatment. Consequently, the inclusion of a heat-treatment step in the purification protocol facilitates the separation of MAP2 from other microtubule-associated proteins that should denature and precipitate (Herzog and Weber, 1978; Sloboda and Rosembaum, 1982). An alternative protocol for MAP2 purification has also been published (Williams and Lee, 1982).

Materials

Porcine or bovine brains or alternatively microtubule protein stored at −80°C or liquid nitrogen (Basic Protocol 1)
Buffer A (see recipe)
NaCl
2-mercaptoethanol
Ammonium sulfate
Sepharose 4B resin (GE Healthcare-Pharmacia)

Teflon-glass homogenizer
Ice-water bath
Centrifuge
Centrifuge rotors: GSA or JA-10, Type 50.2 Ti and 70.1 Ti for the Beckman
Boiling water bath

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*)

Isolate MAP2

1. Follow steps 1 to 17 of Basic Protocol 1.
2. Depolymerize microtubules in cold buffer A using a Teflon-glass homogenizer to obtain microtubule proteins (10 to 20 mg/ml).

Intermittent homogenization of the mixture with a Teflon-in-glass homogenizer (10 strokes) will facilitate microtubule depolymerization.

3. Incubate in an ice-water bath for 30 min.
4. Centrifuge the mixture 15 min at 25,000 × *g*, 4°C.
5. Collect the supernatant and dilute to a protein concentration of 1 mg/ml with buffer A. Then, add NaCl and 2-mercaptoethanol to a final concentration of 1 M and 10 mM, respectively.
6. Heat the resulting protein solution for 5 min at 100°C in a boiling water bath.

7. Centrifuge 10 min at 10,000 × *g*, 25°C.

   A white precipitate containing denatured protein should be obtained.

8. Then, collect the supernatant in an Erlenmeyer flask and add ammonium sulfate salt to 35% (w/v) saturation. Incubate 10 min at room temperature.

   A total of 20.9 g of ammonium sulfate should be added to 100 ml of solution to obtain a 35% saturated solution.

9. Centrifuge 10 min at 10,000 × *g*, 4°C, then discard the supernatant and resuspend the pellet in 2 to 5 ml of buffer A containing 1 M NaCl.

10. Load resuspended protein onto a Sepharose 4B column equilibrated with buffer A containing 1 M NaCl.

11. Characterize the proteins present in the different collected fractions by SDS-PAGE (*UNIT 6.1;* Fig. 3.29.6).

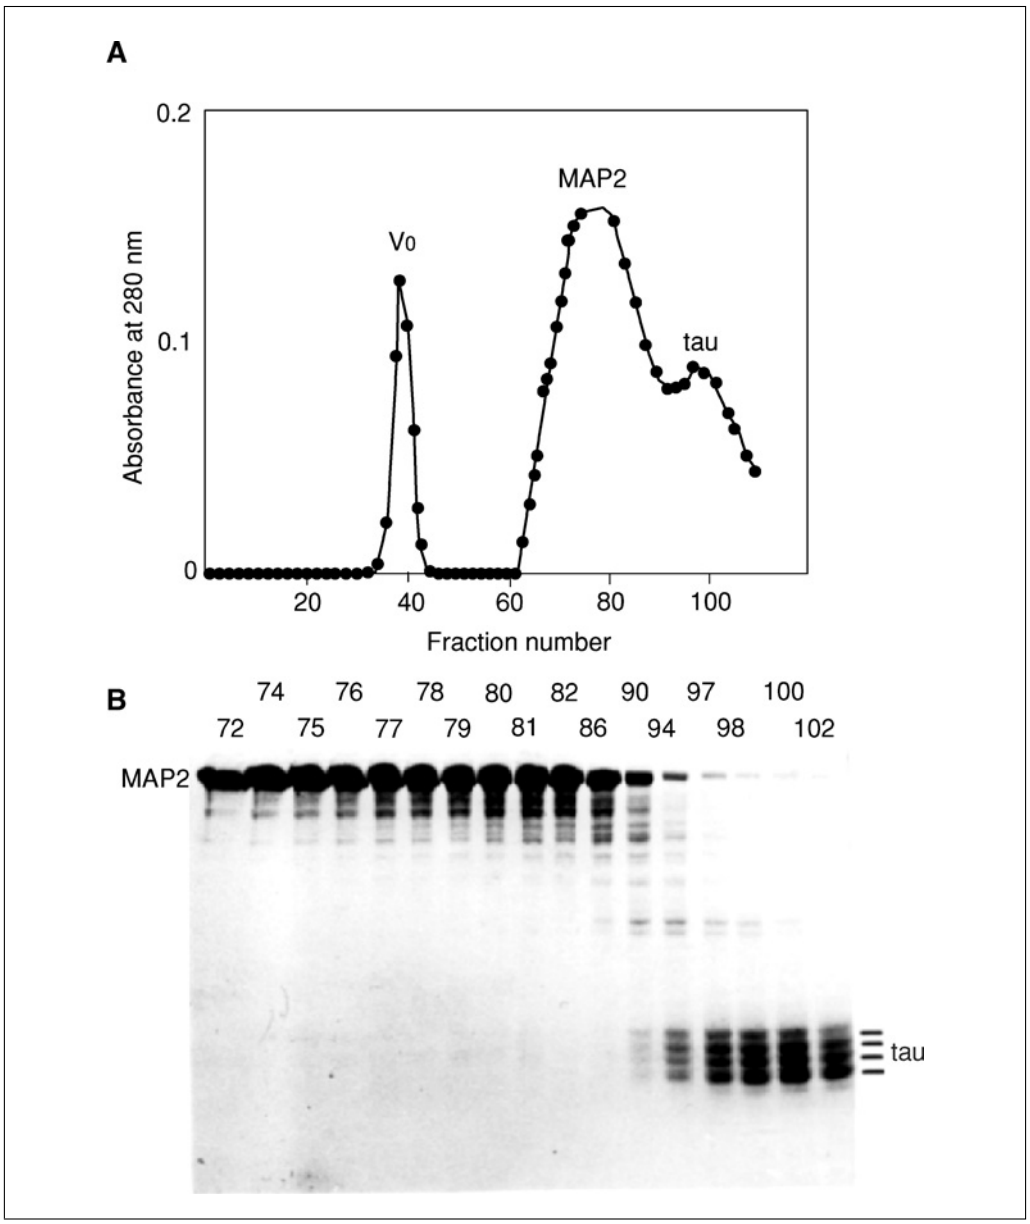

Figure 3.29.6 (**A**) Fractionation of heat-resistant MAPs by chromatography on Sepharose 4B (Basic Protocol 5). (**B**) SDS-PAGE analysis of the corresponding eluted fractions. The gel was stained with Coomassie blue as explained in *UNIT 6.6.* Abbreviations: V_o, void volume.

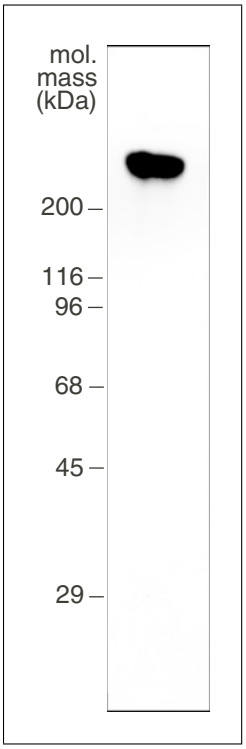

Figure 3.29.7 Characterization of the isolated high-molecular-weight MAP2 protein (Basic Protocol 5) by denaturing SDS-PAGE (7% acrylamide). The gel was stained with Coomassie blue as explained in *UNIT 6.6.*

12. Pool fractions containing MAP2 and precipitate protein by the addition of ammonium sulfate to 50% saturation. Collect the precipitated protein by centrifuging 10 min at 15,000 × *g*, room temperature.

    A total of 31.3 g of ammonium sulfate should be added to 100 ml to obtain a 50% saturated solution.

13. Add 1 ml of buffer A to resuspend the pellet and dialyze against 1 liter of the same buffer.

14. Store protein samples in a freezer at −20°C (Fig. 3.29.7).

BASIC PROTOCOL 6

ISOLATION OF TAU PROTEIN

The primary gene transcript of tau is a well-known example of alternative splicing in the mammalian brain (Himmler et al., 1989). Furthermore, tau possesses multiple phosphorylation sites that are selectively used to create polypeptides with different functions. The post-translational modifications of the various tau isoforms result in multiple protein behaviors (Lindway and Cole, 1984). For example, not all the phosphorylated tau isoforms bind to microtubules. For this reason there are two alternate procedures depending on whether we want to isolate all the isoforms, or just those that bind to microtubules (Garcia de Ancos et al., 1993).

To isolate total tau isoforms (Garcia de Ancos et al., 1993), adjust the concentration of NaCl and DTT to 1 M and 1 mM, respectively in the homogenate obtained in step 12 of Basic Protocol 1, and boil for 5 min and chill on ice. Further steps of the purification are indicated below. In this protocol we describe the isolation of microtubule binding tau isoforms. In addition to this protocol, there are other tau purification procedures that have also been described (Herzog and Weber, 1978; Sobue et al., 1981; Drubin and Kirschner, 1986; Garcia de Ancos et al., 1993).

Materials

Porcine brain
Buffer A (see recipe)
Perchloric acid
Ammonium sulfate
Glycerol

Ice-water bath
Boling water bath
Centrifuge
Centrifuge rotors: GSA or JA-10. Type 50.2Ti and 70.1 Ti for the Beckman

Isolate tau

1. Follow steps 1 to 17 of Basic Protocol 1.
2. Resuspend microtubule proteins in 25 ml of buffer A. Leave 30 min in an ice-water bath.
3. Centrifuge 15 min at 20,000 × *g*, 4°C.
4. Collect the supernatant in a 100-ml Erlenmeyer flask and correct the concentrations of NaCl and DTT to 1 M and 1 mM, respectively. Then boil samples for 5 min and immediately chill on ice for 5 min.
5. Centrifuge samples 30 min at 35,000 × *g*, 4°C.
6. Add perchloric acid to the supernatant to a 2.5% (v/v) final concentration. Keep on ice for 10 min.
7. Centrifuge 15 min at 35,000 × *g*, 4°C.
8. Recover the supernatant, collecting it in a 100-ml Erlenmeyer flask, and add ammonium sulfate up to 50% saturation. Incubate 30 min at 4°C.

   A total of 313 g of ammonium sulfate should be added to 1 liter to obtain a 50% saturated solution.

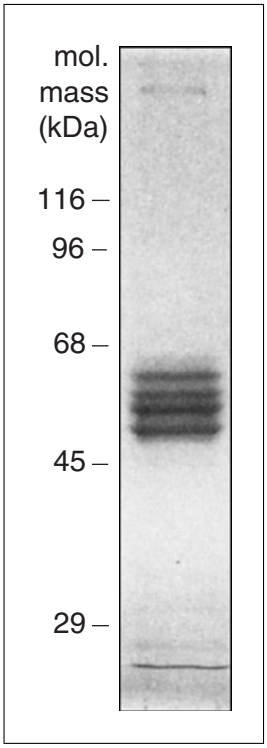

Figure 3.29.8 Characterization of different isoforms of the isolated tau protein by denaturing SDS-PAGE (10% acrylamide). The gel has been stained with Coomassie blue as explained in *UNIT 6.6.*

9. Centrifuge 15 min at 35,000 × *g*, 4°C.

10. Dissolve the pellet in buffer A (to a final concentration of 1 to 5 mg/ml), bring up to 2.5% perchloric acid, and centrifuge 15 min at 35,000 × *g*, 4°C.

11. Decant supernatant and add glycerol to a final concentration of 25% (v/v). Centrifuge 15 min at 35,000 × *g*, 4°C.

12. Resuspend the pellet—which should appear as a translucent film stuck to the centrifuge tube wall—in buffer A to a final concentration of 0.5 to 2 mg/ml. Store samples in a freezer at −20°C (Fig. 3.29.8).

SUPPORT PROTOCOL 1

NONDENATURING POLYACRYLAMIDE GEL ELECTROPHORESIS AS A SIMPLE METHOD TO QUANTIFY/CHECK POLYMERIZATION-COMPETENT TUBULIN

The determination of the purity of the different protein fractions from the various purification steps can be monitorized using SDS-denaturing gels (*UNIT 6.1*). Purified tubulin is usually analyzed by SDS-PAGE. Under denaturing conditions, α- and β-tubulin polypeptides have different mobilities, both polypeptides in the molecular mass range of 55 kDa. However, the analysis and quantification of the amount of tubulin by most of the known biochemical methods does not provide information about the native state of the tubulin in the preparation. To distinguish between folded and unfolded tubulin (noncompetent for microtubule assembly) we can take advantage of an old, but still very important, nondenaturing gel electrophoresis technique first applied by Ornstein (1964) for the analysis of water-soluble serum proteins (see *UNIT 6.5*). This method can be used only under conditions that preserve the native state of soluble individual proteins or complexes. In contrast to classic SDS-denaturing electrophoresis, the migration of proteins in native gels is essentially dependent on their isoelectric point and the pH of the buffer (Safer, 1994). Consequently, in native electrophoresis it is crucial to select the appropriate buffer for each protein under analysis. The behavior of native tubulin under nondenaturing conditions was established by Zabala and Cowan (1992). Although many times it is advantageous to use a discontinuous system to maximize the resolution of the protein bands, we have found that this is not required for tubulin, and it is easier and faster to prepare a continuous system. To prepare and to run a native electrophoresis, carefully follow the safety indications explained in Chapter 6.

Materials

Gel solutions (Table 3.29.1)
4× loading buffer [50 mM MES, pH 6.7, containing 30%(v/v) glycerol or 25%(w/v) sucrose
Electrophoresis (running) buffer (see recipe)
GTP
Protein sample to be analyzed
10× transfer buffer (see recipe), optional
Electrophoresis equipment (Chapter 6; e.g., Miniprotean from Bio-Rad and 0.75-mm spacers)

Additional reagents and equipment for gel staining (*UNIT 6.2*)

1. Assemble the gel glass-plate sandwich and fit it to the gel electrophoresis unit casting stand according to manufacturer's instructions.

2. Prepare the gel solution as indicated in Table 3.29.1.

3. Pour the gel mix to the top of the gel mold and insert the comb (0.75-mm spacers and 10 wells per comb). Avoid trapping air bubbles under the comb teeth. Allow gel to polymerize for 30 to 60 min.

Table 3.29.1 Recipe for Gel Preparation Using a Native Continuous Buffer System[a]

Stock solution (ml)[b]	Final acrylamide concentration in gel (%)[c]			
	4	5	6	7
Distilled water	6.48	6.15	5.81	5.48
30% acrylamide/0.8% bisacrylamide[d]	1.33	1.66	2	2.33
0.5 M MES, pH 6.7	2	2	2	2
1 M $MgCl_2$	0.01	0.01	0.01	0.01
0.5 M EGTA	0.02	0.02	0.02	0.02
1 M GTP	0.01	0.01	0.01	0.01
10% (w/v) APS (ammonium persulfate)[e]	0.14	0.14	0.14	0.14
TEMED[f]	0.01	0.01	0.01	0.01

[a]Preparation of the gel: Use a 75 or 100-ml Erlenmeyer flask or in order to speed polymerization, degas the mix under vacuum several minutes in a side-arm flask. Mix the ProtoGel[c] solution with 0.5M MES pH 6.7, 1M $MgCl_2$, 1M GTP and 0.5M EGTA. Add 10% (w/v) ammonium persulfate and TEMED.
[b]All reagents and solutions used must be prepared with Milli-Q purified water or equivalent.
[c]The recipe is for 10 ml solution, which is adequate for 2 minigels (7 cm × 8 cm) 0.75 mm thickness.
[d]The polyacrylamide can be prepared as described in Chapter 6, but it is more convenient to use a ready-to-use commercial solution, we usually use ProtoGel 30% (w/v) acrylamide:0.8% (w/v) bis-acrylamide from National Diagnostics, England.
[e]It can be prepared and stored frozen at −20°C in aliquots but we prefer to use freshly made.
[f]Add just before polymerization.

4. Mix the protein sample to be analyzed with 4× native loading buffer [50 mM MES, pH 6.7, containing 30% (v/v) glycerol or 25% (w/v) sucrose] for a final concentration of 1×.

   For better sample visualization small amounts [0.025% (w/v)] of bromphenol blue can be added in the loading buffer.

5. Assemble the gel unit and fill the upper tank with enough electrophoresis buffer with GTP added to 0.01 M. Use the rest of the 800 ml of electrophoresis buffer, without GTP, to fill the rest of the cell. Remove the comb and rinse wells with buffer.

6. Carefully load a maximum of 25 μl of the samples starting up from the bottom of the wells.

   Use a micropipet or alternatively a Hamilton syringe to load the gel.

7. Connect the unit to the power supply. Set at constant voltage of 80 V for 2 hr.

   We usually run one gel per cell unit, for no longer than 2 hr at room temperature.

   Gels can run longer than 2 hr if the electrophoresis buffer is replaced with freshly prepared electrophoresis buffer in order to maintain the pH. The apparatus needs to be turned off before exchanging the buffer.

8. Turn off the power supply. Disassemble the unit and remove gel from glass sandwich. Stain the gel according to *UNIT 6.6*.

   Coomassie blue or silver staining is the usual method to detect tubulin depending on the amount of tubulin loaded into the gel (Fig. 3.29.9). Alternatively, gels can be transferred onto nitrocellulose or PVDF membranes prior to antibody detection in immunoblots (UNIT 6.2) by using a typical transfer buffer where methanol is omitted.

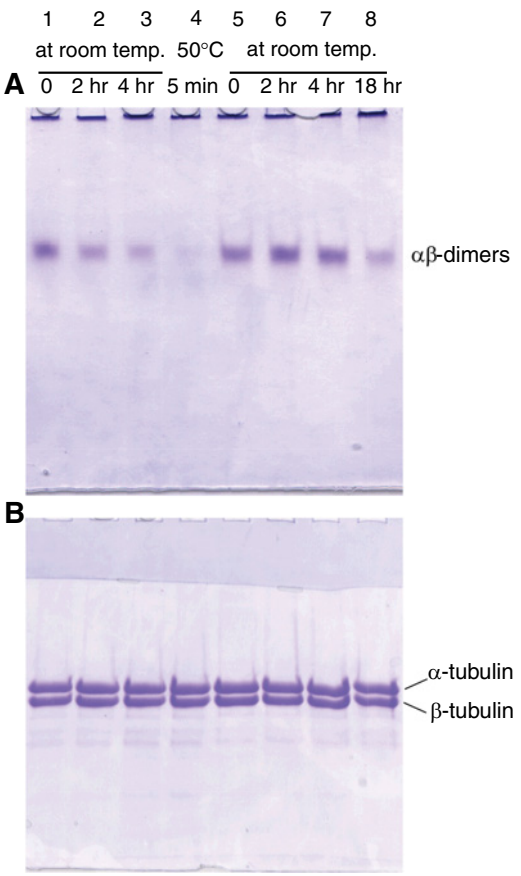

Figure 3.29.9 Assessment of the quality of native tubulin heterodimers by non-denaturing and denaturing gel electrophoresis. (**A**) Nondenaturing PAGE (8.5% acrylamide) characterization of 1-μl aliquots (Support Protocol 1) of purified tubulin (at 6 μg/μl) diluted to 10 μl with water Milli-Q (lanes 1 to 4) or 50 mM MES, pH 6.7 (lanes 5 to 8), and incubated for the indicated times at room temperature with the exception of the aliquot analyzed in lane 5, which was incubated 5 min at 50°C. (**B**) The same tubulin samples were loaded on a gel prepared and run as described in Support Protocol 1. Both gels were stained with Coomassie blue and then scanned before drying. For color version of this figure see *http://www.currentprotocols.com*.

SUPPORT PROTOCOL 2

VISUALIZATION OF POLYMERIZED MICROTUBULES BY ATOMIC FORCE MICROSCOPY (AFM)

Atomic Force Microscopy (AFM) is a powerful technique with a wide range of applications in biology, allowing not only imaging, but also different types of probing and manipulation at nanometric scale. AFM systems are becoming widely available, and new developments are reported everyday, many of them in biological research. In AFM a sharp tip (local probe) is moved over a surface at constant (van der Waals) interaction force between the tip and the surface, allowing the reconstruction of the surface topography. This measurement process can be performed in different ambient conditions, e.g., in vacuum, air, or liquid, over a broad temperature range. These characteristics and the possibility to observe features at nanometric scale in a nondestructive manner are a strong motivation for the use of AFM on biological systems. As compared to existing microscopy techniques in the same range (as electron microscopy), sample preparation is also much easier and less time-consuming, allowing one to perform measurements even on live systems (Fotiadis et al., 2002). The list of examples is now almost endless. For example, AFM

techniques have been extensively used to image the surface of cells (Dufrêne et al., 1999; Charras and Horton, 2002), nucleic acids (Pande et al., 1998; Scheuring et al., 1999), proteins (Round et al., 2002), chromosomes (Radmacher et al., 1994; Fritzsche et al., 1997), viruses (Dubrovin et al., 2007), and biomaterials (Wallwork et al., 2001). Besides being used as a powerful imaging technique, AFM shows a strong potential as a unique tool for nanometric probing of physical (e.g., elasticity or viscosity of surfaces, binding forces, strength of protein folding) and chemical properties (by using a chemically activated tip) and for precise local manipulation (Rief, et al., 1997; Sritharan et al., 1998; Raab et al., 1999; Dufrêne, 2000). It is nowadays a fundamental tool for nanomedicine (medicine approached at a molecular level) and its relevance can no longer be overlooked

Microtubules may be characterized by AFM (Ramalho et al., 2007), which permits nanometer-scale resolutions and topographic characterization of the sample, allowing one to visualize the assembled microtubules.

Here we introduce a protocol adapted from Martins et al. (2005) and Moreno-Herrero et al., (2002, 2005) describing how to adsorb microtubules on a substrate to visualize them by AFM. In this protocol, microtubules are adsorbed to mica functionalized with APTES, a silane with an amine group that is positively charged at around pH 7. Since mica is composed of layers, which can be cleaved ("peeled" off) to expose a new clean surface and, unlike more traditional glass, no preliminary washing procedures are necessary.

Materials

Mica (muscovite; SPI Supplies)
Nail polish or water-resistant glue (e.g., epoxy resin)
Silanization solution: 0.1% (v/v) 3-aminopropyl-triethoxysilane (APTES; Fluka, 96%) freshly prepared with Milli-Q water
Milli-Q water; if unavailable, bidistilled water filtered through a 0.22-μm pore filter
GTP
Paclitaxel (taxol)
Sample of purified tubulin (Basic Protocol 3)
0.1 M PIPES, pH 6.9
1 mM EGTA
1 mM $MgCl_2$
1 mM PMSF

Sharp scissors
Glass coverslips or slides
Duct tape
Micropipet
30°C thermostatic bath
AFM Si tapping mode tips (Olympus, OTESP)

Functionalize the mica

1. Use sharp scissors to cut mica squares of appropriate dimensions (2 to 5 mm) and mount them on glass coverslips or slides (for easier handling) with nail polish or water-resistant glue (e.g., epoxy resin). Remove the upper layers of the mica squares by pulling off the top layer with a piece of duct tape.

2. Immediately apply 10 μl silanization solution on the exposed surface, taking care not to spill on the sides. To complete silanization let it rest for 10 min.

   While the nail polish will secure the mica even if wet, silanization solution may still get between the mica layers and distort them.

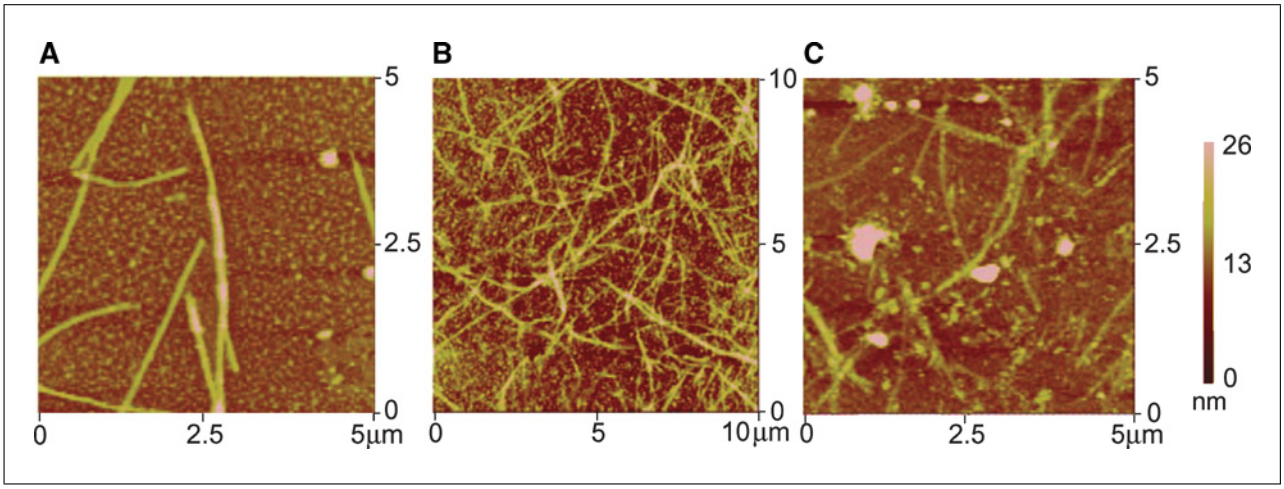

Figure 3.29.10 (**A**) AFM topography images of polymerized microtubules adsorbed to silanized mica where a few individual microtubules with a well preserved structure are easily observed. (**B**) A microtubule-rich region in the sample showing contaminant material. (**C**) Distortion of measurements due to the contaminants in a dirty sample. For color version of this figure see *http://www.currentprotocols.com*.

3. Remove the silanization solution as much as possible with a micropipet and avoid scratching the mica surface. Wash off the mica three times, each time with 10 µl of Milli-Q water and allow the mica to air dry.

   It is quite important that mica surface is maintained clean during this process in order to guarantee that environmental dust does not stick to it during the process of silanization.

Polymerize and adsorb microtubules

4. Add 2 µl of 100 mM GTP (to a final concentration of 1 mM) to 200 µl of a purified tubulin solution in 0.1 M PIPES pH 6.9, 1 mM EGTA, 1 mM $MgCl_2$, 1 mM PMSF, at 1 mg/ml on ice.

5. Transfer to a 30°C thermostatic bath and incubate for 45 min.

6. Add 4 µl of 1 mM paclitaxel (taxol) to give a final concentration of 20 µM. Incubate for another 15 min at the same temperature.

   Optionally, microtubules may be concentrated by sedimenting them at 15,000 × g for 120 min. This will usually require more than one aliquot to give a visible pellet.

   If you are not going to immediately use the assembled microtubule suspension then aliquot it in suitable volumes, promptly freeze in liquid nitrogen, and store at −80°C.

7. When appropriate, thaw the microtubule suspension by placing on ice. Apply 5 µl of the microtubule suspension on the surface of the functionalized mica. Incubate for 5 to 10 sec. Immediately carefully remove the liquid with a micropipettor.

8. Gently wash the preparation twice with 10 µl Milli-Q water. Allow remaining water to air dry and observe with AFM as soon as possible.

   Avoid touching the mica surface with the tip of the micropipet in steps 1 and 2.

   For AFM measurements we use a Dimension 31 00 (Veeco/Digital Instruments) microscope with nanoscope III a controller and silicon nitride tips (SiN_2). All samples are observed in tapping mode at atmosphere in order to minimize de-adsorption (Fig. 3.29.10).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BRB80 buffer

80 mM PIPES, pH 6.8
1 mM EGTA
1 mM $MgCl_2$
Store up to 2 months at 4°C

Buffer A, 10×

1 M MES, pH 6.7
20 mM EGTA
10 mM $MgCl_2$
Store up to 2 months at 4°C

Buffer B

0.15 M PIPES, pH 7.0 (see recipe)
2 mM EGTA
0.1 mM $MgCl_2$
Store up to 2 months at 4°C

Buffer C

0.1 M PIPES, pH 7.0 (see recipe)
2 mM EGTA
Store up to 2 months at 4°C

Buffer D

0.1 M PIPES, pH 7.0 (see recipe)
2 mM EGTA
1 M NaCl
Store up to 2 months at 4°C

EGTA, 0.5 M

Dissolve 19 g EGTA [ethylene glycol-bis-(2-aminoethyl)-N,N,N′,N′-tetraacetic acid] in 80 ml water. Titrate to pH 8 with KOH or NaOH. Adjust to a final volume of 100 ml. Store up to 2 years at room temperature.

Electrophoresis (running) buffer

0.1 M MES, pH 6.7
1 mM $MgCl_2$
1 mM EGTA

Dilute and adjust with distilled water 160 ml 0.5 M MES, pH 6.7 (see recipe), 800 µl 1 M $MgCl_2$, and 1.6 ml 0.5 M EGTA (see recipe) to 800 ml. Prepare fresh just prior to use.

GTP, 1 M

1.5 ml distilled H_2O
1 g Na_2GTP
Bring to final volume of 1.91 ml with H_2O.

Do not let stand at room temperature or at 4°C. Aliquot in small volumes and store at −80°C.

Isotonic buffer

0.32 M sucrose
1 mM EGTA
1 mM $MgCl_2$
10 mM phosphate buffer, pH 7 (*APPENDIX 2A*)
Store up to 2 months at 4°C

MES, 0.5 M, pH 6.7

Dissolve 53.3 g MES monohydrate in 400 ml water. Titrate to pH 6.7 with KOH or NaOH. Adjust to a final volume of 500 ml with water. Store up to 6 months at 4°C.

Paclitaxel, 10 mM

10 mM paclitaxel (taxol; Sigma). Prepare in DMSO. Store 50-µl aliquots at −80°C and use at final concentration of 20 µM.

PIPES, 1 M (pH 7.0)

151.2 g PIPES (free acid)
H_2O to 400 ml
Add concentrated KOH dropwise to achieve pH 7.0.
Bring to final volume of 500 ml with H_2O
Store up to 2 months at 4°C

Protease inhibitors

100 mM phenylmethylsulfonyl fluoride, (PMSF; *APPENDIX 2A*) prepare fresh, use at 1 mM, dissolve in DMSO
1000× leupeptin, prepare 1 µg/µl in Milli-Q water
1000× pepstatin A, prepare 1 µg/µl in DMSO
1000× aprotinin, 10 µg/ml in Milli-Q water (sodium azide or 0.2% Triton X-100 can be added to avoid contamination)

CAUTION: *Phenylmethylsulfonyl fluoride is toxic.*

Transfer buffer, 10×

Dissolve the following in water:
15.13 g Tris base (250 mM)
72.067 g glycine (1.92 M)
Adjust to a final volume of 500 ml with H_2O

COMMENTARY

Background Information

The generation of complex neuronal morphologies during vertebrate neurodevelopment is characterized by the production of long cytoplasmic processes known as neurites. These processes, referred to as axons and dendrites, will eventually generate a complex network of neuronal synaptic contacts. Although microtubules are universal polymers in all eukaryotic cell types, in neurons they are highly specialized and more abundant, and play crucial roles in the determination of the cell shape, being organized in long bundles within the axons and dendrites of mature neurons. Microtubules are dynamic structures in vitro, where possible regulatory factors of the process have been thoroughly studied. These investigations led to the discovery of a group of proteins that bind to tubulin "in vitro" during microtubule polymerization assays, promoting the polymerization and further stabilizing the polymer structure. These proteins are referred to as microtubule-associated proteins or MAPs. Three major families of MAPs have been identified and characterized: MAP1 (Vallee, 1990), MAP2 (Murphy et al., 1977), and tau proteins (Cleveland et al., 1977).

MAP1 proteins

The MAP1 protein family consists of two distinct, but related, polypeptides, MAP1A and MAP1B (Schoenfeld et al., 1989). MAP1A has a molecular mass of 299 kDa, whereas MAP1B has a molecular mass of 255 kDa as predicted from their respective amino acid sequences (Noble et al., 1989; Langkopf et al., 1992).

There are also three low-molecular-weight proteins associated with the microtubule-binding domains of both MAP1A and MAP1B; these are referred to as light chains: LC1 (34 kDa), LC2 (30 kDa), and LC3 (19 kDa; Schoenfeld et al., 1989).

In the mammalian brain there is a strong developmental control of the expression patterns of these MAPs. The first MAP expressed in neurons is MAP1B (Tucker et al., 1988). Immunohistochemical analyses in developing brain tissue have shown that this protein is highly concentrated in the growing axons of the developing neurons, exhibiting a more moderate expression in both axons and dendrites of mature neurons (Schoenfeld et al., 1989). Indeed, MAP1B expression is down-regulated during brain development (Binder et al., 1984; Bloom et al., 1985; Riederer et al., 1986; Tucker et al., 1989; Garner et al., 1990). On the contrary, MAP1A is more abundant in mature neurons (Bloom et al., 1984).

MAP2

There are several developmentally regulated isoforms of MAP2 arising from alternative mRNA splicing. MAP2B is a high-molecular-weight isoform which contains 1828 amino acids and has an apparent molecular mass of 270 kDa as determined by SDS-PAGE (Lewis et al., 1988). Also, MAP2A shows a slower electrophoretic mobility (Matus, 1988). There is a smaller form, referred to as MAP2C that contains 467 amino acids and has an apparent molecular mass of 70 kDa as determined by SDS-PAGE. MAP2B is a neuron-specific phosphoprotein which is selectively localized in the cell bodies and dendrites (Caceres et al., 1984; Huber and Matus, 1984). MAP2C is expressed perinatally in rats, coincident with the period of maximal dendritic outgrowth and synaptogenesis (Riederer and Matus, 1985). There is an additional MAP2 isoform which is more abundant in glial cells named MAP2D (Doll et al., 1993).

Tau

There are several tau proteins with apparent molecular masses ranging from 55 kDa to 68 kDa (as determined by SDS-PAGE); they are found in the central nervous system (Weingarten et al., 1975). This large number of tau isoforms is generated by alternative splicing from a primary transcript (Himmler et al., 1989; Goedert et al., 1992). Based on their domain characteristics, two classes of tau isoforms have been described. One class contains three tubulin-binding motifs that are predominantly expressed in the developing brain; a second class contains four motifs and is mostly expressed in the adult brain (Kosik et al., 1989; Goedert et al., 1991).

An additional tau isoform, with an apparent molecular mass of 110 kDa, has also been identified in the peripheral nervous system (Georgieff et al., 1991). This high-molecular-weight tau contains four repeated motifs in its microtubule-binding domain; it is similar to the adult brain tau isoform but has an additional insertion of 254 amino acids in its amino-terminal region (Goedert et al., 1991; Couchie et al., 1992).

Critical Parameters and Troubleshooting

Our experience suggests that, although a higher yield of microtubule proteins is usually obtained from porcine brain tissue, cow brains do also give good tubulin yields. Tubulin has traditionally been considered an extremely labile protein that becomes noncompetent for polymerization if left on ice for long periods of time. However, as Figure 3.29.9 shows, tubulin is a stable dimer for >4 hr at room temperature in MES buffer at pH 6.7 (at a concentration as low as 0.6 μg/μl, with no magnesium ions or GTP added). In fact, the tubulin dimer becomes unstable only after 18 hr or longer incubation periods. Our experience also shows that tubulin can be stored at temperatures between −70 and −80°C. Regarding the size of the preparation, we usually prepare medium-scale tubulin preparations. This guarantees a faster protein extract preparation, which is key to preserving a good-quality tubulin, as explained in the Time Considerations section. The intermediate-step tubulin aliquots obtained can be fast-frozen and stored at −80°C instead of in liquid nitrogen. For each experiment, appropriate-size aliquots can be thawed, mixed well by flicking, and centrifuged 20 min at 20,000 × *g*, 4°C, before use, to discard insoluble material. Although repeated freezing and thawing of aliquots is not recommended, we find that tubulin will still work fine in freeze-thawed aliquots. Another

crucial point to obtaining a good homogenate when isolating tubulin from brain extracts is not to destroy the tissue excessively. The use of a classical blender, even at low speed, is not recommended since vigorous homogenization leads to the formation of aggregates that persist during the purification. Moreover, this procedure also provokes the formation of tubulin aggregates. We recommend the use of a Polytron set at low speed, or just a Teflon-in-glass homogenizer at 2,000 rpm for 5 to 10 sec, with the pestle moving up and down the homogenizer. A commercial drill adapted as a homogenizer is a cheaper alternative.

Preparation of microtubule samples for AFM entails adsorption onto an adequate substrate (positively charged) and washing off the buffer as much as possible in order to avoid artifacts resulting from salt crystallization. Otherwise, salt crystals will rapidly grow over the mica surface after the microtubule suspension has dried, completely impairing the AFM measurements. Washes must be carefully performed to avoid microtubule damage or removal from the surface. So, drop and remove water from the surfaces containing microtubules during washes.

Since microtubules are adsorbed to mica functionalized with APTES, the time of incubation of microtubules on the functionalized mica is one of the most important parameters in this method. Longer incubation times tend to yield "dirty" samples due to the adsorption onto the surface of nonpolymerized tubulin and other contaminants (even if they are scarce in the sample). On the other hand, shorter incubation times will result in sparser distributions of microtubules on the surface, allowing a better visualization. The more microtubules are adsorbed onto the surface, the more difficult it will be to observe detailed features. Incubation times of 5 to 10 sec will usually give good results with microtubules polymerized from ~1 mg/ml brain tubulin solution. However, longer times may be necessary for lower concentrations. Attention should also be paid to the concentration of microtubules in suspension, since an increase in polymer concentration would lead to aggregation and microtubule bundle formation.

Anticipated Results

The cytosolic extract obtained after the first centrifugation of the isolation procedure of microtubule proteins usually contains a protein concentration in the range of 20 to 40 mg/ml of protein and ~4 to 8 mg/ml of tubulin. Phosphocellulose-FPLC chromatography purified bovine brain tubulin should give a single band upon electrophoresis under native conditions—in the presence of GTP—which serves as a reference marker for native tubulin heterodimers. The amount of tubulin in this unique band is extremely useful to quantify the amount of tubulin dimers capable of polymerization. Proteins that have denatured or aggregated during these purification steps will remain at, or close to, the origin of the native gel (Fig 3.29.9). Therefore, this type of electrophoresis will serve to estimate the amount of tubulin that should be used in any other experiment requiring native tubulin. The use of GTP during native gel electrophoresis is critical for this type of analysis. In the absence of GTP we have found that the intensity of the native tubulin heterodimer band decreases, indicating that tubulin dimers have became unstable in the absence of GTP. This could be due to denaturation of the β-tubulin that loses GTP during the running of native gel electrophoresis in the absence of this nucleotide (Zabala and Cowan, 1992). Be aware that ATP (used instead of GTP for actin) cannot replace GTP in this type of electrophoresis.

There are a number of different gel staining protocols that can be used (*UNIT 6.6*). Coomassie blue or silver staining are the usual ways to detect tubulin depending on the amount of sample loaded on the gel. Protein in these gels can also be transferred to nitrocellulose or PVDF membranes prior to antibody detection by immunoblots (*UNIT 6.2*). In this case, a typical transfer buffer without methanol should be used.

In vitro polymerized microtubule samples observed by AFM are typically heterogeneous. These samples will characteristically present areas with fewer microtubules, but also fewer interfering contaminants (Fig. 3.29.10A), along with areas denser in microtubules but presenting more contaminants (Fig. 3.29.10B) or areas with many amorphous structures (precipitates from the microtubule solution) that will make the analysis more difficult (Fig.3.29.10C). Denser areas, as well as bundles of microtubules, and generally more contaminants, are often observed in samples prepared from more concentrated microtubule solutions. On the other hand, concentrations lower than those recommended will result in very scattered samples where microtubules may be difficult to find.

Time Considerations

The most critical step in the tubulin protein purification protocol is the time spent from the

time of slaughter to the end of the first microtubule polymerization. It is crucial to obtain brains of freshly sacrificed animals and to remove the skulls as soon as possible. These must be immediately stored at 4°C wrapped in plastic bags or similar wrapping material, to avoid direct contact with ice. The brain cytosolic protein extract should be prepared as soon as possible. Everything needed for the isolation/purification procedure should be already prepared in the laboratory. In the same way, extreme care should be taken to avoid any delay in washing and cleaning the brains.

For AFM, waiting periods for sample drying should typically be of 0.5 to 1 hr, depending on room temperature and humidity. For reproducibility, microtubule incubation times must be carefully observed, even if chosen times differ from those detailed in this protocol. Nonetheless, this procedure should take a maximum of 4 hr. Similarly, samples must be observed with AFM as soon as microtubules are adsorbed to functionalized mica, thus avoiding artifacts caused by dust or degradation. Samples can be kept for at least a week at 4°C (in a sealed container) although some degradation and contamination can occur.

Purification of Intact Chloroplasts from *Arabidopsis* and Spinach Leaves by Isopycnic Centrifugation

Daphné Seigneurin-Berny,[1] Daniel Salvi,[1] Jacques Joyard,[1] and Norbert Rolland[1]

[1]Laboratoire de Physiologie Cellulaire Végétale, CNRS and Université Joseph Fourier, Grenoble, France

ABSTRACT

Chloroplasts are plant-specific organelles. They are the site of photosynthesis but also of many other essential metabolic pathways, such as syntheses of amino acids, vitamins, lipids, and pigments. This unit describes the isolation and purification of chloroplasts from *Arabidopsis* and spinach leaves. Differential centrifugation is first used to obtain a suspension enriched in chloroplasts (crude chloroplasts extract). In a second step, Percoll density gradient centrifugation is used to recover pure and intact chloroplasts. The Basic Protocol describes the purification of chloroplasts from *Arabidopsis* leaves. This small flowering plant is now widely used as a model organism in plant biology as it offers important advantages for basic research in genetics and molecular biology. The Alternate Protocol describes the purification of chloroplasts from spinach leaves. Spinach, easily available all through the year, remains a model of choice for the large-scale preparation of pure chloroplasts with a high degree of intactness. *Curr. Protoc. Cell Biol.* 40:3.30.1-3.30.14. © 2008 by John Wiley & Sons, Inc.

INTRODUCTION

Plastids are semiautonomous organelles found in plants and some protists. In plant leaves, plastids are photosynthetically active and named chloroplasts. They are also the site of essential metabolic pathways, such as syntheses of amino acids, vitamins, lipids, and pigments (Wise and Hoober, 2006). Biochemical, physiological, and proteomic analyses of the chloroplast can only be achieved using pure and intact chloroplasts that have conserved their metabolic activities and functional surrounding envelope membranes (Block et al., 2007). Localized at the interface between the plastid stroma and the cytosol, the envelope membranes have to remain intact to allow, for instance, physiological characterization of the various transport systems regulating plastid metabolism. Therefore, the isolation of pure and intact organelles becomes essential when characterization of plastid functions is expected. The procedure described here couples differential centrifugation to obtain a crude extract of chloroplasts with isopycnic centrifugation (Percoll-based density gradients) to recover pure and intact chloroplasts.

The Basic Protocol describes the step-by-step purification procedure to isolate chloroplasts from *Arabidopsis* leaves. Since the complete sequencing of its genome (The AGI, 2000), *Arabidopsis thaliana*, a small flowering plant, has become a widely used model organism in plant biology. The generation of large collections of insertion mutants, together with growing numbers of gene expression databases, offer important advantages for basic research in genetics and molecular biology. This Basic Protocol, to isolate chloroplasts from *Arabidopsis thaliana*, is provided with some tricks to optimize yield and purity. Conditions to grow *Arabidopsis* plants suitable for chloroplast isolation are also described in the Support Protocol.

Current Protocols in Cell Biology 3.30.1-3.30.14, September 2008

DOI: 10.1002/0471143030.cb0330s40

The Alternate Protocol describes the purification of chloroplasts from spinach (*Spinacia oleracea* L.) leaves. Due to its almost permanent availability in markets, this plant remains a traditional model plant for physiologists and biochemists. Spinach also contains low levels of phenolics and other inhibitory compounds (prevalent in numerous cultivated species), and thus is a good choice to easily obtain fully competent CO_2-fixing chloroplasts. Finally, the Alternate Protocol allows isolating large amounts of pure and intact chloroplasts.

BASIC PROTOCOL

ISOLATION OF PURE AND INTACT CHLOROPLASTS FROM *ARABIDOPSIS* LEAVES

The chloroplast is, in general, an extremely fragile structure. Thus, skill and expertise are required in order to avoid large-scale rupture of the two envelope membranes during chloroplast isolation. The media used throughout the procedure must contain an osmoticum (0.4 M sorbitol for *Arabidopsis* chloroplast) to avoid osmotic shock and thus, disruption of the organelles. The homogenization of the tissue is another critical step. The grinding process must be as short as possible. Longer blending, while apparently strongly improving the yield of recovered chlorophyll, rapidly increases the proportion of broken chloroplasts in the crude cell extract and strongly affects further purification steps. Filtration of the homogenate then allows limiting contamination with cellular debris and unbroken cells. A first centrifugation allows obtaining a crude chloroplast suspension. Intact chloroplasts are then purified by isopycnic centrifugation on preformed continuous Percoll gradients. The outline of the strategy is described in Figure 3.30.1.

Materials

Percoll gradients solution (see recipe)
Four to six boxes containing 3- to 4-week-old *Arabidopsis* plantlets (400 to 500 g of rosette material, see Support Protocol)
Grinding medium (see recipe)
Washing medium (see recipe)
80% (v/v) acetone

50-ml polypropylene tubes
Superspeed refrigerated centrifuge (e.g., Sorvall RC5), with the following rotors and corresponding tubes: fixed angle rotors GS-3 with six 500-ml plastic bottles and SS34 with eight 50-ml polypropylene tubes; swinging bucket rotor HB-6 with six 50-ml polycarbonate tubes or equivalent
1000-ml and 5-liter beakers
Ice and ice buckets
Motor-driven blender, 3 speeds, 1 gallon (3.785 liter; e.g., Waring blender)
Muslin or cheesecloth, 80-cm
Nylon blutex (50-μm aperture; Tripette et Renaud)
Pasteur pipet
Vacuum aspirator with a flask as a liquid trap
Curved plastic spatula
1- and 10-ml pipets
1-ml microcentrifuge tube
Vortex
1-ml spectrophotometer glass cuvette
UV spectrophotometer

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout.

NOTE: All operations are carried out at 0° to 5°C either by keeping samples on ice or by working in a cold room.

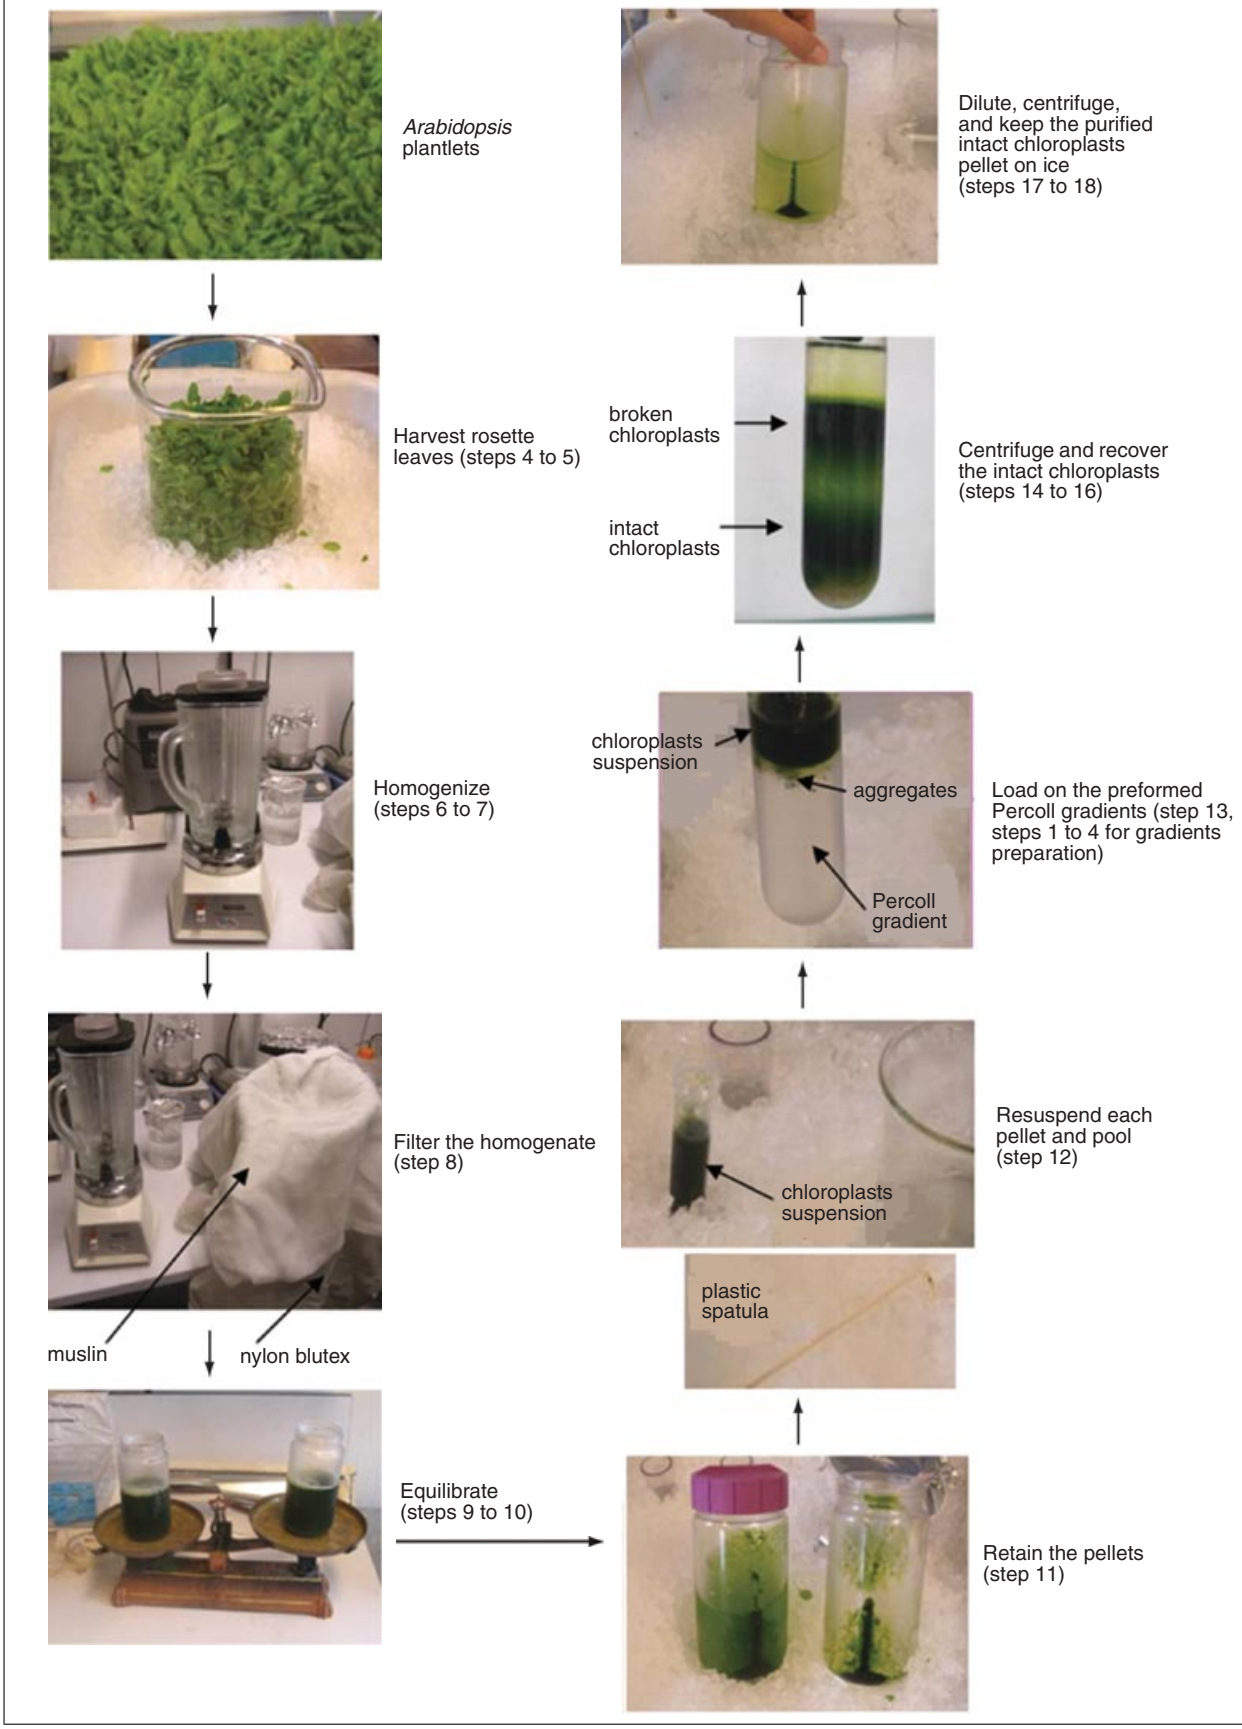

Figure 3.30.1 Outline of the strategy used to purify intact chloroplasts from *Arabidopsis* leaves. For color version of this figure see *http://www.currentprotocols.com*.

Prepare preformed continuous Percoll gradient

1. Prior to the experiment, prepare six 50-ml polypropylene tubes containing 30 ml Percoll gradients solution.

2. Preform Percoll gradients for chloroplast purification by centrifuging 55 min at 38,700 × *g* (Sorvall SS-34 rotor), 4°C.

   Vertical rotors can easily be used to obtain preformed Percoll gradients and subsequently purify chloroplasts (Douce and Joyard, 1982). It is recommended that the brake be disconnected or that the automatic rate controller (if available) of the centrifuge be used to prevent mixing of the gradients at the critical stage of deceleration.

3. Store the tubes containing preformed continuous Percoll gradients in the cold room until use.

   Percoll gradient can be prepared 1 or 2 days before the experiment.

Prepare Arabidopsis leaves and homogenize the tissue

4. Harvest 400 to 500 g of rosette leaves from boxes containing 3- to 4-week-old *Arabidopsis* plantlets.

   It is tempting to start from large amounts of material (huge rosettes with large leaves). It however appears that staring from younger leaves (3- to 4-week-old) improves yield, purity, and integrity of the purified organelles.

   The number of starch granules present in chloroplasts is critical for the preparation of intact chloroplasts: chloroplasts containing large starch grains will usually be broken during centrifugation (Douce and Joyard, 1982). Therefore, prior to the experiment, the plants should be kept for several hours in a dark and cold room (4°C) to reduce the amount of starch. A good way to proceed is to place the plants under such conditions the day before the extraction (we usually perform this at the beginning of the afternoon prior to the day of the experiment).

5. Preweigh a 1000-ml beaker, cool the beaker on ice, then place the rosette leaves inside the beaker. Reweigh the beaker and record the tissue weight. Transfer the beaker to a cold room for the next steps.

6. Put the leaf material and enough leaf grinding buffer (with BSA) to cover the leaves (usually ~2 liters of grinding medium for 400 to 500 g leaves) in the blender cup.

   The buffer to tissue ratio is 4 ml/g.

   A minimum of 60 g of leaves is required to obtain intact and purified chloroplasts.

7. Homogenize the leaf material three times, each time 2 sec in a Waring blender at high speed (see Video 1 at *http://www.currentprotocols.com*).

   The grinding process should be as short as possible. Longer blending improves the yield of recovered chlorophyll, but increases the proportion of broken chloroplasts in the homogenate, and then affects further purification steps.

8. Rapidly filter the homogenate through 4 to 5 layers of muslin and one layer of nylon blutex that line the inside of a precooled funnel placed over a 5-liter beaker. Collect the filtered homogenate in the beaker below the funnel. Gently squeeze the homogenate leaves inside the muslin/nylon blutex bag (see Video 1 at *http://www.currentprotocols.com*), to extract all the liquid.

   The filtration process should also be rapidly performed. After the grinding process, organelles are released in a crude extract consisting of broken cells, having released some very aggressive compounds (e.g., proteases, lipases, and phenolic compounds). Storing the organelles for too long in such a homogenate strongly affects their integrity and functioning. A short delay between grinding (step 7) and concentration (step 10) is thus expected to improve yield of intact chloroplasts.

9. Put the remaining tissue in the blender cup with enough grinding buffer to cover the tissue, and repeat steps 7 and 8. Collect the filtered homogenate in the same beaker.

Centrifuge the homogenate

10. Equally distribute the filtered suspension into six 500-ml bottles for centrifugation and centrifuge them 2 min at 2070 × *g* (Sorvall GS-3 rotor), 4°C.

    Do not forget to equilibrate the pairs of bottles on a balance prior to centrifugation.

11. Carefully discard the supernatant from each tube, retaining the pellets (pour out the liquid holding the tube with the pellet on the top of the tube; see Video 1 at *http://www.currentprotocols.com*). Remove the remaining supernatant with a Pasteur pipet connected to a vacuum aspirator with a flask as a liquid trap. Keep the pellets on ice.

    These pellets contain crude chloroplast fractions.

Purify the chloroplasts

12. Carefully resuspend each pellet, representing crude chloroplast fraction, by adding a minimal volume of washing medium using a curved plastic spatula (see Video 1 at *http://www.currentprotocols.com*).

    Use a 10-ml pipet to add 2 to 3 ml of washing medium in each tube. Carefully resuspend each pellet and gently aspirate the resuspended chloroplasts with a 10-ml pipet (do not use pipets with very fine tips, to limit mechanical breaking of the organelles).

    In order to homogenize chloroplast aggregates found in the bottom of the tube, carefully mix the suspension.

13. Pool the resuspended chloroplasts in one tube. Rinse each tube with additional washing medium.

    The final volume should not exceed 36 ml.

14. Load the crude chloroplast suspension on the top of the six preformed Percoll gradients (6 ml per tube).

    For this step, carefully tilt the Percoll gradient tube and load the chloroplast suspension very slowly, trying not to mix the chloroplast suspension with the upper Percoll layer. Again, do not use pipets with too fine tips.

15. Centrifuge the gradients 10 min at 13,300 × *g* (Sorvall swinging HB-6 rotor), 4°C. Carefully remove the upper part of the gradient containing the broken chloroplasts (Fig. 3.30.1) by aspirating with a Pasteur pipet connected to a vacuum aspirator with a flask as a water trap (see Video 1 at *http://www.currentprotocols.com*).

    It is recommended the brake be disconnected or that the automatic rate controller (if available) be used to prevent mixing of the gradients at the critical stage of deceleration.

16. Recover intact chloroplasts (a broad dark green band in the lower part of the gradient) with a 10-ml pipet. Gently pool the intact chloroplasts in a 500-ml plastic bottle.

    Broken chloroplasts are present in the upper part as a broad band. A small pellet containing cell pieces and large debris is found at the bottom of the tube. To limit cross-contamination with other cell fractions, do not aspirate this debris with the intact chloroplasts.

17. Dilute the chloroplast suspension 3- to 4-fold (up to a final volume of 500 ml) with 200 to 300 ml washing medium. Centrifuge the suspension 2 min at 2070 × *g* (Sorvall GS-3 rotor), 4°C.

18. Discard the supernatant and keep the purified intact chloroplasts pellet on ice.

    At this stage, the yield of intact chloroplasts is 50 to 60 mg protein.

19. Before use, add a minimal volume (~1 ml) of washing medium, or any other buffer containing an osmoticum, to resuspend the purified chloroplasts. Keep the purified chloroplast as a concentrated suspension on ice.

The excellent purity of the Arabidopsis chloroplasts prepared by the Percoll purification step was confirmed using immunological detection of marker enzymes from other subcellular compartments (Seigneurin-Berny et al., 2006). It is worth mentioning that mitochondrial and plasma membrane markers were not detected in the Percoll-purified Arabidopsis chloroplasts. This is also in good agreement with proteomic analyses, which demonstrated that only 5% (6 out of 112) of the Arabidopsis proteins identified in purified chloroplast envelope membranes (Ferro et al., 2003) may correspond to nonplastid proteins. Among them, only one protein appeared to correspond to a previously characterized major plasma membrane component; four proteins may indicate contamination by major tonoplast proteins, and one from glyoxysomes. Considering the high sensitivity of present mass spectrometers it is not surprising to detect minute amounts of these few extra-plastidial contaminants, which are major proteins in their respective subcellular compartments.

Quantify chlorophyll content

20. Quantify the chlorophyll content according to Bruinsma (1961). Add 10 µl of the purified chloroplasts to 1 ml 80% (v/v) acetone in a 1-ml microcentrifuge tube.

21. Vortex the mixture, incubate on ice and in the dark for 15 min, and centrifuge 15 sec at 16000 × *g*, 4°C.

22. Pour in a 1-ml spectrophotometer glass cuvette. Measure the absorbance at 652 nm against a tube containing 80% (v/v) acetone for the zero.

A ratio of $OD_{652}/36 = 1$ corresponds to 1 mg chlorophyll ml^{-1}.

23. Determine integrity of the organelle preparation.

In addition to morphological analysis by microscopy, the integrity of the purified chloroplasts can be confirmed using an oxygen electrode and performing the ferricyanide test for intactness (Walker, 1990). When lacking microscopy or oxygen electrode facilities, a simple way to estimate the integrity of the purified chloroplasts relies on the use of an SDS-PAGE analysis. This method relies on the demonstration that soluble proteins from the stroma are not lost during the purification procedure (Fig. 3.30.2). A protein profile obtained from pure and intact chloroplast preparations reveals that the amount of major soluble protein (RbcL or RubisCO) from the stroma is higher than the amount of the major thylakoid membrane proteins (LHCPs or Light Harvesting Complex Proteins). When broken chloroplasts are analyzed, and due to the loss of soluble proteins resulting from the breakage of the limiting envelope membranes, the ratio of RbcL/LHCPs is strongly reduced. This is illustrated in the Fig. 3.30.2, using broken or intact chloroplasts as obtained, respectively, from upper and lower layers of the Percoll-density gradient.

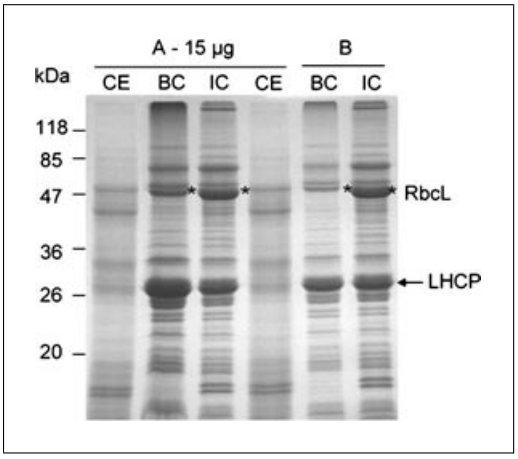

Figure 3.30.2 SDS-PAGE analysis of Percoll-purified chloroplasts from *Arabidopsis*. Fractions (15 µg protein) were analyzed on a 12% SDS-PAGE followed by Coomassie-blue staining. In lanes B, the amount of protein was calculated in order to load the same amount of LHCP in the two lanes of the gel. The star and the arrow respectively indicate the major soluble protein from the stroma, RbcL, and the major membrane proteins from the thylakoids, the LHCPs. Note that the ratio of RbcL/LHCPs is strongly reduced in broken chloroplasts, as a consequence of breakage of the limiting envelope membranes and thus of loss of soluble proteins from the stroma. Abbreviations: CE: crude extract, BC: broken chloroplasts, IC: intact chloroplasts.

ISOLATION OF PURE AND INTACT CHLOROPLASTS FROM SPINACH LEAVES

ALTERNATE PROTOCOL

Spinach leaves remain a tissue of choice for the preparation of chloroplasts with a high degree of intactness. They can be obtained in large amount from markets all through the year, and thus do not require plant growth facilities. Furthermore, chloroplasts isolated from spinach leaves are less fragile than chloroplasts purified from *Arabidopsis* leaves, and due to the unlimited availability of starting material, large amounts of chloroplasts can be obtained daily. Several important differences exist between the protocols used to purify spinach or *Arabidopsis* (Basic Protocol) chloroplasts. First, as starting material can be obtained in large amount, volumes of buffers or numbers of bottles and tubes need to be adapted. Second, the composition of buffers varies (the osmoticum used is sucrose instead of sorbitol). Finally, and as another difference between the two protocols described here, spinach chloroplasts are purified on a discontinuous Percoll gradient (Douce and Joyard, 1982) instead of preformed continuous Percoll gradient.

Materials

3 kg of spinach leaves from the market
Spinach leaf grinding medium (see recipe)
Ice
Spinach washing medium (see recipe)
40% (v/v) Percoll and 80% (v/v) Percoll solutions (see recipes)

Motor-driven blender, 3 speeds, 1 gallon (3.785 liter; Waring blender)
Muslin or cheesecloth, 80-cm
Nylon blutex (50-μm aperture; Tripette et Renaud)
5-liter beakers
Superspeed refrigerated centrifuge (Sorvall RC5), with the following rotors and corresponding tubes: fixed angle rotors GS-3 with six 500-ml plastic bottles and SS34 with eight 50-ml polypropylene tubes; swinging bucket rotor HS-4 with four 150-ml polycarbonate tubes or equivalent
Pasteur pipet
Vacuum aspirator with a flask as a liquid trap
Ice buckets
Curved plastic spatula
1- and 10-ml pipets
250-ml cylinder

NOTE: All solutions, glassware, centrifuge tubes, and equipment should be precooled to 0° to 4°C and kept on ice throughout.

NOTE: All operations are carried out at 0° to 5°C either by keeping samples on ice or by working in a cold room.

Prepare spinach leaves and homogenize the tissue

1. Wash the spinach leaves and then remove large veins from the leaves. Strain the leaves and store them in the dark and in a cold room (4°C) overnight.

   The overnight storage in the dark reduces the amount of starch granules in the spinach leaves (as for Arabidopsis leaves).

2. Put the leaf material and enough spinach leaf grinding buffer (with BSA) to cover the leaves (usually ~3 liters of spinach leaf grinding medium for 3 kg leaves) in the blender cup.

3. Homogenize the leaf material two times, each time 2 to 3 sec in a Waring blender at low speed and a third time (2 to 3 sec) at high speed.

   The grinding process should be as short as possible (see Basic Protocol, step 7).

4. Rapidly filter the homogenate through 4 to 5 layers of muslin and one layer of nylon blutex as described in Basic Protocol, step 8. Collect the filtered homogenate in a 5-liter beaker.

   Proceed rapidly.

Centrifuge the homogenate

5. Equally distribute the filtered suspension into 500-ml bottles for centrifugation and centrifuge them 10 min at 1200 × *g* (Sorvall GS-3 rotor), 4°C.

   Do not forget to equilibrate the pairs of bottles on a balance.

6. Carefully discard the supernatant from each bottle, retaining the pellets. Remove the remaining supernatant with a Pasteur pipet connected to a vacuum aspirator with a flask as a liquid trap. Keep the pellets on ice.

   These pellets contain crude chloroplast fraction.

Purify the chloroplasts by isopycnic centrifugation

7. Carefully resuspend each pellet, containing a crude chloroplast fraction, by adding 10 ml spinach washing medium using a curved plastic spatula.

   Carefully resuspend each pellet and gently aspirate the resuspended chloroplasts with a 10-ml pipet (do not use pipets with very fine tips).

8. Pool the chloroplast suspension in one tube. Rinse all tubes with additional spinach washing medium.

   The final volume should not exceed 200 ml.

9. Filter the crude chloroplast suspension through one layer of nylon blutex in order to separate the aggregates, and adjust the final volume to 200 ml with spinach washing buffer using a 250-ml cylinder.

10. Prepare the discontinuous Percoll gradients by successively layering 20 ml of 80% and 50 ml of 40% Percoll solutions in four separate 150-ml polycarbonate tubes.

11. Load the crude chloroplast suspension on the top of the discontinuous Percoll gradients (50 ml per tube).

    Carefully layer the chloroplast suspension on the top of the gradients trying not to mix the chloroplast suspension with the upper Percoll layer. Again, do not use pipets with too fine tips.

12. Centrifuge the gradients 20 min at 3000 × *g* (Sorvall swinging-bucket HS-4 rotor), 4°C.

    Intact chloroplasts are recovered at the bottom interface (80%/40% Percoll) and broken chloroplasts + extrachloroplastic membrane systems form a band at the upper interface (sample/40% Percoll; Fig. 3.30.3).

    It is recommended that the brake be disconnected or that the automatic rate controller (if available) be used to prevent mixing of the gradients at the critical stage of deceleration.

13. Carefully remove the upper part of the gradient containing the broken chloroplasts by aspirating with a Pasteur pipet connected to a vacuum aspirator with a flask as a liquid trap.

14. Recover intact chloroplasts (at the interface 80%/40% Percoll) with a 10-ml pipet. Gently pool the intact chloroplasts in a 500-ml plastic bottle.

15. Dilute the chloroplast suspension 3- to 4-fold (up to a final volume of 500 ml) with the spinach washing medium (500 ml final). Centrifuge the suspension 5 min at 4000 × *g* (Sorvall GS-3 rotor), 4°C.

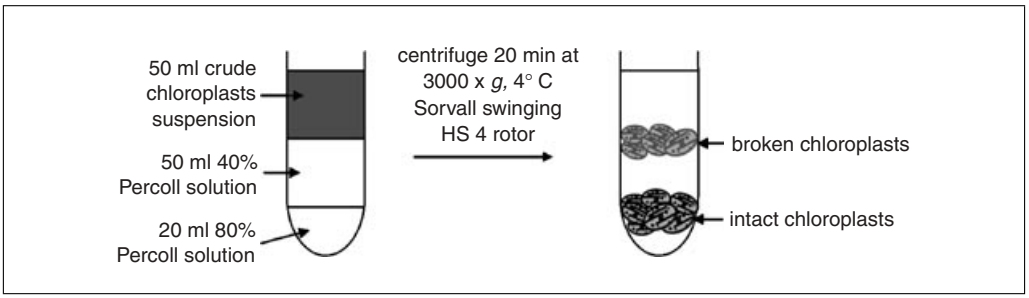

Figure 3.30.3 Schematic representation of the discontinuous Percoll-gradient fractionation of the crude spinach chloroplasts preparation to yield intact and broken chloroplasts.

16. Carefully discard the supernatant and repeat the wash step. Gently resuspend the purified pellet with 150 ml of spinach washing medium and equally distribute the suspension in 50-ml polypropylene tubes.
17. Centrifuge 5 min at 3000 × *g* (Sorvall SS34 rotor), 4°C.
18. Discard the supernatant and keep the pellet (purified intact chloroplasts) on ice.

At this stage, the yield of intact spinach chloroplasts is 150 to 200 mg chlorophyll or 2.5 to 4 g proteins.

After this purification step, the chloroplast preparation is devoid of enzymatic activities such as NADH:cytochrome c oxidoreductase, fumarase, catalase, glycolate oxidase, or nitrate reductase, indicating that it is essentially free of contamination by endoplasmic reticulum, mitochondria, peroxisomes, or cytoplasmic proteins.

Integrity of the chloroplast obtained is determined by phase contrast microscopy (Douce and Joyard, 1982), using an oxygen electrode and the ferricyanide test for intactness (Walker, 1990), or by SDS-PAGE analysis (Fig. 3.30.2).

GROWING OF *ARABIDOPSIS* PLANTLETS

SUPPORT PROTOCOL

Rosette leaves from 3- to 4-week-old *Arabidopsis thaliana* plantlets are required for isolation of the chloroplasts.

Materials

Arabidopsis thaliana seeds
Compost

Large plastic cases (30-cm × 45-cm)
Growth rooms

1. Fill large (30-cm × 45-cm) plastic cases with compost and water.
2. Sow seeds onto the surface of the compost by scattering them carefully at a high density (~30 mg of seeds for a whole box).
3. Grow *A. thaliana* plantlets in growth rooms with a 12-hr light cycle at 23°C (day)/18°C (night) with a light intensity of 150 μmol.m^{-2}sec^{-1}.

Four to six boxes containing 3- to 4-week-old Arabidopsis plantlets are expected to provide 400 to 500 g of rosette material.

4. Harvest the rosette leaves when they are ~1 to 2 cm (~3 to 4-week-old).

The chloroplasts purification procedure described in this unit was applied efficiently to both Columbia and Wassilewskija ecotypes of Arabidopsis.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

EDTA, pH 8

104.05 g EDTA (0.5 M final)
Adjust pH to 8 using NaOH
Add H_2O to 500 ml
Store up to 6 months at 4°C

Grinding medium

291.5 g sorbitol (0.4 M final)
80 ml 1 M Tricine buffer, pH 8.4 (20 mM final; see recipe)
80 ml 0.5 M EDTA, pH 8 (10 mM final; see recipe)
3.36 g $NaHCO_3$ (10 mM final)
Adjust to pH 8.4 using NaOH
Add H_2O to 4 liters
Store up to 1 to 2 days at 4°C
Add 4 g BSA (0.1% w/v) just before use

MOPS buffer, pH 7.8

41.85 g MOPS (1 M final)
Adjust to pH 7.8 using NaOH
Add H_2O to 200 ml
Store up to 6 months at 4°C

Percoll gradients solution

Mix 1 vol of Percoll with 1 vol of 2× washing medium stock solution (see recipe) to obtain a 50% (v/v) Percoll/0.4 M sorbitol solution.

Percoll solution, 40% (v/v)

20.6 g sucrose (0.33 M final)
80 ml Percoll (Pharmacia; 40% v/v final)
2 ml 1 M MOPS (10 mM final; see recipe)
Adjust to pH 7.8 using NaOH
Add H_2O to 200 ml
Store up to 1 to 2 days at 4°C

Percoll solution, 80% (v/v)

10.3 g sucrose (0.33 M final)
80 ml Percoll (80% v/v final)
1 ml 1 M MOPS (10 mM final; see recipe)
Adjust to pH 7.8 using NaOH
Add H_2O to 100 ml
Store up to 1 to 2 days at 4°C

Spinach leaf grinding medium

451 g sucrose (0.33 M final)
30 g pyrophosphate (30 mM final)
Adjust to pH 7.8 using NaOH
Add H_2O to 4 liters
Store up to 1 to 2 days at 4°C
Add 4 g BSA (0.1% w/v final) just before use

Spinach washing medium

112 g sucrose (0.33 M final)
20 ml 1 M MOPS (20 mM final; see recipe)
Adjust to pH 7.8 using NaOH
Add H_2O to 1 liter
Store up to 1 to 2 days at 4°C

Tricine buffer, pH 7.6

89.6 g Tricine (1 M final)
Adjust to pH 7.6 with KOH
Add H_2O to 500 ml
Store up to 6 months at 4°C

Tricine buffer pH 8.4

89.6 g Tricine (1 M final)
Adjust to pH 8.4 with KOH
Add H_2O to 500 ml
Store up to 6 months at 4°C

Washing medium

2× stock solution:
73 g sorbitol (0.8 M final)
20 ml 1 M Tricine buffer, pH 7.6 (40 mM final; see recipe)
5 ml 1 M $MgCl_2$ (5 mM final)
5 ml 0.5 M EDTA, pH 8 (2.5 mM final; see recipe)
Adjust to pH 7.6 using NaOH
Add H_2O to 500 ml
Store up to 1 to 2 days at 4°C

1× working solution:
Add 100 ml of 2× washing medium stock (see recipe) solution to 100 ml distilled water.

The final concentrations in the working solution are 0.4 M sorbitol, 20 mM Tricine, 2.5 mM $MgCl_2$, and 1.25 mM EDTA.

COMMENTARY

Background Information

The development of methods for the isolation of functional chloroplasts from plant tissue has been a long process, starting from the late 1930s when Robert Hill prepared chloroplast fractions shown to evolve oxygen in presence of an artificial oxidant, but not in presence of CO_2 (Hill, 1937, 1939). For a long time, chloroplast preparation was restricted to the isolation of green particles capable of supporting the Hill reaction. Arnon and coworkers (for instance Arnon et al., 1954; Allen et al., 1955) demonstrated CO_2-dependent O_2 evolution by chloroplast suspension, but the rates were considerably lower than those of intact leaves. It is only when the importance of maintaining chloroplast integrity throughout the preparation process was fully recognized that preparations showing high rates of CO_2-dependent O_2 evolution were obtained (Walker, 1964; Kalberer et al., 1967; Walker and Hill, 1967; Walker, 1971). Indeed, the use of sugar as an osmoticum (as suggested initially by Hill) together with a very brief homogenization and rapid separation allowed the isolation of chloroplasts with an intact envelope (Walker, 1964). Furthermore, Jensen and Bassham (1966) significantly improved the medium, especially the buffer, used for chloroplast isolation. Thus, in the late 1960s, methods to prepare physiologically active chloroplasts by differential centrifugation were widely available. Indeed, such chloroplast preparations paved the way for an extensive characterization of metabolite transport and mechanisms across the envelope membranes, studies of protein,

and lipid synthesis. For instance, Heber and Santarius (1970) demonstrated the exchange of ATP and ADP across the chloroplast envelope, whereas Heldt and Sauer (1971) identified the inner chloroplast envelope membrane as the site of specific metabolite transport. One should also mention the parallel development of non-aqueous methods to prepare chloroplast (for example, see Stocking, 1959), with the aim of analyzing the intracellular distribution of water-soluble molecules between plastids and the cytosol. Despite their interest, the development of such procedures remained limited.

Although physiologically and structurally intact, chloroplast fractions prepared by differential centrifugation were actually rather crude since they contained pieces derived from other cell compartments (e.g., nuclei and mitochondria) and even a few intact cells. The next step was therefore to remove these contaminants and prepare chloroplasts as pure as possible. Sucrose was first used for preparing gradients to separate chloroplasts (Leech, 1964), and then various media like colloidal silica-derived compounds (such as Ludox) were developed (for example, see Morgenthaler and Price, 1974). Unfortunately, chloroplasts purified on sucrose gradients were unable to perform CO_2-dependent oxygen evolution, mostly because the envelope became leaky during the course of the centrifugation at a high sucrose concentration. Actually, the development of Percoll (review by Pertoft, 2000) was the major breakthrough that allowed (around 1980) the development of procedures to prepare intact and almost pure chloroplasts from a wide variety of tissues (for example, see Takabe et al., 1979; Grant and Wright, 1980; Ortiz et al., 1980; Mourioux and Douce, 1981). Percoll-purified chloroplasts were able to achieve CO_2-dependent oxygen evolution almost identical (on a chlorophyll basis) to that of the leaves (Mourioux and Douce, 1981). Percoll has several key characteristics for the purification of physiologically active organelles: (1) Percoll is made of silica beads of various size and is highly suitable to the formation of density gradients that can be self generated just by high-speed centrifugation; (2) Percoll is an inert compound, its low osmolarity does not change that of the assay medium, even at a high concentration, thus maintaining the integrity of the organelle structure during density gradient centrifugation; (3) in Percoll, silica beads are coated with polyvinylpyrrolidone, which helps remove harmful phenolic compounds from the medium. In the early 1990s, a large number of publications were produced with the term "Percoll" as a keyword (i.e., 50 papers in 1990, 241 in 1991, and 224 in 1992). Screening the literature with the term "Percoll" now identifies >5000 published papers, thus demonstrating the importance of a powerful method—density gradient centrifugation—applicable to any cells or organelles in suspension for which differences in size or buoyant density exist (Pertoft, 2000).

Chloroplast purification was an essential step to prepare and characterize envelope membranes (Douce and Joyard, 1979). Since in chloroplasts, envelope membranes only represents a minor fraction (1% to 2% of the total chloroplast proteins), any contamination of the initial chloroplast fraction is expected to represent, at the end, a major proportion of the fraction enriched in envelope membranes. Indeed, Douce et al. (1973) used sucrose-purified chloroplasts to prepare and characterize envelope membranes from spinach chloroplasts, whereas Percoll-purified chloroplasts were used by Cline et al. (1981) and Block et al. (1983a,b) to prepare and characterize inner and outer envelope membranes from pea and spinach, respectively.

The Alternate Protocol described here to perform Percoll purification of pure and intact chloroplasts from spinach leaves essentially relies on a method published by Douce and Joyard (1982). More recently, and since the complete sequencing of the *Arabidopsis* genome (The AGI, 2000), *Arabidopsis thaliana* has become a widely used model organism, supplanting spinach and pea as model plants. Somerville et al. (1981) had already described the isolation of photosynthetically active protoplasts and chloroplasts from *Arabidopsis thaliana*. However, the method did not rely on the use of Percoll-gradients to isolate the organelles. More recently, Kuntz (1998) and Ferro et al. (2003) published alternative methods for the Percoll-based purification of chloroplasts from *Arabidopsis*. The Basic Protocol presented here, to isolate chloroplasts from *Arabidopsis thaliana*, is adapted from these previously published protocols, and provided with some tricks to optimize yield and purity.

Critical Parameters and Troubleshooting

There are several essential points to take into consideration for successful purification of chloroplasts, e.g., the leaf material, medium composition, and critical steps of the protocol.

The best results are obtained when starting from 3- to 4-week-old *Arabidopsis* rosette leaves. Leaves that are too old are enriched in phenolic compounds that are known to affect integrity of the chloroplasts (Walker, 1990). The quantity of leaves is also critical. No intact chloroplasts can be recovered when the leaf starting material is <50 g. The day before the extraction, put the plants (*Arabidopsis* or spinach) overnight at 4°C in the dark to reduce the amount of starch in leaves. Chloroplasts containing large starch grains will generally be broken during centrifugation (Douce and Joyard, 1982).

For *Arabidopsis* chloroplast purification, we found that the optimal osmoticum concentration was 0.4 M sorbitol instead of 0.33 M (Kuntz, 1998). Addition of EDTA in the grinding and washing media is necessary to recover intact *Arabidopsis* chloroplasts as EDTA has a protective effect (Sommerville et al., 1981).

When purification is performed with less material than the amount described in the protocols described here, the number of Percoll gradient tubes should also be reduced (e.g., use only one preformed Percoll gradient when starting from 60 g of *Arabidopsis* leaves). The tissue must remain cold throughout the protocol to help reduce endogenous protease activities. The grinding process must be as short as possible. Longer blending improves the yield of recovered chlorophyll, but increases the proportion of broken chloroplasts.

The crude chloroplast suspension obtained after homogenization of leaves that are too young is mainly composed of broken chloroplasts. Once the leaf material has been homogenized, rapidly filter and centrifuge the homogenate to protect chloroplasts from activities of proteases released after disruption of the cells. Addition of BSA immediately before use of the grinding medium helps to limit the activity of proteases.

Anticipated Results

Using the Basic Protocol for *Arabidopsis* chloroplast purification, an average of 54 mg chloroplast proteins can be purified from 500 g of 3- to 4-week-old *Arabidopsis* leaves. Excellent purity of these Percoll-purified *Arabidopsis* chloroplasts was confirmed through immunological detection of markers enzymes (Seigneurin-Berny et al., 2006) and proteomic analysis (Ferro et al., 2003). Only 5% (6 out of 112) of the identified *Arabidopsis* proteins may correspond to non-plastid proteins. On a chlorophyll basis, we determined that the yield (~2% to 3%) of Percoll-purified and intact chloroplasts is equivalent in *Arabidopsis* and spinach (Douce and Joyard, 1982), the major limit for *Arabidopsis* being the availability of large amounts of starting material. The yield of intact spinach chloroplasts obtained from 3 kg of leaves is ~150 to 200 mg chlorophyll or 2.5 to 4 g proteins. A classical preparation of *Arabidopsis* chloroplasts starts from 500 g of leaves. On average, the yield of intact *Arabidopsis* chloroplasts obtained from 3 kg of leaves would be ~45 to 55 mg chlorophyll or 0.18 to 0.32 g proteins.

Time Considerations

An efficient chloroplast preparation should be completed within 1 to 1.5 hr. Preformed continuous Percoll gradients can be prepared 1 or 2 days before. Concentrated purified chloroplasts can be stored on ice for a few hours before loss of their structural and metabolic integrity. *Arabidopsis* chloroplasts are more fragile than spinach chloroplasts and can be stored intact for 3 to 4 hr only. Intact chloroplasts do not survive freezing. Buffers with osmoticum must be used to keep the chloroplasts intact.

Isolation of Neuromelanin Granules

Florian Tribl[1]

[1]Medizinisches Proteom-Center, Ruhr-Universitaet Bochum, Bochum, Germany

ABSTRACT

Neuromelanin granules are pigmented organelles in the human midbrain that give name to a brain area, substantia nigra pars compacta, which macroscopically appears as a dark brown region in the midbrain due to the insoluble pigment neuromelanin. The substantia nigra pars compacta massively degenerates in Parkinson's disease and gives rise to severely disabling movement symptoms. It has been suggested that neuromelanin granules play an important role in the neurodegenerative events in Parkinson's disease: redox-active iron is bound to neuromelanin and thereby retained within this compartment, but in Parkinson's disease it is thought to be increasingly released into the cytosol, promoting oxidative stress. This unit includes a methodological workflow for the isolation of neuromelanin granules from the human midbrain. This top-down approach (describes an approach that reduces the complexity of the sample stepwise from the level of tissue to cell, and from cell to organelle) encompasses the organelle isolation by sequential density gradient centrifugation and the assessment of the isolation efficacy by western blotting. *Curr. Protoc. Cell Biol.* 41:3.31.1-3.31.15. © 2008 by John Wiley & Sons, Inc.

Keywords: human brain • neuromelanin • lysosome-related organelle • organelle isolation • density gradient

INTRODUCTION

In the human brainstem, a region termed "substantia nigra pars compacta" is detectable by the naked eye due to its brown to black color (see Fig 3.31.3A, B). The characteristic pigmentation of the human substantia nigra pars compacta arises from specific organelles termed neuromelanin granules.

These organelles contain the insoluble pigment neuromelanin, which is biosynthesized from dopamine or noradrenalin. Interestingly, neuromelanin granules are absent in laboratory animals, such as mice and rats. In contrast, neuromelanin granules are found in most catecholaminergic neurons of primates and reach their maximal appearance in humans. A contribution of neuromelanin granules to the pathomechanisms of Parkinson's disease has been suggested. In Parkinson's disease, neuromelanin granules are engaged in iron-related oxidative stress and in the selective deposition of α-synuclein on the organellar lipid components. The lack of accessible model systems, however, has so far impeded the functional analysis of neuromelanin granules by molecular approaches.

Recently, the successful isolation of neuromelanin granules from human brain tissue led to their fundamental characterization as a lysosome-related organelle. The scope of this unit is to provide a detailed protocol for the isolation of neuromelanin granules from the human brain. Briefly, neuromelanin granules are isolated via a top-down approach by reducing the complexity of the sample stepwise. First, human substantia nigra pars compacta tissue is mechanically dissociated into a suspension of cells. Then, the pigmented neurons are enriched by centrifugation through a discontinuous sucrose gradient. While the glial cells and membranous matter accumulates at the sucrose layer interfaces, the dark brown neuronal cell bodies can be collected as a pellet, isolated, and homogenized. The homogenate containing a variety of cellular organelles is then centrifuged through

Current Protocols in Cell Biology 3.31.1-3.31.15, December 2008

DOI: 10.1002/0471143030.cb0331s41

a Percoll cushion. This step separates the very dense neuromelanin granules from the remaining cellular components.

Neuromelanin granules isolated by this manner were initially used for proteomic investigations (Tribl et al., 2005). Nevertheless, isolated neuromelanin granules could be applied in cellular assays, e.g., to compare the function of neuromelanin in conditions of health and disease. Furthermore, detailed biochemical analyses of the lipidic components of neuromelanin granules, or the metal ions present in the organelle, should be feasible.

Although the purpose of the Basic Protocol is to isolate neuromelanin granules from the human brain, an application of an adapted protocol on, e.g., brains of human and nonhuman primates, is thinkable.

NOTE: All protocols using human tissue must be reviewed and approved by an ethics committee, and must conform to governmental regulations regarding the acquisition and distribution of human post-mortem tissue.

BASIC PROTOCOL

ISOLATION OF NEUROMELANIN GRANULES FROM HUMAN SUBSTANTIA NIGRA PARS COMPACTA TISSUE

The protocol described here is optimized for the isolation of neuromelanin granules from human brain and yields this organelle in high purity. The purity of the isolated organelles is sufficiently high for proteomic analyses (Tribl et al., 2005). Additionally, this procedure is very mild and preserves the major morphological features of neuromelanin granules; in particular the lipidic components remain attached to the granules after isolation, as demonstrated by transmission electron microscopy (see Fig. 3.31.1).

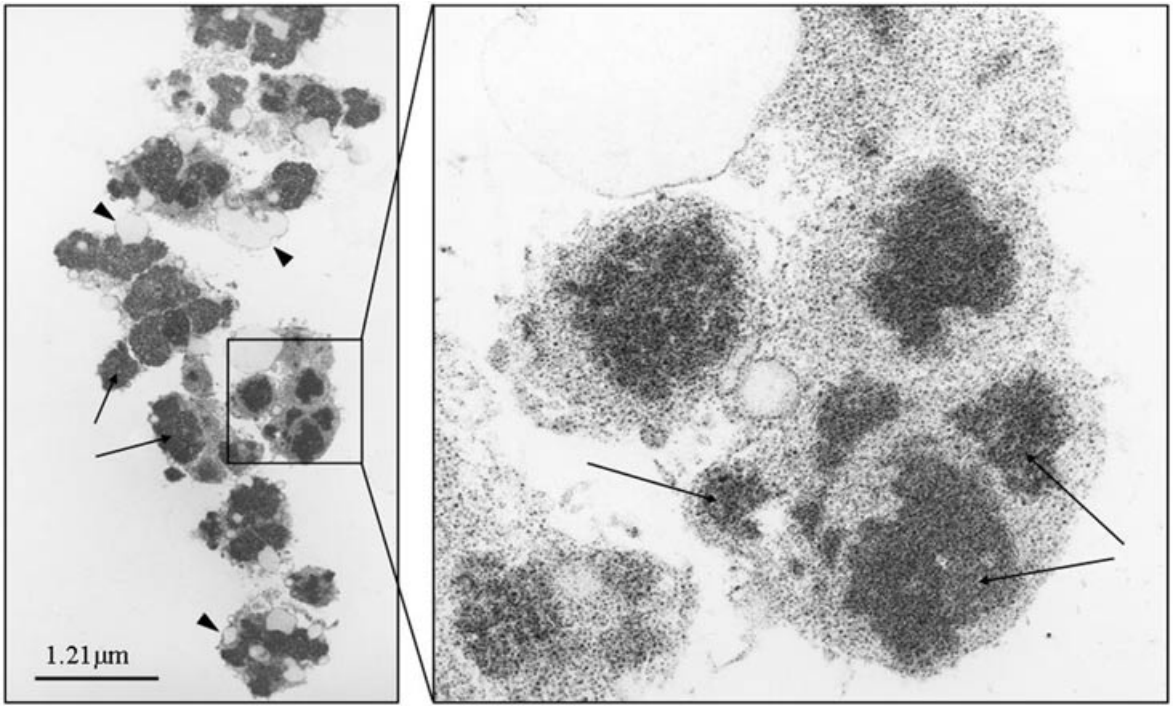

Figure 3.31.1 Quality assessment of the organelle preparation on a morphological level by transmission electron microscopy. Isolated neuromelanin granules are virtually free of contaminating organelles and retained their morphological appearance after isolation. Dark areas represent the electron-dense neuromelanin (highlighted by arrows), which is embedded in a protein matrix. Lipid component (arrowheads) that are characteristic for neuromelanin granules are still attached to the organelles. Reproduced from Tribl et al., 2005.

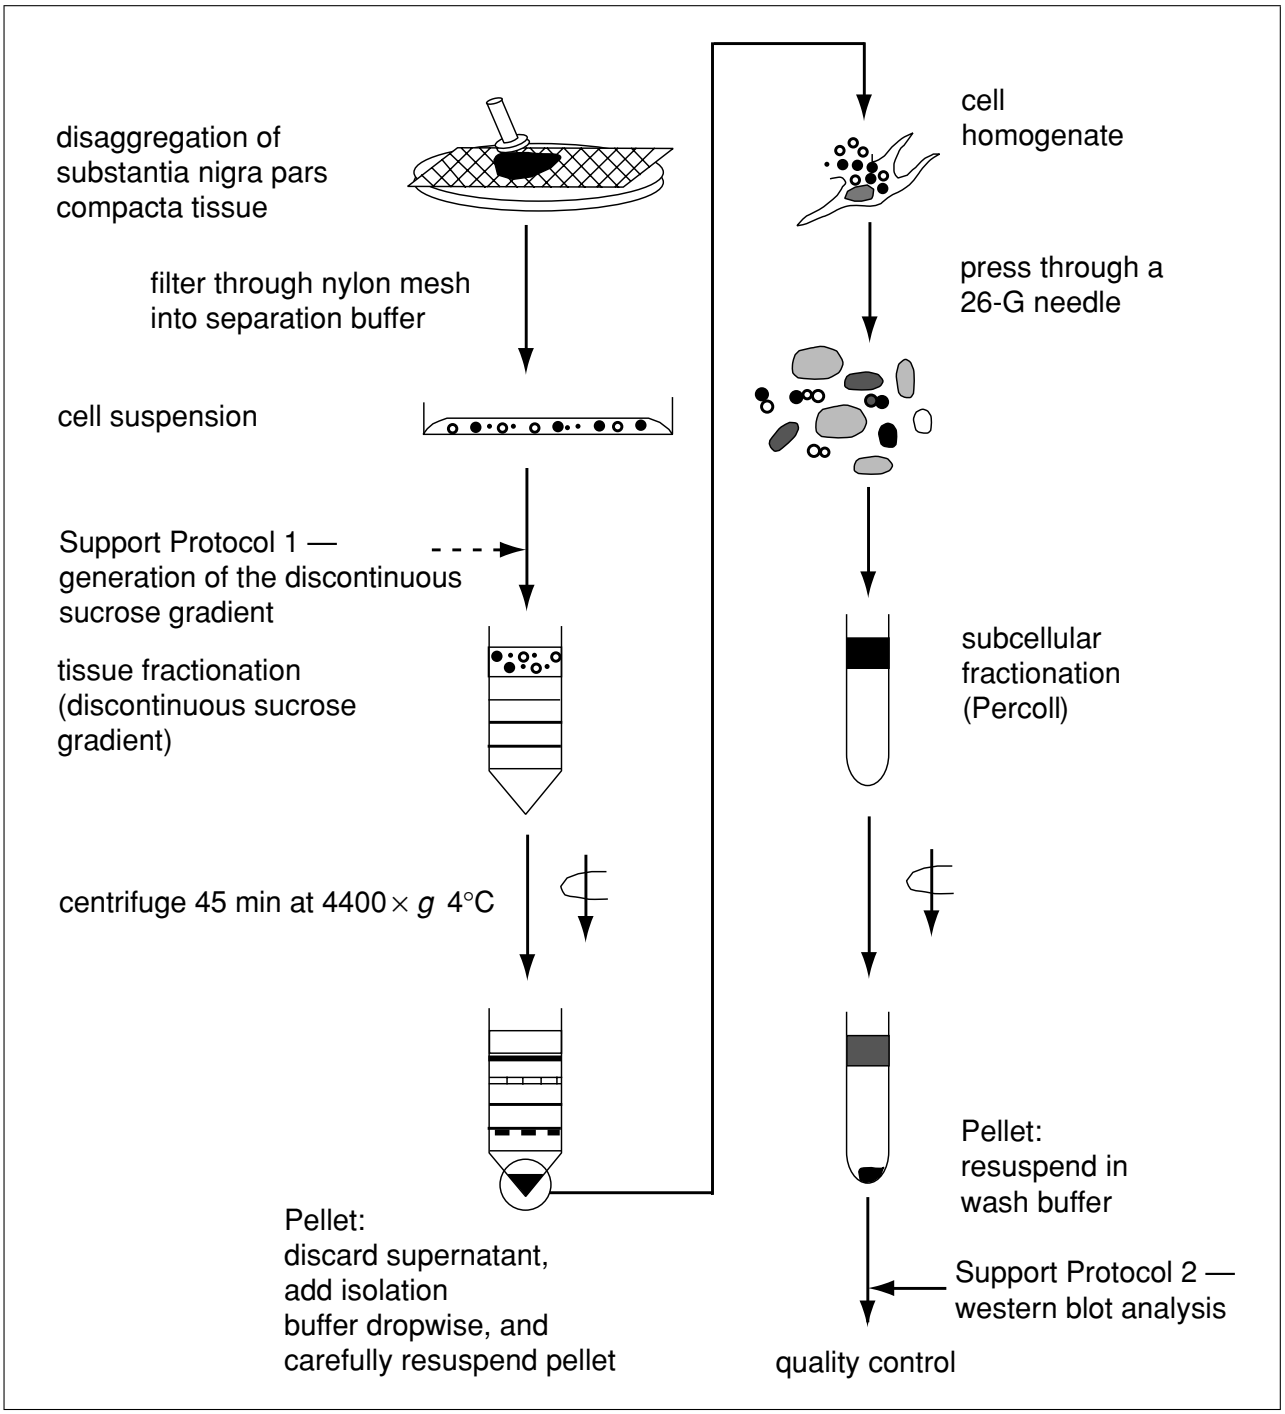

Figure 3.31.2 Flowchart of the Basic Protocol and Support Protocols 1 and 2, providing a schematic overview of the major steps to purify neuromelanin granules from human post-mortem substantia nigra pars compacta. Reproduced from Tribl et al., 2005.

The schematic flowchart provides a visual summary of the major purification steps (see Fig. 3.31.2).

Materials

Disinfecting agents for dissecting instruments and surfaces (e.g., any liquid formulation used to clean metal surgical instruments is appropriate)

Dissected, unfixed human substantia nigra pars compacta, prepared at the Brain Bank (stored at −80°C)

Separation buffer (see recipe), cooled to 4°C

Ice
20-ml discontinuous sucrose gradients in 50-ml conical polyethylene screw-cap centrifuge tubes (see Support Protocol 1)
Isolation buffer (see recipe)
80% (v/v) Percoll solution (see recipe)
Wash buffer (see recipe)
Liquid nitrogen

Cooling plate
Plastic sack (e.g., an autoclave bag)
250- and 500-ml beakers
Petri dishes, 100-mm in diameter
Scissors
150-μm nylon mesh
Balance accurate to ±0.1 g
Dissecting instruments including:
Scalpels or single-edge razor blades
Forceps
10-ml syringes (B. Braun Melsungen AG), single-use
15- and 50-ml conical polyethylene screw-cap centrifuge tubes
Styropor boxes
Refrigerated Rotanta 96 RS centrifuge (Hettich GmbH) with swing-out rotor inserts for 15-ml and 50-ml conical polyethylene screw-cap centrifuge tubes
1.5-ml microcentrifuge tubes (Eppendorf)
1-ml syringe equipped with a 26-G needle
−80°C freezer

Additional reagents and equipment for preparing a discontinuous sucrose gradient (Support Protocol 1)

NOTE: It is highly recommended to use human substantia nigra pars compacta that is prepared by experienced pathologists. Substantia nigra pars compacta should be dissected from transverse brain tissue plates of the brain stem (see Fig. 3.31.3A, B) and should be kept intact.

NOTE: For biosafety reasons, during the tissue preparation steps use personal protective equipment including a laboratory coat, a surgical mask, safety glasses, and gloves to avoid dermal and mucous membrane contact with blood and brain tissue. Wear a laboratory coat, safety glasses, and gloves throughout the other procedures. All steps should be performed at 4°C.

Disaggregate human substantia nigra pars compacta

1. Set the cooling plate to −10°C.
2. Cover the metal surface of the cooling plate with a plastic sack.

   This will allow the most secure disposal of residual tissue from the cooling plate.
3. Prepare a 500-ml beaker with disinfecting agent for the scalpels and forceps.
4. Place the 100-mm petri dish on the cooled metal plate of the cooler and cover the dish with a nylon mesh.

   Using scissors, cut the nylon mesh into 12 × 12–cm squares. The nylon mesh should be large enough to cover the entire petri dish properly. It is not necessary to additionally fix the mesh on the petri dish.

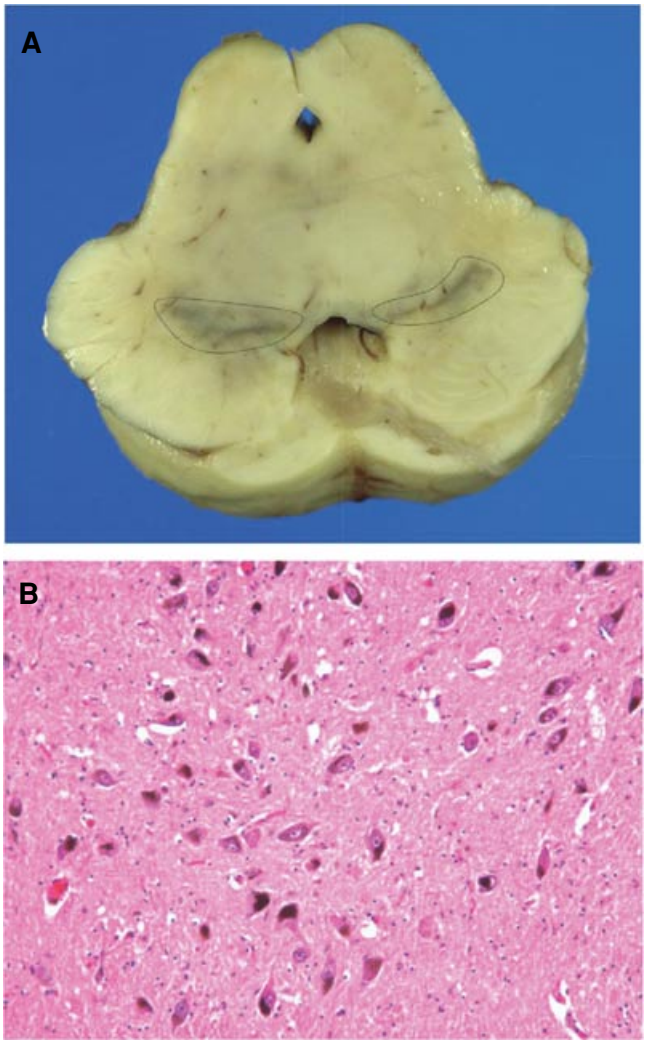

Figure 3.31.3 (**A**) A macroscopic aspect of a tissue slice of a human brain stem. The dark areas represent the substantia nigra pars compacta that is additionally highlighted by dotted lines. (**B**) Human substantia nigra pars compacta tissue under the light microscope (hematoxylin-eosin stain, 10×). The brownish neuromelanin granules are clearly visible within the cytosol of the dopaminergic neurons.

5. Place the pieces of frozen human substantia nigra pars compacta into separation buffer (cooled to 4°C). Add 5 g of intact tissue and bring to 7.5 ml with separation buffer. Let the tissue thaw in the buffer.

   All buffers should be supplemented with protease inhibitors (see Reagents and Solutions) to prevent proteolytic activity of endogenous proteases in the tissue. It is also possible to use a commercial protease inhibitor cocktail.

6. Using the forceps, place one total piece of brain tissue on top of the nylon mesh (~500 to 1000 mg per substantia nigra pars compacta). If necessary, remove excessive white matter and trim the substantia nigra pars compacta using a scalpel. Add 500 to 1000 µl of separation buffer to the tissue.

7. Using the plunger of the 10-ml single-use syringe, press the brain tissue through the nylon mesh. Make sure that the tissue stays in contact with the ice-cold liquid.
8. As soon as the piece of tissue has been disaggregated completely, remove the nylon mesh from the petri dish and transfer the suspension into a 50-ml conical polyethylene screw-cap centrifuge tube. Place the centrifuge tube into a styropor box filled with ice.
9. Repeat this procedure with the remaining pieces of brain tissue and combine the tissue suspensions.

Fractionate tissue

10. Overlay 7.5 ml of the suspension dropwise onto one ice-cold discontinuous sucrose gradient (see Support Protocol 1).
11. Transfer the centrifuge tubes into the refrigerated centrifuge (e.g., Rotanta 96 RS) equipped with swing-out rotor inserts for 50-ml conical polyethylene screw-cap centrifuge tubes (or equivalent). Centrifuge 45 min at 4400 × *g*, 4°C, to sediment the cells.

    After centrifugation, a dark brown (neuromelanin-containing) pellet is visible, while fine layers of pale particles (debris, myelin sheaths, etc.) are visible at the sucrose solution interfaces.

Prepare cell homogenate

12. Carefully aspirate the supernatant with a pipet and discard into a 250-ml beaker containing a disinfecting agent.
13. Add 500 µl of isolation buffer dropwise to the dark brown pellet and gently resuspend by pipetting up and down.
14. Centrifuge in the Rotanta 96 RS centrifuge 15 min at 4400 × *g*, 4°C, and discard the supernatant.
15. Again, add 500 µl of isolation buffer dropwise to the dark brown pellet and gently resuspend by pipetting up and down. Transfer the suspension into a 1.5-ml micro-centrifuge tube.
16. Coat a 1-ml syringe equipped with a 26-G needle with the isolation buffer. Pass the buffer several times through the needle.
17. Homogenize the dark brown pellet by passing it through the needle ten times to release cellular organelles.

    Avoid the generation of air bubbles. Slowly aspirate the suspension into the syringe and slowly press back the solution into the 1.5-ml reaction tube.

Perform subcellular fractionation

18. Add 5 ml ice-cold 80% (v/v) Percoll solution into a 15-ml conical polyethylene screw-cap centrifuge tube.
19. Layer the homogenate dropwise on top of the 80% Percoll solution.
20. Transfer the centrifuge tube into the refrigerated centrifuge (Rotanta 96 RS) equipped with swing-out rotor inserts for 15-ml conical polyethylene screw-cap centrifuge tubes (or equivalent). Centrifuge 15 min at 4400 × *g*, 4°C, to sediment the neuromelanin granules.

    After centrifugation, a dark brown pellet is visible, while a fine layer of pale particles is visible at the Percoll solution interface.

21. Aspirate the supernatant with a pipet and discard into a 250-ml beaker containing a disinfecting agent.
22. Add 500 µl of wash buffer dropwise to the dark brown pellet and gently resuspend by pipetting up and down.
23. Centrifuge in the Rotanta 96 RS centrifuge 15 min at 4400 × *g*, 4°C, and discard the supernatant.
24. If not proceeding further, freeze the isolated neuromelanin granules in liquid nitrogen and store at −80°C.

Based on a transmission electron microscopic inspection, neuromelanin granules appear to be pure (Fig. 3.31.1).

Neuromelanin granules isolated following this protocol were used for proteomic analyses (Tribl et al., 2005). Nevertheless, neuromelanin granules isolated in this manner could be applied in cellular assays to compare the function of neuromelanin in health and disease. Furthermore, biochemical investigations of the lipidic components of neuromelanin granules, or the metal ions present in the organelle, should be feasible.

PREPARATION OF A DISCONTINUOUS SUCROSE GRADIENT

SUPPORT PROTOCOL 1

The discontinuous sucrose gradient is used to prefractionate the tissue suspension.

Materials

1.0 M sucrose gradient solution, ice cold (see recipe)
1.2 M sucrose gradient solution, ice cold (see recipe)
1.4 M sucrose gradient solution, ice cold (see recipe)
1.6 M sucrose gradient solution, ice cold (see recipe)
Ice

50-ml conical polyethylene screw-cap centrifuge tubes
Test tube rack
150-mm glass Pasteur pipets with a straight tip, constricted, but unplugged
Styropor box

1. Place a 50-ml conical polyethylene screw-cap centrifuge tube into a test tube rack.
2. Place the Pasteur pipet into a 50-ml conical polyethylene screw-cap centrifuge tube. Using an e.g., automatic pipettor with a 1-ml tip, add five 1-ml aliquots stepwise of ice-cold 1.0 M sucrose gradient solution into the Pasteur pipet and let the solution flow into the 50-ml centrifuge tube (see Fig. 3.31.4).

NOTE: *After the last aliquot is added, quickly close the Pasteur pipet with a thumb before the meniscus of the sucrose solution would enter the constriction of the tip. This largely prevents the formation of air bubbles after addition of the second layer. Air bubbles may disturb the formation of sharp interfaces between two sucrose layers.*

3. Keep the Pasteur pipet from step 2 in the 50-ml centrifuge tube and underlay the 1.0 M sucrose layer by adding 5 ml of ice-cold 1.2 M sucrose gradient solution.
4. Underlay the 1.2 M sucrose layer by adding 5 ml of ice-cold 1.4 M sucrose gradient solution.
5. Underlay the 1.4 M sucrose layer by adding 5 ml of ice-cold 1.6 M sucrose gradient solution.
6. Place the discontinuous sucrose gradients on ice into the styropor box until the application of the sample.

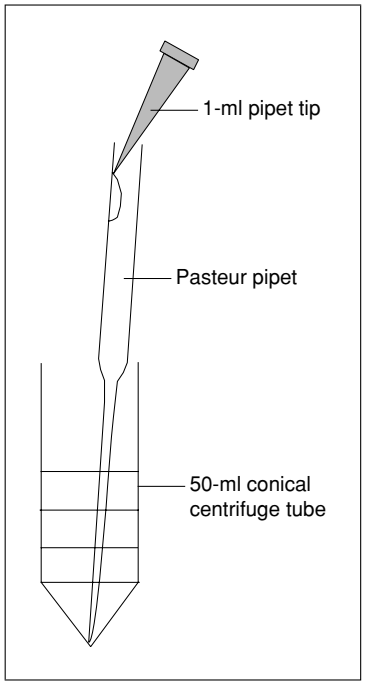

Figure 3.31.4 Figure shows the preparation of the discontinuous sucrose gradient. The sucrose solutions are pipetted into a Pasteur pipet and allowed to flow into the 50-ml conical polyethylene screw-cap centrifuge tube.

SUPPORT PROTOCOL 2

QUALITY CONTROL BY IMMUNOBLOT ANALYSIS

Quality control of organelle preparations is indispensable to monitor the success of the isolation and to exclude the presence of contaminating organelles as opposed to detecting neuromelanin markers.

An extensive quality control for organelle preparations on a molecular level, e.g., by immunoblot analyses, is crucial to evaluate the degree of enrichment. Antibodies against several organelle marker proteins, which are specific for a given cellular compartment, are commercially available and allow for visualizing the purity of the sample (see Fig. 3.31.5).

Materials

2× tricine/SDS sample buffer (Novex)
Polyacrylamide gels, e.g., precast 10% to 20% gradient tricine gels (Novex), or equivalent gels (*UNIT 6.1*)
10 × tricine/SDS running buffer (Novex)
10× reducing agent (Novex)
Isolated neuromelanin granules sample (see Basic Protocol)
Molecular weight markers
Ice
Tris-glycine transfer buffer, 20× (Novex)
Ponceau red solution (Pierce)
Tris-buffered saline (TBS; *APPENDIX 2A*)
Blocking solution (see recipe)
Primary antibodies
Secondary antibodies (HRP-conjugated)
Tris-buffered saline-Triton X-100 (TBS-T; see recipe)
ECL solutions (Pierce)

Heater
Power supply
XCell II Mini Gel Electrophoresis System (Novex)
XCell II blot module, blotting cassette, and sponges (Novex)

Benchtop centrifuge
Gel knife
Precut nitrocellulose membranes (Invitrogen GmbH)
Sponges
Whatman 3MM Chr paper (Schleicher & Schuell)
Rocking platform
Gel documentation system

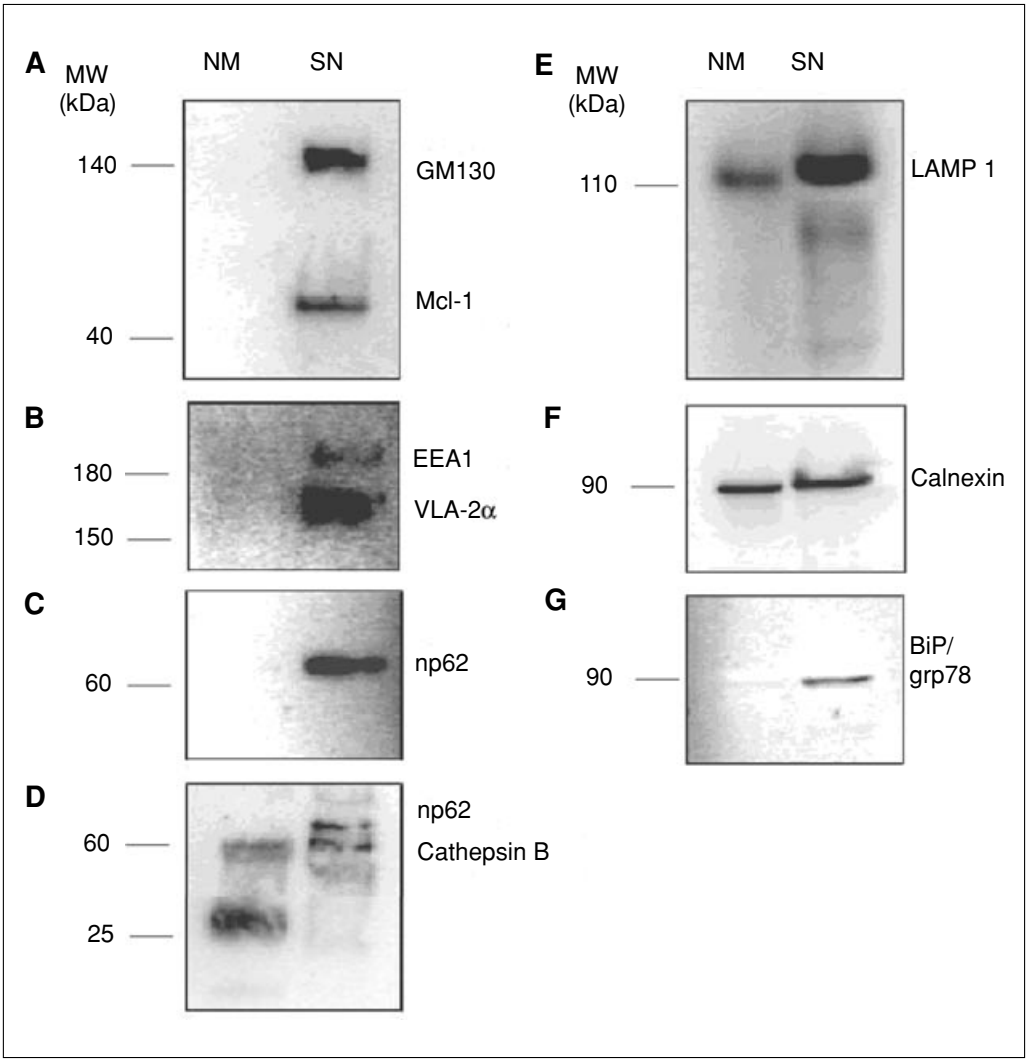

Figure 3.31.5 Assessment of the neuromelanin granule purification on a molecular level by western blot analyses. Probing for organelle marker proteins enables visualization of the purity of isolated neuromelanin granules (NM) compared to total substantia nigra pars compacta tissue homogenate (SN). Marker proteins for (**A**) the Golgi network (GM130), mitochondria (Mcl-1), (**B**) early endosomes (EEA-1), the plasma membrane (VLA-2a), and (**C**) the nucleus (np62) are not detected in the neuromelanin granule preparation, while (**D, E**) late endosomes and lysosomal marker proteins (cathepsin B, LAMP1) are present. (**F**) Calnexin is predominantly detected in the endoplasmic reticulum, but also plays a role in pigmented organelles as a melanogenic chaperone and is detected in considerable amounts in neuromelanin granules. (**G**) BiP/grp78, however, a classical marker protein for the endoplasmic reticulum, is absent. Reproduced from Tribl et al., 2005.

Perform SDS-polyacrylamide gel electrophoresis

These instructions assume the use of precast gels, e.g., 10% to 20% gradient tricine gels and the XCell II Mini Gel Electrophoresis System (Novex), but are easily adaptable to other formats, including self-cast minigels.

1. Set a heater at 90°C and bring the tricine/SDS sample buffer (2×) to room temperature.

   NOTE: *SDS precipitates at 4° C. Incomplete dissolution may hamper proper solubilization of the proteins.*

2. Remove the gel from the bag, briefly rinse with water, peel the tape from back of gel, and remove the comb.

3. Pour ~100 ml of the 1× tricine/SDS running buffer into the electrophoresis chamber; place the gel into the XCell II module, fill the upper chamber with the 1× tricine/SDS running buffer, and check for leaks. Remove air bubbles, if necessary.

4. Prepare the isolated neuromelanin granules sample for electrophoresis by adding 2× tricine/SDS sample buffer (1× final concentration) and an aliquot of the 10× reducing agent (1× final concentration), and then incubate the sample 5 to 10 min at 90°C.

5. Incubate the sample on ice 10 sec to briefly cool the heated sample and spin in a benchtop centrifuge 10 min at 16,000 × *g*, room temperature.

6. Load 20 µl of the sample onto the gel and include one well for molecular weight markers.

7. Run the gel at 200 V constant voltage for ~50 min.

   Expect a current of 100 to 120 mA at the beginning and 60 to 70 mA at the end of the electrophoresis.

Immunoblot the gel

8. Remove the gel from the plastic cassette and cut off the wells with a gel knife. Then cover the gel with 1× Tris-glycine transfer buffer.

9. Wet the precut nitrocellulose membranes in 1× Tris-glycine transfer buffer.

   The membrane should be completely covered with buffer.

10. Presoak 6 to 7 sponges in 1× Tris-glycine transfer buffer. Gently press to remove air from the sponges, which accomplishes the complete uptake of buffer.

11. Prepare the XCell II blot module and transfer three sponges into the blotting cassette.

12. Prepare the gel sandwich as follows: wet a sheet of Whatman paper by briefly dipping into 1× Tris-glycine transfer buffer and place the gel onto it. Cover the gel with the nitrocellulose membrane and put a second sheet of wet Whatman paper onto the nitrocellulose membrane. Remove air bubbles by applying gentle pressure to allow uniform protein transfer onto the membrane. Then, to transfer the gel sandwich onto the sponges, cover it with the remaining sponges and close the cassette.

13. Place the cassette into the XCell II blot module and perform the protein transfer onto the membrane at 70 V for 90 min.

14. Monitor the transfer efficacy briefly by dipping the membrane into the Ponceau Red solution, which reversibly visualizes red protein bands. Then, destain the membrane either briefly in TBS or directly transfer it into 30 ml of blocking solution.

15. Block nonspecific antibody binding sites 1 hr at room temperature on a rocking platform (10 to 15 cycles/min).
16. Discard the blocking solution. Dilute the primary antibody appropriately in 10 ml blocking solution for probing. Gently pour the antibody solution onto the membrane and incubate for 1 hr at room temperature on a rocking platform.

    Antibodies are diluted in a range of 1:1000 (v/v) to 1:2000 (v/v).
17. Remove the primary antibody and wash the membrane three times, each time for 15 min with 30 ml TBS-T.
18. Dilute the secondary antibody in TBS-T. Discard the blot washing buffer and incubate the membrane with the secondary antibody for 1 hr at room temperature on a rocking platform.
19. Finally, remove the secondary antibody and wash the membrane three times, each time for 15 min with 30 ml TBS-T.
20. During the last washing step, warm 1 to 2 ml of the ECL solutions to room temperature and prepare a 1:1 (v/v) mixture.
21. Briefly rinse the membrane in TBS, and then add the mixed ECL solution onto the membrane and disperse evenly.

    Exposure time in ECL solution ranges between 30 sec to 1 min.
22. Finally, monitor chemiluminescence in a gel documentation system.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking solution

TBS-T (see recipe)
5% (w/v) non-fat dry milk
Store up to 2 days at 4°C

Isolation buffer

100 mM KCl
10 mM HEPES, pH 7.5
1 mM disodium EDTA
10% (m/v) sucrose
0.01% (v/v) protease inhibitor cocktail (see recipe)
Filter through a 0.2-μm filter device (Millipore)
Store up to several days at 4°C

Percoll solution

80% (v/v) Percoll (Fluka)
0.25 M sucrose
10 mM HEPES, pH 7.5
0.01% (v/v) protease inhibitor cocktail (see recipe)
Store up to 6 months at room temperature

Percoll consists of colloidal silica beads coated with polyvinlpyrrolidone.

Protease inhibitor cocktail

1 mg/ml aprotinin in H_2O
0.5 mg/ml pepstatin in methanol
0.05 M phenylmethylsulfonyl fluoride (PMSF) in DMSO
Store up to 2 years at −20°C
Add the protease inhibitor cocktail to the buffer solutions at 0.01% (v/v)

Separation buffer

100 mM KCl
10 mM HEPES, pH 6
10% (w/v) glucose
0.01% (v/v) protease inhibitor cocktail (see recipe)
Filter through a 0.2-μm filter device (Millipore)
Store up to several days at 4°C

Sucrose gradient solutions, 1.0 M, 1.2 M, 1.4 M, and 1.6 M

1 M sucrose
10 mM KCl
10 mM HEPES, pH 7.5
0.01% (v/v) protease inhibitor cocktail (see recipe)

1.2 M sucrose
10 mM KCl
10 mM HEPES, pH 7.5
0.01% (v/v) protease inhibitor cocktail (see recipe)

1.4 M sucrose
10 mM KCl
10 mM HEPES, pH 7.5
0.01% (v/v) protease inhibitor cocktail (see recipe)

1.6 M sucrose
10 mM KCl
10 mM HEPES, pH 7.5
0.01% (v/v) protease inhibitor cocktail (see recipe)
Store sucrose gradient solutions up to 2 months at 4°C

Tris-buffered saline, supplied with Tween (TBS-T)

Tris-buffered saline (TBS; see *APPENDIX 2A*)
0.1% (v/v) Tween-20
Store up to 3 months at 4°C

Wash buffer

250 mM NaCl
10 mM HEPES, pH 7.5
0.01% (v/v) Triton X-100
0.01% (v/v) protease inhibitor cocktail (see recipe)
Prepare fresh

COMMENTARY

Background Information

Neuromelanin granules are absent in the brains of most laboratory animals currently used, e.g., fish, rodents, or rabbits, but these pigmented organelles are found in most primates, and in highest quantities in humans (Marsden, 1961). In the human brain, neuromelanin granules are especially found in the dopaminergic substantia nigra pars compacta, and also in the catecholaminergic locus

ceruleus. Neuromelanin granules appear at the age of 3 to 5 years and are formed until ~20 years of age (Halliday et al., 2006). Different from melanosomes that form the basis of oculo-cutaneous pigmentation and develop by a maturation process from unpigmented stage I melanosomes via striated stage II melanosomes to pigmented stage III and IV melanosomes, no precursor compartment of neuromelanin granules is currently known. After the age of 20, no further generation of neuromelanin granules takes place, while the pigment continues to be formed.

Neuromelanin is an amorphous, insoluble pigment of unknown structure that is suggested to be a polymer formed from dopamine (substantia nigra pars compacta) or from noradrenalin (locus ceruleus; Fedorow et al., 2005). Comparable to the melanin in highly pigmented stage IV melanosomes, the pigment neuromelanin is responsible for the high density of neuromelanin granules. For isolation, density gradient centrifugation has been widely applied to isolate a great variety of cellular organelles (Whittaker, 1965; Graham and Rickford, 1997). Due to the exceptional high density of pigmented organelles, this approach has been applied very successfully to yield oculo-cutaneous melanosomes in high purity in sucrose gradients (Seiji et al., 1963; Gahl et al., 1995), and in an isotonic solution of 80% (v/v) Percoll (Rogers et al., 1998). In addition, Percoll is applicable to isolate neuromelanin granules. Affinity-based purification, in contrast, is not recommendable for neuromelanin granules, since no membrane protein unique for these organelles has been found so far.

Critical Parameters

Neuromelanin granules are absent in most laboratory animals. Moreover, there is no cell culture system that reliably forms neuromelanin granules. Unlike other organelles or subcellular compartments, highest quantities of neuromelanin granules are present in human brain substantia nigra pars compacta. Although high-quality human brain tissue is collected and preserved in brain bank centers, the availability of human substantia nigra pars compacta tissue with a post-mortem delay of up to 12 hr, however, may represent the bottleneck of the entire isolation process. Additionally, it is currently not known to what extent factors such as the post-mortem delay, the agonal status, gender, age, and storage time may affect the isolation of neuromelanin granules from human autopsy tissue. Fortunately, most nucleic acids and proteins are reasonably stable in the brains, allowing reliable analyses (Hynd et al., 2003).

Neuromelanin granules belong to the group of lysosome-related organelles, which are not primarily engaged in the digestion of macromolecular polymers such as proteins, lipids, or glycosides, as this is accomplished by conventional lysosomes (Tribl et al., 2006). Nevertheless, hydrolytic enzymes, most importantly proteases, are still present and eventually active in these lysosome-related organelles. It is thus critical to keep the sample at 4°C and to perform all experimental steps on ice. Moreover, it is recommended to use a cocktail of protease inhibitors to keep the protease activity at a minimum.

Contamination of neuromelanin granules by other organelles is not a major concern, since the extraordinary density of neuromelanin granules is far beyond that of organelles such as mitochondria or lysosomes. Nevertheless, quality control is crucial to monitor the success and the efficacy of the isolation procedure. Since there is currently no unique protein available to allow for an unambiguous identification of neuromelanin granules, several methodologies should be applied, most importantly immunoblot analyses to exclude contaminations at the molecular level (see Support Protocol 2), and transmission electron microscopy to identify neuromelanin granules by their characteristic morphology (see Fig. 3.31.1).

Anticipated Results

One gram of substantia nigra pars compacta yields ~1 to 2 mg neuromelanin granules. Both substantia nigra pars compacta tissue and isolated neuromelanin granules should be saved for quality control analyses. These include immunoblot analysis of organellar marker proteins of the endoplasmic reticulum (BiP/grp78), the Golgi complex (GM180), early endosomes (EEA1), lysosomes (Lamp-1, cathepsin B), mitochondria (mcl-1), the nucleus (np62), and the plasma membrane (VLA-2α; Fig. 3.31.5). Although lysosomal marker proteins are present in the sample, all other organellar marker proteins are absent.

When monitoring the isolation efficacy by transmission electron microscopy, the neuromelanin sample should be virtually free of contaminating organelles or subcellular structures.

Table 3.31.1 Troubleshooting Guide for Neuromelanin Granule Isolation

Problem	Cause	Solution
No pellet after sucrose gradient centrifugation	Wrong sucrose density	Check that the sucrose densities are correct
	Inefficient homogenization process	Extend the homogenization and thoroughly sieve the tissue through the mesh
Neuromelanin granules enter inefficiently into the Percoll layer	Granules are bound to less-dense cellular components	This is regularly observed and may be improved by repeated passage of the interface fraction through the 26-G syringe
Protein degradation visualized by western blot	Protein degradation	Use protease inhibitors, extend the already applied protease mix; use tissue with a smaller post-mortem delay

Troubleshooting

Table 3.31.1 highlights the most commonly encountered problems and provides suggestions for their solutions.

Time Considerations

The time required to isolate neuromelanin granules depends on the brain tissue used. Homogenization of substantia nigra pars compacta tissue requires 10 to 15 min per gram. The preparation of the gradients takes ~30 to 45 min, if the underlaying procedure (see Support Protocol 1) is used. Since the weight of the sucrose layers is increased step by step, underlaying additional sucrose layers will take more time. Centrifugation of the tissue suspension will require 45 min, but may be extended to 90 min to eventually obtain higher yields. The isolation of the pellet after this first centrifugation step will require an additional 30 to 45 min. If several gradients are to be handled, additional time is required.

The homogenization of this pellet by passage through a 26-G needle may require 30 min, since the aspiration of the suspension into the narrow needle is rather slow. Overlaying the sample onto the Percoll layer and the sedimentation of the neuromelanin granules are estimated to require 30 min. Additional time has to be considered, if the yield in this step is not satisfactory (see Table 3.31.1). In general, a high-purity preparation of neuromelanin granules requires 6 to 8 hr including the preparation of buffers and solutions.

Acknowledgments

Isolation of Dense Core Secretory Vesicles from Pancreatic Endocrine Cells by Differential and Density Gradient Centrifugation

John C. Hutton,[1] Randall Wong,[1] and Howard W. Davidson[1]

[1]Barbara Davis Center for Childhood Diabetes, University of Colorado at Denver and Health Sciences Center, Aurora, Colorado

ABSTRACT

Methods are presented for the separation of dense core secretory vesicles from insulin-secreting tissues (insulin granules) based on a combination of differential and density gradient centrifugation on various media. Emphasis is given to the use of transplantable tumors, tissue culture cell lines, and pancreatic islets as a tissue source. *Curr. Protoc. Cell Biol.* 42:3.32.1-3.32.20. © 2009 by John Wiley & Sons, Inc.

Keywords: insulin granules • DCV • insulinoma • Min6 • INS1 • homogenization • centrifugation

INTRODUCTION

The techniques in this unit have been tailored for the isolation of insulin secretory granules under conditions that retain their integrity through the use of isoosmolar conditions. The same procedures can, in principle, be adapted to isolate dense core vesicles (DCVs) from other tissue types but require careful empirical analyses of the behavior of the organelles relative to other major cellular components. Different density media, even under isoosmotic conditions, have dramatically different capacities to separate DCVs from lysosomes and mitochondria that presumably relate to the interaction of the density media components with the granule membrane. Protocols need to be developed for the specific organelle and tissue by application of quantitative analyses of organelle markers so that the purity and relative specific activity of markers can be calculated. The literature abounds with examples of claims of co-localization of specific proteins to DCVs based on co-sedimentation on a density gradient though often this has been based on fractions in which the organelle contributes <5% of the total protein. In such cases other supporting data such as electron microscopy, co-immunoprecipitation, or the use of multiple analytical gradients should be used.

Procedures for the isolation of insulin granules from pancreatic β-cells are detailed below. Basic Protocol 1 describes isolation of purified granules from a transplantable rat insulinoma (Hutton et al., 1982; Roep et al., 1991) that can be propagated in gram quantities (2 to 20 g wet wt.) in an inbred Wistar rat strain from the New England Deaconess Hospital (NEDH rats; Chick et al., 1977). The tumors have a high hormone content (3% to 10% of total cellular protein) and give preparations of high purity and yield. There are several variants on the gradients that are used for granule purification (see Alternate Protocols 1 through 4) depending on the experimental objective. Subsequent protocols outline the adaptation of the procedures to INS-1E and Min6 cell lines (see Basic Protocol 2) that can be maintained in tissue culture (Konrad et al., 1995; Mohlig et al., 1997). The latter have the advantage of starting with a more homogeneous tissue source containing fewer dead cells, and the avoidance of animal husbandry. The cell lines

Current Protocols in Cell Biology 3.32.1-3.32.20, March 2009
Published online March 2009 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb0332s42

are practical for routine isolation of sub-milligram quantities of granules starting from 0.2 to 0.5 g wet weight. The lines are less granulated than either solid tumors or pancreatic islets, and the purity and yield of material is correspondingly lower. An adaptation for pancreatic islets is also given. Key considerations are the homogenization procedure and the choice of density gradient medium. Emphasis is given to the use of isoosmotic media so that the organelles remain intact and can be recovered for functional studies such as ion uptake measurements (Hutton, 1982). Vesicles derived from disrupted intracellular membranes distribute over a broad range of densities under isoosmotic conditions and the distribution is directly proportional to the volume/surface area ratio of the vesicle. Fractionation under hyperosmotic conditions (e.g., sucrose density gradients) reduces the complexity of density gradient profiles because such vesicles shrink and their densities approximate their protein/lipid ratio. Granules remain intact under such conditions and thus sucrose has its place as a gradient medium. Insulin granules, however, do not separate well from lysosomes or mitochondria on sucrose, and they lyse if diluted in isoosmolar solutions. Finally, Support Protocols 1 through 5 describe enzyme assays, which are used to characterize the gradient fractions.

BASIC PROTOCOL 1

PREPARATION OF DCVs FROM INSULINOMAS

The transplantable rat insulinoma was used to develop the insulin granule isolation protocol described here (Hutton et al., 1982; Roep et al., 1991). The tumor was generated by whole body irradiation of an animal that was linked to a parabiont and was derived from a number of different spontaneous tumors that subsequently arose (Chick et al., 1977). It was subsequently maintained and propagated by serial transplantation in the same strain of inbred rats (New England Deaconess Hospital—NEDH—rats) for >30 years (see Support Protocol 1). Tumor pieces can be cryopreserved in 10% (v/v) DMSO in RPMI in liquid nitrogen storage to preserve early passage number. One variant of the tumor that was propagated from a liver metastasis, MSL-G2 (Madsen et al., 1986), has been shown to have the interesting property of expressing insulin in tissue culture but glucagon as a tumor in vivo. The tumor was first successfully adapted to monolayer tissue culture as the RINm5F cell line, which secreted insulin in response to cAMP and alanine but not glucose (Praz et al., 1983) and later to a glucose-sensitive line INS1-E, which remains popular as an in vitro model of insulin gene transcription and cell biology (Asfari et al., 1992). Such cells, while slow growing, can be expanded to large numbers and have been used for subcellular fractionation (Bhathena et al., 1982). INS1-E cells can be passaged in the NEDH rat in vivo. The principal advantage of using the original tumor lies with an insulin content that is up to 30% of pancreatic islet tissue and the fact that large quantities of tissue can be harvested on a single day (10 to 20 g), which makes it ideal for homogenization and subcellular fractionation.

Percoll (a colloidal suspension of polyvinylpyrrolidone-coated silica particles) has negligible osmolarity (<20 mosmol/liter), produces a self-forming gradient up to $\rho = 1.16$, and is used to separate insulin granules from plasma membrane, ER, Golgi, endosomes, peroxisomes and synaptic-like vesicles, and mitochondria. Partial overlap of granules with lysosomes occurs at the higher density end of gradients. Percoll's major drawback is the additional steps needed to separate granules from the medium. It is suited for experiments where time is of the essence and subsequent experimentation requires freshly prepared organelles. Differential centrifugation is combined with the density gradient step. Equipment is pre-cooled to 4°C and all steps are performed at 4°C or on ice.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

Materials

Rats (NEDH strain, either sex, 150 to 200 g)
70% (v/v) ethanol or iodine
Sterile phosphate-buffered saline: 10 mM Na phosphate in 150 mM NaCl, pH 7.4, on ice
Ice-cold β-cell homogenization medium (β-HM; see recipe)
27% Percoll medium (see recipe)

Sterile dissection instruments (large and small scissors, large and small forceps, scalpels)
Sterile Petri dishes
50-ml sterile plastic centrifuge tubes
Refrigerated low-speed centrifuge accepting 50-ml capacity tubes (2.5-cm diameter)
Dounce homogenizer (40-ml capacity with loose (B) and tight (A) glass pestles; Wheaton)
Cheesecloth
Potter-Elvehjem homogenizer (25-ml capacity, Teflon pestle, 0.1-mm nominal clearance—a bench or wall-mounted variable speed drive capable of 2500 rpm for homogenization or a domestic drill mounted in a drill press)
9 × 2.5–cm polycarbonate centrifuge tubes
30-ml syringe fitted with lumbar puncture needle or peristaltic pump
High-speed refrigerated centrifuge with Beckman Type 30 and SW28 rotors

Remove tumor

1. Identify tumor-bearing rats by inspection of the inoculation site or from symptoms of hypoglycemia (ataxia or hind limb paralysis).

2. Euthanize tumor-bearing rat in accordance with an IACUC-approved method.

   Carbon dioxide asphyxiation, if permitted, is convenient.

3. Sterilize skin with 70% ethanol or iodine. Identify tumors that have developed as non-invasive subcutaneous adenomas at the inoculation site. Remove tumor after exposing the tumor on a flap of skin and dissect from surrounding connective tissue. Reject any obviously necrotic or cystic tumors.

4. Transfer tumor to a Petri dish. Trim off and remove fat and connective tissue, cut tumor open with scalpel, and scrape tissue into cold PBS. Cut tissue into pieces of ~1 to 5 mm using small scissors, transfer to a 50-ml plastic centrifuge tube, and fill with cold PBS.

5. Remove debris and blood by letting tissue sediment under gravity or centrifuge for 10 sec at 1000 × *g*, 4°C. Wash two additional times adding 40 ml PBS per wash.

Homogenize tissue

6. Suspend the insulinoma pieces harvested from 5 to 20 animals (~2.5 to 10 g wet weight) in 40 ml ice-cold β-HM and centrifuge 5 min at 800 × *g*, 4°C.

7. Resuspend pellet in 5 vol of 1× β-HM.

8. Homogenize in Dounce homogenizer with four passes (four times down and up) with loose pestle and four passes with tight pestle.

9. Centrifuge 10 min at 1700 × *g*, 4°C. Retain supernatant.

10. Resuspend pellet in 5 vol of ice-cold β-HM, filter through two layers of cheesecloth.

11. Homogenize filtrate with Potter-Elvehjem homogenizer 10 to 20 passes at 2500 rpm.

12. Centrifuge 10 min at 1700 × *g*, 4°C. Combine supernatant with that from step 9 above–post-nuclear supernatant (PNS).

Prepare granules on self-forming Percoll density gradients

13. Pipet 10-ml aliquots of PNS into a series of 9 × 2.5–cm polycarbonate centrifuge tubes.

14. Underlay the sample with 25 ml of 27% Percoll medium using a 30-ml syringe fitted with lumbar puncture needle or pumped in by peristaltic pump.

15. Centrifuge in Beckman Type 30 rotor for 40 min at 35,000 × *g*, 4°C, with slow deceleration below 775 × *g*.

16. Fractionate the gradient by pumping out or displacement into 25 tubes (1-ml each).

17. Discard the first dense fractions (clear but containing lysosomes) and pool the following white turbid fractions (two to seven fractions) that contain the granules (ρ = 1.09 to 1.14).

18. Dilute the pooled fraction to 35 ml with β-HM and centrifuge 15 min at 20,000 × *g* in a Beckman SW28 rotor, 4°C.

19. Recover the granules from the floating pellicle in the bottom of the tube.

20. Repeat steps 17 and 18 above until the granules form a pellet in the base of the tube.

    At the indicated centrifugal forces, Percoll forms a gradient with a steep profile at the top and bottom of the tube with a near-linear intervening segment. A glassy pellet of Percoll forms in the bottom of the tube and should be avoided when removing fractions with a pump or syringe as it will occlude the tubing.

    Other angle-type rotors may be used such as Sorvall SS34 and Beckman 50.2 rotors. In each case the best centrifugation conditions need to be established empirically by varying the initial Percoll concentration (25% to 30% range), centrifugation speed, and time. Optimization of the shape of the gradient and the resolution in the ρ = 1.09 to 1.14 range can be performed on dummy gradients using the refractive index to monitor the sedimentation of the Percoll particles. Colored Percoll density marker beads are useful for this exercise.

    Percoll does not generally affect marker enzyme assays or SDS-PAGE of gradient fractions. Concentration of proteins from fractions by ultrafiltration, or trichloroacetic acid or organic solvent precipitation, is impractical as the medium also precipitates.

21. Resuspend final pellet in 1 ml β-HM for further analysis or store at −80°C.

PREPARATION OF GRANULES ON PREFORMED NYCODENZ GRADIENTS

Nycodenz (5-(*N*-2,3-dihydroxypropoylacetamido)-2,4,6-tri-iodo-*N*,*N*′-bis(2,3-dihydroxypropoyl)-isophthalamide) is used to prepare isoosmotic gradients up to ρ = 1.15 (27.6% w/v solution). It is superior to Percoll in separating insulin granules from lysosomes but contamination with intracellular membranes is greater. ER and mitochondria are also well separated but, unlike Percoll, sediment at a higher density than granules. Nycodenz can be used for preformed, self-formed continuous gradients, and step gradients. It is easily removed by dilution and centrifugation, gel filtration, and dialysis. Gradient profiles can be easily determined from the refractive index of the fractions and using the refractive index of the homogenization medium and the isotonic 27.6% Nycodenz solutions as reference values.

Preparation of Granules Using Nycodenz Continuous Gradients

There are many commercially available devices for pouring continuous gradients; however, they can be generated simply and reproducibly with common laboratory equipment. Two approaches for preparing isotonic 10% to 27.6% Nycodenz gradients are described (also see Alternate Protocol 2). The benefit of the continuous gradient over the step gradient is the case of preparation. The use of the continuous gradient over the step gradient may be due to lack of equipment or time.

Materials

β-HM medium (see recipe)
Nycodenz
Post-nuclear supernatant (PNS; see Basic Protocol 1)

9 × 2.5–cm polycarbonate centrifuge tubes
Parafilm
Multichannel peristaltic pump (Fig. 3.32.1)
Beakers
Stir plate and magnetic stir bar
Velcro
Pasteur pipets with 0.5-cm wide bores
Centrifuge with a Beckman SW28
5-ml syringe with long (8-cm) needle, 16-G lumbar puncture set

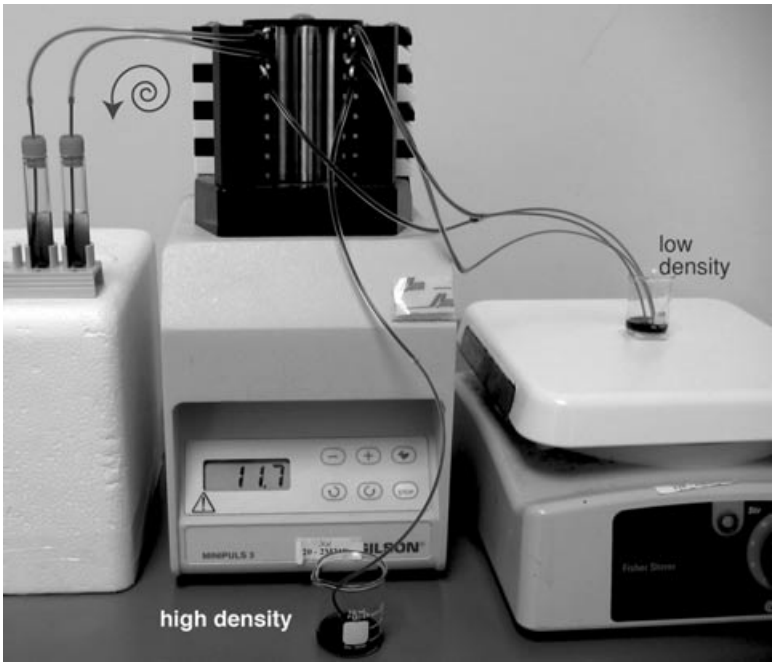

Figure 3.32.1 Gradient former. The setup shown can be used to generate pairs of matched gradients with a density range that spans the two starting solutions. The pump tubing must be of the same diameter as the tubes positioned in the two beakers, and the stirrer speed controlled so as to avoid the introduction of bubbles. The initial volume in the mixing beaker is equivalent to the final volume of each.

Prepare gradients

1. Prepare a series of mixtures of β-HM and buffered isotonic Nycodenz in the ratios of 9:1, 7:3, 5:5, 3:7, and 1:9 by transfering 5 ml of the first solution into the bottom of a 9 × 2.5–cm polycarbonate centrifuge tube, then underlay successively with 5 ml of the solutions of increasing density, ending with buffered isotonic Nycodenz.
2. Cap or seal with Parafilm, lay horizontally, and leave at room temperature or 4°C to allow diffusion of the layers (>2 hr).

   The process can be accelerated by inverting the tube once and returning it to the upright position.
3. Assemble a multichannel peristaltic pump with three tubes of equal diameter, a beaker with a stir bar fastened by a Velcro strip to a stir plate, and a reservoir of isotonic Nycodenz in a second beaker as shown in Figure 3.32.1. Ensure that the tubing from the reservoir to the mixing beaker is primed with liquid and the two tubes from the mixer are primed with air.
4. Place 36 ml low-density solution into the beaker and direct the two exit tubes to the bottom of two 9 × 2.5–cm polycarbonate centrifuge tubes. Start the stirrer and pump, and stop just before air is about to enter the centrifuge tube.

   Two identical linear gradients of ~25 ml each will be generated. The procedure can be repeated for additional gradients and can be used to prepare gradients of any volume; each gradient will approximate 0.7 of the volume initially placed in the stir plate beaker.
5. Leave the gradients at 4°C until use.

   Gradients are stable for up to 24 hr. Figure 3.32.1 shows a typical setup.

Centrifuge

6. Transfer 10-ml aliquots of PNS onto the top of each gradient. Use a Pasteur pipet with a wide bore (0.5-cm) immersed just under the top of the gradient to minimize mixing.
7. Centrifuge in a Beckman SW28 rotor for 1 hr at 100,000 × *g*, 4°C, with slow deceleration below 12 × *g*.
8. Fractionate the gradient by pumping out or by displacement into 25 tubes (1 ml each fraction).

   Granules appear as a diffuse cloudy band in the middle of the tube ($\rho = 1.10$ to 1.13).
9. Recover granules with a 5-ml syringe fitted with a long 8-cm needle (16-G lumbar puncture set). Avoid picking up the flocculent band of ER/lysosome/mitochondria that sediments as a tight layer below the granules.
10. Dilute the pooled fraction to 35 ml with β-HM and centrifuge 15 min at 20,000 × *g*, 4°C, in a Beckman SW28 rotor to recover the granules as a pellet. Resuspend the pellet for further analysis or store at −80°C.

ALTERNATE PROTOCOL 2

Using Nycodenz Step Gradients for Crude Granule Preparations

Alternatively, a Nycodenz step gradient can be used to prepare a crude granule fraction.

Materials

Post-nuclear supernatant (PNS; see Basic Protocol 1)
4.4%, 8.8%, and 17.2% (v/v) Nycodenz solutions (see recipes)
β-HM medium (see recipe)

9 × 2.5–cm polypropylene centrifuge tubes
Centrifuge with a Beckman SW28 rotor
5-ml syringe with 16-G needle

1. Transfer 20 ml of post-nuclear supernatant into two 9 × 2.5–cm polypropylene centrifuge tubes (40 ml total PNS).
2. Carefully underlay a step gradient comprised of 5 ml each of 4.4%, 8.8%, and 17.2% isotonic Nycodenz solution into each tube.
3. Centrifuge in a Beckman SW28 rotor 1 hr at 100,000 × *g*, 4°C, with slow deceleration below 12 × *g*.

   Mitochondria, lysosomes, and ER form a pellet in the tube. The interface between the original sample and the 4.4% Nycodenz layer is enriched in plasma membrane markers.
4. Recover the granules from the interface between the 8.8% and 17.2% Nycodenz layers using a 5-ml syringe fitted to a 16-G needle.
5. Resuspend granules in 35 ml β-HM medium and recover by centrifugation for 15 min at 20,000 × *g*, 4°C, in a Beckman SW28 rotor to recover as a pellet. Resuspend cell pellet for further analysis or store at −80°C.

   Step gradients are best designed after an initial analysis of the PNS on a continuous Nycodenz gradient and measurement of marker proteins (Fig. 3.32.2). There is variation between batches of Nycodenz probably related to the water content, and it is better to prepare the steps based on the refractive index and density. The steps can also be tailored to the experimental requirements as there is an inevitable trade off between recovery and purity of the fractions.

Granule Purification by Combined Nycodenz-Percoll Gradients

ALTERNATE PROTOCOL 3

Combined gradients of Nycodenz and Percoll are used for the additional isolation of granules as a more purified fraction at the expense of less material.

Materials

Nycodenz step gradient (see Alternate Protocol 2)
27% (v/v) Percoll (see recipe)
β-HM medium (see recipe)

9 × 2.5–cm polycarbonate centrifuge tube
Refrigerated centrifuge with Beckman Type 30 and SW28 rotors

1. Perform the Nycodenz step gradient procedure as in Alternate Protocol 2 omitting the final washing step 5.
2. Recover material from the 8.8%/17.2% interface in a total volume of 4 ml.
3. Transfer recovered material to a 9 × 2.5–cm polycarbonate centrifuge tube and suspend uniformly with 32 ml of 27% (v/v) Percoll.
4. Centrifuge in a Beckman Type 30 rotor for 40 min at 35,000 × *g*, 4°C, with slow deceleration below 11 × *g*.
5. Remove the clear layer below the granule band (1 to 2 ml) and discard. Pool the following white turbid fraction (∼5 to 7 ml) that contains the granules (ρ = 1.09 to 1.14).
6. Dilute the pooled fraction to 35 ml with β-HM and centrifuge 15 min at 20,000 × *g*, 4°C, in a Beckman SW28 rotor.

7. Recover the granules from the floating pellicle in the bottom of the tube.
8. Repeat steps 6 and 7 above until the granules form a pellet in the base of the tube. Resuspend pellet for further analysis or store at −80°C.

ALTERNATE PROTOCOL 4

Separations Using Self-Forming Nycodenz Gradients

Nycodenz gradients can be self-formed by centrifugation at high speeds; however, they will inevitably be somewhat hypotonic at the low-density end and hypertonic at the high-density end. It is nevertheless a convenient approach for preparing gradients in small volumes (2 to 4 ml) with benchtop ultracentrifuges. A protocol for an 8-place Beckman TLA 110 rotor that generates an approximation of a 10% to 30% Nycodenz gradient is described here.

Materials

27.6% isotonic Nycodenz
β-HM (see recipe)
Post-nuclear supernatant (PNS; see Basic Protocol 1)

13 × 50–mm centrifuge tubes
Refrigerated ultracentrifuge with a Beckman SW50.1 swing-out rotor

1. Mix 16 ml of 27.6% isotonic Nycodenz and 16 ml β-HM.
2. Transfer 3.3 ml to 13 × 50–mm centrifuge tubes.
3. Centrifuge 5 hr at 440,000 × *g*, 4°C.
4. Carefully remove the top 0.8 ml from each tube and replace with 0.8 ml PNS or other tissue fraction suspended in β-HM.
5. Centrifuge 60 min at 100,000 × *g*, 4°C, in a Beckman SW50.1 swing-out rotor.

The tube used is shorter than the conventional 13 × 56–mm TLA 110 rotor tube. Gradients can be prepared in advance and can be stored at 4°C for at least 24 hr. The gradient profile can be manipulated by changing the starting concentration of Nycodenz and the cumulative g × min for which the centrifuge is run. The Nycodenz will eventually clear from the top down. Other angle-head rotors can be used but in each case pilot studies are required to optimize the gradient shape based on measurement of the refractive index or density of gradient fractions.

INSULIN GRANULE PREPARATIONS FROM OTHER TISSUE SOURCES

Tumors

The INS1 cell line can usually be propagated in the NEDH rat as a solid tumor if required; however, results are variable in terms of the insulin content of the solid tumors that arise.

The procedures used to isolated rat insulinoma granules have been applied to mouse insulinomas (Bergman et al., 2000) using primary insulinomas from mice carrying a T antigen oncogene driven by the rat insulin II promoter (Efrat et al., 1988). This study used the non-obese diabetic (NOD) mouse on an immunodeficient *scid* background, a strain combination that poses logistical problems in terms of the longevity and care of the mice, but alternative insulinoma-bearing mice can be developed on other backgrounds by intercrossing with RIP T antigen transgenic mice. Once established, tumors and the derived cell lines can be passaged in mice of the same background, or more conveniently on a *scid* background, and harvested from animals after 3 to 6 weeks.

Cell Lines

A number of insulin-secreting cell lines derived from tumors can be grown in sufficient bulk to generate on the order of 0.1 to 1 g wet weight of tissue. These include the hamster insulinoma, HIT cell (Wang, 1989), rat INS-1 (Asfari et al., 1992), RINm5F (Bhathena et al., 1982) lines, and mouse β-TC (Efrat et al., 1988) and Min6 lines (Miyazaki et al., 1990), and derivatives thereof. Granules have been prepared from each of these sources using essentially the same procedures as described in Basic Protocol 1 for the solid tumors. Such procedures are best performed in smaller volumes using smaller rotors with modified homogenization procedures. A major determinant of the purity of the isolated granule fraction is the extent of granulation of the starting material, which for many lines may be <1% of pancreatic islets or solid tumors. It is thus essential to establish the suitability of the cell source based on insulin content before embarking on the isolation procedures. The buoyant density of granules can be expected to vary with the cellular source and species and, probably, clonal variation and passage number of the cell line in question. Pilot studies using continuous density gradient centrifugation are essential before proceeding to procedures based on step gradients. A procedure for isolation of granules from Min6 cells is detailed in Basic Protocol 2.

Pancreatic Islets

Pancreatic islets, in principle, should be an ideal source of starting material. The β-cell approximates 60% to 70% of the islet cell population, the rest being comprised of cells that store glucagon, somatostatin, pancreatic polypeptide, and ghrelin in dense core vesicles. Islets comprise only 2% to 5% of the pancreas volume and need to be isolated first by collagenase digestion and gradient purification. Inevitably there is some contamination with pancreatic acinar tissue, a cell type that is also extensively granulated. It is feasible to generate ∼1 mg wet weight of islets from a single mouse, and 5 to 10 mg from a rat. In both cases up to ten animals can be processed on a single day. The islet yield from a single human cadaveric pancreas can exceed 1 g wet weight, although the contamination with ductal and acinar tissue is usually high (10% to 50%).

PREPARATION OF GRANULES FROM CULTURED Min6 INSULINOMA CELLS

BASIC PROTOCOL 2

The following protocol uses the same gradient materials as those above for solid tumors but are adapted to the smaller amounts of tissue that are available from cell lines and isolated islets. The other major modification is the homogenization technique. Cultured cells appear more difficult to break than solid tissue and once dissociated into single cells appear resistant to homogenization by methods that rely on shearing such as the Potter-Elvejhem homogenizer. INS-1E monolayer cultures are used as an example. This harvesting, homogenization, and centrifugation protocol has been applied successfully to mouse β-TC3 and Min6 cells.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Materials

50× media supplement stock (see recipe)
Basal RPMI 1640 medium (see recipe)
Mm 6 cells in culture (75% to 80% confluent in 75-cm^2 tissue culture flask; Miyazaki)
0.25% (w/v) trypsin-EDTA (GIBCO cat. no. 25200)

Calcium- and magnesium- free PBS (GIBCO cat. no. 10010)
Cell dissociation medium (GIBCO cat. no. 13150-016)
β-HM (see recipe)
DNase I
30% Percoll (see recipe)

150-cm^2 tissue culture flasks
150-mm Petri dishes treated for tissue culture (Nunc cat. no. 168381)
Cell lifter (Costar cat. no. 3008)
2-ml Dounce homogenizer with loose-fitting (A) and tight-fitting (B) glass pestles (Wheaton), pre-chilled
1.5-ml microcentrifuge tubes
70-μm mesh filter *or* insulin syringe and 28-G needle (Becton Dickenson cat. no. 309309)
3-ml syringe
Ball-bearing cell cracker (0.1576-in. ball; 0.1586-in. bore; Industrial Tectonics)
13 × 56–mm polycarbonate centrifuge tubes
Centrifuge with Beckman TLA110 rotor
Screw-capped microcentrifuge tubes

Split cells

1. Add 10 ml media supplement stock solution to a 500-ml bottle of basal RPMI 1640 medium.
2. Split Mm 6 cells in a 1:4 ratio for culture in 150-cm^2 flasks under 5%CO_2/95% air atmosphere.
3. The day preceding the granule isolation recover the cells from each flask by trypsinization with 0.25% trypsin-EDTA (*UNIT 1.1*) and re-seed on 150-mm diameter Petri dishes treated for tissue culture at 5×10^6 cells per flask.

Harvest cells in GIBCO cell dissociation medium

4a. Prepare 5 to 20 flasks/dishes for each isolation ($0.2–1 \times 10^9$ cells in total).

5a. Rinse monolayers with Ca^{2+} and Mg^{2+}-free PBS to remove serum proteins and non-adherent cells.

6a. Dissociate cells from plastic with 2 to 5 ml cell dissociation medium.

7a. Pool tissue from all flasks and collect by centrifuging 5 min at 800 × *g*, 4°C.

8a. Rinse pellet two times by resuspending in 20 to 30 ml PBS and centrifuging 5 min at 800 × *g*, 4°C.

9a. Rinse once in 20 to 30 ml β-HM. Proceed to step 10.

Harvest cells in hypotonic medium

4b. Prepare 5 to 20 dishes for each isolation ($0.2–1 \times 10^9$ cells).

5b. Rinse monolayers with ≥4 ml Ca^{2+}- and Mg^{2+}-free PBS to remove serum proteins and non-adherent cells.

6b. Place each dish on ice and add 2.5 ml β-HM diluted 1:5 with water for 10 min.

7b. Harvest cells by scraping dish with cell lifter. Rinse with an additional 0.5 ml of 0.2× β-HM.

8b. Recover cells by centrifuging for 5 min at 800 × *g*, 4°C.

9b. Resuspend cell pellet in 5 vol β-HM just before proceeding to the homogenization step 10.

Homogenize cells

10. Estimate the volume of the cell pellet, resuspend in 5 vol β-HM containing 10 μg/ml DNase I and transfer 2-ml aliquots to the chilled 2-ml Dounce homogenizer.
11. Homogenize with 20 up and down strokes with the tight-fitting pestle (B).
12. Transfer homogenate to a series of 1.5-ml microcentrifuge tubes and microcentrifuge 5 min at 800 × *g*, 4°C.
13. Retain supernatant.
14. Resuspend pellet in original volume, pass through 70-μm mesh filter to remove any large aggregates of debris.

    Alternatively, aspirate and express through a 28-G needle attached to an insulin syringe.

15. Recover the filtrate in a 3-ml capacity syringe and pass five to ten times (back and forth) through a ball-bearing cell cracker (0.1576-in. ball; 0.1586-in. bore).
16. Transfer homogenate to a series of 1.5-ml microcentrifuge tubes and centrifuge 5 min at 800 × *g*, 4°C.
17. Recover supernatant and pool with supernatant obtained from step 13.

Perform differential and density gradient centrifugation

18. Transfer supernatants to a 13 × 56–mm polycarbonate centrifuge tube and centrifuge 10 min at 20,000 × *g*, 4°C, in a Beckman TLA110 rotor.
19. Gently resuspend the pellet in 1.0 ml β-HM using the loose-fitting pestle of the Dounce homogenizer. Transfer to a chilled 2-ml Dounce homogenizer and homogenize with several passes with a loose-fitting pestle (A) to ensure that pelleted material is well dispersed.

Perform Percoll gradient

20. Load 13 × 56–mm polycarbonate centrifuge tubes each with 0.5 ml of the resuspended 20,000 × g pellet from step 19.
21. Underlay with 3 ml isotonic 30% (v/v) Percoll. Mix and centrifuge 60 min at 25,000 × *g*, 4°C, in a TLA 110 rotor.
22. Fractionate the gradient into eighteen 1.5-ml screw-capped microcentifuge tubes either by pumping out the gradient from the bottom of the tube or by carefully removing 200-μl samples from the top of the gradient.

    The two-step homogenization procedure should release up to 60% to 80% of the secretory granules from cells as measured by the granule marker enzyme carboxypeptidase E (CPE) activity in the 10-min 800 × g supernatant. A CPE activity of 50% to 75% should be recoverable in a pellet produced by centrifugation of the supernatant 10 min at 20,000 × g.

    The harvest of tissue using the hypotonic medium does not cause cell lysis and the cells remain in clumps but are obviously swollen. A greater proportion of the cells can be broken with the Dounce homogenizer by this method, and the granules band at the same density on Percoll gradients without loss of yield.

PROPAGATION OF SOLID TUMORS

SUPPORT PROTOCOL 1

This is best performed at the time of harvesting but will require additional assistance. Select freshly harvested solid tumors that developed to a size of ∼0.3 g or less after 5 to 6 weeks from hypoglycemic animals as the source. Alternatively, use material from archived sources that were frozen at −80°C in 10% (v/v) DMSO in PBS and stored in liquid nitrogen. They can be thawed by dilution in PBS immediately prior to use.

Materials

Ethanol
Tumor pieces in PBS (see Basic Protocol 1) in 1-ml syringe and 16- or 18-G needle

1. Sterilize the injection site (scruff of neck or groin) with ethanol.
2. Inject ~0.1 ml of a suspension of tumor pieces prepared as in Basic Protocol 1 in PBS aiming at transferring 1 to 3 mg wet weight tissue per animal.

   Recipients were typically 8 weeks old of mixed sex.

   It is essential to monitor the stability of the tissue line. Tumor lines that develop quickly (<3 weeks) or grow to a large size (>2 g) without inducing hypoglycemia indicate a reduction of insulin biosynthetic capacity and should be rejected. Select against tumors that appear to be infiltrated by lymphocytic tissue (cheese like nodules) or small tumors that produce severe hypoglycemic symptoms. The phenotype can change at any time and it is advisable to periodically monitor the insulin content of the tumor fragment line (usually 10 to 40 μg/mg protein). Blood glucose levels are conveniently measured using any commercially available glucose monitor as used by diabetes patients by nicking the tip of the tail of the animal with a razor blade or the point of a 18- to 29-G hypodermic needle and expressing ~50 μl of blood. A normal random blood glucose in the rat is 5 to 10 mM (80 to 200 mg/dl).

ENZYME MARKER ASSAYS

Density gradient fractions should be analyzed for a series of marker proteins to evaluate the success of the procedure and the overlap between fractions. Quantitative analyses allow the determination of specific activity and enrichment. Immunoblotting is inferior in this regard but can provide information regarding compartmentalization as revealed by different molecular sizes of precursor and mature forms. A simple Coomassie or silver stained gel of fractions is useful in revealing major contamination arising from subcellular membranes that do not have specific markers. For pancreatic endocrine cells, immunoblots for Na/K ATPase (plasma membrane), Golgin 48 (Golgi), carboxypeptidase E (granules), and Cathepsin B (lysosomes) provide good signals. Enzyme assays for 5′ nucleotidase (plasma membrane), NADPH cytochrome *c* reductase (ER, see Support Protocol 3), cytochrome oxidase (mitochondria, see Support Protocol 4), CPE (granules, see Support Protocol 5), and *N*-acetylglucosaminidase (lysosomes; see Support Protocol 2) are sensitive and simple to perform. Examples of four such assays are given.

SUPPORT PROTOCOL 2

Enzyme Assay for β,*N*-Acetyl Glucosaminidase

β,*N*-acetyl glucosaminidase is a lysosomal marker.

Materials

Sample material: gradient fractions
β,*N*-acetyl glucosaminidase reaction mixture (see recipe)
1 M Na_2CO_3
4-Methylumbelliferone (standard)

96-well plate suitable for fluorimeter
37°C heating block
Fluorimeter

1. Transfer samples (1 to 10 μl) to a 96-well plate suitable for fluorimeter in use (black for top reading instrument; clear for bottom-reading instrument).
2. Add 50 μl β,*N*-acetyl glucosaminidase reaction mixture.

3. Incubate 10 to 30 min at 37°C.
4. Add 200 µl of 1 M Na_2CO_3 per well to stop the reaction.
5. Read fluorescence at excitation 360 nm, emission 488 nm against the 4-methylumbelliferone standard.

The fluorescence is greatly enhanced by the addition of Na_2CO_3 at the end of the incubation. Nevertheless the time course of substrate hydrolysis can be monitored at excitation 360 nm, emission 500 nm to establish the optimal sample volumes and incubation times for the assay.

Enzyme Assay for NADPH–Cytochrome *c* Reductase

SUPPORT PROTOCOL 3

NADPH-cytochrome *c* reductase is a marker for endoplasmic reticulum and Golgi.

Materials

Samples
NADPH-cytochrome *c* reductase reaction mixture (see recipe)

96-well plate
Spectrophotometer

1. Transfer samples (1 to 10 µl) to a 96-well plate.
2. Add 200 µl NADPH-cytochrome *c* reductase reaction mixture.
3. Monitor the increase in OD_{550nm} for 10 to 30 min at 37°C.

It is important to set the spectrophotometer at 550 nm as absorption peak is very narrow.

Reduction is monitored at 550 nm using molar absorbance indices of 27.7 × 10^3 $cm^2m^{-1\text{-}1iter}$. NADPH-linked assays should not be confused with the rotenone insensitive NADH-cytochrome c reductase that is mainly located in the outer mitochondrial membrane (Sottocasa et al., 1967).

Enzyme Assay for Cytochrome Oxidase

SUPPORT PROTOCOL 4

Cytochrome oxidase is a marker for mitochondria.

Materials

Samples
Cytochrome oxidase reaction mixture (see recipe)
100 mM potassium ferricyanide

96-well plate
Spectrophotometer

1. Transfer samples (5 to 25 µl) to a 96-well plate.
2. Add 200 µl of cytochrome oxidase reaction mix.
3. Monitor the OD_{550nm} for 2 to 10 min and calculate the enzyme rate from the linear segment of the time course.
4. Determine the absorbance of the oxidized form by the subsequent addition of 5 µl of 100 mM potassium ferricyanide and the difference in the OD_{550nm} used to quantitate the rate of reaction.

If no activity is detected in the assay, try shaking the reaction mixture again to remove residual dithionite.

SUPPORT PROTOCOL 5

Enzyme Assay for Carboxypeptidase E

Carboxypeptidase E is a marker for secretory granules.

Materials

Samples: granules isolated from insulinomas or cell lines
Carboxypeptidase E reaction mix A (see recipe)
Carboxypeptidase E reaction mix B (see recipe)
Acidified chloroform (see recipe)

1.5-ml microcentrifuge tubes
37°C heating block
96-well silica glass plate
Fluorimeter (360-nm excitation; 500-nm emission)

1. Transfer samples (1 to 10 μl) to each of two series of 1.5-ml microcentrifuge tubes: (A) total activity; (B) inhibited activity.
2. Add 200 μl carboxypeptidase E reaction mix A or B to the appropriate tubes and incubate 30 min to 1 hr at 37°C.
3. Add 300 μl acidified chloroform, vortex vigorously for 1 min.
4. Centrifuge 1 min at 2000 × *g*, room temperature and aspirate majority of upper phase.
5. Transfer 200 μl of the lower phase to 96-well silica glass plate.
6. Read the fluorescence at excitation 360 nm/emission 500 nm.

Although the fluorescence signal is not high, the signal-to-noise ratio is ~100:1 for a 100 μM solution of product. The CPE activity is the difference between the total (A) and GEMSA-inhibited (B) activity.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Acidified chloroform

Add 10 μl of 10 M HCl to 50 ml chloroform in glass bottle. Shake to dissolve. Prepare fresh.

Basal RPMI 1640 medium

Basal RPMI 1640 medium (Sigma cat. no. R 8758) containing:
11.1 mM D-glucose
10% (v/v) fetal bovine serum
500 U penicillin
0.5 mg streptomycin
Store up to 2 months at 4°C

β-HM, 2×

14 ml 60% (w/w) sucrose (see recipe)
1 ml 100 mM EGTA-K^+ (see recipe)
1 ml 1 M $MgSO_4$
2 ml 100 mM MES-K^+, pH 6.5 (see recipe)
Add H_2O to 50 ml
Store for 1 to 2 days at 4°C

β-HM

Add equal volumes of 2× β-HM (see recipe) and water. Store for 1 to 2 days at 4°C.

β, N-acetyl glucosaminidase reaction mixture

0.1 M citric acid NaOH, pH 5.6
0.1 mM 4-methylumbelliferyl-2-acetamido-2-deoxy-β-D-glucopyranoside
0.1% (v/v) Triton X-100
Prepare fresh

β, N-acetyl glucosaminidase or 4-methyl umbelliferone standard

Prepare a 10 mM stock solution of 4-methyl umbelliferone or β, *N*-acetyl glucosaminidase in water. Store frozen and protected from light. Dilute 1:100 in the reaction mix and prepare a standard curve with 1, 2, 5, 10, 20, and 50 μl in the reaction mix and make to a final volume of 50 μl.

Carboxypeptidase E reaction mix A

100 mM acetate buffer, pH 5.5
0.2 mM $CoCl_2$
0.2 mM dansyl phenylalanyl, alanyl, arginine (from 10 mM aqueous stock)
Store up to 3 months at −20°C

Carboxypeptidase E reaction mix B

Carboxypeptidase E reaction mix A (see recipe) with 10 μM GEMSA (guanidinyl ethane mercaptosulfonic acid; Calbiochem)
Store up to 3 months at −20°C

Carboxypeptidase E standard

Prepare 5 mM dansyl chloride solution in acidified chloroform (Sigma; see recipe). Prepare standard curve by addition of 1, 2, 5, and 10 μl of 5 mM dansyl solution to 200 μl final volume of acidified chloroform. Prepare fresh.

Cytochrome oxidase reaction mix

Add 10 μl of freshly prepared 1.2 M sodium dithionite solution (0.238 mg/ml in 50 mM sodium phosphate, pH 7.5) to 5 ml of 17 μM cytochrome *c*.

The solution will change color from orange to pink reflecting the reduction of the cytochrome.

Inactivate any excess dithionite by shaking the solution in the flask vigorously for 10 to 30 sec to allow atmospheric oxygen to oxidize the dithionite.

If the enzyme reaction appears to fail with a sample that is known to contain cytochrome oxidase activity, it is usually because there is residual dithionite, in which case repeat the shaking procedure.

EGTA-K^+, 100 mM

Add 3.8 g EGTA free acid in 80 ml water
Adjust to pH 7 with 1 M KOH
Adjust to 100 ml
Store 2 weeks at 4°C

The solid dissolves as neutrality is reached.

Isotonic Nycodenz, 4.4% w/v (pH 6.5)

3.2 ml 27.6% isotonic Nycodenz (see recipe)
8.4 ml 2× β-HM (see recipe)
8.4 ml H_2O
Store up to 1 to 2 days at 4°C

Isotonic Nycodenz, 8.8% w/v (pH 6.5)

6.4 ml 27.6% isotonic Nycodenz (see recipe)
6.8 ml 2× β-HM (see recipe)
6.8 ml H_2O
Store up to 1 to 2 days at 4°C

Isotonic Nycodenz, 17.6% w/v (pH 6.5)

12.8 ml 27.6% isotonic Nycodenz (see recipe)
3.6 ml 2× β-HM (see recipe)
3.6 ml H_2O
Store up to 1 to 2 days at 4°C

Isotonic Nycodenz, 27.6% w/v (pH 6.5)

Nycoprep Universal (500 g Nycodenz; Axis-shield cat. no. 1113058)

Media supplement stock, 50×

0.5 M Na^+-HEPES
100 mM L-glutamine
50 mM Na-pyruvate
2.5 mM β-mercaptoethanol
Filter sterilize through 0.2-μm filter and store up to 3 months at −20°C in 10-ml aliquots

MES-K^+, 100 mM (pH 6.5)

1.95 g mercaptoethanesulfonic acid hydrate
Adjust with 1 M KOH to pH 6.5
Add H_2O to 100 ml
Store 2 weeks at 4°C

$MgSO_4$, 1 M

12 g anhydrous $MgSO_4$ salt to 100 ml water. Store indefinitely at 4°C.

NADPH cytochrome c reductase reaction mixture

0.1 mM NADPH
0.3 mM KCN
0.1 mM horse heart cytochrome
50 mM sodium phosphate buffer, pH 7.5
Prepare fresh

Percoll, 27% (v/v)

13.5 ml Percoll suspension (Sigma)
Mix well by repeated inversion
25 ml 2× β-HM (see recipe)
11.5 ml H_2O
Stable for 48 hr at 4°C

Percoll, 30% (v/v)

15 ml Percoll suspension
Mix well by repeated inversion
25 ml 2× β-HM (see recipe)
10 ml H_2O
Stable for 48 hr at 4°C

Sucrose, 60% (w/w)

Slowly add 300 g sucrose to 500 ml water while stirring
Stable indefinitely at 4°C

COMMENTARY

Background Information

Dense core vesicles (DCVs) are the primary storage organelle for the secretion products of endocrine and exocrine tissues involved in regulated release of proteins such as polypeptide hormones and digestive hormones. They share common features: a simple phospholipid bilayer envelops a core comprised of condensed, often crystalline, protein that is usually specific for the cell type in question and often heterogeneous in composition. The dimensions of these vesicles are usually characteristic of the cell type in question, presumably related to the physico-chemical properties of the major protein components. They range from spheres of constant diameter (50-nm to 1-μm diameter) filled with cargo of uniform composition to cigar-shaped structures with longitudinally arranged fibrils. The high protein-to-water content and high protein-to-lipid ratio place these organelles among those with the highest buoyant densities ($\rho > 1.10$) in the cell, and thus they are generally readily separable from other organelles in high yield. That said, the pool of granules is usually comprised of immature, mature, and senescent populations and in some cell types mixed populations of granules occur that contain different proportions of major secretory products. The granule membranes are sites of active transport of protons and ions and susceptible to osmotic changes; the membranes are reactive to the ionic composition of the isolation medium. The spherical shape and close approximation of the membrane to the core make these organelles particularly susceptible to osmotic distension and breakage; thus they are best isolated under isoosmotic or hyperosmotic conditions.

Critical Parameters and Troubleshooting

The single most important variable that affects the success of the organelle isolation is the tissue homogenization process. The objective is to disrupt the majority of cells and release the organelles without breaking them. Homogenization procedures that work well with millimeter size pieces of soft tissues that depend on shearing in a motor-driven pestle and glass tube are inefficient with tissue culture cells. Conversely, ball-bearing homogenizers that work well with culture cells have limited application for tissue pieces. The authors' experience with blade homogenizers and nitrogen decompression methods with tissues has been that they disrupt cells efficiently but also cause excessive disruption of organelles, particularly nuclei and dense core vesicles. An approach that uses two or three cycles of tissue disruption, each with increasing severity and followed by centrifugation to separate released organelles from debris and unbroken cells, is preferable. This typically involves one round with a Dounce homogenizer, aspiration of the cells through a hypodermic syringe needle of 25- to 28-G, and finally, several passages through a ball-bearing homogenizer. It is important to determine the effectiveness of each step, and it usually suffices to determine the activity of a marker such as CPE (see Support Protocol 5) in the pellet generated by the 5-min, 800 $\times g$ centrifugation pellet, the corresponding supernatant, and the pellet and supernatant obtained by further centrifugation of the PNS for 10 min at 20,000 $\times$ g. Excessive homogenization not only reduces the yield of organelles but also leads to the generation of artifacts, which manifest as multiple sharply defined layers on density gradient centrifugation or as aggregated material of high density. With cultured cells it is usually better to err on the side of less efficient cell disruption and sacrifice yield.

The other important parameter to follow on gradient centrifugation is the density of the fractions. This is best achieved indirectly by measuring the refractive indices of the component solution of the gradient and the gradient

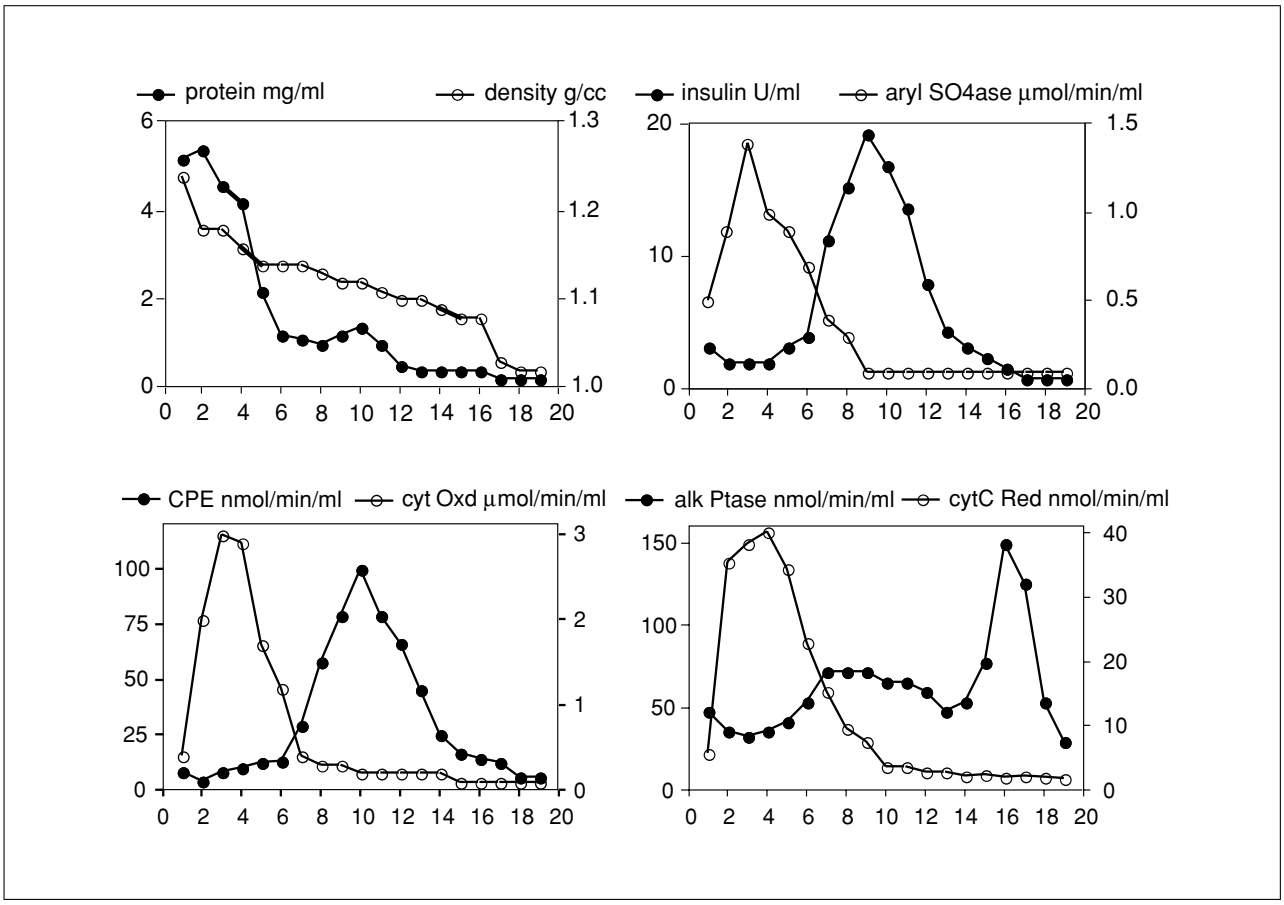

Figure 3.32.2 Ultrastructure and electrophoretic profile of granules isolated from a transplantable rat insulinoma by Percoll gradient centrifugation. An electron micrograph of a typical rat insulinoma cell is shown alongside the final preparation of granules equivalent to fraction B in Fig. 3.32.4 and the SDS PAGE separation of the major fractions A through G that result from the procedure (see Fig. 3.32.4 and Anticipated Results).

fraction. A useful device for these measurements are hand-held refractometers calibrated to measure sucrose concentrations in the 0% to 28% and 28% to 62% range (e.g., SHILAC models SH/MNL 1125 and SH/MNL2862; Camlab).

Ball-bearing homogenizer are not generally available commercially but can be manufactured in a well-equipped machine shop. The original design was prepared by Hans Issel (1667 Anamor Street, Redwood City, CA 94061, tel. 650-368-5417).

Anticipated Results

Insulin granule preparations from solid tumors typically yield on the order of 10 mg insulin granule protein (fraction B) from 10 to 20 g wet weight of washed tumor pieces. Typical marker protein profiles can be found in the literature (Hutton et al., 1982, 1983; Hutton and Peshavaria, 1983). The ultrastructural appearance of the final preparation is illustrated in Figure 3.32.2 along with the starting material and an SDS-PAGE analysis of the major fractions that are recovered from the gradient.

Preparations on Nycodenz gradients generally yield more material as there is less loss of granules at the final steps that involve repeated washes to remove gradient medium. An example of marker profiles is shown in Figure 3.32.3 and reported in Roep et al. (1991).

Granule preparation from cell lines is dependent both on the amount of starting material and the extent of granulation. Figure 3.32.4 illustrates results that were obtained from a Percoll gradient–based preparation from Min6 cells that contained ~10% of the insulin content (10 µg/mg protein) of rodent islet. The banding pattern observed on the gradient (Fig. 3.32.4B) is very similar to that obtained with solid tumors prepared on a larger scale, and the marker enzymes distributed in essentially the same way. The side fractions generated by the Percoll fraction while containing a mixture of organelles are often useful for other studies and can be recovered by the same procedure of repeated washing. They can be broadly described as follows:

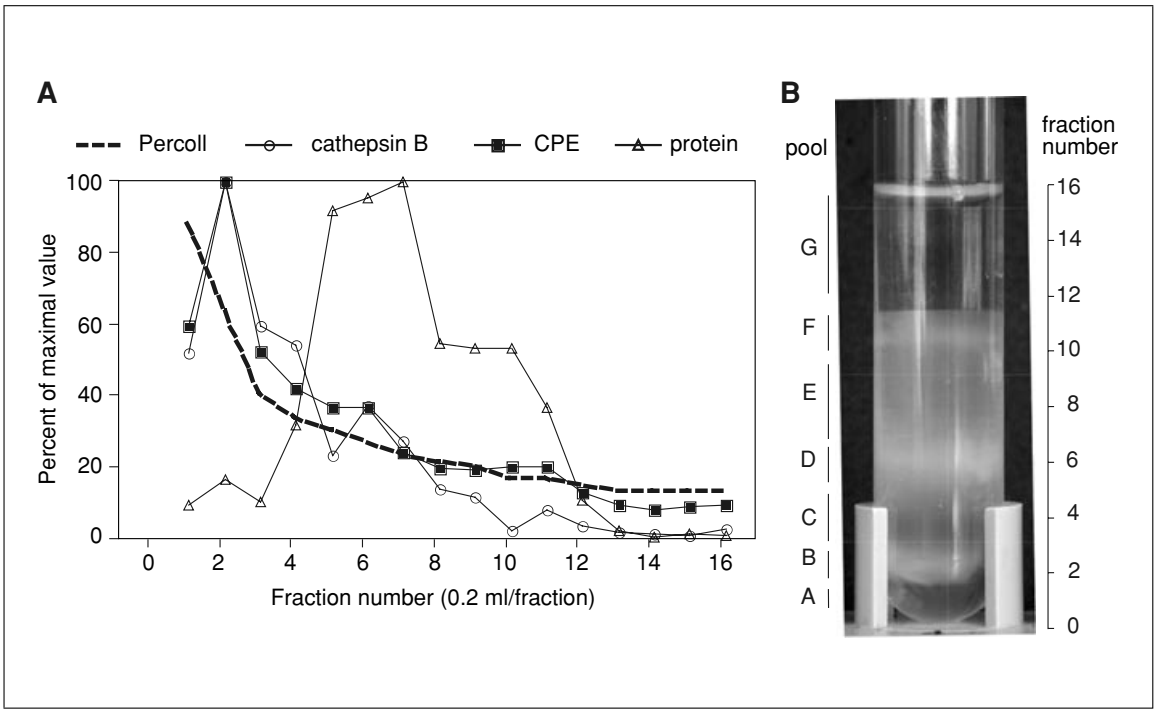

Figure 3.32.3 Percoll density gradient subfractionation of mouse Min6 cell homogenate A panel of lysosomal (cathepsin B) and granule (CPE) markers are shown alongside the gradient that was analyzed. The equivalent positions of fractions A through G that are shown in Figure 3.32.4 are indicated alongside the centrifuge tube.

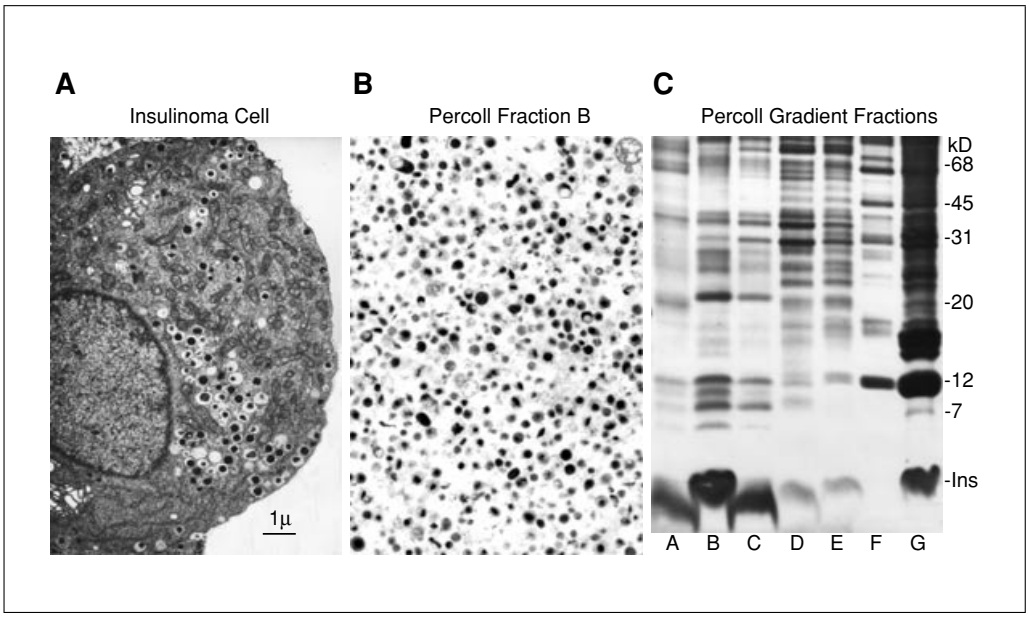

Figure 3.32.4 Nycodenz density gradient subfractionation of rat insulinoma tissue. Tissue was fractionated according to the protocol above and analyzed for markers of secretory granules (insulin and CPE), lysozomes (aryl sulfatase), mitochondria (cytochrome oxidase), ER (NADPH cytochrome *c* reductase), and plasma membrane (alkaline phosphatase). Profiles such as these are used in the design of step gradients. Steps corresponding to the Nycodenz concentration in fractions 7 and 15 would be a reasonable compromise between purity and yield. The purest fractions appear to correspond to the interval between fractions 12 and 15.

1. A secretory granule fraction containing the majority of cellular lysosomes.

2. The highest purity secretory granule fraction.

3. Granules with the lowest lysosomal contamination but containing significant mitochondrial and endoplasmic reticulum.

4. A mixed mitochondrial, ER, Golgi, and endosomal fraction with the highest specific activity of mitochondrial markers.

5. A mixed mitochondrial, ER, Golgi, and endosomal fraction with the highest specific activity of ER markers.

6. A mixed ER, Golgi, and endosomal fraction with the highest specific activity of plasma membrane markers.

7. A fraction containing all the cytosolic proteins together with proteins released from rupture of intracellular organelles.

Time Considerations

The time taken to complete the entire fractionation procedure from transplantable tumors is ~7 hr. Solution preparations, tissue harvesting, and initial preparation of tissue require ~120 min. Homogenization and preparation of the nuclear-free supernatant takes 60 min, and a single gradient centrifugation procedure another 60 min. Fractionation of the gradient is achieved in <60 min but the granule washing steps and clean up requires an additional 120 min. The procedure based on Nycodenz gradients can save 60 min principally as the wash steps are shorter.

Procedures based on the use of cell lines require ~6 hr, the time-saving part being on the initial tissue propagation.

Isolation and Biochemical Characterization of Amyloid Plaques and Paired Helical Filaments

Agueda Rostagno[1] and Jorge Ghiso[1, 2]

[1]Department of Pathology, New York University, New York, New York

ABSTRACT

Extracellular deposits of amyloid fibrils in the form of parenchymal plaques and cerebrovascular lesions, as well as intracellular accumulation of paired-helical filaments in the form of neurofibrillary tangles (NFT) in selected neuronal populations are the main neuropathologic hallmarks of Alzheimer's disease. Amyloid fibrils composed of polymeric structures of the amyloid-β (Aβ) concentrate at the center of senile plaques and accumulate in the walls of cerebral blood vessels, exhibiting extensive Congo red/thioflavin S staining. Intraneuronal NFT are composed of building blocks of aberrantly hyperphosphorylated species of the microtubule-associated protein tau, which accumulate in the perinuclear cytoplasm of vulnerable neurons in the form of paired helical filaments (PHF). This unit presents a variety of protocols for the isolation, biochemical analysis, and characterization of amyloid fibrils and neurofibrillary tangles. *Curr. Protoc. INTRODUCTION

The profuse deposition of amyloid fibrils in the parenchymal and vascular extracellular spaces of the cerebral cortex and leptomeningeal vessels is one of the hallmark lesions of Alzheimer's disease (AD). Fibrillar, compact deposits composed of amyloid-β (Aβ) and exhibiting extensive Congo red/thioflavin S staining concentrate at the center of the senile plaques or accumulate around cerebral blood vessels. In addition to compact plaques, typically surrounded by dystrophic neurites, activated microglia, and reactive astrocytes, most Alzheimer brains contain amorphous and less dense deposits, which are commonly referred to as diffuse or pre-amyloid plaques (reviewed in Selkoe, 1994; Ghiso and Frangione, 2002; Fig. 3.33.1). Under electron microscopy, these diffuse lesions—negative under Congo red or thioflavin S staining—display very few, if any, structurally altered neurites, astrocytes, or microglial cells, and in spite of their immunoreactivity with anti-amyloid antibodies, fibrillar components are very sparse or absent.

The presence of neurofibrillary tangles (NFTs), another histopathological trademark of AD, was described by Alzheimer himself in affected limbic and cerebral cortices via light microscopic evaluation following silver tissue impregnation by the Bielschowsky method (Fig. 3.33.1). Tangles are composed of building blocks of aberrantly phosphorylated species of the microtubule associated protein tau, which accumulates in the perinuclear cytoplasm of selected neurons in the form of paired, helically wound filaments (PHF; Grundke-Ikbal et al., 1986a,b; Ballatore et al., 2007).

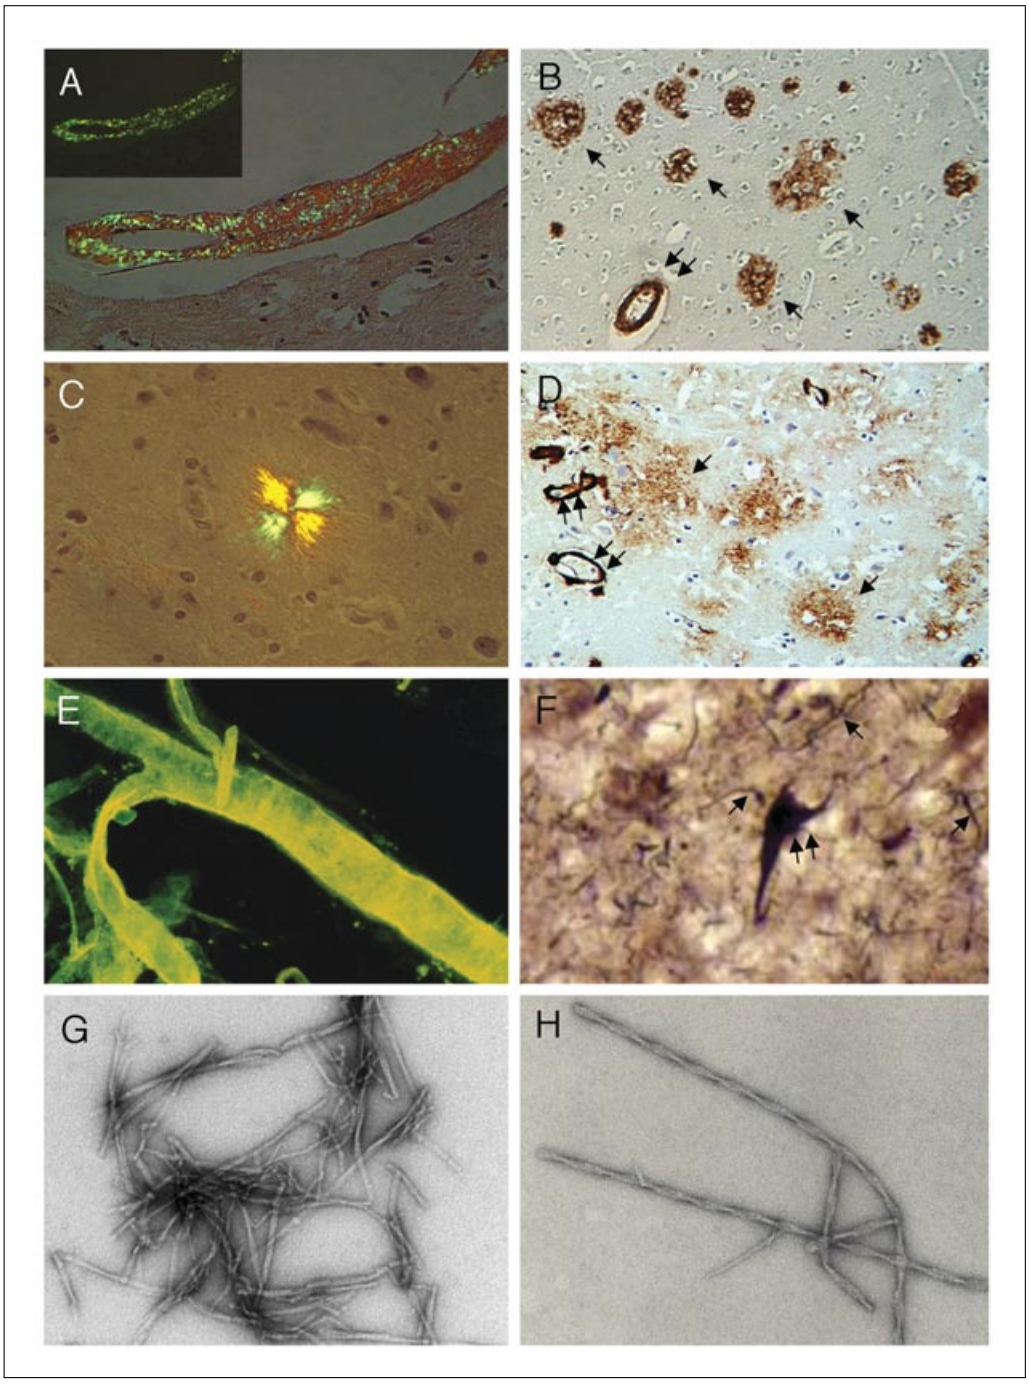

Figure 3.33.1 Microscopic examination of fibrillar deposits in Alzheimer's disease. (**A**) Vascular amyloid deposits in a medium-size leptomeningeal artery visualized by polarized microscopy after Congo red staining. Note the change in color from red to apple green (inset) when the light is polarized (100×). (**B**) Immunohistochemical detection of parenchymal amyloid plaques (arrow) and cerebrovascular Aβ lesions (double arrow) using specific anti-Aβ antibodies (100×). (**C**) Typical maltese cross aspect of a parenchymal plaque stained with Congo red and visualized by polarized microscopy (400×). (**D**) Parenchymal pre-amyloid lesions (arrows) and vascular deposits (double arrow) stained with anti-Aβ antibodies as in B (100×). (**E**) Leptomeningeal amyloid deposits in an isolated vessel observed under fluorescence microscopy after thioflavin S staining (100×). (**F**) Neurofibrillary tangles (double arrow) and dystrophic neurites (arrows) are visualized by Bielschowsky silver impregnation (1000×). (**G, H**) Electron microscopy images of amyloid fibrils (G) and PHF (H) obtained after negative staining with uranyl acetate (110,000×). For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0333*.

The biochemical characterization of both amyloid deposits and NFTs, initially hampered by their poor solubility properties, revealed a high degree of molecular heterogeneity and enrichment in post-translationally modified species. Due to their tissue localization and fibrillar configuration, protocols developed to isolate and purify amyloid fibrils and PHF primarily relied on physical methodologies (e.g., homogenization, filtration, standard and gradient centrifugation, FACS analysis), whereas improvements in solubilization were based on the use of detergents (SDS, sarkosyl), chaotropes (guanidine-HCl, guanidine-SCN, urea), or concentrated formic acid. Below, we describe different combinations of these approaches that have been successfully implemented in numerous laboratories (Iqbal et al., 1984; Gorevic et al., 1986; Grundke-Ikbal et al., 1986a,b; Roher et al., 1986; Selkoe et al., 1986; Tomidokoro et al., 2005).

Tissue Source For the Isolation of Amyloid and PHF

The isolation of amyloid and PHF requires the use of frozen brain tissue obtained at autopsy from AD patients with short post-mortem delay, preferable 4 to 8 hr (ideally $<$2 to 4 hr), to minimize the mostly enzymatically driven protein modifications occurring after death. The magnitude of the neuropathological lesions is highly variable not only among different AD cases but also among different regions of the same brain. This makes it necessary to select specimens with abundant AD-related pathology, as assessed by histopathological standard protocols (Hyman and Trojanowski, 1997), to ensure a high yield of purified amyloid and/or PHF. In general, most published protocols perform extractions from cortical regions after gross dissection of the gray matter, since plaques and NFTs are typically absent from the white matter (Braak and Braak, 1991; Lee et al., 1999).

AMYLOID/ PRE-AMYLOID PURIFICATION

Aβ deposits in brain parenchyma and cerebral blood vessels are challenging lesions to study. Their heterogeneous composition and rather poor solubility properties are perhaps the most important reasons to rely in a combination of procedures rather than in a single approach at the time of performing the studies. Whereas new technical approaches have been incorporated—particularly at the detection level—many of the current purification procedures were adapted from existing protocols to study systemic amyloid lesions. Classical protocols to study amyloid deposits generally include physical purification steps (e.g., centrifugation, filtration, and microdissection) combined with differential solubilization approaches (e.g. solubility in water, use of various chaotropes, organic solvents, and strong acids). The following protocols describe step-by-step procedures to isolate Aβ from different lesions and use an array of analytical detections.

Extraction and Solubilization of Amyloid and Pre-Amyloid Deposits for Subsequent Biochemical and Mass-Spectrometry Studies

BASIC PROTOCOL 1

The following extraction strategy takes advantage of the differential solubility properties of pre-amyloid deposits, which are usually poorly soluble in water-based solutions but extractable with SDS-containing buffers, in comparison with fibrillar amyloid structures, which are highly insoluble under both prior conditions but able to be solubilized by treatment with 70% to 99% formic acid. This differential-solubility based protocol for the extraction of amyloid and pre-amyloid materials has been widely used for the subsequent biochemical analysis of the Aβ species composing the lesions, typically by amino acid sequence analysis and more recently by a combination of immunoprecipitation and mass spectrometry. The latter is an extremely sensitive methodology, and has allowed the further identification of numerous truncated and post-translationally modified Aβ species as components of the deposits (Golde et al., 2000; Tomidokoro et al., 2005).

Materials

Frozen brain tissue
Tissue homogenization buffer 1 (THB-1; see recipe)
2% (w/v) SDS in 20 mM Tris·Cl, pH 7.4: prepared by diluting 1:5 a commercially available 10% SDS solution (BioRad) in 20 mM Tris·Cl, pH 7.4
70% (v/v) formic acid: prepared by diluting 99% formic acid (Sigma) with de-ionized water

Sterile dissecting instruments including:
Scalpel
Tweezers
Small spatula
Razor blades
Dounce glass homogenizer
300- and 70-μm Spectra/mesh nylon filters (Spectrum Laboratories)
10.4-ml polycarbonate bottles (Beckman) for ultracentrifugation (step 4)
XL100K ultracentrifuge (Beckman Coulter) equipped with a Beckman 70.1 Ti rotor, or equivalent
Ice bath
Vortex
5417 refrigerated microcentrifuge (Eppendorf), or equivalent

NOTE: All solutions should be ice-cold and procedures should be carried out on ice or inside a 4°C cold room.

Dissect brain (Fig. 3.33.2)

1. From frozen brain tissue, remove leptomeninges and large blood vessels. Separate gray from white matter with the aid of sterile dissecting tools (scalpel, tweezers, small spatula).

   To obtain a high yield in the extraction of amyloid, it is indispensable to verify the magnitude of the deposits using immunohistochemistry (Support Protocol 1) prior to the start of the isolation procedure.

2. Finely mince the gray matter (∼2.5 g) with a razor blade, add 12.5 ml of ice-cold THB-1, and homogenize in a Dounce glass homogenizer immersed in ice until no large pieces are visible.

   A useful alternative to the Dounce glass homogenizer, particularly when many samples are processed at once, is the use of a mechanical homogenizer equipped with disposable probes for soft tissues (e.g., Omni International).

Fractionate brain tissue

3. After homogenization, eliminate tissue debris via filtration through a 300-μm mesh nylon filter followed by subsequent removal of small vessels by filtration through a 70-μm nylon mesh.

   The vessel fraction may be reserved for further analysis of vascular amyloid (see Basic Protocol 3).

4. Subject the filtrate of the 70-μm filter to ultracentrifugation in a XL100K ultracentrifuge (Beckman Coulter) with a Beckman 70.1 Ti rotor 1 hr at 112,000 × *g*, 4°C, and save the THB-1-extracted supernatant enriched in soluble Aβ species for further analysis.

   The PBS supernatant typically contains soluble brain proteins and a minor proportion of soluble Aβ species (primarily monomers/dimers).

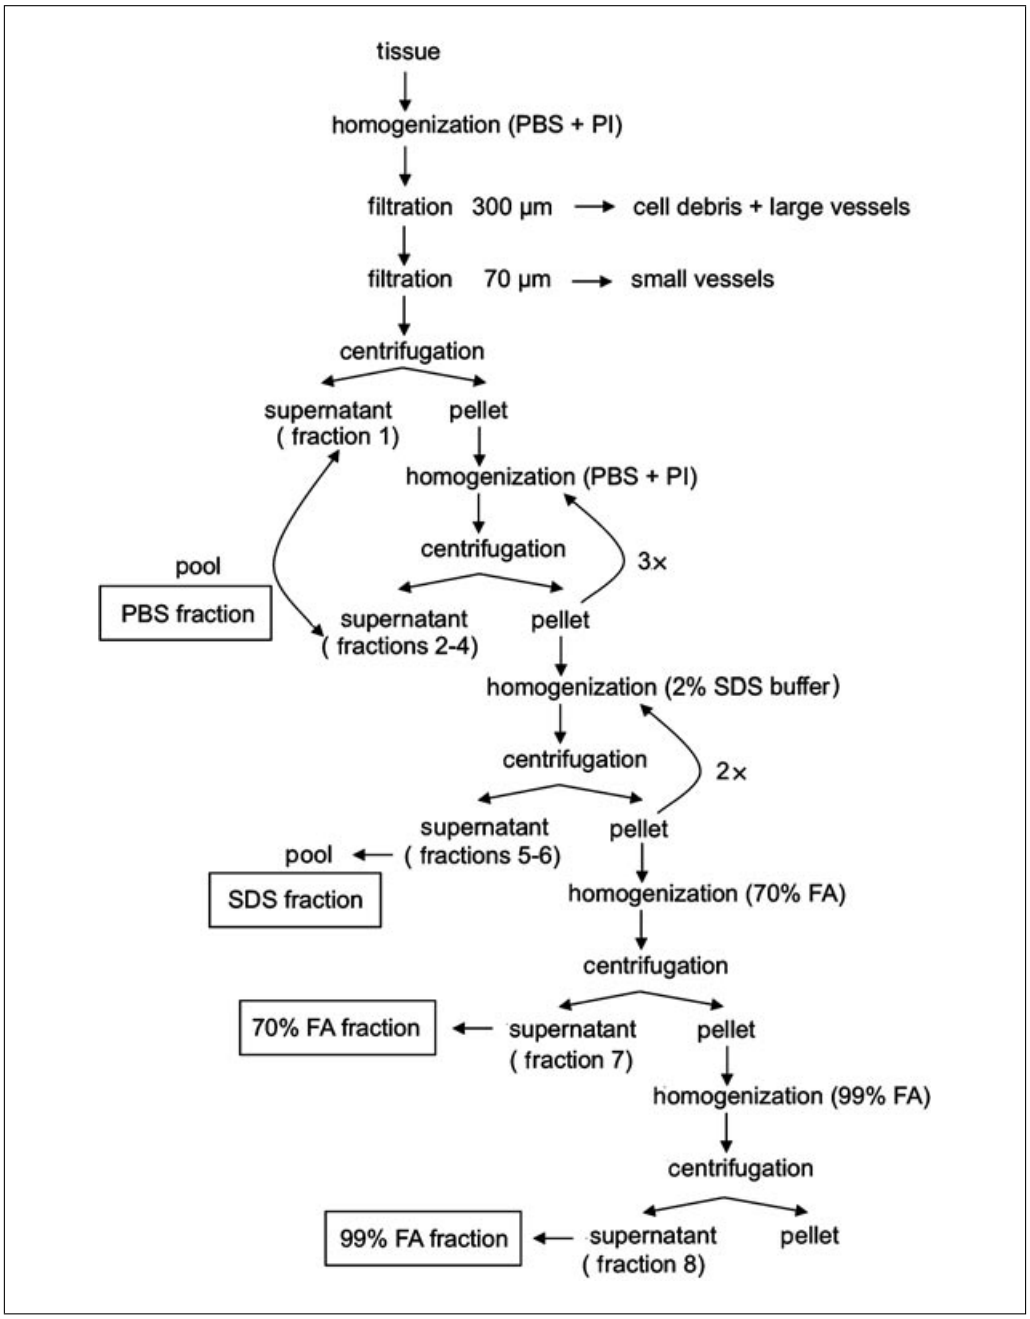

Figure 3.33.2 Schematic representation of the sequential extraction of pre-amyloid and amyloid species for subsequent biochemical and mass spectrometry studies, as described in Basic Protocol 1.

5. To ensure removal of undesirable water-soluble proteins, and extraction of most of the soluble Aβ, repeat the homogenization/centrifugation procedure at least 3 times. Combine and analyze the resulting supernatants as the PBS fraction.

6. Resuspend the PBS-insoluble pellet containing amyloid and pre-amyloid materials in 12.5 ml of 2% SDS in 20 mM Tris·Cl, pH 7.4, at room temperature.

   IMPORTANT NOTE: *The use of this solution at 4°C will result in crystallization of SDS.*

7. Ultracentrifuge samples 1 hr at 112,000 × *g*, 10°C, as above, and save the SDS-extracted supernatant rich in pre-amyloid species for further analysis.

Depending on the pre-amyloid load of the specimen, steps 6 to 7 should be repeated 2 to 3 times not only to increase pre-amyloid yield in the SDS-extracts but to minimize contamination of the fibrillar amyloid to be extracted in step 8.

8. Resuspend the pellet in 1 ml 70% formic acid, vortex 2 min, and centrifuge in a 5417 microcentrifuge 15 min at 18,000 × *g*, 4°C.

   The resulting supernatant (70% FA fraction) contains solubilized amyloid-rich fraction for further analysis.

   Depending on the load of dense plaques in the specimen, it might be necessary to add an additional extraction (step 9) using 99% FA to maximize the yield of solubilized amyloid. Use the initial immunohistochemical analysis to assess compact plaque density.

9. Resuspend the remaining pellet in 1 ml 99% formic acid, vortex 2 min, and centrifuge in a 5417 microcentrifuge 15 min at 18,000 × *g*, 4°C, as above.

   The resulting supernatant (99% FA fraction) also contains solubilized amyloid-rich fraction for further analysis.

   Regardless of the compact plaque density, proceed with step 9 if the pellet after step 8 is still significant. Typically, after 99% FA the remaining pellet is minimal or not existent.

ALTERNATE PROTOCOL 1

Extraction of Amyloid Fibrils and Plaque Cores

The isolation of amyloid plaque cores from homogenized gray matter tissue from AD cases (see Basic Protocol 1, steps 1 and 2) primarily rely on gradient density centrifugation. The most commonly used are discontinuous sucrose gradients (Selkoe et al., 1982; Gorevic et al., 1986; Selkoe et al., 1986; Roher and Kuo, 1999), although Ficoll density gradients have also been successfully used (Roher et al., 1986).

Materials

Frozen brain tissue
Tissue homogenization buffer 2 (THB-2 see recipe)
1.0, 1.2, 1.4, 2.0 M sucrose gradient solutions (see recipe)

Dounce glass homogenizer
100°C water bath
300-μm, 70-μm, and 35-μm Spectra/mesh nylon filters (Spectrum Laboratories)
Ultracentrifuge XL100K (Beckman Coulter) equipped with 70.1 and SW40 Ti rotors, or equivalent
10.4-ml polycarbonate bottles (Beckman) for ultracentrifugation (step 5)
Ultra clear tubes (14 × 95–mm; Beckman) for ultracentrifugation (step 7)

Additional reagents and equipment for dissecting gray matter (Basic Protocol 1) and microscopic detection of amyloids using Congo red staining (Support Protocol 2), Thioflavin S staining (Support Protocol 3), and electron microscopy (Support Protocol 4)

Prepare tissue sample (Fig. 3.33.3)

1. Select cerebral cortex rich in dense plaque cores (assessed by standard immunohistochemical analysis of the AD brain specimen), remove leptomeninges and large blood vessels, and dissect gray matter as described in Basic Protocol 1.

Homogenize tissue

2. Add THB-2 to the dissected tissue at a 1:1 (w/v) ratio and homogenize at 4°C in a Dounce glass homogenizer until a homogeneous suspension is obtained.

   A mechanical homogenizer equipped with disposable probes for soft tissues (e.g., Omni International) provides a useful alternative to the Dounce glass homogenizer.

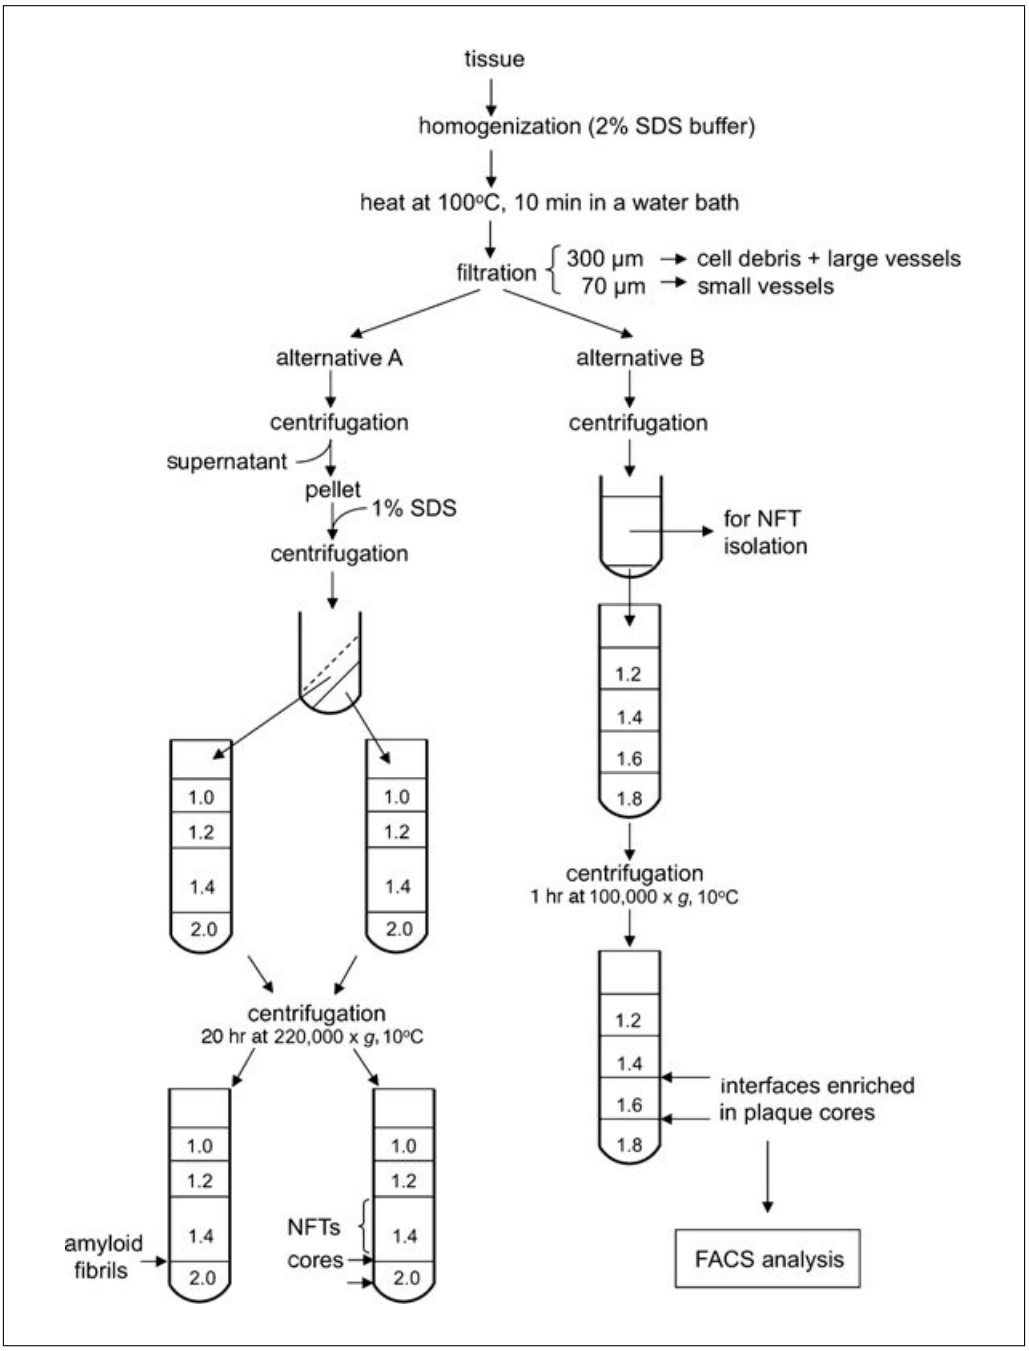

Figure 3.33.3 Schematic representation of the extraction procedure of amyloid fibrils and plaque cores, as described in Alternate Protocol 1 (alternative A) and Alternate Protocol 2 (alternative B).

3. Heat the mixture 10 min at 100°C in a water bath.
4. Sieve the homogenate through sequential nylon-meshes (300-µm and then 70-µm) to remove debris and blood vessels.

Fractionate the tissue

5. Centrifuge 1 hr at 100,000 × *g*, 10°C using a Beckman XL100K ultracentrifuge and a 70.1 Ti rotor.

   Depending on the number of samples and the starting material a 50.2 Ti rotor may be used to handle larger volumes or number of fractions.

6. Discard the supernatant and resuspend the pellet in THB-2, this time containing 1% SDS (ratio buffer to pellet 2:1) and repeat the centrifugation of step 5.

   The resulting pellet will be composed of two well-defined layers: an upper beige fluffy layer and a lower dark-brown hard layer. Both layers can be easily separated by carefully resuspending the top layer in THB-2 containing 1% SDS with the aid of a Pasteur pipet. Each layer will be used separately for further purification.

7. Load each layer separately onto a discontinuous sucrose gradient (1.0/1.2/1.4/2.0 M sucrose in 50 mM Tris·Cl, pH 7.6, containing 1% SDS).

   Layering of the sucrose solutions should be carefully performed with the aid of a Pasteur pipet and without disturbing the bottom layer. The tube should be kept at eye-level and observed against a light-source to allow visualization of the interfaces created by the different density levels of the various sucrose solutions. Start with 2 ml of the 2.0 M solution at the bottom of the tube. Sequentially, layer carefully 3 ml of the 1.4 M solution followed by 2 ml of the 1.2 M and 2 ml of the 1.0 M sucrose solution. Finally, load 2.3 ml of the resuspended layer on the top of the sucrose gradient.

8. Centrifuge 20 hr at 220,000 × *g*, 10°C in a Beckman XL100K ultracentrifuge using a SW 40 Ti rotor.

   The resulting interfaces and layers are easily visualized with indirect light against a dark background. Removal of each fraction can be achieved with the aid of a Pasteur pipet.

   The 1.4/2.0 interface obtained from the upper beige fluffy layer in step 6 is highly enriched in amyloid fibrils, whereas the same 1.4/2.0 interface from the dark-brown layer in step 6 contains mainly amyloid cores and some loose fibrils (Fig. 3.33.2). The 1.4 sucrose layer from the latter is enriched in PHF and could be saved for further purification.

9. Resuspend the 1.4/2.0 interface fractions containing either fibrils or a mixture of fibrils and cores in 8 ml distilled water and centrifuge 1 hr at 100,000 × *g*, 4°C, using a 70.1 Ti rotor.

10. Confirm the presence of fibrillar-amyloid-rich structures by light microscopy after Congo Red staining (Support Protocol 2), fluorescence microscopy following Thioflavin S staining (Support Protocol 3), or by electron microscopy after negative staining with uranyl acetate (Support Protocol 4) (Gorevic et al., 1986; Westermark et al., 1999).

11. Store purified amyloid fractions at −80°C until use.

ALTERNATE PROTOCOL 2

Extraction of Plaque Cores

The following protocol is based on the classical approach first described by Selkoe et al. (1986). As in the case of Alternate Protocol 1, it consists of a series of density centrifugation steps following tissue homogenization in the presence of SDS and with heating at high temperature to disrupt the tissue architecture and allow the release of the amyloid material.

Additional Materials *(see Alternate Protocol 1)*

Wash buffer (see recipe)
1.2, 1.4, 1.6, 1.8 M sucrose gradient solutions (see recipe)

100-μm and 35-μm Spectra/mesh nylon filters (Spectrum Laboratories)
J-6B refrigerated centrifuge (Beckman Coulter)
XL100K Ultracentrifuge (Beckman Coulter, Fullerton, CA) equipped with SW40 Ti rotors, or equivalent
Ultra-clear tubes (14 × 95–mm; Beckman) for gradient centrifugation (step 6)

Additional reagents and equipment for preparing brain homogenates (Alternate Protocol 1)

Prepare brain homogenates (Fig. 3.33.3, Alternative B)

1. Dissect gray matter, homogenize tissue, heat at 100°C, and sieve to remove debris and blood vessels as described in Alternate Protocol 1 (steps 1 to 4).

Fractionate the tissue

2. Centrifuge the filtrate 30 min at 300 × *g*, 100°C in a J-6B centrifuge. The supernatant, which contains abundant NFTs, may be saved for further purification of PHF (steps 5 to 16 of Basic Protocol 3). For amyloid core isolation, continue with steps 4 to 10.
3. Wash the pellet by resuspending in wash buffer and pelleting as described in step 2.
4. Repeat washes (steps 2 and 3) two times.
5. Resuspend the pellet thoroughly, sieve through a 35-μm nylon filter, and load on a gradient composed of 1.2 M, 1.4 M, 1.6 M, and 1.8 M sucrose.
6. Centrifuge 60 min at 72,000 × g, 10°C using an XL100K ultracentrifuge and SW40 Ti rotors.
7. Collect the 1.6/1.8 and 1.4/1.6 M sucrose interfaces, which typically show the greatest enrichment in plaque cores, separately.
8. Dilute each interface five-fold with wash buffer and pellet as described in step 2.
9. Store plaque cores at −80°C until further use.

Further purification of the amyloid core preparation may be achieved by fluorescence-activated cell sorting (FACS), if desired.

This procedure is highly specialized and it requires sophisticated and expensive equipment. It is therefore performed primarily at dedicated Flow Cytometry Facilities. For processing of the amyloid samples (step 9) for subsequent FACS analysis, please see (Roher et al., 1986; Selkoe et al., 1986). For detailed protocols on flow cytometry, please refer to Robinson et al. (2009).

Extraction of Amyloid from Leptomeningeal Vessels and Microvessels

ALTERNATE PROTOCOL 3

The presence of cerebrovascular amyloid is a common finding in AD and other vascular dementias (reviewed in Ghiso and Frangione, 2002). Interestingly, and driven by mechanisms still to be elucidated, there is not a completely homogeneous distribution of Aβ species between parenchymal and vascular AD deposits. While Aβ peptides ending at position 42 are found predominantly associated with parenchymal plaques, vessel-associated components are highly enriched in Aβ species ending at residue 40. Therefore, when a precise biochemical analysis of the vascular amyloid components is required, vessels need to be isolated prior to amyloid extraction. Sometimes the degree of amyloid load in leptomeningeal vessels is so overwhelming that just the dissection of a few large vessels provides enough material for biochemical studies. When leptomeninges are either not available or the leptomeningeal involvement is minimal, a thorough isolation of brain microvessels is mandatory.

Materials

Cortical brain tissue (e.g., frontal lobe)
Tissue homogenization buffer 3 (THB-3; see recipe)
Protease inhibitor cocktail (Complete; Roche Applied Science)
26% (w/v) dextran (MW 65,000-85,000) in THB-2
Percoll (Sigma)

Dounce glass homogenizer
J-6B refrigerated centrifuge (Beckman Coulter), or equivalent

350-, 150-, and 70-μm nylon mesh filters
50-ml polypropylene tubes (Fisher Scientific)
XL100K ultracentrifuge (Beckman Coulter) equipped with a Beckman SW40 Ti rotor, or equivalent (for Percoll gradient)
15 × 95–mm ultraclear tubes (Beckman)

Prepare tissue (Pardridge et al., 1987; Morelli et al., 2004)

1. Dissect cortical tissue (typically from frontal lobe of affected individuals) from leptomeningeal vessels.

   Not all sporadic AD cases present with the same level of vascular involvement and, in some cases, amyloid is mainly restricted to parenchymal distribution. Therefore, to obtain a high yield in the extraction of vascular amyloid, it is indispensable to verify the magnitude of the vascular deposits by immunohistochemistry, prior to the start of the isolation procedure (Support Protocol 1).

   For the isolation of amyloid from leptomeningeal vessels, skip steps 2 to 5. The leptomeningeal fractions obtained in step 1 of Basic Protocol 1, and Alternate Protocols 1 and 2 can be used for the isolation.

Homogenize tissue

2. Homogenize cortical tissue devoid of leptomeninges in 5 vol of ice-cold THB-3 containing protease inhibitor cocktail (see Basic Protocol 1) using ∼15 up and down strokes of a Dounce glass homogenizer immersed in ice.

3. Add an equal volume of a 26% dextran solution prepared dissolving dextran of 65,000 to 85,000 molecular weight in THB-3, and homogenize.

4. Centrifuge 15 min at 5,800 × *g*, 4°C in a J-6B Beckman centrifuge (or equivalent).

5. Resuspend the pellet in 10 vol THB-3 and sieve sequentially through 350-, 150-, and 70-μm nylon meshes.

   From this point onwards, microvessel fractions obtained in either step 3 from Basic Protocol 1 or step 4 in Alternate Protocol 1 can be also used in the purification procedure.

Isolate the vessel fractions

6. Collect the material that remained on top of the 150- and 70-μm meshes by inverting the filters on top of a 50-ml polypropylene tube and washing them with a stream of ice-cold THB-3 (∼20 to 30 ml).

7. Pellet these fractions 10 min at 1,000 × *g* in the J-6B refrigerated centrifuge.

8. Resuspend in 1 to 2 ml THB-3 and load on top of a preformed Percoll gradient (50% in THB-3, pre-generated by centrifuging 1 hr at 27,000 × *g*, 4°C, in the ultracentrifuge using 14 × 95–mm ultraclear tubes.

9. Centrifuge 10 min at 1,000 × *g*, 4°C, collect the middle white layer, and repeat the centrifugation on the Percoll gradient one more time.

Extract the vessel fractions

10. Combine the vessel fractions, homogenize, and proceed to sequential extraction with SDS and formic acid, as described in Basic Protocol 1 (steps 6 to 9).

    At this point many published protocols insert an extra step in which collagenase (1:20 to 1:50 enzyme/extract ratio) is added to the vessel preparation in order to degrade the collagen matrix and release the fibrils from the deposits, therefore increasing the yield of amyloid in the extracts (Roher et al., 1986; Tennent, 1999). However, keep in mind that collagenase also degrades Aβ generating proteolytic fragments that are not usually present in the deposits. If the operator is interested in the assessment of all Aβ species present in the various lesions, the use of collagenase should be avoided.

Plaque Isolation by Laser Capture Microdissection

Traditional biochemical methods like the ones described above have certain limitations since they fail to achieve the isolation of plaques to homogeneity. These restrictions were recently overcome with the advent of the laser capture microdissection (LCM) methodology allowing the collection of microscopic regions as small as 3- to 5-μm in diameter (Ahram et al., 2003; *UNIT 2.5*). It is possible to use LCM to capture neuropathological structures (e.g., plaques) with high purity, but the amount of sample material collected by this methodology is often limited, complicating the subsequent analysis. The recent development of highly sensitive proteomic technologies like liquid chromatography combined with tandem mass spectrometry (LC-MS/MS), which can directly analyze thousands of proteins from complex protein samples with sensitivity levels in the low femtomolar range, have made possible the successful use of LCM–obtained samples (Liao et al., 2004; Gozal et al., 2006).

Materials

Post-mortem blocks of frontal or temporal cortex
Cryostat mounting medium (Tissue-Tek O.C.T.; Jed Pella)
2-methylbutane (Fisher Scientific)
75% ethanol
Thioflavin S (Sigma)
Graded ethanol solutions: 50%, 95%, and 100% (v/v) ethanol
Xylene

HM500OM cryotome (MICROM International), or equivalent
Uncoated and uncharged glass slides (Fisher Scientific)
Fluorescence microscope equipped with a Pixcell II laser capture device (Arcturus), or similar
CapSure Macro LCM cap (Arcturus)

Additional reagents and equipment for laser capture microdissection (Liao et al., 2004)

Prepare tissue

1. Embed fresh post-mortem blocks of frontal and/or temporal cortex obtained at autopsy from neuropathologically diagnosed AD cases in cryostat mounting medium to allow for the cryopreservation of the tissue architecture.
2. Freeze tissue on dry, ice-cold 2-methylbutane, and store at −80°C until sectioning.
3. Prepare 10-μm tissue sections in a HM500OM cryotome (or equivalent).

   Laser capture microscopy may be conducted on tissue sections ranging from 5- to 10-μm thickness, too thin a section may prevent complete removal of Aβ plaques with concomitant loss of material, whereas too thick a section may result in the acquisition of contaminating excess material.

4. Mount the cryosections on uncoated and uncharged glass slides, and thaw at room temperature.
5. Briefly fix sections for 1 min at room temperature with 75% ethanol to histologically preserve the section while maintaining the quality of macromolecules for subsequent proteomic profiling.

   Despite being considered the "gold standard" for histopathological preservation, the use of aldehyde-based fixatives (e.g., formalin) should be avoided because the high level of covalently cross-linked proteins typically observed with such fixation is incompatible with current proteomic analysis protocols (Ahram et al., 2003; Gozal et al., 2006).

6. Visualize Aβ plaques by staining cryosections 1 min at room temperature with 1% thioflavin S in deionized water.
7. Differentiate by removing excess thioflavin S by incubating in 75% ethanol for 1 min at room temperature.
8. Dehydrate by sequential incubations of 2 min each in graded ethanol solutions (50%, 95%, and 100%,), clear for 5 min in fresh xylenes, air-dry for 5 min, and desiccate sections before LCM.

Perform laser capture microdissection (Liao et al., 2004)

9. Perform LCM the same day the cryosections are stained with thioflavin S and desiccated (as described in steps 6 to 8). Carry out the procedure in a fluorescence microscope attached to a Pixcell II laser capture device with the following settings: excitation wavelength, 495 nm; laser power, 60 to 80 mW; duration, 1 msec; laser spot size, 7.5 μm.
10. Collect ~500 to 2000 amyloid plaques from the tissue sections.

    The number of plaques dissected depends on the sensitivity of the analytical procedure to follow. A total of 2000 plaques allowed the complete proteomic analysis of plaque components with the individualization of >400 constituents of the amyloid deposits (Liao et al., 2004).

11. Capture a similar number of spots in nonplaque areas as control tissue.

    Each CapSure Macro LCM cap is used for the capture of ~500 plaques or control tissue spots from one slide.

12. *Optional:* Employ microdissected samples for mass spectrometry analysis.

    Typically, quadrupole time-of-flight mass spectrometry and liquid chromatography coupled with ion-trap tandem mass spectrometry (LC-MS/MS) are the most sensitive and widely used methodologies. Due to the sophisticated equipment and specific methodology involved in these analyses, readers should refer to specially dedicated reviews in the field (Gozal et al., 2006; Nesvizhskii, 2007).

MICROSCOPIC DETECTION OF AMYLOID

Amyloid and pre-amyloid deposits are easily visualized by immunohistochemical analysis with specific anti-amyloid antibodies and light microscopy evaluation. All amyloid deposits, irrespective of the amyloid subunit that compose the fibrils, share common physical, tinctoreal, and structural properties that include: (1) high degree of insolubility, (2) β-pleated sheet rich structures, (3) apple-green birefringence under polarized light after Congo red staining, (4) yellow fluorescence after Thioflavin S staining, and (5) fibrillar appearance after negative staining. Thus, microscopes with different levels of detection and resolution in conjunction with staining techniques with a diverse degree of specificity are very useful tools in amyloid research. Light and/or fluorescence microscopy are the methods of election for the general visualization of amyloid (e.g. using general amyloid dyes like Congo red or Thioflavin S), as well as for the identification of their individual components (e.g. through the use of specific antibodies). Electron microscopy provides the necessary resolution to visualize the actual fibrils and assess morphological parameters. The following are protocols to perform immunohistochemical, histological, and electron microscopic analysis of amyloid lesions and/or tissue extracts.

Aβ Immunohistochemistry

Immunohistochemical analysis of the brain tissues to be employed for amyloid isolation is indispensable for the evaluation of amyloid load and the adequate selection of the brain areas to be used. It is beyond the scope of this unit to describe the protocols for fixation and paraffin embedding of the brain specimens, as well as the preparation of adequate sections (see Hofman, 2002). This protocol describes a procedure for the immunohistochemical staining of amyloid and pre-amyloid Aβ deposits for subsequent light microscopy visualization.

Materials

8-μm thick Paraffin-embedded brain tissue sections on glass microscopy slides
Xylene
100%, 95%, and 75% ethanol
De-ionized water
98% (w/v) formic acid
Ready-to-use peroxidase blocking reagent (DakoCytomation)
Vecstatin ABC kit (Vector Laboratories) including:
  Blocking reagent
  Secondary antibody
  Vectastatin ABC
Phosphate-buffered saline (PBS; see recipe)
4G8 and 6E10 mouse monoclonal anti-Aβ antibodies (Covance)
Ready-to-use antibody diluent (DakoCytomation)
Tween 20
DAB Chromogen (DakoCytomation)
3% hydrogen peroxide
Hematoxylin (DakoCytomation)
Cytoseal-60 low-viscosity mounting medium (Richard-Allan Scientific)

60°C oven
Paper towels
Olympus BX60 microscope, or equivalent

Deparaffinize the sections

1. Dry slides 1 hr in a 60°C oven.

   This drying procedure removes water from underneath the tissue sections and makes them adhere better to the slide.

2. Deparaffinize the sections by placing the slides for three 5-min changes each in xylene and 100% ethanol followed by one 5-min change in 95% ethanol. Between changes, quickly blot the edge of the slide on a paper towel to remove excess liquid, but do not allow the slide to dry.

   Immersion steps are performed using Coplin jars or staining dishes with slide racks, depending on the number of slides that are being processed. The containers are filled so that the slides are completely immersed when they are inside the container. The solutions are reusable and should usually be changed after every 50 slides.

3. Rinse with de-ionized water.

Perform tissue pretreatment

4. Incubate with 98% (w/v) formic acid in de-ionized water for 10 min at room temperature.

   This step is necessary to increase access of the antibodies to the Aβ epitopes, which may be masked not only due to the protein cross-linking caused by paraformaldehyde but also due to the highly insoluble and fibrillar conformation of the protein within

the deposits. This pretreatment is commonly performed not only for Aβ but also for the immunohistochemical analysis of other amyloids. The incubation time is critical as prolonged incubations may result in the loss of the protein immunoreactivity.

5. Rinse thoroughly with de-ionized water.
6. Incubate 10 min at room temperature with ready-to-use peroxidase blocking reagent.

Immunohistochemical procedure

7. Block for 20 min with the blocking reagent of the Vecstatin kit diluted by adding 3 drops of the stock solution to 10 ml PBS.
8. Incubate 1 hr at room temperature with a combination of 4G8 and 6E10 antibodies diluted in ready-to-use antibody diluent at 1/200 each.
9. Wash the slides for three 5-min changes of PBS containing 0.1% Tween 20.
10. Incubate 30 min at room temperature with the secondary antibody (anti-mouse IgG) included in the Vecstatin kit diluted as indicated by the manufacturer.

    During this incubation prepare the ABC reagent, which needs to stand for 30 min before it can be used, following the manufacturer's instructions.

11. Wash the slides for three 5-min changes of PBS containing 0.1% Tween 20.
12. Incubate with Vecstatin ABC for 30 min at room temperature.

    At the time of setting this incubation, start dissolving the DAB. For this, add 1 tablet DAB to 10 ml PBS, and vortex. Protect from light until use.

13. Wash the slides with three 5-min changes of PBS containing 0.1% Tween 20.
14. Prepare the DAB chromogen solution by combining 2 ml DAB (prepared as in step 12) with 15 µl of 3% hydrogen peroxide.

    The DAB chromogen should be protected from light by covering the tube with aluminum foil. It is only stable for 2 hr at room temperature, therefore it is better to prepare it immediately before use and discard any remnant solution.

15. Coat sections with DAB chromogen solution and incubate 3 to 5 min at room temperature.
16. Rinse immediately with abundant de-ionized water.
17. Counterstain with hematoxylin for 6 min at room temperature.
18. Rinse with de-ionized water until wash solution is uncolored.

Mounting slides

19. Dehydrate sections by placing the slides for one 5-min change in 95% ethanol followed by three 5-min changes each in 100% ethanol and xylene.
20. Mount with low-viscosity mounting medium, coverslip, and visualize the staining in an Olympus BX60 microscope, or equivalent.

SUPPORT PROTOCOL 2

Congo Red Staining

Staining with Congo red in association with polarization microscopy is the most universally used methodology for the demonstration of amyloid in tissue specimens. The procedure is sensitive and simple to perform, two factors that have contributed to its incorporation to routine staining panels in pathological examinations. In order to be reliable, not only must the staining be performed under well-controlled conditions, but also tissue examination and staining evaluation require experienced operators using appropriate microscopy equipment and filters for polarization.

Materials

Congo red (Sigma)
80% (v/v) ethanol
Tissue samples
1 M NaOH
4% (v/v) paraformaldehyde in PBS
Deionized water

Whatman no. 1 filter paper
Positively charged microscope slides (Fisher Scientific)
Super Pap Pen (Invitrogen)
Olympus BX60 microscope equipped with crossed polarizers, or equivalent

Prepare the Congo red solution

1. Prepare 100 ml of a 1% (w/v) Congo red solution in 80% ethanol.
2. Stir 1 hr at room temperature.
3. Add 1 ml of 1 M NaOH.
4. Filter the solution through Whatman no.1 filter paper.

Fix and stain the isolated amyloid-fractions

5. Spot 5 to 10 µl of the resuspended fractions to be checked for the presence of fibrillar amyloid materials on a positively charged microscope slide.
6. Air dry for 30 min.
7. Circle the area of the dry drop with a Super Pap Pen.

   Circling the pertinent areas with a Pap Pen prior to histological or immunohistochemical procedures creates a water-repellent circle around the section preventing the waste of valuable reagents and at the same time ensuring that the staining solution remains in contact with the section during the staining procedure. The chemistry involved is formulated to withstand alcohol treatment.

8. Fix the material by incubating with 4% (v/v) paraformaldehyde (in PBS) 10 min at room temperature.
9. Rinse the slides with deionized water and air dry.
10. Stain the slides for 30 min at room temperature with the Congo red solution prepared in step 4.
11. Rinse the slides briefly (~10 sec) in 80% ethanol, and air dry.
12. Observe by polarization microscopy in an Olympus BX60 microscope equipped with crossed polarizers, or equivalent.

    Polarized light is a contrast-enhancing technique that improves the quality of the image obtained with birefringent materials. Under these conditions, amyloid shows a bright green birefringence, often referred to as apple-green birefringence (see Fig. 3.33.1).

    For polarization analysis, the microscope must be equipped with both a polarizer, positioned in the light path before the specimen, and an analyzer (a second polarizer) placed in the optical pathway between the objective rear aperture and the observation tubes. Image contrast arises from the interaction of plane-polarized light with a birefringent (or doubly refracting) specimen to produce two individual wave components that are each polarized in mutually perpendicular planes (Howie et al., 2008). After exiting the specimen, the light components become out of phase, but they are recombined with constructive and destructive interference when they pass through the analyzer.

SUPPORT PROTOCOL 3

Thioflavin S Staining

Thioflavin S and thioflavin T are sulfur-containing compounds that bind to amyloid fibrils; the latter is mostly used in spectrofluorometric studies while the former is preferably employed in histological protocols. Thioflavin staining is currently very popular for amyloid studies, not only for the detection of amyloid in tissue sections, but also for the study of fibril formation in vitro. The staining is easy to perform, but the requirement of fluorescence microscopy creates limitations for some facilities.

Materials

Amyloid-containing tissue sections
4% (v/v) paraformaldehyde in PBS
Thioflavin S (Sigma)
80% (v/v) ethanol
Mounting medium for fluorescence microscopy (Vector Laboratories)
Olympus BX60 epi-fluorescence microscope or equivalent

1. Fix the isolated amyloid-containing materials to be analyzed with 4% (v/v) paraformaldehyde 10 min at room temperature (as described in steps 5 to 9 of Support Protocol 2).

   The type of fixation procedure is not critical; different available methodologies are compatible with the immunofluorescence staining.

2. Incubate sections in 1% (w/v) thioflavin S in distilled water for 5 to 10 min at room temperature protected from light.

   IMPORTANT NOTE: *It is recommended that a new solution is freshly prepared the day of use and maintained protected from light (e.g., in amber-color or aluminum-foil-covered containers).*

3. Differentiate the sections in 80% (v/v) ethanol to remove excess fluorochrome and facilitate visualization.

4. Mount with fluorescence microscopy mounting medium (or equivalent).

5. Visualize in an Olympus BX60 or comparable fluorescence microscope, equipped for evaluation of green fluorescence (excitation 495 nm/emission 519 nm; see Fig. 3.33.1).

SUPPORT PROTOCOL 4

Electron Microscopy

Electron microscopy (EM), with a resolution of ~2 nm, offers a useful technique for the ultrastructural characterization of proto-filaments and mature fibrils formed during in vitro fibrillogenesis. The method also constitutes an invaluable tool to follow-up the isolation of amyloid plaque material in the various fractions as described above. For contrast enhancement of specimens, the samples to be evaluated are typically subjected to negative-staining techniques (Gorevic et al., 1986; Ward et al., 2000).

It is beyond the scope of this unit to describe the preparation of EM-grids and the use of the EM. Below is a description of the procedure to load the samples on the grid and perform the negative staining.

Materials

Sample to be analyzed, e.g., resuspended fraction
Milli-Q water (purified water with resistivity values at 25°C <18.2 Mho/cm), sterile
1% uranyl acetate, pH 6.0 (Electron microscopy grade, Spi-Chem)
300 mesh, electron microscope cooper or nickel grids (Canemco & Marivac, Quebec)

Filter paper
CM12 Philips Transmission Electron Microscope or equivalent

1. Apply 5 μl of the sample to be analyzed (e.g., a suspension of the washed pellet containing the amyloid fraction isolated from the sucrose gradient) on Formvar-carbon-coated, copper or nickel, 300 mesh, electron microscope grids and let stand for ~2 min.
2. Gently rinse with sterile milli-Q filtered water.
3. Add 5 μl of freshly prepared aqueous (milli-Q filtered water) 1% (w/v) uranyl acetate, pH 6.0, and incubate 15 to 20 sec for negative-contrast stain

   CAUTION: *Uranyl salts are both toxic and radioactive (low-intensity emitter of α-particles). Follow general safety precautions for handling radioactive compounds and dispose of contaminated waste in accordance with Institutional Policies.*
4. Blot dry with a strip of filter paper until the last drop is drained off, leaving only a thin film on the grid, and air dry.

   The stained grids can be stored at room temperature without adverse effects.
5. Evaluate amyloid fibrillar structures by transmission electron microscopy on a CM12 Philips Transmission Electron Microscope, or equivalent.

   Electron microscopy requires specialized equipment, handled by experienced operators and it is typically performed at dedicated facilities. For detailed description of microscope operation, image capture, and evaluation consult dedicated reviews (Holm et al., 1999; Westermark et al., 1999).

BIOCHEMICAL ANALYSIS OF AMYLOID IN THE BRAIN EXTRACTS

Biochemical analysis of the brain extracts are usually aimed to identify the main constituent of the amyloid deposits. Therefore, it combines the use of specific antibodies to either retrieve the molecule of interest from the extracts (e.g. using immunoprecipitation procedures) or identify its presence (e.g. by immunoblot analysis). This is done using methodologies that provide additional information about the analytes under study (e.g. a more precise molecular mass and/or amino acid sequence data using mass spectrometry techniques and automated amino acid sequence analysis). The following protocols provide a detailed description of the methodologies that can be carried out in a non-specialized research laboratory and the preparation of samples to be further analyzed at dedicated facilities.

Immunoprecipitation of Amyloid and Pre-Amyloid Extracted Fractions

BASIC PROTOCOL 2

Immunoprecipitation is a widely used methodology to enrich a preparation in a given protein, allowing subsequent elution of the precipitated protein and further analysis by gel electrophoresis (*UNIT 6.1*), mass spectrometry, immunoblotting (*UNIT 6.2*), amino acid sequence analysis, or any other method for identifying protein constituents in a sample. Different methods are available for the immobilization of the formed antigen-antibody complex, among them those based on its capture by immobilized Protein A or Protein G. More recently, new methods have been developed based on the use of paramagnetic beads precoated with secondary antibodies, which can be easily immunoreacted with the desired primary antibodies. After immunoprecipitation and following respective washes, paramagnetic beads are rapidly and efficiently collected with the aid of a magnet yielding high recoveries.

Materials

Paramagnetic beads coated with goat anti-mouse IgG (Dynabeads M-280, Dynal/Invitrogen)
Phosphate-buffered saline (PBS; see recipe)
4G8 and 6E10 monoclonal anti Aβ antibodies (Covance)
Blocking buffer: PBS containing 0.1% (w/v) bovine serum albumin (BSA; Sigma)
SDS-OUT (Pierce Biotechnology)
0.5 M Tris·Cl, pH 11.0
10% 2-mercaptoethanol (Sigma)
Milli-Q water (Purified water with resistivity values at 25°C <18.2 Mho/cm)
4:4:1 mixture of isopropyl alcohol/water/formic acid

1.5-ml microcentrifuge tubes
Eppendorf tube-rack equipped with a removable slide-out magnet (Dynal MPC-S)
Mini labRoller bi-directional rotator (Labnet International)
Savant SpeedVac concentrator (Global Medical Instrumentation)

Additional reagents and equipment for immunoblot assay (Support Protocol 5)

Coat paramagnetic beads with anti-Aβ antibodies

1. Resuspend the mouse-IgG-coated paramagnetic beads by inverting the vial several times. Transfer 50 µl of the suspension to a 1.5-ml microcentrifuge tube and position the tube in the rack equipped with a removable slide-out magnet.

   It is very important to use specially designed racks, which are equipped with potent magnets allowing the compacting of the beads at the bottom of the tube for volumes of 0.5 µl to 2 ml. The strong magnetic field permits total recovery of the beads without losses of material in the subsequent steps of the immunoprecipitation.

2. Wash the beads three times, each time with 1 ml PBS.

   For washing, remove the tube from the magnetic rack, add the PBS, resuspend by inverting the tube, position it back in the magnet-equipped rack, and remove the supernatant after the beads have compacted down.

3. Incubate pelleted beads with 3 µg each of anti-Aβ 4G8 and 6E10 overnight, at 4°C with bi-directional rotation in a Mini labRoller rotator or equivalent in a final volume of 100 µl.

   Coating with primary antibodies is also successfully performed by incubating 2 to 3 hr at room temperature. The proportions shown above are enough for one immunoprecipitation; if more samples are to be processed, the protocol should be scaled up accordingly.

4. Collect the beads by placing the tube on the magnet rack for 2 min. Remove and discard the supernatant.

5. Block the beads by resuspension in 1 ml blocking buffer and subsequently wash three times, each time with 1 ml of the same solution.

   Blocked beads can now be safely stored at 4°C; otherwise, proceed with the immunoprecipitation steps below.

Immunoprecipitate

6. Pretreat the brain extracts to allow for a successful immunoprecipitation. Treat SDS-extracts with SDS-OUT reagent, following the manufacturer's instructions to eliminate SDS. Neutralize formic acid extracts using 0.5 M Tris·Cl, pH 11 (Tomidokoro et al., 2005).

   Incomplete neutralization or lack of SDS removal will result in partial or total failure to immunoprecipitate Aβ from the brain extracts. Immunoprecipitation is based on the specific antigen-antibody reaction, in this case the interaction of Aβ species with the

immobilized anti-Aβ 4G8 and 6E10 antibodies. Extreme pH values and presence of detergents are among the known elements that disrupt antigen-antibody interactions.

7. Incubate anti-Aβ coated beads with neutralized amyloid- or SDS-free pre-amyloid-rich extracts overnight in a 4°C cold room and with bi-directional rotation, as above.

   The volumes of the tissue-extracted fractions to be incubated with the beads depend on the Aβ load of the different cases, as well as to the detection method that follows. Typically, immunoprecipitation of ~4% of the formic-acid- and ~20% of the SDS-extracts prepared in accordance to Basic Protocol 1 yield enough material for subsequent immunoblot and mass spectrometry analyses.

8. Wash the magnetic beads three times, each time with 1 ml PBS.

9. Elute the material bound to the paramagnetic beads in accordance to the assays that will be performed subsequently on the eluted material.

10a. *For immunoblot analysis:* Resuspend the beads in 10 µl of Tris-tricine SDS sample buffer containing 10% 2-mercaptoethanol and directly apply onto 16% Tris-Tricine gels for SDS-PAGE and immunoblot analysis, as described in Support Protocol 5.

   2-mercaptoethanol may be substituted by 5 µl of 1 M dithiothreitol (DTT; Sigma).

10b. *For MALDI-TOF mass spectrometry:* Wash the beads three times, each time with Milli-Q water and dry them in a SpeedVac concentrator system. Elute bound Aβ peptides with 5 µl of a 4:4:1 mixture of isopropyl alcohol/water/formic acid (Ghiso et al., 2001). Store the eluate at −80°C until MALDI-TOF mass spectrometry analysis.

   This analysis requires specialized equipment and it is typically performed at dedicated facilities; therefore, it will not be described herein.

Immunoblot Analysis

SUPPORT PROTOCOL 5

Immunoblot analysis is used to assess the presence of amyloid in purification fractions. Chemiluminescent substrates have been steadily gaining in popularity throughout the past decade to become the detection method of choice in most protein laboratories due to several advantages they have over other detection methods. ECL not only allows multiple exposures to obtain the best image, but also, the detection reagents can be stripped away and the entire blot reprobed to optimize detection conditions, test different antibodies, or visualize other proteins, including control proteins for normalization purposes. A large linear response range allows detection and quantitation over a large range of protein concentrations. Most importantly, chemiluminescence yields the greatest sensitivity of any available detection method with detection limits in the low picogram range.

Materials

Acrylamide stock: 40% acrylamide/Bis solution, 29:1 (3.3% C; BioRad)
Gel buffer: 3 M Tris·Cl, 0.3% (w/v) SDS, pH 8.45
Glycerol
Deionized water
10% (w/v) ammonium persulfate (APS)
TEMED (N,N,N,N′-tetra-methyl-ethylendiamine; BioRad)
Isopropanol
Samples to be analyzed
Tris-tricine sample buffer (BioRad)
Cathode buffer: Tris-Tricine-SDS buffer 10× concentrate (Sigma)
Anode buffer (10× concentrate): 2 M Tris·Cl, pH 8.9

Transfer buffer: 10 mM 3-cyclohexylamino-1-propanesulfonic acid (CAPS, Sigma), pH 11.0, containing 10% (v/v) methanol
Blocking solution: 5% non-fat dry milk in PBS containing 0.1% Tween 20 (Sigma)
Monoclonal anti-Aβ antibodies, 4G8 and 6E10 (Covance)
Tris-buffered saline (Fisher Scientific) containing 0.1% Tween 20 (TBS-T)
HRP-labeled F(ab′)2 anti–mouse IgG (GE Lifesciences)
Western Blotting ECL Detection Substrate (SuperSignal West Pico, Pierce Biotechnology)

Hoeffer MiniVE Mini Vertical Electrophoresis Unit (Fisher Scientific)
Nitrocellulose membranes for chemiluminescence (Hybond ECL; GE Lifesciences), prewet
Hoeffer TE22 Mini Tank Blotting Unit (Fisher Scientific)
Orbital Shaker (Bellco Biotechnology) or equivalent
Film for chemiluminescence (Hyperfilm ECL, GE Lifesciences)
M35A X-OMAT Film Processor (Eastman Kodak Company) or equivalent
Power supply Power Station 300 plus (Labnet International, Inc.) or equivalent

Prepare slab gels for Tris-Tricine SDS-PAGE (Schagger and Von Jagow, 1987)

1. For two 16% running gels (12 × 10–cm × 1.5–mm) combine:

   12.4 ml acrylamide stock solution
   10 ml gel buffer
   3.2 ml glycerol
   4.5 ml deionized water.

2. Add 150 µl 10% APS and 15 µl TEMED and pour immediately between the two previously set up glass plates. Overlay with isopropanol and leave at room temperature until polymerized.

3. Once polymerized, remove the isopropanol layer, and pour the stacking gel prepared as follows:

   1.6 ml acrylamide stock solution
   3 ml gel buffer
   7.4 ml deionized water.

4. Add 80 µl 10% APS and 14 µl TEMED, pour on top of the running gel, and carefully insert the comb avoiding the formation of bubbles.

Perform electrophoresis

5. Resuspend the samples to be analyzed—either purified and lyophylized amyloid and pre-amyloid extracts or paramagnetic beads containing the immunoprecipitated material (see Basic Protocol 2, step 10a)—in ~20 µl Tris-tricine sample buffer containing 10% 2-mercaptoethanol.

6. Boil for 5 min and load onto the gel previously assembled into the electrophoresis unit with the cathode buffer in the upper chamber and the anode buffer in the lower chamber.

7. Run electrophoresis at ~45 V (20 mA) for 15 to 30 min until samples have entered the running gel; at this point, increase voltage to 120 to 150 V until completion (~2 to 3 hr).

   For organization purposes, sometimes it is convenient to run the gels overnight. In this case, after the sample is inside the running gel, lower the voltage to ~20 V (<10 mA) for the overnight run.

Transfer the proteins

8. Remove the gel, equilibrate in transfer buffer for a few minutes, and assemble the transfer cassette positioning the prewetted nitrocellulose membrane carefully on top of the gel.

   Avoid touching the gel, nitrocellulose, transfer sponges, and cassettes without gloves. Make sure there are no air bubbles trapped between the gel and the nitrocellulose, which will prevent successful transfer.

9. Electrotransfer 45 min at 400 mA in a Hoeffer TE22 Mini Tank Blotting Unit, or equivalent

   To analyze the degree of Aβ oligomerization in the extracts increase the transfer time up to 2 hr to allow proper electrotransfer of higher-molecular-mass assemblies.

Expose the blot to antibodies

10. Carefully disassemble the transfer cassette and remove the nitrocellulose sheet. Rinse the membrane with 20 to 30 ml PBS, and block with 15 ml blocking solution for 3 hr at 4°C while rocking in a rotating platform.

    Blocking time is not critical and it can be extended overnight or even performed during the weekend depending on individual schedules.

11. Remove the blocking solution and incubate 3 hr at room temperature with a 10 ml combination of 4G8 and 6E10 at a final concentration of 1 μg/ml each in TBS-T, while on a shaker.

12. Wash the membrane three times, each time for 10-min with 20 ml TBS-T while rocking vigorously.

13. Incubate with 10 ml of the secondary antibody at a 1:10,000 dilution in TBS-T for 1 hr at room temperature.

14. Wash the membranes three times, each time for 10 min with 20 ml TBS-T while rocking vigorously.

Visualize the signal

15. Prepare the two-component ECL substrate, consisting of a stable luminol solution with an enhancer and a stable peroxide solution, by mixing the two components together at a 1:1 ratio.

    Once prepared, the ECL substrate working solution is stable for a minimum of 24 hr at room temperature.

16. Immerse the nitrocellulose sheet in the ECL substrate working solution and incubate for 2 min at room temperature. Assemble the autoradiography cassette positioning the drained nitrocellulose membrane between regular plastic sheet protectors making sure that no bubbles remain on top of the nitrocellulose membrane.

17. In a darkroom, assemble the autoradiography cassette by putting a sheet of film on top of the sheet protector sandwich containing the transferred membrane covered by the ECL substrate. Close the cassette and expose the membrane for ~30 sec to 1 min.

    Exposure times should be determined empirically and range from 3 to 5 sec to 10 to 20 min depending on the intensity of the signals, which in turn are related to the protein load on the gel, the concentration of Aβ of the samples analyzed, as well as the strength of the primary antibody. It is recommended to start with a medium time, ~30 sec to 1 min, each time developing the film as described below. Depending on the quality of the image obtained, either decrease or increase the exposure time, accordingly.

18. Develop the film in a M35A X-OMAT Film Processor, or equivalent.

SUPPORT PROTOCOL 6

Amino Acid Sequence Analysis

Determination of the primary amino acid sequence of a protein is the gold standard for protein identification delivering picomole-order sensitivity. Most sequence analyzers determine the N-terminal amino acid sequence through the Edman degradation reaction, labeling the amino terminal residue, which is then cleaved from the rest of the peptide, derivatized, and identified through the elution time in high-pressure liquid chromatography in comparison with standards (Edman, 1950; Niall, 1973). In this unit, we will restrict our discussion to the preparation of the samples for amino acid sequencing since the procedure requires specialized equipment and it is performed at dedicated facilities.

Materials

100% methanol
Milli-Q water (Purified water with resistivity values at 25°C <18.2 Mho/cm)
Transfer buffer: 10 mM 3-cyclohexylamino-1-propanesulfonic acid (CAPS, Sigma), pH 11.0, containing 10% (v/v) methanol
Sample to be sequenced
Protein stain solution: 0.125% (w/v) Coomassie Blue R-250 in 50% methanol
Destaining solution: 50% methanol

Polyvinylidene difluoride membranes (PVDF; Immobilon-P; Millipore)
Scalpel
Microcentrifuge tubes
494 Procise Protein Sequencer (Applied Biosystems) or equivalent

Additional reagents and equipment for immunblot assay (Support Protocol 5)

Prepare samples

1. PVDF membranes are hydrophobic and need to be pre-wetted in 100% methanol for 15 seconds before being transferred to a container with Milli-Q water for 2 min, and equilibrated in CAPS transfer buffer prior to the assembly of the transfer cassette. Do not leave any dry spots that can result in an unsuccessful transfer.
2. Separate the sample of interest in SDS-PAGE and electrotransfer to PVDF membranes following the procedure for immunoblot analysis (see Support Protocol 5).
3. After transfer, rinse the membrane with Milli-Q water, stain for 1 min with protein stain, and differentiate with several washes (15-sec each) of 10 ml destaining solution.

   The destaining procedure should be performed under continuous, vigorous shaking and with several changes of the destaining solution for more efficient removal of excess dye.
4. Rinse the transferred membrane with 30 ml Milli-Q water, excise the bands of interest with a scalpel, and keep them in a microcentrifuge tube under Milli-Q water at 4°C until sequencing at a dedicated facility.

   It is recommended that PVDF membranes do not dry at any time, since due to their hydrophobicity they will require re-wetting in 100% methanol to re-establish their hydrophilicity.

PURIFICATION AND CHARACTERIZATION OF PAIRED HELICAL FILAMENTS

Neurofibrillary tangles found in Alzheimer's disease brain are composed of twisted fibers known as paired helical filaments (PHFs). The biochemical characterization of the components of PHF eluded investigators for many years principally due to the difficulties in disrupting their structure and achieving solubilization. Eventually, it was demonstrated that PHF was constituted by self-assembled tangles of hyperphosphorylated tau proteins, a family of various isoforms of microtubule-associated proteins abundant in neurons. Through their interaction with tubulin, tau proteins promote tubulin assembly

into microtubules and stabilize these microtubules mostly by phosphorylation (reviewed in Ballatore et al., 2007).

Protocols employed for the purification of PHF are, like in the case of amyloid, mostly based on a combination of different solubilization strategies (e.g., use of various detergents, sonication and boiling, and addition of chaotropes) together with enrichment by sedimentation centrifugation and in some cases column chromatography. Below we describe two basic procedures successfully employed for the isolation of PHF from AD tissues (Iqbal et al., 1984; Lee et al., 1999).

Isolation of PHF by Sedimentation Centrifugation

BASIC PROTOCOL 3

This method for isolating PHFs is adapted from Lee et al. (1999) and summarized in Figure 3.33.4.

Materials

Frozen brain tissue enriched in NFT, as determined by standard immunohistochemistry
Tissue homogenization 4 (THB-4; see recipe)
PHF extraction buffer (see recipe)
Sarkosyl (Sodium Lauroyl Sarcosinate)
RAB buffer (see recipe)
Sucrose gradient solutions (see recipe)
Protease Inhibitors Cocktail (Roche)
2 M guanidine isothiocyanate

Dounce glass homogenizer
Ultracentrifuge XL100K (Beckman Coulter, Fullerton, CA) equipped with 70.1 and SW40 Ti rotors, or equivalent
Sonicator

Additional reagents and equipment for preparing a discontinuous sucrose gradient (Alternate Protocol 1)

Prepare tissue (Figure 3.33.4)

1. Dissect the gray matter clean of leptomeninges and large blood vessels.
2. Homogenize in tissue homogenization buffer 4 at a ratio of 1.5 ml buffer per gram of tissue using a Dounce homogenizer (20 strokes).
3. Incubate 20 min at 4°C to depolymerize any residual microtubules.
4. Centrifuge 20 min at 11,000 × *g*, 4°C, using the 70.1 rotor.

Separate PHF

5. Collect the supernatant and recentrifuge 60 min at 100,000 × *g* for 60 min, 4°C using the same rotor.

   The resulting supernatant contains primarily soluble normal tau while PHF remains in the pellet.

6. Combine the pellets from the first and the second cold centrifugations and resuspend in PHF extraction buffer at 1:10 (w/v) ratio (e.g., for 1 g starting material use 10 ml extraction buffer).
7. Centrifuge 20 min at 15,000 × *g*, 4°C.

   In the presence of 10% sucrose and at low-speed centrifugation, isolated PHF, as well as small PHF aggregates remain in the supernatant whereas intact or fragmented NFTs and larger PHF aggregates are pelleted.

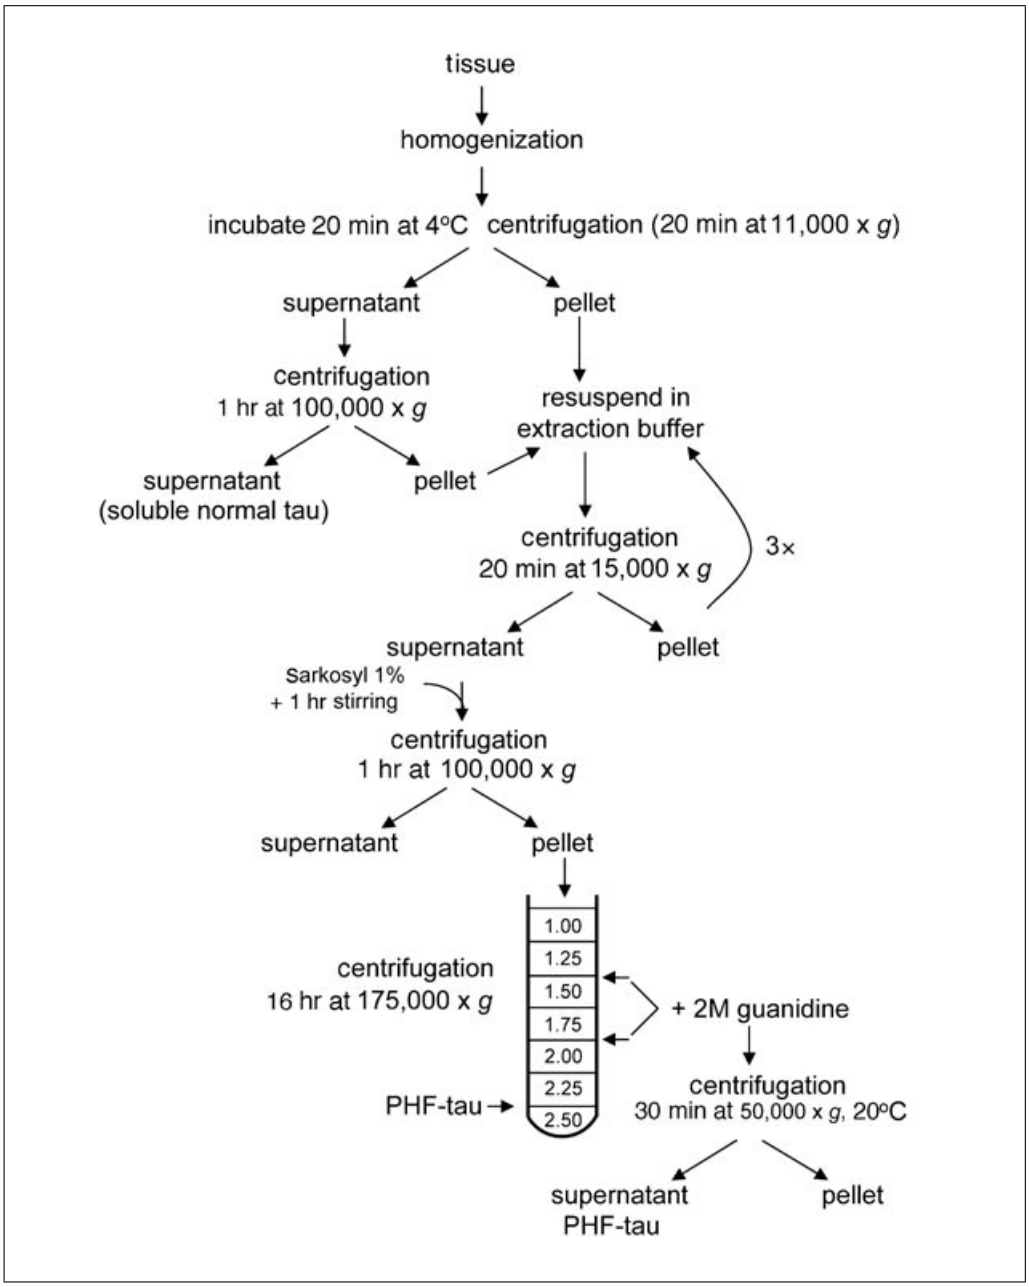

Figure 3.33.4 Schematic representation of the isolation of PHF by the sedimentation centrifugation procedure described in Basic Protocol 3.

8. Re-extract the pellet repeating steps 6 and 7 and pool the supernatants.

Remove membranes

9. Add Sarkosyl to a final concentration of 1% and stir 1 hr at room temperature.

   Sarkosyl treatment removes membranous material from the crude preparation thereby enriching the solution in PHF-tau.

10. Centrifuge for 30 min at 100,000 × *g*, 4°C, in the 70.1 Ti rotor.

11. Resuspend the pellet containing PHF in 1 to 5 ml THB-4 depending on the amount of starting material (1 ml buffer for 25 g of starting gray matter), sonicate until smooth, and boil for 5 min.

Purify PHF fraction

12. Load 0.5-ml aliquots onto a discontinuous sucrose gradient (1.0, 1.25, 1.5, 1.75, 2.0, 2.25, and 2.0 M sucrose in THB-3).

13. Centrifuge 16 hr at 175,000 × *g*, 10°C, using the SW40 Ti swinging bucket rotor.

14. Discard the white flocculent layer containing mostly membranes on the top of the gradient. Collect the 1.25/1.5 M interface, the 1.75/2.0 M interface, and the 2.25/2.5 M interface.

    A thick brown band is recovered between the 1.25 and 1.5 M sucrose interface, thick brownish material is found on the 1.75 and 2.0 M interface, and a small light-brown material between the 2.25 and 2.5 M sucrose layers.

    Typically, only the heaviest fraction contains PHF uncontaminated with amorphous material. However, this fraction represents <20% of the total PHF-tau recovered from all three fractions of the sucrose gradient—from 10 g of enriched gray matter only ∼1 μg of nearly pure intact PHFs is generated from this heaviest fraction.

15. If fractions from the two lightest sucrose interfaces are to be further purified for PHF-tau, after collecting the material, add 2 M guanidine isothiocyanate (∼1 ml per gram wet tissue) and stir for 1 hr at 37°C.

16. Centrifuge 30 min at 50,000 × *g*, 25°C, discard the pellet, dialyze the supernatant against several changes of distilled water to remove the guanidine isothiocyanate, and lyophilize.

    PHF-tau proteins are ready for further use; the fibrillar structure may be confirmed by Thioflavin S fluorescence assay (Support Protocol 3) or EM (Support Protocol 4) as described for amyloid preparations.

    The measurement of Thioflavin S fluorescence is a good indicator of PHF formation and it is generally employed in in vitro assays of tau assembly. Nevertheless, it is not an absolute proof of PHF existence since not only is it positive for tau aggregation into amorphous structures but also a shift in the thioflavin fluorescence is seen in the presence of amyloid fibrils and protofibrils, as described above.

    The ultimate demonstration of PHF purification is achieved by EM, revealing the typical 10 to 20 nm-wide filaments and showing the characteristic twist with a cross-over repeat of ∼80 nm (Wisniewski and Wen, 1985; Barghorn et al., 2005; von Bergen et al., 2005).

An Alternative for Isolation of PHF by Sedimentation Centrifugation

ALTERNATE PROTOCOL 5

This alternative protocol is also based on density centrifugation enrichment of NFTs, but it incorporates an additional glass beads chromatography step to eliminate contamination with capillary vessels (Iqbal et al., 1984).

Materials

Tissue
0.32, 1, 1.05, 1.1, 1.15, 1.2, 1.8, 2, 2.2 M sucrose (see recipe)
0.32 M sucrose-equilibrating buffer (see recipe)
Sodium dodecyl sulfate (SDS)

Dounce homogenizer
J-6B refrigerated centrifuge (Beckman Coulter), or equivalent
150-, 70-, 35-μm nylon mesh
150- and 30-ml tubes
Glass bead column (bead sizes 0.25 to 0.30-mm and 0.45 to 0.5-mm)

Additional reagents and equipment for transmission electron microscopy (Support Protocol 4)

Prepare tissue

1. Separate ~60 g of gray matter from meninges and white matter, homogenize in a 5-fold volume of 0.32 M sucrose in a Dounce homogenizer, and sieve through 150- and 70-μm nylon meshes (as in Basic Protocol 1).
2. Bring up the sucrose concentration of the filtrate to 1 M by adding 3.4 ml of 2 M sucrose for every 10 ml of filtrate.
3. Centrifuge 40 min at 4,800 × *g*, 10°C.
4. Remove the floating material, as well as the supernatant by aspiration and discard.

Fractionate the pellet

5. Resuspend the pellet in 1 M sucrose, rehomogenize, and load over a discontinuous density gradient of 20 ml each of 1.8, 1.2, 1.15, 1.1, and 1.05 M sucrose in 150-ml capacity tubes.
6. Centrifuge 50 min at 4800 × *g*, 10°C.
7. Remove the floating pad and all material above the 1.2/1.8 M sucrose interface and discard it. Pool together the layer banding at the 1.2/1.8 M sucrose interface and the pellet, which are enriched in NFTs, for further purification.
8. Dilute the pooled NFTs fractions five- to six-fold with deionized water, centrifuge as above (step 3), and discard the supernatant.
9. Resuspend the pellet in 0.32 M sucrose (as described in step 1) using a Dounce homogenizer, and further sieve the suspension through a 35-μm nylon mesh.

Run a glass bead column

10. Pass the filtrate through a glass bead column to remove the bulk of the capillaries present as a contaminant. Elute the column with the 0.32 M sucrose-equilibrating buffer.
11. Centrifuge the eluate as described in step 3, discard the supernatant, and re-homogenize the pellet in 0.32 M sucrose.
12. Add SDS to a 2% (w/v) final concentration and incubate at room temperature 3 to 5 min.

    Non-ionic detergents like Triton X-100 are considerably milder in their solubilization capacity and consequently leave a number of subcellular structures intact (e.g., neurofilaments). Therefore, their use for PHF isolation is not recommended.

13. Bring the sucrose concentration to 1 M by addition of 2 M sucrose (as in step 2). Layer on a discontinuous gradient of 5 ml of 2.2 M and 10 ml of 1.1 M sucrose in a 30-ml tube. Centrifuge as above (step 6), but increase the temperature to 20°C.

    SDS-containing samples cannot be maintained at low temperatures (see comments in Basic Protocol 1 for amyloid isolation).

14. Harvest NFTs, typically they are in the 1.1/2.2 M sucrose interface; a minor fraction may be found at the 1.0/1.1 M interface.

Assess the purity

15. Assess the purity of NFTs by EM using the same procedure as described above for amyloid and visualization by transmission electron microscopy (Support Protocol 4).

    PHFs extracted from Alzheimer's brain exhibit a characteristic twist with a cross-over repeat of ~80 nm (Fig. 3.33.1). The filaments have a typical width of 10 to 20 nm and a minimum width at crossing points of 9 to 9.5 nm. Single filaments twist over themselves to give the appearance of flat ribbons.

NFT Isolation by Laser Capture Microdissection

LCM provides advantages for the purification of NFTs, as in the case of amyloid plaques, being the most significant method with the capability of obtaining samples without cross-contamination with other tissue structures. This protocol is essentially the same as that described for the LCM of amyloid plaques (Alternate Protocol 4), also using 10-μm-thick cryostat sections of AD brain tissue. The individualization of NFT prior to the dissection is performed by routine immunohistochemistry using, as the primary antibody, mouse monoclonal anti-tau antibodies (tau-2, Sigma; Wang et al., 2005) or equivalent. This may be followed by either immunofluorescence detection via secondary antibodies conjugated to fluorescent dyes or by traditional HRP-labeled secondary antibodies followed by ABC complex and diaminobenzidine detection.

Materials

Tissue sections
Acetone, cold
0.1% Triton X-100
70% formic acid

Sonicator
Vacuum centrifugation system

1. Follow steps 1 to 4 of Alternate Protocol 4 for tissue preparation for LCM.
2. Fix sections in cold acetone for 10 min and permeabilize with 0.1% Triton X-100 for 10 min, and follow routine immunohistochemical procedures for NFT detection (Wang et al., 2005).
3. Follow step 9 of the microdissection procedure in Alternate Protocol 4. Collect ~2000 NFT-containing cells for a successful proteomic analysis, as well as a similar number of cells free of NFT to be used as controls.
4. Solubilize microdissected samples in 70% formic acid with 1 min sonication. Dry samples through vacuum centrifugation and proceed with mass spectrometry analysis.

   Typically, liquid chromatography coupled with ion-trap tandem mass spectrometry (LC-MS/MS) is one of the most sensitive and widely used methodologies for minute samples of complex protein mixtures. Due to the sophisticated equipment and elaborate methodology involved in these analyses, readers are referred to specially dedicated reviews in the field (Gozal et al., 2006; Nesvizhskii, 2007).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Phosphate-buffered saline

10 mM phosphate buffer, pH 7.4, containing 2.7 mM KCl and 137 mM NaCl. Dissolve one tablet of phosphate-buffered saline (PBS; Sigma) in 200 ml of de-ionized water. Scale up as needed. Store up to 6 months at 4°C.

PHF extraction buffer

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
10% sucrose
0.85 M NaCl
1 mM EGTA

continued

Adjust pH to 7.4 using 0.5 M NaOH
Store up to 3 months at 4°C

Sucrose-equilibrating buffer, 0.32 M

0.32 M sucrose
50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
0.1 M 2-mercaptoethanol
2% (w/v) SDS
Protease inhibitors cocktail (Complete; Roche Applied Sciences; prepared in accordance to the manufacturer's specifications)

Sucrose gradient solutions

Sucrose to appropriate molarity
50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
Prepare fresh

Tissue homogenization buffer 1

10 mM phosphate buffer, pH 7.4, containing 2.7 mM KCl and 137 mM NaCl. Dissolve one tablet of phosphate-buffered saline (PBS; Sigma) in 200 ml of deionized water. Scale up as needed. Add:

Protease inhibitors cocktail (Complete; Roche)
Dissolve one tablet of protease inhibitors cocktail per 50 ml of PBS
Store up to 1 week at 4°C

Tissue homogenization buffer 2

50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
2% (w/v) SDS
Protease inhibitor cocktail (Complete; Roche Applied Sciences; prepared in accordance to the manufacturer's specifications)
0.1 M 2-mercaptoethanol (add immediately prior to use)
Store up to 3 months at room temperature (without the addition of 2-mercaptoethanol)

Tissue homogenization buffer 3

15 mM HEPES, pH 7.4
103 mM NaCl
4.7 mM KCl
2.5 mM $CaCl_2$
1.2 mM $KHPO_4$
25 mM $NaHCO_3$
10 mM glucose
10 IU/ml heparin
Store up to 3 weeks at 4°C

Tissue homogenization buffer 4

100 mM 2-(*N*-morpholino) ethanesulfonic acid (MES)
0.75 M NaCl
1 mM EGTA
0.5 mM $MgSO_4$
2 mM DTT
Adjust pH 6.8 using 0.5 M NaOH
Store up to 3 months at 4°C

Wash buffer

150 mM NaCl
0.1% SDS
0.02% NaN_3
Store up to 3 months at room temperature

COMMENTARY

Background Information

Cerebral amyloid diseases are considered part of an emerging complex group of chronic and progressive entities collectively known as "Disorders of Protein Folding" that include sporadic and familial Alzheimer's disease, cerebellar ataxias, Parkinson's and prion diseases, tauopathies, type-II diabetes, systemic amyloidosis, Huntington's disease, and cataracts, among others (Dobson, 2001; Taylor et al., 2002; Lovestone and McLoughlin, 2002; Temussi et al., 2003). In these diseases, through mechanistic pathways poorly understood, soluble proteins normally found in biological fluids change their conformation and form insoluble structures that accumulate in the form of either intra- and extra-cellular aggregates or fibrillar lesions usually resulting in cell damage, organ dysfunction, and eventually death. Only about one-third of amyloid proteins known to be linked with human disease are associated with neurodegenerative disorders (Taylor et al., 2002; Rostagno and Ghiso, 2003). In AD two proteins aggregate in an abnormal fashion, the Aβ peptide, which builds the plaques in the parenchymal extracellular space and deposit around blood vessels, and the microtubule-associated protein tau, which polymerizes in the form of intraneuronal paired helical filaments, the building blocks of NFTs (Johnson and Bailey, 2002; Selkoe, 2003).

Regardless of the nature of the misfolded proteins involved, all extracellular fibrillar deposits, generically referred to as amyloid, share common physical, structural, and tinctorial properties (see Fig. 3.33.1). In general, they are (1) highly polymerized and poorly soluble assemblies, features that require the use of strong detergents, harsh acid conditions, or concentrated chaotropes to partially extract them from the tissue deposits; (2) structurally rich in β-pleated sheet conformations, a property responsible for the apple-green birefringence of the deposits when observed under polarized light after Congo red staining, as well as for their yellow-green fluorescence after thioflavin S staining; and (3) fibrillar in shape when negatively stained and observed under the electron microscope (LeVine, 1995; Klunk et al., 1999; Ghiso and Frangione, 2002). These properties are also shared by PHF, which show a high degree of insolubility, an enrichment in β-sheet configuration when compared with the unfolded structure of soluble tau (Vallet et al., 1992), and a typical fibrillar structure under the electron microscope (Gorevic, 1986; Barghorn et al., 2004; Fig. 3.33.1).

The high insolubility of the amyloid deposits and NFTs challenged investigators for many years and prevented the individualization of the respective proteins constituting the lesions. The methods employed to isolate plaques and tangles were mostly based on their physical properties, and consisted in various combinations of sieving through different sized meshes to eliminate microvascular components, density centrifugation to enrich preparations in heavier components (plaques and tangles), addition of different detergents and chaotropic agents, and heating and sonication in attempts to solubilize the materials (Selkoe et al., 1982, 1986; Masters et al., 1985; Gorevic et al., 1986; Roher et al., 1986; Greenberg and Davies, 1990; Iqbal and Grundke-Iqbal, 2006). Above we have presented a group of protocols exemplifying the use of these different methodological approaches. Other protocols, not described here, represent variations of the main procedures and are based on the same principles (Ihara et al., 1983; Masters et al., 1985; Rubenstein et al., 1986; Greenberg and Davies, 1990; Roher and Kuo, 1999). An exception is constituted by a few methods that in addition to the traditional tissue homogenization and gradient centrifugation steps employ fluorescence-activated cell sorting (FACS) techniques to separate plaques and tangles after their immunoreaction with either anti-Aβ or anti-tau antibodies, respectively, followed by secondary antibodies conjugated to fluorescent dyes (Roher et al., 1986; Selkoe et al., 1986). We did not describe the FACS-based methods in these protocols due to their requirement for cell sorting equipment, which is not always widely available.

The advent of mass spectrometry methodologies provided invaluable tools for the analysis of the components of plaques and tangles and were instrumental in the assessment of post-translational modifications associated with both deposits. In the case of Aβ, mass spectrometry corroborated the presence of cyclic pyroglutamate-modified fragments, exclusively associated with deposited N-terminally truncated Aβ species not detected in biological fluids, and demonstrated an abundance of soluble N-, and C-terminal degraded species likely representing the action of an array of diverse proteases and clearance mechanisms (Vigo-Pelfrey et al., 1993; Kuo et al., 1997; Tomidokoro et al., 2005). Mass spectrometry was also instrumental in the identification of many of the abnormal hyperphosphorylated sites of PHF-tau protein extracted from AD cases (Hasegawa et al., 1992; Hanger et al., 1998; Iqbal and Grundke-Iqbal, 2006). The recent development of proteomic technologies based on the use of more sophisticated mass spectrometry methods, capable of identifying minute components in complex protein mixtures, became an invaluable tool for the analysis of AD-related lesions. Their extraordinary sensitivity, in combination with the high selectivity of laser-capture microdissection techniques, allows the isolation of plaques and tangles without cross-contamination with other tissue structures. Using this approach, >400 proteins have been demonstrated in AD senile plaques (Liao et al., 2004; Gozal et al., 2006) while 155 different components have been shown to form part of the protein deposits in NFTs (Wang et al., 2005).

We have limited the scope of the protocols presented above to the isolation of amyloid and NFTs from AD brains. Nevertheless, the same methodological approaches may be adapted to the isolation of plaques and tangles found in other cerebral amyloidosis. It should be emphasized that although AD is by far the most common brain amyloidosis, other disorders share the presence of parenchymal amyloid and pre-amyloid deposits and, in some cases, even NFTs with identical pattern of PHF-tau (reviewed in Ghiso and Frangione, 2002). Among the non-Aβ amyloidosis, two diseases, familial British and Danish dementias, show striking clinical and neuropathological similarities to AD (reviewed in Ghiso et al., 2006). We have adapted the protocols described above for the extraction and biochemical identification of the vascular and parenchymal amyloid and pre-amyloid deposits in familial British and Danish dementia cases, and successfully achieved the identification of the deposited species via mass spectrometry (Tomidokoro et al., 2005). Through slight modifications, the methodology described above may also be employed for other amyloid disorders either cerebral or systemic, with differences in solubility being the major consideration.

Critical Parameters and Troubleshooting

The accurate biochemical evaluation of amyloid and PHF extracted from brain specimens of affected individuals requires minimization of the mostly enzymatic-driven protein modifications occurring after death. It is therefore imperative to use tissue that was collected with the shortest post-mortem delay—ideally no more than 2 to 4 hr—to ensure high recovery and minimal changes. In addition, the appropriate selection of tissues is perhaps one of the most critical factors in determining a good recovery. The extension of the neuropathological lesions is highly variable not only among different AD cases but also among various regions of the same brain. It is therefore advisable to select specimens with abundant AD-related pathology to guarantee high yields in the preparations. The use of widely available standardized protocols and abundant commercial sources of antibodies for both Aβ and PHF-tau allows the immunohistochemical evaluation of the neuropathological compromise, which should be performed prior to starting the isolation procedure and should also serve as a guidance as to the starting amount of tissue.

All the procedures described in this unit involve tissue homogenization prior to the different extraction protocols. The use of protease inhibitors and the maintenance of the specimens at 4°C are imperative to prevent undesired enzymatic degradation after the release of intracellular proteases occurring during cell lysis. We have described the use of a cocktail of inhibitors, which is routinely employed in our laboratory. Nevertheless, there are multiple options available on the market (including individual inhibitors) that could replace the one we suggest. After homogenization, many of the protocols require density gradient centrifugation. It should be emphasized that it is essential to observe the recommended temperatures during the full procedure, since the density of the different solutions composing the various gradients, either sucrose, Percoll, or Ficoll depends on the temperature. The

localization of amyloid and PHF in the different gradient interfaces may vary slightly with the preparation of the different solutions. It is advised that, at least the first time the protocols are run in the laboratory, the presence of fibrillar materials in the fractions—either amyloid or PHF—be confirmed by electron microscopy.

Anticipated Results

A typical purification of amyloid plaques results in their enrichment in the 1.4 M/2.0 M sucrose interfaces (Alternate Protocol 1). In the case of PHF isolation (Basic Protocol 2), the most pure fraction is typically located between the 2.25 M and 2.5 M sucrose layers, although representing only a minor part (~20%) of the total PHF-tau; the rest of PHF is recovered from the 1.25/1.5 and 1.75/2.0 M interfaces. The ultimate confirmation of the presence of amyloid and PHF requires electron microscopy evaluation after negative staining with uranyl acetate as described above (Support Protocol 4). Figure 3.33.1 shows the expected morphological features of the purified elements. Amyloid fibrils, irrespective of their origin, are arranged in random arrays and are nonbranching with a typical 8- to 10-nm width. PHF exhibits a characteristic twist with a crossover repeat of ~80 nm; the filaments have a typical width of 10 to 20 nm and a minimum width at crossing points of 9 to 9.5 nm. Single PHF filaments twist over themselves to give the appearance of flat ribbons.

The biochemical evaluation of amyloid Aβ deposits by mass spectrometry typically demonstrates high heterogeneity. The major species expected are Aβ1-40 and Aβ1-42, for vascular and parenchymal deposits, respectively. Nevertheless, N-, and C-terminal truncated species representing proteolytic degradation of the deposited species, as well as a variety of different post-translationally modified fragments including oxidation-derived and pyroglutamate derivatives, are common findings.

Time Considerations

The protocols for the isolation of plaques and PHF involve several rounds of sedimentation centrifugation and require ~1 week for completion, although much of this time is spent waiting for centrifugations and does not involve continual lab-bench work. On the contrary, the sequential extraction of amyloid and pre-amyloid deposits described in Basic Protocol 1 utilizing short-duration centrifugations, requires a more constant dedication to the procedure, which will take ~3 days for completion.

Extra time should be allotted to the characterization of the purified material by immunoblot, mass spectrometry, amino acid sequence analysis, and electron microscopy studies, which will easily use up 7 to 10 days, depending on the experience of the operator, his/her work-day schedule, and the availability of the equipment. In many circumstances, the evaluation of the isolated material by mass spectrometry, sequence analysis, and electron microscopy requires the use of specially dedicated facilities. Although the analyses themselves do not require more than a few hours, the workload of the dedicated facilities in some cases may add extra time to the overall procedure.

Isolation of *Legionella*-Containing Vacuoles by Immuno-Magnetic Separation

Simon Urwyler,[1] Ivo Finsel,[1] Curdin Ragaz,[1] and Hubert Hilbi[1]

[1]Institute of Molecular Life Sciences, University of Zürich, Zürich, Switzerland

ABSTRACT

The environmental bacterium *Legionella pneumophila* naturally parasitizes free-living amoebae. *L. pneumophila* is an opportunistic human pathogen that grows in macrophages, thus causing a life-threatening pneumonia termed Legionnaires' disease. The bacteria replicate intracellularly in environmental and immune phagocytes within a unique compartment, the *Legionella*-containing vacuole (LCV). Formation of LCVs is a complex and robust process involving >150 secreted bacterial effector proteins, which are believed to subvert host cell signaling and vesicle trafficking pathways. This unit describes a simple approach to purify intact LCVs from *Dictyostelium discoideum* amoebae. The method comprises a two-step purification protocol that includes immuno-magnetic separation by means of an antibody against an effector protein specifically binding to LCVs, followed by density gradient centrifugation. The use of *D. discoideum* producing a fluorescent LCV marker and fluorescently labeled *L. pneumophila* allow tracking the enrichment of LCVs by light microscopy. *Curr. Protoc. Cell Biol.* 46:3.34.1-3.34.14. © 2010 by John Wiley & Sons, Inc.

INTRODUCTION

Many intracellular pathogens reside and replicate in vacuolar compartments, which are custom-tailored for each invader. A model used for vacuolar pathogens is *Legionella pneumophila*, the causative agent of the severe pneumonia Legionnaires' disease (Fields et al., 2002). *L. pneumophila* is a Gram-negative environmental bacterium that parasitizes free-living amoebae, including the social soil amoeba *Dictyostelium discoideum*. The bacteria grow mechanistically similarly within amoebae and macrophages in a membrane-bound compartment termed the *Legionella*-containing vacuole (LCV; Hilbi et al., 2007). The formation of LCVs is a complex and robust process involving the bacterial Icm/Dot type IV secretion system and >150 secreted effector proteins, which subvert multiple host-cell signaling and vesicle trafficking pathways (Segal et al., 2005; Isberg et al., 2009).

In previous attempts to investigate the process of phagocytosis and the formation of pathogen-containing vacuoles, these compartments were enriched, and their proteome was determined by 2-D gel electrophoresis or liquid chromatography coupled to mass spectrometry. Subcellular vacuoles isolated from mammalian macrophages include latex bead phagosomes (Garin et al., 2001) and vacuoles containing intracellular (pathogenic) microorganisms, such as *Mycobacterium avium* (Sturgill-Koszycki et al., 1994, 1997), *Salmonella enterica* serovar Typhimurium (Mills and Finlay, 1998), *Listeria innocua* (Lührmann and Haas, 2000), *Rhodococcus equi* (Fernandez-Mora et al., 2005), or *Leishmania* parasites (Kima and Dunn, 2005). Furthermore, *D. discoideum* amoebae have been used to enrich phagosomes containing latex beads (Gotthardt et al., 2002, 2006) or *Legionella pneumophila* (Shevchuk et al., 2009).

Published online March 2010 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb0334s46

The enrichment protocols employed in these studies were based on density gradient centrifugation using sucrose or iodinated non-ionic materials such as Optiprep (iodixanol) or Histodenz/Nycodenz (iohexol). In these preparations, no specific molecular features of the pathogen vacuoles were exploited, and thus, the discrimination between functionally relevant vacuole components and co-purified irrelevant proteins was difficult. Moreover, due to the lack of fluorescent or other labels, the intact vacuoles had to be visualized by tedious and time-consuming electron microscopy.

To overcome these intrinsic limitations, a purification scheme was developed for pathogen vacuoles, which exploits the presence of a bacterial effector protein that specifically localizes to the compartment to be enriched (Urwyler et al., 2009b). The microbial vacuole marker is detected by a polyclonal antibody, followed by a secondary antibody coupled to magnetic beads. Thus, the pathogen vacuole can be enriched by immuno-magnetic separation using a MACS (magnetic cell sorting) column in the presence of a strong magnet. Furthermore, by using fluorescently labeled bacteria and an ectopically produced fluorescent host cell marker of the pathogen vacuole, the purification can be easily followed by light microscopy rather than by electron microscopy.

D. discoideum producing green fluorescent calnexin-GFP (see Support Protocol 1), a marker of the endoplasmic reticulum (ER) and LCVs, was used, and the amoebae were infected with *L. pneumophila* labeled with the red fluorescent protein DsRed-Express (see Support Protocol 2). After homogenization, green fluorescent LCVs harboring red fluorescent *L. pneumophila* were enriched by immuno-magnetic separation, followed by Histodenz density gradient centrifugation. For characterizing pathogen vacuoles, this approach has a number of advantages: (1) *D. discoideum* grows clonally in tissue culture flasks, and thus, large numbers of identical host cells are available; (2) *L. pneumophila* growing in liquid culture yields a morphologically and metabolically homogenous population of infectious bacteria, which forms relatively homogenous LCVs of ~2 μm in diameter in the amoeba host; (3) the infection can be synchronized and controlled kinetically; (4) intact LCVs can be isolated and purified by a simple and fast two-step protocol, exploiting the presence of markers specific for LCVs; and (5) fluorescently labeled bacteria and host cells allow tracking the LCV purification by light rather than electron microscopy (see Support Protocol 3). Purified LCVs can be readily used for further analysis, including SDS-PAGE/protein staining (*UNITS 6.1 & 6.6*), western blotting (*UNIT 6.2*), immuno-fluorescence microscopy (*UNIT 4.2*), and mass spectrometry.

BASIC PROTOCOL

ISOLATION OF *LEGIONELLA*-CONTAINING VACUOLES

D. discoideum amoebae producing calnexin-GFP (see Support Protocol 1) are infected with DsRed-Express–labeled *L. pneumophila* grown to early stationary phase (see Support Protocol 2) and incubated at 25°C. All subsequent steps are performed at 4°C using buffers, tubes, and equipment pre-cooled to this temperature. The infected *D. discoideum* amoebae are washed and subsequently lysed with a ball homogenizer. For the immuno-magnetic separation step, the homogenate is blocked and incubated with affinity purified primary antibody against a bacterial LCV marker, followed by a secondary antibody coupled to magnetic beads. Antibody decorated LCVs are retained on a magnetic cell sorting (MACS) column by a magnet, eluted upon removal of the magnet, and subjected to density centrifugation through a Histodenz gradient. Purification of LCVs is followed by fluorescence microscopy (see Support Protocol 3).

CAUTION: L. pneumophila is a Biosafety Level 2 microorganism, and thus, the corresponding biosafety regulations need to be observed.

Materials

Dictyostelium discoideum (see Support Protocol 1)
HL5 medium (see recipe)
AYE medium (see recipe)
Legionella pneumophila (see Support Protocol 2)
SorC buffer (see recipe), ice cold
HS buffer (see recipe), cold
Blocking reagent (e.g., NHS: normal human serum; Blutspendezentrum Zürich)
Primary antibody against a bacterial LCV marker (e.g., affinity-purified polyclonal rabbit anti-SidC serum; NeoMPS SA)
Secondary antibody coupled to MACS micro-beads (e.g., MACS goat anti-rabbit IgG micro-beads; Miltenyi Biotec)
Histodenz (Sigma-Aldrich) solution in PBS (see recipe)

75-cm^2 tissue culture flasks
Incubators (23°C, 25°C, 37°C) with and without wheel or shakers
15-ml test tubes
Spectrophotometer
Tissue culture centrifuge with swing-out rotors for plates, flasks, and 15-ml tubes
Plastic cell scraper
3-ml plastic Luer-lok syringes
Stainless-steel ball homogenizer (8-μm clearance, 0.5-ml chamber; Isobiotec), cold
15-ml centrifuge tubes with screw caps
Overhead spinning wheel at 4°C
MACS-MS separation columns (Miltenyi Biotec, cat. no. 130-042-201)
MACS separator (e.g., MACS Multistand; Miltenyi Biotec)
1.5-ml microcentrifuge tubes
Glass Pasteur pipets (230-mm, plugged)

Infect Dictyostelium discoideum with Legionella pneumophila

1. Seed 1×10^7 *D. discoideum* in a 75-cm^2 tissue culture flask and grow overnight in 10 ml HL5 medium at 23°C.

   The yield is ~2×10^7 cells per flask (70% to 80% confluency). Up to three flasks per infection, and a total of 6×10^7 D. discoideum per sample (bacterial strain) are used.

   Importantly, any antibiotic used to grow D. discoideum (e.g., G418; see Support Protocol 1) must be removed prior to infection with L. pneumophila.

2. Inoculate 3 ml AYE/Cm medium in a 15-ml test tube with *L. pneumophila* ($OD_{600} = 0.1$) and grow on a wheel or shaker for 21 to 22 hr at 37°C (final $OD_{600} > 3.0$).

3. Add 100 μl of *L. pneumophila* culture ($OD_{600} = 3.0$) per 75-cm^2 tissue culture flask (from step 1) and gently swirl.

   The multiplicity of infection (MOI) is 100 bacteria per D. discoideum cell.

   An MOI of 100 is appropriate for infections lasting up to 6 hr. Due to intracellular bacterial replication, lower MOIs should be used for longer infections (e.g., an MOI 20 for a 14-hr infection). L. pneumophila does not grow in amoeba medium.

4. Centrifuge the 75-cm^2 tissue culture flask containing *L. pneumophila* and *D. discoideum* 10 min at $500 \times g$, 25°C, to synchronize the infection.

5. Incubate 1 hr at 25°C.

   An incubation period of 1 hr is the standard infection time for the isolation of LCVs (Fig. 3.34.1). However, LCVs have been successfully purified after infections ranging from 15 min up to 14 hr.

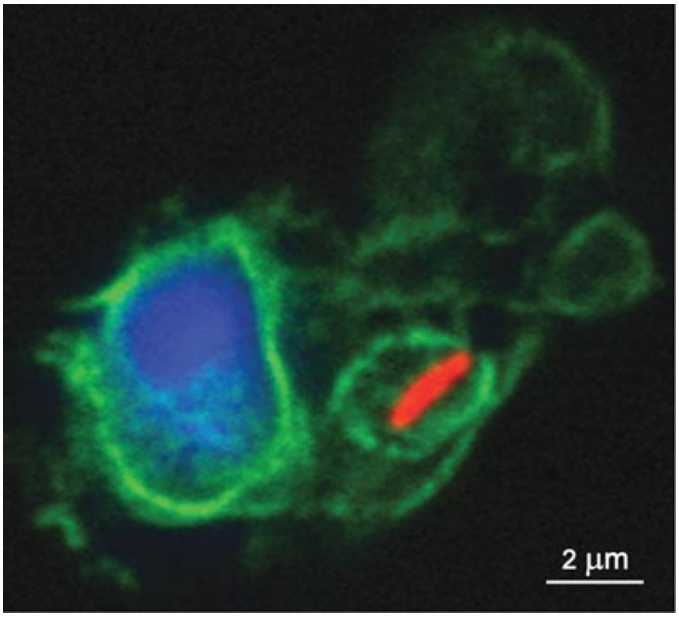

Figure 3.34.1 *D. discoideum* amoebae infected with *L. pneumophila*. *D. discoideum* producing the ER/LCV marker calnexin-GFP (green) was infected with DsRed-Express labeled *L. pneumophila* Philadelphia-1 wild-type strain JR32 (red) at an MOI of 100 and incubated 1 hr at 25°C. The nucleus of *D. discoideum* is stained with DAPI. Image kindly provided by Stefan S. Weber. For color figure go to *http://www.currentprotocols.com/protocol/cb0334*.

Homogenize infected D. discoideum

6. Place infected *D. discoideum* on ice, and wash cells two to three times with 10 ml ice-cold SorC buffer to remove medium and non-phagocytosed bacteria. To wash, replace HL5 medium with SorC buffer and gently agitate without dislocating the cells.

   If the infected D. discoideum cells lift off the tissue culture flask, carefully wash only once.

7. Resuspend up to 2×10^7 infected *D. discoideum* cells in 3 ml ice-cold HS buffer using a plastic cell scraper. Transfer the suspension of infected amoeba in HS buffer into a 3-ml disposable Luer-lok syringe. Set aside 180 µl suspension of infected *D. discoideum* for fluorescence microscopy.

   For 6×10^7 infected D. discoideum, a total of 9 ml suspension is obtained. The protease inhibitor in the HS buffer may be omitted, without significantly changing the results.

8. Rinse ball homogenizer extensively with distilled water before use to remove any contaminating detergent. Flush the chilled ball homogenizer (8-µm clearance) with cold HS buffer and remove any air bubbles with buffer.

9. Mount the syringe containing the infected *D. discoideum* cells, and press the suspension of infected amoebae through the homogenizer into a second syringe. Passage the suspension back and forth seven to eleven times, until the homogenate becomes clear. Keep homogenate on ice. Set aside 180 µl homogenate of infected *D. discoideum* for fluorescence microscopy.

   Use an odd number of strokes to homogenize the suspension; thereby, allowing unbroken cells to remain in the first syringe and not end up in the second syringe (homogenate).

   Before processing a different sample (bacterial strain), dismantle and thoroughly clean the ball homogenizer.

Purify Legionella-containing vacuoles by immuno-magnetic separation

10. Pool homogenates of infected *D. discoideum* (~9 ml per 6×10^7 infected *D. discoideum*) into a 15-ml plastic tube.

11. Add NHS as blocking reagent to a final concentration of 2% (w/v), invert tube, and incubate 30 min on an overhead spinning wheel (10 to 20 rpm) at 4°C.

    The blocking reagent and concentration should be optimized for each primary antibody. Other reagents such as BSA may be more appropriate for other antibodies.

12. Vortex the primary antibody solution prior to use. Add primary antibody directed against a bacterial marker specifically binding to LCVs, invert tube, and incubate 1 hr on an overhead spinning wheel at 10 to 20 rpm, 4°C.

    Affinity-purified polyclonal rabbit antiserum directed against the L. pneumophila effector protein SidC (Weber et al., 2006; Ragaz et al., 2008) was used at a dilution of 1:3000. However, antibodies against other markers exclusively present on LCVs should also be suitable.

13. Centrifuge homogenate 15 min at $600 \times g$, 4°C. Remove supernatant completely, resuspend pellet in 1.5 ml HS buffer per homogenate of 6×10^7 *D. discoideum*, and transfer to a new 15-ml centrifuge tube.

    After the centrifugation step, resuspend only the pellet and not the debris on the wall of the tube.

14. Vortex the micro-beads suspension prior to use. Add secondary antibody coupled to MACS magnetic micro-beads, invert tube, and incubate 30 min on an overhead spinning wheel at 10 to 20 rpm, 4°C.

    MACS goat anti-rabbit IgG micro-beads were used for the polyclonal rabbit antiserum directed against SidC at a concentration of 20 µl magnetic bead slurry per 0.5 ml concentrated homogenate.

15. Place a magnetic MACS-MS separation column (60 µl void volume) into a MACS separator and equilibrate with 0.5 ml ice-cold HS buffer. Allow the buffer to pass through the column by gravity flow.

16. Load the suspension of antibody-treated homogenate (1.5 ml, corresponding to 6×10^7 *D. discoideum*) onto an equilibrated MACS-MS column by gravity flow. Set aside 30 µl of the antibody-treated homogenate for fluorescence microscopy.

17. Wash loaded MACS columns three times with 0.5 ml ice-cold HS buffer by gravity flow. Set aside 30 µl of the flow-through for fluorescence microscopy (Fig. 3.34.2A).

18. Remove loaded MACS columns from the MACS separator (and thus, the magnetic field), and firmly press 0.5 ml ice-cold HS buffer through the column to elute the bound beads linked to LCVs into a 1.5-ml microcentrifuge tube. Set aside 10 µl of the eluate for fluorescence microscopy (Fig. 3.34.2B).

    IMPORTANT NOTE: Apply firm pressure to elute the column; this will substantially increase the yield of LCVs.

Purify Legionella-containing vacuoles by Histodenz gradient centrifugation

19. Prepare a linear gradient of 10% to 35% Histodenz in a total of 11.5 ml PBS. To this end, fill 5.75 ml of 35% Histodenz/PBS into a 15-ml capped centrifuge tube and carefully top with 5.75 ml of 10% Histodenz/PBS without mixing the two solutions. Cap the tube.

20. Gently lay the tube down horizontally for 1 hr and then slowly return it back into a vertical position.

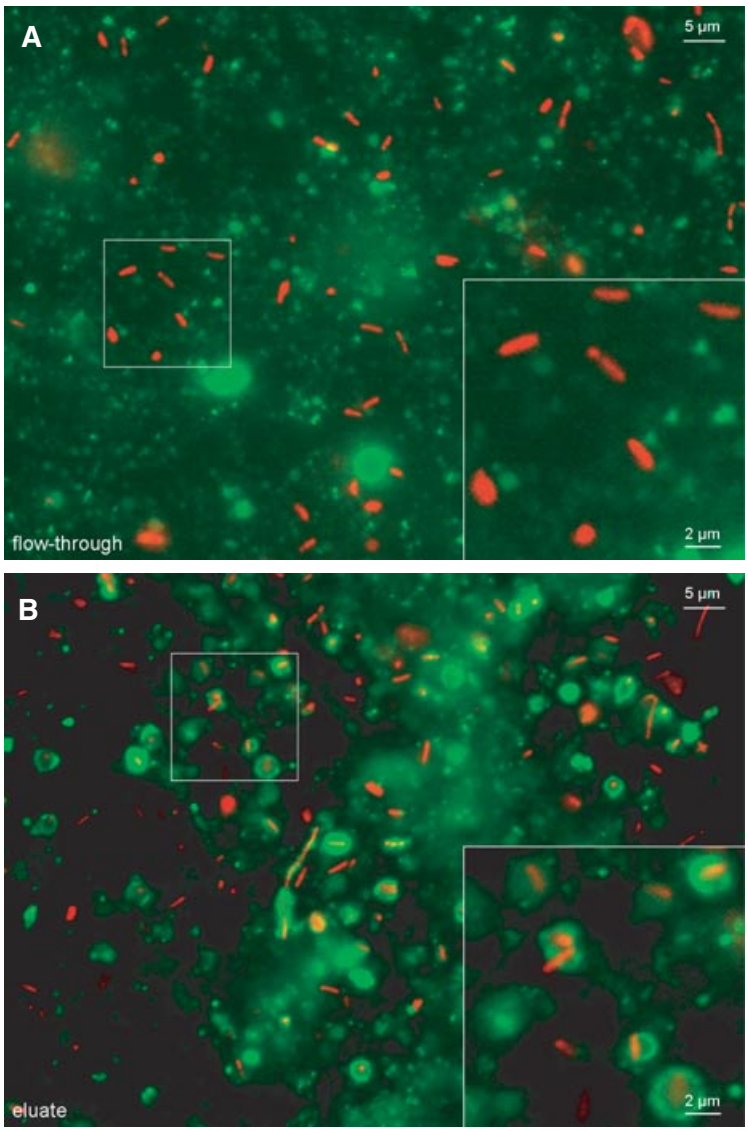

Figure 3.34.2 Immuno-magnetic separation of *Legionella*-containing vacuoles. (**A**) Flow-through and (**B**) eluate of a MACS (magnetic cell separation) column loaded with antibody-treated homogenate of *L. pneumophila*-infected *D. discoideum*. Homogenates of *D. discoideum* producing calnexin-GFP (green) infected with DsRed-labeled *L. pneumophila* (red) were treated with a primary antibody (polyclonal serum) against the bacterial LCV marker SidC and a secondary antibody coupled to magnetic micro beads. Intact LCVs on a MACS column were selectively retained by a magnet and eluted upon removal of the magnet. The insets show magnifications of the marked areas. For color figure go to *http://www.currentprotocols.com/protocol/cb0334*.

21. Load 0.5 ml of LCVs enriched by immuno-magnetic separation (step 18) on top of the 11.5 ml gradient of 10% to 35% Histodenz and centrifuge 1 hr at 3350 × *g*, 4°C.

    If the yield of LCVs after the immuno-magnetic separation step is high, multiple aliquots of 0.5-ml LCV preparation can be loaded onto separate Histodenz gradients.

22. From the bottom of the 15-ml tube holding the 12-ml Histodenz gradient, collect eight 1.5-ml fractions using a Pasteur pipet, and place on ice. Set aside 150 µl of each of the eight Histodenz fractions for fluorescence microscopy.

    Always collect the bottom fraction first. In cases where several tubes are used to separate aliquots of the same sample, the identical fractions can be pooled.

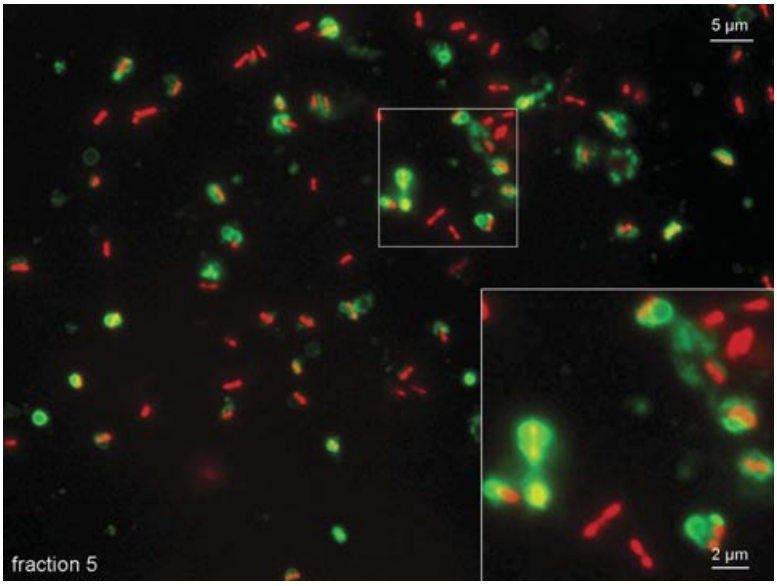

Figure 3.34.3 Density centrifugation of *Legionella*-containing vacuoles. The eluate from a MACS (magnetic cell separation) column was centrifuged through a linear (10% to 35%) Histodenz density gradient and collected in 8 fractions of 1.5 ml. Intact LCVs accumulate in the fractions 4 and 5 (image shown). The inset shows a magnification of the marked area. For color figure go to *http://www.currentprotocols.com/protocol/cb0334*.

To assess the quality of the LCV preparation, smaller volumes (e.g., 30 µl) of the fractions of interest (fractions 4 and 5) are sufficient (Fig. 3.34.3).

23. Follow the enrichment of LCVs by fluorescence microscopy (see Support Protocol 3), examining the reserved fractions.

24. Analyze the purified LCVs (fractions 4 and 5 after Histodenz density centrifugation, step 22) by SDS-PAGE (*UNIT 6.1*)/protein staining (*UNIT 6.6*), western blotting (*UNIT 6.2*), immuno-fluorescence microscopy (*UNIT 4.2*), and mass spectrometry.

GROWTH OF *DICTYOSTELIUM DISCOIDEUM*

SUPPORT PROTOCOL 1

The amoebae used for this protocol are *D. discoideum* wild-type strain Ax3 producing calnexin-GFP, an ER-resident protein that also localizes to LCVs (Müller-Taubenberger et al., 2001; Lu and Clarke, 2005; Weber et al., 2006).

Materials

HL5 medium (see recipe)
G418 (geneticin; Invitrogen)
D. discoideum wild-type strain Ax3 bearing a plasmid for expression of calnexin-GFP (Müller-Taubenberger et al., 2001)
SM/5 agar plates (see recipe)
Klebsiella pneumoniae (grown in LB medium; *APPENDIX 2A*)

75-cm^2 tissue culture flasks
23°C incubator

1. Supplement HL5 medium (see recipe) with 20 µg/ml G418 to maintain the plasmid encoding calnexin-GFP.

The stock concentration of G418 (geneticin) is 20 mg/ml in water. Filter-sterilize 500-µl aliquots using 0.22-µm filters and store upto 2 years at −20°C.

2. Grow *D. discoideum* in 10 ml HL5/G418 medium in 75-cm^2 tissue culture flasks at 23°C, and split the culture two times a week.

3. Prior to infections, split the culture, seed 1×10^7 *D. discoideum* cells in a 75-cm^2 tissue culture flask and allow growth overnight in 10 ml HL5 medium without antibiotic at 23°C, to yield $\sim 2 \times 10^7$ cells per flask.

   Prior to infection, the D. discoideum cells should have reached a confluency of 80%; a higher cell density will negatively affect the uptake efficiency. To this end, the inoculum and the growth time of the amoebae may need to be adjusted. Any antibiotic used to grow D. discoideum (e.g., G418) must be removed prior to infection with L. pneumophila.

4. For optional viability assays, plate *D. discoideum* cells on SM/5 agar plates together with *Klebsiella pneumoniae* (grown in LB medium; *APPENDIX 2A*), and count plaque-forming units (pfu) after 3 to 4 days incubation at 23°C (Sussman, 1987).

   D. discoideum grows axenically (in absence of bacteria) in a complex medium (e.g., HL5) at 21° to 23°C. Above 25°/26°C, the amoebae will respond with a heat shock reaction and eventually die. D. discoideum is light sensitive, and therefore, frequent alternation between light and dark should be avoided (turn on light in incubator, if possible).

SUPPORT PROTOCOL 2

GROWTH OF *LEGIONELLA PNEUMOPHILA*

The bacteria used for this method are *L. pneumophila* wild-type strain JR32 Philadelphia-1, producing the red fluorescent protein DsRed-Express encoded on plasmid pSW001 (Mampel et al., 2006). An OD_{600} of 0.3 corresponds to 2×10^9 bacteria/ml.

CAUTION: L. pneumophila is a Biosafety Level 2 microorganism, and thus, the corresponding biosafety regulations must be observed.

Materials

Frozen glycerol stocks of *Legionella pneumophila* bearing Ds-Red Express on plasmid pSW001
Charcoal yeast extract (CYE) agar plates (see recipe)
Chloramphenicol (Cm)
ACES yeast extract (AYE) broth (see recipe)

37°C incubator with and without shaker
15-ml test tubes
Spectrophotometer

1. Streak out *L. pneumophila* from frozen glycerol stocks onto a CYE agar plate containing 5 μg/ml chloramphenicol to maintain plasmid pSW001. Incubate 3 days at 37°C (*L. pneumophila* grown to stationary growth phase).

   The stock concentration of Cm is 30 mg/ml ethanol. Filter-sterilize aliquots and store at −20°C.

2. Prepare AYE broth and freshly add 5 μg/ml Cm.

3. Inoculate 3 ml AYE/Cm medium in a 15-ml test tube with *L. pneumophila* scraped from CYE agar plates ($OD_{600} = 0.1$), and allow to grow on a wheel (or shaker) for 21 to 22 hr (final $OD_{600} > 3.0$) at 37°C.

   L. pneumophila bacteria grown to post-exponential/early stationary growth phase in liquid AYE medium are morphologically uniform (~2 × 0.5 μm), i.e., the proportion of long, filamentous L. pneumophila (>20 μm) is much smaller than in bacterial cultures grown on CYE agar plates. The morphology of the bacteria can be easily checked by light microscopy using a small volume (10 μl) of the bacterial culture. The final OD_{600} should not be <3.0, otherwise the infection efficiency is severely compromised.

   The glassware used should not be contaminated with residual detergents, as L. pneumophila is very sensitive.

4. As a control for *L. pneumophila* viability, plate 20 µl of a 10^5/ml bacterial solution on CYE agar plates and count colony forming units (cfu) after incubation for 3 days at 37°C.

ANALYSIS OF LCV PURIFICATION BY FLUORESCENCE MICROSCOPY

SUPPORT PROTOCOL 3

The purification of LCVs formed by DsRed-Express-labeled *L. pneumophila* upon infection of *D. discoideum* producing calnexin-GFP can be followed by epifluorescence microscopy. The enrichment is quantified by counting (100×) intact LCVs per field of view.

Materials

0.1% (w/v) poly-L-lysine sterile solution (Sigma)
D. discoideum Infected with *L. pneumophila* (see Basic Protocol)
HS medium (see recipe), ice cold
4% (w/v) paraformaldehyde in PBS (see recipe)
SorC buffer (see recipe)
Mounting medium (e.g., Vectashield; Vector Laboratories)

Round microscope coverslips, sterile
24-well flat-bottomed tissue culture plate
Microscope slides
Epifluorescence microscope equipped with filters for GFP and Ds-Red

1. Coat a sterile, round microscopy coverslip with poly-L-lysine (sterile 0.01% solution), and place it into the well of a 24-well flat-bottomed tissue culture plate.
2. Prepare samples of adherent *D. discoideum* infected with *L. pneumophila* (see Basic Protocol, steps 1 to 5; Fig. 3.34.1) by seeding cells directly onto the coated coverslips.

   The infection efficiency should be checked by fluorescence microscopy prior to proceeding with the purification protocol.

3. Add samples containing suspensions of infected *D. discoideum* or cell-free LCVs [e.g., from Basic Protocol, steps 7, 9, 16 to 18 (Fig. 3.34.2), and 22 (Fig. 3.34.3)] to the poly-L-lysine-coated coverslips in the wells. Fill wells containing samples from step 22 with 1 ml of ice-cold HS buffer to dilute high Histodenz concentrations and centrifuge 15 min at 600 × *g*, 4°C.
4. Carefully remove supernatant, add 0.5 ml/well 4% paraformaldehyde in PBS and incubate 30 min at 4°C.
5. Wash coverslip two times with 0.5 ml/well SorC buffer each time, removing the supernatant.
6. Mount coverslip on microscope slide using mounting medium (e.g., Vectashield).
7. Analyze the morphology, integrity, and quantity of LCVs per field of view with an epifluorescence microscope equipped with filters for GFP and Ds-Red.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AYE medium (Feeley et al., 1979)

Prepare in 1 liter water the following:
55 mM *N*-(2-acetamido)-2-aminoethanesulfonic acid (ACES)

continued

10 g Bacto yeast extract (Difco)
3.3 mM L-cysteine
0.6 mM $Fe(NO_3)_3 \cdot 9H_2O$

Dissolve ACES and yeast extract in 900 ml H_2O. While stirring, slowly add 10 ml cysteine, followed by 10 ml iron nitrate. Adjust pH to 6.9 with 10 M KOH, and add H_2O to 1 liter. Filter six to eight times through a glass fiber filter and filter-sterilize afterwards (500-ml Stericup; Millipore). Store up to 1 year at 4°C in the dark. If required, add filter-sterilized chloramphenicol (final concentration: 5 μg/ml; 30 mg/ml stock concentration in ethanol) immediately before use.

CYE agar plates

Prepare in 1 liter water the following:
55 mM *N*-(2-acetamido)-2-aminoethanesulfonic acid (ACES)
10 g Bacto yeast extract (Difco)
2 g activated charcoal powder (puriss. p.a.)
3.3 mM L-cysteine
0.6 mM $Fe(NO_3)_3 \cdot 9H_2O$
15 g agar (Serva)

Suspend ACES, yeast extract, charcoal, and agar in 1 liter water. Adjust pH to 6.9 with 10 M KOH and autoclave. Allow to cool to ~50°C, and add filter-sterilized cysteine as well as iron nitrate in 10 ml water each. If required, add filter-sterilized chloramphenicol (final concentration: 5 μg/ml; 30 mg/ml stock concentration in ethanol). Pour plates, allow them to dry for 1 day, and store up to 6 months inverted at 4°C.

Histodenz (10% or 35%) solution

Dissolve 10 g or 35 g Histodenz (Sigma-Aldrich) in PBS (*APPENDIX 2A*) to an end volume of 100 ml. Store up to 2 years at 4°C in the dark.

HL5 medium (Watts and Ashworth, 1970)

Prepare in 1 liter water the following:
2.5 mM KH_2PO_4
2.5 mM Na_2HPO_4
11 g glucose
5 g BBL yeast extract (Becton Dickinson)
5 g Bacto proteose peptone (Becton Dickinson)
5 g BBL thiotone E peptone (Becton Dickinson)
Adjust pH to 6.5 ± 0.1 with 1 M NaOH or 1 M HCl
Autoclave and store 1 year at 4°C

HS buffer

20 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES)
250 mM sucrose
0.5 mM ethylene glycol tetraacetic acid (EGTA)
Complete, EDTA-free protease inhibitor cocktail tablet (Roche)
Adjust to pH 7.2 with 1 M KOH
Filter sterilize using a 0.22-μm filter (do not autoclave)
store 6 months at 4°C

(Optional) Add protease inhibitor cocktail tablet freshly according to the manufacturer's instructions.

Paraformaldehyde, 4% (w/v)

Wear gloves and mask and weigh 40 g paraformaldehyde (Sigma-Aldrich) in a chemical fume hood. Dissolve in 1 liter PBS (*APPENDIX 2A*), while constantly stirring and heating the solution to 50°C. Store up to 2 years at −20°C.

SM/5 agar plates

Prepare in 1 liter water the following:
14 mM KH_2PO_4
5.7 mM K_2HPO_4
0.4 mM $MgSO_4 \cdot 7H_2O$
0.2 g Bacto yeast extract (Difco)
2 g Bacto peptone (Oxoid)
2.2 g glucose
Adjust pH with 1 M KOH or 1 M HCl to 6.9, and then add 15 g agar (Serva)
Autoclave and pour plates after cooling to ∼50°C
Allow plates to dry for 1 day and store up to 6 months inverted at 4°C

SorC buffer (Sörensen phosphate buffer; Malchow et al., 1972)

15 mM KH_2PO_4
2 mM Na_2HPO4
50 μM $CaCl_2$
Adjust to pH 6.0 with 1 M KOH or 1 M HCl
Autoclave and store up to 2 years at room temperature

COMMENTARY

Background Information

The social soil amoeba *D. discoideum* is haploid and genetically tractable. Many genetic and cell biological tools are available, including defined mutants and strains stably producing GFP fusion proteins. *D. discoideum* is a phagocytic predator that naturally feeds on bacteria. However, a number of environmental bacteria avoid being digested and instead grow within the amoebae. *L. pneumophila* is such an amoebae-resistant bacterium, and *D. discoideum* has been established as a valuable model system to analyze the virulence of this pathogen on a cellular and molecular level (Hägele et al., 2000; Solomon et al., 2000). As an example, *D. discoideum* has been used to investigate the role of phosphoinositide (PI)-metabolizing enzymes during uptake and intracellular replication of *L. pneumophila* (Weber et al., 2006, 2009), as well as to study the recruitment kinetics to LCVs of several small GTPases fused to GFP (Urwyler et al., 2009b).

The mechanism of intracellular replication of *L. pneumophila* within free-living protozoa (*D. discoideum* and other amoeba) and metazoan macrophages is very similar. Indeed, an analysis of *D. discoideum* phosphoinositide (PI) 5-phosphatases implicated in intracellular replication and LCV formation revealed that the *D. discoideum* PI 5-phosphatase Dd5P4 inhibits bacterial growth, and Dd5P4 as well as its mammalian ortholog OCRL1 are recruited to LCVs via an N-terminal domain (Weber et al., 2009). In agreement with a similar function of these PI 5-phosphatases during LCV formation in protozoan and mammalian phagocytes, OCRL1 is also recruited to the LCV membrane in macrophages. These findings illustrate the usefulness of *D. discoideum* as a model to analyze the virulence of *L. pneumophila* and other human pathogenic bacteria (Hilbi et al., 2007).

Further underscoring the similarity of LCV formation within amoeba and macrophages, the protocol outlined here was successfully employed to enrich intact LCVs from murine RAW264.7 macrophage-like cells (data not shown). The protocol used was identical to the Basic Protocol, except that the addition of the protease inhibitor cocktail prior to homogenization and a constant temperature of 4°C during the immuno-magnetic separation were essential for a successful enrichment. Based on these results, the protocol described here is likely useful (with some appropriate modifications) for the isolation of vacuoles established by other pathogens in *D. discoideum* or

macrophages. The immuno-magnetic separation method should, in principle, be applicable for any marker exclusively present on a distinct pathogen vacuole. To this end, the optimal concentration and conditions will have to be determined for each antibody.

To analyze the proteome of purified pathogen vacuoles, powerful liquid chromatography-tandem mass spectrometry techniques are available (Urwyler et al., 2009b). Given the ease and speed of vacuole purification and further proteome analysis, the immuno-magnetic separation method is likely useful for comparative proteomics. It would be of interest to analyze and compare proteomes of vacuoles harboring distinct bacterial mutant strains, or proteomes of vacuoles formed by the same bacterial strain in different isogenic *D. discoideum* mutant strains.

Critical Parameters

To isolate intact LCVs from *D. discoideum* infected with *L. pneumophila*, a number of parameters are critical for a high yield and purity. Prior to an infection, the *D. discoideum* cells should have grown to a confluency of $\leq$80%, since a higher cell density will decrease the uptake efficiency of bacteria. *L. pneumophila* liquid cultures should consist of a mostly homogenous population of small rod-shaped cells ($\sim 2 \times 0.5$ μm). A uniform bacterial culture is a prerequisite for the formation of a homogenous population of LCVs. Furthermore, antibiotics used to grow *D. discoideum* interfere with a productive infection by *L. pneumophila* and must be removed.

For the infection, some points must also be considered. To synchronize the infection, the centrifugation force should not exceed 500 × *g*. Since the plate holders mounted onto the swing-out rotor are not in a fully horizontal position, an MOI gradient will be formed. At high MOIs, the infected *D. discoideum* cells tend to lift off the tissue culture flasks, and this process is promoted upon increasing the *g*-force during centrifugation. Along the same line, the infected amoebae must be washed very gently to prevent the loss of too many cells.

Critical for the homogenization and immuno-magnetic separation steps is that even traces of detergent will lyse the LCV membrane. Therefore, prior to use, care should be taken to rinse all equipment and glassware well with distilled water or buffer. Moreover, the application of pressure while eluting the MACS column will increase the yield of purified LCVs substantially. If the problem of a low yield persists, perform Basic Protocol, steps 6 through 21, at 4°C and in the presence of a protease inhibitor to minimize the proteolytic degradation of the surface marker targeted by the primary antibody for immuno-magnetic separation.

Anticipated Results

Approximately 6×10^7 *D. discoideum* amoebae grown in three tissue culture flasks are infected with *L. pneumophila* wild-type JR32 at an MOI of 100. After an incubation period, the infected amoebae are lysed, and intact LCVs are purified in a two-step process, involving immuno-magnetic separation and density centrifugation. The purification by magnetic immuno-separation yields $\sim 1 \times 10^6$ intact LCVs per 1×10^7 infected amoebae. LCVs harboring wild-type *L. pneumophila* are about seven-fold enriched in the eluate compared to the flow-through (Urwyler et al., 2009b). In contrast, LCVs harboring an *L. pneumophila sidC-sdcA* mutant strain do not accumulate in the eluate, indicating that the enrichment using an anti-SidC antibody is strictly dependent on the bacterial LCV marker SidC. LCVs eluting from the MACS column are further purified by centrifugation through a cushion of a linear 10% to 35% gradient of Histodenz. The majority of the LCVs accumulated in fractions 4 and 5 of a total of 8 fractions at a ratio of $\sim 2 \times 10^5$ intact LCVs per 1×10^7 infected amoebae (Urwyler et al., 2009b). Thus, using the protocol described here, the overall yield of purified LCVs is $\sim 1 \times 10^6$ intact LCVs per 6×10^7 infected *D. discoideum* cells.

Purified LCVs tested positive for markers of different subcellular compartments, such as the ER (calnexin-GFP), mitochondria (porin), and *L. pneumophila* SidC, while some markers of the Golgi apparatus and late endosomes were not detected. The proteome of purified LCVs is determined by reversed-phase micro-capillary liquid chromatography (RP-μLC) electrospray ionization tandem mass spectrometry (ESI MS/MS). This approach reveals the presence of >560 host proteins (Urwyler et al., 2009b). In the LCV proteome, many mitochondrial proteins, as well as proteins localizing to phagocytic vesicles or the ER-Golgi compartment and close to 70 ribosomal components, were identified. These findings are in agreement with the notion that LCVs sequentially interact with mitochondria, smooth vesicles, and rough vesicles/ER. A number of proteins previously not recognized to be associated with LCVs are

also identified. These include the coat protein clathrin and several small GTPases or GTPase-associated proteins (Arf1, Rab1a, -1d, -7a, -8a, -14, RabC, RabGDI, RasG, RanA, RanGAP, RhoGDI). Only Arf1 and Rab1, which promote the formation of LCVs, were previously identified on this compartment. To confirm the results obtained upon analyzing the LCV proteome by LC-MS/MS, GFP fusion proteins of Rab1a, Rab7a, Rab8a, and Rab14 in *D. discoideum* were produced and it was found that the proteins selectively localize to LCVs harboring wild-type but not *icmT* mutant *L. pneumophila*. In summary, these findings indicate that LCVs not only communicate with the early secretory pathway, but also with the late, endosome-dependent secretory pathway, as well as with the early and late endocytic pathway (Urwyler et al., 2009a).

Time Considerations

The two-step vacuole isolation protocol outlined here takes ~5 to 6 hr (post-infection) to be completed, and thus is straight-forward and rapid.

ABSTRACT

Functional analysis of platelet intracellular structures requires isolation and purification of these cellular compartments. With regard to the function of platelets, both, dense (delta) and alpha granules are relevant target structures. However, the availability of sufficient purification protocols for these structures is rather limited. This unit describes two protocols for isolation and purification of platelet granule structures. The Basic Protocol describes a new technique based on immunolabeling with target-specific antibodies followed by magnetic sorting, whereas the Alternate Protocol describes the more traditional procedure based on differential centrifugation and density-based sedimentation. For both methods, the degree of granule purification can be most easily determined by immunoblotting using various antibodies that recognize structure-specific proteins. The immunomagnetic sorting method is especially good for studies requiring highly purified material (e.g., for the identification of specific transporters and receptors). *Curr. Protoc. INTRODUCTION

Besides red blood cells, platelets are the second anuclear blood compartment. They have a crucial role in primary hemostasis, as well as in a variety of other physiological processes. To fulfill these functions, platelets contain a variety of mediators, which are stored in intracellular vesicles or granules. Using morphologic criteria, three secretory granule classes are distinguished: alpha granules, delta or dense granules, and lysosome-like granules (Fig. 3.35.1; Bentfeld and Bainton, 1975; Fukami and Salganicoff, 1977; White, 1994). Both types of granules and the lysosomes contain specific mediators and molecules. While small molecules as ADP, ATP, GTP, GDP, calcium, and serotonin are stored in the dense granules, polypeptides like von Willebrand Factor (vWF), fibrinogen, thrombospondin, and platelet factor 4 are found in α-granules. Lysosomes contain a number of specific hydrolases. The localization of secretory substances within the platelets is of paramount importance for understanding platelet function. To study the underlying processes, methods for subfractionation of human platelets resulting in highly purified fractions are required. The membrane of the granules and the plasma membrane also contain specific proteins as receptors and transport proteins. For example, the lysosome-associated membrane glycoprotein 2 (LAMP2) is mainly located on dense granules and lysosomes, whereas P-selectin is specific for the membrane of α-granules, and the surface glycoproteins GPIb and GPIIb/IIIa are marker proteins for the plasma membrane (Fig. 3.35.1). The organelle-specific membrane proteins are the basis for the subfractionation by immunomagnetic sorting (Basic Protocol), as depicted in Figure 3.35.2A. Alternatively, the organelles can be separated by centrifugation in a density gradient (Alternate Protocol). Here, the subfractions form zones according to their density (Fig. 3.35.2B).

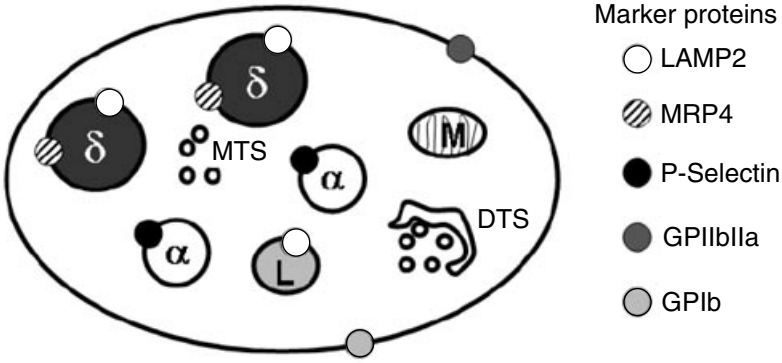

Figure 3.35.1 Scheme of the cellular compartments in a platelet and the marker proteins in the respective membrane. α, δ, L: alpha, dense, and lysosomal granules; MTS: microtubular system; DTS: dense tubular system.

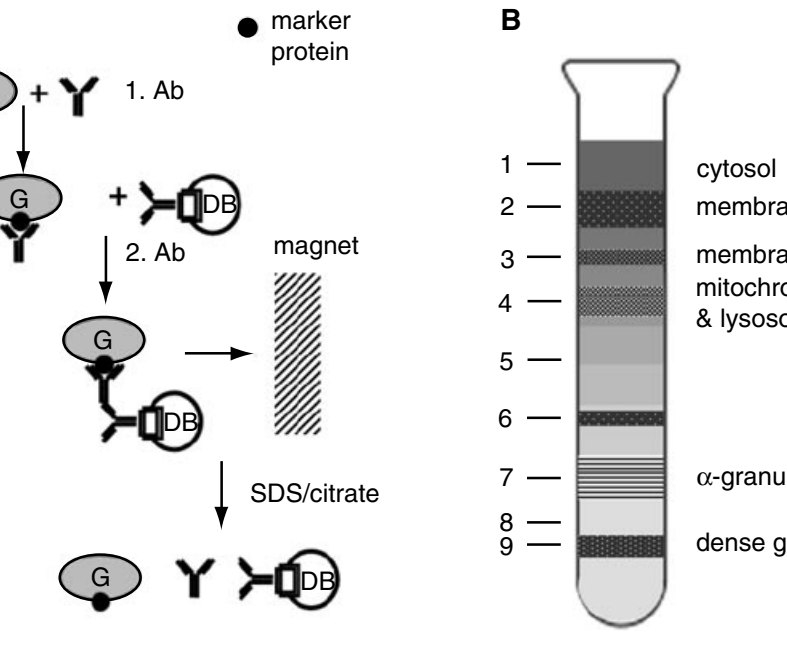

Figure 3.35.2 Biophysical principles of the two separation methods. (**A**) Immunomagnetic sorting: Platelet lysate including the granules (G) is incubated with the primary antibody (1. Ab). This binds to a marker protein on the target granule. Dynabeads (DB) coated with the secondary antibody (2.Ab) are added to form the Dynabead-antibody-organelle complex. This complex is extracted by a magnet. Separation of the Dynabead-antibody-organelle-complex is achieved by SDS (Support Protocol 1) or mild citrate elution (Support Protocol 2). (**B**) Sucrose density gradient separation (modified scheme according to Broekman, 1992). Nine zones are indicated. Visible bands/zones can be isolated and are enriched in cytosol (1), plasma membrane (2,3), mitochondria and lysosomes (4), alpha granules (7) and dense granules (9).

STRATEGIC PLANNING

General

Two major platelet granule isolation procedures, based on the methods published by Broekman (1992) and Niessen et al. (2007) are described in this unit. Both of these utilize platelet homogenates made from platelet concentrates. The protocols differ mainly in the biophysical principles. In the protocol according to Broekman (1992; see Alternate

Protocol), granules are separated by centrifugation of the cell homogenate in a sucrose density gradient. This procedure is based on previous work published by Marcus et al. (1966), Siegel et al. (1971), Klempner et al. (1980), and Kjeldsen et al. (1999). In contrast, Basic Protocol (Niessen et al., 2007) is based on immunomagnetic sorting. This technique separates the subcellular fractions based on granule-specific marker proteins, thereby avoiding problems associated with separating structures of similar sizes or densities compared with the density gradient technique. Platelet granules purified by the density gradient method retain fraction losses and mixed fractions (Zhang et al., 2003; Lawson et al., 2006). However, depending on the further application as well as the yield and the purity required, the reader may select the Basic Protocol or the Alternate Protocol. The degree of the granule purification can be easily determined today by immunoblot using various antibodies that recognize granule-specific proteins (Support Protocols 1 and 2). The assessment of platelet granule purity based on marker enzyme activities or on the evaluation of the fractions by electron microscopy represent older alternative methods (Broekman et al., 1992).

The very high sensitivity of platelets to various physical and chemical factors is linked to the specific functions of these cells (Warren et al., 1975). The presence of a contractile apparatus, similar to the actomyosin complex in muscles, in platelets enables them to change the shape of their surface actively from a smooth disc to a contoured sphere, with the formation of pseudopodia (Bottechia et al., 1977). This property makes it difficult to isolate platelets in an inactivated form, i.e., in the morphological and functional state in which they circulate in the blood stream. Successful preparation of platelet subcellular structures requires knowledge and experience with platelet isolation and platelet handling.

A prerequisite for both fractionation protocols is the preparation of platelet-rich plasma (PRP) from blood samples according to an established standard protocol (e.g., Greinacher et al., 1991). Briefly, platelets are obtained by double-arm cytapheresis, in which adenine-citrate dextrose is used as an anticoagulant. The resulting platelet concentrate is filtered via a leukocyte depletion filter (99.999% reduction of leukocytes). By cell counting using a Nagotte chamber or flow cytometry, leukocyte contaminations should be $<1/\mu l$. If even higher purity of platelets is desired, (e.g., for concomitant RNA studies), the leukocyte-depleted platelet concentrate can again be filtered over a second leukocyte filter.

Homogenization of the platelets is achieved in both protocols given below by repeated cycles of freezing and rapid thawing shock. Alternatively, nitrogen cavitation ("French press") may be applied as described by Broekman (1992).

ISOLATION OF PLATELET GRANULES BY IMMUNOMAGNETIC SORTING

BASIC PROTOCOL

In this protocol, platelet granules are isolated using compartment-specific antibodies.

This protocol will take 1 to 2 days. All samples, buffers, and equipment must be maintained at 4°C. Because of the risk of platelet activation, the initial centrifugation steps must be performed without brake.

Materials

Adenine-citrate-dextrose-anticoagulant (ACD-A; code RDB8652, Baxter Healthcare)
Platelet-rich plasma (PRP)
Washing buffer A (see recipe)
Apyrase (Sigma)
Hirudin (Pharmion)

Tyrode buffer (see recipe)
Washing buffer B (see recipe)
Homogenization buffer (see recipe)
1000× protease inhibitors (stock solution, see recipe) or Boehringer Complete protease inhibitor (Roche Applied Science)
Liquid nitrogen
Tris/sucrose buffer (see recipe)
Target-specific primary antibody (see Table 3.35.1)
Dynabeads M-280 Sheep anti-rabbit IgG (Invitrogen)
Dynabeads Pan anti-mouse IgG (Invitrogen)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)

Centrifuge
10-ml polystyrol centrifuge tubes
37°C incubator
Refrigerated Hettich Rotixa 50 RS Centrifuge (Hettich) with 4256 swing-out rotor (or equivalent)
Loose-fitting Dounce homogenizer, 15-ml capacity (Wheaton)
Beckman ultracentrifuge with 70.1Ti rotor and corresponding polycarbonate ultracentrifuge tubes (12-ml or equivalent)
Tight-fitting Dounce homogenizer, 15-ml capacity (Wheaton)
Teflon pestle glass homogenizer (Glas-Col)
DynaMag-2 magnet (Invitrogen)

NOTE: Carry out all procedures at 4°C using solutions prechilled to that temperature.

Wash the platelets

1. Add 111 μl/ml ACD-A and 5 μl/ml of 1000 U/ml apyrase to PRP in a 12-ml polystyrol tube. Centrifuge 7 min at 650 × *g*, room temperature, without brake.
2. Discard the supernatant and wash platelets three times, each time with 10 ml washing buffer A containing 5 U/ml apyrase and 2 U/ml hirudin.
3. Incubate platelets for 15 min at 37°C.
4. Centrifuge platelets 7 min at 650 × *g*, room temperature, without brake.
5. Discard the supernatant and resuspend the platelets in ∼2 ml Tyrode buffer to obtain 300,000 platelets/μl.

Prepare the platelet homogenate

6. Add 4 ml of washing buffer B to the platelet suspension and centrifuge 10 min at 2800 × *g*, 4°C.
7. Resuspend the pellet in 1 to 2 ml of homogenization buffer supplemented with 1× protease inhibitors (stock solution diluted 1:1000).
8. Lyse the platelet suspension by repeated cycles of rapid freezing (in liquid nitrogen) and thawing (5 times) and bring it to a final volume of 10 ml with ice-cold Tris-sucrose buffer supplemented with 1× protease inhibitors.
9. Homogenize the lysate with 30 strokes of a loose-fitting Dounce homogenizer.
10. Transfer the homogenate to a 15-ml tube. Centrifuge the platelet homogenate 5 min at 90 × *g*, 4°C, to remove cell debris. Following the centrifugation, transfer the supernatant into a 12-ml ultracentrifuge tube.
11. Ultracentrifuge the supernatant 30 min at 100,000 × g, 4°C, with centrifuge acceleration and brake set to the maximum.

12. Resuspend the pellet in 10 to 15 ml Tris-sucrose buffer and homogenize with 30 strokes of a tight-fitting Dounce homogenizer. Transfer the homogenate into a 12-ml ultracentrifuge tube.
13. Ultracentrifuge the homogenate 30 min at 100,000 × g, 4°C, with centrifuge acceleration and brake set to the maximum.
14. Resuspend the pellet in 1.5 to 2 ml Tris-sucrose buffer. Transfer to the homogenizer and homogenize with 20 strokes of a Teflon pestle glass homogenizer.

The obtained crude preparation of granules and plasma membrane can be shock-frozen in liquid N_2 and stored in aliquots at –80°C.

Perform immunomagnetic separation

15. Add the target-specific (alpha- and dense-granule, plasma membrane) primary antibody (see Table 3.35.1 for antibodies with best performance for immunomagnetic isolation) to the platelet pellet homogenates (100 µg per reaction batch) in 1/100 dilution (for all used primary antibodies) and bring it to a final volume of 1 ml with ice-cold PBS supplemented with 1× protease inhibitors.
16. Incubate the platelet-primary antibody homogenate for 1.5 hr at 4°C, with gentle tilting and rotation of the tube.
17. Ultracentrifuge 30 min at 100,000 × g, 4°C.
18. Discard the supernatant. Resuspend the pellet by gentle repeated pipetting and bring it to a final volume of 1 ml with ice-cold PBS buffer supplemented with 1× protease inhibitors.
19. Ultracentrifuge 30 min at 100,000 × g, 4°C.
20. Discard the supernatant. Resuspend the pellet by repeated pipetting and bring it to a final volume of 1 ml with ice-cold PBS supplemented with 1× protease inhibitors.
21. Add 50 µl of coated Dynabeads and incubate for 1.5 hr at 4°C with gentle tilting and rotation.

Table 3.35.1 Antibodies Used for Immunomagnetic Isolation and Immunoblotting of Platelet Granules[a]

Antigen	Name and isotype	Reactivity	Performance with		Supplier
			Immunomagnetic isolation	Immunoblotting	
MRP4	SNG rabbit	Human	(X)	X	NC
	M_4I-10 rat	Human	NT	X	Axxora
GPIb	Gi27 mouse	Human	X	(X)	NC
GPIIb/IIIa	Gi5 mouse	Human	X	(X)	NC
P-selectin	CD62P mouse	Human	X	(X)	Beckman Coulter
LAMP2	Mouse	Human	(X)	X	Santa Cruz
GPIb	CD42Iβ goat	Human	NT	X	Santa Cruz
vWF	Goat	Human	NT	X	Santa Cruz
PDI	Mouse	Human	(X)	X	ABCAM
P-selectin	Goat	Human	(X)	X	Santa Cruz

[a]Abbreviations: X, best performance; (X), satisfactory performance; NT, not tested; NC, not for sale; PDI, protein disulfide isomerase.

22. Place the sample in the magnetic field for 2 min, thereafter discard the liquid phase and remove the tube from the magnet.
23. Resuspend the Dynabead fraction in ice-cold PBS with protease inhibitors and bring it to a final volume of 1 ml.
24. Repeat steps 22 and 23 two times.
25. Elute the target from the magnetic bead complex (see Support Protocol 1 or 2).

ELUTE TARGET PROTEIN FROM THE MAGNETIC BEAD-COMPLEX

Conventional elution methods can be applied for the elution of target structure from the Dynabeads. One of the major advantages using Dynabeads in subcellular isolation is the ability to elute in small volumes. Boiling the bead-target complex in SDS-PAGE application buffer for direct characterization of proteins using sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) is the most efficient elution method. Also low pH (2.8 to 3.5; Support Protocol 2), change in ionic strength, affinity elution, electrophoresis, polarity reducing agents, or deforming eluants can be applied. The method of choice depends on the affinity of the immunoglobulins for the specific target protein, stability of the target structures, and the downstream applications and detection methods. Most complexes will be eluted at pH 3.1. Some protein and organelle functionality might be lost under these conditions. If maintaining functionality is important, milder elution conditions such as high salt (e.g., 2 M NaCl) or stepwise elution, reducing pH from 6 down to 3 can be used. This is also recommended if the bead-bound antibody must remain functional to allow reuse of the Dynabeads. Here, the denaturing method with SDS and the milder citrate elution are described as possible techniques for the elution of the target subcellular fraction from the magnetic bead–complex.

If the target protein to be investigated is in the range of a molecular weight of 50 or 100 kDa, covalent binding of the Fc-part of the IgG by a hydrazide reaction to the bead reduces the load of IgG (heavy chain) on the gel.

SUPPORT PROTOCOL 1

Elute Target Protein from the Magnetic Bead Complex by Denaturing Elution

This method of eluting the target protein from the complex is used for subsequent direct characterization of proteins by SDS-PAGE.

Materials

Platelet fraction–Dynabead complex (see the Basic Protocol)
4% (w/v) SDS (*APPENDIX 2A*)

95°C heating apparatus
DynaMag-2 magnet
−80°C freezer

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*)

1. Resuspend the pelleted Dynabead complex (Basic Protocol) in 0.5 ml 4 % (w/v) SDS.
2. Mix well by tilting and rotation for 2 min.
3. Boil 5 min at 95°C for elution of the bead-target complex.
4. Place the tube in the magnetic field for 2 min.

5. Recover the liquid phase and remove the tube from the magnet.

   The supernatant now contains the respective subcellular structure and the denatured antibodies.

6. Again, add 0.5 ml 4% (w/v) SDS to the beads to elute any remaining bead-target complexes.
7. Mix well by tilting and rotation for 2 min.
8. Place the tube on a magnet and pool the supernatants containing the purified target structure.
9. Store fractions in 50-µl aliquots at −80°C.
10. For further characterization, perform SDS-PAGE (*UNIT 6.1*).

    NOTE: *Dynabeads cannot be reused after elution with denaturing agents.*

Elute Target Protein from the Magnetic Bead Complex by Mild Elution with Citric Acid

SUPPORT PROTOCOL 2

This protocol is used for milder elution conditions that allow reuse of the Dynabeads.

Materials

Target protein–Dynabead complex (see the Basic Protocol)
0.1 M citric acid
1 M NaOH
DynaMag-2 magnet
−80°C freezer

1. Add 0.5 ml 0.1 M citric acid to the pelleted Dynabead complex (Basic Protocol).
2. Mix well by tilting and rotating for 2 min.
3. Place the test tube on a magnet and transfer the supernatant, containing the purified subcellular structure and immunoglobulins to a clean tube.
4. Again, add 0.5 ml 0.1 M citric acid to the beads to elute any remaining ligands.
5. Mix well by tilting and rotating for 2 min.
6. Place the test tube on a magnet, recover the eluate, and pool the supernatants.
7. Using 1 M NaOH, adjust the pH to 7.0-7.4 and store in 50-µl aliquots at −80°C.

   Dynabeads can be reused at least five times after this elution. For re-use, the beads should immediately be brought to neutral pH after elution using PBS/BSA (5%) buffer and should be stored in this buffer.

ISOLATION OF PLATELET GRANULES USING A DENSITY GRADIENT

ALTERNATE PROTOCOL

This protocol will take 1 to 2 days to complete. All procedures, buffers, and equipment must be maintained at 4°C to perform the purification. Due to the risk of platelet activation, the initial centrifugation steps must be performed without brake.

Materials

Platelet-rich plasma (PRP)
Washing buffer B (see recipe)
Homogenization buffer (see recipe)
1000× protease inhibitors (stock solution; see recipe) or Boehringer Complete protease inhibitor (Roche Applied Science)

Tris/sucrose buffer (see recipe)
60% (w/v) sucrose solution in 5 mM EDTA, pH 7.4

Refrigerated Hettich Rotixa 50 RS centrifuge (Hettich) with 4256 swing out rotor (or equivalent)
Ultrasonic processor UW60 (Bandelin Electronic)
Loose-fitting Dounce homogenizer, 15-ml capacity (Wheaton)
15-ml centrifuge tubes
Ultracentrifuge (Beckmann) with 70.1Ti fixed-angle rotor and a swing-out rotor (Beckmann SW40 or Sorvall TH-641) and corresponding polycarbonate ultracentrifuge tubes (or equivalent)
Tight-fitting homogenizer Dounce, 15-ml capacity (Wheaton)
Teflon pestle glass homogenizer (Glas-Col)

NOTE: Carry out all procedures at 4°C using solutions prechilled to that temperature, except when noted otherwise.

Wash the platelets

1. Wash the platelet-rich plasma as described in Basic Protocol (steps 1 to 5).

Prepare platelet homogenate

2. Suspend 2 ml washed platelets in 4 ml of washing buffer B in a 15-ml tube and centrifuge 10 min at 2800 × *g*, 4°C.

3. Resuspend the pellet in 1 to 2 ml of homogenization buffer supplemented with 1× protease inhibitors.

4. Lyse the platelet suspension by repeated cycles of rapid freezing and thawing (5 times).

5. *Optional:* To achieve complete homogenization, sonicate platelet suspension using an ultrasonic processor two times (4°C, 3 sec of sonication followed by a 15-sec period on ice that allows the sample to chill down).

6. Bring the homogenate to a final volume of 10 ml with ice-cold Tris/sucrose buffer supplemented with 1× protease inhibitors.

7. Transfer the homogenate to a 15-ml Dounce homogenizer with loose-fitting pestle. Homogenize using 15 strokes.

8. Transfer the homogenate to a 15-ml tube and centrifuge the platelet homogenate 5 min at 90 × g, 4°C.

9. Collect the supernatant in a new tube.

Perform sucrose density gradient separation

10. Prepare sucrose solutions with concentrations stepwise decreasing from 60% to 30% sucrose (60%, 55%, 50%, 45%, 40%, 35%, and 30%) by diluting the 60% sucrose stock solution with 5 mM EDTA.

    IMPORTANT NOTE: *The 60% sucrose solution should be used at room temperature, to decrease its viscosity!*

11. Prepare a stepwise sucrose gradient in an ultracentrifuge tube for the swing-out rotor by layering 1 ml of each sucrose concentration in decreasing order (from the bottom up) over a cushion of an extra 0.5 ml of 60% (w/w) sucrose/EDTA.

    The cushion prevents pelleting of the heaviest fraction (enriched in dense granules) to the bottom of the gradient tube.

12. Leave this stepwise gradient at 4°C overnight to allow diffusion to result in an approximately linear gradient by the following day.

    Alternatively, a commercial time-saving gradient-forming apparatus (e.g., cat. no. 350052, Spinco Division, Beckman Instrument) may be used for formation of continuous gradients.

13. Carefully layer 3 to 4 ml of platelet homogenate onto the linear gradient.

14. Place the gradient tubes in the swing-out rotor and ultracentrifuge for 90 min at 200,000 × *g*, 4°C.

15. Following ultracentrifugation, identify the nine bands as indicated in Figure 3.35.2B. Collect the bands by carefully pipetting from the top.

    Commercial fraction collection equipment can also be used.

16. Dilute fractions to a final volume of 8 ml each with ice-cold Tris/sucrose buffer and homogenize with 30 strokes of a tight-fitting homogenizer.

17. Centrifuge 30 min at 100,000 × *g*, 4°C, using the 70.1Ti (fixed-angle) rotor.

18. Resuspend the pellet in 1.5 to 2 ml of Tris/sucrose buffer and homogenize with 20 strokes of Teflon pestle-glass homogenizer.

    The fractions can be stored in 50-µl aliquots at −80°C.

CHARACTERIZATION OF PLATELET SUBCELLULAR FRACTIONS BY IMMUNOBLOT ANALYSIS

SUPPORT PROTOCOL 3

The Basic Protocol and Alternate Protocol yield subcellular fractions in which the respective organelles are highly enriched over the platelet homogenate. To determine the degree of purification, fraction-specific assays and markers should be utilized to determine the contamination by other organelles. Today the purity of the fractions can be easily determined by immunoblot using various organelle-specific antibodies. Formerly, the efficacy of the purification procedures was confirmed by electron microscopy or by assaying specific marker enzymes, as described by Broekman (1992).

Immunoblot analysis (*UNIT 6.2*) is a standard procedure and therefore is not described in detail in this unit. An example is given in Niessen et al. (2007). Briefly, 50 µg protein of each fraction—protein concentrations of subcellular fractions can be analyzed e.g., by the BCA method (Smith et al., 1985)—is resuspended in SDS-PAGE sample buffer (see recipe) and loaded on a 7.5% sodium dodecyl sulfate–polyacrylamide gel after denaturation at 95°C for 5 min. Immunoblotting to PVDF or nitrocellulose membranes should be performed using a tank blotting system (Bio-Rad or equivalent). The membrane can be blocked with 5% (w/v) dry milk and 5% (v/v) fetal bovine serum (FBS) in Tris-buffered saline containing 0.05% (v/v) Tween 20 and 1% (w/v) BSA (TBST). Primary antibodies (see Table 3.35.1, antibodies with best performance for immunoblotting) are diluted in TBST to the following final concentrations: MRP4 serum 1:1000 (alternatively commercially available mouse monoclonal antibody 1:500), anti-PDI 1:1000; anti-LAMP2, polyclonal P-selectin, and anti-vWF 1:500; and anti-GPIbβ 1:50. Secondary horseradish peroxidase–conjugated goat anti-rabbit and goat anti-mouse IgG antibodies (e.g., Bio-Rad) and horse anti-goat IgG antibody (e.g., Vector Laboratories) are used at 1:2000 dilutions. Signals are detected on X-ray film using an enhanced chemiluminescence detection system (G.E. Healthcare). Results can be quantified by densitometric analysis (e.g., software Image Quant 5.0, Molecular Dynamics), as shown in Figure 3.35.3.

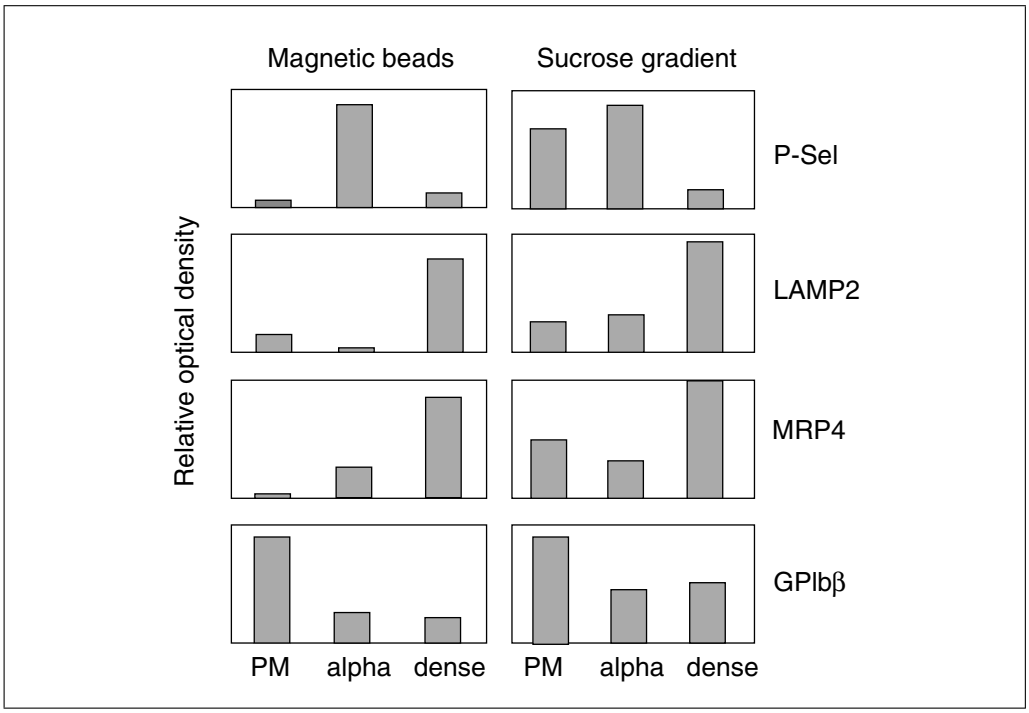

Figure 3.35.3 An example of analysis of platelet subcellular fractions. Platelet subcellular fractions are separated by sucrose density gradient or by immunomagnetic sorting. Equal protein amounts of each fraction are separated by SDS-PAGE and transferred to a PVDF membrane. The blots are probed with antibodies against fraction-specific markers: anti-P-selectin antibody for the alpha granules, anti-LAMP2 and anti-MRP4 for the dense granules, and an antibody against the GPIbβ receptor for the outer plasma membrane (PM). The results are quantified by densitometric analysis and the immunodetection in each fraction is here expressed as percentage of the sum of the optical densities of the respective proteins in all fractions (relative optical density). For original data and blots, see Jedlitschky et al. (2004) and Niessen et al. (2007).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Homogenization buffer

100 mM KCl
25 mM NaCl
2 mM $MgSO_4$
12 mM sodium-citrate
10 mM glucose
25 mM HEPES [*N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid]
5 mM ATP
0.35% (w/v) bovine serum albumin (BSA)
Adjust pH to 7.0 with 1 M HCl or 1 M NaOH
Filter sterilize
Store for only a few days at 4°C

Protease inhibitors, 1000×

Prepare the following together in H_2O:
5 mg/ml leupeptin
10 mg/ml aprotinin
Store up to 3 months at −20°C

continued

Separately prepare the following stocks fresh:
1 mM phenylmethylsulfonyl fluoride (PMSF) in ethanol
Add to solutions at 1× concentration as recommended in the protocols

PMSF is very sensitive to water, so it should be added fresh to the solutions just before contact with biological material.

SDS-PAGE sample buffer (4× Laemmli buffer)

0.25 M Tris·Cl, pH 6.8 (*APPENDIX 2A*)
1.92 M glycine
8% (w/v) SDS
5% (v/v) 2-mercaptoethanol
0.005% (w/v) bromphenol blue
Store up to 1 month at room temperature

Tris/sucrose buffer

10 mM Tris ultra [tris(hydroxymethyl)aminomethane]
250 mM sucrose
Adjust pH to 7.4 using 1 M HCl or 1 M NaOH
Filter sterilize
Store for a few days at 4°C

Tyrode buffer

150 mM NaCl
12 mM $NaHCO_3$
2.5 mM KCl
1 mM $MgCl_2$
2 mM $CaCl_2$
5.5 mM D-glucose
1 mg/ml BSA
Adjust pH to 7.4 with 1 M HCl or 1 M NaOH
Filter sterilize
Store for only a few days at 4°C

Washing buffer A

150 mM NaCl
12 mM $NaHCO_3$
2.5 mM KCl
1.5 mM NaH_2PO_4
5.5 mM D-glucose
1 mg/ml bovine serum albumin (BSA)
Adjust pH to 6.3 with 1 M HCl or 1 M NaOH
Filter sterilize
Store for only a few days at 4°C

Washing buffer B

0.9% (w/v) NaCl
10 mM tetrasodium EDTA
0.2% (w/v) BSA added just before use
Prepare fresh

COMMENTARY

Background Information

Platelets circulate in the blood of mammals and are involved in hemostasis, leading to the formation of blood clots. These anuclear blood cells are also surprisingly multifunctional and play a fundamental role in many physiological and pathophysiological processes including hemostasis and thrombosis, clot retraction, vessel constriction and repair, inflammation including promotion of atherosclerosis, host defense, even tumor growth/metastasis. They are also a natural source of growth factors (Bottechia et al., 1977; Rodgers, 1999; Michelson, 2002; Sunitha and Munirathnam, 2008). One of the central platelet functions is the so-called release reaction where material stored in granules is secreted into the extracellular medium on exposure of the platelets to stimuli like thrombin, collagen, or high levels of ADP (Davey and Luscher, 1968; Keenan and Solum, 1972; Koutts et al., 1978; Kaplan et al., 1979; Zucker et al., 1979).

The high mediator concentrations inside the platelet granules, as ADP in dense granules (0.6 M), suggest the localization of active transport proteins in the granular membrane. The multidrug-resistance protein MRP4 (ABCC4) represents such an active pump localized in the granule membrane (Jedlitschky et al., 2004). Furthermore, transport proteins (Niessen et al., 2009) and membrane receptors like GPIIb/IIIa or GPIb in the platelet plasma membrane play a crucial role in platelet function.

While the molecular consistence of subcellular platelet structures are of high physiological, therapeutic, and pharmacological interest, detailed analyses of these structures are difficult as no easily applicable method has been developed to obtain highly purified fractions of the respective structures. Traditional fractionation protocols make use of physical properties of intracellular organelles and membranes such as their density and a density gradient ultracentrifugation of platelet cell homogenates can be performed. Gogstad characterized a procedure with respect to recovery of intact granules using a French pressure cell (nitrogen cavitation) to prepare a granule-rich homogenate followed by further purification of the granules by centrifugation in metrizamide gradients (Gogstad, 1980). For preparation of dense granules, a method using mepacrine-labeled granules isolated by a short metrizamide gradient was described (Rendu et al., 1982). Fukami and Salganicoff (1977) presented a modified procedure with a pretreatment of human platelets with metabolic inhibitors to prevent activation before French press homogenization, which led to the isolation of dense granules in an overall yield of ~20%. Furthermore, a method for isolating platelet plasma membranes using polylysine-coated beads has been described (Jacobson and Branton, 1977; Kinoshita et al., 1979). With this method, surface membranes of cells attach to the polylysine beads and, after cell disruption, relatively pure preparations of plasma membranes remain attached to the beads.

The most common methods for subcellular fractionation consist mainly of a homogenization step e.g., by nitrogen cavitation and, after elimination of remaining cell debris, ultracentrifugation in a sucrose gradient (Marcus et al., 1966; Klempner et al., 1980, Broekman, 1992; Kjeldsen et al., 1999). Siegel et al. (1971) compared the ultracentrifugation in Ficoll and sucrose density gradients and found the sucrose gradient as the preferable one, because of its better ability to form complexes with cellular components. Given the overlap in size and density of the different granules, fraction losses and mixed fractions are common problems with techniques based on these attributes (Zhang et al., 2003; Lawson et al., 2006). Therefore, this unit describes a new method based on immunomagnetic sorting (Niessen et al., 2007) and, in addition, a protocol based on a common sucrose density gradient. The new purification method is based on immunolabeling with target-specific antibodies and magnetic sorting (Niessen et al., 2007) and has already been used to separate and isolate different cells and other cellular compartments like mitochondria (Safarik and Safarikova, 2004; Lawson et al., 2006). In contrast to the methods mentioned above, which discriminate between the different fractions based on their density, this technique separates the fractions based on specific marker proteins.

Critical Parameters

The two platelet granule isolation protocols described here differ in complexity and granule yield and quality due to differences in the technique. The density gradient method is relatively time- and labor-intensive, in which one of the important problems is the small difference in density between the respective structures. Therefore, the resulting fractions are often of lesser purity because of

cross-contamination by other compartments (Zhang et al., 2003; Lawson et al., 2006). In fact, even within well-defined and adequately separated fractions, the admixture of organelles from adjacent zones is frequently observed. Furthermore, high-density sucrose solutions put an osmotic stress on organelles, and repeated and prolonged centrifugations must be avoided. Many, if not most, organelles are rather labile structures which are particularly easily affected by a disturbed osmotic equilibrium.

Concerning the immunomagnetic sorting, the selection of the primary antibodies is the most important factor for successful subcellular fractionation. Some antibodies showed reduced antigen-binding efficacy when coated onto beads, even though they show clear signals when used in other immunological assays like immunofluorescence. So, a prerequisite of this technique is applicable and target-specific antibodies. Not insignificant disadvantages that have been identified so far are the expensive price of magnetic beads, which can be a limiting factor for isolating large quantities and problems with the disintegration of the Dynabead-protein complex, depending on the further applications.

Anticipated Results

The outcome of both purification methods of platelet granules should be an enrichment of platelet granule markers to some magnitudes over the starting homogenate. Although these protocols are well established, users should check the purity of platelet granules after the purification procedure. A good record of volumes and protein concentrations of all different fractions should be maintained. The preparations yielded by the protocols described here have been analyzed for the presence of contaminant membranes using immunoblot analysis (Fig. 3.35.3; original data are taken from Jedlitschky et al., 2004 and Niessen et al., 2007). In general, a higher fraction purity was observed by immunomagnetic sorting (as indicated from the immunoblot data). As indicated by immunoblotting for the lysosomal marker beta-glucuronidase (not shown), only a minor contamination of the dense fraction with lysosomes in the immunomagnetic sorting using LAMP2 as separating antibody was observed. It should be noted that for accurate immunoblot analysis it is important to maintain sample integrity throughout the procedure. Always maintain protease inhibitors in all buffers and store fractions at −80°C.

Time Considerations

Platelet granule preparation by sucrose density gradient centrifugation is relatively time-consuming (~8 hr). In comparison to this technique, the Dynabead method requires less time (~4 hr). The preparation of washed platelets, as well as platelet homogenates is a prerequisite for both methods and requires ~2 to 3 hr. The preparation of a stepwise sucrose density gradient and leaving this at 4°C to get an approximately linear gradient requires an overnight step. With a commercial gradient-forming apparatus for continuous gradient formation, time can be saved. The main separation steps in both methods are manageable in 3 to 4 hr. Finally, the characterization of the obtained subcellular fractions by immunoblot analysis with fraction-specific antibodies needs another day. Platelet subcellular granule fractions can be stored at −80°C for a reasonably long time (>1 year).

ABSTRACT

Nucleoli are now recognized as multi-functional nuclear domains involved in several fundamental cell processes such as ribosome biogenesis, regulation of the assembly of non-ribosomal ribonucleoprotein complexes, tRNA maturation, sequestration of protein, viral infection, and cellular ageing. Extensive proteomic analyses of these nucleolar domains after their purification have contributed to the description of their multiple biological functions. Because nucleoli are the largest and densest nuclear structures, they are easily amenable to purification from nuclei of cultured animal cells using the protocol described in this unit. *Curr. Protoc. Cell Biol.* 47:3.36.1-3.36.10. © 2010 by John Wiley & Sons, Inc.

Keywords: nuclear domain • nucleoli • cell fractionation

INTRODUCTION

Nucleoli are the largest and densest nuclear structures. They were the first nuclear domains to be observed by contrast microscopy (Fontana, 1781). The number and size of nucleoli vary depending on cell type, metabolic activity, and physiopathological conditions (Carter et al., 1993; Lewis and Tollervey, 2000; Dundr and Misteli, 2001). Observations by electron microscopy show that mammalian nucleoli are organized in three distinct domains: fibrillar center (FC), dense fibrillar component (DFC), and granular component (GC; Granboulan and Granboulan, 1965; Stoykova et al., 1985; Melese and Xue, 1995; Olson et al., 2000; Fig. 3.36.1). Nucleoli are dynamic nuclear domains that constantly communicate with the cytoplasm and other nuclear domains (e.g., Cajal body, perinucleolar compartment; Sleeman and Lamond, 1999; Phair and Misteli, 2000). It was demonstrated in the 1960s that nucleoli are the sites of ribosome biogenesis. Moreover, nucleoli are also implicated in the regulation of several other major cellular processes such as the biogenesis of non-ribosomal ribonucleoprotein complexes, tRNA maturation, sequestration of protein, viral infection, and cellular ageing (Coute et al., 2006). The activity, number, and morphology of nucleoli vary greatly during cell cycle progression. In fact, nucleoli are assembled at the end of mitosis, upon entry into telophase when ribosomal DNA (rDNA) transcription is reinitiated around the nucleolar organizing regions (NOR). They remain active and assembled during the interphase and completely disassemble at pro-metaphase when ribosomal gene expression ceases. At this stage they lose their structural integrity and their components are dispersed throughout the mitotic cells (Comai, 1999; Olson, 2004).

The development of large-scale purifications of nucleoli from cells of animal and plant origins permitted the establishment of their protein content using proteomic approaches (Andersen et al., 2002, 2005; Scherl et al., 2002; Gonzalez-Camacho and Medina, 2004; Brown et al., 2005; Pendle et al., 2005). To date, >700 different proteins have been

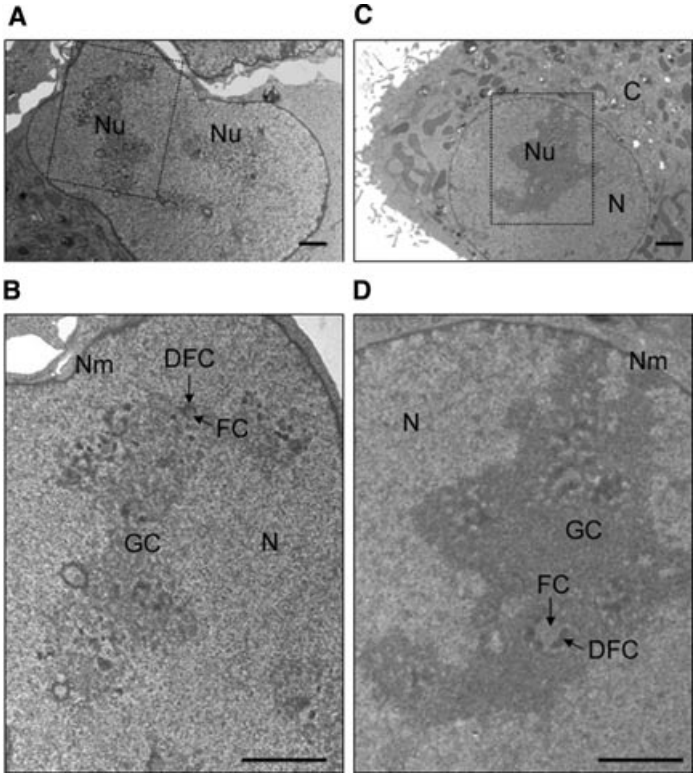

Figure 3.36.1 Electron micrograph of human epithelial polarized cells (**A,B**) and enlargement of respective nucleoli (**C,D**). Three constitutive nucleolar components are observed: the central fibillar center (FC) is surrounded by the dense fibrillar component (DFC) and both are embedded within the granular component (GC). Abbreviations: C, cytoplasm; ch, perinuclear layer of condensed chromatin; GC, granular components; N, nucleus; Nm, nuclear membrane; Nu, nucleolus. Scale bars = 2000 nm.

identified in human cells. A function for ~85% of these proteins has been proposed either after extensive biological studies or after bioinformatics analyses, whereas the roles of the remaining 15% remain elusive.

Figure 3.36.1, which presents an electron micrographic view of a human epithelial cell line, illustrates the ultrastructural organization of nucleoli and the variations of their morphological aspects depending on the physiological state of the cell. The nucleolus of actively growing cells is large and occupies a significant part of the nucleus (Fig. 3.36.1A-D). The number of FC also correlates with the cellular activity, as observed in Figure 3.36.1C. The DFC forms irregular strands, which are intermingled with GC and the border between nucleolus and nucleoplasm is irregular. A compacted large nucleolus (Fig. 3.36.1D, framed in 3.36.1B) reflects enhanced cellular activity and usually contains multiple FC that are surrounded by thick DFC and large areas of GC.

BASIC PROTOCOL

ISOLATION OF NUCLEOLI FROM ADHERENT CELL CULTURES

This protocol is adapted from previously published protocols (Muramatsu et al., 1963; Ochs, 1998; Scherl et al., 2002). The main steps for purification performed with HeLa cells are illustrated in Figure 3.36.2. After harvesting, HeLa cells are subjected to osmotic shock by incubation in an appropriate hypotonic buffer, resulting in swelling of cytoplasm and detachment from the nuclei. The efficiency of this treatment can be monitored by visual inspection of the cells by phase contrast microscopy. The swelling of the cytoplasm is clearly distinguishable. Cells are then lysed by addition of NP-40 and homogenized using a Dounce homogenizer. Nuclei are purified through a sucrose cushion

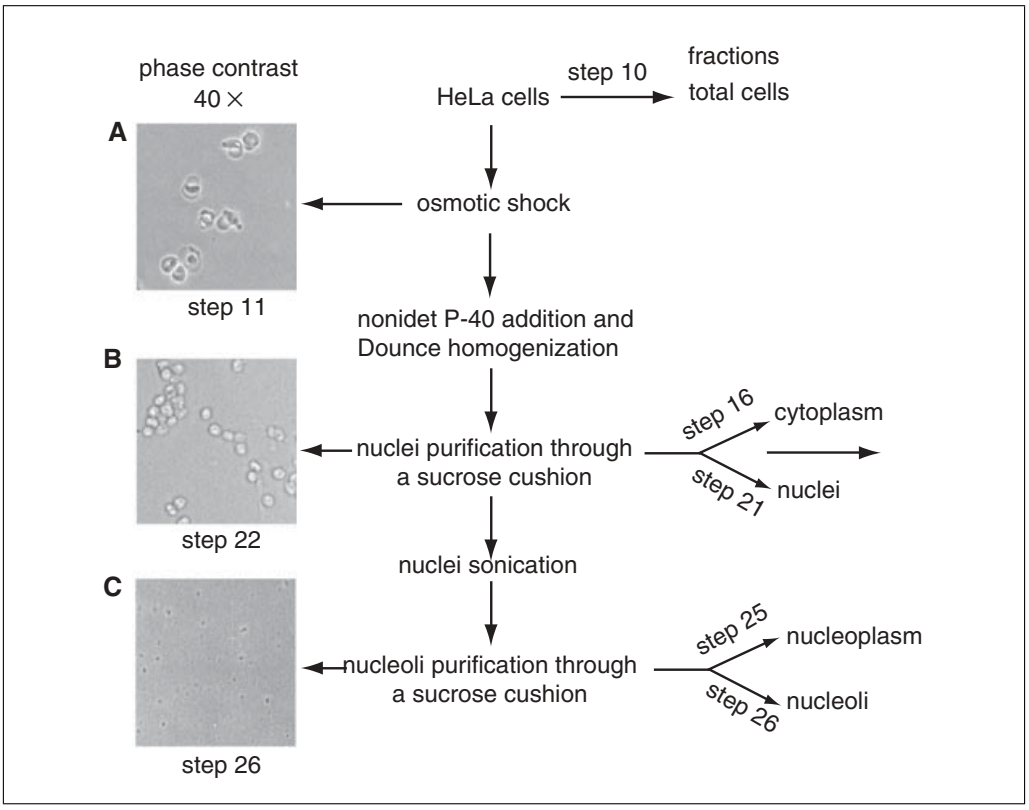

Figure 3.36.2 Main steps of the Basic Protocol. Left section of figure is the verification under phase contrast microscopy of the appearance of different fractions using a 40× objective lens. (**A**) Appearance of the sample after treatment with hypotonic buffer (step 9). (**B**) Appearance of the nuclei after addition of the sucrose cushion (step 18). (**C**) Appearance of the nucleoli after addition of the sucrose cushion (step 24). Middle section of the figure is a succinct description of the main steps of the protocol. The right section of the figure shows steps at which samples should be collected.

and the efficiency of nuclei purification can be monitored by visual inspection using phase contrast microscopy. Nuclei appear as rounded particles devoid of filamenteous structures. Finally, nucleoli are purified through a sucrose cushion after sonication of the purified nuclei and the efficiency of nucleoli purification can be monitored by visual inspection using phase contrast microscopy. Nucleoli appear as very small birefringent dots. No intact nuclei should be visible.

NOTE: Carry out all procedures at 4°C using pre-chilled solutions and equipment.

NOTE: This protocol was optimized for HeLa cells.

Materials

15×10^6 cultured adherent cells plated on 100- or 150-mm Petri dishes
Dulbecco's phosphate buffered saline for cell culture (DPBS; *APPENDIX 2A*), ice cold
Nucleoli standard buffer (NSB; see recipe)
10% (v/v) Nonidet P-40 (NP-40)
250 mM sucrose/10 mM $MgCl_2$
880 mM sucrose/5 mM $MgCl_2$
340 mM sucrose/5 mM $MgCl_2$
0.34 M sucrose buffer

Cell scrapers (Biologix Research Company)
15-ml polypropylene centrifuge tubes
Refrigerated centrifuge (Jouan, CR422)

Micropipets
Phase contrast microscope
0.4-mm clearance Dounce homogenizer (Wheaton type; Kimble/Kontes)
Sonicator (Vibracell 72434; Bioblock Scientific)

Culture and harvest cells

1. Plate cells on 100-mm diameter Petri dishes in the usual medium 48 hr before purification of the nucleoli.

   For HeLa cells, plate 1.5 × 10^6 cells per dish 48 hr before purification of nucleoli to obtain ∼6 × 10^6 cells per 100-mm Petri dish the day of nucleoli isolation. See Critical Parameters for comments about timing.

   Good nucleolar preparations require a minimum of 15 × 10^6 cells; 100 × 10^6 cells yield 150 μg of nucleolar protein.

2. At 80% confluence, wash cells two times with 10 ml of ice-cold DPBS, pH 7.4, per dish.

3. Scratch the Petri dishes with a cell scraper in a minimal volume (1 ml) of ice-cold DPBS.

4. Pool cells three plates (to obtain 30 μg nuclear protein) in a pre-cooled 15-ml centrifuge tube. Collect cells by centrifuging 5 min at 500 × *g*, 4°C.

Determine reference volume

5. Discard supernatant.

6. To determine the reference volume (RV), first visually determine the volume of the pellet that contains the cells. Add ∼2 vol ice-cold NSB and resuspend the cells by gentle pipetting up and down.

7. At this stage, measure exactly, using a micropipettor, the new volume obtained that represents the initial volume of the cells and the volume of added NSB.

   See Critical Parameters for comments on RV.

8. Calculate the volume of cells (RV) as the difference between this measured total volume and the added volume of NSB.

   The volume of the cells, which has been precisely determined, becomes the RV for the following steps. Each volume of buffer, which will be added, will be calculated based on this RV.

9. Adjust the volume of the cellular suspension with ice-cold NSB to 15 times the RV. Incubate for 30 min on ice.

   In this step, cells are in hypotonic buffer and their cytoplasm swells and the cytoplasm starts to detach from the nuclei.

10. Save ∼1/20 of the total cell suspension and store up to 6 months at −80°C for future SDS-PAGE analysis (see Support Protocol; also see *UNIT 6.1*).

    See Critical Parameters for comments on samples to save for evaluating purification.

11. Collect a drop of the homogenate with a micropipet and check the purification by visualizing under a phase contrast microscope (see Fig. 3.36.2).

Prepare cytoplasmic fraction

12. To perform cell lysis, add the appropriate volume of 10% NP-40 solution in the homogenate to obtain a final concentration of 0.3%.

    NP-40 is a nonionic detergent that facilitates cell lysis by inducing weakness of the plasma membrane.

13. Invert the suspension in the tube four to six times to homogenize.

14. Transfer the homogenate (~15 ml) immediately to a 0.4-mm clearance 15-ml Dounce homogenizer for gentle separation of nuclei and cytoplasm.

15. Carry out ten strokes with the Dounce pestle and verify under a phase contrast microscope that nuclei appear devoid of plasma membrane remnants.

    See Critical Parameters for comments on homogenization.

16. Transfer homogenate into a 15-ml centrifuge tube and centrifuge 5 min at 1200 × *g*, 4°C. Collect the supernatant to a new 15-ml tube.

    The supernatant contains the cytoplasmic fraction that is harvested for further analyses.

Fractionate nuclear fraction

17. Resuspend the pellet containing the nuclear fraction in 10 RV of the 250 mM sucrose solution containing 10mM $MgCl_2$.

18. Add 10 RV of 880 mM sucrose containing 5 mM $MgCl_2$ under the nuclear fraction.

19. Purify nuclei by centrifuging 10 min at 1200 × *g*, 4°C, through this sucrose cushion.

    See Critical Parameters for comments on nuclear purification.

20. Discard the supernatant. Resuspend the nuclear pellet in 10 RV of 340 mM sucrose solution containing 5mM $MgCl_2$.

21. Collect 1/20 of the nuclear fraction and store up to 6 months it at −80°C for future SDS-PAGE analysis (see Support Protocol; *UNIT 6.1*).

    See Critical Parameters for comments on sample to save for purification.

22. Collect a drop of nuclear fraction with a micropipet and verify purification by visualizing under a phase contrast microscope (see Fig. 3.36.2).

Prepare nucleoplasmic and nucleolar fractions

23. Break the nuclei by sonicating the nuclear fraction on ice using several bursts of 30 sec at 40 V at 5-min intervals. After each burst, verify the appearance of the suspension by examining a drop of the suspension by phase contrast microscopy. Stop the sonication when intact nuclei cannot be detected in the suspension.

    Nucleoli should be visible as dark dense structures under phase contrast microscopy (see Fig. 3.36.2).

24. Very gently add 10 RV of 880 mM sucrose under the sonicated nuclei with a micropipettor and then centrifuge 20 min at 2000 × *g*, 4°C.

25. After centrifugation, collect the supernatant, which contains the nucleoplasmic fraction, for further analysis. Save a sample of the nucleoplasm for further purification analysis and store up to 6 months at −80°C.

26. Resuspend the purified nucleolar fraction in a minimal volume of 0.34 M sucrose buffer and check the quality of purification by visualizing under a phase contrast microscope. Save a sample for purification analysis and store up to 6 months at −80°C.

    Nucleoli appear as very small birefringent structures (see Fig. 3.36.2).

    For an RV of 0.5 ml (three plates), the minimum volume is 20 μl and the maximum volume would be 200 μl for 100 × 10^6 cells.

Validate purification by one-dimensional gel electrophoresis

27. Thaw the samples collected in steps 10, 16, 21, 25, and 26 corresponding to each fraction obtained during the purification and stored at −80°C.

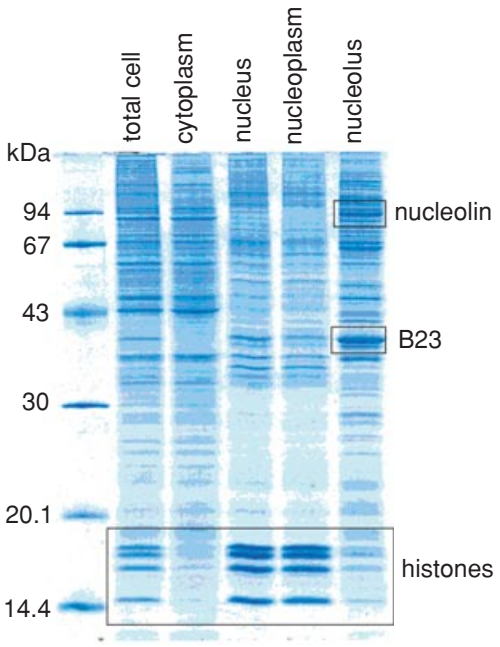

Figure 3.36.3 Analysis of the cellular fractions obtained during nucleoli purification. One-dimensional electrophoretic separation of 10 μg of proteins extracted from total cells, cytoplasmic fraction, nuclear fraction, nucleoplasmic fraction, and nucleolar fraction on a 12.5% polyacrylamide gel. Proteins are stained with Coomassie blue R250. Nucleolin, B23, and histones are indicated by insert and stars for histones. Size of molecular weight markers are indicated on the left.

28. Quantify proteins using the Bradford method (Simonian and Smith, 2006; *APPENDIX 3H*).

29. Separate 10 μg of each fraction by 12.5% SDS-PAGE and stain with Coomassie blue (see Support Protocol).

    An image of a typical gel is presented in Figure 3.36.3.

    A visual inspection of the gel makes it easy to monitor the efficiency of the purification.

    In general, the SDS-PAGE protein profiles of total and cytoplasmic fractions are very similar, except for histones (indicated by stars in Fig. 3.36.3), which are more enriched in the total fraction. The low abundance of these proteins in the cytoplasmic fraction is the basis for verification of the efficiency of the separation of nuclei and cytoplasm.

    In contrast, the SDS-PAGE profile of the cytoplasmic fraction is very different from the nuclear SDS-PAGE protein profiles (nucleus and nucleoplasm). In particular, there is an important enrichment in the four bands of low-molecular mass (indicated by stars in Fig. 3.36.3) that correspond to histones 1 to 4.

    Finally, the nucleolus fraction exhibits a very specific SDS-PAGE profile with a very clear enrichment of B23 (35 to 40 kDa) and of nucleolin (90 to 100 kDa).

    Obtaining an SDS-PAGE profile similar to that presented in Figure 3.36.3 is classically sufficient to assess the purity of the nucleolar fraction.

SUPPORT PROTOCOL

ONE-DIMENSIONAL SDS GEL ELECTROPHORESIS OF PROTEINS

To prepare the samples for SDS-PAGE, thaw each aliquot of fractions obtained in Basic Protocol steps 10, 16, 21, 25, and 26 during the purification slowly on ice. Quantify the protein in each samples using the Bradford protocol (Simonian and Smith, 2006; *APPENDIX 3H*) using a blank for each aliquot that contains the correct buffer: for total fraction, use NSB blank; for cytoplasm, use NSB plus 10% NP-40 blank; for nuclear

fraction, nucleoplasm fraction, and nucleolar fraction, use 340 mM sucrose solution for blank. After the quantification of the proteins, add 2 vol of 2× Laemmli electrophoretic sample buffer (see recipe) to ~10 μg of each fraction. Separate the proteins on a 12.5% one-dimensional SDS-PAGE gel (*UNIT 6.1*) and stain by Coomassie blue (*UNIT 6.6*). An image of a typical gel is presented in Figure 3.36.3.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Laemmli electrophoretic sample buffer, 2×

62.5 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
1% (w/v) SDS
10% (v/v) glycerol
0.1 M DTE
Traces of bromophenol blue
Dispense into 500-μl aliquots and store up to 6 months at −20°C

Nucleoli standard buffer (NSB), pH 7.4

10 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
10 mM NaCl
0.5 to 2 mM $MgCl_2$
Add water to 50 ml
1 tablet of Boehringer complete protease inhibitor (Roche Applied System)
Store up to 2 to 3 weeks at 4°C

COMMENTARY

Background Information

Nuclei of eukaryotic cells are highly organized organelles in which tens of different transient non-membrane bound structures, called nuclear domains or nuclear bodies, support most of the nuclear functions (Dundr and Misteli, 2001). Nucleoli are the most prominent of these nuclear domains with diameters ranging from 0.5 to 5 μm. The history, from their first description by Fontana in the second half of the 18th century to the modern research on the functions of nucleoli, has been properly summarized by Raska et al. (2006).

Nucleoli are present in every eukaryotic cell. They are formed around specific genetic loci, the nucleolar organizing regions, each of them containing tens of repeated ribosomal DNA genes (Henderson et al., 1972). The main biological role of nucleoli as ribosome subunit factories was proposed 50 years ago. Ribosome biogenesis is a very complex process requiring the contribution of numerous accessory factors, probably >100 factors that are not part of the ribosome itself (Kressler et al., 1999; Venema and Tollervey, 1999; Coute et al., 2006). This function gives rise to the characteristic ultrastructural organization of nucleoli consisting of three main compartments—the fibrillar center, the dense fibrillar component, and the granular component (Melese and Xue, 1995). The fibrillar center contains hundreds of rRNA genes not being transcribed. The dense fibrillar component contains rRNA genes that are actively transcribed by RNA polymerase I. The granular component contains rRNA being processed, and proteins added to it, to form ribosomal subunits that will be exported into the cytoplasm to initiate protein translation. More recently, the discovery of several molecules, with no obvious relation to ribosome biogenesis, were accumulating within nucleoli, which has promoted the emergence of a modern concept of nucleoli, where they are now considered as plurifunctional nuclear domains (Pederson, 1998; Olson et al., 2000; Raska et al., 2006). Nucleoli play crucial roles in several cellular processes such as the biogenesis of nonribosomal ribonucleoprotein complexes, cell cycle regulation, cellular ageing, and stress sensing. At the biomedical level, more and more evidence suggests their involvement in cancer (Montanaro et al., 2008), as well as viral infections (Hiscox, 2007).

The extreme concentrations of proteins and RNAs within nucleoli explain their very

high density, rendering them highly robust and quite easy to purify. The first efficient preparations of nucleoli from cells of various origins were obtained by pioneer works by Busch, Muramatsu, and colleagues (Busch et al., 1963, 1965, 1966; Muramatsu et al., 1963). Most of the isolation methods described later were based on the principles they proposed. First, highly purified nuclei have to be prepared. Then, nuclear organization has to be disrupted in order to free nucleoli; for this, controlled sonication in a solution containing a well-defined concentration of divalent cations is used. Finally, controlled centrifugation makes it possible to separate nucleoli from the rest of the nuclear components.

The efficiency of nucleoli purification can then be evaluated using various techniques: electron microscopy to ensure the conservation of classical nucleolar ultrastructure, immunoblotting to evaluate contamination from other cell compartments, or incorporation of labeled nucleotides to prove the maintenance of transcriptional activity.

After obtaining the nucleolar fraction, proteins can be identified by mass spectrometry as well. The first nucleolar proteomes were obtained in 2002. Two separate analyses identified 271 proteins (Andersen et al., 2002) and 213 nucleolar proteins (Scherl et al., 2002) for a total of 350 proteins after merging the two studies. Complementary studies were performed in 2005 that allowed the identification of 489 proteins (Andersen et al., 2005). Partial lists of nucleolar proteins as well as pictures of nucleolar proteins separated by one- or two-dimensional gel electrophoresis are available in SWISS-2D PAGE: *http://www.expasy.ch/swiss-2dpage/map=nucleoli_hela_1d_human* and *http://www.expasy.ch/swiss-2dpage/map=nucleoli_hela_2d_human*.

A nucleolar proteome database is also available (*http://www.lamondlab.com/NOPdb3.0/*) containing all the proteins identified in the nucleolar fraction by mass spectrometry (Ahmad et al., 2009).

Critical Parameters

In Basic Protocol steps 11, 15, 16, 22, 23, and 26, verify the appearance of the fractions by phase contrast microscopy (40× objective) using a drop of the fraction deposited between the microscope slide and a coverslip. The appearance of each fraction under phase contrast microscopy is illustrated in Figure 3.36.2.

In Basic Protocol step 1, the time at which the cells are plated before beginning the purification of nucleoli is critical. This can vary according to the cell line used. This time should be adapted to obtain 80% cell confluence at the beginning of the purification.

In Basic Protocol step 9, an aliquot of cell fraction should be analyzed by SDS–PAGE for the verification of the purification. This aliquot should be taken before adding 15 vol of NSB buffer to the remaining cell fraction for an optimal protein concentration.

In Basic Protocol step 15, the number of strokes should be optimized for each experiment. After four strokes, observe the cells under the phase contrast microscope. If the majority of the cells appear without their cytoplasm, proceed to the next step. If numerous nuclei are still encircled with remnants of cytoplasm (that appears under these conditions as more or less homogeneous filamentous structures attached to nuclei), subject the cells to another four strokes, then observe under the microscope. If necessary, repeat until nuclei are free of cytoplasm. For some cell lines (C2C12), >40 strokes are necessary. The concentration of $MgCl_2$ at this step is crucial (see below).

In Basic Protocol step 18, avoid mixing the suspension of nuclei with the sucrose cushion, usually the sucrose cushion is underlaid below nuclei suspension using a Pasteur pipet.

In Basic Protocol step 23, the number of sonicator bursts and the concentration of $MgCl_2$ (divalent cation) in NSB buffer must be adapted to each cell line and each physiological condition.

The concentration of divalent cation in hypotonic buffer is a very important parameter that allows lysis while preserving the nuclear membranes. A too high divalent cation concentration does not allow effective lysis; although too low a concentration leads to very effective cell lysis, it also induces a high destabilization of the nuclear membranes, which results in the disruption of nuclei at the centrifugation step.

Sonication of the nuclear suspension allows disruption of the nuclear membrane and the chromatin matrix and should be adapted for each cell line in terms of power and timing period (control by observing the suspension with a microscope).

Anticipated Results

A concentration of 1×10^8 adherent cells are expected to yield ~150 μg of nucleolar proteins. It is recommended to initiate the purification using 1 mM $MgCl_2$ and then optimize the concentration if the quality of the

fractionation is not satisfactory. It is not possible to obtain an efficient purification with a number of cells that was $<15 \times 10^6$.

Nucleolar fractions of good quality with good yields can be obtained using the following cell lines: HeLa (ATCC #CCL-2), IMR32 (ATCC #CCL-127), HEK-293 (ATCC #CRL-1573), MCF7 (ATCC #HTB-22), HEp-2 (ATCC #CCL-23), C2C12 (ATCC #CRL-1772), and RKO (ATCC #CRL-2577).

For nucleoli purification from these cell lines, the $MgCl_2$ concentration was experimentally determined to be between 0.5 mM and 2 mM.

The number of homogenizer strokes varied from 4 to 45 for these cells lines (see Critical Parameters).

The number of sonication bursts varied from one time for 30 sec at 40 V to five times for 30 sec at 40 V.

Time Considerations

Generally, 48 hr are sufficient to obtain each plate of $\sim 6 \times 10^6$ adherent cells at 80% confluency. However, this time could vary depending on the cell type used.

Nucleoli purification and storage of the purified fractions requires 1 day.

Quality control of the purification using one-dimensional electrophoresis and immunoblot analyses takes 1 to 2 days. The immunoblotting is not systematically done; however, it might insure that all steps were correctly performed. For immunoblotting, antibodies for beta actine (Sigma, cat. no. A 5228, diluted 1/1000), Fibrillarin (Abcam, cat. no. 4566, diluted 1/1000), and Histone H3 (Abcam, cat. no. 1791, diluted 1/1000) are regularly used. A detailed protocol for immunobloting can be found in Gallagher et al. (2008).

Note that it is difficult to perform nucleoli purifications from different cell lines in parallel due to the different steps of optimization that can vary a lot from one cell line to another.

ABSTRACT

Killer lymphocytes induce apoptosis by the release of cytotoxic mediators from specialized secretory lysosomes, called cytotoxic granules, into the immunological synapse formed with a cell targeted for elimination. Methods are presented here for isolating CTL and NK cell cytotoxic granules using cell disruption by nitrogen cavitation followed by continuous Percoll density gradient fractionation. Protocols are also given for purifying the key cytolytic molecules (perforin, granzyme A, granzyme B, and granulysin) from isolated cytotoxic granules by fast protein liquid chromatography. *Curr. Protoc. Cell Biol.* 47:3.37.1-3.37.29. © 2010 by John Wiley & Sons, Inc.

INTRODUCTION

Cytotoxic T lymphocytes (CTL) and natural killer (NK) cells play key roles in the immune response against virus-infected cells and tumors. These killer cells eliminate infected or transformed cells principally by releasing the contents of cytotoxic granules that contain programmed cell death–inducing serine proteases, called granzymes (for granule enzyme), and membranolytic pore-forming molecules, perforin (PFN) and granulysin (GNLY; Russell and Ley, 2002; Voskoboinik et al., 2006; Pipkin and Lieberman, 2007; Chowdhury and Lieberman, 2008). Recognition and binding of target cells by CTL and NK cells leads to highly polarized exocytosis of cytotoxic granules into the immunological synapse formed with the target cell. Granzyme entry into the target cell requires perforin.

Cytotoxic granules are complex secretory lysosomes that contain both effector molecules responsible for target cell elimination and resident lysosomal proteins (Table 3.37.1). These include PFN, calreticulin, and granzymes, which are complexed with a chondroitin sulfate–rich proteoglycan termed serglycin (for its alternating serine-glycine backbone; Lieberman, 2003). The dense core of activated human CTL and NK cells cytotoxic granules also contain GNLY, a member of the saposin-like protein (SAPLIP) family that exhibits a broad spectrum of antimicrobial activity, killing bacteria, fungi, and parasites (Stenger et al., 1998). Other than calreticulin, the expression of these proteins is largely restricted to activated CTL and NK cells. However, some of the granzymes, especially granzyme B, are also expressed together with mast cell proteases, but without perforin, in activated myeloid cells and some other cell types (Rissoan et al., 2002; Strik et al., 2007).

Protocols have been developed for cytotoxic granule isolation in order to study the composition of these organelles, as well as to purify native PFN and granzymes for in vitro studies of their respective roles in inducing target cell apoptosis. There is also increasing evidence for noncytotoxic functions of the granzymes in inflammation. Methods to

Table 3.37.1 CTL and NK Cell Cytotoxic Granule Contents

Protein	Function
Dense core	
Perforin	Pore formation; internalization of granzymes
Granzymes	Serine proteases
Granulysin	Microbicidal activity
Calreticulin	Calcium storage and perforin inhibitor
Cathepsin C	Granzyme processing
Serglycin	Proteoglycan matrix
Periphery (resident lysosomal proteins)	
Lamp-1	Lysosomal membrane proteins
Lamp-2	Lysosomal membrane proteins
CD63	Lysosomal membrane proteins
H^+ ATPase	Lysosomal acidification
Cathepsin B	Protection of killer cell from perforin
Cathepsin D	Lysosomal hydrolases
A-glucosidase	Lysosomal hydrolases
B-glucuronidase	Lysosomal hydrolases

express and purify recombinant versions of these proteins are also available (Sun et al., 1999; Martinvalet et al., 2008b; Sutton et al., 2008), but the procedure for purifying recombinant perforin is very challenging and not reproducible in our hands.

Basic Protocol 1 describes the isolation of cytotoxic granules from human lymphokine-activated killer (LAK) cells obtained from interleukin-2 and phytohemagglutinin (IL2/PHA)-activated peripheral blood mononuclear cells (PBMC) or human NK cell lines (i.e., YT-Indy) using a modification of the Borregaard method (Borregaard et al., 1983). This method (and all of the procedures described here) can also be used to isolate rodent granules and purify their cytolytic molecules. The Borregaard method is based on nitrogen cavitation of activated effector cells designed to disrupt the plasma membrane without lysing cytotoxic granules. The cytotoxic granules are then separated from other cell components by Percoll density gradient fractionation. Cytotoxic granules may also be isolated by the same method from RNK-16 cells, a rat NK-like leukemia cell line, grown as ascites for higher yields (see Alternate Protocol 1). Once the cytotoxic granules have been isolated, they can be lysed and either used directly to treat target cells to induce apoptosis (Support Protocols 9 and 10), or their cytolytic effector molecules can be purified by fast protein liquid chromatography (FPLC; Basic Protocol 2 and Alternate Protocol 2). We describe the purification of PFN (Basic Protocol 2), and the major granzymes—GzmA, GzmB, and GNLY (Alternate Protocol 2). PFN and granzyme expression can be detected immunologically (Support Protocols 1 and 2). After purification, PFN activity may be measured by different methods, including hemoglobin release assay (Support Protocol 3) or propidium iodide uptake (Support Protocol 4). GzmA and GzmB proteolytic activity is tested by peptide substrate (BLT and AAD) hydrolysis (Support Protocols 5 and 6), and GNLY activity by a colony-forming unit assay (Support Protocol 7) and turbidimetry (Support Protocol 8). We also describe two common assays (chromium release assay and annexin-V assay) to assess PFN and granzyme-induced cell death and apoptosis obtained by these methods (Support Protocols 9 and 10).

BORREGAARD METHOD OF CTL AND NK CELL CYTOTOXIC GRANULE ISOLATION

BASIC PROTOCOL 1

This is a 1-day protocol. CTL or NK cells are disrupted by nitrogen cavitation in a physiological buffer to release cytotoxic granules from whole cells. Isolated granules obtained from human LAK cells contain PFN and both major granzymes, GzmA and GzmB, as well as GNLY. YT-Indy NK cells contain PFN, GzmB, and GNLY, but not GzmA or K, and they are especially recommended for high-yield hGzmB purification. Alternatively, cytotoxic granules can be isolated from rat RNK-16 NK-like leukemia cells, serially passaged in vivo as ascites in Fischer F344 rats for higher yield purification (Alternate Protocol 1).

Granules may be purified from various sources, three of which are described in this protocol. The advantage of using human cells is that all effector molecules will be of the same species and from the same source. Additionally, primary human cells are rapidly dividing, and the transformed human NK lines highly over-express granzymes. The disadvantages of these techniques are the cost of IL-2 when expanding primary human cells and that the transformed human NK lines expand slowly and require a large amount of culture medium.

Materials

Human blood *or* buffy coats for LAK cell production *or* YT-Indy NK cells (ATCC)
Ficoll-Paque PLUS (GE Healthcare)
K10 medium (see recipe)
K10 + IL-2: K10 medium plus 1000 IU/ml human IL-2 (Chiron)
PHA-P (Sigma)
Hanks' balanced salt solution (HBSS) without calcium, magnesium, and phenol red
Relaxation buffer (see recipe)
Continuous 40% (w/v) adjusted Percoll gradient (see recipe)
Solubilization buffer (see recipe)

50-ml centrifuge tubes
Centrifuge
1000-µl pipettor *or* serological pipet
Cavitation/disruption bomb (Parr Instrument Company)
Magnetic stirrer
Refrigerated centrifuge with Sorvall SS-34 rotor (or equivalent), and corresponding 26-ml rigid polycarbonate tube (Beckman Instruments)
20-G spinal needle (Popper & Sons)
Beckman ultracentrifuge with Sw28Ti rotor (or equivalent) and thick-wall polycarbonate tubes (cat. no. 355631)

Additional reagents and equipment for counting the cells (*UNIT 1.1*), flow cytometry (Support Protocol 2), and fluorescence microscopy (Support Protocol 1)

NOTE: All procedures, buffers, tubes, and equipment must be maintained at 4°C during the purification unless otherwise noted.

NOTE: Make sure to handle human blood products with universal precautions following the rules of your institution.

Isolate and culture cells

1. For purification from NK cell lines, skip to step 8. For purification from PBMC or human buffy coats, layer 30 ml of whole blood or buffy coat onto 20 ml prewarmed Ficoll in a 50-ml centrifuge tube. Layer the blood on top of the Ficoll by slowly

running the blood down the side of the tube, making sure not to disrupt the phase layers during layering.

2. Centrifuge the tubes 30 min at 950 *g*, room temperature, and turn off the brake of the centrifuge.

   Active braking will disturb the lymphocyte layer. Do not centrifuge at 4°C, as this will alter cell/Ficoll density.

3. Remove tubes carefully from the centrifuge.

   The top layer will be plasma, the middle white layer (interface) will be PBMC, the clear layer will be Ficoll, and the bottom layer will be red blood cells.

4. Carefully remove the lymphocyte layer from the tubes with a 1000-µl pipettor or serological pipet, making sure to remove the least amount of Ficoll possible.

5. Wash the PBMC three times, each time for 5 min in 50-ml 37°C K10 medium to remove Ficoll and resuspend in 10 to 50 ml K10. Count an aliquot of the cells (*UNIT 1.1*).

6. Culture cells at 10^6 cells/ml for 3 days in K10+IL-2 supplemented with 4 µg/ml PHA-P in 75-cm^2 cell culture flasks at 37°C, 5% CO_2.

   Alternatively, one may select for $CD3^+CD8^+$ cells to enrich for cytotoxic T cells or for $CD3^-CD56^+$ cells to enrich for NK cells. Reduced doses of IL-2 may be used, but high doses of IL-2 improve yields by up-regulating expression of the effector proteins.

7. On the fourth day, resuspend the cells in fresh K10+IL-2 (without PHA-P) and reseed at 10^6 cells/ml and expand culture, splitting every several days to maintain a density of 1×10^6 cells/ml, until the desired cell number is achieved.

   At least 5×10^9 total cells are suggested for granule purification.

   These LAK cells should grow very rapidly; expanding from $0.1–1 \times 10^8$ cells (the expected yield of PBMCs is at least 10^6 cells/ml of blood) should take less than 2 weeks.

   Cells should be harvested 1 to 3 weeks after PHA stimulation for optimal expression of cytotoxic molecules.

8. For cultures beginning with NK cell lines, maintain YT-Indy cells in K10 medium at densities of $0.1–1 \times 10^6$ cells/ml. Split the cells by diluting 1:2 to 1:3, adding new medium to older medium.

   Do not completely change medium as the cells rely on secreted IL-2 to proliferate.

9. Expand the cells to $3–5 \times 10^9$ total cells, which is adequate for granule purification.

   The cells do not divide very rapidly, so expect the expansion to take ~3 weeks.

10. After cell expansion, test expression of PFN and/or granzymes contained in cytotoxic granules by flow cytometry (Support Protocol 2) or fluorescence microscopy (Support Protocol 1) before isolation of cytotoxic granules or effector molecule purification (Fig. 3.37.1).

Disrupt cells by nitrogen cavitation

11. Prechill the cavitation/disruption bomb at 4°C overnight before procedure.

12. Collect at least $3–5 \times 10^9$ cells, wash the cells twice with cold HBSS (keep at 4°C at all times), and then resuspend at 10^8 cells/ml in relaxation buffer.

13. Place cells in the cavitation bomb on top of a magnetic stirrer.

    If the cell suspension is ≤50 ml, place the cells in a 50-ml centrifuge tube and then place the tube in the bomb with ice surrounding the tube of cells.

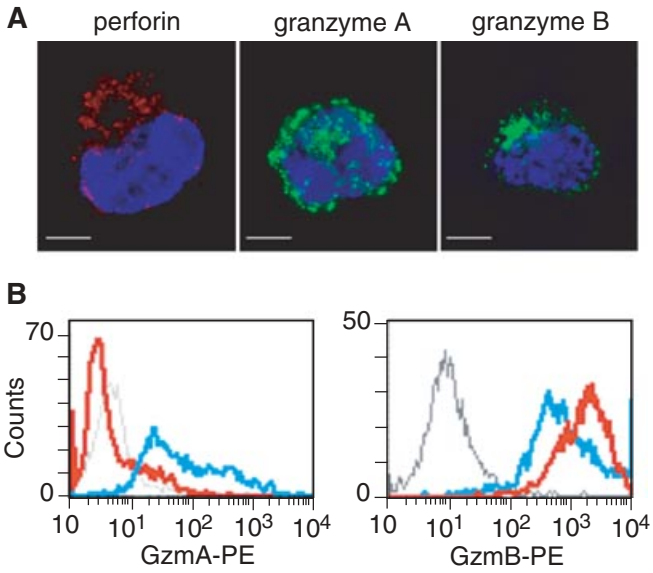

Figure 3.37.1 Analysis of cytotoxic granule content. (**A**) Cytotoxic granules of day 10 LAK cells were stained with anti-PFN, anti-GzmA, or anti-GzmB monoclonal antibodies before fluorescence microscopy analysis. Scale bars: 5 μm. (**B**) Jurkat (gray), YT-Indy (red), or day 10 LAK cells (blue) cells were stained with GzmA (left panel) or GzmB (right panel) monoclonal antibodies and expression was determined by FACS analysis. Jurkat cells do not express GzmA or GzmB while YT-Indy cells only express GzmB. LAK cells express both GzmA and GzmB. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0337*.

14. Slowly pressurize to 450 psi with N_2 and stir at 4°C for 20 min. Then, gradually release pressure and harvest the contents dropwise into a new tube on ice. If pressure drops below 250 psi, release remaining pressure quickly through the intake valve and collect remaining sample.

    The yield of granules is markedly influenced by the cavitation process. Excessive cavitation will rupture the cytotoxic granules. The stir plate must be adjusted to a speed that minimizes foaming.

Concentrate granules and remove nuclear and cytoplasmic contamination

15. To remove nuclei by differential centrifugation, centrifuge the sample 10 min at 400 × *g*, 4°C, and retain the supernatant.

16. Wash the pellet twice in equal volumes of relaxation buffer, centrifuge 5 min at 400 × *g*, 4°C, and add supernatants to the original supernatant.

17. Centrifuge the pooled supernatants 5 min at 400 × *g*, 4°C.

    The final post-nuclear supernatant (PNS) should be free of nuclei and whole cells.

18. Centrifuge the PNS 10 min at 15,000 × *g*, 4°C, to pellet granules and heavy organelles and resuspend the pellet in 20 ml relaxation buffer with a 20-G spinal needle.

Fractionate and collect cytotoxic granules

19. Preform a 20-ml continuous gradient of 40% adjusted Percoll (4°C) in four rigid polycarbonate tubes by centrifuging 10 min at 48,000 × *g*, 4°C, in an SS-34 rotor.

    "Adjusted" means that the Percoll concentration is adjusted with relaxation buffer to a final concentration of 40%.

20. Carefully, layer 5 ml of PNS/tube onto the 20 ml of preformed gradient of 40% adjusted Percoll. Centrifuge for 35 min at 48,000 × *g*, 4°C.

21. Extract cytotoxic granules with a 20-G spinal needle from the bottom of the gradient by harvesting the bottom 5 to 7 ml from each tube.

    Granules should form a visible refractile layer.

22. Pool the granule fractions and then remove Percoll by pelleting it by centrifugation overnight at 64,000 × *g* in 28-ml thick-wall polycarbonate tubes, 4°C, in a Sw28Ti rotor.

    Granules form a thin layer above the Percoll pellet.

Pellet granules

23. Remove the supernatant and resuspend the granules in solubilization buffer with a 20-G spinal needle (2 ml per 10^9 original cells) and store at −80°C.

    After resuspension, the granules can be stored indefinitely at −80°C before further protein purification.

    Disruption of the granule membranes and solubilization of granule proteins is optimal after at least one freeze/thaw cycle after storage overnight at −80°C followed by two freeze/thaw cycles in liquid N_2.

    The solubilized granules can also be used directly to treat cells for apoptosis assays provided the total salt is diluted to 150 mM NaCl with HE buffer (Support Protocol 9).

ALTERNATE PROTOCOL 1

PURIFICATION OF CYTOTOXIC GRANULES FROM RAT RNK-16 CELLS

The advantage of this method is that RNK-16 granule isolation described below is best suited for high-yield purification. The disadvantage of this technique is the need to use rats to serially passage RNK-16 NK-like leukemia cells as ascites in vivo since these cells do not grow in tissue culture. Typically, ascites from each rat yields 1–5 × 10^9 cells.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

Materials

F344 rats (200 to 225 g; Harlan Laboratories)
Pristane (2,5,10,14-tetramethyl-pentadecane; Sigma)
RNK-16 cells
Hanks' balanced salt solution (HBSS) without calcium, magnesium, and phenol red
HHH buffer (see recipe)
Ice
Red blood cell lysis buffer (Sigma)

3-ml syringe and 23-G needle
Dissecting pad
Scissors
10-ml pipet

Additional reagents and equipment for euthanizing the rat (Donovan and Brown, 2006)

Prepare the peritoneal cavity

1. Inject F344 rats intraperitoneally with 1.5 ml of sterile Pristane using a 3-ml syringe with a 23-G needle 4 to 7 days before RNK-16 cell injection to prepare the peritoneal cavity to host the cells.

Grow RNK-16 cells in rats

2. Wash 5–10 $\times$ 10^7 RNK-16 cells/rat twice, each time in 50 ml HBSS and resuspend in 2 ml of HBSS per rat for intraperitoneal (i.p.) injection.
3. Inject about 5–10 $\times$ 10^7 RNK-16 cells into each rat i.p. using a 3-ml syringe and 23-G needle.
4. Beginning 11 days post i.p. injection of RNK-16 cells, monitor rats for ascites production. Monitor rats every day for ascites production by abdominal palpation and progressive ascites fluid distention of the abdomen.

   Most of the time, rats are sacrificed 12 to 15 days post i.p. injection and RNK-16 cells are harvested immediately.

Harvest RNK-16 cells

5. Sacrifice the rat using CO_2 asphyxiation (Donovan and Brown, 2006) and perform bilateral thoracotomy (a small incision into the pleural space of the chest) 5 min after CO_2 exposure for euthanasia before harvesting the cells.
6. To harvest cells, pin the rat on its back to a dissecting pad and using scissors make a midline vertical slit in the abdominal skin to expose the peritoneal membrane without damaging it.
7. Then make a small incision with scissors into the left peritoneal membrane and slowly inject 10 ml of cold HHH buffer with a 10-ml pipet into the peritoneal cavity.
8. Mix carefully with the pipet to mobilize the ascitic fluid from the cavity, withdraw the peritoneal wash fluid containing RNK16 cells, and place on ice until the end of the procedure.
9. Repeat washing and harvesting cells until washes are clear.

   Expect to use 100 to 150 ml HHH buffer to extract all RNK-16 cells in one rat.

10. Centrifuge 5 min at 200 $\times$ *g*, 4°C, and remove the supernatant (carefully take the top layer first, which is pristane, and then remove the HHH buffer).

    The pristane is a distinguishable white layer above the HHH buffer.

    If RNK-16 cells are contaminated with blood, incubate the pellet with red blood cell lysis buffer for 10 min at 4°C.

11. Wash the cells three times, each time with at least 100 ml cold HBSS (keep at 4°C at all times) and then resuspend the cells at 10^8/ml in relaxation buffer.

    Aliquots of RNK-16 cells that appear viable by trypan blue staining from rats that produce a high yield of cells without blood contamination are used for re-injection or immediately frozen for future use.

Isolate granules

12. Proceed immediately with cell disruption by nitrogen cavitation and Percoll gradient fractionation of cytotoxic granules (Basic Protocol 1, steps 11 through 23).

PURIFICATION OF PERFORIN FROM CYTOTOXIC GRANULES

BASIC PROTOCOL 2

Rodent and human granzymes and PFN are cross-reactive at inducing cell death across species, although with some differences in substrate activity (Casciola-Rosen et al., 2007; Cullen et al., 2007). PFN can be purified from cytotoxic granules isolated from human LAK cells, YT-Indy NK cells, or rat RNK-16 cells. Because YT-Indy NK cells lack GzmA and GzmK expression and have high GzmB yields, those cells are preferred for GzmB purification, but GzmB can also be purified from rat RNK-16 cells. Because

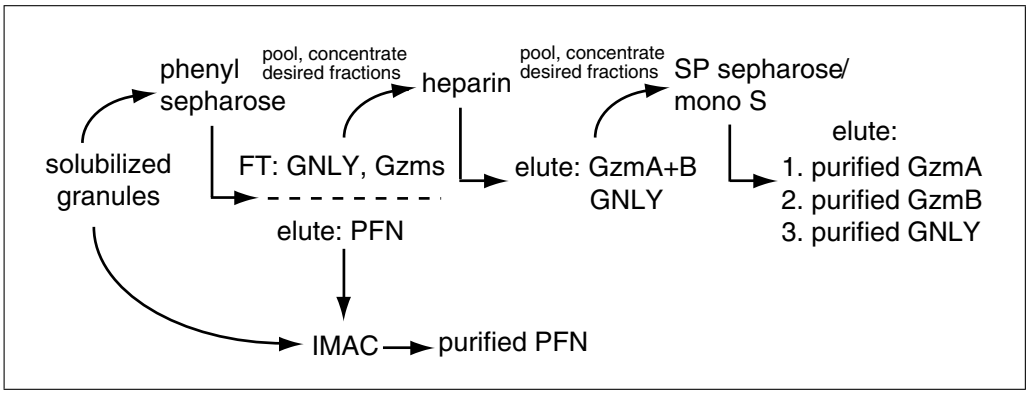

Figure 3.37.2 Procedure for purification of cytotoxic granule effector proteins by fast protein liquid chromatography (see Basic Protocol 2 and Alternate Protocol 2 for details). Abbreviations: FT, flow through; IMAC, immobilized metal affinity chromatography.

GNLY is not expressed in rodents, YT-Indy or human LAK cells preferentially are used for GNLY purification. A schematic of the different purification procedures is described in Figure 3.37.2.

For perforin isolation, an IMAC (immobilized metal affinity chromatography) purification method has been optimized by Winkler et al. (1996) to separate PFN from other granule components.

Materials

Cytotoxic granules (Basic Protocol 1), frozen
Ice
Equilibration buffer A1 (see recipe)
IMAC resin charged with Cobalt (TALON Superflow Metal Affinity Resin; Clontech)
0.5 M EGTA in H_2O
Elution buffer B1 (see recipe)
BCA assay (Pierce)

Rabbit anti-PFN (Cell Signaling, cat. no. 3693)
0.45-μm low-protein-binding syringe filter (Millipore)
10-ml desalting columns (Econo-Pac 10DG disposable chromatography columns; Biorad)
50-ml Superloop (Amersham)
Fast Protein Liquid Chromatography (FPLC) system (Biorad) and columns (Pharmacia Biotechnology)
Ultrafiltration concentrator (Amicon Ultra centrifugal filter device with low binding; Millipore)
Nitrocellulose membrane

Additional reagents and equipment for hemoglobin release assay (Support Protocol 2), BCA assay (*APPENDIX 3H*), SDS-PAGE (*UNIT 6.1*), immunoblotting (*UNIT 6.2*), and silver staining (*UNIT 6.6*)

NOTE: All buffers and suspensions are kept on ice.

Prepare granules

1. Place the frozen tube of solubilized granules (Basic Protocol 1, step 23) on ice for 2 hr, mixing the suspension by inverting the tube every 15 to 20 min.
2. Centrifuge the suspension 10 min at 15,000 × *g*, 4°C.

3. Carefully decant the supernatant and filter through a 0.45-μm low-protein-binding syringe filter to remove membrane fragments

   If the filter is blocked, carefully change the filter.

Desalt the suspension

4. During step 1, equilibrate desalting columns with 25 ml of cold equilibration buffer A1. Prepare one column for every 2.5 ml of supernatant.

5. Run 2.5 ml of supernatant through each desalting column, discard the flow-through, and then add 3.5 ml of equilibration buffer A1. Retain the flow-through and combine all samples for FPLC purification.

6. Filter the sample again through a 0.45-μm low-protein binding syringe filter.

   It is very important to note that at this point perforin is no longer in a chelated buffer and can be inactivated by multimerizing in the presence of trace amounts of Ca^{2+}. Therefore, the FPLC step must be performed as quickly as possible.

Perform FPLC

7. During step 5, prepare a 5-ml column of IMAC TALON Superflow resin and equilibrate it with 10 column volumes (CV) of equilibration buffer A1.

8. Load filtered sample into a superloop and attach to an FPLC workstation.

   Add 50 or 20 μl of 0.1 M EGTA into each fraction collector tube before FPLC run (if collecting 5- or 2-ml fractions to yield 1 mM final concentration of EGTA) to prevent perforin inactivation.

9. Run the following FPLC program with equilibration buffer A1 and elution buffer B1:

   a. Wash the column with 100% buffer A1 at 1.5 ml/min for 1 CV.
   b. Inject sample at 1 ml/min.
   c. Wash the column with a linear gradient of 1% to 2% buffer B1 at 1 ml/min for 5 CVs.
   d. Then elute with a linear gradient of 2% to 40% buffer B1 at 1.5 ml/min for 7 CVs and 40% to 100% buffer B1 at 1.5 ml/min for 5 CVs.

   Elution fractions are continuously monitored for absorbance at 280 nm. With this method one peak, absorbing at 280 nm, containing perforin is observed (Fig. 3.37.3A).

Identify PFN-containing fractions

10. Assay 10 to 20 μl of each fraction for hemolytic activity by a hemoglobin release assay (see Support Protocol 2; Fig. 3.37.3B).

11. Then, collect and pool all hemolytic positive fractions (containing perforin).

12. Concentrate with an ultracentrifugation concentrator to a final volume of 200 to 500 μl (10 mg/ml) to prevent lost of PFN due to binding to concentrator tube membrane.

13. Determine protein concentration by BCA assay (*APPENDIX 3H*) using BSA for calibration.

14. Divide purified active perforin and store indefinitely at −80°C.

    Since PFN is not stable with freeze thawing and loses activity at 4°C within a week, it is important to store it in small aliquots in an amount that will be used for just a few experiments. We generally divide our samples into 5-μl aliquots.

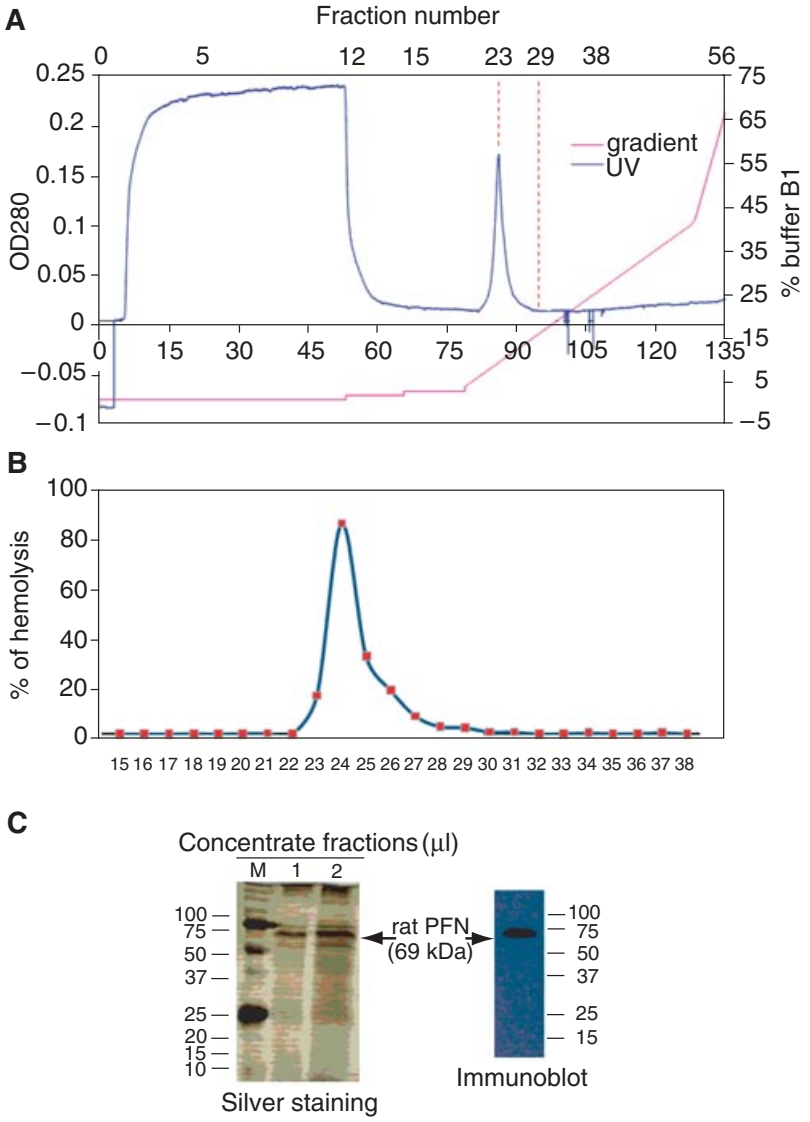

Figure 3.37.3 Purification of PFN from cytotoxic granules by fast protein liquid chromatography. (**A**) The profile of eluted protein from the FPLC is shown. Perforin activity is eluted over an imidazole gradient (pink line) and coincides with a single absorption peak at 280 nm (blue line) as shown by (**B**) testing the hemolytic activity of collected fractions by hemoglobin release assay. (**C**) After concentration of hemolytic positive fractions, 1 and 2 µl were used to assess the purity of the purified PFN by electrophoresis on a 12% polyacrylamide gel. Rat PFN (69 kDa) is visualized by silver staining (left) and an immunoblot (right). Abbreviations: M, protein markers. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0337*.

Analyze purity

15. Analyze purified perforin by SDS-PAGE (*UNIT 6.1*) and immunoblotting (*UNIT 6.2*) to assess purity. Stain the protein gel by silver staining (*UNIT 6.6*). Transfer to nitrocellulose membrane and detect with rabbit anti-PFN (Fig. 3.37.3C).

    The staining is performed according to the manufacturer's protocol (dilution 1:1000, incubation overnight at 4°C).

    Immunoblots can also be probed for granzymes and GNLY to verify that there is no cross-contamination.

    It is important to note that cell sensitivity to PFN follows a very steep dose response curve that differs from cell to cell and varies even for the same cell under different culture

conditions (such as variations in cell density; Keefe et al., 2005). At high concentrations (termed lytic) perforin on its own triggers necrosis by causing irreparable membrane damage. At lower concentrations (termed sublytic) perforin on its own triggers necrosis in only a minority of cells (generally 5% to 20%, assessed by propidium iodide incorporation; Support Protocol 4), but is able to deliver granzymes into cells to induce apoptotic death. At still lower concentrations (when PI incorporation is <5%), perforin is not active at delivering granzymes. Sublytic concentrations are used to load granzymes into target cells to mimic CTL or NK cell-mediated cell death (which is apoptotic rather than necrotic). Because of this steep dose dependence (often a factor of 2 is all that distinguishes an inactive concentration from a lytic concentration), our practice is to titrate the perforin concentration to be used for each experiment on the day of the experiment or the day before (see Support Protocol 4).

PURIFICATION OF GRANZYME AND GRANULYSIN FROM CYTOTOXIC GRANULES

ALTERNATE PROTOCOL 2

A method adapted from Shi et al. (2000) is detailed here for purifying human GzmB and GNLY from the cytotoxic granules of YT-Indy cells, an autonomously growing human NK cell line expressing high levels of GzmB, perforin, and GNLY. YT-Indy cells do not express GzmA or GzmK (Froelich et al., 1996), which facilitates the purification of GzmB. However, RNK cell granules can also be used as starting material. RNK cells do not express GNLY, but express GzmA, GzmK, and GzmB. The granzymes are all highly basic (they are among the most basic proteins in mammalian cells with pI >9), making them easy to separate from other granule components. However, because of the similar chemical properties of these homologous enzymes, the purified granzymes need to be carefully screened by immunoblot and activity assay for cross-contamination. Since GzmA and GzmB have distinct substrate activity (GzmA is a tryptase, while GzmB cuts after aspartic acid residues), either antibodies or protease assays can be used to detect contamination. It is possible to separate GzmA and GzmB from LAK or RNK cell granules using a Mono-S column for the final step purification as previously described (Hanna et al., 1993). However, this must be done with care. An alternative is expression and purification of recombinant GzmA or GzmB as described elsewhere (Martinvalet et al., 2008b).

Materials

Granules from YT-Indy cells (Basic Protocol 1)
Phenyl Sepharose chromatography elution buffers A2 and B2 (see recipes)
Liquid nitrogen
Heparin chromatography buffers A3 and B3 (see recipes)
SP Sepharose (or MonoS) chromatography elution buffers A4 and B4 (see recipes)
BCA protein assay kit (Pierce)

Fast Protein Liquid Chromatography (FPLC) and columns (GE Healthcare)
Centrifuge
0.45-μm low-protein-binding syringe filter (Millipore)
Phenyl Sepharose High Performance, SP Sepharose High Performance, 5 ml of each densely packed in a column (GE Healthcare)
Ultracentrifugation concentrator
HiTrap heparin column, 5 ml (GE Healthcare)
MonoS column (GE Healthcare)

Additional reagents and equipment for SDS-PAGE (*UNIT 6.1*), staining with Coomassie brilliant blue (*UNIT 6.6*), and immunoblotting (*UNIT 6.2*)

NOTE: For the purification of rat granzymes the use of a MonoS column (GE Healthcare) instead of SP Sepharose is highly recommended.

Prepare for purification

1. Attach all columns to the FPLC system in a cold room.
2. Solubilize cytotoxic granules from YT-Indy cells in 10 ml buffer A2.
3. Subject the samples to three freeze/thaw cycles in liquid N_2.
4. Centrifuge 15 min at 15,000 × *g*, 4°C.
5. Collect the supernatant, filter it through a 0.45-μm low-protein-binding filter, and store on ice until use.

Remove PFN

6. Equilibrate the Phenyl Sepharose column with 10 CV of buffer A2.

   A Phenyl Sepharose column is used to separate PFN, which binds to the column, from granzymes and GNLY, which do not bind.

7. Load the filtered supernatant manually at ∼1 ml/min.
8. After the sample loading, wash the column with 10 ml buffer A2 until the UV detector baseline is reached (usually 2 CVs). Collect flowthrough and initial wash fractions, which contain granzymes and GNLY.

   Collect 2-ml fractions for a total of 20 ml (10 fractions).

9. Pool and concentrate these fractions to a volume <1 ml using an ultracentrifugation concentrator with a molecular cutoff <10 kDa before loading on the heparin column.
10. Elute perforin.

    PFN can be eluted from the Phenyl Sepharose column using the following program (flow: 1 ml/min): wash 10 min with buffer A2, elute with a 0–2 M NaCl (0% to 100% buffer B2) linear gradient for 20 min. Peak fractions contain perforin and are pooled, concentrated to a final volume of ∼2.5 ml, and stored at −80°C until IMAC purification (Basic Protocol 2).

Pass the sample through the heparin column

11. Equilibrate the HiTrap heparin column with 10 CVs of buffer A3.
12. Dilute the concentrated flowthrough and wash fractions from the Phenyl Sepharose column 20-fold in buffer A3 prior to loading manually on the heparin column at 1 ml/min.
13. Wash the column until the UV absorbance baseline is reached.
14. Elute granzymes and GNLY from the heparin column using the following program at a flow rate of 1 ml/min:

    a. Wash with 2 CVs of buffer A3.
    b. Elute with a 0−2 M NaCl (0%–100% buffer B3) steep linear gradient for 10 min.
    c. Finally, elute with 100% buffer B3 for 10 min.

    A typical chromatogram for YT-Indy cell granules is shown in Figure 3.37.4A.

    AAD esterolytic activity (GzmB, see Support Protocol 4) is found in elution peak 3 and 4 while antibacterial activity is mainly found in the peak 4. Since measuring GNLY antibacterial activity takes at least 12 hr, we recommend pooling the GzmB-containing fractions with the last elution peak without testing for GNLY before further purification on the S-column.

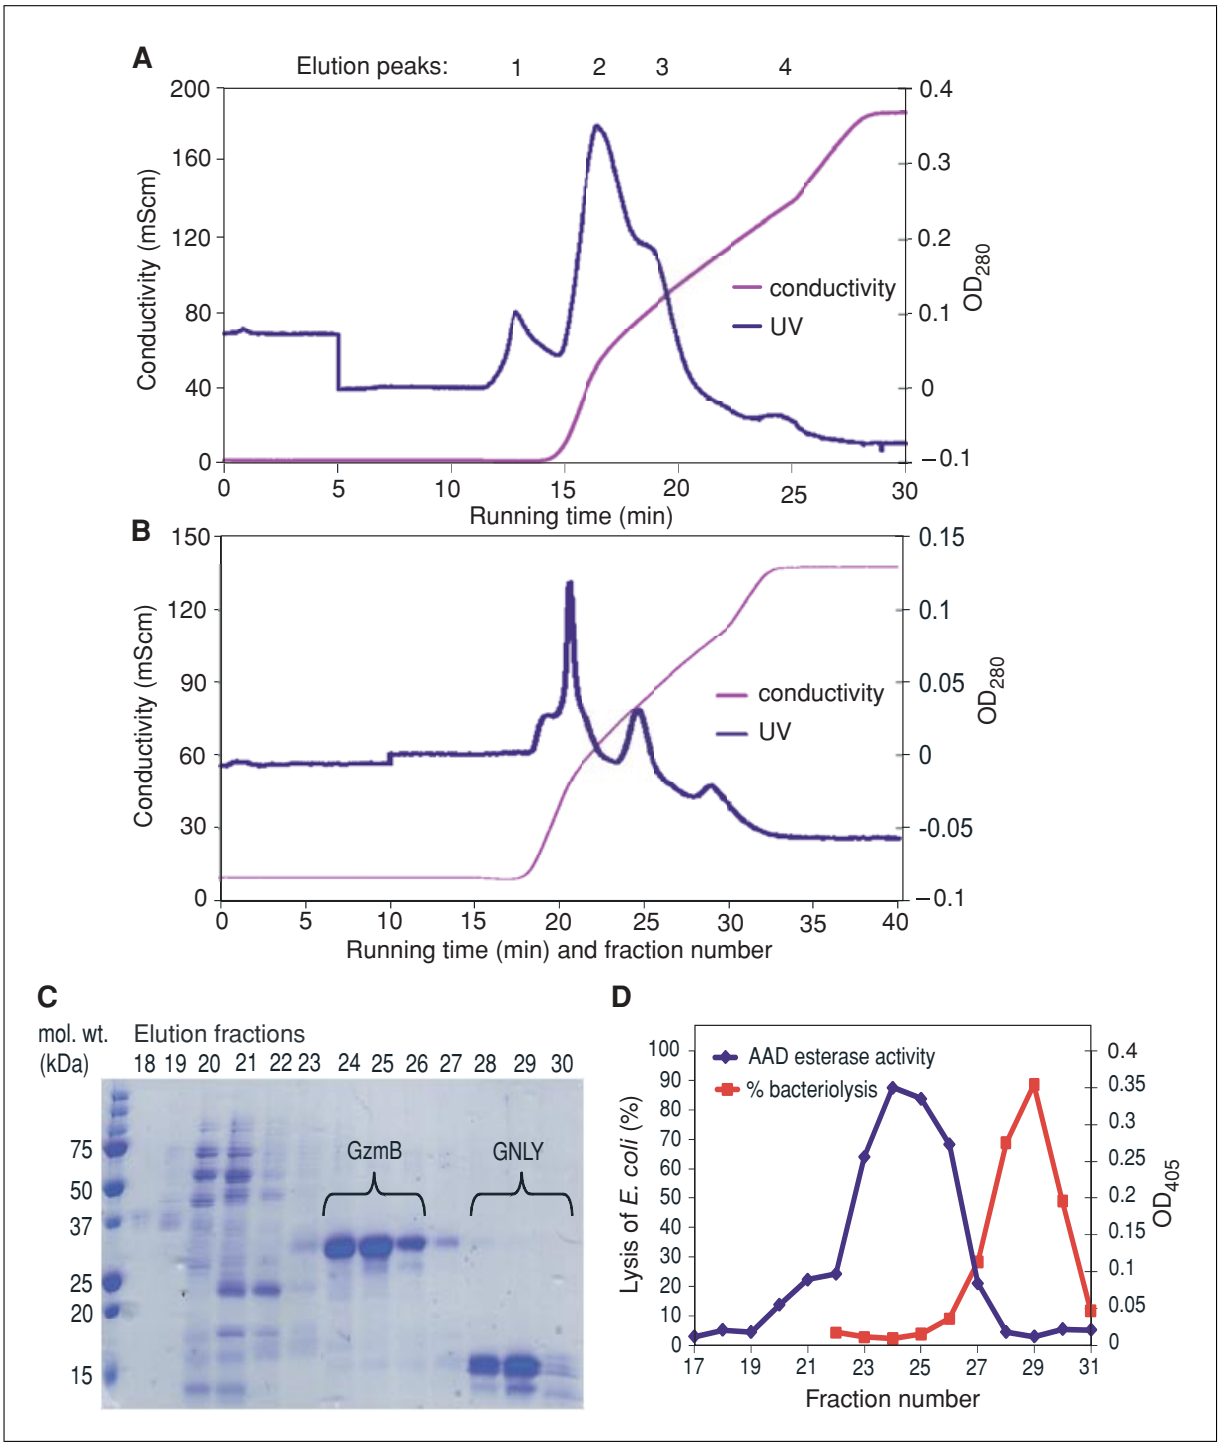

Figure 3.37.4 GzmB and GNLY purification from YT Indy cells. A Chromatogram (OD_{280} and conductivity) of the protein elution from the heparin column is shown in (**A**), and from the SP Sepharose column in (**B**). The eluted fractions from the SP Sepharose column were further analyzed by electrophoresis on a 12.5% polyacrylamide gel and by Coomassie blue staining (**C**) by AAD esterase assay and bacteriolytic activity (CFU assay) (**D**). For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0337*.

15. Concentrate the pooled fractions to a final volume ≤1 ml using an ultracentrifugation concentrator with a molecular cutoff ≤10 kDa.

    If granules containing GzmA and GmzB are used as starting material, the eluate fractions should also be screened for BLT activity (see Support Protocol 5).

16. Equilibrate the SP Sepharose column with 10 CV of buffer A4.

17. Dilute the pooled and concentrated fractions of the heparin column 20-fold in buffer A4.

18. Manually load the sample on the S-column at 1 ml/min.

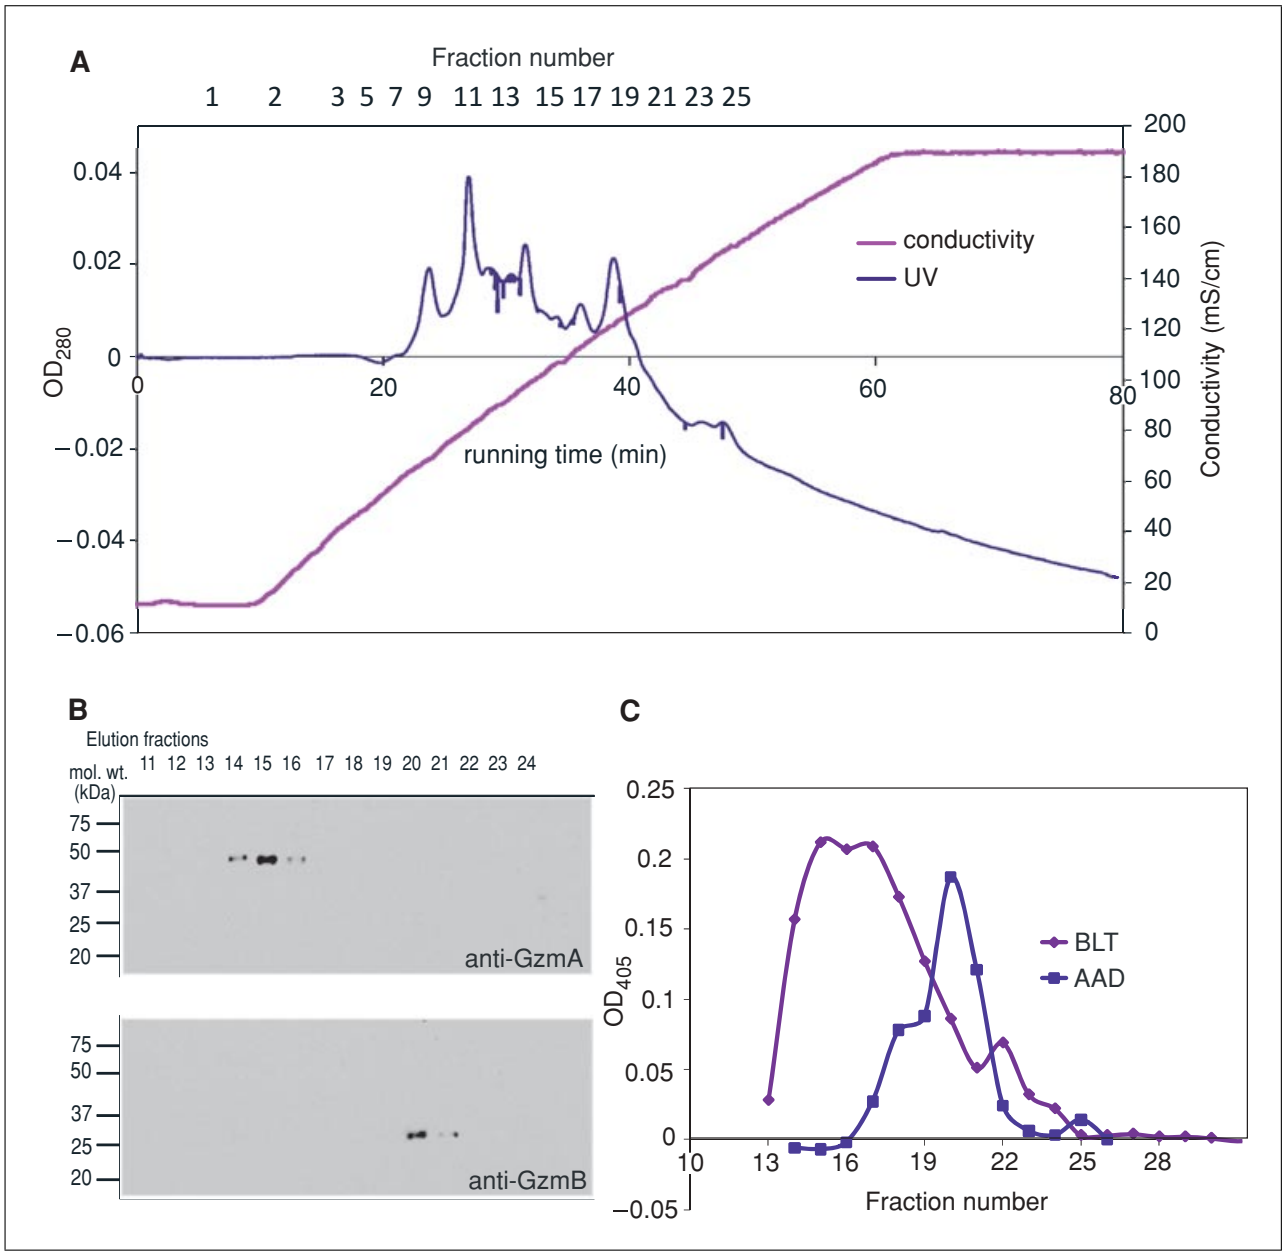

Figure 3.37.5 GzmA and GzmB purification from human LAK cells. The chromatogram (OD_{280} and conductivity) of the protein elution from the Mono-S column is shown in (**A**). The fractions were analyzed by electrophoresis on a 12.5% polyacrylamide gel and immunoblotting using anti-GzmA and anti-GzmB antibodies (**C**). The elution fractions were further screened for esterase activity (BLT and AAD) (**D**). Note there is BLT activity in fractions that stained negative for GzmA (fractions 17 and 18). The source of the esterase activity is most likely GzmK (not specifically tested in this purification). For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0337*.

19. Wash the column with buffer A4 until the UV baseline is reached (2 to 3 CV).

Substitute a MonoS column if granules contain GzmA and GzmB to separate these.

Separate granzymes and GNLY on SP Sepharose column

20a. Use the following program at a flow rate of 1 ml/min to elute granzymes and GNLY from the SP Sepharose column using the following program:

i. Wash with an additional 2 CVs of buffer A4.
ii. Elute with a 0–1 M NaCl (0%–100% buffer B4) linear gradient for 20 min.
iii. Finally. elute with 100% buffer B4 for 10 min. GzmB elutes at ~60%–70% of buffer B4, GNLY at ~90%–100% buffer B4 (Fig. 3.37.4B).

21a. Analyze elution fractions using SDS-PAGE (*UNIT 6.1*) and stain with Coomassie brilliant blue (*UNIT 6.6*; Fig. 3.37.4C). Test purity by immunoblotting (*UNIT 6.2*). Perform activity testing (Support Protocols 3 to 9; Fig. 3.37.4D).

22a. Separately pool and concentrate fractions containing GzmB (28 kDa) or GNLY (15 and 10 kDa) to a final volume of ~250 µl before dividing into 5-µl aliquots and storing at −80°C.

Separate GymA and GzmB on Mono-S column

20b. If GzmA and GzmB–containing granules are used as starting material, perform the purification on a Mono-S column to allow better resolution of the cationic granule proteins.

21b. Apply the following program at a flow rate of 0.5 ml/min for elution:

i. Wash 20 min with buffer A4.
ii. Elute with a 0.05–1 M NaCl (0%–100% buffer B4) linear gradient for 60 min.
iii. Finally, elute with 100% buffer B4 for 20 min.

GzmA elutes at ~50% to 60% and GzmB at 60% to 70% of buffer B4 (Fig. 3.37.5A).

Be aware that GzmK (found in LAK cells as well as RNK granules) elutes also in this salt concentration range and exhibits BLT activity (see Support Protocol 4; Fig. 3.37.5B). The eluting fractions should therefore be carefully screened using SDS-PAGE under reducing and non-reducing conditions to distinguish between monomer- and dimer-containing fractions (GzmA is a dimer and GzmK a monomer under non-reducing conditions), as well as immunoblotting using GzmA, B, and K antibodies (Fig. 3.37.5C).

22b. Proceed to step 23.

23. Determine the protein concentration with the BCA protein assay kit.

24. Test protein activity as described in Support Protocols 5 and 6.

IMMUNOSTAINING ASSAY FOR PERFORIN AND/OR GRANZYME EXPRESSION

SUPPORT PROTOCOL 1

Immunostaining of cells can be used to assess expression of perforin and granzymes.

Materials

Poly-L-lysine (Sigma)
Cultures of CTL or NK cells
Phosphate-buffered saline (PBS; Cellgro, cat. no. 21-031-CV)
4% (w/v) PFA in PBS, pH 7.4
Permeabilization buffer: 0.2% (v/v) Triton X-100 in PBS
Blocking buffer: 10% (v/v) FBS in PBS
Mouse anti-human PFN, clone Pf80/164 (Mabtech); 1:600 dilution for microscopy

Mouse anti-human GzmB, clone GB11 (Caltag Laboratories); 1:300 dilution for microscopy
Mouse anti-human GzmA, clone CB9 (BD Pharmingen); 1:300 dilution for microscopy
Mouse anti-granulysin (BD Pharmingen)
Incubation buffer: PBS/0.05% (v/v) Triton X-100
Fluorochrome-conjugated secondary antibody (Molecular Probe)
Vectashield mounting medium containing DAPI (Vector Laboratories)

18-mm circle coverslips
96-well plates
Centrifuge, adaptors for plates
Fluorescence microscope

1. One day before staining, prepare Poly-L-lysine–coated 18-mm circle coverslips in 12-well plates.
2. Wash CTL or NK cells in 10 ml PBS and resuspend in 0.5 ml PBS.
3. Add 50,000 cells to the coated coverslips or into a 96-well plate for flow cytometry analysis, centrifuge 3 min at 500× *g*, room temperature, and remove supernatants.
4. Fix the cells 20 min in PBS containing 2% PFA at room temperature.
5. Wash the cells three times, each time with 1 ml PBS and permeabilize for 5 min in 1 ml permeabilization buffer.
6. Wash twice, each time in 1 ml PBS and add 1 ml blocking buffer for 30 min.
7. Wash one time in 1 ml PBS.
8. Add the required dilution of primary antibody (see Materials list) for PFN, GzmB, GzmA, or GNLY to the cells and incubate 1 hr at room temperature in 0.2 ml incubation buffer.

   Use incubation buffer to achieve the appropriate antibody dilutions.
9. Wash the cells three times, each time with 1 ml incubation buffer and incubate 1 hr at room temperature with fluorochrome-conjugated secondary antibodies (diluted 1:500 in incubation buffer or according to the manufacturer's protocol) in 0.2 ml incubation buffer.
10. Wash cells three times, each time in 1 ml PBS and mount in a small drop (~10 to 20 μl) Vectashield mounting medium before fluorescence microscopy analysis (see Fig. 3.37.1A).

SUPPORT PROTOCOL 2

FLOW CYTOMETRY ASSAY FOR PERFORIN AND/OR GRANZYME EXPRESSION

As an alternative to microscopy, flow cytometry can be used to screen for PFN, granzyme, and GNLY expression.

Materials

Jurkat (ATCC), LAK cells, *or* YT-Indy cells from Basic Protocol 1 (step 10)
4% (w/v) PFA in PBS, pH 7.4
FACS buffer (see recipe)
Phosphate-buffered saline (PBS; Cellgro, cat. no. 21-031-CV)
Saponin (Sigma)
Mouse anti-human PFN, clone δG9 (BD Pharmingen) for flow cytometry

Mouse anti-granulysin (BD Pharmingen) for flow cytometry
Mouse anti-GzmA (clone CB9, BD Pharmingen)
Mouse anti-GzmB (clone GB11, Catlag)
Secondary antibody

Microcentrifuge tubes *or* 96-well V-bottom plates
Centrifuge
Flow cytometer

1. Dispense 1–5 × 10^5 cells in microcentrifuge tubes or in 96-well V-bottom plates. Centrifuge cells 3 min at 400 × *g*, room temperature, to pellet cells.
2. Resuspend the cells in 50 µl of PBS containing 2% paraformaldehyde. Incubate 20 min at room temperature.
3. Wash the cells with 1 ml FACS buffer (microcentrifuge tubes) or twice with 200 µl FACS buffer (96-well plate), centrifuging the cells 5 min at 400 × *g*, room temperature, each time, and aspirating the supernatants.
4. Resuspend the cells in 50 µl PBS containing 0.1% (w/v) saponin to permeabilize the cells for intracellular staining.
5. Add 1 µl anti-GzmA, 5 µl anti-GzmB, 2.5 µl anti-perforin, or 2.5 µl anti-GNLY antibody. Incubate 30 min at room temperature in the dark.
6. If a secondary antibody is required, wash the cells as in step 3, and resuspend in 50 µl PBS containing 0.1% (w/v) saponin and the appropriate dilution of fluorochrome-conjugated secondary antibody.
7. Wash the cells as in step 3, and resuspend the cells in 100 µl FACS buffer.

   The cells are now ready for flow cytometry analysis (Fig. 3.37.1B).
8. Using a nonstained control sample, determine the optimal Forward Scatter and Side Scatter settings and adjust the fluorophore channels to baseline levels. Using stained samples, measure the fluorescence intensity of effector molecule-stained cells compared to the appropriate isotype control-stained samples.

MEASURING PERFORIN ACTIVITY BY HEMOGLOBIN RELEASE ASSAY

SUPPORT PROTOCOL 3

Perforin induces membrane damage by calcium-dependent multimerization to form pores in target cell membranes. Hemoglobin release from sheep red blood cells is commonly used to detect perforin activity during purification.

Materials

Sheep red blood cells (Rockland Immunochemicals)
Hanks' balanced salt solution (HBSS), without calcium, magnesium, and phenol red, ice cold
HBSS + 4 mM $CaCl_2$, ice cold
FPLC fractions of perforin purification (Basic Protocol 2)
Saponin (Sigma)

96-well round-bottom microplate
96-well flat-bottom microplates
Microplate reader

1. Wash sheep red blood cells three times, each time with 50 ml cold HBSS and resuspend at 1% (v/v) in HBSS containing 4 mM $CaCl_2$.

2. Transfer 100 μl of red blood cell solution to a well of a 96-well round-bottom microplate.
3. Add 10 to 20 μl of each FPLC fraction to the well.
4. Incubate the plate 20 min at room temperature.
5. Centrifuge the plate 5 min at 400 × *g*, 4°C.
6. Transfer 50 μl of cell-free supernatant from each well to a 96-well flat-bottom microplate.
7. Detect the hemoglobin release into supernatant by reading absorbance at 412 nm (Fig. 3.37.3B).
8. Calculate the percent release relative to the maximal hemolysis determined by adding 0.01% (v/v) saponin to the red blood cells as (experimental hemolysis − spontaneous hemolysis)/(maximal hemolysis − spontaneous hemolysis) × 100.

SUPPORT PROTOCOL 4

MEASURING PERFORIN ACTIVITY BY PROPIDIUM IODIDE UPTAKE

Propidium iodide uptake is usually used to determine the sublytic level of PFN for a given cell type to establish the conditions for efficient delivery of granzymes for apoptosis assays.

Materials

Target cells
Buffer C (see recipe)
FPLC fractions from perforin purification (Basic Protocol 2)
Buffer P (see recipe)
An5 buffer
Propidium iodide (PI; Sigma)

37°C incubator
Flow cytometer

1. Wash 5 × 10^4 target cells of interest in 0.5 ml buffer C and resuspend in 30 μl of the same buffer.
2. Make dilutions of purified perforin in 30 μl of buffer P.

   The diluted form at this stage is at a concentration of 2×.
3. Add 30 μl of the diluted perforin to 30 μl of cells from step 1.

   Because different PFN dilutions/concentrations need to be tested, it is convenient to use a 96-well V-bottom microplate for this assay.
4. Incubate 15 min at 37°C.
5. Wash cells once with 100 μl An5 buffer.
6. Resuspend cells in 50 μl An5 buffer with 2 μg/ml propidium iodide.
7. Measure PFN-induced necrosis immediately by flow cytometry by measuring PI uptake (Fig. 3.37.6).

   A PFN concentration that causes ∼5% to 20% cell death is considered a sublytic dose that is ideal for granzyme delivery and induction of apoptosis (Keefe et al., 2005). It is also important to note that the sublytic dose of PFN varies from cell to cell and must be determined for each experiment.

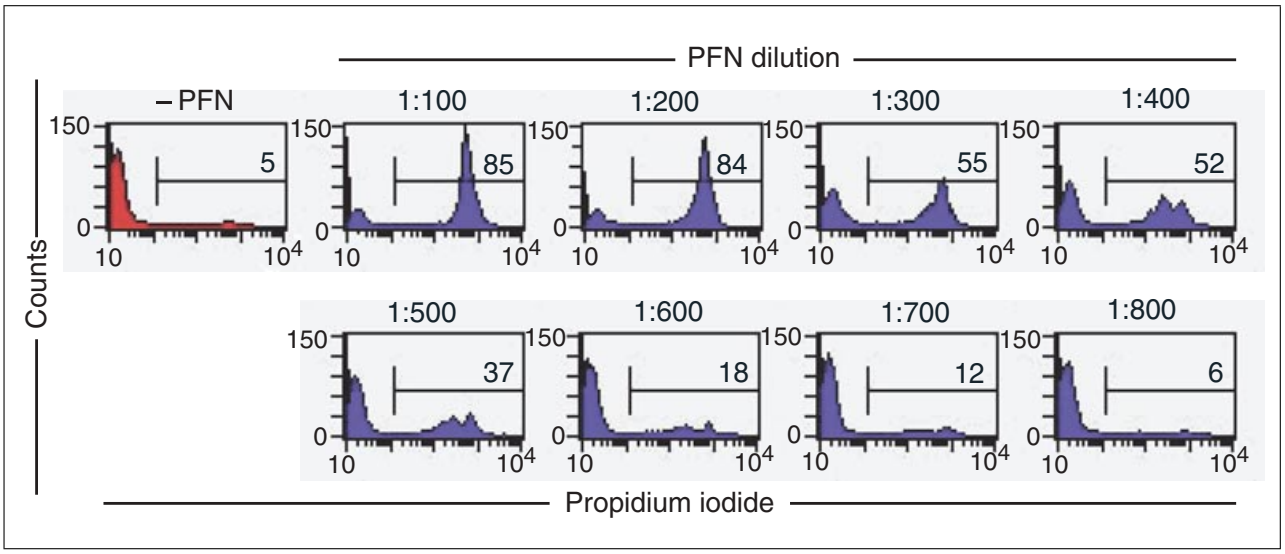

Figure 3.37.6 Measuring PFN activity by flow cytometry by propidium iodide uptake. HeLa cells were treated with different dilutions of purified native rat PFN for 15 min at 37°C before staining with propidium iodide (PI) and analysis by flow cytometry. Percentage of PI positive cells is indicated. In this experiment, the sublytic PFN concentration is between 1:600 and 1:700.

MEASURING GzmB ACTIVITY

SUPPORT PROTOCOL 5

The GzmB activity is measured by assessing its proteolytic activity. The measurement of peptide substrate (AAD) hydrolysis is commonly used during the purification of GzmB. GzmB-induced apoptosis can also be detected by various methods (see Support Protocols 9 and 10).

Materials

AAD assay buffer (see recipe)
FPLC fractions of GzmB purification (Alternate Protocol 2)

96-well flat-bottom plates
Microplate reader

1. Make fresh AAD assay buffer. Make sure to mix thoroughly.
2. Combine 5 µl of FPLC fractions or control buffer (for blank control) with 200 µl of AAD assay buffer in a 96-well flat-bottom plate.
3. Incubate the plate for 5 min at 37°C.
4. Measure $OD_{405\ nm}$ using a microplate reader.

Fractions with OD >0.1 are considered positive for GzmB activity (see Fig. 3.37.4D).

MEASURING GzmA ACTIVITY

SUPPORT PROTOCOL 6

GzmA activity is measured by assessing its proteolytic activity. The measurement of peptide substrate (BLT) hydrolysis is commonly used during the purification of GzmA. GzmA-induced apoptosis can also be detected by various methods (see Support Protocols 9 and 10).

Materials

BLT assay buffer (see recipe)
FPLC fractions for GzmA purification (Alternate Protocol 2)

96-well flat-bottom plate
37°C incubator
Microplate reader

1. Freshly add BLT and DTNB to make BLT assay buffer. Make sure to mix thoroughly.
2. Combine 5 µl of FPLC fractions or control buffer with 200 µl of BLT assay buffer in a 96-well flat bottom plate.
3. Incubate the plate for 5 min at 37°C.
4. Measure $OD_{405\ nm}$ using a microplate reader.

   Fractions with $OD_{405\ nm}$ >0.2 are considered positive for GzmA activity. These fractions may be pooled and concentrated using the Centricon MWCO 10 kDA concentrating units (Fig. 3.37.5C).

SUPPORT PROTOCOL 7

MEASURING GNLY-MEDIATED ANTIBACTERIAL ACTIVITY BY COLONY-FORMING UNIT ASSAY

The effect of GNLY on bacteria can be measured by quantifying bacterial numbers by colony formation on agar plates.

Materials

Bacteria: *E. coli, Listeria, Salmonella*, or whatever lab-strain is available
LB medium and LB agar plates (*APPENDIX 2A*)
Colony forming and turbidimetry unit assay buffer (see recipe)
Fractions for GNLY purification (Alternate Protocol 2)
37°C incubator

NOTE: NaCl concentrations higher than 50 mM interfere with GNLY activity.

1. Grow bacteria to mid-log phase ($OD_{600\ nm} = 0.5$ equaling $\sim 10^8$/ml viable bacteria) in LB medium in a bacterial culture shaker at 37°C.
2. Wash bacteria three times, each time in 1 ml colony forming and turbidimetry unit assay buffer and dilute to 5×10^5 bacteria/ml.
3. Prepare serial dilutions (between 2 µM and 0.06 µM) of GNLY in 25 µl of colony forming and turbidimetry unit assay buffer. Use buffer only as the negative control.

   Serial dilutions of antibiotics or of human beta-defensin 1 (Innavogen) can serve as positive control.

4. Add 25 µl of bacterial dilutions (equaling $\sim 1.25 \times 10^4$ viable bacteria) to each reaction, mix gently, and incubate 1 hr at 37°C. Include a no-bacteria control (assay buffer only).
5. Add 250 µl of LB medium to each reaction and prepare 10-fold serial dilutions from each reaction.
6. Plate 50 µl of the dilutions on LB agar plates and incubate at 37°C overnight prior to colony counting.
7. Calculate the percent lysis using the following equation: % specific lysis = $CFU_{GNLY\text{-}treated}/CFU_{buffer\text{-}treated} \times 100$ (Fig. 3.37.4D).

MEASURING GNLY-MEDIATED ANTIBACTERIAL ACTIVITY BY TURBIDIMETRY

The effect of GNLY on bacteria can also be measured by quantifying bacterial numbers by the change in turbidity of liquid cultures.

Materials

Bacteria: *E. coli, Listeria, Salmonella*, any non-virulent bacterial lab-strain
LB medium (*APPENDIX 2A*)
Colony forming and turbidimetry unit assay buffer (see recipe)
Fractions for GNLY purification (Alternate Protocol 2)

96-well transparent flat-bottomed plates
37°C incubator
Microplate reader (with ability to monitor kinetics at 37°C and discontinuous shaking; Spectra Max 340PC, Molecular Devices)

1. Grow bacteria to mid-log phase ($OD_{600} = 0.5$ equaling $\sim 10^8$/ml viable bacteria) in LB medium
2. Wash bacteria three times in 1 ml colony forming and turbidimetry unit assay buffer and dilute to 10^5 bacteria/ml
3. Prepare serial dilutions of GNLY in 25 µl of colony forming and turbidimetry unit assay buffer in a flat-bottomed, transparent 96-well plate. Use buffer only as a negative control.

   Serial dilutions of antibiotics or human beta-defensin 1 (Innavogen) can serve as positive control.

4. Add 25 µl of bacterial dilutions (equaling $\sim 2.5 \times 10^3$ viable bacteria) to each well, mix gently, and incubate 1 hr at 37°C.
5. Add 150 µl of LB medium to each well. Monitor $OD_{600\ nm}$ in the plate reader while shaking at intervals for 12 hr or until the steady-state of the bacterial growth curve is reached.

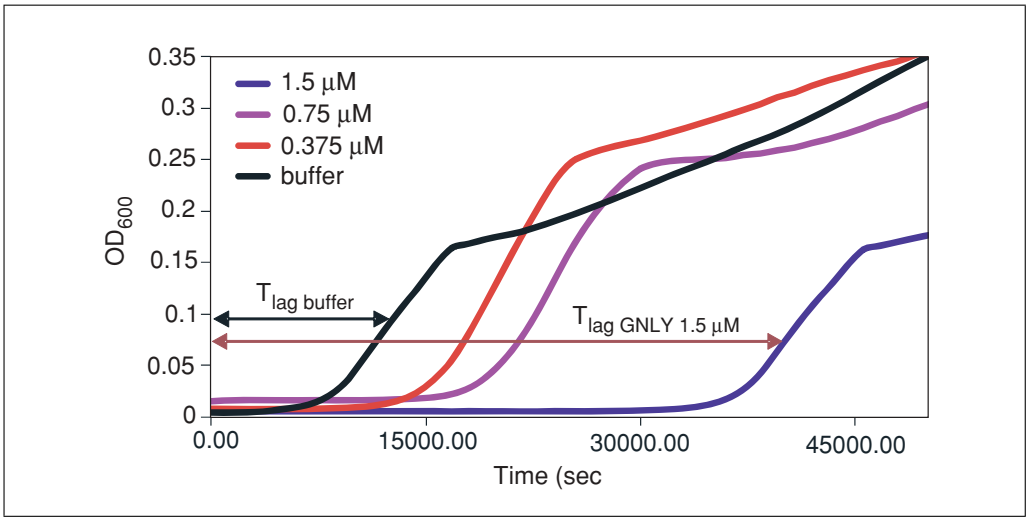

Figure 3.37.7 Measuring the antibacterial activity mediated by GNLY using turbidimetry. Typical bacterial growth curves from buffer- as well as GNLY-treated *E. coli* are shown. A possible read-out from these curves is to measure the time until a certain threshold OD is reached (T_{Lag}) and compare control versus test curves. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0337*.

6. Analyze the bacterial growth curves.

   The length of the lag-phase (T_{Lag}) of the bacterial growth curves (Fig. 3.37.7) reflects the initial bacteria count and can therefore be used to quantify the antibacterial activity of GNLY.

SUPPORT PROTOCOL 9

GRANZYME-MEDIATED CHROMIUM RELEASE APOPTOSIS ASSAY

To measure the activity of granzymes in cells, purified granzymes and PFN are added and cell death can then be monitored by a number of assays. Here, we provide the most sensitive measure of total cell death (apoptosis + necrosis), which is a chromium release assay.

Materials

Target cells
K10 medium: RPMI 1640 + 10% (v/v) FBS
^{51}Cr-labeled Na_2CrO_4 (NEN BioLabs), 5 μCi/μl
Hanks' balanced salt solution (HBSS)
Buffer C (see recipe)
Purified granzymes and perforin
Buffer P (see recipe)

96-well V-bottom plate
37°C incubator
TopCount scintillation counter and LumaPlate 96 (PerkinElmer)

1. Harvest target cells and resuspend the cells in 1 ml K10 medium and label with 100 μCi of ^{51}Cr for 1 hour at 37°C.
2. Wash the labeled target cells three times, each time in 10 ml HBSS.
3. Resuspend cells in buffer C at the same density used to determine the sublytic perforin concentration (see Support Protocol 4).

   Generally, 10^4–10^5 cells per well in 30 μl are dispensed in triplicate in a 96-well V-bottom plate.

4. Dilute perforin in 30 μl buffer P to 2× the sublytic dose previously determined.
5. Dilute the purified granzyme to 2× the final concentration in the same tube of buffer P and add 30 μl to cells.

   Include perforin only and granzyme only controls. Additionally, include buffer only controls (spontaneous release) and cells in 1% NP-40 (maximal release).

6. Incubate the plate for 1 to 4 hr at 37°C.
7. Pellet cells and cell debris by centrifuging the plate for 5 min at 400 × *g*, room temperature.
8. Remove 30 μl of supernatant, taking care not to disturb the cell pellet, and add to a LumaPlate 96.
9. Allow the supernatant to dry several hours or overnight before measuring ^{51}Cr release into the supernatant using a TopCount counter.

   Calculate the percent release relative to the maximal release determined by adding NP40 to the target cells as (experimental release − spontaneous release)/(maximal release − spontaneous release) × 100.

GRANZYME-MEDIATED ANNEXIN-V/PROPIDIUM IODIDE (PI) ASSAY

To measure the activity of granzymes in cells, purified granzymes and PFN are added and cell death can then be monitored by a number of assays. Here we provide a flow cytometry–based assay that distinguishes apoptotic cells (generally Annexin V^+) from necrotic cells (generally Annexin V^-).

Materials

Target cells
Buffer C (see recipe)
Buffer P (see recipe)
Purified granzymes and perforin
An5 buffer (see recipe)
Annexin-V-APC (Caltag)
Propidium iodide (PI)

96-well V-bottom plates
37°C incubator
Centrifuge with plate-adaptor

1. Wash cells once with 5 ml buffer C.
2. Resuspend cells and dispense 10^5 cells/well of 96-well V-bottom plates in 30 µl buffer C.
3. Dilute perforin in 30 µl buffer P to 2× the sublytic dose previously determined.
4. Dilute the purified granzyme to 2× the final concentration in the same tube of buffer P and add 30 to cells.

   Make sure to include PFN only, granzyme only, and buffer-only treated cells.

5. Incubate the treated cells for 30 to 60 min at 37°C.
6. Add 100 µl An5 buffer to each well.
7. Centrifuge the plate 3 min at 500 × *g*, room temperature, in a centrifuge containing a plate-adaptor.
8. Resuspend the cells in 100 µl An5 buffer containing APC-conjugated Annexin V (1:33 dilution) and incubate 10 min at room temperature in the dark.
9. Wash the cells twice, each time in 100 µl An5 buffer.
10. Resuspend the pellet in An5 buffer containing 2 µg/ml propidium iodide and analyze cells by flow cytometry (Fig. 3.37.8).

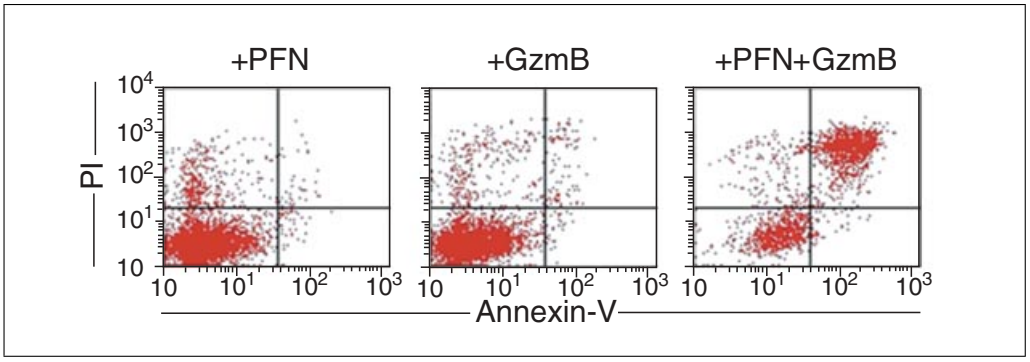

Figure 3.37.8 Analysis of PFN and GzmB-mediated apoptosis by Annexin-V/PI assay. HeLa cells were treated for 1 hr at 37°C with sublytic rat PFN and purified human GzmB before staining with Annexin-V and propidium iodide. Cells were analyzed by flow cytometry. For the color version of this figure go to *http://www.currentprotocols.com/protocol/cb0337*.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

AAD assay buffer

H_2O containing:
50 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
0.2 mM Boc-Ala-Ala-Asp-Thiobenzyl ester (AAD; MP Biomedicals), 20 mM stock solution in DMSO (Sigma)
0.22 mM of 5,5′-dithio-bis(2-nitrobenzoic acid) (DTNB; Sigma), 0.55 M stock solution in DMSO
Prepare fresh

An5 buffer

H_2O containing:
10 mM HEPES, pH 7.5
140 mM NaCl
2.5 mM $CaCl_2$
Store up to 6 months at room temperature

BLT assay buffer

H_2O containing:
50 mM Tris·Cl, pH 7.5
0.2 mM Nα-benzylozycarbonyl-L-lysine thiobenzyl ester (BLT; Sigma), 0.5 M stock solution in DMSO
0.22 mM 5,5′-dithio-bis(2-nitrobenzoic acid) (DTNB; Sigma), 0.55 M stock solution in DMSO
Prepare fresh

Buffer C

Hanks' balanced salt solution (HBSS)
10 mM HEPES, pH 7.5
4 mM $CaCl_2$
0.4% (w/v) bovine serum albumin (BSA)
Store up to 1 month at 4°C

Buffer P

Hanks' balanced salt solution (HBSS)
10 mM HEPES, pH 7.5
Store up to 1 month at 4°C

Colony forming and turbidimetry unit assay buffer

H_2O containing:
20 mM HEPES, pH 7.4
10 mM NaCl
Store up to 1 month at 4°C

Continuous 40% adjusted Percoll gradient

Relaxation buffer (see recipe) containing:
40% (w/v) Percoll (Sigma)
250 mM sterile sucrose
10 mM HEPES pH 7.2
7 mM HCl
Prepare fresh

Elution buffer B1

Equilibration buffer A1 (see recipe) containing 1 M imidazole, pH 7.5. Store up to 1 month at 4°C.

Elution buffer B2

H_2O containing:
20 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)
1 mM EGTA
Store up to 1 month at 4°C

Elution buffer B3

H_2O containing:
20 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)
0.1 mM EGTA
2 M NaCl
Store up to 1 month at 4°C

Elution buffer B4

H_2O containing:
20 mM bis-Tris, pH 5.8
1 M NaCl
Store up to 1 month at 4°C

Equilibration buffer A1

Distilled H_2O containing:
1 M NaCl
20 mM HEPES, pH 7.2
10% (w/v) Betaine (Sigma)
Store up to 1 month at 4°C

Equilibration buffer A2

H_2O containing:
20 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)
1 mM EGTA
2 M NaCl
Store up to 1 month at 4°C

Equilibration buffer A3

H_2O containing:
20 mM Tris·Cl, pH 7.2 (*APPENDIX 2A*)
0.1 mM EGTA
Store up to 1 month at 4°C

Equilibration buffer A4

H_2O containing:
20 mM bis-Tris, pH 5.8
50 mM NaCl
Store up to 1 month at 4°C

FACS buffer

Phosphate-buffered saline (PBS; Cellgro, cat. no. 21-031-CV)
2% (v/v) fetal bovine serum (FBS; heat-inactivated)
Store up to 6 months at 4°C

HE buffer

H_2O containing:
150 mM NaCl
10 mM HEPES, pH 7.5
2 mM EDTA, pH 8.0 (*APPENDIX 2A*)
Store up to 1 month at 4°C

HHH buffer

Hanks' balanced salt solution (HBSS) containing:
10 mM HEPES, pH 7.2
100 U/ml heparin (Sigma)
Prepare fresh

K10 medium

RPMI-1640 medium supplemented with:
10% (v/v) fetal bovine serum (FBS; heat-inactivated)
100 U/ml penicillin (from a 20× stock)
100 μg/ml streptomycin (from a 20× stock)
6 mM HEPES
1.6 mM L-glutamine
50 μM 2-mercaptoethanol
Store up to 1 to 2 months at 4°C

Relaxation buffer

H_2O containing:
10 mM KCl
3.5 mM $MgCl_2$
10 mM PIPES pH 6.8
1.25 mM EGTA pH 8.0
1 mM ATP (Sigma)

Relaxation buffer can be prepared in advance without ATP. This buffer can be stored 1 to 2 days at 4°C prior to addition of the ATP. Once ATP is added the buffer must be discarded after each use.

Solubilization buffer

H_2O containing:
1 M NaCl
20 mM sodium acetate, pH 4.5
2 mM EDTA, pH 8.0 (*APPENDIX 2A*)
Store up to 6 months at 4°C

COMMENTARY

Background Information

Cytotoxic T lymphocytes and NK cells deliver their effector molecules via specialized secretory lysosomes. These lysosomes, or cytotoxic granules, are dual-function organelles, containing both lysosomal proteases, which function at acidic pH, and secretory products such as perforin, which function at neutral pH when they are released from the killer cells to induce target cell death. Indeed, when cytotoxic T lymphocytes and natural killer cells form an immune synapse with a specifically recognized target cell destined for elimination, cytotoxic granules move to the immune synapse where the cytotoxic granule membrane fuses with the killer cell membrane, releasing the granule contents into the synaptic cleft (Voskoboinik and Trapani, 2006; Chowdhury and Lieberman, 2008). These cytotoxic granules contain perforin (PFN), needed to deliver the granzymes into the target cell (Keefe et al., 2005), and a family of highly homologous serine proteases named granzymes (Gzms), whose major job is to

induce programmed cell death to eliminate virus-infected and tumor cells (Stinchcombe et al., 2001). By activating apoptosis instead of necrosis, inflammation is minimized to focus on the intended target and minimize effects on bystander cells. Cytotoxic granules of human NK cells and cytotoxic T cells also contain granulysin (GNLY), a protein with antimicrobial activity against a broad spectrum of microbial pathogens. Isolation of cytotoxic granules and further purification of native PFN, granzymes, and/or GNLY allows researchers to study how the granzymes initiate programmed target cell death pathways, how PFN induces internalization of granzymes into the target cell cytosol, and how GNLY induces the death of microbial pathogens.

The protocols described in this unit are based on isolation of cytotoxic granules from CTL and NK cells by nitrogen cavitation as originally developed by Borregaard (Borregaard et al., 1983). CTL and NK cells are resuspended in relaxation buffer designed to mimic the conditions found in the cytosol of neutrophils, facilitating the separation of cytoplasmic organelles from nuclei. Cells are lysed by nitrogen cavitation and cytotoxic granules are purified over a Percoll density gradient. Although purified granules can be used for some studies, further FPLC purification of effector molecules is often necessary for other purposes. Active recombinant mouse GzmB and human GzmA can also be expressed and purified (Martinvalet et al., 2008b). A method was also developed to express and purify active recombinant GNLY (Ernst et al., 2000). However, active recombinant PFN is difficult to purify and even purified native PFN is tricky to work with (as discussed above). For that reason, many researchers substitute a bacterial pore-forming protein such as streptolysin O for PFN as the delivery agent to introduce granzymes into target cells. However, we feel that using native PFN is a more physiologically relevant system. Thus, isolation of cytotoxic granules is a reliable source of active native PFN, granzymes, as well as GNLY. For perforin isolation, IMAC (immobilized metal affinity chromatography) procedure is preferred. The advantage of cobalt IMAC for PFN purification is that there are few other co-purifying proteins, and this method allows better separation between granzymes and PFN (Winkler et al., 1996). Both GzmB and GNLY are purified by a 3-step method adapted from Shi et al. (2000), taking advantage of hydrophobic interactions of PFN with phenyl Sepharose to separate PFN from the other granule components, followed by two consecutive cation-exchange columns (heparin and SP Sepharose or MonoS) to separate the more basic granule components.

Critical Parameters

The two-step cytotoxic granule isolation protocol described here is particularly suitable for use of granules and/or purified effector proteins in studies that aim to define the different mechanisms of target cell death by the CTL/NK cells granule pathway. Cytotoxic granules can also be isolated using a protocol described by Millard et al. (1984). This method includes heparin in the cell lysis buffer to optimize granule yield, and DNase I to digest DNA released from nuclei damaged during the cell lysis step. However, the use of these granules for further studies of granzyme-mediated cell death is not recommended because DNase I added during purification can contribute to nonspecific DNA fragmentation. By comparison, cytotoxic granule extracts by the Borregaard method are free of non-specific nuclease activity (Davis et al., 2003). Before any cytotoxic granule purification, LAK, CTL, or NK cells activation state should be tested by a PFN and/or granzyme expression assay.

One of the most important variables that affect the success of granule isolation is the cell lysis by nitrogen cavitation. Indeed, as mentioned before, the yield of granules is markedly influenced by the cavitation process and excessive cavitation ruptures the cytotoxic granules.

The other important step is the continuous Percoll density gradient. The number of cell equivalents loaded into a preformed 20-ml Percoll continuous gradient should not exceed 10^{10} in 5 ml. When more cells are used, the users are encouraged to prepare additional tubes of Percoll gradient. Moreover, users are strongly encouraged to test harvested granule fractions for activity. Usually granules are harvested by withdrawing the bottom 5 ml from each tube. The highest granule titer is in the first 4 ml, but it is sometimes necessary to harvest 7 ml in order to fully recover granules. Isolated cytotoxic granules must be properly stored in solubilization buffer at -80°C.

At present, rat RNK-16 cells are the best source of high-quality and high-yield native PFN. The use of YT-Indy NK cells also offers a reliable source of human PFN that avoids in vivo propagation, but with a much lower yield. Because NK cell lines expand slowly, it can be difficult to reach the number of cells necessary for purification of high-yield protein. One of the critical steps before

chromatography purification of PFN from cytotoxic granules is granule solubilization. At least two freeze/thaw cycles are necessary to solubilize granules fully. Best results are obtained with a freeze cycle at −80°C overnight, followed by thawing for 2 hr on ice, and a freeze/thaw cycle with liquid nitrogen. After buffer exchange with a desalting column it is also crucial to note that PFN is no longer in a Ca^{2+}-chelated buffer and can be inactivated by traces of Ca^{2+}. Hence, the FPLC step must be performed as quickly as possible. Moreover, EGTA must be added into each fraction collector tube before the FPLC run to prevent PFN inactivation by traces of Ca^{2+}. Concentrated purified PFN must be stored at −80°C. PFN must be handled on dry ice, and PFN remaining after an assay can be saved at −80°C, pooled, and activity retitered before using.

The best results for isolating GzmB and GNLY using YT-Indy cells as the source of granules are usually obtained if the protocol is completed within 1 day. Furthermore, to optimize the yield, it is critical that the NaCl concentration of the loading samples for the cation exchange columns not exceed 100 mM; the granzymes and GNLY will otherwise not bind to the heparin or S-column. To improve activity in subsequent experiments using purified GzmB and GNLY, it is necessary to concentrate the proteins to >20 μM. High NaCl concentration (almost 1 M) in the eluate fractions will interfere with protein activity. Concentrated, purified granzymes must be stored at −80°C. It is also important to note that measuring purified GzmA activity with BLT is highly sensitive but might not be as specific as substrate cleavage. We highly recommend to test purified GzmA for cleavage of its substrate SET (Beresford et al., 2001) either using recombinant SET (Martinvalet et al., 2008a) or whole-cell lysate (Bovenschen et al., 2009).

Anticipated Results

Cytotoxic granule preparation depends on the amount of starting material. Typically, preparation of cytotoxic granules from RNK-16 harvested from ten F344 rats yields 50 to 100 μg of purified native PFN. We also usually purify about 500 μg GzmB and about 300 μg GNLY from 3×10^9 YT Indy cells and about 100 to 150 μg GzmA from 7.5×10^9 LAK cells. Although these protocols are well established and characterized, users should take care to assess their purified PFN, granzymes, or GNLY for contaminants by SDS-PAGE and silver or Coomassie staining and/or by probing with antibodies specific for PFN, GzmB, GzmA, or GNLY.

Time Considerations

The protocols for isolation of cytotoxic granules from human LAK cells or YT-Indy cells (Basic Protocol 1) or from rat RNK-16 cells (Alternate Protocol 1) involve several steps and require about 1 day. The in vitro growth of LAK/YT-Indy or in vivo amplification of RNK-16 cells require about 3 weeks to reach the desired number of cells. Extra time should also be allotted to characterize PFN and Gzms expression in the cells used for granule extraction, either by microscopy (6 hr; Support Protocol 1) or by flow cytometry (2 hr; Support Protocol 2).

Purification of the effector proteins (PFN, GzmA, GzmB, GNLY) by FPLC requires an additional day to complete (Basic Protocol 2 and Alternate Protocol 2). Although analysis of the activity of purified proteins does not require more than a few hours, this analysis must be performed before pooling positive fractions and adds extra time to the overall procedure. During purification of effector proteins, measuring PFN activity in isolated fractions by hemoglobin release assay (Support Protocol 3) requires ∼1 hr. Then, measurement of PFN activity in concentrated, pooled positive fractions and determination of the sublytic concentration can be easily performed by propidium iodide uptake (Support Protocol 4) in ∼30 min. Similarly, measuring GzmB (Support Protocol 5) or GzmA (Support Protocol 6) activity by AAD or BLT assays, respectively, can be performed in 30 min. Finally, measuring GNLY activity by colony-forming assay (Support Protocol 7) or turbidimetry (Support Protocol 8) requires ∼16 hr (which includes an overnight incubation).

Purified effector proteins (PFN/GzmA/GzmB) can then be used to induce apoptosis of target cells. The chromium release assay described in Support Protocol 9 necessitates ∼6 hr for completion, whereas measuring Gzm-induced cell death by Annexin-V/PI staining (Support Protocol 10) can be performed in 2 hr.

Isolation of Aggresomes and Other Large Aggregates

Anatoli B. Meriin,[1] Yan Wang,[1] and Michael Y. Sherman[1]

[1]Department of Biochemistry, Boston University School of Medicine, Boston, Massachusetts

ABSTRACT

Upon permanent stresses and in various diseases, small protein aggregates may accumulate in cells and cause toxicity. A recently discovered protective system transports these aggregates to the centrosome location via microtubules, to form a large agglomerate of aggregates called the aggresome. Here, we describe a newly developed method for isolating aggresomes. This principle can also be used for purification of other large structures and even organelles. *Curr. Protoc. Cell Biol.* 48:3.38.1-3.38.9. © 2010 by John Wiley & Sons, Inc.

INTRODUCTION

Molecular chaperones and the ubiquitin-proteasome system (UPS; *UNIT 15.9*) play an important role in handling soluble abnormal polypeptides that arise as a result of misfolding, damage, or mutations. However, under certain conditions these systems fail to repair or destroy abnormal species, leading to formation of small cytoplasmic aggregates. Mechanisms of intracellular protein aggregation attract growing attention because of their relevance to a number of neuropathological conditions. In many major neurodegenerative diseases, such as amyotrophic lateral sclerosis, Alzheimer's disease, Parkinson's disease, and Huntington's disease, the pathology and the eventual death of specific neuronal populations occur due to accumulation of certain abnormal polypeptides, which can form insoluble aggregates (for review see Sherman and Goldberg, 2001).

Recently, it was discovered that special machinery has evolved that transports small protein aggregates in a microtubules-dependent manner to the centrosome, forming an organelle called the aggresome (Chung et al., 2001; Corboy et al., 2005). The aggresome serves as a storage compartment for protein aggregates, and it could be actively involved in their refolding and degradation. In fact, major chaperones, like Hsp70 or Hsp27, and components of the UPS are recruited to the aggresome (Garcia-Mata et al., 1999; McNaught et al., 2002; Ahn and Jeon, 2006; Kovacs et al., 2006). Furthermore, recently it was demonstrated that autophagic clearance of protein aggregates also occurs in association with the aggresome (Garcia-Mata et al., 2002; Pankiv et al., 2007; Olzmann and Chin, 2008).

There is a notion in the field that aggresome formation represents a protective cellular response to a buildup of aggregating abnormal polypeptides under the conditions when chaperones and UPS machineries fail to handle abnormal species (Tanaka et al., 2004; Olzmann and Chin, 2008). Indeed, it was reported that there is a close correlation between aggresome formation and cell survival (Taylor et al., 2003). Furthermore, toxicity of abnormal proteins is strongly enhanced by inhibition of the microtubule-dependent transport, which is required for aggresome formation. In line with this concept, inhibition of aggresome formation was recently suggested as an approach to enhance the cytotoxicity of proteasome inhibitors to facilitate their anti-cancer activity (Nawrocki et al., 2006; Piazza, et al., 2007).

Current Protocols in Cell Biology 3.38.1-3.38.9, September 2010
Published online September 2010 in Wiley Online Library (wileyonlinelibrary.com).
DOI: 10.1002/0471143030.cb0338s48

Beside aggresome formation, other protein aggregation pathways also appear to exist in mammalian cells. For example, mutant glial fibrillary acidic protein (GFAP) expressed in cells seems to be unable to form aggresomes, and usually forms small multiple aggregates all around the cytoplasm (Quinlan et al., 2007). In another example, we have recently demonstrated that while synphilin 1, a protein associated with Parkinson's disease, forms aggresomes, its mutant form lacking an ankyrin repeat domain can only form multiple cytoplasmic aggregates (Zaarur et al., 2008). To understand the aggresome response it is critical to use clear mechanistic criteria of aggresomes. The characteristic features of aggresomes that distinguish them from other types of protein aggregates include the microtubules-dependence of aggresome formation and its co-localization with the centrosome.

A number of factors have been implicated in aggresome formation. For example, a microtubule-associated histone deacetylase, HDAC6, was shown to interact with cytoplasmic aggregates of ubiquitinated proteins via its ubiquitin-binding BUZ domain, and facilitate their association with the dynein motor protein that drives this cargo to the aggresome (Kawaguchi et al., 2003). Other proteins also play a role in aggresome formation, e.g., PLIC, ataxin 3 (Burnett and Pittman, 2005; Heir et al., 2006), p62/sequestosome (Donaldson et al., 2003; Seibenhener et al., 2004; Lim et al., 2005), and Parkin (Lim et al., 2006). Nevertheless, our current knowledge about the mechanisms of aggresome formation is very limited. Among the major questions in the field are: (1) how the aggresome machinery recognizes protein aggregates and distinguishes them from monomeric abnormal proteins; (2) how these aggregates are recruited to microtubules; (3) how small aggregates in the aggresome are kept together; and (4) how aggresome formation suppresses the toxicity of protein aggregates. One of the approaches to address these questions would be to identify factors associated with the aggresome-forming abnormal polypeptide.

We have developed a novel method for isolation of aggresomes and other types of aggregates, utilizing a recently established yeast model of aggresome formation (Wang et al., 2007). In this model, we used as a substrate a fragment of huntingtin, a pathological protein that causes Huntington's disease. Upon expansion of its polyglutamine (polyQ) domain, huntingtin becomes toxic and aggregation-prone. An important mechanistic insight into the aggresome machinery was the finding that aggresome formation by the huntingtin fragment requires a distinct proline-rich region of this protein, which serves as a special aggresome-targeting signal (Wang et al., 2009). Accordingly, the polyQ polypeptide without the proline-rich region (103Q) formed multiple toxic aggregates, while the polyQ polypeptide with this domain (103QP) formed typical nontoxic aggresomes. This model allows separately isolating aggresomes and multiple aggregates and analyzing differences in their composition.

BASIC PROTOCOL

ISOLATION OF AGGRESOMES FROM YEAST

Yeast are grown and induced to express the GFP-containing plasmid. The cells are lysed and fractionated. Fractions expressing GFP are collected.

Materials

Wild-type yeast strain W303 (*MATa ade2-1 trp1-1 leu2-3,112 his3-11,15 ura3-52 can1-100 ssd1-d*)

pYES2 vector (used as a negative control) *or* pYES2-based plasmids for expression of 103QP or 103Q constructs under control of the *Gal*1 promoter (Meriin et al., 2001); 103QP encodes the full exon 1 of mutant (103 glutamines extension) htt tagged with FLAG at the N-terminus and with EGFP at the C-terminus; 103Q is the same construct missing the proline-rich domain of the exon 1

Selective medium with 2% (w/v) glucose (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Selective medium with 2% (w/v) galactose (see recipe)
Lysis buffer (see recipe)
Glass beads (Sigma, cat. no. G8772)
Mouse anti-FLAG monoclonal antibody (Sigma)
AffiniPure rabbit anti–mouse and goat anti–rabbit IgGs (H+L; Jackson ImmunoResearch Laboratories)
50% (w/v) sucrose in lysis buffer

30°C incubator
Bullet blender (NextAdvance)
50-ml Sephacryl S-400 HR 2.5 (dia.) × 10–cm gel filtration column
Fluorescent microscope
15-ml test tubes

Grow, induce, and collect yeast

1. Grow 250 ml of the yeast W303 cells, transfected with the appropriate plasmid, on a shaker (250 rpm) overnight at 30°C on the selective minimal medium with 2% glucose.
2. In the morning, wash the cells as follows:
   a. Collect the cells by centrifuging 10 min at 3000 × *g*, room temperature.
   b. Bring the cells into suspension with 50 ml PBS (without calcium and magnesium).
   c. Collect the cells again.
   d. Repeat the procedure once more.
3. Transfer the collected cells into 2 liters of selective medium with 2% galactose and grow 6 hr at 30°C to logarithmic phase. Collect the cells by centrifuging (see above).

   At this point, the cell pellet can be frozen.

Lyse the cells

4. To 1 g of wet cells, add 1 ml of the lysis buffer.

   This step and ALL of the following processes are conducted at 4°C.
5. Disrupt with glass beads using the Bullet blender according to the manufacturer's instruction.
6. Collect the cell lysates into an appropriate centrifugation tube and centrifuge 2.5 min at 1000 × *g*, to remove the debris.
7. Collect the supernatant, measure the total protein concentration in the clarified lysate, and adjust with the lysis buffer to equalize protein concentrations in all samples.

Fractionate the sample

8. Load the sample onto a the 2.5 (dia.) × 10–cm gel filtration column (50-ml Sephacryl S-400 HR) with a cut-off range of ~8 MDa.
9. Collect 1.7-ml fractions at 0.85 ml/min flow rate.
10. Analyze the fractions using a fluorescent microscope for the presence and abundance of the GFP-labeled aggregates.
11. Combine four fractions with the highest content of the aggresomes.

    As a control, use the corresponding fractions from the lysates of cells with vector only.

Treat the fractions with the antibody

12. Transfer the pooled fractions into a 15-ml test tube. Add the primary antibody (mouse anti-FLAG IgG) to the pooled fractions to achieve a final concentration of 70 μg/ml and incubate the solution for 1.5 hr with rotation.

    Of note, if aggresomes of a distinct protein are isolated, corresponding primary antibodies should be used for decoration of aggregates.

13. Add the secondary antibody (rabbit anti–mouse IgG) to a final concentration of 140 μg/ml and incubate the solution for 1 hr.

14. Add the tertiary antibody (goat anti–rabbit IgG) at 300 μg/ml and incubate the solution for 1.5 hr.

Isolate the aggregates

15. Overlay the samples on the 2 ml of the 50% sucrose dissolved in the same lysis buffer in 15-ml test tubes.

16. Centrifuge 2.5 min at 600 × *g*, 4°C.

17. Aspirate the supernatant and store the purified aggregate pellet at −20°C.

    We have never studied the stability of the aggregates. Obviously, it is determined by the stability of the most unstable protein(s) in the aggregates. If there are some doubts, the aggregates can be kept at −80°C. On the other hand, if the aggregates are to be assayed for enzymatic activities, freezing should be avoided altogether and isolated samples should be assayed instantly.

    The most obvious reason for isolation of aggregates is to determine their protein composition. It can be examined by one- or two-dimensional protein gel and/or by mass-spectrometry (Wang et al., 2007; Wang et al., 2009). Additionally, enzymatic activities of the particular components of the aggregates may be assayed in vitro. The aggregates are not homogeneous in regard of both their size and composition; such heterogeneity, as we explained in the Background Information, necessitated the development of the new approach to aggregates isolation.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Lysis buffer

50 mM HEPES, pH 7.5
150 mM NaCl
1% Triton X-100
1 mM PMSF
1 mM benzamidine
5 μg/ml of each: leupeptin, pepstatin A and aprotinin
Prepare fresh

Selection medium

For 1 liter of medium combine the following:
1.7 g yeast nitrogen base (w/o amino acids and ammonium sulfate)
5.0 g ammonium sulfate
20 mg adenine sulfate
Add the following amino acids (final concentrations given):
40 mg/liter L-tryptophan-40
20 mg/liter L-histidine-HCl
20 mg/liter L-arginine-HCl

continued

20 mg/liter L-methionine
30 mg/liter L-tyrosine
60 mg/liter L-leucine
30 mg/liter L-isoleucine
30 mg/liter L-lycine-HCl
50 mg/liter L-phenylalanine
100 mg/liter L-aspartic acid
100 mg/liter L-glutamic acid
150 mg/liter L-valine
200 mg/liter L-threonine
400 mg/liter L-serine
Store the medium at room temperature prior to the addition of the amino acids; with amino acids, store at 4°C
Bring to 900 ml with water
Filter-sterilize
Store up to 1 week at room temperature
To make selection medium with 2% glucose: Add 100 ml of autoclaved 20% glucose (keep at room temperature)
To make selection medium with 2% galactose: Add 100 ml of autoclaved 20% galactose (keep at room temperature)

COMMENTARY

Background Information

Multiple attempts have been undertaken to identify proteins associated with various types of protein aggregates, including aggresomes; most have employed two-hybrid screens (Faber et al. 1998, Kaltenbach et al. 2007; *UNIT 17.3*). The two-hybrid approach, however, does not allow a comprehensive search for proteins sequestered in various types of aggregates, since some of these proteins may interact only with the soluble forms of abnormal polypeptides, or be recruited via indirect interactions.

Another approach would be to isolate the aggresome and determine its composition, since factors involved in various stages of aggresome formation, as well as factors involved in the aggresome-mediated cell protection, may physically associate with the aggresome. Broad analysis of the components associated with the aggresome and other types of aggregates is hampered by the difficulties in isolation of aggregates. These difficulties, which include extreme heterogeneity of size and charge of the aggregates, preclude application of conventional biochemical methods to the purification of aggregates, e.g., gel filtration or ion-exchange chromatography. In addition, enormous sizes of aggregates practically preclude using various types of affinity chromatography for their isolation. In fact, aggregates are washed-out from affinity chromatography columns due to a shear force upon wash, even if they are covalently cross-linked to the beads. Previously, isolation of aggregates was performed by utilizing the ionic detergent insolubility of amyloids (Doi et al., 2004) or density gradient fractionation (Suhr et al., 2001). While these methods may be useful to address certain questions about the structure of protein aggregates, they are inadequate for identification of the aggregate-associated proteins. In fact, SDS treatment causes dissociation of most of the associated proteins, while density gradient isolation yields a high fraction of non-specifically associated polypeptides. Another method using a fluorescence-activated cell sorter to separate GFP-tagged aggregates overcame some of these problems. However, the cell sorter approach has several obvious limitations: it requires very large and highly homogeneous aggregates, and provides low yields (Mitsui et al., 2006). Furthermore, this method is not applicable to the isolation of aggregates from clinical samples.

Our method of aggresome isolation is based on affinity purification without involvement of a solid phase. It allows isolation of aggresomes under mild conditions that preserve associated proteins. The yields are sufficient for a broad proteomics study.

Following yeast cell lysis, the unbroken cells and cell debris are sedimented by centrifugation, which leaves aggresomes and large aggregates in the supernatant. The first step

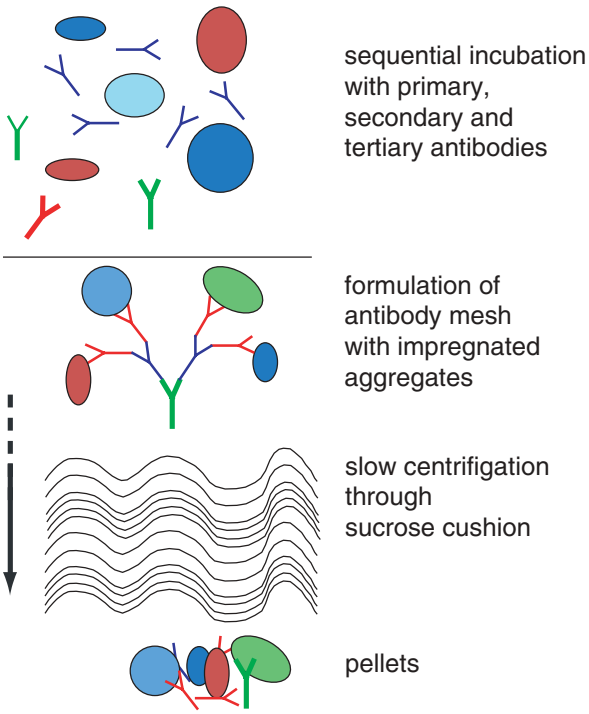

Figure 3.38.1 Scheme of Basic Protocol steps 12 through 16 of aggresome isolation.

is separation of the aggresomes from soluble mono- and oligomeric forms of the same polypeptide, as well as from soluble cellular proteins using gel filtration and collecting void volume fractions highly enriched with aggresomes. The cut-off range of the column is chosen to yield in void volume only very large structures, including aggresomes and other types of large aggregates.

The second and the main isolation step employs an approach eliminating the need for a solid support in affinity purification (Fig. 3.38.1). We first decorated aggresomes with a primary antibody (anti-FLAG, since our aggresome-forming polypeptides were FLAG-tagged). Then, we built a three-dimensional antibody mesh that incorporated aggresomes by consequent additions of an excess of secondary antibody, and finally of an excess of tertiary antibody. As a result of the consecutive incubations, the aggregates became impregnated into an IgG mesh (Fig. 3.38.2). The size of this mesh is much greater than the sizes of free large intracellular particles, like components of cytoskeleton that remain in the supernatant after the first centrifugation. Therefore, the mesh could be effectively separated from other large particles by a very low-speed centrifugation through a dense sucrose cushion. In fact, since the centrifugation through the cushion was run at a speed lower than the speed used to clarify yeast lysates before gel filtration, even the largest particles un-associated with the IgG mesh did not sediment under these conditions, and remained in supernatant.

The method allows isolation of aggresomes and other types of protein aggregates together with associated proteins. Indeed, we identified more than thirty associated proteins, including a set of molecular chaperones, several glycolytic enzymes, components of the ubiquitin-proteasome machinery, and other polypeptides (Wang et al., 2007). Beside aggresomes, this approach can be applied to isolation of any types of large structures, like other types of aggregates, components of cytoskeleton, and even organelles.

Critical Parameters

Upon adaptation of this methodology to isolation of various types of structures, one should consider that it involves two centrifugation steps. At the first centrifugation, extremely large complexes and unbroken cells are removed, and structures of interest should remain in supernatant. Then these structures are incorporated into the IgG mesh, become much larger, and could sediment at lower speeds through the dense sucrose cushion. The critical consideration is that in order to avoid contamination with unrelated complexes,

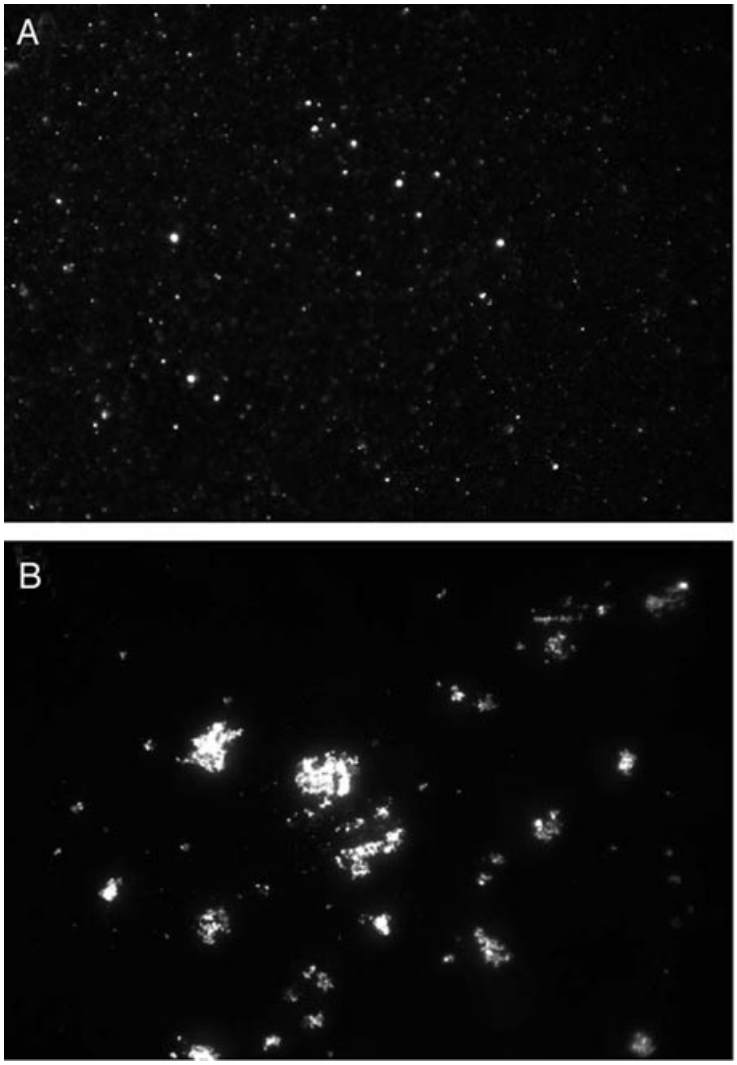

Figure 3.38.2 Appearance of aggregates before (**A**) and after (**B**) formation of the IgG mesh.

the speed of the first centrifugation must be higher than the speed of the second centrifugation. This speed difference ensures that the unrelated complexes remain in supernatant while the IgG-impregnated structures sediment.

To separate the aggresome and the associated proteins from the IgG molecules, biotinylated IgG could be used in the experiment, allowing their efficient removal after solubilization of pellets using streptavidin beads.

Anticipated Results

The described method provides yield of ~2 mg of aggresome preparation from 1 g of yeast protein. The first step of size-exclusion chromatography purifies aggresomes about 7-fold, and the second step of immunoisolation purifies them about 20-fold.

Time Considerations

Yeast growth and collection of cells takes 24 hr. The entire purification procedure should take one working day. At the end of the day, purified aggresome fractions can be frozen and stored. Analysis of the isolated fractions by two-dimensional SDS-PAGE should take another day. *Optional:* Before the gel analysis, one extra day could be spent for the removal of the antibodies using streptavidin column.

Isolation of Chromaffin Granules

Carl E. Creutz[1]

[1]Department of Pharmacology, University of Virginia, Charlottesville, Virginia

ABSTRACT

Adrenal medullary chromaffin granules (dense core secretory vesicles) have been a valuable model system for the study of the proteins and membrane components involved in the process of exocytosis. Because of the abundance of chromaffin granules in a readily available tissue source, bovine adrenal medullae, and their unique sedimentation properties, it is possible to obtain large quantities of highly purified granules and granule membranes in a short period of time. Two protocols are presented here for the isolation of chromaffin granules: a basic protocol based on differential centrifugation in an iso-osmotic medium that yields intact chromaffin granules, and an alternate protocol based on sedimentation through a density step gradient that provides a greater yield of more highly purified chromaffin granules. Since in the latter case the granules cannot be returned to a medium of physiological osmolarity without lysis after purification on the step gradient, the alternate protocol is more useful to obtain the granule membranes or contents for further study. *Curr. Protoc. Cell Biol.* 48:3.39.1-3.39.10. © 2010 by John Wiley & Sons, Inc.

INTRODUCTION

Two protocols are presented here for the isolation of chromaffin granules, the dense core secretory vesicles of the adrenal medulla. Although the protocols can be applied to other species, the granules are usually isolated from bovine adrenals. Using 25 to 50 glands, about 50 mg of chromaffin granule protein can readily be obtained in 4 hr after adrenal glands arrive in the laboratory. The first procedure is based on differential centrifugation in an iso-osmotic medium and yields intact chromaffin granules (Hillarp, 1958; Taugner and Hasselbach, 1966; Pollard et al., 1976; see Basic Protocol). The second procedure is based on sedimentation through a density step gradient and provides a greater yield of more highly purified chromaffin granules (Smith and Winkler, 1967; Bartlett and Smith, 1974; see Alternate Protocol). Since in this case the granules cannot be returned to a medium of physiological osmolarity without lysis after purification on the step gradient, the second protocol is more useful to obtain the granule membranes or contents for further study.

ISOLATION OF CHROMAFFIN GRANULES BY DIFFERENTIAL CENTRIFUGATION IN ISO-OSMOTIC MEDIUM

BASIC PROTOCOL

This protocol yields intact chromaffin granules useful for studies of the properties and interactions of the whole organelle in vitro. The alternate protocol described below provides a greater yield of granules for biochemical studies of the membrane components or granule contents.

Materials

5 to 30 bovine adrenal glands, freshly collected and transported to the laboratory
Cold 0.3 M sucrose solution (store at 4°C to inhibit bacterial growth), 1 liter

Surgical scissors, 2-in. blades
500-ml beakers

Current Protocols in Cell Biology 3.39.1-3.39.10, September 2010
Published online September 2010 in Wiley Online Library (wileyonlinelibrary.com).
DOI: 10.1002/0471143030.cb0339s48

Kitchen cutting board
Surgical scissors, 1-in. blades
Mouse-tooth forceps, 5-in.
Waring blender
Potter-Elvehjem glass homogenizer with a loose-fitting Teflon pestle, 15 to 20 ml volume (a loose fitting pestle is one that shows little or no resistance or suction when moved up and down in the glass tube in air)
1/4-in. electric hand drill for Potter-Elvehjem pestle
Gauze sponges
Rubber band
8-in. stainless steel spatula with a 1/4-in. wide, rounded blade
Clear, 40-ml polycarbonate centrifuge tubes
Refrigerated high speed centrifuge with Sorvall SS-34 rotor or equivalent
40-ml Dounce homogenizer with loose-fitting (type B) pestle
15-ml Dounce homogenizer with loose fitting (type B) pestle

NOTE: All glassware and equipment must be completely free of detergents in order to preserve the integrity of the chromaffin granule membranes.

NOTE: After initial dissection of the adrenal glands, all materials are kept on ice.

Obtain and prepare the bovine adrenal glands

1. Obtain bovine adrenal glands at a slaughterhouse not more than 90 min away from the laboratory. Call the slaughterhouse just before going in order to ensure that they are slaughtering that day.

   Small, local slaughterhouses often operate erratically.

2. To obtain the most rapid post-mortem chilling stand on the killing room floor and receive the adrenals as they are removed.

   This requires dressing with rubber boots, laboratory coat, hairnet, hard hat, safety glasses, and surgical gloves.

   The glands are removed by slaughterhouse workers along with the kidneys right after the carcass is sawn in half. The glands are often embedded in fat and not visible. An experienced floor worker will be able to slice the gland from the kidney. A monetary gratuity may help provide the most intact glands.

3. Trim additional fat from the gland with surgical scissors (2-in. blade) to expose the gland and promote rapid cooling before plunging it into a plastic bag in an ice bucket.

   Some companies offer to remove adrenals at a slaughterhouse and ship them on ice overnight (not frozen which would destroy the chromaffin granules). However, there appears to be little or no published experience with trying to isolate chromaffin granules from such a source. In general, it is felt that the best practice is to minimize the length of time from killing to chilling, and subsequently to dissecting the medullae from the glands.

Dissect the adrenal medullae from the glands

4. Record the weight of one 500-ml beaker and place it on ice.

5. Remove the glands from the ice bucket one at a time and dissect them on the cutting board at room temperature.

   The bovine adrenal gland is about the size of a human thumb. It is also similar in shape to a thumb, but the actual shape varies considerably. Adrenal medullary tissue is pink-orange due to the presence of cytochrome b561 in the chromaffin granule membrane (responsible for electron transport supporting the activity of dopamine-β-hydroxylase in the granule interior; Fleming and Kent, 1991), and so can easily be distinguished from the liver-colored adrenal cortical tissue that forms a 3- to 5-mm layer surrounding the medulla. Outside the cortex, the gland is encased in a fairly tough, membranous capsule.

6. Remove any significant remaining chunks of fat with the 2-in. surgical scissors.
7. With the 1-in scissors, cut directly into the gland through the capsule 3- to 5-mm deep along the longest circumference of the gland.

   That is, if the gland lies flat on the cutting board, the incision would be all the way around the edge, parallel to the cutting board surface (although it is easier to pick up the gland when making this cut). The object is to cut through the cortex, all the way around the gland, but not deeply into the medulla.

8. Now, lay the gland flat on the cutting board. With the mouse-tooth forceps, grasp the top edge of the incision at one end of the gland. Lift the cortical tissue to reveal the medullary tissue.
9. Carefully cut between the pink-orange medulla and the brown cortex with the 1-in. surgical scissors all the way across the top of the gland. Discard the cortical tissue.
10. Then grasp the pink-orange medullary tissue with the forceps and lift it up as you cut with the scissors between the medulla and the cortex on the bottom half of the gland, all the way across the gland. Discard the remaining cortical tissue, and immediately drop the medullary tissue into the 500-ml weighed beaker chilled on ice.

    With practice, the dissection takes about 5 min per gland. When dissecting multiple glands it is helpful to recruit others in the laboratory to assist with the dissection.

    Each gland will yield 1 to 2 g of medullary tissue (beef steer have smaller glands; culled bulls and dairy cows have larger glands). The dissection does not have to be perfect. It is more important to minimize the loss of medullary tissue than to remove every trace of cortical tissue.

Homogenize the adrenal medullary tissue

11. Determine the mass of adrenal medullary tissue by weighing the previously tared and chilled 500-ml beaker, and add 5 vol of ice-cold 0.3 M sucrose.
12. Homogenize the tissue in an ice-cold Waring blender on high setting for two 3-sec bursts.
13. Pour the homogenate, 15 to 20 ml at a time, into the Potter-Elvehjem homogenizer.
14. Homogenize with the pestle driven by the electric drill at high speed, one pass, down and up.

    Because of the high speed and force of the motor-driven pestle in the glass homogenizer, this step is potentially dangerous as the glass homogenizer may shatter if the pestle is inadvertently pushed into the glass tube at an angle. If this step is done with a hand drill, wear a heavy glove, like an autoclave glove, on the hand holding the glass tube. An alternative that reduces the chance of shattering the glass homogenizer is to drive the pestle with a small drill press.

15. Take four gauze sponges, unfold them, and stack them to form a layer of gauze four-ply thick. Attach the gauze layer to the top of a 500-ml beaker on ice with a rubber band.
16. Pour the homogenate fractions from the Potter-Elvehjem homogenizer onto the gauze. Promote the drainage of the homogenate through the gauze by using the stainless steel spatula to spread the homogenate across the surface of the gauze.
17. After all of the homogenate has been poured onto the gauze, extract the rest of the well-dispersed material by removing the rubber band, picking up the gauze and squeezing out the remaining liquid to add to the filtered homogenate. Transfer to 40-ml centrifuge tubes.

Isolate the chromaffin granules by differential centrifugation.

18. Centrifuge the homogenate 10 min at 500 × *g* (e.g., 2000 rpm in the SS-34 rotor), 4°C, to sediment nuclei and partially broken cells.

    If, for example, 25 ml of medullary tissue were homogenized initially, about 120 ml of homogenate will be obtained and that will fit conveniently into four SS-34 tubes.

19. Decant the supernatant into a new set of 40-ml tubes and centrifuge 30 min at 20,000 × *g* (13,000 rpm in the SS-34 rotor), 4°C.

20. Discard the supernatant and add 5 ml of cold 0.3 M sucrose to wash the upper part of the pellet in each tube. Use a gentle swirling motion that removes the looser, brownish part of the pellet. Discard the wash.

21. Resuspend the pellet (known as the "large granule fraction") from each tube with 30 ml of 0.3 M sucrose per tube. Add the sucrose solution, and then use the spatula to slice up and free the pellet from the tube wall. Do not disturb, and leave behind, any dark brown material or red blood cells that may appear at the very bottom of the pellet.

22. With a swirling motion, decant the resuspended pellet into a cold 40-ml Dounce homogenizer with a loose-fitting pestle. Homogenize the pellet with 3 to 4 gentle strokes of the pestle.

23. Pour the suspensions into a new set of centrifuge tubes and centrifuge 30 min at 10,000 × *g* (9,400 rpm in the SS-34 rotor), 4°C.

    After this centrifugation, the pellets will tend to have two zones, a firm pink zone at the bottom of the pellet enriched in chromaffin granules, and a looser, brownish upper layer enriched in mitochondria.

24. Discard the supernatant and swirl off the upper layer, as before, with 5 ml of cold 0.3 M sucrose solution.

    As much as half of the volume of the pellet may be washed away at this step.

25. Resuspend the remaining, pink part of the pellet, as before, with 30 ml of 0.3 M sucrose solution and repeat the Dounce homogenization.

26. Centrifuge the homogenized pellets 30 min at 7000 × *g* (7700 rpm in the SS-34 rotor), 4°C.

27. Discard the supernatant, wash the pellet as before with 5 ml of 0.3 M sucrose solution, then resuspend all pellets together (e.g., from four tubes) in a total of 10 ml of 0.3 M sucrose using a 15-ml Dounce homogenizer with a loose-fitting pestle. Store the purified granules at 4°C, or on ice, in the 0.3 M sucrose for 2 or 3 days maximum.

    The preparation can be frozen indefinitely at −70°C if intact granules are no longer needed (e.g., to isolate membranes or granule contents at a later time).

ALTERNATE PROTOCOL

ISOLATION OF CHROMAFFIN GRANULES BY SEDIMENTATION THROUGH A SUCROSE DENSITY STEP

Chromaffin granules of higher purity can be obtained by sedimenting the large granule fraction obtained after the 20,000 × *g* centrifugation in the Basic Protocol on a sucrose step gradient.

***Additional Materials** (also see Basic Protocol)*

250 ml cold 1.6 M sucrose solution, store at 4°C to inhibit bacterial growth
Clear, thick-walled, 60-ml polycarbonate ultracentrifuge tubes
10-ml pipet

Refrigerated ultracentrifuge and large-capacity fixed-angle rotor, e.g., Beckman Type 45 Ti

Tight-fitting, type A pestle for the 40-ml Dounce homogenizer

NOTE: All additional steps below are performed at 4°C or on ice. These steps must be undertaken immediately after the preparatory steps in the Basic Protocol above; granules kept for hours or longer gradually lose their contents and will not sediment properly in a density gradient.

Collect the chromaffin granules

1. Carry out steps 1 through 20 of the Basic Protocol.
2. Pour 40 ml of 1.6 M sucrose into each of several 60-ml ultracentrifuge tubes (number equal to the number of chromaffin granule pellets in step 20 of the Basic Protocol).
3. Resuspend each pellet from step 20 of Basic Protocol in 20 ml 0.3 M sucrose, leaving behind brown matter and red cells, and homogenize with a Dounce homogenizer with a loose-fitting pestle.
4. Carefully overlay the 20 ml of granule suspension from each tube on top of the 1.6 M sucrose in a 60-ml ultracentrifuge tube. Use a 10-ml pipet and gently allow the suspension to run down the inner wall of the centrifuge tube without stirring the underlying 1.6 M sucrose.
5. Centrifuge the step gradients for 60 min at 100,000 × *g* (e.g., 35,000 in the Beckman Type 45 Ti rotor), 4°C.
6. After the centrifugation, the pink chromaffin granules will be in the pellet and the other organelles, mainly mitochondria, will be in a band at the interface between the 0.3 M and 1.6 M sucrose fractions. Decant the supernatant, and save the pellet.

   The purified granules from the steps above can be stored intact in 1.6 M sucrose for a few days. However, most applications of these granules involve studies of the membranes from the granules, or the secretory contents of the granules (catecholamines, ATP, chromogranins, bioactive peptides, dopamine-β-hydroxylase, etc.).

Prepare chromaffin granule membranes and lysate

7. To separate the chromaffin granule membranes from secretory contents, resuspend each pellet in 25 ml deionized water with eight vigorous strokes with a 40-ml Dounce homogenizer, using a tight-fitting pestle.
8. Collect the membranes by centrifuging 30 min at 39,000 × *g* (e.g., 18,000 RPM in a Sorvall SS-34 rotor), 4°C.
9. Resuspend the pellets in 5 ml water or appropriate experimental buffer with a 15-ml Dounce homogenizer.
10. Save the supernatant for studies of the granule contents and the resuspended pellets for studies of the membranes.

    Both membranes and supernatant may be stored indefinitely at −70°C.

COMMENTARY

Background Information

"Previous studies have emphasized the necessity to get more exact information on the structure, composition, and enzyme activities of the specific granules storing the catechol amines of the adrenal medulla. Without such information, it does not seem possible to elucidate some essential problems concerning the storage and release of the amines. Several data of interest in this respect are, however, difficult to obtain unless specific granules of high purity are available. The present work is a first report of some experiments to separate the large granules of the adrenal medulla into

fractions and to isolate the specific granules. (Hillarp, 1958)"

This opening paragraph of Nils-Åke Hillarp's landmark paper on the isolation of chromaffin granules reflected the aspirations of many who pioneered the field of molecular cell biology in the 1950s and 60s. Organelle isolation was to become a sine qua non for understanding the molecular basis of intracellular activities. As a model secretory vesicle, the chromaffin granule (so named due to the affinity of the organelle for chromium used in histological studies of the adrenal medulla) has played an important role in the development of our understanding of the secretory pathway and the process of exocytosis. Indeed, the determination that the contents of isolated chromaffin granules are identical to the materials that are secreted by the adrenal medulla is one of the critical experimental underpinnings of the concept that exocytosis is a process in which a secretory vesicle membrane fuses with the plasma membrane and its contents are expelled from the cell (Douglas and Poisner, 1966; Kirshner et al., 1966).

Several characteristics have made chromaffin granules a particularly rewarding target for cell fractionation and organelle isolation. First, they are abundant. The cytoplasm of the highly differentiated chromaffin cell of the adrenal medulla is densely packed with the organelles (Fig. 3.39.1), and bovine adrenal medullary tissue itself is readily available in 100-g quantities. Second, they are dense. This unusual

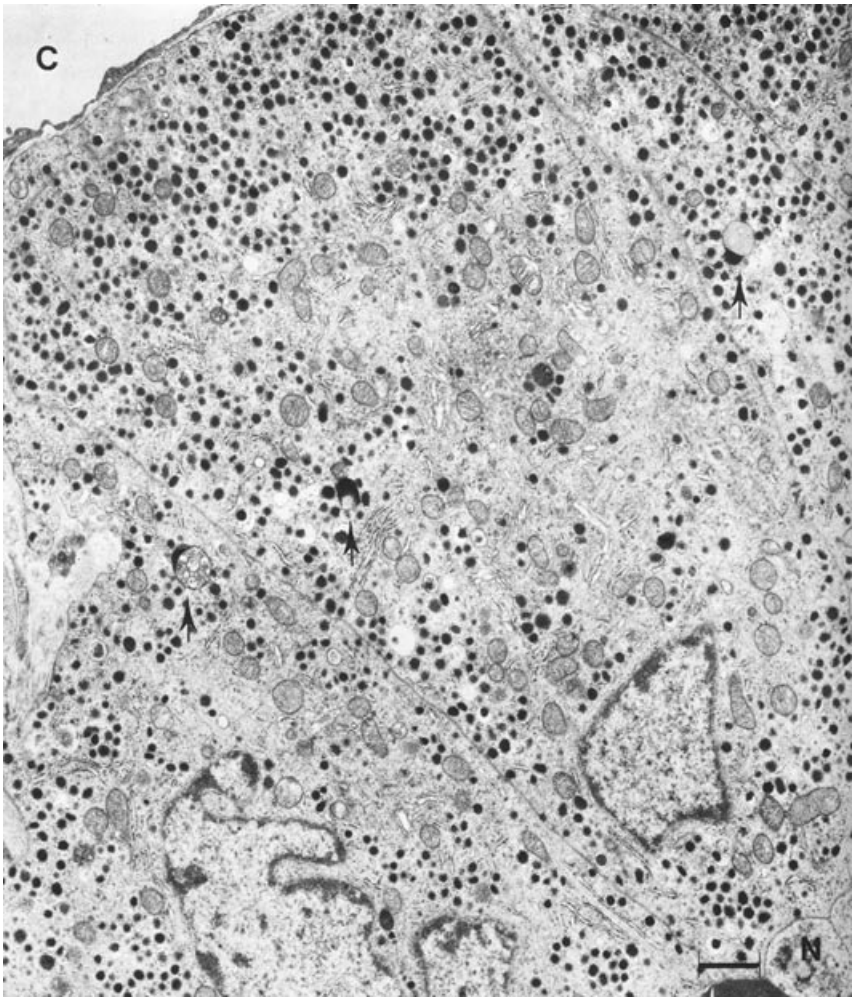

Figure 3.39.1 Electron micrograph of a thin section of several chromaffin cells of the adrenal medulla of the hamster. The cytoplasm of the chromaffin cells is seen to contain numerous, dense-core chromaffin granules. C, lumen of an adrenal medullary capillary, which receives the contents of the chromaffin granules when they are discharged by exocytosis. N, nerve terminal involved in chromaffin cell stimulation. density compared to other organelles, which is enhanced by dehydration in hyperosmotic sucrose solutions, greatly facilitates their isolation by differential and/or density gradient centrifugation. Third, they are pink. Due to the presence of cytochrome b561 in their membranes, they carry a readily visible marker that aids in following their purification.

Critical Parameters

Of the many published procedures for the purification of chromaffin granules, almost all are based on differential or gradient purification methods with minor variations. The procedures described here are essentially those that were standardized in the laboratory of Harvey Pollard at the NIH during the 1970s. An essential element is the use of iso-osmotic solutions (0.3 M sucrose) to maintain the integrity of the granules, which are osmotically quite labile. If they lose their contents, their characteristic behavior on centrifugation is lost.

Another critical parameter is the use of low-ionic-strength solutions (again, 0.3 M sucrose). In the presence of physiological ionic strengths (even as little as 30 mM KCl) the organelles in the large granule fraction (pellet from 20,000 × *g* centrifugation in the Basic Protocol) remain bound to one another by residual cytoskeletal components, and the chromaffin granules do not separate well from the other organelles during centrifugation. This is why the granules are mixed throughout the first high-speed pellet with other organelles, and only begin to separate with the repeated washes and the series of centrifugations at descending *g*-forces (Taugner and Hasselbach, 1966; Pollard et al., 1976).

When working with the unbuffered sucrose solutions, the pH of the homogenate is around pH 6.0. This is close to the internal pH of chromaffin granules (Pollard et al., 1979) and is likely due to the natural buffering provided by granule contents leaked from broken granules. This slightly acidic pH tends to stabilize the granules and aids further in separating organelles from cytoskeletal components. However, in some cases buffering of the homogenate may be desirable, for example when isolating calcium-dependent, chromaffin granule–binding proteins (the chromobindins; Creutz, 1981; Creutz et al., 1983) from the soluble fraction of the same homogenate used to isolate granules, or to ensure that the purified organelles do not have residual amounts of these peripheral proteins bound to them. In this case, one can add 2 mM EGTA to the sucrose solution to chelate calcium and 5 to

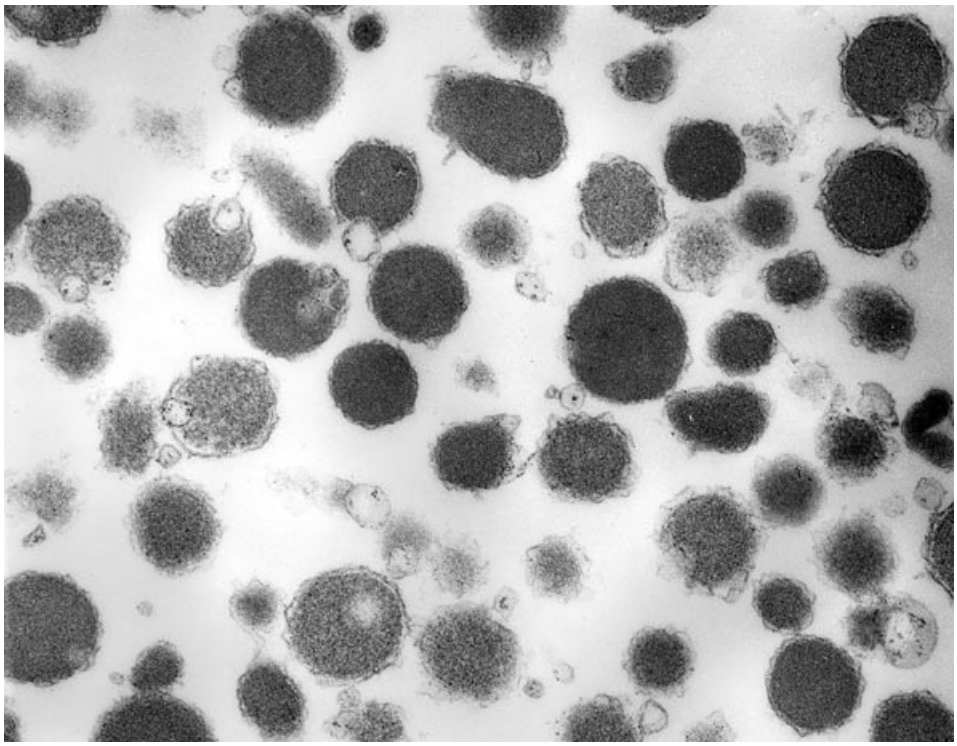

Figure 3.39.2 Electron micrograph of a thin section of a preparation of isolated bovine adrenal medullary chromaffin granules.

10 mM HEPES-NaOH, pH 7.3, to ensure that the affinity of EGTA for calcium, which is reduced at acidic pH, will remain high. These additions may reduce the purity and yield of granules slightly, but this does not seem to be prohibitive for most applications. The addition of protease inhibitors at the low concentrations usually used in biochemical extractions is also not a significant problem.

The two protocols described here provide two types of granule preparations. The Basic Protocol yields intact organelles that can be used in more physiological experimentation, but these granules are of lower purity (around 80% to 90% chromaffin granules), with the major contaminant being mitochondria. Examples of electron micrographs of granules prepared this way can be seen in Creutz et al., 1978, and in Figure 3.39.2. The Alternate Protocol yields more and higher purity granules (more than 95% chromaffin granules) useful primarily for study of the biochemistry of the granule membrane and membrane proteins. Figure 3.39.3 shows a representative two-dimensional gel of the membrane proteins. If higher purity, intact chromaffin granules are needed, one may use alternative procedures based on the use of iso-osmotic density gradients of Metrizamide (Morris and Schovanka, 1977; Pollard et al., 1979), Percoll (Gratzl et al., 1981), or Ficoll (Trifaro and Dworkind, 1970).

The protocols described here are preparative in nature. Some contaminating organelles are still present in the final products. If one wishes to determine, for example, if a given protein or lipid is a specific component of the chromaffin granule, one must resort to traditional, analytical, continuous density gradient centrifugation, using a sucrose gradient (e.g., Parsons and Creutz, 1986) or one of the iso-osmotic gradient methods cited above. The distribution of the marker of interest is then compared with accepted markers for

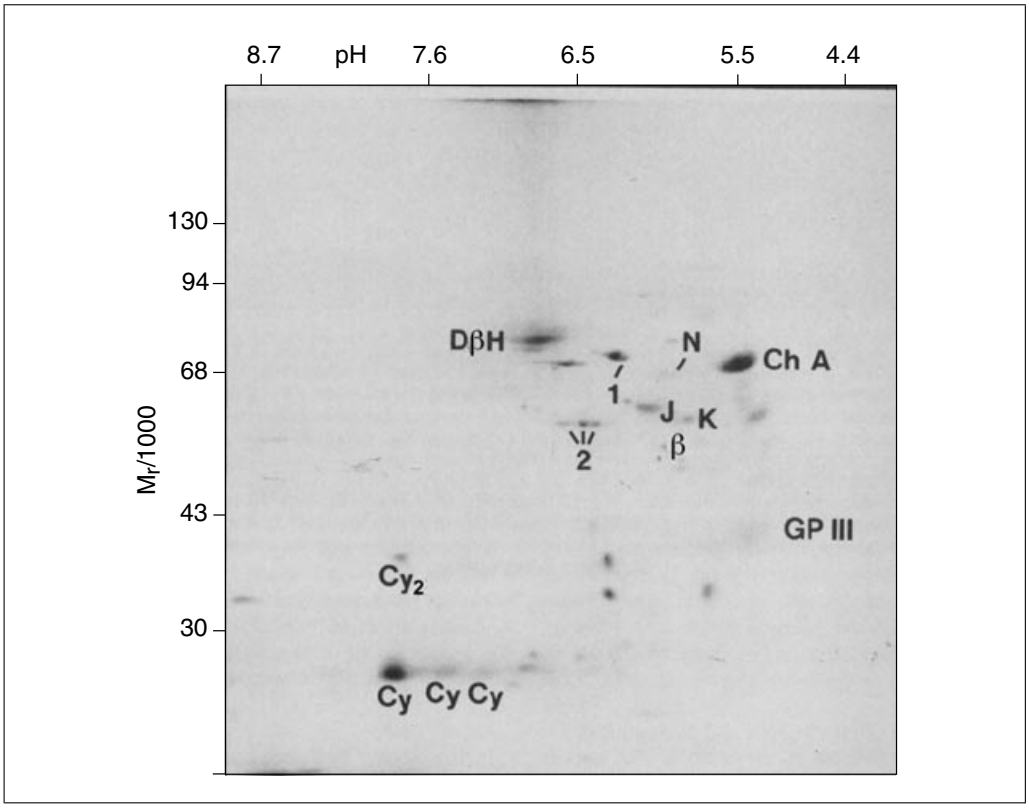

Figure 3.39.3 Two-dimensional electrophoretic gel of bovine chromaffin granule membrane proteins stained with Coomassie blue. Major proteins identified are Ch A, chromogranin A (a residual content protein); DβH, dopamine-β-hydroxylase; Cy and Cy_2, cytochrome b561 (monomeric and dimeric forms); GP III, glycoprotein III (poorly stained with Coomassie blue); J,K, glycoproteins J and K; N, nucleotide carrier; β, subunit of F1-ATPase from contaminating mitochondrial membranes; 1,2, subunits of the chromaffin granule ATPase I. Also known to be present from functional studies but unidentified or unstained: synaptobrevin, a catecholamine transporter, phosphatidyl inositol kinase, and a calcium transporter. (Reproduced from Winkler et al., 1986 with permission from Elsevier).

chromaffin granules, such as the catecholamines, chromogranin A, cytochrome b561, or dopamine-β-hydroxylase.

Procedures similar to those described here have been used to isolate chromaffin granules from a range of animals including cows, sheep, humans, dogs, cats, and rats. For systems where the amount of tissue is quite limited, the procedures must be correspondingly reduced in scale because chromaffin granules are less stable in highly dilute homogenates. With the probable development of genetically engineered mice with interesting mutations in chromaffin granule proteins, it seems likely that isolation of chromaffin granules on a very small scale may become increasingly important in the future. However, the principles and practice of isolation described here should still apply.

Troubleshooting

In actual practice, all of the following problems have caused these protocols to fail:

1. Too long a post-mortem delay before the glands are removed and chilled.

2. Too long a delay before beginning the dissection.

3. Homogenizing medium is not iso-osmotic: Solution incorrectly prepared or some of the sucrose consumed by bacteria.

4. Contamination of solutions with detergent.

5. Failure of the ultracentrifuge to complete the run with the sucrose gradients.

Anticipated Results

Starting with 50 g of adrenal medullary tissue, the Basic Protocol should yield a final 10-ml suspension of 5 mg/ml chromaffin granule protein. Using Alternate Protocol, the yield will be about twice as great. The yield of chromaffin granule membrane protein is about 20% of the total granule protein.

Time Considerations

After the adrenal glands arrive in the laboratory, purified chromaffin granules are obtained in ~4 hr.

ABSTRACT

Highly conserved during evolution, the ribosome is the central effector of protein synthesis. In mammalian cells, the ribosome is a macromolecular complex composed of four different ribosomal RNAs (rRNA) and about 80 ribosomal proteins. Requiring more than 200 factors, ribosome biogenesis is a highly complex process that takes place mainly within the nucleoli of eukaryotic cells. Crystallographic data suggest that the ribosome is a ribozyme, in which the rRNA catalyses the peptide bond formation and ensures quality control of the translation. Ribosomal proteins are involved in this molecular mechanism; nonetheless, their role is still not fully characterized. Recent studies suggest that ribosomes themselves and/or the mechanisms underlying their synthesis, processing, and assembly play a key role in the establishment and progression of several human pathologies. The protocol described here is simple, efficient, and robust, and allows one to purify high-quality ribosomes from human cultured cell lines. Ribosomes purified with this protocol are adequate for most of the subsequent analyses of their RNA and protein content. *Curr. Protoc. Cell Biol.* 49:3.40.1-3.40.11. © 2010 by John Wiley & Sons, Inc.

Keywords: ribosome • cell fractionation • translation

INTRODUCTION

The ribosome is a cytoplasmic ribonucleoprotein machine involved in a fundamental cell process: protein synthesis. George E. Palade made the first observation of ribosomes in 1955 (Palade, 1955). Transmission electron microscope analyses resulted in the description of ribosomes as spherical and dense structures of about 10 to 15 nm within the cytoplasm of eukaryotic cells. The number of ribosomes is variable and dependent upon the physiological and pathological status of the cell. There are more ribosomes in highly proliferative cells, whereas the number is less important in quiescent cells. The ribosomal production rate in normal cells (yeast) is about 2000 ribosomes per min, and the energy requirement for this may represent ∼60% of the total cell energy (Warner, 1999; Rudra and Warner, 2004).

The structure of the ribosome has been highly conserved during evolution. The ribosome is composed of two subunits: a small 40S subunit (30S in prokaryotes) and a large 60S subunit (50S in prokaryotes), which form the 80S ribosome (70S in prokaryote) when associated together. Each subunit contains ribosomal RNA (rRNA) and ribosomal proteins (RP). In mammals, the small subunit comprises the 18S rRNA (1869 nucleotides) and 33 proteins (RPS). The large subunit comprises three rRNAs—the 28S (5035 nucleotides), the 5.8S (157 nucleotides), and the 5S (121 nucleotides)—and 47 proteins (RPL).

The three-dimensional structure of the ribosome was initially determined in prokaryotes. The complete crystal structure of the 70S complex from *Thermus thermophilus* was

Current Protocols in Cell Biology 3.40.1-3.40.11, December 2010
Published online December 2010 in Wiley Online Library (wileyonlinelibrary.com).
DOI: 10.1002/0471143030.cb0340s49

obtained in 2001 at 5.5-Å resolution by X-ray crystallography (Yusupov et al., 2001). The eukaryotic ribosome from yeast was obtained the same year by cryo-electron microscopy (cryo-EM) at a 15-Å resolution (Spahn et al., 2001). The structure of the ribosome in mammals was determined recently from the dog by cryo-EM at a resolution of 8.7 Å (Chandramouli et al., 2008).

Decoding the mRNA and synthesizing the polypeptide chain requires, in addition to the ribosome, transfer RNA (tRNA) and multiple regulatory protein factors for initiation, elongation, and termination. Structural data obtained mainly in prokaryotes strongly support the notion that the ribosome is a ribozyme (Cech et al., 2000; Moore and Steitz, 2002). The rRNAs are organized in functional domains which catalyze the peptide bond formation and enable quality control of the translation. Nonetheless, proteins and tRNAs may be involved in these processes, but their role is still unclear (Nissen et al., 2000). Most of these studies have been performed in prokaryotes, and many data are still missing to elucidate the structure-function relationship of eukaryote ribosomes, in particular human ribosomes, and to complete the scheme of their evolutionary adaptation. In addition, numerous recent studies suggest that the ribosome could be involved in different pathological processes, such as cancer (Ruggero and Pandolfi, 2003; Belin et al., 2009), genetic diseases (Yoon et al., 2006; Idol et al., 2007; Narla and Ebert, 2010), and viral infections (Diaz et al., 1989, 1993, 1996, 2002; Simonin et al., 1995a,b, 1997; Greco et al., 2001; Belin et al., 2010). However, in most of these studies, the link between ribosome composition (RNA and proteins) and the pathological process is still not established in great detail.

In this unit, we describe a protocol to purify ribosomes from human cell lines that allow their subsequent biochemical analyses (see Figure 3.40.1). This protocol is easily adaptable to many cultured animal cell lines.

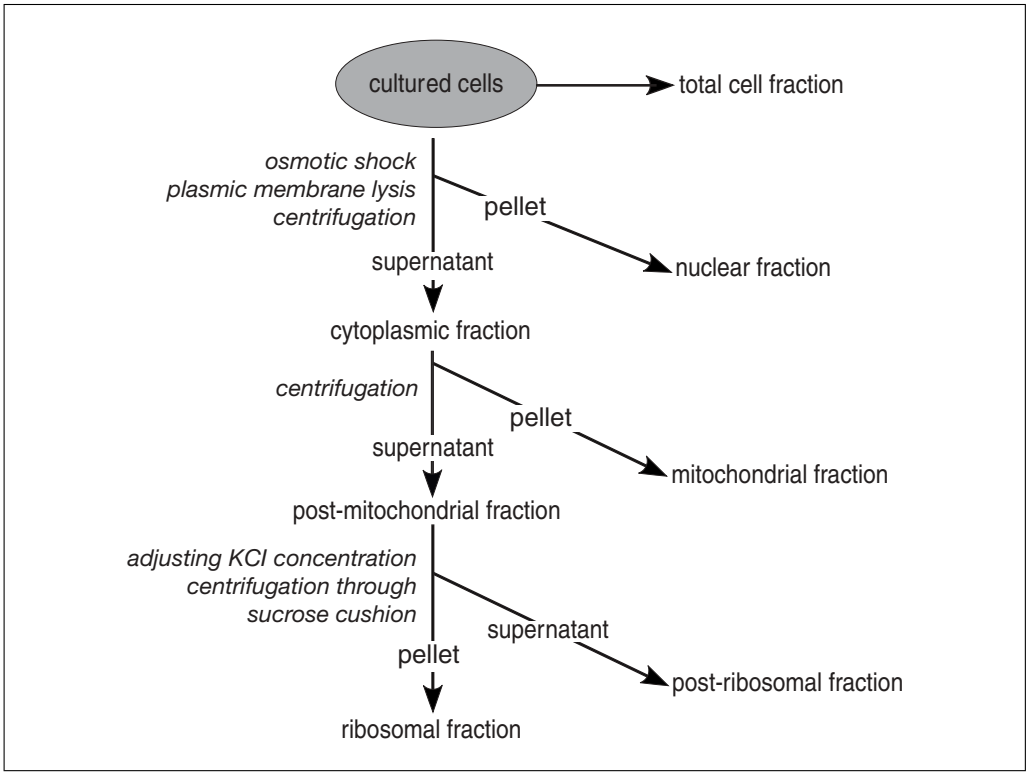

Figure 3.40.1 Synopsis of the Basic Protocol. The technical manipulations underlying this protocol are described in details in the text.

PURIFICATION OF RIBOSOMES

BASIC PROTOCOL

This protocol was adapted from previously published protocols (Madjar et al., 1977; 1979; Madjar and Fournier, 1981; Diaz et al., 1989; Massé et al., 1990a,b; Madjar, 1994; Simonin et al., 1995b, 1997; Chan et al., 1996). The main steps of the basic protocol are illustrated in Figure 3.40.1 for a purification performed from human cultured cell lines. After harvesting, cells are submitted to an osmotic shock by incubation in an appropriate hypotonic buffer containing NP-40. After a first centrifugation at 750 × *g*, the nuclear fraction is removed and stored. The cytoplasmic fraction is submitted to centrifugation at 12,500 × *g* to remove the mitochondrial fraction. The concentration of the post-mitochondrial fraction is then adjusted to 0.5 M KCl to disrupt most interactions between ribosomes and other proteins of the other cell compartments. Finally, ribosomes are purified through a sucrose cushion (containing also 0.5 M KCl) by ultracentrifugation. The ribosomes are in the pellet that appears translucent and very compact.

Materials

Cultured adherent cells
Appropriate medium for cells to be cultured
Dulbecco's phosphate-buffered saline (DPBS; *APPENDIX 2A*)
Buffers A, B, and C (see recipes)
10% (v/v) Nonidet P-40
4 M KCl
Sucrose cushion (see recipe)
12.5% SDS-PAGE gel (Gallagher, 2006)

150-mm diameter Petri dishes
15- and 50-ml conical polypropylene centrifuge tubes (e.g., BD Falcon)
Cell lifters (Biologix Research Company; *http://biologixresearch.com/*)
Refrigerated centrifuge (e.g., Jouan CR422) for cell harvesting
3-ml thick-walled polycarbonate tubes (Beckman)
Refrigerated ultracentrifuge with fixed-angle rotor (e.g., Beckman TL-100.3) for ribosome harvesting
Spectrophotometer capable of measuring at 260 nm

Additional reagents and equipment for protein quantification (see Support Protocol and Simonin and Smith, 2008), SDS-PAGE (see Support Protocol and Gallagher, 2006), and staining gels (see Support Protocol and Sasse and Gallagher, 2009)

NOTE: Carry out all procedures at 4°C using prechilled solutions.

NOTE: This protocol is optimized for dissociated cytoplasmic ribosomal subunits. To purify polysomes, 40S and 60S subunits, or monosome 80S, buffers have to be modified. See Critical Parameters for more details.

Culture and harvest cells

1. At a time point 48 hr before purification of ribosomes, plate 8×10^6 cells per 150-mm diameter Petri dish in the appropriate medium.
2. At 80% confluence, wash cells three times with 15 ml per dish of cold DPBS, pH 7.4.
3. Scrape the Petri dish with a cell scraper into 10 ml of DPBS.
4. Pool cells in a cold 50-ml conical polypropylene centrifuge tube.

5. Collect cells by centrifugation 5 min at 500 × *g*, 4°C.

   Cells should not be spin at more than 500 × g.

6. Discard supernatant, saving an aliquot for subsequent SDS-PAGE analysis.

Prepare cytoplasmic and nuclear fractions

7. Resuspend gently by pipetting (do not use vortex) the cellular pellet with cold buffer A added in three sequential steps with gentle pipetting (homogenization) between additions of buffer A.

   The volume of buffer A is three times the volume of the cell pellet. It is very important to obtain a homogeneous cell suspension.

8. Save ∼1/20th of the suspension and store it at −80°C for subsequent SDS-PAGE analyses.

9. To perform cell lysis, add the appropriate volume of NP-40 from a 10% solution in the cell suspension to obtain a final concentration of 0.7% (v/v).

10. Incubate on ice for 10 to 15 min. Homogenize the suspension by gentle pipetting at the beginning of the incubation and 5 min following the incubation.

    For example, add 28 μl of 10% NP-40 solution for 300 μl of homogenate.

    In this step, the cytoplasm detaches from the nuclei. NP-40 is a nonionic detergent that facilitates the cell lysis by inducing weakness of the plasma membrane.

11. Centrifuge the cell lysate 10 min at 750 × *g*, 4°C, to pellet nuclei.

    The supernatant contains the cytoplasmic fraction with cytoplasmic ribosomes. The pellet contains nuclei.

12. Save the nuclear pellet and store it at −80°C for further SDS-PAGE analyses.

Prepare cytoplasmic fraction without mitochondria

13. Centrifuge the cytoplasmic fraction 10 min at 12,500 × *g*, 4°C, to obtain a pellet containing the mitochondria.

14. Carefully decant and retain the post-mitochondrial fraction (PMT), which contains the ribosomes. Save an aliquot for further analysis and store at −80°C.

Determine PMT volume to adjust KCl concentration

15. Accurately measure the volume of the PMT fraction (PMT_{vol}) using a graduated pipet.

16. Calculate the amount of 4 M KCl solution to add to the PMT fraction to give a final concentration of 0.5 M using a 4 M KCl solution as:

    $V_{KCL} = PMT_{vol}/14$

17. Slowly add the 4 M KCl solution to the PMT fraction.

    The volume of the KCl-adjusted PMT is between 100 μl and 600 μl and should not exceed 600 μl.

Harvest the ribosome pellet

18. For a TL100.3 rotor (Beckman) use a 3-ml polycarbonate tube. Add 1 ml of the sucrose cushion.

19. Carefully add the KCl-adjusted PMT fraction above the 1-ml sucrose cushion.

20. Carefully balance the tubes very accurately by weight (within 0.01 g) using buffer B.

    It is not necessary to fill the tubes.

21. Ultracentrifuge these tubes for 2 hr at 250,000 × *g* at 4°C.

22. Discard the supernatant which is the post-ribosomal fraction.

    The pellet appears translucent, and contains ribosome. The pellet is very compact and very dense.

23. Quickly rinse the pellet twice by carefully adding 200 µl cold water to the pellet and removing it immediately without losing the pellet.

24. Resuspend the ribosome pellet with three 100-µl additions of buffer C. After each addition of buffer, gently homogenize the pellet by pipetting, to obtain a ribosome suspension. Save an aliquot for further analysis and store at −80°C.

25. To estimate the amount of ribosomes, measure the optical density of the ribosome suspension obtained with a spectrophotometer at 260 nm.

    OD_{260} = 14 corresponds to 1 mg of ribosomes and about 500 µg of ribosomal proteins.

    Protein concentration of this fraction can also be estimated using the Bradford protocol (Simonin and Smith, 2008).

Validate the purification by one-dimensional gel electrophoresis

26. Thaw samples reserved in steps 8, 12, and 24 corresponding to total cells and to nuclear, post-mitochondrial supernatant, and ribosomal fractions, keeping the samples on ice.

27. Quantify the proteins in each sample using the Bradford assay (see Support Protocol and Simonin and Smith, 2008).

28. Separate 10 µg of each fraction by SDS-PAGE (see Support Protocol and Gallagher, 2006) using a 12.5% gel, then stain with Coomassie blue (see Support Protocol and Sasse and Gallagher, 2009).

    An image of a typical gel stained with Coomassie blue is presented in Figure 3.40.2. Panel A presents the fraction corresponding to total cell fraction (TC), nuclear fraction (N), and post-mitochondrial fraction (PMT). The three first lanes in panel B present the ribosomal fractions purified with 0.5 M KCl. The three next lanes present the same ribosomal fractions but purified with 0.025 M KCl in order to illustrate that the KCl concentration is critical to obtain a ribosome fraction highly enriched with ribosome subunits.

    A visual inspection of the gel makes it easy to monitor the efficiency of the purification. In general, the SDS-PAGE protein profiles of total and nuclear protein profiles are very different. In particular, there is an important enrichment in the four bands of low molecular mass (indicated by asterisks) that correspond to histones in the nuclear fraction. The high abundance of these proteins in the nuclear fraction allows for the verification of the efficiency of the separation of nuclei of total cells.

    The PMT fraction appears very different from those of total cell (TC) and nuclear fraction (N). This fraction is very poor in low-molecular-weight proteins and appears without histones. This is in agreement with an efficient separation of the cytoplasmic fraction.

    The post-nuclear fraction is informative for checking the purity of the cytoplasmic fraction.

    Finally, the ribosomal fraction purified with 0.5 M KCl exhibits a very specific SDS-PAGE profile with a very clear enrichment in low- and medium-kDa proteins, which correspond to ribosomal proteins that have molecular masses between 47.3 kDa for the higher (L4)–mass and 11.5 kDa for the lower (P1)–mass proteins (Wool et al., 1996). This fraction is highly enriched in the 80 ribosomal proteins.

    The SDS-PAGE protein profiles of ribosomal fraction purified with 0.025 M KCl and of ribosomal fraction purified with 0.5 M KCl are very different. In the 0.025 M KCl protein fraction, the ribosomal proteins are visible, as they are in the 0.5 M KCl profile, but there are also a lot of other proteins of high molecular weights. Obtaining an SDS-PAGE profile

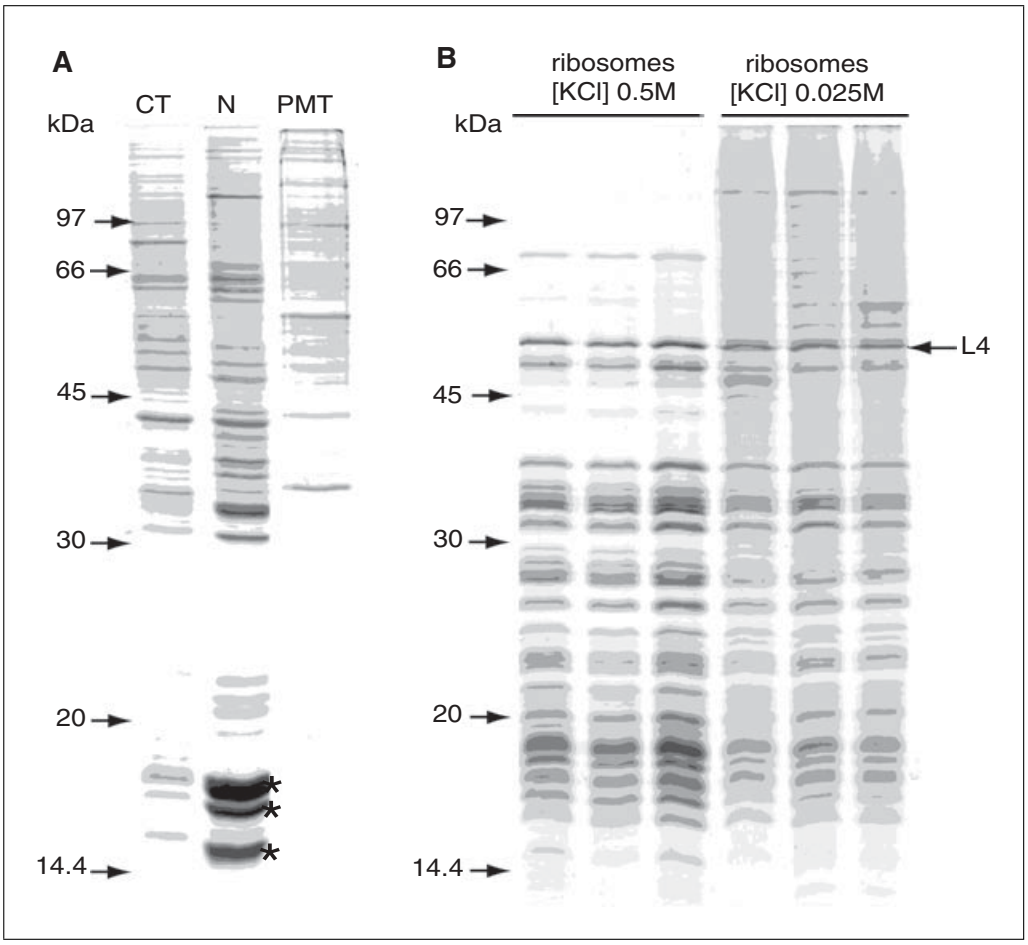

Figure 3.40.2 Analysis of the cellular fractions obtained during ribosomes purification. (**A**) 1-D separation on a 12.5% polyacrylamide gel of 10 μg of proteins extracted from total cells (TC), nuclear fraction (N), and post-mitochondrial fraction (PMT). Histones are indicated by asterisks. (**B**) 1-D separation on a 12.5% polyacrylamide gel of 10 μg of proteins extracted from ribosomal fraction purified at high stringency (0.5 M KCl) and at low stringency (0.025 M KCl). Proteins are stained with Coomassie blue R250. Sizes of molecular weight markers are indicated to the left of the panels.

similar to that presented in Figure 3.40.2 is classically sufficient to assess a satisfactory purity of the ribosomal fraction for most of the further applications, notably analyses of their RNA and protein content. In this protocol it is not necessary to analyze RNA purity, as the protein analysis is necessary and sufficient for estimating the purity of the ribosomal fraction.

SUPPORT PROTOCOL

ONE-DIMENSIONAL SDS POLYACRYLAMIDE GEL ELECTROPHORESIS (SDS-PAGE)

Thaw aliquots of fractions obtained in steps 8, 12, 14, and 24 and during the purification, slowly on ice. Quantify the proteins by the Bradford method (Simonin and Smith, 2008) using the appropriate blank for each aliquot: for the total cell fraction use buffer A as a blank; for the nuclear fraction use buffer A containing 0.7% NP-40 as a blank; for the PMT fraction use buffer B as a blank; and finally, for the ribosomal protein fraction, use buffer C as a blank. After the quantification of the proteins, add 2 volumes of 2× Laemmli electrophoretic sample buffer (see recipe). Separate about 10 μg of each fraction by SDS-PAGE on a 12.5% gel (Gallagher, 2006) and stain by Coomassie blue (Sasse and Gallagher, 2009). An image of a typical gel stained with Coomassie blue is presented in Figure 3.40.2.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Buffer A

250 mM sucrose
250 mM KCl
5 mM $MgCl_2$
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 1 week at 4°C

Buffer B

250 mM sucrose
0.5 M KCl
5 mM $MgCl_2$
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 1 week at 4°C

Buffer C

25 mM KCl
5 mM $MgCl_2$
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 1 week at 4°C

Laemmli electrophoretic sample buffer, 2×

62.5 mM Tris·Cl, pH 6.8 (*APPENDIX 2A*)
1% (w/v) SDS
10% (v/v) glycerol
0.1 M dithioerythritol (DTE)
Traces (e.g., tip of spatula full) of bromphenol blue
Store up to 1 year at −20°C

Sucrose cushion

1 M sucrose
0.5 M KCl
5 mM $MgCl_2$
50 mM Tris·Cl, pH 7.4 (*APPENDIX 2A*)
Store up to 1 year at 4°C

COMMENTARY

Background Information

Genetic information is contained in genes. The first step of gene expression is the transcription of DNA into RNA. Some of these RNAs are dedicated to producing proteins. As such, they contain a coding sequence flanked by regulatory 5′ and 3′ untranslated region (5′ and 3′ UTR). These RNAs are called messenger RNA (mRNA). The translation apparatus is composed of transfer RNA (tRNA), translation regulatory factors, and ribosomes. tRNAs are small RNAs with a sequence of 3 nucleotides at the 3′ end linked to a defined amino acid (aminoacyl-tRNA) and a sequence of three nucleotides, the anticodon that interacts with the mRNA. The translation-regulatory factors are numerous and act at different stages of translation. Ribosomes are the central effector elements, allowing the synthesis of polypeptide chain under strict quality control.

George E. Palade made the first observation of ribosomes in 1955 by performing transmission electron microscopy experiments using 40 different vertebrate cells (Palade, 1955). The same observation was made later in prokaryotes by Tissieres and Watson (1958). The ribosomal function was clearly established during the late 1950s (Balis et al., 1958).

The fine structure of the ribosome has been determined following the achievement of two main goals. First, during the 1980s, many groups worked to obtain the crystal structure of the two subunits or the entire ribosome, but the resolution was not sufficient to have a complete atomic view of the ribosome (Yonath et al., 1984, Makowski et al., 1987, Trakhanov et al., 1989). Then, better resolution was obtained at the end of the 1990s. The structure of the prokaryotic 50S large subunit was obtained at 2.4 Å (Ban et al., 2000; Nissen et al., 2000), the structure of the 30S small subunit was obtained at 3 Å (Wimberly et al., 2000), and the 70S complete structure was obtained at 3.5 Å (Schuwirth et al., 2005).

The structure of the ribosome is highly conserved during evolution. The ribosome is composed of two subunits: a small subunit 40S (30S in prokaryote) and a large subunit 60S (50S in prokaryote) to form a complete ribosome 80S (70S in prokaryote). rRNAs undergo numerous post-transcriptional modifications of three types: base-methylations, 2′-*O*-methylations of the ribose, and pseudouridylations. The position of these modifications on rRNA is highly conserved during evolution, although their numbers increase between prokaryotes and eukaryotes. In eukaryotes and archaeans, post-transcriptional modifications are carried out by small nucleolar ribonucleo-particles (snoRNP), which consist of an RNA guide (snoRNA) and proteins that catalyze the modification. In prokaryotes, each modification is carried out by a specialized enzyme (Decatur and Fournier, 2002). Proteins can also be modified post-translationally, e.g., by phosphorylation. In mammals, the small subunit is constituted by the 18S rRNA (1869 nucleotides) and 33 proteins (RPS). The large subunit contains three rRNAs—the 28S (5035 nucleotides), the 5.8S (157 nucleotides), and the 5S (121 nucleotides)—and 47 proteins (RPL). Ribosome biogenesis is a complex and multistep process, which takes place mainly in the nucleolus of the eukaryotes, but also in the nucleus and the cytoplasm (Fromont-Racine et al., 2003). In mammals, ribosome biogenesis requires more than 200 protein factors and more than 100 snoRNA (Couté et al., 2006). This process is highly regulated to ensure the production of a sufficient supply of ribosomes for the cell.

Although the function of ribosomes in protein synthesis has been demonstrated for over 50 years, the precise mechanisms of translation and the implication of the ribosome became possible only when the high-resolution three-dimensional structure of ribosomes was performed by various groups; these studies were awarded the Nobel Prize in Chemistry in 2009 (V. Ramakrishnan, T.A. Steitz, and A.E. Yonath). According to these structural studies, it has been definitively demonstrated that ribosomes are ribozymes, i.e., the catalysis of peptide bond formation is performed by the RNA (Cech et al., 2000). Today, more and more studies provide data suggesting that ribosomes, at least in humans, are more or less directly involved in different physiopathological processes (Yoon et al., 2006; Idol et al., 2007; Belin et al., 2009, 2010). Furthermore, a recent study performed in yeast has demonstrated that the composition of ribosomal protein in the ribosome could influence the pool of mRNA that is translating, suggesting the existence of a "ribosomal code" (Komili et al., 2007). However, at present, many studies remain to be performed in order to validate this new provocative concept in other organisms.

Many protocols have been developed to purify ribosomes from different eukaryotic species and from different animal tissues. In general, these protocols allow investigators to obtain high-quality purified ribosomal complexes to study ribosomal protein as well as the ribosomal RNA. Here we present a highly robust protocol that we have optimized and validated with numerous cultured human cell lines. The efficiency of ribosome purification can be evaluated using various techniques: electron microscopy to ensure the conservation of classical ribosome ultrastructure; one- and two-dimensional gel electrophoresis; or even immunoblot analysis to evaluate contamination from other cell structures. After obtaining the ribosomal fraction, proteins can be identified by mass spectrometry as well. Several two-dimensional maps of ribosomal proteins have been published for the rat (Madjar et al., 1979) and for cancer cells (Diaz et al., 1989; Görg et al., 1997; Belin et al., 2009). Here, we describe a simple (one-dimensional SDS-PAGE) standard method to check the quality of the purified ribosomes.

Critical Parameters

The time at which the cells are plated before the beginning of the purification of ribosomes is critical. This can vary according to the cell lines used. The time and plating density should be adjusted to obtain about 80% cell confluence at the beginning of the purification (48 hr).

This protocol is optimized for cells that have been harvested by scrapping with a cell lifter and not by trypsinization. Harvesting cells by trypsinization could induce a partial degradation of ribosomal proteins.

This protocol is optimized for purification of ribosomes from cells immediately after harvesting, not from a cell pellet that has been frozen. Freezing the cell pellets could prevent an efficient cell lysis and a good separation of nuclear and cytoplasmic fractions. However, once the protocol is well optimized with "fresh culture" you can try to perform the purification starting with cells that have been frozen directly at −80°C (dry frozen pellet).

This protocol is intended to obtain ribosomes devoid of interacting proteins. This protocol is not suitable for polysome purification. For purification of polysomes it is necessary to use different buffers; in particular, the KCl concentration needs to be lowered to 0.025 M. For this type of purification and analyses see the numerous references in Warner and Knopf (2002).

The final concentration of NP-40 can range from 0.3% to 2%, depending on the cell line used. Plasma membrane lysis can be evaluated by visualizing the nuclei, devoid of cytoplasmic fractions under phase-contrast microscopy.

To obtain the PMT fraction, a first centrifugation at 750 × *g* is necessary to spin down the nuclei. A direct centrifugation at 12,500 × *g* could induce a disruption of nuclei and therefore cause contamination with nuclear content. This contamination is demonstrated by the presence of histones among ribosomal proteins after separation by SDS-PAGE.

The concentration of KCl at 0.5 M is critical to obtain a ribosome fraction with the lowest level of contamination. The stringency of this solution is one of the more important parameters to obtain ribosomes devoid of contamination from other cell fractions. Be aware that the 4 M KCl solution has a tendency to crystallize.

Any centrifuge and rotor that allow ultracentrifugation with tubes containing ∼3 ml can be used. However it is better to use the smallest possible volume (1 ml) for the sucrose cushion.

The ribosome pellet must be resuspended very carefully, to avoid a loss of ribosomes and to obtain a good yield of protein in this fraction. For this, it is very important to pipet the ribosomes resuspended in buffer C up and down many times, with the tubes on ice. Also be aware that the ribosomes are in suspension, and they have a tendency to sediment at the bottoms of the tubes. Therefore, homogenize very carefully by pipetting (try to avoid vortexing) the ribosome suspension before the following steps (i.e, quantification, SDS-PAGE).

Generally, the protein concentration of the fractions is very high, and it is not necessary to concentrate these fractions for further SDS-PAGE analyses.

Anticipated Results

The expected yield from 15×10^6 adherent HeLa cells is ∼2.8 A_{260} units, or about 100 μg of ribosomal proteins.

Time Considerations

It takes 5 hr to purify ribosomes from 80% confluent dishes of adherent cells. Quantification of protein content requires 1 hr and one-dimensional gel electrophoresis and staining require 6 hr

CHAPTER 4
Microscopy

INTRODUCTION

Light microscopy historically has been an important technique of scientific discovery because it provides enlarged images of small objects. Recent advances in optical design and the development of probes have made light microscopy an essential tool for both research and diagnosis, enabling analysis of structure, physiology, and function. This chapter deals with methods for using the microscope, including the principles underlying different applications of light microscopy—e.g., phase-contrast, differential interference contrast (DIC), and fluorescence microscopy—as well as how to align and adjust the microscope for these different applications, prepare and label specimens, and image them accurately.

Although the structural detail in images resolved by the microscope is continually being improved by video and digital cameras and electronic imaging, the quality and accuracy of the image is primarily dependent on proper microscope alignment and adjustment. *UNIT 4.1* details methods for aligning a typical research light microscope for bright-field, phase-contrast, DIC, and epifluorescence microscopy. The unit emphasizes how proper alignment and adjustment are essential for optimal image quality and accurate quantitative measurements. The principles underlying Köhler illumination are explained, providing the background for discussions of image formation and microscope alignment for bright-field, phase-contrast, and DIC imaging. *UNIT 4.1* also describes methods for camera attachment, calibration of image formation, care and cleaning of the microscope, and assessment of microscope performance.

UNIT 4.2 describes fluorescence microscopy and its use as a tool for imaging biological specimens. Fluorescence microscopy has long been used to characterize cellular organization and is based on the property of fluorescent molecules whereby they absorb light of a particular wavelength and emit light at longer wavelengths. This unit includes methods for aligning the arc lamp and provides information on how to choose wavelength selection devices and objectives (also see *APPENDIX 1E*). *UNIT 4.2* also explains how to image fluorescent specimens and optimize image brightness and resolution. The availability in recent years of economical camera and software systems for capturing, storing, and analyzing digital images obtained from fluorescence microscopes has led to the replacement of photography by digital analysis as the preferred method for documenting images. This is described in the section of *UNIT 4.2* entitled "The Digital Darkroom," in which the advantages of digital images over conventional photography are described. These include convenience of image storage, retrieval, and manipulation. In addition, digital imaging allows quantitative analysis of fluorescence data and greatly facilitates the analysis of large numbers of images.

UNIT 4.3 provides methods for what is perhaps the most widely used application of fluorescence microscopy, immunofluorescent staining. In this technique, fluorophore-conjugated antibodies are used as sensitive and specific probes for staining antigens in fixed and/or permeabilized cells, and the location of specific proteins can be determined. When two or more antibodies labeled with different fluorophores are used to stain cells, multiple protein distributions can be visualized simultaneously. This unit provides the basic methodology for fixation and optimal staining of cells and a variety of tips for troubleshooting potential problems.

Current Protocols in Cell Biology 4.0.1-4.0.6, June 2010
Published online June 2010 in Wiley Interscience (www.interscience.wiley.com).
DOI: 10.1002/0471143030.cb0400s47

The advent of fluorescent dyes that selectively label intracellular organelles has resulted in an additional application of light microscopy whereby the spatial distribution of specific cellular components may be examined in vivo. *UNIT 4.4* describes protocols for fluorescently labeling three subcellular organelles—endoplasmic reticulum (ER), Golgi complex, and mitochondria—using selective fluorescent probes, including $DiOC_6(3)$, C_6NBD-ceramide, and BODIPY-ceramide. These lipid-based dyes have been shown to incorporate into the membranes of the ER, Golgi complex, and mitochondria in living cells so they can be used to follow the dynamics of these organelles in real time. This unit includes an extensive troubleshooting guide for staining, as well as detailed descriptions of anticipated results.

Another powerful system for imaging specimens is the confocal microscope, which produces sharp images of structures by selectively collecting light from a thin focal plane within the specimen. *UNIT 4.5* provides important background information for the use of such microscopes in cell biological applications. It details how confocal optical sectioning is accomplished and how the technique can be used to reconstruct a three-dimensional view of a specimen. The unit also describes the different types of confocal microscope systems (including laser-scanning, rapid-scan, and two-photon) and their advantages and disadvantages, and provides practical advice for using these instruments.

UNIT 4.6 describes immunoperoxidase methods for localizing intracellular antigens. With these methods, the distribution of proteins can be characterized at both the light- and electron-microscopic levels, providing insight into cellular organization at different size scales. Included in the description are tips for ensuring that antibodies have access to the intracellular environment where antigen is localized, preserving antigenicity, and maintaining good cellular morphology during fixation and staining. Also described are the advantages and disadvantages of immunoperoxidase staining and practical tips for ensuring its success.

Cryo-immunogold electron microscopy (*UNIT 4.7*) has become the method of choice for high-resolution detection of antigens at the subcellular level. This technique involves preparation of ultrathin cryosections from cells or tissues followed by immunogold labeling to localize antigens. Because harsh organic solvents such as those used for plastic embedding are not required, preservation of protein antigenicity and ultrastructural details is better than with conventional electron microscopic embedding. In cryo-immunogold labeling, gold particles of different sizes conjugated to *Staphylococcus* protein A can be used to label different populations of antibodies that have been bound to antigens. This allows several antigens to be localized simultaneously, which is not possible with other immuno–electron microscopy labeling techniques. *UNIT 4.7* describes how to perform cryo-immunogold electron microscopy labeling of samples, including fixation, embedding, cryosectioning, and labeling. The unit also provides useful discussions on methods for improving the structural integrity of cryosections, the common problems and artifacts that arise during section preparation, and the choice of antibodies and gold particle sizes for optimal immunolabeling results. *UNIT 4.7* has been updated to include silver enhancement of the signal, as well as eleven new videos that show how to perform various steps in this technique, e.g., embedding samples and performing thin sectioning.

UNIT 4.8 describes a method known as correlative video light electron microscopy (CVLEM) that combines fluorescent microscopy and electron microscopy for analyzing dynamic structures with complex morphology within cells. In this technique, cells expressing a fluorescent reporter protein such as a GFP protein chimera are first monitored to identify and record a structure of interest. The cells are fixed, and the same structure of interest is then analyzed by electron microscopy using three-dimensional reconstruction methods. This technique requires considerable skill at the various steps involved

in specimen preparation, but it can yield tremendous insight into the high-resolution organization and morphology of complex structures within the cell, such as the Golgi complex, membrane transport intermediates, and cytoskeletal elements.

UNIT 4.9 describes polarization microscopy, a technique that allows the organization and dynamics of cells and organelles to be studied based on their anisotropic properties, such as birefringence and dichroism. These properties derive from differences in the fine structural detail of an object that make it reflect light in a polarized manner (i.e., differently in different directions). The unit starts out with a brief explanation of the phenomenon of polarized light and birefringence. It then describes how to optimally use a polarizing microscope, which is an ordinary microscope equipped with a polarizer underneath a condenser, an analyzer above the objective, and a compensator in between. Several examples of applications of the polarizing microscope are discussed, including study of the assembly and disassembly dynamics of spindle microtubules and the packing arrangement of DNA in sperm chromosomes.

UNIT 4.10 characterizes a fluorescent imaging technique for visualizing the dynamics, movement, and turnover of intracellular protein assemblies like actin and tubulin—fluorescent speckle microscopy (FSM). The technique is based on the incorporation of low concentrations of microinjected fluorescent subunits into a macromolecular structure through co-assembly with endogenous unlabeled subunits. This results in the structure of interest acquiring a fluorescent speckled pattern that can be observed in resolution-limited fluorescent images. Changes in the fluorescent speckle pattern can then be used to quantitatively analyze the assembly, disassembly, and movement of the structure. The virtue of this technique compared to conventional fluorescent imaging is that it significantly reduces out-of-focus fluorescence so the visibility of the speckles of a fluorescently labeled structure is greatly improved. Moreover, FSM can provide information about protein dynamics throughout the cell in contrast to methods like photoactivation and photobleaching, which follow a small, marked region of a structure. Use of FSM to study microtubules and actin cytoskeleton dynamics in living cells is presented as an example of the usefulness of this technique, so methods for fluorescently labeling tubulin and actin and time-lapse imaging are also detailed.

UNIT 4.11 describes the basic principles and uses of two-photon excitation microscopy. This technique allows three-dimensional imaging of a specimen without absorption above and below the plane of focus. The result is that thick samples, including brain slices, whole organs, and embryos, can be readily imaged, since there is no out-of-focus light. This unit discusses the advantages and limitations of its use relative to confocal and deconvolution microscopy and includes selected applications of two-photon microscopy to illustrate the unique features of this technique, particularly its depth penetration in a specimen, avoidance of phototoxic effects from ultraviolet irradiation, and use in fluorescence lifetime imaging.

UNIT 4.12 discusses total internal reflection microscopy (TIR-FM), also known as evanescent wave microscopy. The fundamental principle of TIR-FM is that light will be totally internally reflected back into a medium with higher refractive index when the incident angle reaches a critical angle. A standing field is then generated into the medium of lower refractive index on the side opposite the incident wave. This field, called the evanescent field, has a short characteristic distance for decay, so it can be used to limit the depth of penetration of excitation light into the specimen. This permits imaging of the specimen within 50 nm of the cell surface. Recent technical advances in fast imaging and image analysis, together with the availability of TIR fluorescence microscopes, has popularized this technique. It is now used in a variety of live-cell applications, including the study of cell-surface contact zones, exocytosis and endocytosis of vesicles, and submembrane

actin dynamics. This unit describes the theory behind TIR-FM; it provides tips for optimizing this method and describes the necessary steps for setting up a TIR-FM system. Finally, the unit discusses how TIR-FM can be used for addressing simple cell biological questions.

UNIT 4.13 describes a range of labeling techniques for fluorescent labeling of yeast cells, which are quite small and difficult to visualize by fluorescence microscopy. Among the techniques described in this unit are fluorescent dye labeling of membranes and visualization of expressed GFP fusion proteins in both fixed and living yeast cells. With these approaches, combined with the use of newer confocal imaging instruments, yeast organelle structure and protein localization can be characterized. Specific applications described include labeling of yeast vacuoles, filamentous actin patterns, and yeast budding morphologies.

UNIT 4.14 describes the technique of fluorescence lifetime imaging microscopy (FLIM), which allows information about the local molecular environment and chromophore photophysics of a fluorescent molecule to be obtained. FLIM is usually used to enhance the image contrast of biological samples, but it can also be used to study molecular interactions of fluorescently labeled biomolecules by fluorescence resonance energy transfer (FRET). This unit focuses on the latter. It describes how to perform FRET imaged by FLIM under physiological conditions using interacting molecules labeled with suitable fluorescent dyes that have the proper optical characteristics. The result is the possibility of mapping interaction events that are on the 10- to 100-Å scale, which significantly increases the diffraction-limited spatial resolution offered by normal light microscope systems. The unit further describes the limitations, pitfalls, and other considerations for FLIM and FRET when used in the study of molecular events in biological samples.

UNIT 4.15 details the technique of second and third harmonic generation microscopy (HGM). This method, which relies on two-photon excitation (*UNIT 4.11*), provides a powerful way to image numerous structural elements of cells and tissues at the resolution of visible light without the use of dyes or other stains. Among the structures that can be observed with this technique are collagen fibers, bone, lipid bodies, blood vessels, and hair. Because the technique involves multiphoton microscopy, it allows deep tissue penetration without phototoxicity, making it suitable for imaging with living organisms. Details of the experimental setup for HGM imaging, as well as examples of its use in three-dimensional tissue reconstruction and dynamic imaging of cell motility in three-dimensional tissues, are presented.

Many protrusive structures play important roles in the interaction between the cell and its environment. These include microvilli, filopodia, lamellipodia, and surface ruffles. *UNIT 4.17* describes an important technique for imaging such cell surface morphologies: scanning electron microscopy (SEM). The high resolution of SEM makes it an ideal technique for imaging the cell surface under different physiological conditions. Depending on the instrument, the scanning electron microscope has a magnification range from 15× to 200,000×, with a resolution between 1 and 20 nm. This unit describes the preparation of cells for SEM examination. In addition, it discusses several critical factors in sample preparation that are necessary to ensure optimal high-resolution imaging of the surface of mammalian cells and tissues with this technique.

UNIT 4.18 describes the fluorescence imaging techniques that are available for studying *Drosophila* embryo development. This unit includes protocols for generating flies expressing fluorescently tagged proteins, as well as for preparing embryos for fluorescent imaging. A detailed description of how to perform time-lapse confocal imaging of live fly embryos is provided. Specific challenges and considerations for fluorescent imaging within a live embryo, including optimizing image acquisition and performing

three-dimensional imaging, are discussed. Techniques that permit optical highlighting of specific subsets of fluorescently tagged proteins and organelles in the embryo, including fluorescence recovery after photobleaching (FRAP), fluorescence loss in photobleaching (FLIP), and photoactivation techniques are presented; these techniques permit analysis of the specific movements of fluorescently tagged proteins within cells. This set of protocols permit researchers to express and image tagged proteins in a specific tissue or at specific developmental times.

Determining the spatial relationship among different molecules within cells is a fundamental aspect of describing biological systems. An important approach for deciphering these relationships is through co-expression of different fluorescently tagged markers within cells and determination by fluorescence microscopy of whether the two molecules are co-localized. *UNIT 4.19* describes protocols for quantifying the extent of co-localization among different fluorescent labels observed in confocal fluorescence microscopy images. The unit discusses a variety of ways to remove background and to adjust brightness and contrast settings to ensure reliable calculation of the extent of co-localization of different fluorescent labels.

UNIT 4.20 describes an in vitro live cell–based method for imaging and quantitatively measuring the degradation of extracellular matrix (ECM) components by live cells. Since proteolytic degradation of ECM components by cells is required for cells to grow, remodel, and migrate through the ECM, this methodology is useful for analyzing ECM degradation in the study of developmental processes as well as pathologies such as cancer. In the protocol, cells are grown in the presence of fluorescent dye-quenched protein substrates that are mixed with protein matrices. Upon proteolytic cleavage, fluorescence is released that directly reflects the level of proteolysis by the cells. Confocal microscopy and advanced imaging software can be used to quantify fluorescence that is released and thereby determine the extent of proteolytic degradation in space and time.

UNIT 4.21 describes the technique of photoactivated localization microscopy (PALM). This super-resolution imaging technique improves the spatial resolution of light microscopy by over an order of magnitude (10 to 20 nm resolution), breaking the diffraction barrier of light. PALM is based on the controlled activation and sampling of sparse subsets of photoconvertible fluorescent molecules whose illumination centroids are fitted and then summed into a final super-resolution image, revealing the complex distribution of dense populations of molecules within subcellular structures with nanometer precision. This unit describes the instrumention for PALM as well as the photoactivatable fluorescent protein (PA-FP) tags that are used as probes in this technique. Both single- and dual-color PALM super-resolution imaging of biological structures are described, with specific focus on adhesion complexes at the leading edge of crawling cells.

UNIT 4.22 describes methods for culturing polarized kidney cells in three dimensions (3-D) and ways to image these cells using new-generation confocal microscopy. Unlike polarized kidney cells that are grown on tissue culture plates, those grown in 3-D cultures of extracellular matrix differentiate into a multicellular structure of polarized cells. This process shares many characteristics with the physiological development of an epithelial tissue and the formation of polarity in epithelial cells. By imaging cells that have polarized in this 3-D context, new insights into the development and maintenance of epithelium becomes possible. Technical aspects for culturing and imaging MDCK 3-D culture for both fixed 3-D cultures and live-cell imaging are discussed.

UNIT 4.23 describes the technique known as Interference Reflection Microscopy (IRM). This technique uses the interference of reflected light waves to generate images with high contrast and definition. Although it is most useful for examining sites of close contact between a cell and substratum, IRM can be used to examine almost any cell attached to

a glass surface. The unit discusses optimal ways of obtaining IRM images using a laser scanning confocal microscope (LSCM). In addition, techniques are presented for imaging fixed and live cells, as well as simultaneous multi-channel capture of fluorescence and reflection images.

UNIT 4.24 focuses on fluorescence correlation spectroscopy (FCS), a technique that uses single-molecule fluorescence to monitor molecular dynamics in living cells. Practical methods are presented for expressing fluorescently labeled proteins and lipids to determine the diffusion timescales and the total number of diffusing fluorescent molecules in the cell. A step-step protocol for performing FCS with a commercial spectroscopy/microscopy system, the Zeiss Confocor 3, is provided, as well as instructions on how to set up live-cell FCS experiments, acquire reliable data, and analyze the data.

UNIT 4.25 describes imaging approaches for analyzing mitochondrial dynamics and function. Mitochondria serve many important cellular functions, including roles in aerobic metabolism, lipid modifications, redox balance, calcium maintenance, and controlled cell death. Mitochondria are motile and highly dynamic organelles due to their ability to undergo fission and fusion among themselves. This unit describes three imaging techniques useful for characterizing mitochondrial dynamism and membrane potential in living cells. The first technique, time-lapse confocal imaging of mitochondria, permits high-resolution, three-dimensional images of mitochondria to be obtained in live cells. The second technique, fluorescence recovery after photobleaching (FRAP), enables the connectivity among mitochondrial elements across the cell to be assessed. The third technique, microirradation of mitochondria loaded with a membrane, potential dye, permits analysis of mitochondrial membrane potential and its loss of potential upon local depolarization of mitochondrial membrane.

Chapter 4 also contains the Organelle Atlas, which is a collection of figures that shows organelles of the cell visualized using a variety of reagents and techniques.

Jennifer Lippincott-Schwartz

Proper Alignment and Adjustment of the Light Microscope

Optical microscopes can be powerful tools in biomedical research and diagnosis if properly aligned and adjusted. This is essential for optimal image quality and accurate quantitative measurements. Video cameras, digital cameras, and electronic image processing can improve visibility of structural detail resolved by the microscope optics in comparison to viewing by eye. However, the quality and accuracy of the image still depends critically on proper microscope alignment and adjustment.

This unit presents protocols for alignment and adjustment of a typical research compound light microscope for transillumination and epi-illumination imaging modes typically used today in biomedical research. The transillumination light modes include bright-field, phase-contrast, and differential interference contrast (DIC). The primary epi-illumination mode is fluorescence microscopy.

The described procedures are for alignment of a research upright microscope (Fig. 4.1.1). The procedures are applicable to inverted microscopes that have similar imaging and illumination light paths to the upright microscope. In either case, the specimen image is produced by an objective lens and the image is projected either to the eye with an eyepiece or to a camera with (and sometimes without) a projection lens. One lamp attached to the back of the microscope provides light for transillumination of the specimen through a condenser lens (Fig. 4.1.2 and Fig. 4.1.3). Another lamp attached to the back of the microscope provides light for epi-illumination of the specimen through the objective using a mirror in a filter cube to bring the illuminating light into the objective light path (Fig. 4.1.4). For both the transillumination and epi-illumination paths, there are field diaphragms for controlling the specimen region illuminated and condenser diaphragms for controlling illumination from the condenser. The lamps, the field diaphragm, and the condenser diaphragm, as well as the condenser and the objective, must be properly focused and centered for the best image formation. In addition, each different mode of image formation has special optical components that also require alignment and adjustment for optimal performance.

The first section in this unit (see discussion of Major Components of the Light Microscope) describes the location and basic functions of the most important features of the upright compound microscope. The second section (see discussion of Basic Imaging and Köhler Illumination Light Paths For Bright-Field and Fluorescence Microscopy) introduces the imaging and illumination light paths of the microscope and describes the principles of Köhler illumination, which is the alignment used typically for both transillumination and epi-illumination in the light microscope. Basic Protocol 1 lists steps in microscope alignment for transmitted-light Köhler illumination. Basic Protocol 2 lists steps in microscope alignment for epifluorescence Köhler illumination. Basic Protocols 3 and 4 provide brief descriptions of the principles of image formation and microscope alignment for phase-contrast and differential interference contrast (DIC) microscopy; these optical modes produce contrast of transparent specimens using transmitted-light illumination. Support Protocol 1 deals with mating cameras to the microscope and Support Protocol 2 deals with calibrating image magnification. Several procedures (see Support Protocols 3, 4, and 5) are given for testing the optical performance of the microscope; these also describe test specimens for microscope performance and their sources. Finally, Support Protocol 6 deals with the care and cleaning of microscope optics. The Commentary refers the reader to references that provide more comprehensive

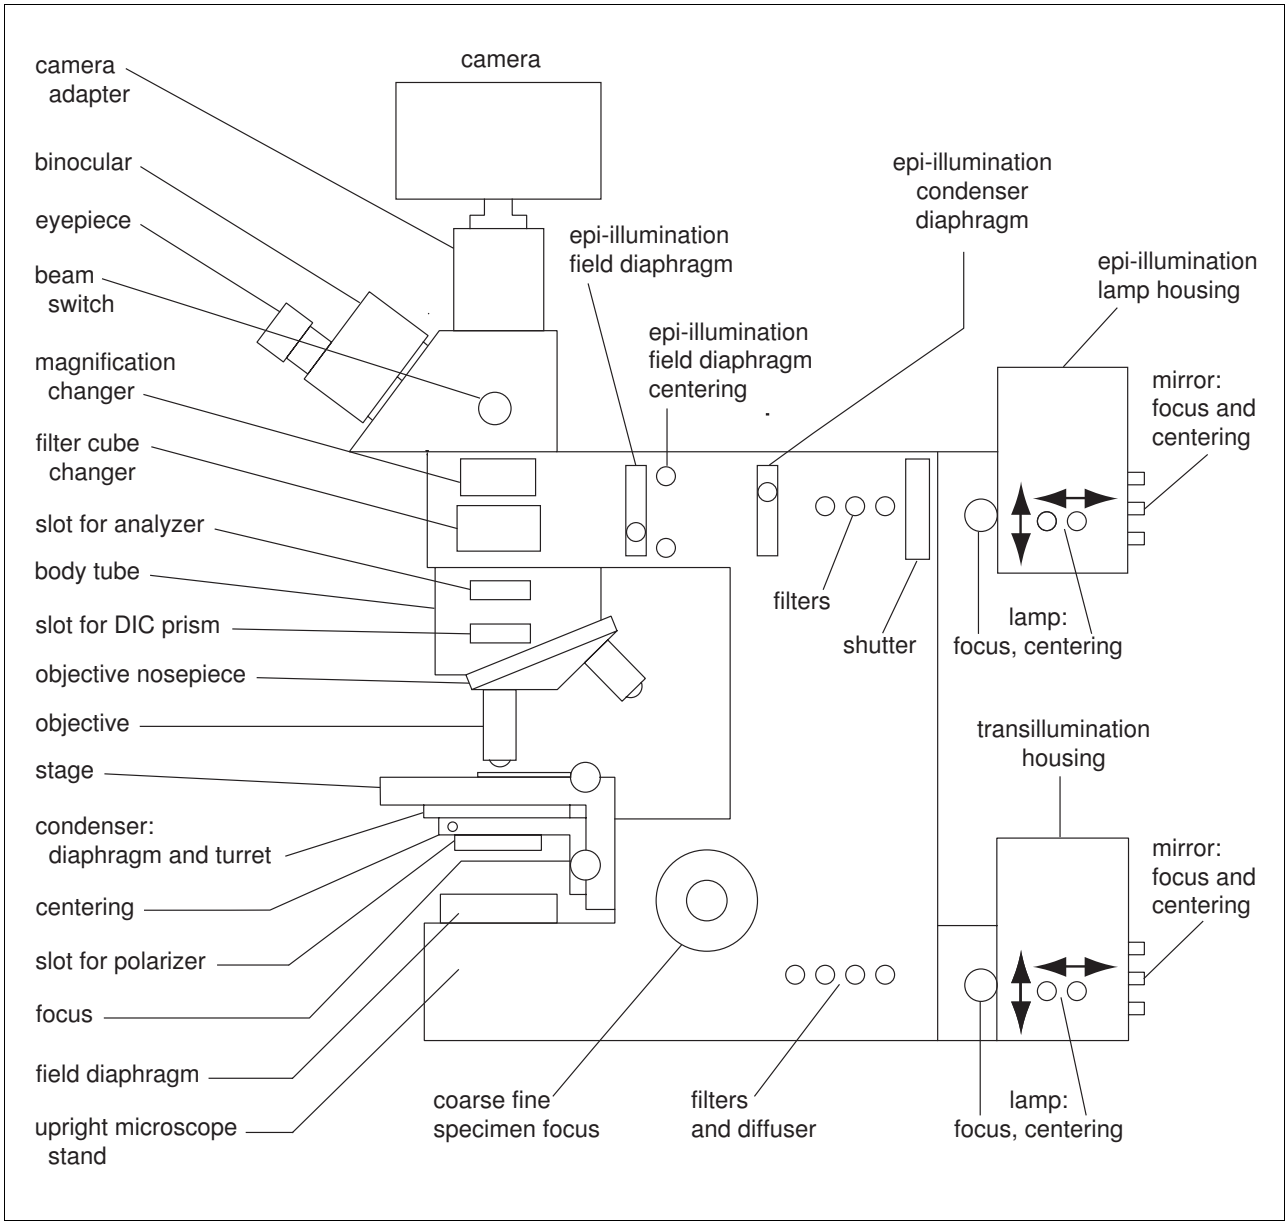

Figure 4.1.1 Diagram of the major component parts and centering screws for a research upright light microscope.

treatments of the basic modes and methods of light microscopy as well as advanced microscope imaging methods like multiwavelength, confocal, or multiphoton imaging, and electronic imaging techniques, including video and digital microscopy.

MAJOR COMPONENTS OF THE LIGHT MICROSCOPE

Familiarizing oneself with the components of the light microscope is best done using the manual for the microscope as reference. Figure 4.1.1 provides a diagram of an upright research compound light microscope equipped for both transmitted light and epifluorescence microscopy. Locate the following components on the microscope, identify their adjustment screws (if applicable) and movements (e.g., condenser focus), and ascertain that they appear correctly mounted. In this and the following sections, z is a direction along the microscope axis; x and y are perpendicular directions.

Image-Forming Components

Specimen stage and focus

A mechanical carrier on the stage holds the specimen slide. Knobs control movement in the *x*–*y* direction. Look for the vernier scales that mark the *x* and *y* positions. Rotatable stages are typically used for DIC microscopy. The objective is usually fixed and the specimen is focused by moving the stage along the *z* axis using coarse- and fine-focus knobs on the microscope body. Check the scale on the fine focus. On research microscopes, this is usually is 1 μm/unit.

Objectives and revolving nosepiece

Examine the different objectives on the nosepiece. Each objective is usually labeled with the following designations: magnification (e.g., 60×); the degree of optical correction (Apochromat is better than Fluor which is better than an Achromat); the label Plan (if both the center and edges of the field are in focus); numerical aperture (NA, which measures the half-angle of the cone of light from the specimen accepted by the objective; Fig. 4.1.3); immersion medium to be used (e.g., air, oil, water, or glycerin between the objective front lens and the specimen); coverslip thickness; optical tube length (previously 160 mm, currently infinity); and other special features like phase contrast, DIC, or long working distance. Working distance refers to the distance from the front element of the objective to the specimen. Working distance usually decreases with increasing objective magnification and NA. Check that the objectives are mounted in series from the objective of the lowest magnification to the objective of the highest magnification. It is usually best to find the specimen or region of a specimen with a low-magnification objective, and then swing in objectives with higher magnifications and shorter working distances. The high-NA, short-working distance oil-immersion objectives often have the ability to lock up the nosepiece when changing objectives. This prevents running the front element of the objective into the mounting medium on the edges of the coverslip. Check that the nosepiece is down for imaging.

Specimen slides and coverslips

Microscope condenser lenses are usually corrected optically for 1-mm-thick glass slides. The objectives are corrected optically for coverslips with a thickness of 0.17 mm; no. 1.5 coverslips are on average this thick. The image quality decreases for thinner (e.g., no. 1) or thicker (e.g., no. 2) coverslips, particularly for non–oil immersion ("dry") objectives with high NA. For oil-immersion objectives, this problem is not critical when the refractive index of the oil and coverslip (~1.515 to 1.52) match. Coverslips thinner than no. 1.5 are often used with oil immersion, to allow greater range of focus.

Body tube

In the modern research light microscope, the imaging light leaving the objective and nosepiece is unfocused and the image is projected to "infinity" (Fig. 4.1.2, left). This infinity space above the objective allows insertion of filters without changing the focal position of the image at the intermediate image plane. A positive focusing lens, the tube lens, above the infinity space, is used to bring the imaging light into focus for the eyepieces or camera.

Check for the following possible inserts in the infinity space of the microscope.

1. DIC prisms for the DIC objectives, which are usually right above the objective.
2. Analyzer; used for DIC microscopy (which should be removed from the light path for bright field, phase-contrast, and fluorescence microscopy).

3. Epi-illuminator filter-cube changer. These devices usually hold 2 to 4 filter cubes for fluorescence microscopy, each of which contains an excitation filter, an emission filter, and a dichroic mirror (Fig. 4.1.4) designed specifically for different fluorophores. Check the numbers on the filter cubes and mark the corresponding positions on the outside of the filter changer to identify the proper cube position for a given fluorophore.
4. Magnification changer and Bertrand lens. Body tube magnifications are selected from a turret, and possible values are 1.0×, 1.25×, 1.5×, and 2.0×. Often one position of the turret contains a Bertrand lens. This lens is used in combination with the eyepieces to produce a telescope view of the objective back focal plane (Fig. 4.1.2, far right). This is an important device for checking that the lamp image is centered and in focus during alignment for Köhler illumination, and for adjustment of the condenser diaphragm (see discussion of Transillumination Components).

Beam switch

This device switches the light between the binocular and the camera port. Check for the percentage of light in each direction. For fluorescence microscopy, it is important to be able to send 100% of the imaging light either to the eye or to the camera.

Eyepieces

Eyepiece magnification to the eye is marked on the barrel (e.g., 10×). Note that there are two and maybe three adjustments. The interpupillary distance for the eyes is adjusted by grasping the bases of the eyepiece tubes and moving them closer or further apart. At least one of the eyepieces is adjustable so that the eyes are parfocal.

Camera adapters

Check the type of camera adapter and whether it matches the detector. There are several different types of camera adapters. One type uses an eyepiece tube (not the binocular tube) and a projection eyepiece combined with a camera lens to project an image onto the camera detector. This method is common in photographic film cameras (which use ≥35-mm film) and for some video cameras with large-size detectors (e.g., 1-in., equivalent to 2.54-cm). The recent video and cooled slow and progressive scan charge-coupled device (CCD) cameras have small detectors (≤⅔ in., equivalent to 1.7 cm). These cameras require smaller projection magnifications or none—in the latter case the detector is mounted at the intermediate image plane, the focal plane of the objective (Fig. 4.1.2), and no eyepiece or projection lens is used.

Transillumination Components

Lamp and housing

The lamp is typically a low-voltage 100-W quartz halogen bulb with a tungsten-filament light source and variable control. Some lamp housings have no adjustments for centering the bulb; the socket is prefixed. Most lamp housings have *x*–*y* adjustments for the bulb socket, while an advanced lamp housing also has a mirror in the back for reflecting an image of the lamp back along the microscope axis. This mirror usually has adjustments for *x*, *y*, and *z* positions of the mirror image of the lamp. There is usually a knob on the side of the lamp housing for moving the collector lens back and forth along the *z* axis to focus the tungsten-filament image onto the condenser diaphragm plane.

Diffuser and filters

A diffuser and other filters are often inserted in slots in the base of the microscope. The diffuser helps spread the image of the source at the condenser diaphragm plane in order to uniformly fill the condenser aperture. This is important for achieving high resolution.

A heat-reflecting filter (e.g., BG 58) blocks infrared light. Video cameras, but not the eye, are often sensitive to this wavelength of light. A green filter is frequently preferred for illuminating living cells. High-efficiency interference filters with a 40-nm bandwidth around 540 nm are often best. Various neutral-density (ND) filters, which are not wavelength selective, are useful for attenuating light to cameras.

Field diaphragm

This is usually located just above or beneath the mirror that deflects the light up to the condenser lens. It controls the specimen area illuminated by the condenser (Fig. 4.1.2, left).

Polarizer

This is inserted below the condenser diaphragm for polarization and DIC microscopy. Otherwise, it is removed from the light path.

Condenser focus knob

This translator moves the condenser along the microscope *z* axis to focus an image of the field diaphragm on the specimen.

Condenser centering screws

There are usually two screws on the condenser carrier which move the condenser in an *x–y* plane. These screws are used to center the image of the field diaphragm on the *z* axis.

Condenser diaphragm

The condenser diaphragm is located on the bottom of the condenser. It controls the angle (NA) of the condenser cone of illumination of the specimen (Fig. 4.1.3).

Condenser turret

Condensers have turrets with inserts for special image-contrast techniques such as phase-contrast and DIC microscopy. Each insert matches certain objectives. In phase-contrast microscopy, the inserts are annuli of different diameters designed to match the phase ring in phase-contrast objectives (Fig. 4.1.5). For DIC, the inserts are typically DIC prisms designed for certain objectives (Fig. 4.1.7). To see these inserts, as well as the opening and closing of the condenser diaphragm, remove the condenser from the condenser carrier by loosening the locking screen and turning it upside down.

Condenser lens

The condenser's main function is to provide bright, uniform illumination of both the specimen field (Fig. 4.1.2, right) and objective aperture (Fig. 4.1.3) for objectives with different NAs. Check the markings on the condenser to see if it is designed for air (dry) or oil immersion with the glass slide. Dry (no oil-immersion) condensers have NA values of ≤0.9 and should not be used with immersion oil. Oil-immersion condensers usually have NA values of 1.0 to 1.4 when using immersion oil.

Epi-illumination Components

Lamp and housing

The light source for the epifluorescence illumination is typically an HBO 50-W or HBO 100-W mercury arc lamp or a xenon lamp of similar wattage. These lamps need to be handled with care because they can blow up if mistreated. Their glass envelopes should be carefully cleaned with 70% ethanol before installation to prevent fingerprints or other materials from inducing hot points that may result in fracturing of the bulbs. Look for the adjustment screws to adjust the *x–y* position of the lamp. Look also for the rear mirror

and its *x*, *y*, and *z* adjustment screws. Identify the focusing knob for the lamp collector lens. Do not turn the lamp on until the bulb has been installed according to the manufacturer's instructions, the collector lens has been inserted properly, and the lamp housing has been installed on the back of the microscope. These lamps produce intense light, and the mercury bulbs have large peaks in the UV range. Therefore, UV-protective glasses should always be worn when handling and installing these lamps. The light intensity decreases and the probability of explosion increases with the number of hours of operation and lamp starts. Check the timer on the lamp power supply to see that the recommended limits are not exceeded.

Shutter
Photobleaching is a big problem in fluorescence microscopy. A shutter is used to block the light from the specimen when not taking exposures on a camera or viewing by eye.

Filters
A heat-reflecting filter is used to prevent infrared illumination of the specimen and to keep infrared scattered light from reaching the camera. Neutral-density (ND) filters are used to reduce the light intensity of fluorescence illumination by the amount indicated on each filter.

Epi-illumination condenser diaphragm
This diaphragm provides variable adjustment of the illumination intensity. Some microscopes lack this diaphragm.

Epi-illumination field diaphragm
This diaphragm controls the area of the specimen illuminated. Look for the centering screws that control the *x*–*y* position of the field diaphragm.

Filter cubes
See discussion of Image-Forming Components.

BASIC IMAGING AND KÖHLER ILLUMINATION LIGHT PATHS FOR BRIGHT-FIELD AND FLUORESCENCE MICROSCOPY

The second major step in learning proper alignment of the light microscope is to understand the basic image-forming and Köhler illumination light paths and the functions of the key optical components and diaphragms. These are outlined in Figure 4.1.2, Figure 4.1.3, and Figure 4.1.4.

Imaging-Ray Paths

The upper left section of Figure 4.1.2 shows ray paths for the image-forming light from the objective. The objective, in combination with the tube lens, produces a real, magnified image of the specimen at the intermediate image plane. The eyepiece provides a second stage of magnification to the eye. The magnification to the eye is the product of objective magnification and eyepiece magnification multiplied by any magnification provided by additional lenses in the body tube of the microscope between the objective and the eyepieces.

When a camera detector—film, video, or charge coupled device (CCD)—is mounted at the intermediate image plane, the magnification to the camera is the magnification produced by the objective and body tube. When a camera is mounted above an eyepiece, then the unfocused light leaving the eyepiece must be focused onto the camera detector by a camera lens, which modifies the total magnification to the detector. Special adapters (see Image-Forming Components, Camera adapters) are also available for projecting the

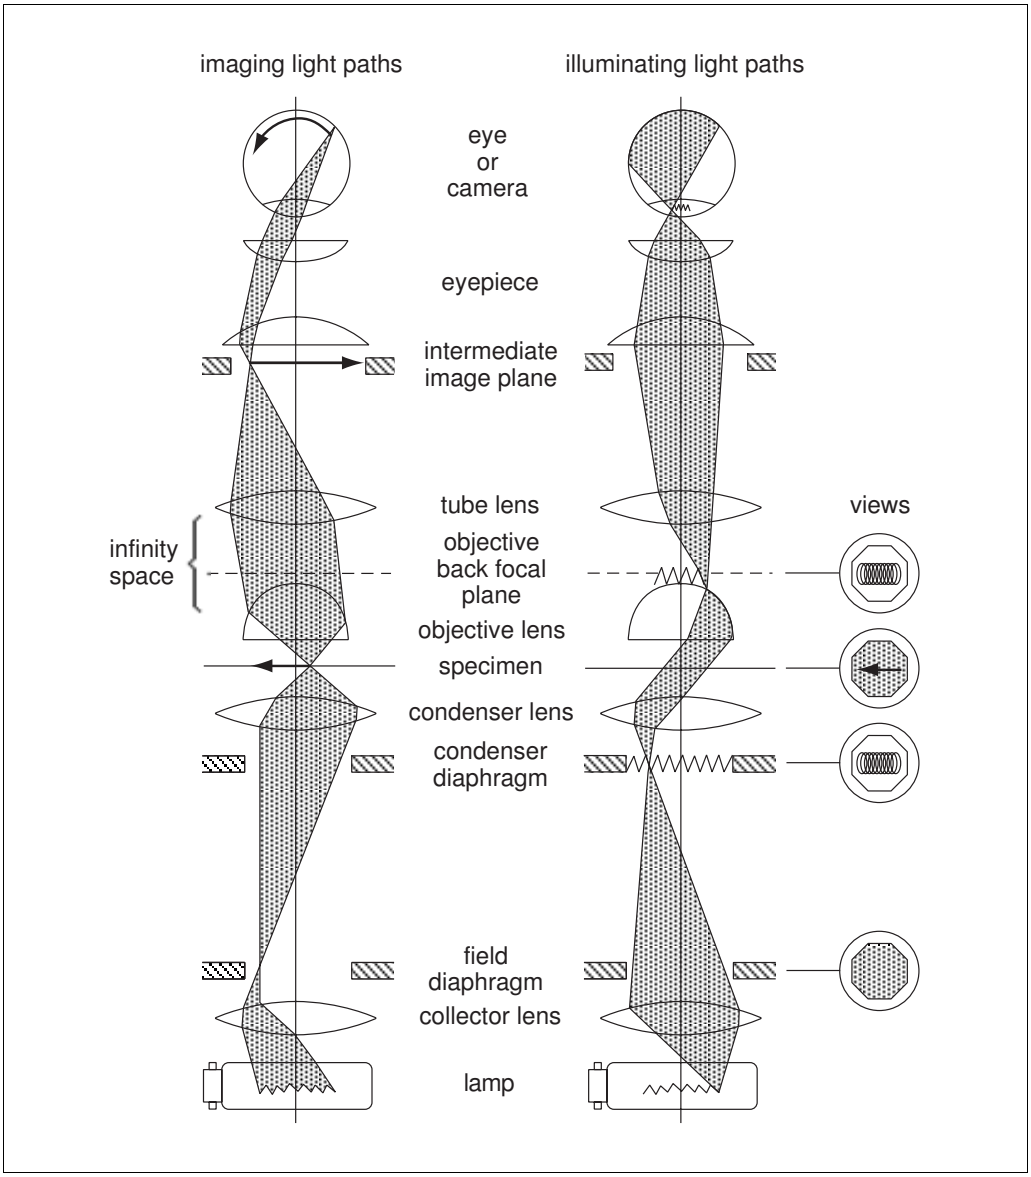

Figure 4.1.2 The imaging and illuminating light paths for a bright-field microscope aligned for transmitted light Köhler illumination. Modified from Keller (1998).

objective image onto a camera detector with magnification, but without the need for an eyepiece.

Transillumination Ray Paths

In the illustration of the standard Köhler method (Fig. 4.1.2), trace the illumination ray paths for a bright-field microscope aligned for Köhler transillumination (right side). A point on the light source is focused by the lamp collector lens onto the front focal plane of the condenser lens, where the condenser diaphragm is located. This light is projected, out of focus, through the specimen by the condenser lens, producing uniform illumination of the specimen. The objective collects the unfocused illumination light and brings an image of the light source into focus at its back focal plane, which is at the back aperture of the objective (Fig. 4.1.3). The light source is again out of focus at the intermediate image plane and at the retina of the eye or the detector of the camera. In between these two points, the light source is in focus at the exit pupil of the eyepiece, at a position ~15

mm above the eyepiece. This position is also called the eyepoint, the position of eye placement above the eyepiece (Fig. 4.1.2, right).

The condenser diaphragm controls the NA (cone angle) of specimen illumination by the condenser lens (Fig. 4.1.3). Opening the diaphragm increases the aperture of illumination, which increases both the light intensity and resolution in bright-field light microscopy (see Support Protocol 3). Note on the right side of Figure 4.1.2 that the image of the condenser diaphragm is in focus where the lamp image is in focus along the microscope axis, at the objective back focal plane and the exit pupil of the eyepiece.

Trace the imaging light rays from the field diaphragm through the microscope (Fig 4.1.2, left). Note that the field diaphragm controls the specimen area illuminated by the condenser. Note also that the field diaphragm is placed between the lamp collector lens and the condenser lens in a plane where the lamp image is out of focus (compare Fig. 4.1.2, left and right). When the condenser lens has focused the image of the field diaphragm onto the specimen, then the field diaphragm will be in focus with the specimen at the intermediate image plane and at the eye or detector.

Epi-illumination Ray Paths

Figure 4.1.4 shows the optical alignment for an epi-illuminator and Köhler illumination through the objective. As in transillumination (Fig. 4.1.2), the light source is focused by a collector lens onto the condenser diaphragm of a condenser lens in the light path. The condenser lens illuminates a field diaphragm. Another lens collects this light and projects it off a reflective mirror into the objective. The image of the light source is focused at the back focal plane of the objective so that it is out of focus at the specimen plane. In epifluorescence microscopy, filter cubes containing dichroic mirrors are used in combination with excitation and emission filters to efficiently reflect the excitation light into the objective and transmit to the eyepiece or camera only the longer-wavelength fluorescent light emitted from the specimen (see *UNIT 4.2* and Taylor and Salmon, 1989).

BASIC PROTOCOL 1

ALIGNMENT FOR KÖHLER ILLUMINATION IN BRIGHT-FIELD, TRANSMITTED LIGHT MICROSCOPY

The following procedures assume that the positions of the quartz-halogen tungsten filament and collector lens are adjustable. Inexpensive, non-research compound microscopes may have the illuminator built into the stand, with no adjustment for the lamp. Such microscopes depend on a ground-glass filter for even illumination. For these microscope stands, skip steps 2, 3, 4, and 8.

Focus the light source

1. If possible, remove the diffusion filter in the transillumination pathway during alignment so that a crisp image of the light source can be viewed at the condenser diaphragm plane and at the objective back focal plane. When alignment is complete, reinsert the diffusion filter.

2. Center and focus the lamp filament near the condenser diaphragm plane. Remove the condenser lens. Place a sheet of lens paper on the microscope stage. Close down the field diaphragm and adjust the intensity of the lamp so that the lens paper is moderately illuminated. Use the lamp-focusing knob to move the condenser lens (or lamp) along the *z* axis until an image of the filament is in focus on the lens paper. Roughly center the lamp on the microscope axis with the adjustment screws on the lamp housing, then adjust the mirror image (if there is a mirror) using its adjustment screws on the lamp housing.

Table 4.1.1 Suppliers for Items Used In Light Microscopy

Test specimen	Supplier
Hematoxylin/eosin-stained skeletal muscle	Carolina Biological Supply
Diatom test plate	Carolina Biological Supply
Squamous cheek cells	Freshly prepared (see Support Protocol 4)
Stage micrometer	Fisher
Red, green, and blue fluorescent tissue culture cells	Molecular Probes

3. Place the lens paper on the condenser carrier and raise the condenser carrier until it is ~20 mm from the top of the stage.

   This is the approximate position of the condenser diaphragm when a condenser is installed and in focus.

4. Refocus the lamp and mirror images at this position of the lens paper.

   If there is no mirror image, center the lamp image. If there is a mirror image, then position the images so that they sit side by side to fill the condenser aperture. Remove the lens paper and replace the condenser.

Focus for low-power viewing

5. Obtain an in-focus image of a specimen with the low-power objective (10× or 16×) by placing a test specimen that absorbs light on the stage (e.g., stained muscle section; see Table 4.1.1).

   The focus position can be estimated from the working distance of the objective lens. For a standard 10× lens, this is ~4 mm. So, use the coarse focus to bring the specimen to ~16 mm from the coverslip by viewing the objective position from the side of the microscope.

6. Move the condenser lens up close to the lower surface of the slide and open the field and condenser diaphragms all the way. Look down the eyepieces, and use the coarse- and fine-focus knobs to bring the specimen into sharp focus.

7. Focus the image of the field diaphragm centered on the specimen by adjusting the condenser *x–y* screws and the condenser focus. Initially close down the field diaphragm until an edge of the image can be focused by the condenser, then close the field diaphragm further as the image is centered, using the *x–y* translation screws.

   Usually, the field diaphragm is opened just enough to match the field of view in the eyepiece or the camera. However, the best image contrast is obtained if the field diaphragm is opened just enough to illuminate the region of interest. This eliminates the presence of scattered light from outside the region of interest.

8. Center an in-focus image of the lamp and mirror images at the objective back focal plane using the focus and adjustment screws on the lamp housing. View the objective back aperture (the position of the back focal plane; Fig. 4.1.3) by using the Bertrand lens in the magnification changer in combination with the eyepieces, by replacing one eyepiece with a telescope, or by simply removing one eyepiece and peering down the body tube. Open the condenser diaphragm all the way. Readjust the collector lens and the mirror so that the lamp images are in focus and sit side by side to fill the objective aperture.

   This is a rough adjustment with the low-power objective and will need to be fine-tuned using the objective with the highest NA.

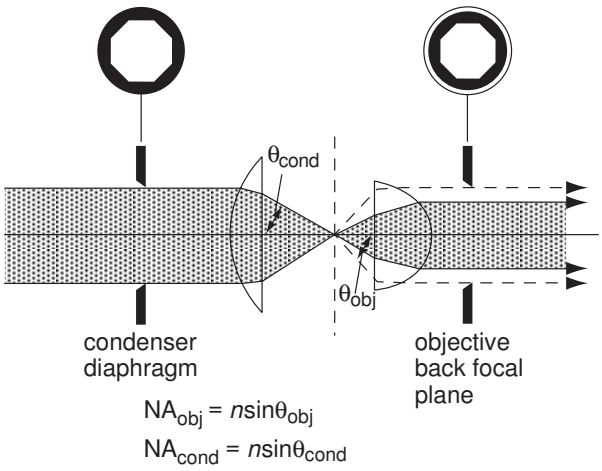

Figure 4.1.3 Numerical aperture (NA) of objective light collection and condenser illumination. The objective numerical aperture (NA_{obj}) depends on the angle of the cone of light from the specimen, which is accepted by the objective aperture while the numerical aperture of condenser illumination (NA_{cond}) is controlled by the condenser diaphragm and limited by the maximum NA of the condenser when the condenser diaphragm is wide open.

9. Adjust the opening of the condenser diaphragm so that the diameter of its image at the objective back focal plane (see far right of Fig. 4.1.2; also see Fig. 4.1.3) is slightly less than the diameter of the objective back aperture.

   Some research condensers also have centering adjustments for the condenser diaphragms. The image of the condenser diaphragm should be centered in the objective back aperture.

10. Adjust the light intensity for comfortable viewing of the specimen by adjustment of the light-source intensity, either using the power-supply rheostat or by inserting neutral-density filters in the illumination light path.

    The microscope is now adjusted properly for the low-power objective.

Adjust for 40× viewing

11. Switch the turret to the 40× high-dry objective.

    Note that because of parfocal objective design the specimen is almost in focus. Focus on the specimen with the fine focus.

12. Focus and center the field diaphragm with the condenser focus and the condenser-carrier *x*–*y* adjustment screws.

13. View the objective back aperture (Fig. 4.1.3).

    Notice that the image of the condenser diaphragm adjusted for the low-power objective is only about half the diameter of the 40× back aperture. The ratio of the diameter of this image to the diameter of the objective back aperture is equal to the ratio of the NA of the condenser illumination to the NA of the objective (Fig. 4.1.3). When the condenser illumination NA equals the objective NA, the aperture of the objective is filled with light and maximum resolution will be achieved for the objective NA (see Commentary).

14. Adjust the condenser diaphragm so that the condenser illumination NA just about matches the objective NA.

    Each time objectives are changed, these procedures should be repeated.

Adjust for high-power viewing

15. Rotate the nosepiece so that the high power (60× to 100×, NA 1.25 to 1.4) oil-immersion lens is coming into place, but stop before it clicks into place. Place a small drop (~2 mm diameter) of immersion oil directly onto the coverslip above the point upon which the condenser beam is focused.

    This oil drop must be free of air bubbles and dirt. The refractive index of the immersion oil should be close to that of the glass coverslip.

16. Complete the rotation of the nosepiece so that the oil-immersion objective clicks into place. Lower the objective nosepiece if appropriate.

    The space between its front lens and the coverslip is now filled with immersion oil.

    IMPORTANT NOTE: *Use only the fine adjustment knob when working with the oil-immersion lenses.*

17. Remove the eyepiece (or use the telescope or Bertrand lens) and inspect the back aperture of the objective. Open the condenser diaphragm as much as possible to try and match its image with the objective aperture (Fig. 4.1.3).

    This will be impossible if the condenser is dry and not designed for oil immersion, since dry condensers have NA ≤0.9 and the relative size of the image of the condenser aperture or condenser diaphragm seen in the objective back focal plane is given by the ratio of NA_{cond}/NA_{obj} *(Fig. 4.1.3).*

18. View the objective back aperture and tune up the focus and position of the lamp images so that they fill the objective aperture with light as uniformly as possible.

19. Replace the eyepiece (or remove the Bertrand lens) and examine the specimen. Adjust the field diaphragm until its margins just match the field of view.

    With inexpensive condensers, the image of the edge of the field diaphragm will not be in good focus, even at the optimum position. If a condenser designed for oil immersion is being used, enormous improvement in the field iris image can be achieved by oil immersion.

20. Oil the condenser (if possible) to achieve the highest resolution and image quality. To oil a condenser, rotate the objective out of the way, remove the slide, oil the condenser (it takes much more air-bubble-free oil than the objective), then replace the slide and refocus the objective.

    Before oiling the condenser, make sure it is not designed to be a "dry" condenser by checking that it is marked with an NA >0.9.

    The image of the field diaphragm should now be much sharper when in focus and centered.

21. Look at the objective back aperture. Again, tune up the focus and position of the lamp images so that they fill the objective aperture with light as uniformly as possible.

    After oiling, the aperture should be filled by the condenser illumination when the condenser diaphragm is wide open.

    Notice also that viewing the objective back aperture is the best way to see if air bubbles have become trapped in the oil. If so, carefully wipe off the oil with lens paper and repeat steps 15 through 21.

22. Reinsert the diffusion glass in the illumination light path.

    This will reduce light intensity, but make the illumination of the objective aperture more uniform.

23. When finished for the day, use lens paper to remove excess oil from the objective and condenser lens surfaces to prevent dripping on specimens.

    It is not necessary, however, to completely clean oil from the optics after every use (see Support Protocol 6).

BASIC PROTOCOL 2

ALIGNMENT OF THE EYEPIECES

The binocular usually has adjustments for the inter-eyepiece distance and visual acuity in each eye. The goal is for the image to be in focus for each eye without any eyestrain or discomfort. Only the left eyepiece tube or eyepiece is adjustable on a typical microscope. However, if the microscope has a target reticle in the microscope stand that can be rotated into view, then usually both eyepieces are adjustable.

1. With a low-power objective (10× or 16×), focus on a stained specimen placed on the stage of the microscope (e.g., stained muscle section, see Table 4.1.1) and align the microscope for Köhler illumination.
2. Move the bases of the eyepiece tubes together or apart to set the proper interpupillary distance for your eyes.

3a. *If the microscope has a target reticle:* Rotate the reticle into the field of view. Close the left eye and use the diopter-adjustment ring on the right eyepiece until the target is in sharp focus for the right eye. Then close the right eye and use the diopter-adjustment ring on the left eyepiece until the target is in sharp focus for the left eye. Remove the target to view the specimen.

3b. *If the microscope has no target reticle:* Set the right eyepiece tube to the inter-eyepiece setting (if possible). Close the left eye and bring into sharp focus a structural detail near the center of the field of view with the right eye. Close the right eye and use the diopter-adjustment ring on the left eyepiece tube to bring the specimen detail into sharp focus for the left eye. With both eyes open, fine tune the focus of the left eyepiece tube.

BASIC PROTOCOL 3

ALIGNMENT FOR KÖHLER ILLUMINATION IN EPIFLUORESCENCE MICROSCOPY

The eye is most sensitive to green light. Hence, the following protocol is best done using a filter cube that produces green excitation light (e.g., a filter cube for rhodamine).

Focus the lamp

1. Remove one objective, and rotate the nosepiece so the open position is centered on the microscope axis. Place a white card on the microscope stage, on top of supports that position the card at ~2 to 3 cm from the nosepiece.

   This is approximately the position of the objective back focal plane, where the images of the light source should be in focus and centered after alignment (Fig. 4.1.4).

   Some microscopes have a special device for lamp alignment. It screws into the objective nosepiece and projects an image of the epi-illumination arc and electrodes onto a small diffusion screen within the barrel of the device.

2. Install the mercury bulb in the lamp housing and attach the lamp housing on the back of the microscope according to the manufacturer's instructions.
3. Turn on the power source and ignite the lamp.

   It takes ~10 min for the arc to brighten.

   CAUTION: *It is usually a good idea to make sure computers in the vicinity are turned off before starting the lamp because the high voltage pulse used to ignite the arc plasma may damage the electronics. Laboratory personnel should protect their eyes against UV light from the lamp.*

4. Close down the field diaphragm and open the condenser diaphragm (if there is one) all the way.

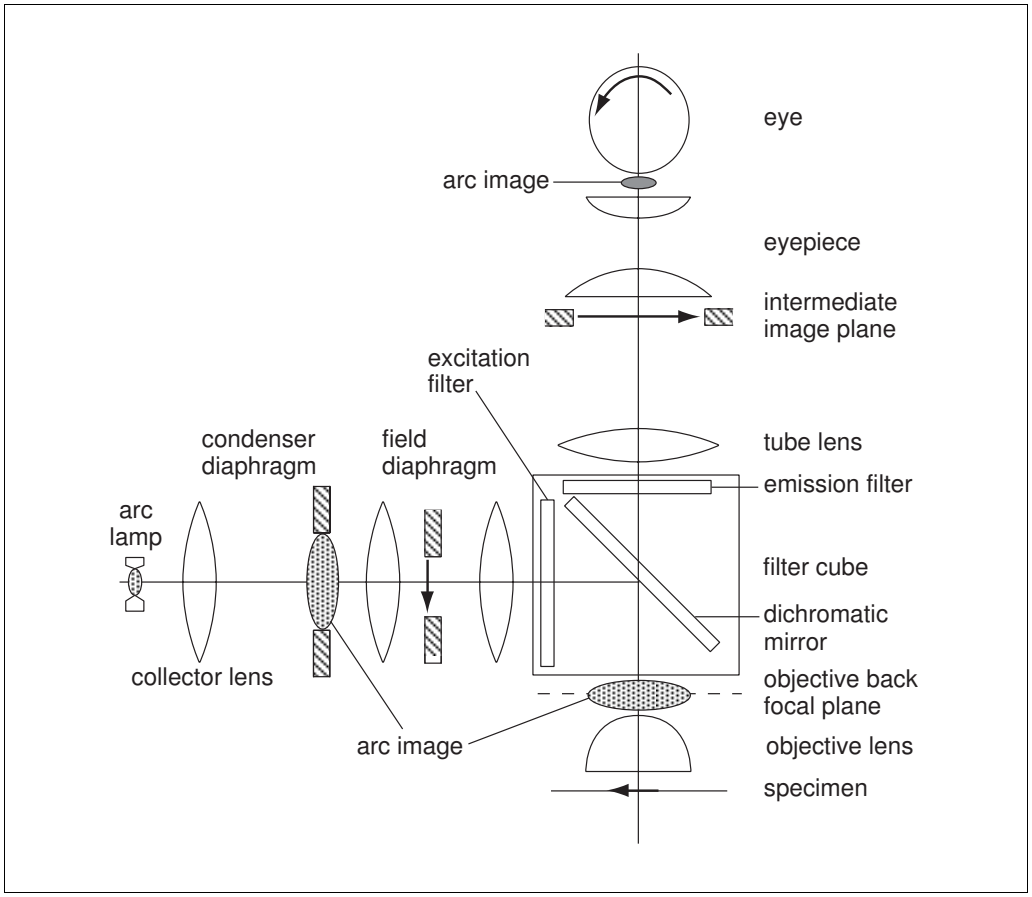

Figure 4.1.4 Microscope alignment for epifluorescence Köhler illumination.

5. On the diffusion glass screen or on the white card on the stage, the image of the arc between the tips of the two electrodes should be visible. Use the lamp focusing knob to obtain an in-focus image of the lamp arc and electrodes. Use the lamp *x–y* adjustment screws to approximately center the image of the arc and electrode tips (see Figure 4.1.2).

6. If there is a lamp mirror, use its adjustment screws to focus the mirror image of the arc and electrode tips, centered on the target.

   Often the primary image and the mirror image of the arc are adjusted side-by-side and slightly overlapping, but centered on the microscope axis.

Focus the field diaphragm

7. Place a test fluorescent specimen (see Table 4.1.1) on the stage and rotate the objective nosepiece to a low-power objective. Select the appropriate filter cube for the fluorescent specimen. Open up the epi-illuminator field diaphragm all the way. Open the shutter and view the specimen.

8. Focus the specimen, then close down the field diaphragm until an edge comes into the field of view. Use the *x–y* adjustment screws for the field diaphragm to center the field diaphragm image within the field of view.

9. Close down the field diaphragm until only the region of interest is illuminated.

   This prevents photobleaching of areas outside the region of interest and reduces the amount of scattered fluorescent light in the image from outside the region of interest.

10. Switch to a high-power objective. For an oil-immersion objective, place a small drop (~2 mm diameter) of immersion oil directly onto the coverslip above the region of interest. Carefully swing in the objective. Open the shutter and focus on the specimen. Readjust the size and centration of the field diaphragm.

    This oil drop must be free of air bubbles and dirt.

11. To prevent photobleaching, be sure to close the epi-illumination shutter when not viewing or taking camera exposures.

BASIC PROTOCOL 4

ALIGNMENT FOR PHASE-CONTRAST MICROSCOPY

Phase-contrast microscopy is often used to produce contrast for transparent, non–light-absorbing, biological specimens. The technique was discovered by Zernike, in 1942, who received the Nobel prize for his achievement (Zernike, 1942, 1955, 1958). The last of these references describes the principles of phase contrast and provides an excellent introduction to the wave optics of image formation, resolution, and contrast in the microscope.

The phase-contrast microscope is a bright-field light microscope with the addition of special phase-contrast objectives (Fig. 4.1.5) containing a phase plate or ring and a condenser annulus instead of a diaphragm; the annulus is usually located on a condenser turret because it has to be selected for different objectives. The microscope optics are usually aligned for bright-field specimen illumination by the standard Köhler method. However, there is no condenser diaphragm to adjust. Instead, the phase annulus must be selected and adjusted properly. Modern phase-contrast objectives have a phase plate containing a ring in the back focal plane within the barrel of the objective. This ring

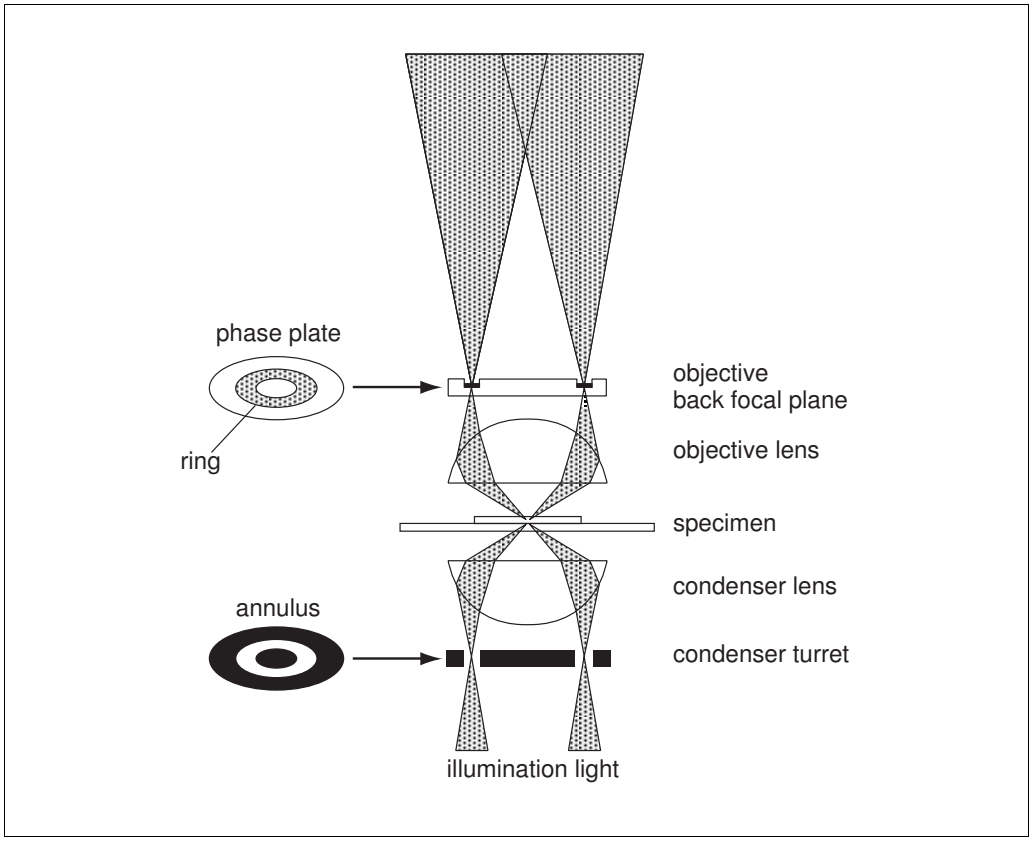

Figure 4.1.5 Illumination light path through the condenser annulus and objective phase ring in a microscope aligned for phase-contrast microscopy.

absorbs and advances the phase of the light passing through it by ¼ wavelength in comparison to light passing through the rest of the objective aperture. For each phase objective, there is a corresponding annulus in the condenser turret that has about the same relative size as the phase ring in the objective. Light passing through this annulus passes through the phase ring in the objective when the annulus is selected and aligned properly. Light scattered by the specimen mainly passes through the objective aperture outside the phase ring. Light scattered from a thin transparent specimen is ~¼ wavelength retarded from the unscattered illumination light. The additional ¼ wavelength retardation between the scattered and illumination light produced by the objective phase ring makes the scattered and illumination light 180° out of phase. They destructively interfere with each other at the image plane to produce the "dark" contrast of structural detail typical of phase contrast images of biological specimens.

Because the phase annulus and the phase ring reduce the intensity of the background light, a bright illuminator—e.g., a 100-W quartz-halogen illuminator—is necessary at high magnifications (because image intensity decreases as 1/magnification^2). For living cells, heat reflection and green illumination filters should be used.

To examine the objective phase ring and matching condenser phase annulus, remove the low- and medium-power phase objectives and the phase condenser from the microscope. View the phase ring (phase plate) within the objective by looking in the back end. The phase ring is located at the position of the objective back focal plane; its diameter is usually ~⅔ that of the objective aperture. Note that it is situated within the objective body and is visible because it absorbs light. Locate the annulus for each objective in the condenser turret. The annulus is located at the condenser diaphragm plane, which is situated at the condenser front focal plane. Notice that as the objective NA increases, the diameter of the corresponding annulus in the condenser turret increases. The NA of condenser illumination from an annulus is designed to match that of the phase ring in the corresponding objective.

Replace the condenser on the microscope and illuminate with white light. Hold a piece of tissue paper near the top of the condenser and examine the illumination cone. Notice that it is an annular cone of illumination. Change the annulus from the setting for the low-power objective to the 40× setting. Note that the NA or angle of illumination increases. Points of illumination further from the central axis in the condenser diaphragm plane produce higher-aperture rays passing through the specimen.

Perform alignment using the following steps.

1. Align the microscope for bright-field Köhler illumination using the low-power phase objective (10× or 16×) and a cheek cell preparation for the specimen (see Support Protocol 4).

   The cheek cell specimen is an excellent transparent test specimen for alignment of the microscope for phase contrast and DIC. The cheek cells are transparent and only barely visible by bright-field illumination. To find the plane of focus in bright field, initially close down the condenser diaphragm and look for the edges of air bubbles in the preparation. These edges scatter much light and appear dark in the image.

2. Align the condenser annulus with the phase ring by rotating the condenser turret to the position where an annulus matches the phase ring in the objective; use the telescope, your eye, or the Bertrand lens to view the objective back aperture.

   As the condenser turret is rotated, notice in the objective back focal plane the images of the different-diameter annuli designed for the different numerical aperture objectives. The correct annulus may not be properly aligned with the objective phase ring.

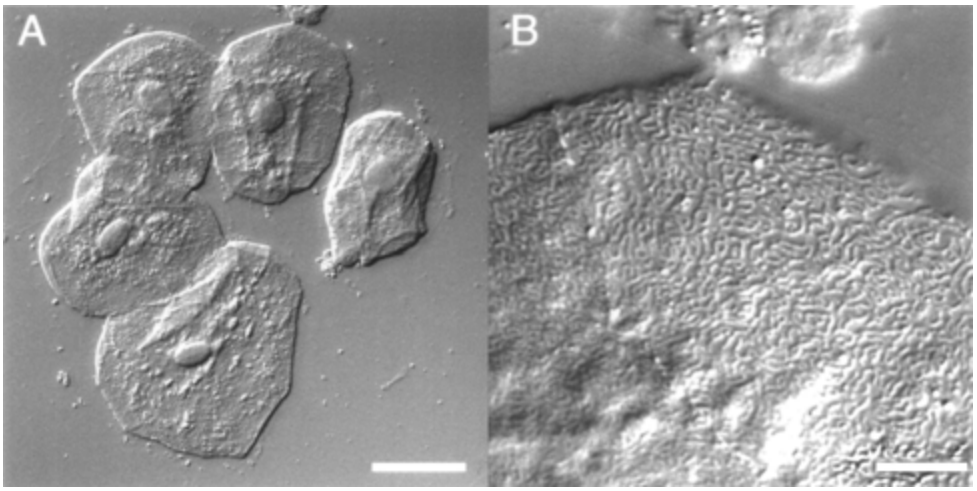

Figure 4.1.6 DIC images of a human cheek cell test specimen. (**A**) Low magnification of cheek cell preparation with a 20× objective. Bar = 20 µm. (**B**) High-resolution image of the surface of the cell at the top of (A) using a 60×/(NA = 1.4) Plan Apochromat objective and matching condenser ilumination. The ridges on the cell surface are often diffraction limited in width. Bar = 5 µm. From Salmon and Tran (1998), reprinted with permission from Academic Press.

3. Use the adjustment screws in the condenser (and the special tools if necessary) to move the annulus in the *x*–*y* plane to achieve alignment with the phase ring in the objective.

   Note that the phase ring is slightly wider than the image of the correct annulus. It is critical that the image of the annulus be within the phase ring, but it is not critical if it is very slightly off center.

4. When the objective phase ring and condenser annulus are aligned, view the specimen and properly adjust the focus and centration of the field diaphragm.

   Notice that if the phase ring and annulus are slightly misaligned (rotate the turret slightly), the background light intensity goes up. This is because the phase ring is designed to absorb much of the illumination light. The unscattered illumination light becomes closer to the intensity of the light scattered by the specimen, which passes through the objective aperture outside of the phase ring. Minimizing the background light intensity while viewing the specimen image can also be used to align the annulus with its phase ring or to touch up the alignment done by viewing down the body tube.

5. Switch to the 40× phase objective and then the high-power 60× or 100× phase objective (NA 1.25 to 1.4) and repeat steps 1 to 4.

   It is necessary to increase light intensity at the higher magnifications. It should be possible to see the ridges on the cell surface (see Fig. 4.1.6 for a DIC image of the ridges). Notice the "phase halos" at discrete edges, a problem that limits conventional phase contrast in high-resolution imaging.

BASIC PROTOCOL 5

ALIGNMENT FOR DIC MICROSCOPY

Since its introduction in the late 1960s (e.g., Allen et al., 1969), DIC microscopy has been popular in biomedical research because it highlights edges of specimen structural detail, provides high-resolution optical sections of thick specimens—including tissue cells, eggs, and embryos—and does not suffer from the "phase halos" typical of phase-contrast images. See Salmon and Tran (1998) for details of image formation and video-contrast enhancement.

Proper Alignment and Adjustment of the Light Microscope

The DIC microscope is a bright-field light microscope with the addition of the following elements (Fig. 4.1.7, middle): a polarizer beneath the condenser; a DIC beam-splitting

prism (Nomarski or Wollaston) in the condenser turret; a DIC beam-combining prism (Nomarski) just above the objective; an analyzer above the objective prism in the infinity body tube space; a compensator after the polarizer or before the analyzer in some microscopes (not shown in Fig. 4.1.7); and a rotatable stage. The microscope optics are usually aligned for bright-field specimen illumination by the standard Köhler method.

The polarizer, which produces plane-polarized light (Fig. 4.1.7, left), is typically oriented with its transmission azimuth in an east-west direction facing the front of the microscope. Polarizers with high transmission efficiency are preferred. Polarizers are usually high-quality polaroid material held between thin optical glass flats. Another polarizer is used as an analyzer. The transmission azimuth of the analyzer is oriented north-south at 90° with respect to the polarizer azimuth to produce extinction of the illumination light in the absence of the DIC prisms.

The specimen is held on a rotating stage. Contrast depends on orientation, and frequently specimens must be reoriented to achieve maximum contrast of the structures of interest. Either the stage or the objective and condenser must be centerable.

For the highest sensitivity, the objective and condenser lenses should be selected free of birefringence (Inoué and Spring, 1997). Rectifiers can be used to correct for the rotation of the plane of polarization of light which occurs at the periphery of lens surfaces (Inoué and Spring, 1997).

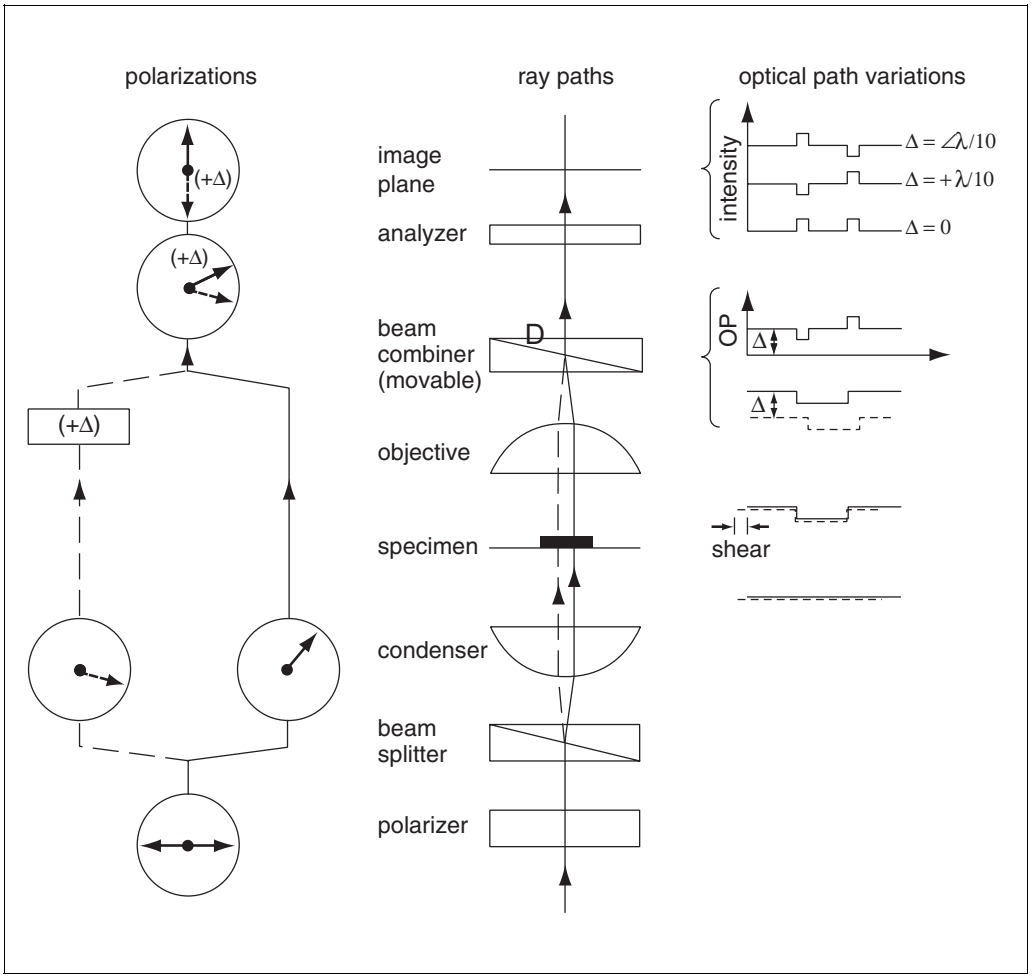

Figure 4.1.7 The optical system for DIC microscopy. From Salmon and Tran (1998), reprinted with permission from Academic Press.

Figure 4.1.7 outlines the principles of DIC image formation and contrast. The DIC beam-splitting prisms are located at the condenser diaphragm plane, just above the polarizer in the condenser turret. Objectives of different magnification and/or NA usually require condenser prisms of different optical characteristics.

The condenser prism splits the light coming from the polarizer into divergent polarized light wavefronts whose planes of polarization are orthogonal to each other and at 45° with respect to the initial plane of polarization (Fig. 4.1.7, left). The divergent beams are converted by the condenser into two wavefronts, which pass through the specimen separated laterally from each other in the direction of the prism wedge (the shear direction, Fig. 4.1.7, middle) by a tiny amount that is usually less than the resolution limit of the condenser-objective lens combination (Fig. 4.1.7, right). These two wavefronts are recombined just above the objective by a beam-combining prism. Often, each objective has its own prism so that it accurately matches the action of the condenser prism. In some microscopes, there is one beam-combining prism for all objectives and a different condenser prism for each objective. Check which is the case for your microscope.

DIC image contrast depends on the "compensation" or "bias retardation" (Δ) between the two wavefronts along the microscope axis (Fig. 4.1.7, right). When the objective beam-combining prism is perfectly aligned with the condenser beam-splitting prism and there is no compensation ($\Delta = 0$), the background light is extinguished and the edges of objects are bright against a black background (Fig. 4.1.7, upper right). When one wavefront is retarded relative to the other by Δ, this increases the optical path (OP) between the wavefronts (Fig. 4.1.7, middle right) and brightens the background light. One edge of an object becomes brighter than the background while the opposite edge becomes darker (Fig. 4.1.7, upper right). This produces the "shadow cast" appearance of DIC images. Reversing the sign of retardation, reverses the contrast of the specimen edges.

In some microscopes, the objective beam-combining prism (Fig. 4.1.7, middle) is used as a compensator by translating the prism in the direction of prism wedge away from the position of background light extinction. One direction produces positive while the other produces negative retardation (Δ). In other microscopes, both the objective and condenser prisms are fixed at positions that produce background light extinction, and typically a deSenarmont compensator (a birefringent quarter-wave retarder in combination with a rotatable polarizer or analyzer; Inoué and Spring, 1997) is inserted just above the polarizer or beneath the analyzer.

Bright illumination sources are required for high magnification because of the crossed polarizer and analyzer; at least the 100-W quartz-halogen illuminator is usually needed.

To examine the DIC prisms, remove the objective prisms and the DIC condenser from the microscope. Examine the objective prism. Notice that it is very thin and wide enough to cover the objective aperture. Also notice if there is a screw that can be used to translate the prism back and forth in one direction across the objective aperture. Examine the prisms in the condenser turret. Notice that there are different prisms for low- and high-NA objectives. The highest-resolution (NA) objectives often have special prisms designed only for the optical properties of that objective. In aligning the microscope for DIC, be careful to use the condenser Wollaston prism that matches the objective in use. Reinstall the condenser.

Steps 1 to 6 in the following procedure are for the initial alignment of the microscope. Once this is done, then begin at step 7 for routine use.

Perform initial alignment

1. Align the microscope initially for Köhler illumination using the low-power objective and the cheek cell preparation. Again look for the bright air-bubbles in the preparation to find the specimen plane.

2. Check that the polarizer is oriented with its transmission azimuth in an east-west direction as determined facing the front of the microscope (look for the line or double-headed arrow on the polarizer mount). Rotate the deSenarmount compensator (if there is one) so that it is at its zero position (no compensation).

3. Remove the objective prism and rotate the condenser turret to an open position. Make sure that the analyzer transmission azimuth is crossed to the polarizer by checking that the background light is at extinction.

   This exercise is best done with the brightest light position of a 100-W quartz-halogen illuminator.

4. Insert the objective DIC prism (observe caution as the image will be very bright). Observe the extinction fringe in the middle of the prism (you must use the telescope, remove an eyepiece, or insert the Bertrand lens to focus on the objective focal plane). Make a drawing of your view of the fringe in the back aperture.

   The fringe should be at 45° with respect to the analyzer-polarizer transmission azimuths.

5. Remove the objective DIC prism and rotate into place the condenser prism that matches the objective. Observe the objective back focal plane.

   The orientation of the fringe should match the orientation of the extinction fringe for the objective prism in your drawing.

6. Insert the objective prism and observe the objective back focal plane. Rotate in the other condenser prisms and notice that the extinction fringe is no longer spread across the objective aperture. Rotate in the correct condenser prism.

   If the condenser and objective prisms are properly matched and oriented in the same direction, the fringe should become spread across the objective aperture (a dark cross will still occur in high-power, unrectified objectives; Inoué and Spring, 1997).

Align for specimen viewing

7. View the specimen with the correct objective and condenser prisms in place. Translate the objective prism (or rotate the deSenarmount compensator if the objective prism is fixed) to induce a retardation (Δ) between the two wavefronts to brighten the background light and make the edges of the cell appear shaded. If possible, rotate the specimen and observe that contrast is directional—45° with respect to the analyzer-polarizer orientations.

   As the upper prism is translated (or the deSenarmount compensator is rotated) to compensation of opposite sign, the initially bright edges become darker and the initially dark edges become brighter than the background.

8. Adjust for proper bright-field, transmitted-light Köhler illumination.

   The quality of the DIC image depends critically on the field diaphragm being sharply focused on the specimen (Fig. 4.1.2, left), since this puts the condenser prism in the proper place. The highest possible resolution is achieved when the condenser diaphragm is adjusted to match the diameter of the objective aperture (view the objective back focal plane during this adjustment).

   Optimum edge contrast is produced when the retardation between the wavefronts is adjusted to extinguish the light coming from one set of edges in the specimen. Further retardation increases light intensity, but not contrast to the eye. When using video cameras,

it is often important to view the specimen by eye and adjust the compensation for best contrast, then change illumination intensity to provide the camera with enough light for good image quality.

9. Repeat steps 2 to 8 for the other objectives.

   Once you are sure of the correct prisms and their orientation, then only steps 7 and 8 are necessary for each objective.

SUPPORT PROTOCOL 1

MATCHING MICROSCOPE MAGNIFICATION TO DETECTOR RESOLUTION

This procedure uses the diatom test slide (see Table 4.1.1 for supplier information). For more details on matching a camera to the microscope see Hinsch (1998) or Inoué and Spring (1997).

1. Look down the eyepieces and obtain an in-focus image of the frustrule pores of the diatom *Pleurosigma angulatum* (Fig. 4.1.8, number 6 in panel A) using 40×/(NA ~0.7) phase-contrast or DIC and proper Köhler illumination.

   The pores should be clearly visible by eye.

2. Project the diatom image onto the faceplate of a video or CCD camera.

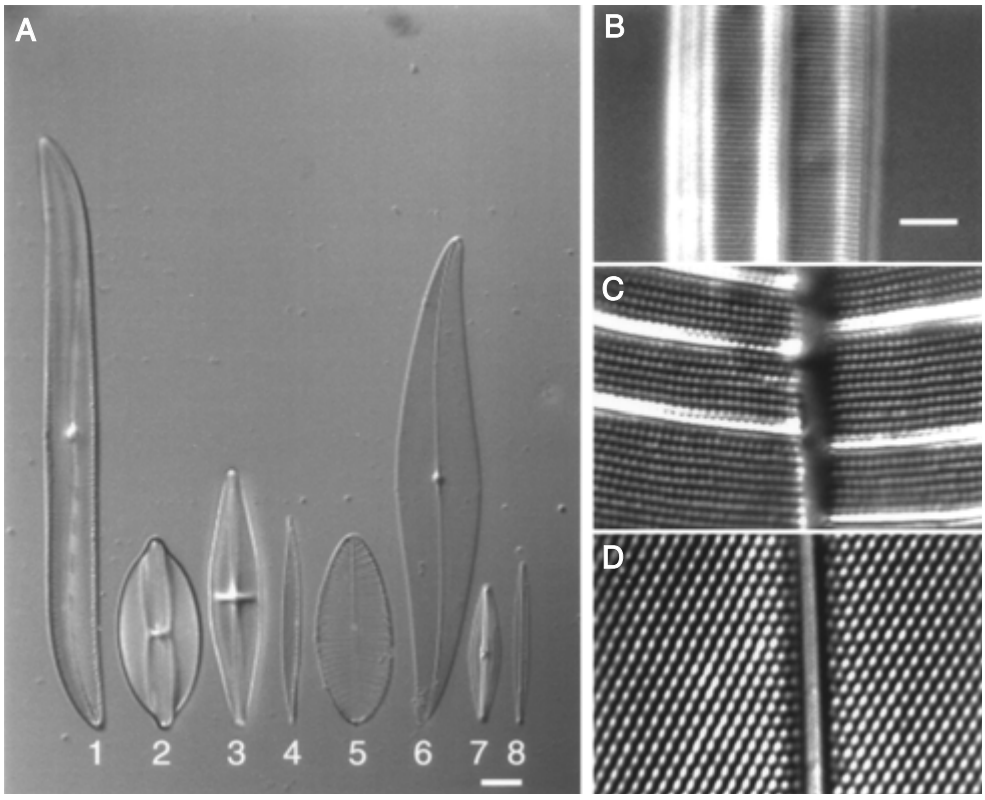

Figure 4.1.8 (**A**) The diatom test plate. The rows of pores are spaced in the silica shell by ~0.25 μm in *Amphipleura pellucida* (panel **B**; also number 8 on panel A), 0.41 μm in *Surrella gemma* (panel **C**; also number 5 on panel A), and 0.62 μm in *Pleurasigma angulatum* (panel **D**; also number 6 on panel A). Bar: panel A, 10 μm; panels B, C, and D, 2.5 μm. From Salmon and Tran (1998), reprinted with permission from Academic Press.

3. Adjust the gain and contrast camera controls for optimum image brightness and contrast.

   As you increase contrast, you will need either more camera gain or brighter illumination. Usually, a better signal-to-noise ratio is achieved by leaving the gain control in the middle of its adjustment and increasing illumination intensity.

   If the projection magnification to the detector is too small, the frustrule pore lattice will be invisible in the video image, although it will be clearly visible when viewing the image by eye.

4. Increase the magnification to the camera as much as possible.

   As magnification increases, resolution in the image becomes less limited by the resolution of the camera. However, the size of the field of view decreases inversely with magnification. In addition, the intensity of light in the image decreases as 1/magnification^2. The image will become noisy at low light intensities. It will be necessary to increase illumination intensity as much as possible at high magnification or increase the integration period for the camera exposure.

CALIBRATING IMAGE MAGNIFICATION WITH A STAGE MICROMETER

SUPPORT PROTOCOL 2

1. Insert the stage micrometer (see Table 4.1.1) on the microscope stage.
2. With the low-power objective, find the region of the micrometer with 10-μm scale intervals.

   The larger intervals are 100 μm.

3. Use the 100- or 10-μm scales to calibrate distance in images taken with your objectives.

   The magnifications on the objective barrel and projection lenses are only approximations; accurate measurements of distances in images require a calibration scale.

4. Acquire images of the scale in both the horizontal and vertical directions to check if the camera has square pixels.

TESTS FOR THE OPTICAL PERFORMANCE OF THE MICROSCOPE

Test slides are used to evaluate the performance of the microscope under different conditions.

Testing Phase-Contrast and DIC Using Diatom Testing Slide

SUPPORT PROTOCOL 3

Diatoms have silica shells shaped like pillboxes. There are pores in the shell arranged in a lattice pattern specific for each diatom species. Figure 4.1.8 shows a low-magnification view of the eight diatoms on the test slide (panel A) plus higher-magnification views of the lattices of three diatoms most useful in testing the resolution performance of microscope optics using phase-contrast or DIC. Number 6 in panel A of Figure 4.1.8, *Pleurosigma angulatum*, has a triangular pore lattice with spacing of ~0.61 μm between rows (illustrated in Fig. 4.1.8, panel D). Number 5, *Surrella gemma*, has rows of pores where the rows are separated by ~0.41 μm (illustrated in Fig. 4.1.8, panel C). Number 8 is *Amphipleura pellucida*, which has horizontal rows of pores separated by ~0.25 μm (illustrated in Fig. 4.1.8, panel B). In transmitted light, the diffraction limit to lateral resolution, *r*, is given by (Inoué, 1989):

$$r = \lambda/(NA_{obj} + NA_{cond})$$

where λ is the wavelength of light, NA_{obj} is the objective NA, and NA_{cond} is the condenser NA (see Fig. 4.1.3). The lateral resolution, *r*, is equal to 0.195 μm for the highest objective

NA, which is equal to 1.4, with $NA_{cond} = NA_{obj}$ and 546 nm green light. As seen in Figure 4.1.8B, this objective is capable of resolving the rows of pores in the shell of *Amphipleura*, but not the individual pores, which are slightly <0.19 µm apart.

Use the above equation to calculate the diffraction limit of resolution for your other objectives and use the diatoms to test whether they achieve their theoretical limits.

SUPPORT PROTOCOL 4

Testing Phase-Contrast and DIC Using Squamous Cheek Cell Test Slide

Cheek cells are a convenient specimen for testing the performance of phase-contrast or DIC microscopes. As seen in the low-magnification view (Fig. 4.1.6A) they are large and flat, ≤3 µm thick except near the cell center which contains the nucleus. The upper and lower surfaces have fine ridges which swirl around much like fingerprints. Many of the ridges are <0.2 µm in width and separated by <0.5 to 1.0 µm.

To prepare the cheek cells, gently scrape the inside of your mouth with the tip of a plastic pipet or similar soft tool and spread the cells and saliva on the center of a clean no. 1.5 coverslip. Invert the coverslip quickly onto a clean slide and press down to spread the cell preparation into a thin layer. Seal the edges with a thin layer of nail polish.

SUPPORT PROTOCOL 5

Testing Fluorescence Using Red, Green, and Blue Fluorescent Tissue Culture Cell Test Slide

The cells in Figure 4.1.9 are triple labeled: DAPI stained nuclei and chromosomes (blue fluorescence; Fig. 4.1.9A); Alexa 488-phalloidin labeled actin filaments (green fluorescence; Fig 4.1.9B); and X-Rhodamine immunofluorescently labeled microtubules (red fluorescence; Fig. 4.1.9C). The microtubules and fine actin filamentous arrays are <100 nm in width, but they should appear sharp and in high contrast in the microscope. There should be no "bleed-through" of fluorescence from one fluorescence channel to another if the filters are chosen properly (Taylor and Salmon, 1989).

In fluorescence microscopy, the diffraction-limited lateral resolution is given by (Inoué 1989; Inoué and Spring, 1997):

$$r = 0.61\lambda/NA_{obj}$$

and the intensity of the image, I_{image}, is given approximately by:

$$I_{image} \approx I_{ex}NA_{obj}^{4}/M_{p}^{2}$$

where I_{ex} is the excitation light intensity entering the objective and M_p is the projection magnification from the objective to the eye or camera. The rate of photobleaching, R_p, of a specimen depends on:

$$R_p \approx I_{ex}NA_{obj}^{2}M_{obj}^{2}$$

where M_{obj}^{2} is the magnification of the objective.

Note from these equations that resolution depends inversely on NA_{obj} (r = 0.24 µm for NA_{obj} = 1.4 and 546 nm green light), image intensity depends on the fourth power of NA_{obj}, while loss of intensity by photobleaching of the fluorophore increases with the square of objective NA (a measure of the excitation light collected by the objective) and magnification (which concentrates the excitation light on the specimen).

Verify these equations by imaging the fluorescent specimen (the microtubules in the spread cells are a good choice) for objectives with different magnifications and numerical apertures. It will quickly be seen why in fluorescence one wants to use the minimum total

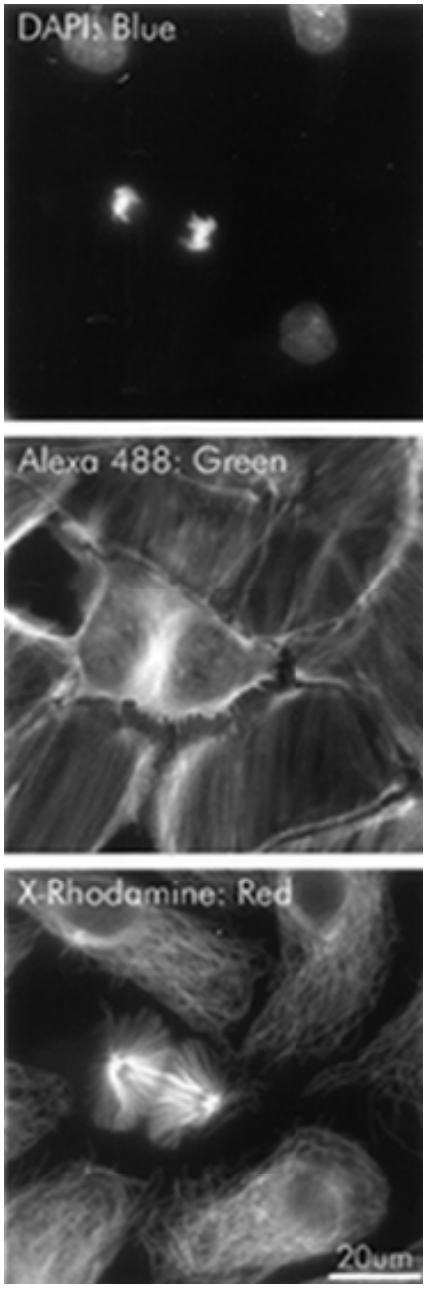

Figure 4.1.9 Epifluorescent images of fixed tissue culture cells stained with (**A**) DAPI, making DNA fluorescent blue; (**B**) Alexa 488 bound to phalloidin to label actin filaments fluorescent green; and (**C**) X-rhodamine labeled antibodies against tubulin to label microtubules fluorescent red. Bar = 20 μm. Images recorded with a 40×/(NA = 1.4) Plan Fluor objective, 1.5 magnification, to a cooled CCD camera and the multi-modem multiwavelength microscope described by Salmon et al. (1998).

magnification necessary to resolve the structures of interest in the detector, as well as use the maximum NA_{obj} in order to maximize light intensity for the least amount of excitation light (and the least amount of photobleaching).

CARE AND CLEANING OF MICROSCOPE OPTICS

SUPPORT PROTOCOL 6

Keeping the microscope optics clean is important for high-quality imaging. Dust, fingerprints, excess immersion oil, or mounting medium on or in a microscope causes reduction in contrast and resolution. DIC is especially sensitive to contamination and scratches on the lens surfaces. Below are steps for keeping the microscope clean.

1. Always keep microscopes covered when not in use.
2. Make sure that all ports, tubes, and unoccupied positions on the lens turrets are plugged.

   Plastic plugs are usually supplied with the microscope.

3. Store objectives in screw-top containers when not on the microscope. Keep accessories—e.g., condensers and compensators—in plastic bags or boxes. Keep slides and coverslips covered.
4. Be careful with salt water, corrosive liquids, and all solvents.
5. When cleaning lens surfaces, avoid touching the lens surface with anything (even lens paper if possible).

   IMPORTANT NOTE: *Never use Kimwipes or commercial facial tissue, because they may contain a filler that is part diatomaceous material (glass). One pass of a Kleenex could ruin an objective.*
6. Remove dust by gently brushing with an oil-free (ether-washed) camel's hair brush or by using a low-velocity stream of purified air.
7. Remove water-soluble contamination using distilled water with a small amount of detergent, such as Kodak Photoflow solution.

   Much (modern) immersion oil can also be removed by washing with detergent.
8. Remove most immersion oil by passing a high-quality lens tissue over the objective or condenser front element.

   IMPORTANT NOTE: *Do not rub. No area on the tissue should come in contact with the lens twice. This prevents dust and dirt removed from the lens from coming back and possibly scratching it. This is easily accomplished by passing the tissue over the lens in a "Z" pattern or by making parallel passes.*
9. Clean objective lenses by holding a piece of doubled lens paper over the objective and placing a few drops of solvent on the paper. Draw the paper across the lens surface so that the solvent flows rapidly in a circular pattern over the recessed lens surface (see Inoué and Spring, 1997). Finish the stroke with a dry portion of the paper. Repeat as necessary.

   In this way, the solvent contacts the lens but the paper does not, because the lens is recessed. For solvent, first use a 1% solution of Kodak Photoflow in distilled water to remove much of the oil and water-soluble material. Then use a small amount of oil solvent like ethyl ether or xylene to clean all the oil from the surface. Avoid soaking a lens with solvent, to prevent damage to lens cements.
10. To clean recessed front elements of dry objective lenses or to remove stubborn dirt, use a cotton-tipped applicator that has been soaked in cleaning solution and then shaken to remove excess fluid. Rotate the cotton tip over the lens surface to clean. Again, first use a 1% solution of Kodak Photoflow in distilled water to remove much of the oil and water-soluble material. Then use a small amount of oil solvent like ethyl ether or xylene to clean all the oil from the surface.
11. Use a detergent solution or ethanol to clean the surfaces of the eyepiece lenses.

    Do not use xylene as it may solubilize enamel surfaces.

COMMENTARY

The development of lasers, electronic cameras, digital image analysis, and specific fluorescent molecular probes have recently made light microscopy an enormously powerful tool in the biomedical sciences. There are a number of excellent books and review articles about these applications, as well as the optical principles of light microscope design and image formation. Listing of all these references is beyond the scope of this unit; only a few of these books and reviews are listed, and these can be used to find other useful references.

Spencer (1982), Zernike (1958), and Keller (1995, 1997, 1998) provide excellent introductions to the principles of image formation and contrast in the light microscope for beginners,

while Pluta (1988, 1989) provides a more comprehensive treatment. Inoué and Oldenbourg (1995) also review the basic concepts and principles of microscope design and different methods of image formation. The abovementioned references describe the many modes of transmitted-light imaging in the microscope, including bright-field, phase-contrast, and DIC, which are described in this unit, as well as dark-field, polarization, interference contrast, Hoffman modulation, and reflection interference contrast methods. Taylor and Salmon (1989) and *UNIT 4.2* give clear introductions to fluorescence microscopy. The recent edition of *Video Microscopy* by Inoué and Spring (1997) is a comprehensive introduction to the principles and practical aspects of light microscopy, video, and digital imaging. The *Video Microscopy* volume of *Methods in Cell Biology* edited by Sluder and Wolf (1998) also has contributions that cover many basic concepts and practical aspects of light microscopy in the biomedical sciences; it also includes chapters on multiwavelength, multimode digital imaging methods, camera selection, ion ratio imaging, and specimen chambers. Salmon and Tran (1998) review the principles of video-enhanced DIC methods used to image macromolecular complexes invisible in the microscope when viewed by eye. Taylor et al. (1992), Salmon et al. (1998), and Rizzuto et al. (1998) review microscope design for multiwavelength, multimode digital imaging of fluorescent specimens, and four-dimensional microscopy. Advanced quantitative fluorescence methods like ratio imaging, photobleaching, photoactivation, resonance energy transfer, chromophore-assisted laser ablation, and fluorescence lifetime imaging are also reviewed in the *Methods in Cell Biology* volumes edited by Taylor and Wang (1989), and Sluder and Wolf (1998) as well as in Herman and Jacobson (1990) and Inoué and Spring (1997). Reviews on imaging cells containing expressed protein coupled to green fluorescent protein (GFP) include Heim and Tsien (1996), and Sullivan and Kay (1998). Agard et al. (1989), Carrington et al. (1995), and Rizzuto et al. (1998) review how deconvolution of three-dimensional image stacks can produce super resolution in the light microscope. The recent edition of *Handbook of Biological Confocal Microscopy* edited by Pawley (1995) is an excellent reference on this important method for imaging fluorescent structures in thick specimens (Smith, 1997). The new technique of multiphoton laser scanning microscopy is described by Denk et al. (1994), while biological applications of optical traps to manipulate organelles and measure molecular forces is reviewed by Svoboda and Block (1994).

Fluorescence Microscopy

Fluorescence is a property exhibited by some molecules whereby energy of a particular wavelength (λ) is absorbed, and, after a certain period of time (termed the fluorescence lifetime), a portion of this absorbed energy is emitted. The amount of energy emitted as fluorescence is always less than the amount of energy absorbed. Absorption of energy by molecules in the form of light and emission of energy in the form of fluorescence can occur only at certain wavelengths, which are characteristic for a given molecule. The difference in the maximal wavelengths (corresponding to energy levels) of absorption and emission is known as the Stokes shift. Each fluorescent molecule is characterized by its own distinct absorption and emission energy levels (i.e., excitation and emission spectrum). This fact—combined with the fact that a number of processes can affect the emission of fluorescence from a fluorophore during its excited-state lifetime—allow the specificity, quantitative and environmental sensitivity, and high temporal resolution provided by fluorescence to be brought to bear in the examination of microscopic structures. To accomplish this, the fluorescence microscope is constructed in such a way as to permit the delivery of excitation energy to the specimen in the form of light of specific energy levels corresponding to wavelengths that match the maximal absorbance band of the fluorescing species. The microscope must also have the capacity to separate the weaker emitted fluorescence light from the brighter excitation light for observation.

FLUORESCENCE MICROSCOPE OPTICS

Fluorescence microscopes must accomplish the following four functions: (1) deliver excitation light of the appropriate wavelengths to the specimen; (2) separate the excitation light from the emitted fluorescence; (3) collect as much of the emitted fluorescence given off by the emitted fluorophores as is possible; and (4) allow observation of fine detail in the specimen.

Fluorescence microscopes have been designed with these functions in mind. Excitation light sources and wavelength-selection devices allow selection of appropriate excitation wavelengths. Excitation light is delivered to the specimen through the microscope objective. A special mirror, known as a dichroic beam-splitting mirror, allows separation of the excitation light from the emitted fluorescence. The dichroic beam-splitting mirror has the special property of being able to reflect light below a specific wavelength, yet allow light above this specific wavelength to pass through the mirror unobstructed. Objective lenses have been developed that allow maximal collection of a portion of the emitted fluorescence from the sample, as well as magnification and observation of fine detail (resolution) of the specimen.

The most commonly employed illumination system is that invented by Ploem, termed Ploem illumination, incident-light illumination, or epiillumination. In epiillumination, a dichroic beam-splitting mirror reflects the excitation light into the back aperture of the objective. The objective acts as a condenser and focuses the excitation light onto the specimen. A portion of the emitted fluorescence (the amount being determined by the numerical aperture, or NA, of the objective) is collected by the objective and passes through the dichromatic beam-splitting mirror either to eyepieces or a detector. The existence of Stokes shift and the special property of the dichroic beam-splitting mirror described above allow the separation of the excitation light from the emitted fluorescence.

COMPONENTS OF THE FLUORESCENCE MICROSCOPE

Excitation Light Sources

There is a variety of excitation light sources that can be used for fluorescence microscopy. The choice of which light source to employ will depend on the fluorescent probes being used. Because many of the available fluorophores (see Table A.1E.1) require excitation in the blue/green portion of the visible light spectrum, mercury (Hg), xenon (Xe), or Hg/Xe combination lamps are generally employed. Lasers can also be used. Each light source has benefits, depending on the wavelength and strength of excitation energy required in a given experimental situation. For example, Hg light sources emit energy at discrete wavelengths (e.g., 365, 400, 440, 546, and 580 nm) making this light source useful for caged compound release—i.e., the release of chemically caged (inert) molecules such as Ca^{2+} and inositol 1,4,5-triphosphate (IP_3) inside living cells with UV excitation—as well as for Hoescht-, 4′,6-di-

Current Protocols in Cell Biology (1998) 4.2.1-4.2.10

amidino-2-phenylindole (DAPI)–, fluorescein- and rhodamine-based fluorophores. Conversely, Xe lamps have a spectrally uniform intensity profile from the ultraviolet to the far red; this light source is particularly suited for use of Fura-2, a calcium-sensitive dye. Metal halide lamp spectral output is the same as that of the Hg arc lamp, but the energy output per unit area for metal halide is less than that of the Hg arc lamp. However, the 150-W metal halide bulb has an average lifespan five times that of an Hg lamp (1000 versus 200 hr). A Xe lamp (75-W) lasts ~400 hr. These times are estimates, as the lifetime of a bulb is determined by the total hours that it is on and the number of times it is turned on and off. When first used or when first ignited, the spark of these lamps can flicker or wander. This can be minimized by an initial 2-hr "burn in" or 10-min warm-up period. If the lamp has been turned off and is to be used again, ≥20 min must pass before turning on the lamp again.

Lasers (light amplification by stimulated emission of radiation) offer monochromatic light of very high energies and can be used in continuous-wave (CW) or pulsed modes of operation. Laser light is coherent, monochromatic (although a single laser can output multiple wavelengths of light), and polarized (propagates in one plane). Pulsed lasers are finding more and more applications in fluorescence microscopy, especially in two-photon excitation microscopy (TPEM) and in the two- and three-dimensional measurement of fluorescence lifetimes in intact cells and tissues. An important concern with the use of lasers in microscopy is the potential for scattering and diffraction due to dirt and interference on optical surfaces in the beam path. This can be overcome by using a multimode fiber-optic or liquid light pipe.

Köhler illumination

When using a fluorescence microscope, it is necessary to provide bright and even illumination of the whole field of view, while at the same time not illuminating any areas outside of the field of view. This reduces scattered light and photodamage. The optical design that can accomplish this, named after its inventor, is known as Köhler illumination (Fig. 4.2.1). In Köhler illumination, a collector lens in front of the excitation light source focuses an image of the excitation light onto a condenser field diaphragm. The condenser lens then focuses an image of the field diaphragm into the plane of the specimen (for a step-by-step procedure see *UNIT 4.1*). When this is done, the microscope is aligned in such a way that the planes carrying the illumination information are separate from the set of planes carrying the specimen information. The advantages of Köhler illumination are that the back focal plane of the objective is fully illuminated, providing a microscope field that is homogeneously bright. In addition, this system makes possible maximal lateral and axial resolution, optimal contrast, and reduction of flare from the microscope optics.

Arc lamp alignment

Alignment of the arc lamp is required each time a new lamp is inserted into the lamp

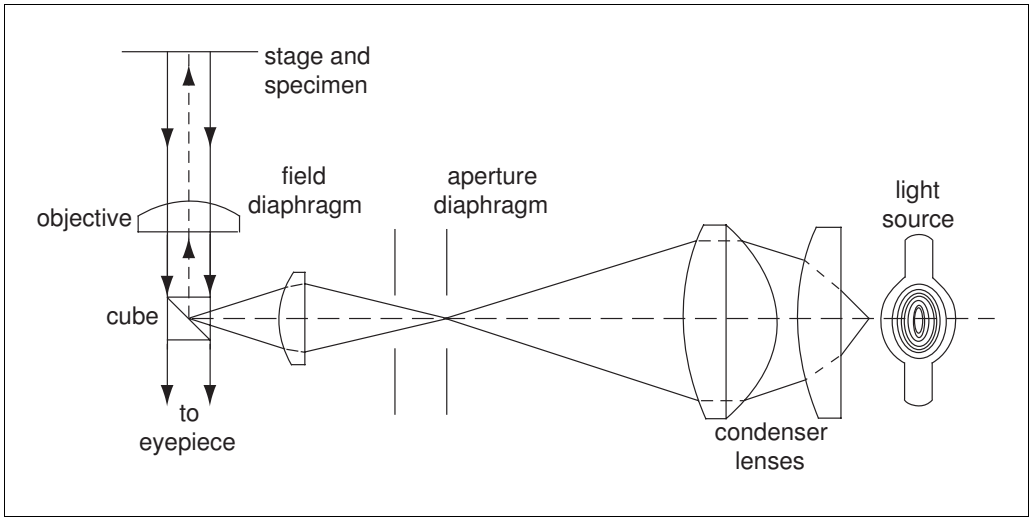

Figure 4.2.1 Köhler illumination. Condenser lenses are placed in front of the light source to make sure that the image of the centerable aperture diaphragm is focused on the back aperture of the objective, which is then focused on the specimen.

housing, and occasionally during routine usage. It is important to remember, when replacing an arc lamp, that the bulb should never be touched with one's hands (lens tissue or lint-free gloves should be used) or when it is hot (because it might explode). Also, whenever an arc lamp is replaced, the lamp power supply should be unplugged, protective eye gear should be worn, the lamp should never be used outside of its housing, and one should never look directly at or expose one's skin to the lamp (because it could cause burns and/or skin cancer). After placing a new lamp bulb in its housing, perform the following steps.

1. Reattach the lamp to the microscope, turn it on, and remove one of the objective lenses. Put a white piece of paper (a business card works well), on the microscope stage to visualize and align the lamp arc.

2. To align the arc (e.g., Hg or Xe) lamp, first focus the real and mirror images of the lamp arc to their smallest size using the collector lens in the lamp housing (Fig. 4.2.2).

3. Next, adjust the real and mirror images so that they are visible in the same field and are at the same focus or size. Adjust the real image until it is centered in the vertical direction in the field and is just to the side of the center. Move the mirror image so that it is also centered vertically in the image, but is on the opposite side of center from the real arc image.

4. Lastly, using the collector lens focusing knob on the lamp housing, defocus the arc image to provide an evenly illuminated field.

Photobleaching

Photobleaching or "fading" is the loss of fluorescence intensity following illumination of the specimen. Photobleaching decreases the fluorescence signal and hence the signal-to-noise (S/N) ratio of the microscope image. Photodynamic photobleaching is the most common type of photobleaching that occurs in fluorescence microscopy; it involves the interaction of the fluorophore with light and oxygen. In their excited state, fluorescent molecules can interact with nearby oxygen (O_2) molecules, resulting in oxidation of the fluorophore and loss of fluorescence. Fluorophores in their excited state can collide with molecular oxygen and "sensitize" singlet oxygen production. Singlet oxygen is highly reactive and can interact with the fluorophore to bleach it. The amount of photobleaching or fading that occurs in a given situation will depend on the concentration of molecular oxygen, the fluorescence life-

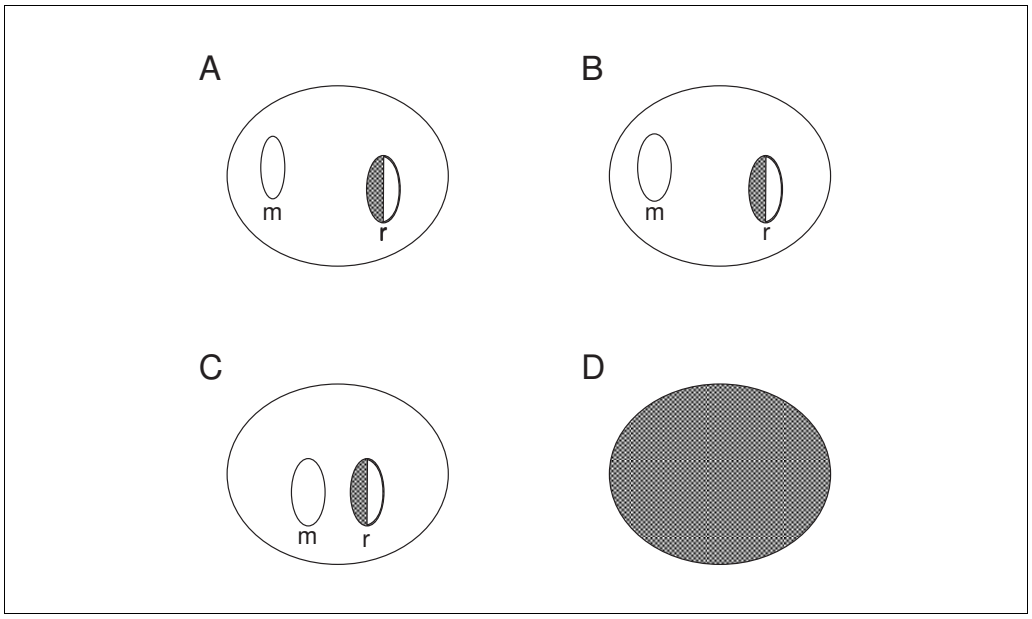

Figure 4.2.2 Alignment of arc lamp. (**A**) After placing a new lamp bulb in the lamp housing, use the collector lens focusing knob on the lamp housing so that the real (r) and mirror (m) images of the lamp bulb are at their smallest size (i.e., most focused). (**B**) Next, using a socket wrench and the ports on the lamp housing, adjust the real and mirror images so that they are visible in the same field and are at the same focus or size. (**C**) Adjust the real image until it is centered in the vertical direction in the field and is just to the side of the center. Move the mirror image so that it is also centered vertically in the field, but is on the opposite side of center from the real arc image. (**D**) Using the collector lens-focusing knob on the lamp housing, defocus the arc image to provide an evenly illuminated field. Once the lamp is focused, replace the objective.

time of the excited state (the longer the lifetime the more chance for interaction with molecular oxygen), and the distance between the fluorophore, molecular oxygen, and any other cellular constituents.

From a theoretical standpoint, whether the excitation energy is delivered in a pulsed versus continuous fashion should not affect the photochemical lifetime (rate of photobleaching). Therefore, at low excitation energy levels, photobleaching is not prevented, but the rate of photobleaching is merely reduced. However, anecdotal reports suggest that the delivery of excitation light in a pulsed versus continuous fashion may have experimental advantages in certain situations. For example, it may be advantageous to get several high signal-to-noise digital video images before photobleaching has occurred, using intense short-duration pulses. Alternatively, for certain cell physiological events, one may need to illuminate for much longer times to study the time evolution of a phenomenon, but at considerably lower S/N ratios in the individual images.

Protection against photobleaching involves reducing exposure time or excitation energy. However, these actions will also reduce the measurable signal. Solutions of molecules or suspensions of cells could also be deoxygenated, although this is not feasible for living cells and tissues. Antifade reagents such as *n*-propyl gallate, or others that are commercially available, can be added to fixed specimens. Singlet oxygen quenchers such as histidine, diphenylisobenzofuran, or crocetin (a water-soluble carotenoid) can also be employed. The use of a computer-controlled electronic shutter that is open only when experimental data is being collected will prolong filter life as well as keep exposure of the sample to harmful radiation at a minimum.

While photobleaching is usually to be avoided at all costs, there is one experimental technique that uses photobleaching to examine the lateral diffusional mobility of fluorescent molecules. This technique, termed fluorescence recovery after photobleaching (FRAP), involves irreversible photobleaching of a small area of fluorescent molecules with a short, intense burst of a laser, and observation of the reappearance of fluorescence in the bleached area (Fig. 4.2.3). The reappearance of fluorescence is due to the diffusion of unbleached fluorescent molecules into the bleached region. The kinetics of this process are related to the lateral diffusional mobility of the fluorescent material.

Wavelength Selection Devices

In the fluorescence microscope, excitation light of a specific energy level (wavelength) from Hg or Xe arc lamps or a laser is isolated using an exciter filter and reflected onto the specimen by a dichroic beam-splitting mirror. The emitted fluorescence is viewed through a cutoff or barrier filter that blocks all wavelengths below a set value from reaching the observer.

Filters can consist of a variety of substances such as absorption glass (including gelatin) or

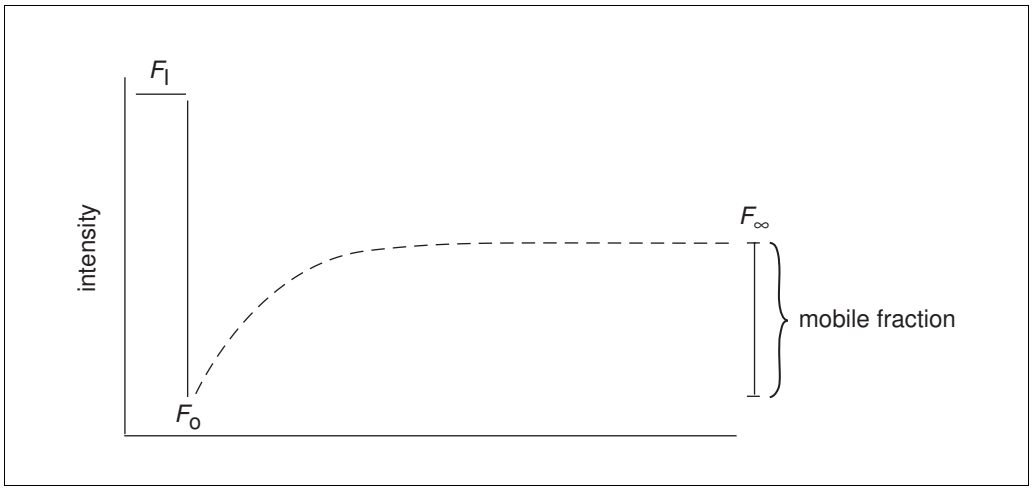

Figure 4.2.3 Fluorescence recovery after photobleaching (FRAP). A small region of the sample containing a fluorophore of some intensity value (F_i) is irreversibly bleached by a strong laser beam resulting in a drop in the observed fluorescence intensity (F_0). A much weaker laser beam then monitors the recovery of fluorescence into the bleached area as a function of time, until there is no further increase in fluorescence. The mobile fraction is defined as the difference between F_∞ and F_0.

thin-film coatings. Thin-film coatings may be either of a metallic nature (for fully reflective mirrors and neutral-density filters) or interference coatings (for interference filters). Several standard exciter filter/dichroic beam-splitting mirror/barrier filter combinations are available from each microscope manufacturer. The choice of which combination to use will depend on the fluorochrome(s) employed.

Filters are described according to their transmission properties. A short-pass filter will pass light up to a certain wavelength, but will not allow light of higher wavelengths to pass through the filter. A long-pass filter will pass only wavelengths above a certain value, and will prevent light of lower wavelengths from passing through the filter. Both short-pass and long-pass filters are named by the wavelength at which the transmission of light is 50% of maximum.

Filters also exist that can transmit only a specific range of wavelengths (interference or band-pass filters). Both wide band-pass and narrow band-pass filters exist. The narrower the range of wavelengths that can pass through the filter, the more specific is its ability to discriminate individual fluorophores in a mixture (i.e., the higher its contrast is). However, higher specificity means less intensity. Broad-band filters provide more signal but less contrast (i.e., where contrast is defined as the ability to distinguish specific versus nonspecific fluorescence or the ability to distinguish individual fluorophores when more than one fluorophore is present). These filters are named by their center wavelength (the arithmetic means of the wavelengths at 50% of peak transmission) and by the range of wavelengths (bandwidth) of light they transmit at 50% peak transmittance (full width half maximum, or FWHM). For example, BP 490/30 is an interference filter with maximal transmission at 490 nm (for fluorescein excitation) and which transmits light from 475 to 505 nm. A short-pass and long-pass filter can be sandwiched together to generate specific band-pass filters.

Dichroic beam-splitting mirrors reflect the shorter wavelengths of excitation light to the specimen and allow the long wavelength emitted fluorescence to pass to the detector, while at the same time preventing the passage of the shorter excitation wavelengths to the detector. Optimally, >90% reflectance of the excitation light and >90% transmission of the emission light is desired. Dichroic beam-splitting mirrors are identified by the highest wavelength of light that will be reflected onto the specimen.

Often more than one fluorophore will be visualized in a single specimen. In order to visualize each fluorophore individually without any contamination from the other fluorophores, microscopes have been designed to accommodate multiple exciter/dichroic/emission filter units, each optimally matched for its respective fluorophore. Of course this type of arrangement does not allow observation of all of the fluorophores simultaneously. To accomplish this, single filters with multiple band passes have been designed that can be used to image more than one fluorophore simultaneously. In addition to filters, monochromators and electro-optic instruments can be employed as wavelength-selection devices.

Fluorescein and rhodamine represent two of the most common fluorophores utilized in fluorescence microscopy. Typical fluorescein and rhodamine filter sets might be constructed according to the following considerations. Fluorescein absorbs maximally at 490 nm and emits maximally at 525 nm. Rhodamine absorbs maximally at 550 nm and emits maximally at 580 nm. Therefore, the two filter sets have to be constructed in such a way that the appropriate wavelengths of excitation (490 nm and 550 nm) can be delivered to the specimen, and the emitted fluorescence (525 nm and 580 nm) can be separated from the excitation light and any other scattered light before reaching the detector. Using an Hg lamp, an excitation interference filter is placed in the light path—comprised of a 450 to 490 nm filter for fluorescein and a 546/12 nm filter for rhodamine—to select the appropriate wavelengths of excitation for the two probes. After passing through the excitation filter, the excitation light encounters a dichroic beam-splitting mirror (DM)—comprised of a DM 510 nm mirror for fluorescein and a DM 580 nm mirror for rhodamine. These dichroic mirrors will reflect light below 510 nm and 580 nm, respectively, into the back focal plane of the objective and then to the sample. The emissions of fluorescein and rhodamine are then isolated using an emission filter—comprised of a long-pass (LP) 520 nm and an LP 590 nm filter. While these filter units work to enable observation of fluorescein and rhodamine independently in the same sample, they do not correct for the following possibility (which actually occurs). Some excitation of the rhodamine can occur at the wavelengths of excitation of fluorescein, and a small portion of the emission spectrum of fluorescein overlaps a portion of the emission spectrum of rhodamine. To overcome this problem, emission

interference filters—515 to 565 nm for fluorescein and LP 610 nm for rhodamine—can be employed to visually isolate, specifically, the emission of fluorescein from rhodamine.

There are other types of filters that are employed in fluorescence microscopy—i.e., heat and neutral-density filters. Heat filters are used to protect the excitation filters and detectors from infrared radiation. They are placed in front of the light source to reduce heat transfer to the excitation interference filter and can also be used to reduce the UV excitation intensity. Neutral-density filters reduce the intensity of all wavelengths of the exciting light equally, and are commonly used for reducing the intensity of the exciting light to prevent photobleaching of fluorophores and photodamage of living cells and tissue. The neutral-density filter should be interposed between the heat filter and excitation filter.

Objectives

In fluorescence microscopy, the microscope objective serves the functions of a condenser, a magnifier, and a collector of the emitted fluorescence. In epifluorescence microscopy, reflected-light objectives have been developed, which feature specially coated glass surfaces to avoid reflection in the optics ("antireflection coating"). Most (if not all) objectives in use today are infinity-focused objectives. In infinity-focused objectives, light rays emanating from any point in the specimen are parallel between the objective and the eyepiece. The advantage of infinity-designed objectives is their insensitivity to other components introduced in the beam path (e.g., filters).

When selecting an objective for use in fluorescence microscopy, it is important to remember that objectives differ in magnification, light-gathering ability (numerical aperture or NA), wavelengths of light that they transmit, immersion medium required, and the specific applications for which they were developed. Table 4.2.1 lists some current types of objectives and their special properties.

Numerical aperture

In most biological applications involving living cells, it is important to collect as much of the emitted fluorescence as possible. Employing the largest NA possible will allow maximal collection of emitted fluorescence. NA (where $NA = \eta \sin\alpha$, η being the refractive index of the medium between the specimen and the objective) is defined as the angle, α, of the emitted fluorescence given off from a fluorophore relative to the original direction of the exciting light (Fig. 4.2.4). Objectives that are capable of collecting light over a large angle α will provide brighter images. Such objectives are said to possess a large NA. However, there is a limit to the size of the NA, resulting from a mismatch between the refractive indices of the medium (air) between the front surface of the objective and the coverslip. To increase the NA of the objective, a better match between the refractive indices of the front surface of the

Table 4.2.1 Properties of Objective Lenses[a]

Lens	Properties	Uses
Plan achromat	Flat field; color-corrected; short working distance	Routine fluorescence
Ultrafluar[b]	Broad spectral transmission (200-700 nm)	Calcium measurements with Fura-2
Quartz	UV transmission	UV fluorescence
Multi-immersion	For use with or without coverslip	Low-magnification, high-NA applications
Water-immersion	High NA	Live cell and tissue physiology
Achromat	Low-cost; partially color-corrected	Phase-contrast microscopy
Plan/Epiplan[b]	Good image contrast; flat field; long working distance	Photomicroscopy
Plan/Epiplan Neofluar[b]	Flat field; corrected for spherical and chromatic errors over broad range of visible spectrum	Calcium measurements with Fura-2

[a]Abbreviation: NA, numerical aperture.

[b]Ultrafluar, Neofluar, and Epiplan are trademarks of Carl Zeiss, Inc.

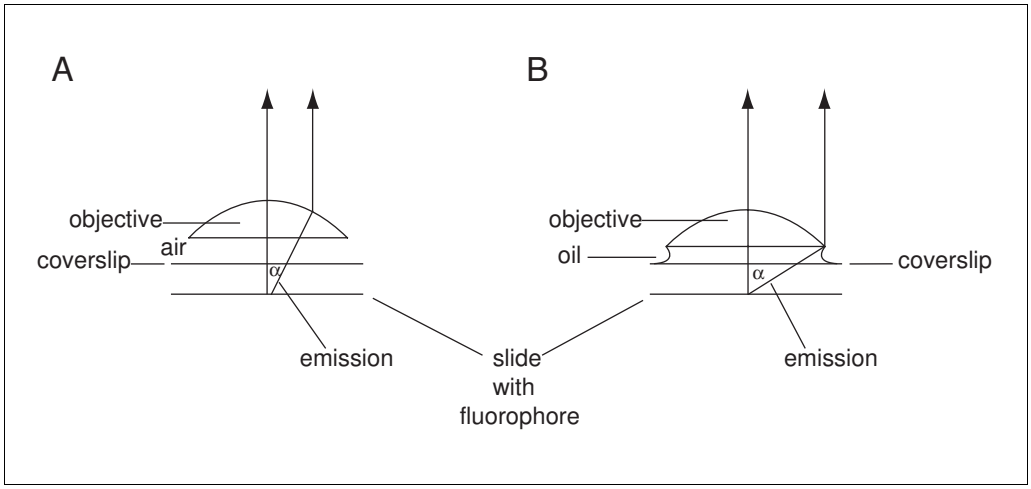

Figure 4.2.4 The numerical aperture (NA) is a measure of the light-collecting ability of an objective lens. The larger the NA, the greater the quantity of light collected by the objective lens. Larger NA is associated with shorter working distance of the objective lens (distance between the front of the objective lens and the sample). Since NA is proportional to the refractive index (η) of the medium between the specimen and the objective, matching the refractive indices of the objective lens and the sample results in a larger NA and collection of more of the emitted fluorescence. Compare (**A**), representing an objective without oil immersion and (**B**), representing an objective with oil immersion to match the refractive indices of lens and sample. Note the shorter working distance and larger angle (α) between the excitation and emission beams in B.

objective and cover glass must be made. This is done by placing immersion oil between the front lens of the objective and the coverslip. The η of both glass and immersion oil is 1.515, thereby eliminating all reflections on the path from the object to the objective and increasing the NA of the objective as well as the amount of light that can be captured by the objective.

Resolution

Resolution (R) is defined as the smallest distance (d) between two small objects that still can be discerned as two separate objects. $R = 0.61(\lambda/\text{NA})$, where λ is the wavelength of light and NA is the numerical aperture of the objective lens. Because R is determined by the wavelength of the light and the objective NA, objectives with higher NA values result in smaller d (i.e., greater resolving power). Shorter wavelengths are also beneficial for increasing objective resolving power.

Magnification

Magnification is defined as the power to cause objects to appear larger than they are. The useful range of overall magnification of a microscope should be >500 times but <1000 times the objective aperture. The magnification and NA of an objective are related to each other in such a way that the brightness of the image decreases as the magnification increases. In the typical fluorescence microscope employing epiillumination, the objective lens serves both as a condenser and an objective. This results in the light intensity (brightness) being proportional to $(\text{NA})^4$. Brightness is also related to the magnification but in the opposite direction—i.e., brightness is proportional to $1/(\text{Mag})^2$. Therefore, the overall brightness is proportional to $(\text{NA})^4/(\text{Mag})^2$. Thus, when performing fluorescence microscopy, it is important to use the highest NA and the lowest overall magnification objective possible.

Optimizing image brightness and resolution

Optimizing image brightness involves the following considerations.

1. The sample should be supplied with sufficient light energy for excitation (but not photobleaching) at the appropriate (fluorophore-dependent) wavelength.
2. The emitted fluorescence should be observed without any contamination from the excitation light.
3. The light source must provide a large amount of excitation energy in very narrow ranges of the spectrum.
4. Appropriate filters that transmit the required wavelengths but block the unrequired ones should be employed.

5. The objectives should have high transmission from the UV through a large part of the visible spectrum.

6. Objectives with the highest NA should be employed. A good rule of thumb is that if the objective aperture is doubled in size, approximately four times more fluorescence light can be gathered.

7. Nonautofluorescent, PCB-free immersion oil with the proper refractive index (η = 1.51), to eliminate light loss caused by light reflection on surfaces, should be used.

8. None of the optical components of the microscope should be autofluorescent. Autofluorescence will increase the brightness of the background and reduce the contrast in the image.

9. The objective lenses must be clean.

10. Coverslips of the appropriate thickness (0.17 mm) should be used. For objectives with NA > 0.7, the thickness of the coverslip can vary ±0.01 mm (from 0.17 mm) and still provide a high-resolution image. When the NA of the objective is between 0.3 and 0.7, coverslip thickness can vary by ±0.03 mm and still provide high-resolution images.

11. Air bubbles must be avoided in the immersion-oil layer.

12. To improve contrast, the field diaphragm should be closed down.

Cleaning the microscope optics

The following are some general rules that should always be followed when working with any optical microscope to maintain optimal performance.

1. Always work in as clean an environment as possible.

2. Avoid dust at all costs.

3. Keep the microscope covered at all times when not in use.

4. Store all microscope components in appropriate containers and avoid salt water, corrosive solvents, and all solvents if possible.

5. Clean the microscope thoroughly after each use.

6. Do not smoke.

7. Before cleaning an objective lens, directly inspect the lens using an inverted ocular from the microscope as a magnifier in room light. It is also possible to inspect the objective lens by placing the lens under a dissecting microscope and focusing on the lens to observe any imperfections.

8. Use oil only on lenses designed to be used with oil. It is a tedious process to clean immersion oil off a dry lens so as not to damage the lens.

9. Properly store objectives that are not in use in the container that they came in.

The first rule of cleaning microscope optics is do not touch the lens surface if at all possible, not even with lens paper. Dust particles in the air and even components of cleaning tissues can contain abrasive materials that will scratch the lens surface. The best way to clean an objective lens is as follows.

1. Soak a previously unused Q-tip in any of the following solvents: a mixture of 55% acetone/30% ether/15% ethanol; pure alcohol; the glass cleaner Sparkle; distilled H_2O; lighter fluid; or a well-shaken 1:1:1 mixture of chloroform/alcohol/water. Avoid benzene, toluene and xylene. The organic solvents are usually more effective, but bear in mind that some of these solvents are carcinogens and flammable and need to be used in a well-ventilated environment with no nearby flames (i.e., no smoking).

2. Very gently roll the solvent-laden Q-tip over the surface of the lens once.

3. Take another fresh Q-tip dipped in solvent and pass it over the lens very gently, barely touching the lens surface. Another option is to place a drop of solvent onto the objective lens (without directly touching the lens), and then gently blot the drop of solvent up using lens paper, but not touching the lens directly.

If you are using oil-immersion objectives and scanning a number of slides, it is not necessary to clean the objective after each slide. Rather, wipe off excess oil with lens paper and place the new slide (with a drop of oil on it) onto the objective so that the oil on the slide and the residual oil on the objective meet without producing air bubbles.

THE DIGITAL DARKROOM

Photographs of images viewed through the microscope have long been the preferred means of disseminating microscopic information. This has historically meant using film as the medium for recording images. However, the use of computers for acquisition and display of images, along with the explosion of the World Wide Web (WWW), has led to the rapid expansion of the use of computer-based image analysis and presentation programs for production of permanent hard-copy microscopic images. Digital imaging provides the user with great latitude with respect to speed of image acquisition and data presentation. While it is a great improvement over film, the use of computer-

based image-analysis and presentation software provides a ready means for altering image information, and care must be taken to maintain the original data in the final image. There are also other problems with electronic image presentation—e.g., there often exists incompatibility between the data formats of the software used for image acquisition and presentation, and the electronic components themselves can induce distortion of the original image information.

The overall design of a typical digital darkroom for fluorescence microscopy is as follows. A one- or two-dimensional detector (e.g., various cameras, photomultiplier tubes, or photodiode arrays) is attached to the microscope port at the in-focus plane of image formation. The image formed by the microscope is recorded by the detector, whose output is sent to a computer. The computer may require specific hardware to receive the image from the camera as well as a substantial amount of fast access RAM and hard disk space to store the image(s). Since images contain a large amount of information (and therefore require huge amounts of storage space), a number of storage media can be employed to store microscopic images for subsequent display and processing in digital format. These include optical memory disk recorder (OMDR), computer floppy disks, Zip drives, Jazz drives, and CD-ROM disks, as well as hard drives, laser disks, and optical disks.

Once in computer memory or on the computer hard disk, a number of software programs (e.g., Image-1, Photoshop, Adobe Illustrator, Designer, and Corel Draw) can be used to create publication-quality images. These programs allow a number of operations, some of which include sharpening or blurring the image, removal of background and/or nonspecific noise, pseudocoloring, creating montages, and labeling of the figure. A word of caution is required regarding these programs. It may be the case that the input/output file formats used by these programs are not compatible with other image presentation-programs. As a general consideration, image-processing software is most efficient and useful if it contains the flexibility of user-defined parameters and multiple data and file formats. It is very advantageous to be able to generate digital data sets for computer-based processing in a uniform format that is easily understood by the variety of image analysis/processing software currently available. The tagged image file format (TIFF) is one such universal file format. Other important needs for software used for presentation of microscopic images include bitmap manipulation capabilities to allow adjustment of the printed color image so that it matches the image seen on the computer monitor. For printing color images, another important feature is the ability to print in both CMYK and RGB format. It is also necessary to make sure that, if the software uses PostScript drivers for color printing, the PostScript color interpreter exploits the full ability of the printing objects.

Once completed, a publication-quality hard copy of the computer image can then be produced using a number of techniques. These include photographic printing and color copiers as well as a variety of types of computer printers—e.g, color or black-and-white laser, ink-jet (which are becoming quite good and cost-effective), and dye-sublimation (which require special paper but have higher resolution and better color rendition). LCD projectors, which allow display of computer acquired/processed images directly from the computer, are also available.

Immunofluorescence Staining

This unit describes the widely used and powerful technique of localization of proteins in cells by immunofluorescence (see Basic Protocol). The location can be determined by double labeling with an antibody directed against a protein of known location. The technique can be used as a supplement to immunolocalization by electron microscopy and subcellular fractionation (Chapter 3). It allows not only identification of the antigen distribution in the cell, but also a survey of the dynamic aspects of protein movements in the cell—on and off membranes, into and out of the nucleus, and through membrane traffic pathways.

IMMUNOFLUORESCENCE LABELING OF CULTURED CELLS

BASIC PROTOCOL

The following is a basic "generic" method for localizing proteins and other antigens by indirect immunofluorescence. The method relies on proper fixation of cells to retain cellular distribution of antigen and to preserve cellular morphology. After fixation, the cells are exposed to the primary antibody directed against the protein of interest, in the presence of permeabilizing reagents to ensure antibody access to the epitope. Following incubation with the primary antibody, the unbound antibody is removed and the bound primary antibody is then labeled by incubation with a fluorescently tagged secondary antibody directed against the primary antibody host species. For example, incubation with a mouse IgG primary antibody might be followed by incubation with a RITC (rhodamine isothiocyanate)–labeled goat anti–mouse IgG secondary antibody. After removal of the secondary antibody, the specimen is ready for viewing on the fluorescence microscope. Once the conditions for observing specific immunolocalization have been identified for a given antibody and cell type, double labeling with two antibodies can be employed to compare localizations. To do this, primary antibody incubation can contain two antibodies generated in two species (e.g., mouse and rabbit), followed by incubation with two secondary antibodies coupled to different fluorophores. Care should be taken, however, that the two antibody combinations, especially the secondary antibodies, do not cross-react.

Materials

Cells of interest, growing in tissue culture
2% formaldehyde (see recipe)
Phosphate-buffered saline (PBS; see recipe), pH 7.4
PBS/FBS: PBS, pH 7.4, containing 10% fetal bovine serum (FBS)
0.1% (w/v) saponin in PBS/FBS: prepare fresh from 10% (w/v) saponin stock solution (*APPENDIX 2A*; store stock up to 2 months at 4°C or in aliquots up to 1 to 2 years at –20°C)
Primary antibody
Controls: preimmune serum (if using rabbit polyclonal antibody) or antigen added in excess to primary antibody
Secondary antibodies (against Ig of species from which primary antibody was obtained) coupled to fluorophore: e.g., RITC (rhodamine isothiocyanate), FITC (fluorescence isothiocyanate) Cy3, or Texas Red
Mounting medium (see recipe)

10-cm diameter tissue culture dishes
12-mm no. 1 round glass coverslips, sterilized by autoclaving or soaking in 70% ethanol
12-well tissue culture plates
150-mm petri dishes

Contributed by Julie G. Donaldson
Current Protocols in Cell Biology (1998) 4.3.1-4.3.6

Watchmaker's forceps
Microscope slides
Nail polish
Fluorescence microscope with 63× oil-immersion lens

Additional reagents and equipment for trypsinization of cells (*UNIT 1.1*)

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

1. For adherent cells, 1 to 2 days prior to experiment trypsinize cells and seed onto 10-cm culture dishes, each containing 15 to 20 sterilized coverslips, so that on day of experiment cells are 20% to 50% confluent.

   Nonadherent cells can be coaxed into adhering to the coverslips by precoating the coverslip with poly-L-lysine (see recipe). Apply 10 to 20 µl of suspended cells to each coverslip, let sit 10 min, then proceed with fixation (step 3).

   Alternatively, cells can be attached to coverslips using a cytocentrifuge by following the manufacturer's instructions.

2. On day of experiment, transfer each coverslip individually to a well of a 12-well tissue culture dish containing 1 ml culture medium. Subject cells to the desired experimental conditions (e.g., treat with various drugs, inhibitors, or temperatures prior to fixation and immunostaining).

3. Aspirate medium and add 1 ml of 2% formaldehyde to each well. Allow cells to fix at room temperature for 10 min.

4. Aspirate the formaldehyde fixative and wash coverslips twice, each time by adding 1 ml PBS, pH 7.4, letting stand 5 min, then aspirating the PBS. Add 1 ml PBS/FBS to the fixed coverslips and let stand 10 to 20 min to block nonspecific sites of antibody adsorption.

   NOTE: *Throughout the procedure, do not let cells dry out.*

5. In 1.5-ml microcentrifuge tubes dilute primary antibodies in 0.1% saponin/PBS/FBS.

   Typically affinity-purified antibodies are diluted in the range of 1 to 10 µg/ml, and rabbit antisera are diluted between 1:100 and 1:1000. If using a commercial antibody, follow suggested dilutions from manufacturer.

   During initial characterization, it is wise to try a range of dilutions of antibody.

6. Prepare controls containing only 0.1% saponin/PBS/FBS or (if available) containing preimmune antiserum (if rabbit polyclonal antibody is being used) or specific (primary) antibody with the antigen added in excess.

   Controls are often the most important part of an immunofluorescence experiment.

7. Microcentrifuge antibody dilutions and control solutions 5 min at maximum speed, room temperature, to bring down aggregates in pellet.

   Pipet the antibody solution from above the aggregate pellet.

8. Place a 10 × 10–cm piece of Parafilm in the bottom of a 150-mm petri dish. In a grid pattern that replicates the 12 wells used to incubate the coverslips, label the appropriate place on the Parafilm for each coverslip with a marker.

9. Apply a 25-µl drop of appropriate primary antibody solution to each numbered section. Carefully remove each coverslip from the 12-well plate with watchmaker's forceps, blot the excess fluid by touching the edge to a Kimwipe, then invert the coverslip over the appropriate 25-µl drop, making sure that the side with the cells is down. Place the top on the petri dish and incubate 1 hr at room temperature.

   Sometimes proper labeling will require a longer incubation time or the petri dish will be incubated >1 hr for convenience. For longer incubations, add some wetted Kimwipes to the dish to maintain a humid atmosphere. The incubation can be extended overnight at 4°C, if necessary.

   NOTE: *It is important to always be aware of which side of the coverslip the cells are on. Cells should be facing up when in the 12-well plate, but facing down when placed on the antibody. Picking up coverslips with the forceps is awkward at first but becomes easier with practice.*

10. Carefully pick up each inverted coverslip and flip it over so that it is cell-side-up, then place in a well of a 12-well plate. Wash each coverslip three times to remove unbound antibody, each time by adding 1 ml PBS/FBS, letting stand 5 min, then aspirating the solution.

11. Dilute fluorophore-conjugated secondary antibodies in 0.1% saponin/PBS/FBS. Mix, then microcentrifuge as in step 7 to remove aggregates.

    Typically, commercial preparations are diluted between 1:100 and 1:500.

12. Prepare an incubation chamber as in step 8. Apply 25 µl of appropriate secondary antibody solution to each numbered section and invert coverslip over drop as in step 8. Cover petri dish and protect from light with aluminum foil or place chamber in drawer. Incubate 1 hr at room temperature.

13. Wash coverslips as in step 10. After removal of last PBS/FBS wash, add 1 ml PBS.

14. Label slides and place 1 drop of mounting medium onto slide. Pick up coverslip from well, gently blot off excess PBS by touching the edge to a Kimwipe, then invert coverslip, cell-side-down, onto drop. Gently blot mounted coverslip with paper towel, then seal edge of coverslip onto slide by painting the edge with a rim of nail polish. Let dry.

    The fixed, mounted, and nail polish–sealed coverslips can be stored in the dark for 6 months to 1 year at 4°C.

15. View specimen on fluorescence microscope using an 63× oil immersion objective.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Formaldehyde, 2%

In a chemical fume hood, dilute 2 ml 37% reagent-grade formaldehyde into 35 ml PBS (see recipe), pH 7.4.

As reagent-grade formaldehyde contains 11% methanol, as an alternative (or if necessary) make up formaldehyde from paraformaldehyde by dissolving 0.4 g paraformaldehyde powder in 10 ml H_2O that has been heated to 60°C, then diluting 1:1 with 2× PBS, pH 7.4. It might be desirable to try both procedures for preparing the formaldehyde solution and see which gives better results.

Mounting medium

Use Fluormount G (Southern Biotechnology) or prepare 50% (w/v) glycerol and 0.1% (w/v) *p*-phenylenediamine in PBS (see recipe), pH 8.0.

Phosphate-buffered saline (PBS)

0.144 g KH_2PO_4
9.0 g NaCl
0.795 g $Na_2HPO_4 \cdot 7H_2O$
H_2O to 1 liter
Adjust to desired pH with 1 M NaOH or 1 M HCl
Store indefinitely at room temperature

Poly-L-lysine-coated coverslips

Apply 25 µl of 1 mg/ml poly-L-lysine to each sterilized no. 1 coverslip in a hood and allow to stand ~10 min. Carefully rinse coverslips three times with water, then allow to air dry.

COMMENTARY

Background Information

The first use of fluorescently labeled antibodies to localize a protein in cells occurred over 50 years ago (see Coons, 1961, for a reminiscence). Since that time, the wide availability of numerous antibodies and improvements in indirect labeling methods and fluorophores has made immunofluorescent localization of proteins in cells both a routine and a vital component in any study. Immunofluorescence labeling is quite effective when combined with biochemical or ultrastructural studies because the technique is rapid and so many parameters can be assessed. Furthermore, in contrast to biochemical studies, which assume uniformity of the sample, immunofluorescence technique allows analysis of individual cell differences.

Immunofluorescence labeling has been employed in a variety of cell-biological studies, including the first description of peptide targeting sequences specifying retention of endoplasmic reticulum (ER) lumenal proteins (Munro and Pelham, 1987) and initial studies describing the dynamic membrane trafficking between the ER and Golgi complex (Lippincott-Schwartz et al., 1990). The first study describing the family of Rab GTPases used immunofluorescence to demonstrate distinct localization of the different Rabs to different organelles in the cell (Chavrier et al., 1990). Finally, immunofluorescent localization of proteins encoded by novel genes, including those associated with human diseases and cancer (Nathke et al., 1996), will provide critical information for determining the cellular function of these proteins.

Critical Parameters

To ensure success with immunofluorescence, three parameters are critical—fixation, permeabilization, and determination of the specificity of labeling. The fixation and permeabilization conditions must be assessed individually for each antibody and each cell type investigated. Refer to Griffiths (1993) for an excellent discussion on fixation and issues related to specificity of antibody labeling.

Different fixatives might be investigated to optimize preservation of the antigen, its distribution, and the morphology of other cellular constituents. For example, some epitopes are lost upon aldehyde fixation but preserved with alcohol fixation, and vice versa. Alternative fixatives to try include methanol at –20°C (5 min exposure) or formaldehyde fixation followed by a brief (1-min) exposure to methanol at 0°C. Methanol fixation is often quite effective for localizing cytoskeletal elements. Alcohols work by extracting lipids and precipitating remaining proteins, whereas aldehydes are cross-linking reagents that generally preserve membranous structures better (McCaffery and Farquhar, 1995).

Sometimes, even when material is appropriately fixed, the epitope is obscured and not accessible to antibody binding. Permeabilizing reagents are typically detergents that partially denature fixed proteins, exposing the epitope. In addition to saponin, which the authors include throughout the staining procedure, treatments after fixation with 0.2% to 0.5% Triton X-100 or SDS can also be tried. Often a short treatment with these reagents prior to antibody incubations is sufficient to expose the epitope. Special attention should be directed toward ensuring that the access to the epitope is the same even if the protein has undergone a translocation; for example proteins that shuttle between the cytoplasm and nucleus are not always equally accessible to antibody labeling (Pines, 1997).

The primary antibody should be purified to the extent that it recognizes only the protein of interest on immunoblots. Although affinity pu-

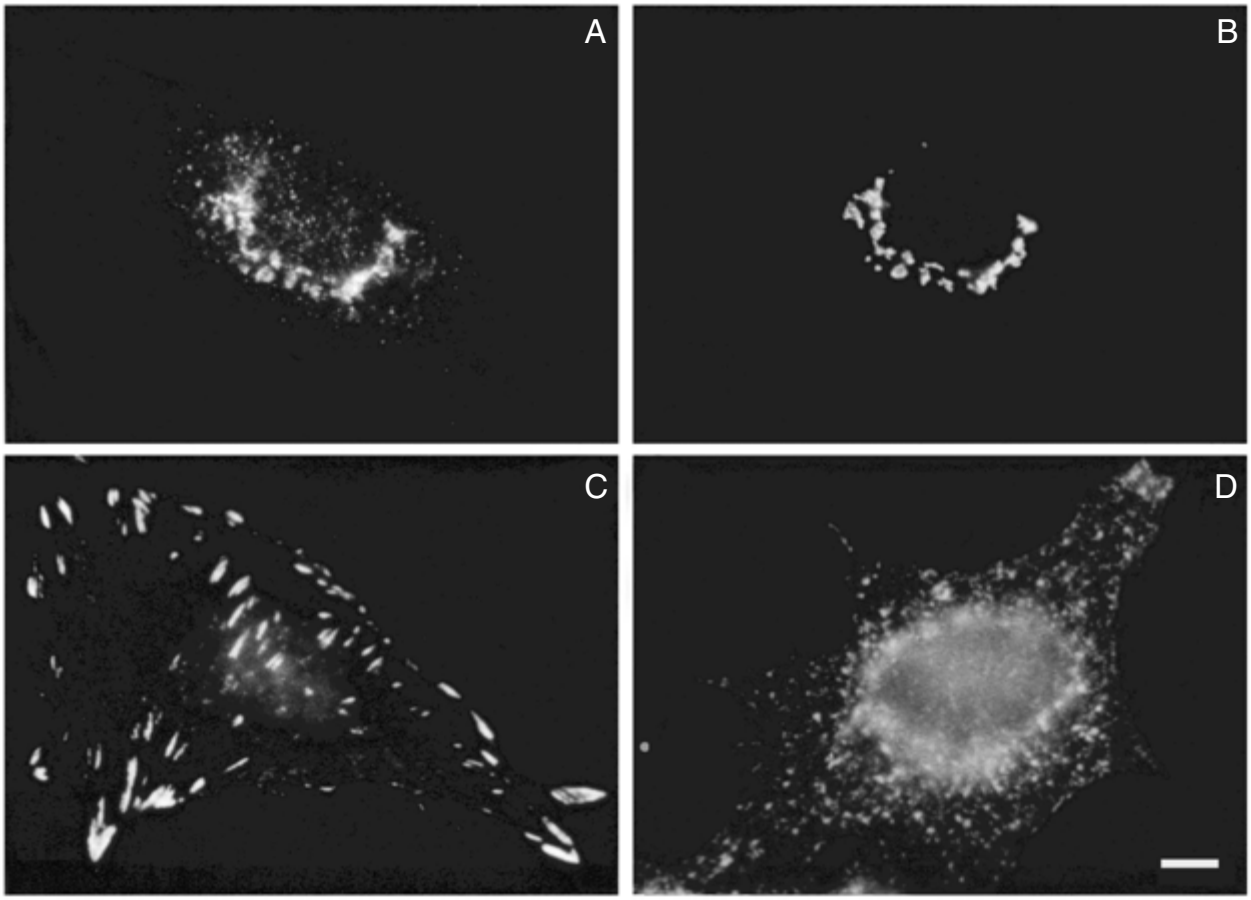

Figure 4.3.1 Examples of immunofluorescence labeling of formaldehyde-fixed cells. rification often resolves this, be aware that "affinity-purified" antibodies do not always result in antibodies that recognize only a single protein. Especially in the case of anti-peptide antibodies, multiple bands are sometimes labeled even after affinity purification. By immunoblotting on a gel (*UNIT 6.2*), it is easy to determine on the basis of molecular weight whether it is the protein of interest that is recognized. However, not all antibodies that can be used to detect a specific protein by immunoblotting work for immunofluorescence detection. Likewise, there are antibodies that recognize the protein by immunofluorescence that do not recognize the separated, denatured proteins transferred to nitrocellulose.

Next, it is important to be able to determine what constitutes "specific labeling" with the antibody. To assess this, control-stained slides (incubated with secondary antibody only or with preimmune serum) should first be viewed to determine what constitutes "nonspecific staining." Ideally this is negligible, and, by contrast, the staining pattern obtained with the specific antibody is much brighter and more distinct. When initially characterizing immunolocalization using a particular antibody, a range of dilutions of the primary and secondary antibodies should be examined to determine optimal concentrations that minimize nonspecific staining and maximize specific staining. Minimal background staining from secondary antibodies can often be achieved by dilution or trying different secondary antibodies made in different host species or obtained from different commercial suppliers. Then, a dilution of the primary antibody is selected to optimally label the specific protein. At this point, further controls should be analyzed to ensure that the staining observed is due to the presence of the protein of

interest. If a rabbit antiserum is used, preimmune serum should yield a pattern of staining similar to that of the secondary antibody alone. If the immunizing antigen is available, it can be added to the antibody dilution to compete for the specific staining; and it should yield "background" levels of fluorescence. Lastly, support for specific labeling can be confirmed by lack of staining in a cell type that does not express the protein of interest and increased labeling in cells overexpressing the protein by transient transfection. Finally, the use of different antibodies to the protein, if available, can independently confirm the localization pattern.

Troubleshooting

If background staining with secondary antibodies is too high, there are several possible remedies. The secondary antibodies may be diluted further, or different secondary antibodies, different hosts, or different fluorophores may be tried. Also, it is possible to try other "sorbing" reagents. PBS/FBS is generally a good sorbing reagent that effectively blocks out nonspecific sites, but other agents can be used—e.g., 1% (w/v) BSA (immunoglobulin-free) or gelatin.

If no specific staining is observed, it is possible to increase the concentration of or the time of exposure to the primary antibody. One can also try alternative fixation and permeabilization regimens to visualize specific staining.

If specific staining is observed, but it is very dim, it is possible to increase the concentration of the primary and/or secondary antibodies. As long as background staining is low, the signal can be enhanced by using a fluorescence double-sandwich technique. To do this, following incubation with primary antibody (e.g., a mouse monoclonal antibody) and washing, incubate first in FITC-conjugated goat anti–mouse IgG and then in FITC-conjugated donkey anti–goat IgG. Caution should be observed that secondary antibodies do not alter the pattern of single antibody labeling.

Anticipated Results

Once conditions for specific localization have been optimized, the distribution of the protein in a variety of cells under a variety of conditions can be observed (see Fig. 4.3.1). Double labeling of two antigens allows the distribution of one protein to be compared with that of another protein in the same sample using two secondary antibodies attached to fluorophores that can be monitored in two different channels by flow cytometry. Thus, the location of a known protein, say an antibody to a Golgi-resident protein, can be used as a marker for the Golgi complex to see whether the antigen under study colocalizes with it (Fig. 4.3.1, panels A and B).

Time Considerations

The entire procedure can be performed in ~3 hr. Fixed, washed coverslips can be stored at 4°C for several days prior to immunolabeling. Incubations with primary antibodies can be extended to overnight at 4°C if necessary (or if it is desirable to increase staining).

Fluorescent Staining of Subcellular Organelles: ER, Golgi Complex, and Mitochondria

The ability to distinguish and identify different subcellular compartments is crucial for understanding organelle function, biogenesis, and maintenance within cells, as well as for defining protein trafficking pathways. This unit describes protocols for labeling three subcellular organelles—endoplasmic reticulum (ER), Golgi complex, and mitochondria—using fluorescent dyes and fluorescently labeled lipid derivatives. Many fluorescent lipid derivatives have been shown to preferentially partition into membrane compartments of living cells. This finding has been used to generate protocols for fluorescently labeling specific intracellular organelles in vivo. Such protocols have been enormously valuable for enabling researchers to identify different organelles and to study their dynamics and spatial organization within cells (Terasaki et al., 1984; Cooper et al., 1990; Pagano et al., 1991).

The unit first describes how to stain the endoplasmic reticulum (ER) by using the fluorescent dye $DiOC_6(3)$. This dye can be used to stain fixed cells (see Basic Protocol 1) or living cells (see Alternate Protocol), and the protocols are very simple. Since the dye stains many other organelles in addition to the ER, $DiOC_6(3)$ is particularly useful for staining the thin peripheral regions of cultured cells, where it is usually easy to distinguish the ER on the basis of morphology.

Fluorescent analogs of ceramide, including *N*-[7-(4-nitrobenzo-2-oxa-1,3-dizole)]-6-aminocaproyl D-*erythro*sphingosine (C_6-NBD-Cer) and *N*-[5-(5,7-dimethyl BODIPY)-1-pentanoyl]-D-*erythro*sphingosine (BODIPY-Cer), have proved to be particularly valuable for labeling the Golgi complex (reviewed in Pagano, 1989), which receives, processes, and sorts newly synthesized proteins exported from the ER. These dyes readily accumulate in the Golgi complex of most cell types by a preferential membrane partitioning process (Lipsky and Pagano, 1983, 1985a; Pagano et al., 1989). They can be used to image the Golgi complex in fixed or living cells (see Basic Protocol 2).

Mitochondria are unique among intracellular organelles in that they have a large membrane potential, which is negative inside. This characteristic makes it relatively easy to specifically stain mitochondria in living cells. Many fluorescent lipophilic cationic molecules can be used. These molecules pass through the plasma membrane by their lipophilicity and then accumulate in the mitochondria as a result of the attraction of the plus charge on the molecule to the high negative mitochondrial membrane potential. This unit describes the use of TMRE (tetramethylrhodamine, ethyl ester) to stain mitochondria in mammalian cells in culture (see Basic Protocol 3). Accumulation of this dye follows the Nernst equation and is therefore independent of other factors such as binding to mitochondrial components (Ehrenberg et al., 1988; Farkas et al., 1989). This establishes TMRE as a good monitor for the mitochondrial membrane potential (Loew et al., 1993). TMRE has an additional advantage in that live cell staining is accomplished simply by equilibrating cells with the dye, then mounting them for observation in the presence of the dye. Other fluorescent dyes are available for investigating mitochondrial properties in interesting ways and are discussed briefly in the Commentary.

Current Protocols in Cell Biology (1998) 4.4.1-4.4.18

BASIC PROTOCOL 1

STAINING THE ENDOPLASMIC RETICULUM IN FIXED CELLS

In this protocol, cells are fixed in glutaraldehyde for 3 min, stained with the fluorescent dye $DiOC_6(3)$ for 10 sec, then mounted in dye-free buffer. Live cell staining is accomplished by mounting cells directly in the fluorescent dye (see Alternate Protocol).

Cells growing on coverslips are handled in a similar way in this protocol as for immunofluorescence, with two major differences. One is that the cells must be kept away from detergents, organic solvents, and nail polish, since these will extract $DiOC_6(3)$. The second is that the time scale is much shorter.

Materials

Fixative: prepare 0.25% glutaraldehyde in PBS (*APPENDIX 2A*) from 7% to 70% commercial stock solution (store up to 1 week at 4°C)
Cells of interest, growing on coverslips
2.5 µg/ml $DiOC_6(3)$ working solution (see recipe)
Phosphate-buffered saline (PBS; *APPENDIX 2A*)
Silicone high-vacuum grease

Small petri dish
Watchmaker's forceps
Microscope slides
Silicon rubber chamber (see recipe)
Fluorescence microscope with fluorescein filters and either 63× or 100× oil-immersion objective (*UNIT 4.2*)

Additional reagents and equipment for fluorescence microscopy (*UNIT 4.2*)

1. Put some fixative in a small empty petri dish. Using watchmaker's forceps, remove coverslip containing cells from culture dish and put it into the fixative. Let cells fix 3 to 5 min.

2. Remove coverslip from fixative and place cell-side-up on a piece of Parafilm. Remove excess fixative using a Pasteur pipet, but do not let the coverslip dry out.

3. Apply enough 2.5 µg/ml $DiOC_6(3)$ working solution to cover the coverslip.

   A volume of 100 µl should be sufficient for most coverslip sizes.

4. After ~10 sec, remove the $DiOC_6(3)$ solution with a Pasteur pipet, then apply sufficient PBS to cover the coverslip.

5. Grease both sides of a silicon rubber chamber sparingly with silicone high-vacuum grease. Press the greased chamber firmly on a microscope slide, avoiding air bubbles. Fill the well with $DiOC_6(3)$ working solution, then place the coverslip, cell-side-down, on the chamber. Press down lightly on the coverslip to make contact between the glass and the silicon rubber and make a seal that keeps the coverslip adherent to the chamber (Fig. 4.4.1). Dry off excess fluid with a Kimwipe.

   One way to do this is to hold the Pasteur pipet used for filling the chamber in the left hand and hold the coverslip with watchmaker's forceps in the right hand.

   Use a minimal amount of grease, since this can be very difficult to remove if it gets onto the microscope objective lens. For short-term observations it is possible to mount coverslips without the silicone grease.

   An alternative method (not involving a silicon rubber chamber) is to gently place the coverslip cell-side-down directly on a microscope slide with a minimum of bubbles. Carefully dry off excess fluid at the sides and especially on top of the coverslip. Sealing the sides is not required for short-term observations. Do not let the microscope immersion oil

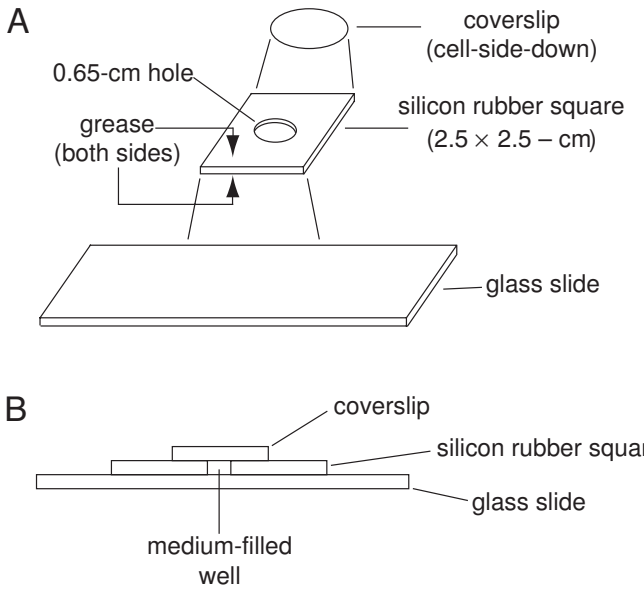

Figure 4.4.1 Microscope slide with silicon rubber chamber. (**A**) Assembly; (**B**) side view in cross-section.

leak underneath the coverslip. Also, be aware that the coverslip will start to dry out from the edges, and that dried cells are not suitable for viewing. If sealing of the coverslip is desired, use paraffin or Valap (UNIT 13.1), not nail polish, because the organic solvents in the nail polish will extract the stain.

6. Observe cells using fluorescence microscope with fluorescein filters and oil-immersion 63× or 100× objective lens.

   The results are best observed during the first 10 to 20 min after staining. Afterwards, the dye starts to accumulate in lysosomes. After longer periods of time, autofluorescence from glutaraldehyde begins to obscure the staining.

STAINING THE ENDOPLASMIC RETICULUM IN LIVING CELLS

ALTERNATE PROTOCOL

The ER of cells that have not been fixed can also be labeled with $DiOC_6(3)$.

Additional Materials *(also see Basic Protocol 1)*

0.5 µg/ml $DiOC_6(3)$ working solution in growth medium appropriate for cells (see recipe)

1. Grease both sides of silicon rubber chamber sparingly with silicone high-vacuum grease and press onto microscope slide.

   The silicon rubber chamber does not need to be sterilized for short-term observations of a few hours.

2. Using watchmaker's forceps, remove coverslip containing cells from culture dish. Fill chamber with 0.5 µg/ml $DiOC_6(6)$ working solution, then put coverslip cell-side-down on chamber. Press down carefully on the coverslip to make a seal that keeps the coverslip adherent to the chamber, and dry off excess fluid with a Kimwipe.

   If a large bubble is seen in the chamber, remount the coverslip. If a chamber with temperature control and ability to perfuse is desired, see Basic Protocol 3, introduction, for information on live cell chamber.

3. Observe cells using fluorescence microscope with fluorescein filters and oil-immersion 63× or 100× objective lens.

It should take 5 to 10 min for ER staining to develop. The mitochondria are usually swollen at dye concentrations that stain the ER. After 10 min, if only the mitochondria are stained, try 1.0 μg/ml $DiOC_6(3)$ staining solution. If the cells look sick and are starting to detach from the coverslip, use a lower concentration of dye. To stain only the mitochondria with $DiOC_6(3)$, use 0.1 μg/ml.

If photodynamic damage or bleaching is hindering the experiments, scavenge the oxygen in the medium with Oxyrase, a bacterial enzyme system. The enzyme is used at 0.3 U/ml (1:100 dilution of enzyme as purchased from Oxyrase, Inc.; Waterman-Storer et al., 1993).

BASIC PROTOCOL 2

STAINING THE GOLGI COMPLEX IN LIVING CELLS

Vital staining of the Golgi complex with C_6-NBD-Cer or BODIPY-Cer involves incubation of cells with either of these fluorescent lipids at low temperature, followed by washing. The ER, nuclear envelope, and mitochondria are initially fluorescent, but over time the Golgi complex begins to fluoresce as a result of preferential insertion of the fluorescent lipids into its membranes. Upon warming the cells to 37°C, intense labeling of the Golgi complex occurs, but only for a finite period of time. This is because the ceramide derivatives within the Golgi complex are metabolized at 37°C to the corresponding fluorescent analogs of sphingomyelin and glucosylceramide. These traffic to the cell surface, causing fluorescent labeling of the plasma membrane over time. Fluorescent labeling of the cell surface can be reduced by incubating cells in medium containing nonfluorescent liposomes or defatted BSA. This results in "back-exchange" of fluorescent sphingomyelin and glucosylceramide into the medium (Lipsky and Pagano, 1985b; van Meer et al., 1987). Labeled cells can be fixed and further processed for double labeling with fluorescently tagged antibodies (see *UNIT 4.3*), to compare the localization of the Golgi complex with other markers within the cell.

Golgi membranes labeled with the fluorescent ceramide derivatives are viewed on a fluorescent microscope equipped with filter combinations appropriate for fluorescein. BODIPY-Cer can also be visualized with filter combinations appropriate for rhodamine optics, since at high concentrations within Golgi membranes BODIPY-Cer forms excimers, which emit >590-nm light when excited with blue light.

Materials

Ethanol
0.05% trypsin in HBSS (*APPENDIX 2A*) without calcium and magnesium
1 mM ceramide fluorescent derivative working solution in ethanol (see recipe)
Serum-free medium appropriate to cells
Cells of interest
Phosphate-buffered saline (PBS; *APPENDIX 2A*), 4°C
10% (w/v) defatted BSA (Sigma) in serum-free medium appropriate to cells
Fluoromount G (Southern Biotechnology Associates or Electron Microscopy Sciences) *or* mounting medium (see recipe)
HEPES-buffered culture medium appropriate to cells, pH 7.0, with 10% serum and without phenol red

12-mm diameter no. 1 round glass coverslips
Watchmaker's forceps
10-cm sterile tissue culture dishes
Hamilton syringe
Silicon rubber chambers (see recipe)
Microscope slides

Conventional fluorescence microscope with standard fluorescein and rhodamine filter cubes *or* confocal microscope with Kr/Ar laser (*UNIT 4.2*)
63× (1.4 NA) or 100× (1.3 NA) oil-immersion objective
Microscope air-stream incubator (Nevtek)

Additional reagents and equipment for growing cells in tissue culture and trypsinization of cells (*UNIT 1.1*) and fluorescence microscopy (*UNIT 4.2*)

Prepare cells on coverslips

1. Sterilize 12-mm diameter no. 1 round glass coverslips by soaking in 95% ethanol and flaming. Handling the coverslips with watchmaker's forceps, place in a 10-cm sterile tissue culture dish (which will accommodate up to eight coverslips).

   Be sure the coverslips are no. 1 thickness for viewing at high magnification on the microscope. Thicker coverslips will not match the numerical aperture of the objective and can give significant spherical aberration, resulting in poor microscopic images.

2. One to two days prior to start of experiment, trypsinize cells (*UNIT 1.1*) in 0.05% trypsin and seed onto the culture dishes containing the coverslips.

   For optimal viewing, the cells should have grown to only ~50% confluency by the day of the experiment.

   If cells fail to grow well, the coverslips can be treated prior to seeding with 1 mg/ml poly-D-lysine or poly-L-lysine for 15 min.

Label cells

3. Take a small aliquot of the 1 mM ceramide derivative in ethanol and disperse it into serum-free medium at room temperature by injecting it into the medium with a Hamilton syringe while rapidly vortexing. Use quantities of Cer-derivative solution and medium such that the final working concentration of Cer-derivative in the medium will be 5 to 10 μM and the final concentration of ethanol will be <0.5% (in order to prevent damage to the cells).

   This step causes the Cer-derivatives to form small vesicles which are more easily delivered to the cell.

4. Place coverslips in a tissue culture dish containing ice-cold PBS for 2 min. Remove PBS and replace with fresh ice-cold PBS, then repeat one more time.

   This step removes serum from outside the cells. Cer-derivatives have a very high affinity for serum, so any serum present on the cells will lower the effective concentration of the Cer-derivative.

5. Add medium containing the Cer-derivative to cells so that the bottom of the dish, along with the surface of the coverslip, is completely covered with medium and incubate 30 min at 4°C.

6. Wash cells three times with cold PBS to remove unbound lipid, then incubate with medium containing 10% defatted BSA for 30 min at 4°C.

   This removes or "back exchanges" the excess NBD- or BODIPY-Cer that is not incorporated into intracellular membranes.

7. Warm cells to 37°C, and continue incubating at that temperature, examining cells under a fluorescence microscope to determine when optimal labeling of the Golgi complex and minimal labeling of other intracellular membranes occurs.

   Golgi labeling should be prominent after 15 to 40 min.

View cells by fluorescence microscopy

8. Place a small drop of Fluoromount G or mounting medium on the cell side of the coverslip. Invert coverslip onto a silicon rubber chamber attached to a microscope slide (see Basic Protocol 1, step 5) that contains HEPES-buffered medium with serum, pH 7.0, without phenol red.

   Phenol red is autofluorescent and therefore increases the background level of fluorescence within cells.

   Alternatively, the cells can be grown in commercially supplied coverslip–bottom open dishes (Lab-Tek chamber coverglass system, item nos. 136307, 136420, Nunc). These dishes allow drugs or other reagents to be easily added while the cells are being imaged. Such chambers, however, can only be used with an inverted microscope.

9. Place a drop of immersion oil on the non-cell side of the coverslip and view cells with a fluorescent microscope using a 63× or 100× oil immersion objective.

   a. View C_6-NBD-Cer–labeled cells using a filter combination on the microscope appropriate for fluorescein optics (i.e., one that excites the fluorophore at 450 to 490 nm and collects its emission at 520 to 560 nm).

   b. View BODIPY-Cer–labeled cells using the above filter combination or a filter combination that excites the fluorophore at 450 to 490 nm and collects its emission at >590 nm. For confocal microscopes, image with the 488-nm line of the Kr/Ar laser.

      The filter set collecting emission at >590 nm allows the distribution of BODIPY-Cer excimers to be visualized. These usually only form in Golgi membranes, where the lipid has become greatly concentrated. Because BODIPY-Cer excimer formation usually only occurs in the Golgi complex, imaging the red-shifted BODIPY-Cer signal rather than the green BODIPY-Cer signal provides a convenient way to avoid imaging the green signal from non-Golgi membranes (including the ER and plasma membrane) containing BODIPY-Cer.

   To keep cells at 37°C while viewing under the microscope, warm microscope stage by blowing warm air upon it with an air-stream incubator.

BASIC PROTOCOL 3

STAINING MITOCHONDRIA

This staining protocol (which is for living cells only, not fixed cells) is simple, since it merely involves incubating the cells in the presence of the dye. An additional consideration, however, is how to maintain normal cell behavior on the microscope stage. For physiological experiments on mammalian cells, where mitochondrial potential is to be measured or where the motility or distribution of mitochondria is being studied, it is necessary to regulate the temperature. The ability to perfuse different solutions or media may also be necessary. Several temperature-regulated chambers are commercially available. For experiments on an inverted microscope, the authors have used a thermoregulated microscope chamber from Bioptechs equipped for perfusion and solution exchange. Coverslips (no. 1, 31-mm diameter) were also obtained from Bioptechs. For experiments in which mitochondria are to be observed at room temperature, simpler mounting strategies can be used (e.g., see Chen, 1989).

Materials

100 nM TMRE working solution (see recipe) in NB
Normal buffer (NB; see recipe)

No. 1, 31-mm diameter coverslips (Bioptechs)
60-mm petri dishes
Forceps

Q tips or Kimwipes
Temperature-regulated microscope chamber (Bioptechs)
Conventional fluorescence microscope with conventional rhodamine filter *or* confocal microscope (*UNIT 4.2*)
40× or greater oil-immersion objective

1. Grow cells on no. 1, 31-mm glass coverslips.

   Culturing procedures will depend on the application. For example, to clearly observe the endoplasmic reticulum network of fibroblasts, trypsinize the cells, plate them on the coverslip at a relatively low density so that most cells are not in contact with another cell, and observe them after allowing them to spread overnight.

2. Fill three 60-mm petri dishes with NB and one tissue culture dish with 100 nM TMRE working solution in NB. Handling the coverslip with forceps, gently wash by serially dipping in the three NB dishes and finally in the TMRE solution. Return the coverslip to a new dish and incubate 10 min in 100 nM TMRE working solution in NB.

3. Remove the coverslip from the culture dish, dry the bottom of the coverslip with a Q-tip or Kimwipe, and mount in a microscope chamber. Fill the chamber with 100 nM TMRE in NB.

4. Observe cells using either a conventional rhodamine filter on a conventional fluorescence microscope or the 540- or 568-nm laser excitation line on a confocal microscope, and a 40× or greater oil-immersion objective lens.

   The staining should be sufficient for observing mitochondrial distribution, motility, or relative levels of mitochondrial membrane potential. Quantitative measurements of the membrane potential requires low-light-level imaging and digitization of images. These topics are covered in Loew et al. (1993) and Loew (1998).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ceramide fluorescent derivatives

Stock solution: For long-term storage, dissolve an appropriate amount of powdered Cer-derivative (C_6NBD-Cer or BODIPY-Cer; Molecular Probes) in a glass scintillation vial with a Teflon-lined screw cap containing 19:1 (v/v) chloroform/methanol. Blow argon gas on top of the liquid before sealing to prevent oxidation. Keep the tubes sealed and store up to 2 years at −20°C.

Working solution (1 mM): When ready to label cells, dry an aliquot of the chloroform stock under nitrogen and redissolve in absolute ethanol to make a solution of 1 mM.

For short-term storage (i.e., 1 to 2 weeks), dissolve the Cer-derivatives in 100% ethanol to a concentration of 1 mM, seal, and keep at −20°C.

$DiOC_6(3)$ stock and working solutions

Stock solution (0.5 mg/ml): Prepare ~10 ml of 0.5 mg/ml $DiOC_6(3)$ (D-273 from Molecular Probes) in ethanol. Store in a scintillation vial wrapped in aluminum foil at room temperature (probably good for several years).

Working solution for Basic Protocol 1 (2.5 μg/ml): Make a 0.5% (v/v) dilution in PBS (*APPENDIX 2A*) of the 0.5 mg/ml $DiOC_6(3)$ stock solution [e.g., 5 μl $DiOC_6(3)$ stock in 1 ml PBS].

Working solution for Alternate Protocol (0.5 μg/ml): Make a 1:1000 dilution of the 0.5 mg/ml stock solution in the growth medium appropriate to the cells of interest.

This working solution can be used for a few hours, but do not store overnight.

Mounting medium

PBS (*APPENDIX 2A*) containing:
50% (w/v) glycerol
0.1% (w/v) *p*-phenylenediamine
Adjust pH to pH 8.0 using NaOH
Store up to 1 to 2 weeks at 4°C

Normal buffer (NB)

7.6 g NaCl (130 mM final)
0.41 g KCl (5.5 mM final)
0.2 g $CaCl_2$ (1.8 mM final)
0.2 g $MgCl_2 \cdot 7H_2O$ (1.0 mM final)
4.5 g glucose (25 mM final)
4.8 g HEPES (20 mM final)
H_2O to 1 liter
Adjust pH to pH 7.4 with 1 N NaOH
Store up to 1 month at 4°C

Silicon rubber chamber

Using a razor blade, cut a 2.5 × 2.5–cm piece of Ronsil calendared sheet, 0.3 in. (0.76 mm) thick (purchase from North American Reiss; 100 feet minimum order). Using a hole puncher, cut a hole ~0.65 cm in diameter in the middle of the square over which the coverslip will be placed.

After the experiment, the silicon rubber chamber can be peeled off the slide, wiped clean with a Kimwipe, and reused.

TMRE

Stock solution (0.5 mM): To make 10 ml, add 2.5 mg TMRE (T-669 from Molecular Probes) to 10 ml of 95% ethanol. Store up to 1 year at −20°C.

Working solution (100 nM): Add 20 µl of 0.5 mM TMRE stock to 100 ml normal buffer (NB; see recipe). Use only on day of preparation.

One may consider using growth medium instead of NB to prepare the working solution, but this often produces higher background fluorescence, probably from phenol red or from serum binding of dyes.

COMMENTARY

Background Information

Endoplasmic reticulum

The endoplasmic reticulum (ER) was discovered by electron microscopy in the peripheral regions of osmium-fixed cells grown on formvar-coated grids (Porter et al., 1945; Porter, 1953). The peripheral regions of cells are thin enough that the organization can be imaged without sectioning. The name ER was given to a network (reticulum) that was more abundant in the central (endoplasmic) portion as opposed to the motile periphery (ectoplasm). Therefore, the ER was first defined purely in terms of morphology. With the advent of thin-section electron microscopy and differential centrifugation, the functions of the membranes became established.

The use of fluorescent dyes to stain the ER grew out of the use of dyes for monitoring membrane potential (Cohen et al., 1974). Dicarbocyanine dyes are of the "slow" class of potential-sensitive dyes (Sims et al., 1974). Rhodamine 123, like many of the dicarbocyanine dyes, was found to label mitochondria in living cells (Johnson et al., 1980). Michael Weiss found that one of the dicarbocyanines labeled a network when viewed at high magnification (Terasaki et al., 1984). Rhodamines and dicarbocyanines were screened, and $DiOC_6(3)$ was chosen as the brightest and most photostable stain for the network. The network was identified as ER, based on its morphology. In addition, conditions for staining fixed cells were described. It was initially stated that the dye did not stain Golgi or endosomes, but it was

later concluded that it did stain these organelles (Terasaki et al., 1986; Terasaki and Reese, 1992). There was some uncertainty among cell biologists whether the network stained was actually the ER, even though this network had been originally defined as the ER. Double imaging of BiP, a protein agreed to be in the ER, proved that the peripheral network stained by $DiOC_6(3)$ was identical to the BiP immunofluorescence pattern (Terasaki and Reese, 1992).

This two-dimensional network of ER in the periphery of many cultured cell types has some noteworthy characteristics. All of the ER network in this region is close to the plasma membrane. This is in contrast to the bulk of the ER of most cells, which is in the interior and not close to the plasma membrane. The ER network is usually composed of tubules that are connected by three-way junctions; sometimes, large sheets that correspond to ER cisternae are also seen (Terasaki et al., 1986). The tubules near the leading edge of the cell are often aligned with microtubules that are responsible for extending the ER tubules outward (Terasaki et al., 1986; Dailey and Bridgman, 1989). It is also noteworthy that the ER network in the periphery is relatively sparse. First of all, due to the limitations in light microscopy, the fluorescence image of the ER tubules is larger than its actual width, which is on the order of 100 nm. When the ER is seen in whole-mount electron micrographs, it looks surprisingly thin (Dailey and Bridgman, 1991). Secondly, it is easy to see that the total amount of ER membrane in the peripheral regions is less than the amount of plasma membrane in those regions. This is in contrast to the situation in most cells, where the area of the ER is many times as large as that of the plasma membrane.

Another dicarbocyanine dye, DiI [$DiIC_{18}(3)$] has been used to label the ER (Terasaki and Jaffe, 1991). This method results in more specific labeling of the ER and is well suited for three-dimensionally arranged ER, but requires microinjection (Terasaki and Dailey, 1995).

Golgi complex

The Golgi complex plays a central role in secretory protein processing and trafficking within cells. It receives membrane-enclosed packets of protein cargo from the ER, modifies and processes cargo proteins, and then repackages them into transport intermediates for delivery to the plasma membrane and other intracellular destinations (Mellman and Simons, 1992). To perform these tasks, the Golgi complex is enriched in a variety of resident enzymes involved in carbohydrate processing. It also has a unique lipid composition that includes high concentrations of cholesterol and other lipids relative to the concentrations found in the ER. This property is the basis for vital staining of the Golgi with fluorescent lipids. The C_6-NBD- and BODIPY-fluorescent analogs of ceramide have proved to be particularly valuable for this purpose. C_6-NBD-Cer is formed by *N*-acylation of the long-chain base, sphingosine, with the short-chain fluorescent fatty acid, *N*-[7-(4-nitrobenzo-2-oxa-1,3-diazole)]-6-aminocaproic acid (C6-NBD-FA). C_6-NBD-Cer can be synthesized in the laboratory (Kishimoto, 1975; Schwarzmann and Sandhoff, 1987) or purchased from Molecular Probes. The newer fluorescent ceramide analog, BODIPY-Cer, is a conjugate of D-*erythro*-sphingosine and a fluorescent fatty acid containing the fluorophore boron dipyrromethene difluoride (BODIPY). It has ~2- to 3-fold higher fluorescent yield and greater photostability than NBD-ceramide (Pagano et al., 1991). An additional advantage of the BODIPY-Cer analog is that its fluorescence emission spectrum is dramatically red shifted as the probe concentrates in membranes. This is due to excimer formation of the BODIPY-Cer molecules. The Golgi complex is usually the only membrane system where BODIPY-Cer accumulates to high enough levels to form excimers and hence is the only organelle where the red shift occurs (Pagano et al., 1991). By using microscope filters appropriate for visualizing the red-shifted BODIPY-Cer that has formed excimers in Golgi membranes, non-Golgi membranes containing low concentrations of the dye will not be visualized.

The mechanism whereby C_6NBD-Cer and BODIPY-Cer initially accumulate in the Golgi complex is not understood. It has been suggested that Golgi labeling by C_6-NBD-Cer and BODIPY-Cer is due to preferential partitioning into Golgi membranes as a result of the specific physical properties of these membranes. This could explain why NBD-Cer labeling of the Golgi complex occurs at low temperature or in the presence of metabolic inhibitors, and can even occur in cells that have been fixed before incubation.

The finding that C_6-NBD-ceramide labels the Golgi complex after cells have been fixed (Pagano et al., 1989) is the basis for a novel methodology for visualizing the Golgi complex at the electron microscope (EM) level (Pagano and Martin, 1998). In this protocol, fixed cells labeled with C_6-NBD-ceramide are photobleached in the presence of diaminoben-

zadine (DAB). The photooxidation products catalyze the polymerization of DAB to yield a high-molecular-weight osmiophilic compound that can be visualized at the EM level. Previous work has shown that under these conditions, the C_6-NBD-ceramide product labels the trans-Golgi elements (Pagano et al., 1989, 1991).

In addition to being useful markers for Golgi membranes in localization studies (Lipsky and Pagano, 1985a; van Meer et al., 1987; Kobayashi and Pagano, 1989; Rosenwald and Pagano, 1993; van't Hof and van Meer, 1990), C_6-NBD-Cer and BODIPY-Cer have been used in fluorescent time-lapse imaging studies to analyze the dynamics of the Golgi complex in cultured cells (Cooper et al., 1990; Sciaky et al., 1997; see Fig. 4.4.2). These studies have shown that while Golgi elements have a large-scale stability in organization, they are remarkably dynamic. Long tubule processes were often seen extending off the rims of Golgi elements during time-lapse imaging. The Golgi tubule processes appeared to serve both to interconnect adjacent Golgi elements and to carry Golgi membrane out to the cell periphery.

Mitochondria

Mitochondria in tissue culture cells can be seen by phase-contrast or bright-field microscopy. Johnson et al. (1980) described the use of rhodamine 123 for viewing mitochondria by fluorescence microscopy. Many fluorescent dyes that had been developed for monitoring plasma-membrane potential have turned out to stain mitochondria similarly. Fluorescence staining of mitochondria produced images of much higher contrast than available with transmitted light microscopy, and it was also realized that they could be used for monitoring mitochondrial membrane potential. Some mitochondrial dyes have been reported to selectively kill cultured cancer cells that retain them longer (Bernal et al., 1982). Molecular Probes has generated the greatest number of new mitochondrial probes in recent years.

Critical Parameters

Endoplasmic reticulum

The best way to fluorescently label the ER is probably to express a GFP chimera targeted to the ER (Hampton et al., 1996; Terasaki et al., 1996). However, it may be difficult to express GFP constructs in a given cell, or the fluorescence may not be bright enough. $DiOC_6(3)$ is an older method for staining the ER, but is still useful because of the ease of use and brightness of staining. Its great weakness is the lack of specificity of staining; $DiOC_6(3)$ will stain all of the ER but will stain other organelles as well.

It must be stressed that $DiOC_6(3)$ does not stain the ER specifically. $DiOC_6(3)$ is a positively charged lipophilic molecule that permeates through the plasma membrane. At low concentrations, it accumulates in mitochondria due to the effect of the large negative mitochondrial membrane potential on the positively charged dye. At higher concentrations, the dye stains other membranes, including the ER. The mitochondria are swollen at these higher concentrations, suggesting that they are no longer concentrating dye, and that the dye is free to associate with other membranes. In fixed cells, the dye stains ER, mitochondria, and large vesicles even at the lowest concentrations. The simplest interpretation is that the dyes are associating with all intracellular membranes. Some of the membranes may be so small that the amount of dye contained in them is not visible. Since $DiOC_6(3)$ probably stains all membranes, it is only useful as an ER stain when the ER pattern can be distinguished from the other membranes. The thin peripheral region of many cultured cells has often been used, because in that region the ER is a single-layered network that is easily identified.

Other dyes with the same staining properties as $DiOC_6(3)$ include rhodamine 6G, $DiOC_6(5)$, $DiIC_6(3)$, and $DiSC_6(3)$ (all screened in Terasaki et al., 1984), as well as hexyl ester rhodamine B (Terasaki and Reese, 1992). All of these are lipophilic cationic dyes that stain only mitochondria at low doses in living cells. If it is desired to observe ER staining with a rhodamine filter set, hexyl ester rhodamine B (Molecular Probes R-648, also known as "R6") may be the best dye to try first.

The quality of the images obtained with $DiOC_6(3)$ is generally much better than that obtained with immunofluorescence staining. One reason is that the glutaraldehyde used for $DiOC_6(3)$ staining is a superior fixative that is usually not used for immunofluorescence because of the autofluorescence that develops with time. $DiOC_6(3)$ methods use lower glutaraldehyde concentrations and images are observed before autofluorescence develops. Another reason is that immunofluorescence requires permeabilization of the cells with detergents or organic solvents. These treatments generally disrupt the delicate membranes of the ER, so that they are no longer continuous, or are so disfigured that the network pattern is no longer discernible. Immuno-

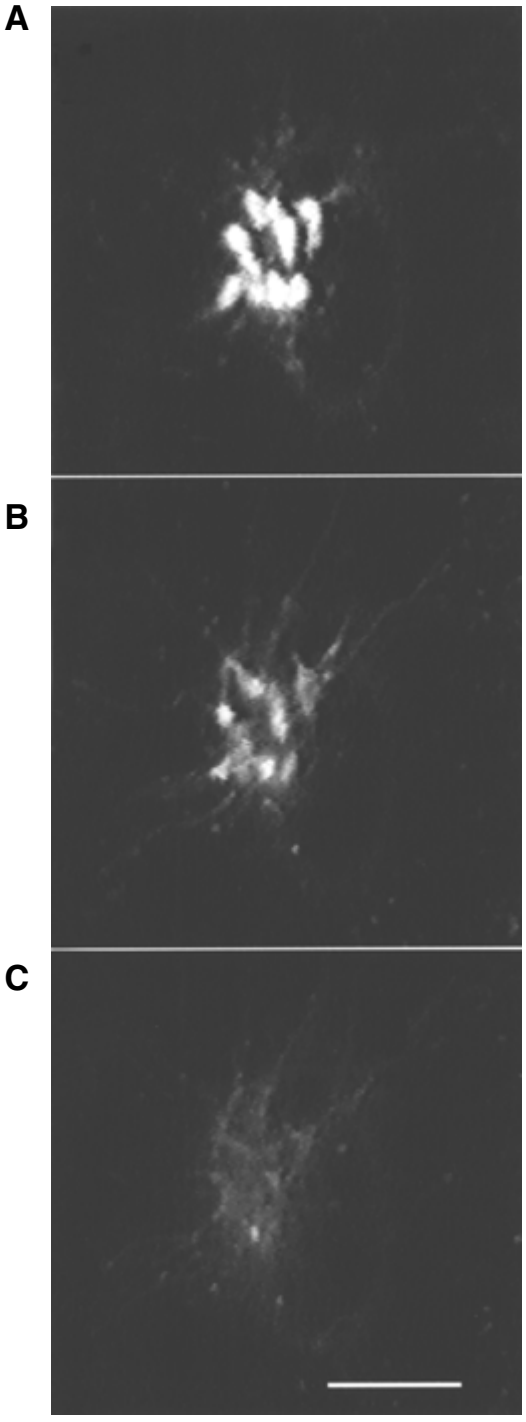

Figure 4.4.2 BODIPY-Cer labeling of Golgi membranes to study the effects of brefeldin A (BFA). Golgi membranes were labeled with BODIPY-Cer and then treated with brefeldin A before imaging at 37°C on a cooled CCD microscope system. Note that Golgi membranes tubulated in response to the drug and then dispersed (Sciaky et al., 1997). (**A**) Image collected immediately after addition of BFA; (**B**) image collected 5 min later; and (**C**) image collected 10 min after addition of drug. Bar is equal to 10 μm.

fluorescence has the advantage, however, of labeling specific molecules in the ER. Immunofluorescence can also show compartmentalization in the ER, and is also much better suited than $DiOC_6(3)$ for screening the results of multiple experimental variations, because of the short period during which the dye staining is optimal.

$DiOC_6(3)$ is well suited for observations in living cells. One drawback is that the mitochondria are swollen at dye concentrations required to stain the ER, so that there is a possibility that the cells are not behaving normally. Nevertheless, $DiOC_6(3)$ has been used successfully for observing ER dynamics at video rates (Lee and Chen, 1988), in time-lapse (Dailey and Bridgman, 1989; Terasaki and Reese, 1994), and during mitosis (Waterman-Storer et al., 1993). It is particularly good for observing ER movements during cytoplasmic streaming in plant cells (Allen and Brown, 1988; Knebel et al., 1990; McCauley and Hepler, 1990). When using the fluorescent dyes on a new organism, it is important to optimize the staining conditions. Koning et al. (1993) give a good description of how the cell chamber and optical conditions were optimized for yeast. For some discussion of other cell preparations and of other aspects of this method, see earlier reviews (Terasaki, 1989, 1993, 1998). For live-cell imaging by confocal microscopy, see Terasaki and Dailey (1995).

Golgi complex

Attention to several critical parameters is important for ensuring the success of C_6-NBD- and BODIPY-Cer labeling of cells. These parameters include the amount of fluorescent lipid added to cells, the length of time for incorporation of the lipid into cells, and the method of imaging cells. Each of these parameters needs to be optimized to ensure that Golgi labeling is bright and specific, and that cells are not damaged during the labeling or imaging process.

Although incubation of cells with medium containing 5 to 10 μM fluorescent Cer-derivative for 30 min at 4°C, washing, and warming to 37°C for 30 min is recommended, the optimal conditions for Golgi labeling vary depending on cell type and therefore need to be tested. The level of brightness of Golgi labeling also depends on the purpose of the experiment. If cells are to be used for time-lapse imaging of the Golgi complex, for example, a brighter signal than normal is recommended since the fluorescent lipid is quickly photobleached during repetitive imaging. To increase levels of Golgi labeling, simply incubate cells with a higher concentration of fluorescent-ceramide solution, and vice-versa for lower levels of Golgi labeling.

Higher levels of Golgi labeling are not always desirable. Labeling of non-Golgi membranes also usually increases under conditions where Golgi labeling increases. In addition, if the Golgi complex is too bright, images will be saturated (with low signal-to-noise ratios) and the risk of photobleaching damage upon imaging is greater.

For time-lapse imaging studies, BODIPY-Cer is preferable to C_6-NBD-Cer because it has a slower rate of photobleaching. Even BODIPY-Cer photobleaches quickly relative to other fluorophores (e.g., rhodamine) so imaging with a low-light detection system is essential. To reduce photobleaching of fluorescent ceramide derivatives in time-lapse studies, minimal exposure of the specimen to bleaching radiation is essential. Control of the exposure time during imaging is critical in these types of experiments. This can be done by using a computer-controlled shutter to control exposure time and by using neutral-density filters during illumination to reduce the light reaching the specimen. Imaging with low light intensity through the use of neutral-density filters will lead to significantly less photobleaching. This is essential for time-lapse studies of C_6NBD- or BODIPY-Cer labeled cells.

Photobleaching results in permanent inactivation of the fluorophore due to its interaction with neighboring molecules. This frequently involves the generation of free radicals that can damage the cell. In time-lapse imaging studies where the specimen becomes photobleached due to repetitive imaging, it is essential to monitor the overall appearance of the cell to assess potential light-induced damage to the cell. A typical response by cells that are being damaged by photobleaching radiation is for them to round up and then eventually die.

The process of finding a labeled cell and focusing it can cause extensive photobleaching if performed without neutral-density filters. A useful approach is to find and focus cells in phase optics before imaging the specimen with fluorescent light. Cells that are fixed after staining for double-label studies should be immediately processed using as little light exposure as possible. The fixed cells should be imaged immediately when they are ready, since they do not store for very long periods. If double labeling with an antibody is being performed after fixa-

Table 4.4.1 Troubleshooting Guide for Fluorescent Staining of Organelles

Problem	Possible causes and/or solution(s)
Endoplasmic reticulum	
Staining pattern is too dense to see a network	This means that the the staining of the ER and/or other organelles is too dense relative to the resolution of light microscopy. If ER membranes are separated from each other or from other organelles by <0.5 μm or so, it will be difficult to resolve them by light microscopy. If the ER has a three-dimensional organization, the overlapping membranes compound the problem. Sometimes, using a 100× lens or a confocal microscope can help. It may be necessary to use another cell type or to resort to other means to localize the ER, such as electron microscopy.
Vesiculation of ER network	One possible cause is poor fixation. Fixation with formaldehyde often causes vesiculation of the ER network. If glutaraldehyde is being used, it may help to try a fresh stock solution. Another cause of vesiculation is the fixation buffer. Make sure that the tonicity and pH are physiological. For fixed cells, it may help to replace PBS with another buffer (100 mM sucrose/100 mM sodium cacodylate, pH 7.4). Another cause of vesiculation is drying of the cells during the processing. It is important to keep the cells hydrated at all times.
Smeared-out network	This can be caused by organic solvents or detergents that extract the membranes and the dye staining. Do not use nail polish to seal coverslips to microscope slides since the organic solvents in the nail polish will have this same effect.
Out-of-focus, distorted network	This is usually a problem of the microscope optics. Make sure that there is no water in the immersion oil on the coverslip. Also check for dried material, broken pieces of coverslip, and other debris on the objective lens.
No network visible	In one cell type, fish chromatophores, $DiOC_6(3)$ did not stain the ER and gave a diffuse background staining (M. McNiven, pers. comm.). This was surprising, since preparations from many higher vertebrates, as well as many invertebrates and unicellular organisms, have been successfully stained with $DiOC_6(3)$. Perhaps the lipid composition of the ER in the fish chromatophores somehow prevents the partitioning of $DiOC_6(3)$ into the membrane bilayer.
Golgi complex	
Background labeling with fluorescent lipid is too high	Use lower concentrations of fluorescent lipid (<5 μM) during initial labeling of cells.
There is no specific labeling	Check stock solutions of fluorescent lipids to see if they were properly prepared and are not too old. Check to see if incubation with fluorescent lipid solution for longer times at 4°C and/or 37°C result in specific labeling.
Nonspecific labeling is too high	Reduce concentration of fluorescent lipid added to cells. Wait for longer times after shift to 37°C before viewing cells. Check to make sure cells are not autofluorescent (i.e., whether unlabeled cells show the same non-specific labeling). Consider labeling with BODIPY-Cer and viewing cells in rhodamine optics so that fluorescence from the BODIPY-Cer excimers is only being imaged.
Specific staining is too dim	Add higher concentrations of fluorescent lipid to cells and incubate at 4°C for longer periods.

continued

Table 4.4.1 Troubleshooting Guide for Fluorescent Staining of Organelles, continued

Problem	Possible causes and/or solution(s)
Cells round up and appear unhealthy during imaging	Use attenuated light to image cells. Image for only short time periods. Label cells with lower concentrations of fluorescent lipid.
Fluorescence is lost too quickly because of photobleaching	Find cells and focus them using phase optics to reduce the extent of photobleaching prior to imaging. Use attenuated light to image cells and image for as short a time as possible. Imaging systems that detect low light levels are useful since photobleaching is reduced when specimens are imaged with less light. Use BODIPY-Cer instead of NBD-Cer since the former photobleaches less rapidly than the latter.
Mitochondria	
Dim labeling	This probably means that the dye staining concentration or incubation period needs to be increased. If this does not help, perhaps this is due to a very low mitochondrial membrane potential. This in turn may be due to poor health of cells.
Swollen mitochondria; labeling of ER (fine reticular network throughout cell) in addition to mitochondria; cell death	These are indications that there is too much dye in the cells. The solution is to decrease dye staining concentration.

tion of the C_6-NBD-Cer or BODIPY-Cer labeled cells, it is crucial to check that there is minimal cross-over of the fluorescent Cer into the channel used for revealing the fluorescent antibody staining. BODIPY-Cer labeled cells usually cannot be be used in double-labeling experiments, since BODIPY-Cer emits light at multiple wavelengths due to excimer formation.

Mitochondria

Since the first report of fluorescent dye staining of mitochondria (Johnson et al., 1980), many dyes have been found that have similar properties. Generally, these dyes are all small, lipophilic cationic molecules. The lipophilicity allows them to cross the plasma membrane, and the positive charge causes them to be accumulated in the mitochondria, which have a high negative membrane potential.

Rhodamine 123, the first fluorescent dye for mitochondria (Johnson et al., 1980), is used to stain cells at 10 μg/ml for 10 min followed by a brief wash and mounting in dye-free growth medium (Chen, 1989). The stock solution used for this dye is 1 mg/ml in water. Because the staining is observed in dye-free medium, mitochondrial staining eventually decreases due to leakage from the cells. The leakage rate is highly dependent on cell type. In some cases, the dye is retained for over an hour, but in others, it leaks out within 10 min.

Several rhodamine and dicarbocyanine dyes have similar staining properties to those of rhodamine 123, although rhodamine 123 may be less toxic (Chen, 1989). Two examples are rhodamine 6G and the dicarbocyanine dye $DiOC_6(3)$. The staining concentrations are lower for several of these dyes, and some of them can be left in the medium because they have a relatively low background. Other reasons for using one of these other dyes are brightness, slower bleaching rate, or convenience of fluorescence spectrum. Rhodamine 123 has an advantage in that it does not stain the ER at high doses, whereas most of the other dyes do. The dye described in Basic Protocol 3, TMRE, is well documented for quantitative measurements of the mitochondrial membrane potential (Loew et al., 1993).

Several other mitochondrial dyes are available for studying mitochondrial properties in interesting ways. The MitoTracker series of dyes can be fixed in place once they have been stained (Poot et al., 1996; Poot, 1998). JC-1 dyes change fluorescence after they form "J aggregates" which is potential dependent (Smiley et al., 1991). The CM-H2TMRos dye is nonfluorescent until it becomes oxidized in

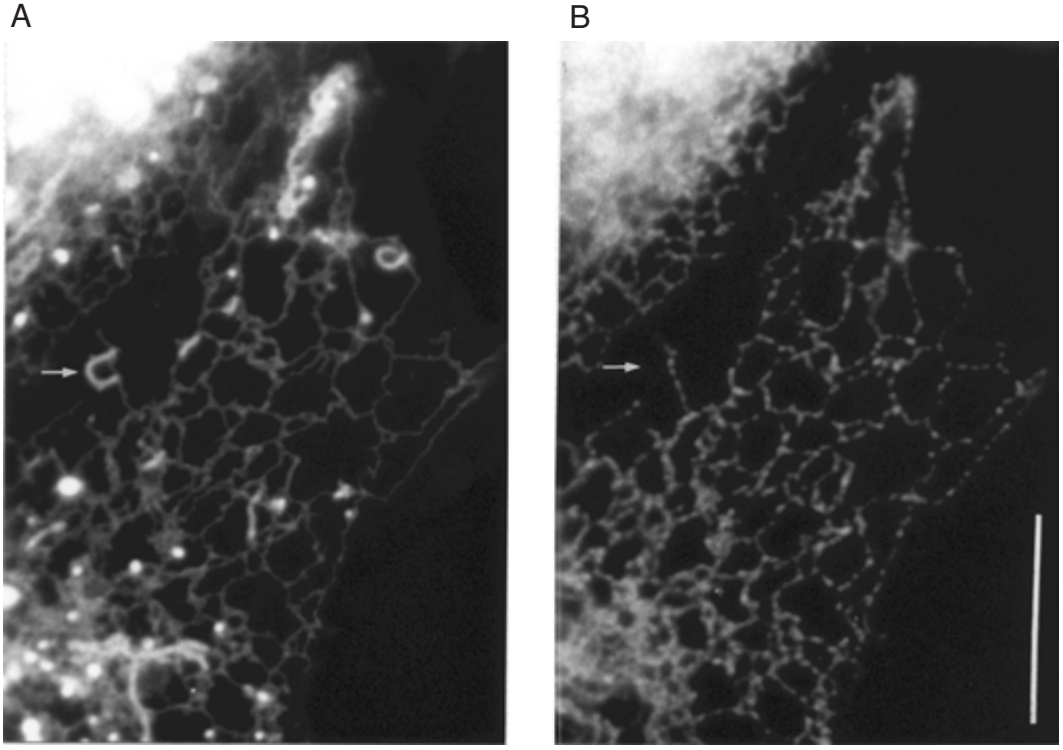

Figure 4.4.3 CV-1 cell double-labeled with (**A**) $DiOC_6(3)$ and (**B**) immunofluorescent staining of BiP, a protein in the ER. Bar is equal to 10 μm.

the mitochondria. Nonyl acridine orange is thought to bind to cardiolipin rather than respond to membrane potential. A good place to get a more detailed overview of the different kinds of mitochondrial stains is the Molecular Probes catalog (Haugland, 1996).

Troubleshooting

Table 4.4.1 lists some problems that may be encountered in fluorescent staining the ER, Golgi complex, and mitochondria along with some possible causes and solutions.

Anticipated Results

Endoplasmic reticulum

The ER is best seen in the thin peripheral region of cultured cells, where it has a two-dimensional distribution. In some cell types, this peripheral region is very narrow or nonexistent, in which case $DiOC_6(3)$ will probably not be of use. The ER pattern differs considerably from cell type to cell type, and also from cell to cell in a population. It is usually a network of tubes, but can also contain sheets or membrane cisternae. The overall pattern often seems to mirror underlying stresses or morphogenetic processes of the cytoplasm, and can be anything from a closely spaced isotropic meshwork to a highly unrestrained pattern (seen more often in primary cultures).

Figure 4.4.3 shows a CV-1 cell (from African green monkey kidney), double-labeled with $DiOC_6(3)$ (panel A) and immunofluorescence of BiP (panel B), a protein in the ER. Note that $DiOC_6(3)$ stains a continuous network as well as mitochondria (arrow). Anti-BiP labels a vesiculated network, but does not label the mitochondria. The cells were first fixed lightly with glutaraldehyde (0.025% for 5 min), stained with $DiOC_6(3)$, photographed, then permeabilized with −20°C methanol and processed for immunofluorescence (Terasaki and Reese, 1992). The vesiculated network seen in immunofluorescence was caused by the methanol permeabilization.

Golgi complex

Once conditions for specific labeling of the Golgi complex have been optimized, the localization and dynamics of the Golgi complex can be studied. Golgi membranes usually appear as a ribbon-like structure near the microtubule organizing center adjacent to the nucleus (Rogalski and Singer, 1984; Cole et al., 1996). Frequently, thin tubule processes interconnect the larger Golgi structures (Cooper et al., 1990). Because the normal distribution of Golgi mem-

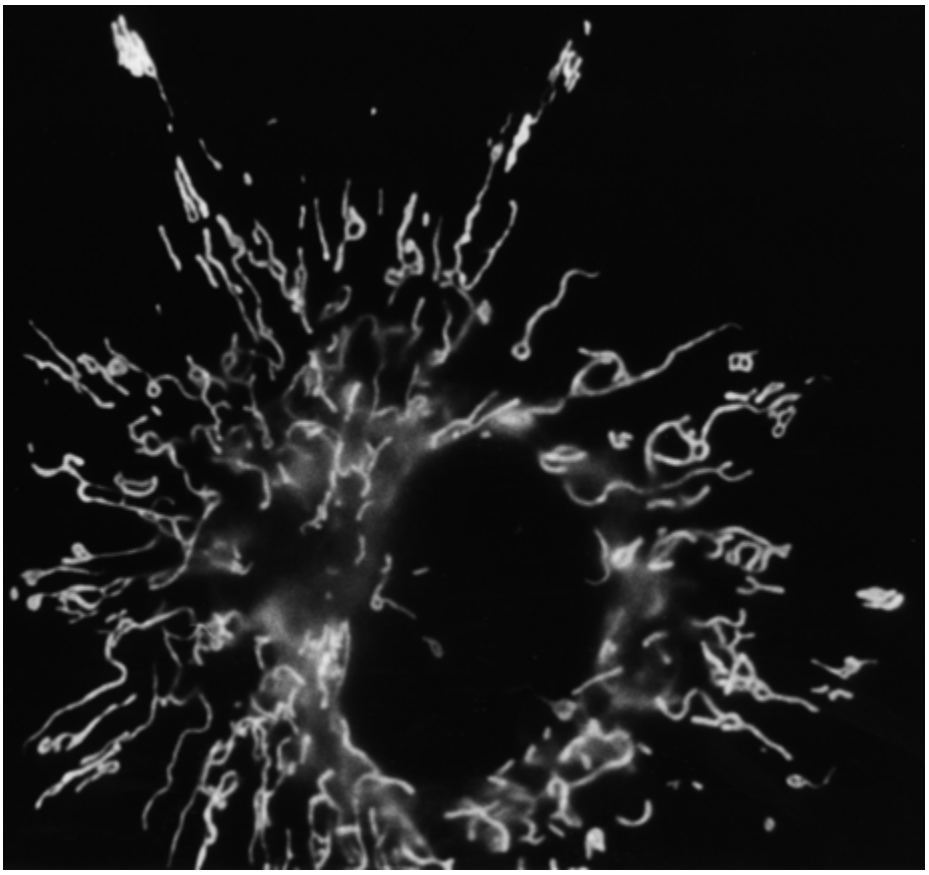

Figure 4.4.4 Labeling of the mitochondria in a CV-1 cell.

branes within cells represents a dynamic steady state of forward and recycling pathways connecting the Golgi and ER, any condition that perturbs forward traffic into the Golgi complex without a corresponding effect on recyling will result in redistribution of Golgi material to the site of perturbation (Cole et al., 1996). One example where the Golgi complex undergoes such reorganization is during microtubule disruption, which causes extensive fragmentation of the Golgi into hundreds of elements scattered throughout the cell (Turner and Tartakoff, 1989). Microtubules are known to serve as tracks for delivery of ER-derived transport intermediates into the centrosomal Golgi region (Presley et al., 1997; Scales et al., 1997) and are not as important for Golgi-to-ER traffic (Cole et al., 1996), therefore when net forward transport into the Golgi is blocked during microtubule depolymerization, Golgi proteins accumulate at ER exit sites and regenerate short Golgi stacks at these sites (Cole et al., 1996).

Mitochondria

Labeling of the mitochondria in a CV-1 cell (African green monkey kidney) is shown in Figure 4.4.4. The appearance of the mitochondria can be very variable. In some cell lines, they are short, in others very long. Mitochondria are often aligned with cytoskeletal elements (Summerhayes et al., 1983).

Time Considerations

This is a rapid staining procedure once all the equipment and materials are in place. Equilibration time for staining is ~10 min.

The time required for making the chamber and getting the microscope set should be 5 to 10 min. Staining the ER with $DiOC_6(3)$ is very rapid as compared to immunofluorescence. A certain amount of preparation is required, but once everything is in place, fixation, staining and microscopy can be done in 20 min or so.

The entire labeling procedure for the Golgi complex can be performed in ~1 hr. Although samples can be subsequently fixed and used for double-labeling studies with antibodies, they usually cannot be stored for very long (due to signal loss from photobleaching), so immediate use in imaging studies is recommended.

Once the equipment and reagents are prepared, mitochondrial staining is rapid.

Basic Confocal Microscopy

Confocal microscopy produces sharp images of structures within relatively thick specimens (up to several hundred microns). It is particularly useful for examining fluorescent specimens. Thick fluorescent specimens viewed with a conventional widefield fluorescent microscope appear blurry and lack contrast because fluorophores throughout the entire depth of the specimen are illuminated, and fluorescence signals are collected not only from the plane of focus but also from areas above and below. Confocal microscopes selectively collect light from thin (~1-μm) optical sections representing single focal planes within the specimen. Structures within the focal plane appear more sharply defined than they would with a conventional microscope because there is essentially no flare of light from out-of-focus areas. A three-dimensional view of the specimen can be reconstructed from a series of optical sections at different depths.

The confocal microscope is the instrument of choice for examining fluorescence-stained cells in tissue slices or small, intact organisms such as *Drosophila* (Fig. 4.5.1A,B) and zebrafish embryos. It is also useful for localizing fluorescent-tagged molecules in dissociated cells (Fig. 4.5.1C,D). Its sensitivity even allows fluorescence in living specimens to be monitored, making it feasible to follow the movements in living cells of fluorescent probes such as the green fluorescent protein (GFP; Fig. 4.5.1D). In addition, some types of confocal microscopes can be configured to perform photobleach experiments (Fig. 4.5.1D) and to photoactivate "caged" molecules (molecules that are inactive until released with UV illumination).

Biologists use confocal microscopy in a number of creative ways that are beyond the scope of this article. The information presented herein is intended to provide background and practical tips needed to get started with confocal microscopy. An excellent source of theoretical and technical information is the *Handbook of Biological Confocal Microscopy* (1995; edited by J. Pawley). Also recommended are *Cell Biological Applications of Confocal Microscopy* (1993; edited by B. Matsumoto), a good source of practical information; *Confocal Microscopy* (1990; edited by T. Wilson), for theoretical background; and *Video Microscopy* (1997; Inoué and Spring) for fundamentals of microscopy.

BASIS OF OPTICAL SECTIONING

Confocal microscopes accomplish optical sectioning by scanning the specimen with a focused beam of light and collecting the fluorescence signal from each spot via a spatial filter (generally a pinhole aperture) that blocks signals from out-of-focus areas of the specimen. The physical basis of optical sectioning in fluorescence confocal microscopy is illustrated in Figure 4.5.2. A point light source (typically a laser) evenly illuminates the back focal plane of the objective, which focuses the light to a diffraction-limited spot in the specimen. The irradiation is most intense at the focal spot, although areas of the specimen above and below the focal spot are also illuminated. Fluorescent molecules excited by the incident light emit fluorescence in all directions. The fluorescence collected by the objective comes to focus in the image plane, which is conjugate (confocal) with the focal plane in the specimen. A pinhole aperture in the image plane allows fluorescence from the illuminated spot in the specimen to pass to the detector but blocks light from out-of-focus areas.

The diameter of the pinhole determines how much of the fluorescence emitted by the illuminated spot in the specimen is detected, and the thickness of the optical section. From wave optics we know that a point light source in the plane of focus of an objective produces a three-dimensional diffraction pattern in the image plane. The cross section at the image plane is an Airy disk, a circular diffraction pattern with a bright central region. The radius of the bright central region of the Airy disk in the reference frame of the specimen is given by

$$R_{\text{Airy}} = 0.61\lambda/\text{NA}$$

where λ is the emission wavelength and NA is the numerical aperture of the objective (see *UNIT 4.1* for a discussion of NA). At the image plane (the location of the pinhole aperture), the radius of the central region is R_{Airy} multiplied by the magnification at that plane (for a more complete explanation see Wilson, 1995).

Adjustment of the pinhole to a diameter slightly less than the diameter of the central region of the Airy disk allows most of the light from the focal point to reach the detector and reduces the background from out-of-focus areas by ~1000-fold relative to widefield microscopy (Sandison et al., 1995). The separation of the in-focus signal from the out-of-focus back-

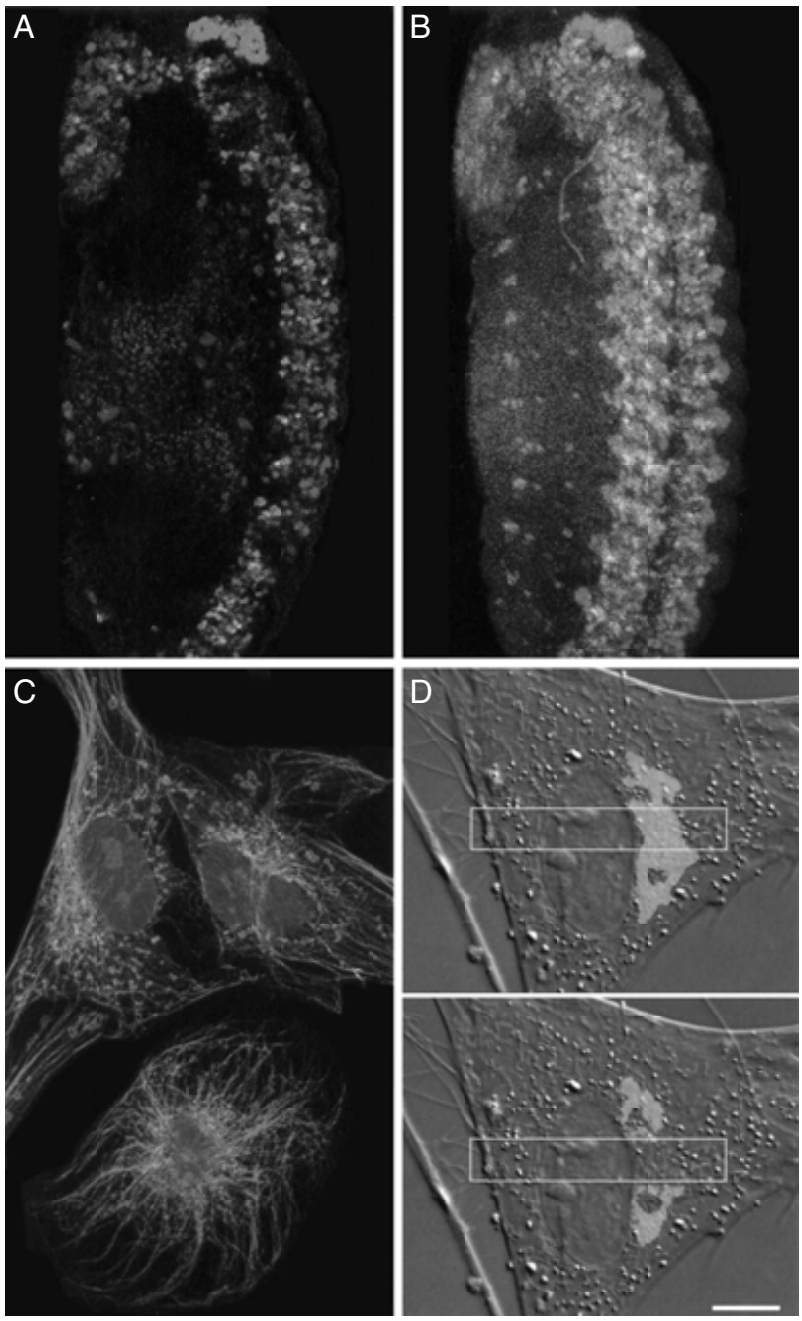

Figure 4.5.1 Applications of laser scanning microscopy. Top images (from W. Odenwald; see Kamabadur et al., 1998) show three-dimensional analysis of thick specimens. Different neuronal populations of an ~250-μm-thick *Drosophila* embryo were immunolabeled with antibodies against three transcription factors. (**A**) Approximately 2.5-μm optical section collected with 25×, 0.8-NA objective using a detector pinhole diameter of ~1.3 Airy units. Labeled neurons in the plane of focus appear sharply defined, while those outside it are not visualized. (**B**) Projection (superimposition) of 65 optical sections collected at 2-μm intervals in the *z* axis. Neurons at different focal planes appear to overlap in this flattened image, but are distinct in a 3-D reconstruction. (**C**) Localization of intracellular structures. Dissociated rat fibroblasts were immunolabeled with anti-tubulin antibodies to visualize microtubules (green) and stained with fluorescent probes for mitochondria (Mitotracker, red) and DNA (DAPI, blue). The image is a projection of 20 optical sections collected at 0.3-μm intervals in the *z* axis with 100×, 1.4-NA objective. (**D**) Measuring molecular motility. In a living fibroblast expressing a Golgi membrane protein (galactosyltransferase) fused to GFP (S65T-GFP), GFP fluorescence (green) localized to the Golgi complex, shown superimposed on a DIC image of the cell. After the first image was collected, the boxed region (yellow) was scanned with full laser power; this photobleached the GFP in the boxed area as shown in the second image collected ~2 sec later. The rate of fluorescence recovery into the photobleached zone (not illustrated) indicated that the GFP-galactosyltransferase fusion is highly mobile in Golgi membranes. **See color figure.**

ground achieved by a properly adjusted pinhole is the principle advantage of confocal microscopy for examination of thick specimens (see Fig. 4.5.1A,B).

Point illumination and the presence of a pinhole in the detection light path also produce improved lateral and axial resolution relative to conventional microscopy (Table 4.5.1). The actual extent of improvement depends on the size of the pinhole. Near-maximal axial resolution is obtained with a pinhole radius ~$0.7 \times R_{Airy}$ whereas optimal lateral resolution is obtained with a pinhole smaller than $0.3 \times R_{Airy}$ (Wilson, 1995). However, a pinhole smaller than ~$0.7 \times R_{Airy}$ significantly reduces the total signal, a sacrifice that may not be worth the gain in resolution, especially when imaging dim samples. In fluorescence imaging, resolution also is influenced by the emission and excitation wavelengths (Table 4.5.1).

TYPES OF CONFOCAL MICROSCOPES

Several types of confocal microscopes are available, each having unique features and advantages. Those most commonly used for examining fluorescence specimens are laser-scanning confocal microscopes. These microscopes, as their name implies, use lasers as light sources and collect images by scanning the laser beam across the specimen.

Lasers provide intense illumination within a narrow range of wavelengths. The emission wavelengths of several types of lasers, together with the excitation spectra of familiar fluorophores, are illustrated in Figure 4.5.3. Mixed krypton-argon gas lasers are popular for multi-wavelength confocal microscopy because they emit at three well-separated wavelengths (488, 568, and 647 nm) that can be used to simultaneously image two or three fluorophores (e.g., FITC, lissamine rhodamine, and Cy5). The disadvantage of krypton-argon lasers is that

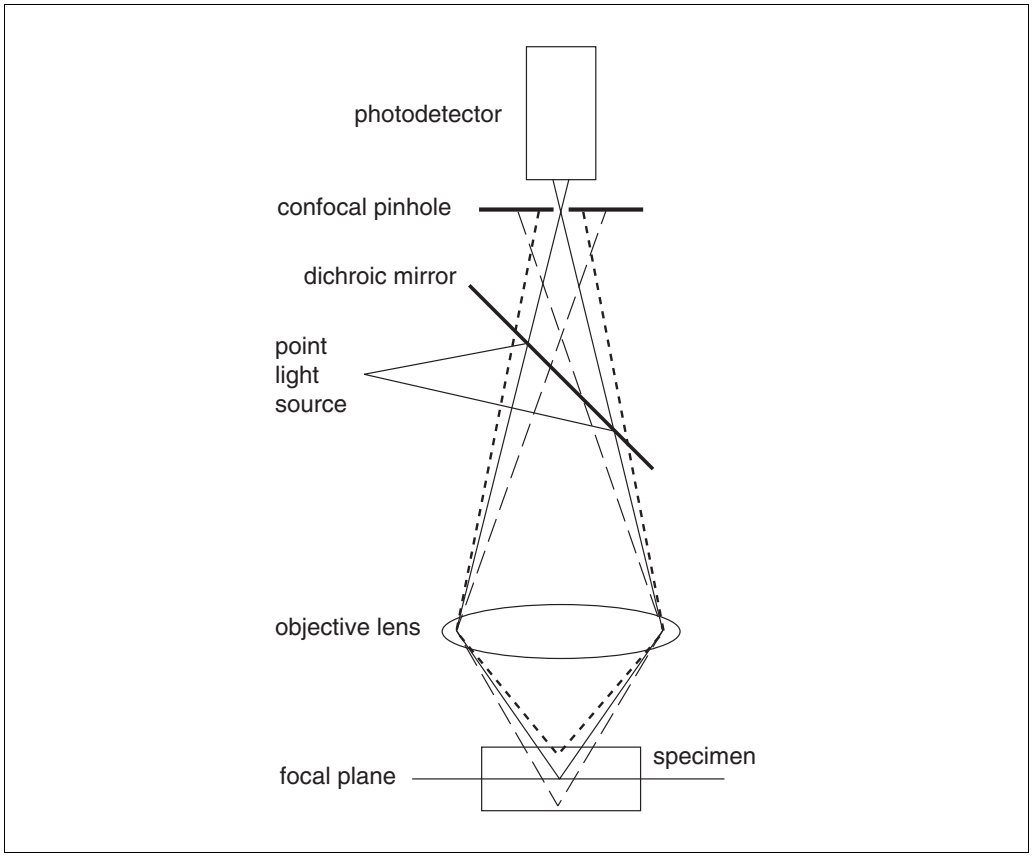

Figure 4.5.2 The basis of optical sectioning in confocal epifluorescence microscopy. Illumination from the point light source is reflected by the dichroic mirror and focused by the objective lens to a diffraction-limited spot within the specimen. Fluorophores within the focal spot as well as in the cone of light above and below it are excited, emitting fluorescence at a longer wavelength than the incident light. The fluorescence captured by the objective passes through the dichroic mirror because of its longer wavelength. The confocal pinhole allows fluorescence from the plane of focus in the specimen to reach the photodetector but blocks fluorescence from areas above and below the plane of focus. Redrawn from Shotton (1993).

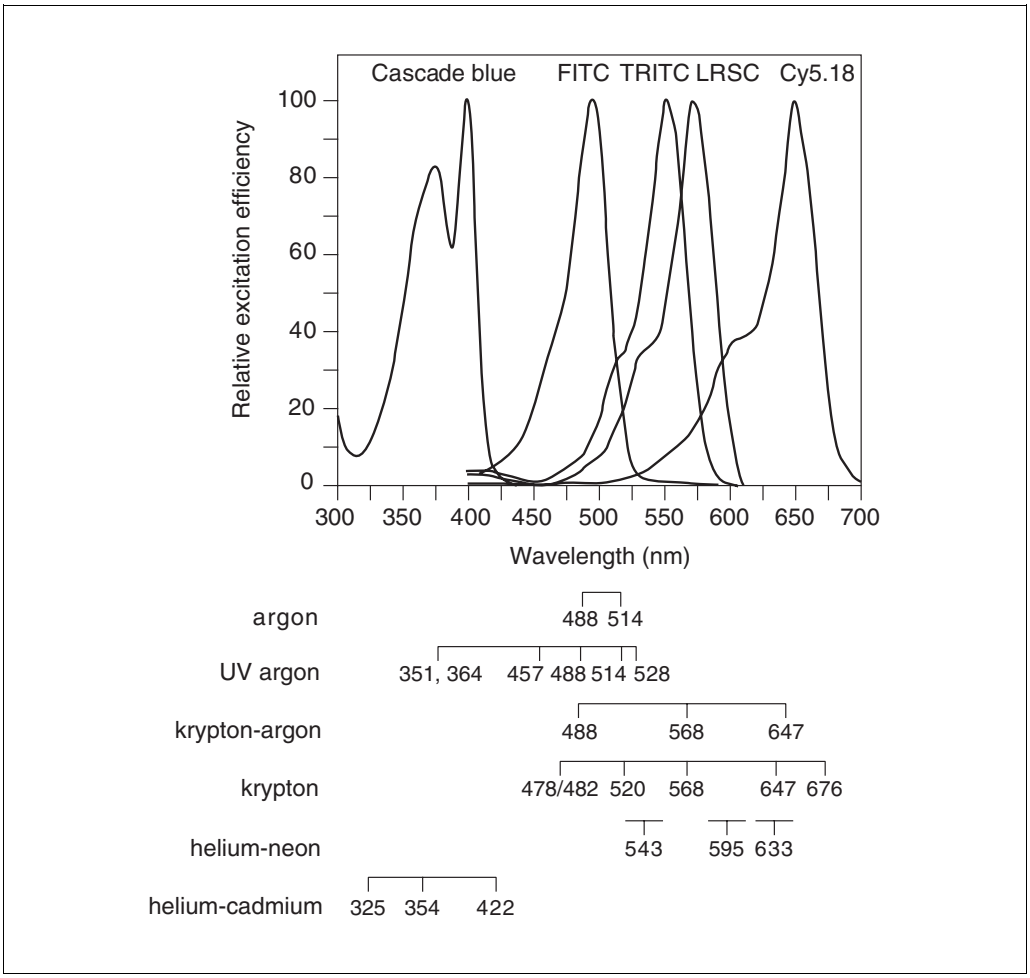

Figure 4.5.3 Comparison of the emission wavelengths of various lasers and the excitation spectra of representative fluorophores. The lasers most commonly used for laser-scanning confocal microscopy are air-cooled argon (488 and 514 nm), krypton-argon, and helium-neon lasers. UV argon lasers generally require water cooling and are more expensive. They may be configured to provide only UV wavelengths (351 nm and 364 nm) or both UV and longer wavelengths. Data for the excitation spectra of Cascade blue, fluorescein (FITC), tetramethylrhodamine (TRITC), lissamine rhodamine (LRSC), and cyanine 5.18 (Cy5.18) are from Wessendorf and Brelje (1993) and were downloaded from the web page of Aryeh Weiss, *http://optics.jct.ac.il/~aryeh/Spectra*. Modified from Brelje et al. (1993).

their life spans are short (~2000 hr). Another way to achieve multiwavelength excitation is to combine the outputs of two or more lasers.

Several methods have been devised for scanning the sample with the laser beam to illuminate different positions in the specimen. The most common method employs a pair of galvanometer mirrors to both scan the laser beam across the specimen and collect the fluorescence emitted from the specimen (Fig. 4.5.4). One galvanometer mirror scans sequential spots along the *x* axis, and the second mirror moves from line to line in the *y* axis. The fluorescence emission is separated from the illuminating beam by a dichroic beam splitter and is directed to a photomultiplier tube which collects the fluorescence produced as each spot in the specimen is illuminated. The photodetector output is converted to a digital image that can be displayed on a monitor and stored as a digital image file for later analysis. Most laser-scanning confocal microscopes have 8-bit digitizers that encode 256 gray levels, although some recent models have 12- or 16-bit digitizers. Collection of a full-size image (typically 1024 × 1024 pixels) takes ~2 sec. Laser-scanning microscopes that employ galvanometer mirror scanners sometimes are called "slow-scan" microscopes because of their relatively slow image acquisition rates. Slow-scan microscopes are available from several sources (Bio-Rad, Zeiss, Leica, Olympus, Nikon, Molecular Dynamics, and Meridian; see *SUPPLIERS APPENDIX*).

The movements of the galvanometer mirrors in laser-scanning microscopes are under the control of a computer, providing flexibility in the scanning pattern. For example, it is possible to "zoom" a region of interest (visualize it at higher magnification) by reducing the scan area and the distances between sample points. In addition, many laser-scanning microscopes have the ability to repetitively scan a single line or to "park" the scanner to monitor fluores-

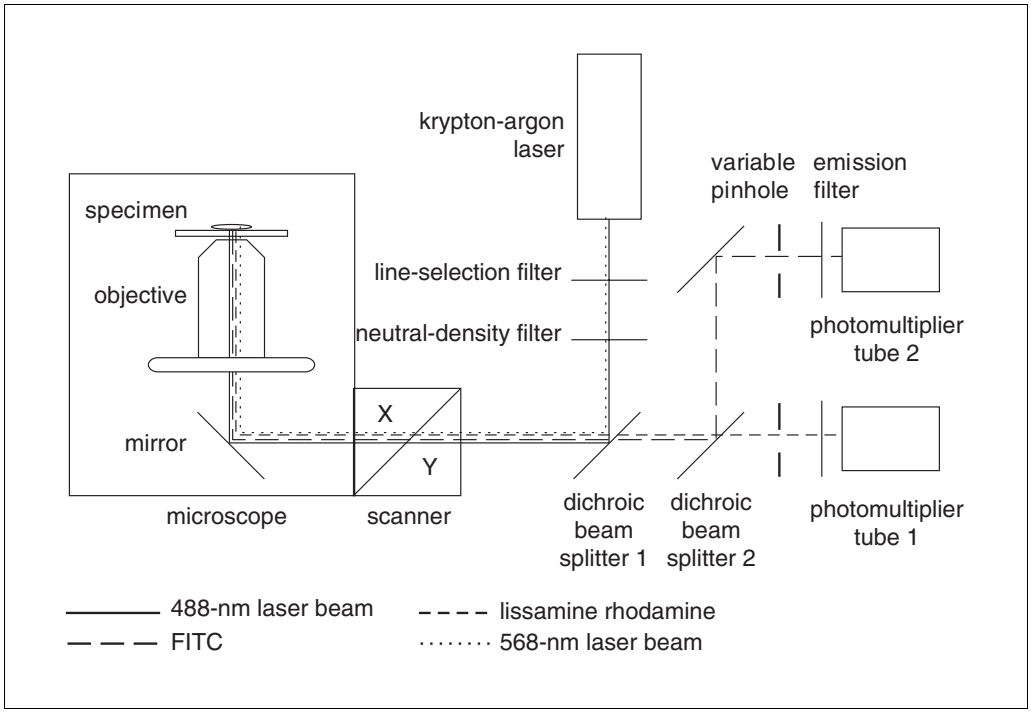

Figure 4.5.4 The light path of a laser-scanning confocal microscope set up for simultaneous imaging of FITC and lissamine rhodamine. The 488-nm and 568-nm lines of a krypton-argon laser are reflected by dichroic beam splitter 1 into the optical axis of the microscope. The scanner contains two galvanometer mirrors, which generate the *x* and *y* axis movements of the beam. The beam is reflected by a mirror into the objective which focuses the beam onto the specimen. The specimen is scanned line by line in a raster pattern. Fluorescence emitted by the specimen as each spot is illuminated travels the reverse path through the scanning system. The FITC fluorescence (peak at 520 nm) and lissamine rhodamine fluorescence (peak at 590 nm) pass through dichroic beam splitter 1 to dichroic beam splitter 2, which transmits the lissamine rhodamine fluorescence to photomultiplier tube 1 and reflects the FITC fluorescence to photomultiplier tube 2. A variable pinhole in front of each photodetector blocks light from out-of-focus areas of the specimen while allowing light from the illuminated spot to reach the detector.

cence at a single spot. The latter technique is particularly useful for studying rapidly changing fluorescence signals, such as those produced by a Ca^{2+} indicator in an active neuron.

Laser-scanning microscopes are available (from Noran, Life Sciences Resources, and Meridian; see *SUPPLIERS APPENDIX*) that can collect images at video rates (30 frames/sec) or faster. Several methods for achieving rapid scanning rates have been employed, such as acousto-optical deflection devices, rotating mirrors, or resonating mirrors (reviewed by Art and Goodman, 1993; Tsien and Bacskai, 1995). The gain in imaging speed always comes at a cost, however. For example, rapid-scan confocal microscopes do not provide the degree of control over the scan pattern offered by top-of-the-line slow-scan microscopes, and some video-rate confocal microscopes are incapable of multiwavelength illumination. Video-rate microscopes that rely on slit apertures rather than pinhole apertures have slightly poorer lateral and axial resolution.

A type of rapid-scan confocal microscope that deserves mention because of its lower cost (among other reasons) uses a spinning disk with multiple pinholes (~200,000) to simultaneously illuminate and detect emission from many spots in the specimen. The light source can be a laser or a broad-spectrum lamp like that used for conventional epifluorescence microscopy. The principle advantage of this type of confocal microscope is that it is capable of collecting images very rapidly (up to 700 frames/sec at 5000 lines resolution; Kino, 1995). The images can be examined directly by eye or captured with a sensitive camera. The main disadvantage is that the disk transmits only ~1% of the available light because the holes in the spinning disk need to be widely spaced. A new type of spinning-disk confocal microscopy has recently become available that uses "microlenses" to improve optical throughput and achieve high-speed confocal imaging with better sensitivity (Ultra View; Life Sciences Resources; see *SUPPLIERS APPENDIX*).

Another form of laser-scanning microscopy that promises to be of great value uses two-photon (and three-photon) excitation to induce fluorescence emission (Denk et al., 1995). Two-photon excitation occurs when a fluorophore absorbs two photons, each having half the energy needed to raise the fluorophore to the excited state. The light intensities required for simultaneous absorption occur only at the focal point, so only fluorophores at the focal point are excited. Therefore, two-photon excitation allows optical sectioning without a spatial filter in front of the detector. Moreover, since fluorophores outside the focal point are not excited, the specimen is less subject to photobleaching than in a conventional laser-scanning microscope. The wavelengths needed to excite standard visible light fluorophores by two-photon absorption are longer and penetrate tissue better than the wavelengths used for one-photon excitation, making it possible to look deeper into a specimen. In addition, UV fluorophores can be imaged without many of the problems that arise when UV wavelengths are used in conventional laser-scanning microscopes. A current drawback of two-photon confocal microscopy is the high cost of an appropriate laser (~$100,000). Two-photon scanning microscopes are now available from commercial sources (Bio-Rad, Leica; see *SUPPLIERS APPENDIX*).

PRACTICAL GUIDELINES

Sample Preparation: Immunofluorescence in Fixed Specimens

Additional guidelines for sample preparation are discussed in *UNIT 4.3*.

Fixation

The best fixative is one that accurately preserves the three-dimensional geometry of the specimen. The standard fixative for fluorescence microscopy (2% to 4% formaldehyde in PBS) is not ideal because it can cause blebbing of the plasma membrane, vesiculation of intracellular membrane compartments, and other alterations in cellular morphology. Moreover, some commercial preparations of formaldehyde contain methanol, which shrinks cells. Techniques for optimizing formaldehyde fixation are described by Bacallao et al. (1995). The buffer should be chosen to match the osmolality and pH of the specimen. Fixatives containing 0.125% to 0.25% glutaraldehyde in addition to formaldehyde preserve cellular morphology better than those containing formaldehyde alone. Some investigators avoid using glutaraldehyde for fluorescence microscopy because it induces autofluorescence. However, autofluorescence can be reduced by treating the sample after fixation with $NaBH_4$ (1 mg/ml in PBS, pH 8.0, using two treatments of 5 min each for dissociated cells, longer for thicker samples). A more serious drawback of glutaraldehyde for immunofluorescence studies is that it destroys the antibody recognition sites of some antigens.

An alternative fixation technique that preserves tissue better than chemical fixation is rapid freezing followed by freeze substitution (Bridgman and Reese, 1984).

Choices of fluorophores

Criteria to consider in selecting fluorophores for fluorescence microscopy are described in *UNIT 4.2 & APPENDIX 1E*. The only additional consideration for confocal microscopy is to choose fluorophores that can be excited by the wavelengths provided by the available lasers. However, it is not essential for the excitation spectrum peak to precisely match the laser wavelength because the lasers on most microscopes are sufficiently powerful to maximally excite fluorophores at off-peak wavelengths. For experiments that depend on imaging two fluorophores, it is best to select fluorophores whose excitation and emission spectra have minimal overlap. Good choices for multiwavelength imaging with a krypton-argon laser are: FITC/Oregon green/Alexa 488 (Molecular Probes) for excitation at 488 nm; lissamine rhodamine/Cy3/Texas red/Alexa 568 (Molecular Probes) for excitation at 568 nm; and Cy5 for excitation at 647 nm. UV fluorophores also are good for multicolor imaging (with absorption at 350 to 390 nm; some of the best dyes for DNA are UV fluorophores).

Control samples

Confocal microscopes rely on electronic image enhancement techniques that can make even a dim autofluorescence signal or nonspecific background staining look bright. In order to be able to distinguish a real signal from background it is essential to prepare appropriate control samples. For immunofluorescence experiments with one primary antibody, the appropriate control samples are unstained specimens and specimens treated with the secondary antibody but no primary antibody. Experiments with two primary and secondary antibodies require additional controls to test whether the secondary antibodies cross-react with the "wrong" primary antibody. Other control experiments may be required to verify the specificity of labeling.

Mounting the specimen

The mounting medium should preserve the three-dimensional structure of the specimen. PBS (*APPENDIX 2A*) or a mounting medium consisting of 50% glycerol/50% PBS preserves the shapes of cells quite well, but Mowiol and gelvatol cause a 10% decrease in height (Bacallao et al., 1995). Adding an antioxidant to the mounting medium helps to alleviate photobleaching. One of the best antioxidants is 100 mg/ml 1,4-diazabicyclo[2,2,2]octane (DABCO; Sigma; Bacallao et al., 1995). *n*-propyl gallate (Giloh and Sedat, 1982) and *p*-phenylenediamine (PPD; Johnson et al., 1982) also are effective antibleaching agents, but the former may cause dimming of the fluorescence while the latter may damage the specimen (Bacallao et al., 1995). ProLong, a new antifade reagent from Molecular Probes, hardens upon drying and is exceptionally effective in preserving the fluorescence of most fluorophores.

The choice of mounting medium should take into account the type of microscope objective that will be used to observe the specimen. In order for an objective to perform optimally, the mounting medium should have the same refractive index as the objective immersion medium. Table 4.5.2 gives the refractive indexes of standard objective immersion media and mounting media. Mismatches in the refractive indexes produce spherical aberration leading to loss of light at the detector, as well as decreased *z* axis resolution and incorrect depth discrimination. Image deterioration caused by spherical aberration increases with depth into the specimen. Significant losses of signal intensity and axial resolution are apparent at distances of just 5 to 10 μm when an oil immersion objective is used to examine a specimen in an aqueous medium (Keller, 1995).

Most microscope objectives are designed for viewing specimens through a glass coverslip of a specific thickness (typically 0.17 μm, a no. 1½ coverslip). Correct coverslip thickness is especially critical for high-NA (>0.5) dry objectives and water immersion objectives (Keller, 1995). Use of a coverslip that differs from the intended thickness by only 5% causes significant spherical aberration. High-NA dry and water immersion objectives typically have an adjustable collar to correct for small variations in coverslip thickness.

The specimen should be mounted as close to the coverslip as possible, especially for observation with immersion objectives, which have short working distances (~100 to 250 μm, depending on the type of objective). This also helps to avoid image deterioration due to spherical aberration. Fragile specimens should be protected by supporting the coverslip; for example, using a thin layer of nail polish, strips of coverslips, or a gasket made from a sheet of

Table 4.5.2 Refractive Indexes of Common Immersion and Mounting Media

Medium	Refractive index (RI)
Immersion media	
Air	1.00
Water	1.338
Glycerol	1.47
Immersion oil	1.518
Mounting media	
50% glycerol/PBS/DABCO	1.416[a]
5% *n*-propyl gallate/0.0025% *p*-phenylene diamine (PPD) in glycerol	1.474[a]
0.25% PPD/0.0025% DABCO/5% *n*-propyl gallate in glycerol	1.473[a]
VectaShield (Vector Labs)	1.458[a]
Slow Fade (Molecular Probes)	1.415[b]
ProLong (Molecular Probes)	1.3865[b,c]

silicon rubber (Reiss; see *SUPPLIERS APPENDIX*). Sealing the edges of the coverslip—with nail polish or silicon vacuum grease (Dow Corning; see *SUPPLIERS APPENDIX*)—helps to prevent specimen desiccation and movement.

Living Specimens

Confocal microscopy of living preparations is challenging for several reasons. The specimen must be mounted in a chamber that keeps it healthy and immobile while at the same time providing access for the objective. For high-resolution transmitted-light imaging (e.g., by laser-scanning differential interference contrast microscopy), the chamber must be thin enough to accommodate a high-NA (oil immersion) condenser. Fluorescence signals in living specimens generally are weak and the illumination levels needed to detect them can be damaging to the specimen. Photobleaching inevitably is a problem for experiments that require collecting many images. Temperature fluctuations in specimens kept at nonambient temperatures make it difficult to maintain accurate focus.

A simple chamber for culture preparations grown on glass coverslips can be made by forming a well on a glass slide with a gasket cut from a sheet of silicon rubber or a plastic ruler. To prevent the well from leaking, it should be sealed with silicon vacuum grease, a mixture of melted paraffin and petroleum jelly, or Sylgard (Dow Corning; see *SUPPLIERS APPENDIX*). The well is filled with medium and then the coverslip with attached cells is placed, cell side down, on top of the well. The preparation can be kept warm during observation on the microscope with a heated air blower—e.g., a hair dryer with variable power source or a commercial air-stream incubator (e.g., Neutek; see *SUPPLIERS APPENDIX*)—or with infrared lamps. More elaborate chambers, some of which have built-in heaters and ports for changing solutions, are available from commercial sources (see Terasaki and Dailey, 1995, for a partial listing of manufacturers). An important factor to consider in choosing a chamber is whether it maintains the desired temperature while in contact with an immersion objective that acts as a heat sink. One solution to this problem is to heat the objective as well as the chamber. A heated chamber and objective warmer designed for microscopy with a high-NA objective and condenser are available from Bioptechs (see *SUPPLIERS APPENDIX*).

Addition of an oxygen quencher to the medium can help to alleviate photobleaching of the fluorophores. Photobleaching not only leads to dimming of the signal but also to generation of oxygen radicals that can damage cells. Several oxygen quenchers have been re-

ported to be effective, including oxyrase (0.3 U/ml; Oxyrase [see *SUPPLIERS APPENDIX*]; Waterman-Storer et al., 1993); ascorbic acid (0.1 to 3.0 mg/ml; Sigma; Terasaki and Dailey, 1995); a mixture of Trolox (10 μM; Aldrich) and *N*-acetylcysteine (50 μM; Sigma; M. Burack and G. Banker, pers. comm.); and crocetin (Tsien and Waggoner, 1995).

Optimizing Imaging Parameters

Choice of objectives

High-NA objectives generally are preferable for fluorescence microscopy because they collect more light than low-NA objectives (brightness is proportional to NA^4). Most high-quality high-NA objectives have >80% transmission at visible wavelengths, but some have low transmission at UV wavelengths (Keller, 1995).

Water immersion objectives are the best choice for visualizing specimens in aqueous solutions (e.g., living specimens). Several microscope manufacturers recently have introduced high-NA water immersion objectives specifically designed for confocal microscopy of biological specimens. These objectives differ from previously available types of water immersion objectives in that they are intended for viewing specimens mounted under a coverslip. They have working distances of ~250 μm.

Oil immersion objectives can have higher NAs than water immersion objectives. Most have fairly short working distances (~100 μm) although some recently introduced oil objectives have working distances of ~200 μm. A long-working-distance oil objective will be useful only if the specimen is mounted in a medium that matches the refractive index of immersion oil (η = 1.518). If an aqueous mounting medium is used, images from depths at more than ~20 μm into the specimen will be noticeably degraded by spherical aberration. Also, distance measurements in the *z* axis will need to be corrected. The actual movement of the focal plane in the specimen (d_s) produced by a movement of the objective (d_{obj}) depends on the ratio of the refractive indexes of the specimen and immersion medium. A reasonable approximation (Majilof and Forsgren, 1993) of the relationship is given by:

$$d_s/d_{obj} = \eta_s/\eta_{obj}$$

Pinhole size

As was explained above (see Basis of Optical Sectioning), the size of the pinhole has a critical influence on image quality. A pinhole with a radius equal to the radius of the first minimum of the Airy disk—which is approximately equivalent to the diameter at half maximal intensity (Amos, 1995)—will let most of the light from the plane of focus reach the detector, while blocking most of the out-of-focus flare. The lateral resolution will be ~20% better than that obtainable by conventional microscopy with the same optics (Centonze and Pawley, 1995), although not as good as can be achieved with a smaller pinhole. Lateral resolution continues to improve as pinhole radius is decreased down to a pinhole size of ~0.2 × Airy disk radius, but a pinhole this small excludes ~95% of the signal (Wilson, 1995). Axial resolution improves as pinhole size decreases, down to ~0.7 × Airy disk radius, then levels off. The best trade-off between signal intensity and resolution will depend on the characteristics of the sample and aims of the experiment.

Zoom factor

The zoom setting on a confocal microscope determines the size of the scan region and the apparent magnification of the image. A zoom factor of 2 will scan an area half as long and wide as a zoom factor of 1. Images are made up of the same number of samples (points along the horizontal axis, lines along the vertical axis) and are displayed on the image monitor by a fixed number of pixels regardless of the zoom factor. Therefore, the pixels in a zoom-2 image will represent areas within the specimen half as large in each dimension as the areas represented by the pixels at zoom 1. If the pixel size for an objective at zoom 1 represents 0.25 μm × 0.25 μm, then the pixel size at zoom 2 will be 0.125 × 0.125 μm. The pixel dimensions (referring to the specimen) are inversely related to the zoom setting.

For each objective, there is an optimal zoom setting which yields pixel dimensions small enough to take advantage of the full resolution of the objective but large enough to avoid oversampling. In order for the minimum resolvable entity to be visible on the display monitor, the pixel dimensions need to be smaller than (less than one-half) the optical resolution. However, if the pixel size is made too small by using a higher-than-optimal zoom factor, the specimen is subjected to more irradiation than necessary with an increased risk of photobleaching. The rate of photobleaching increases proportionally to the square of the zoom factor (Centonze and Pawley, 1995). A guideline for selecting an appropriate zoom factor derived from informa-

tion theory (the Nyquist Sampling Theorem) states that the pixel dimensions should be equal to the optical resolution divided by 2.3 (see Webb and Dorey, 1995). However, pixel dimensions smaller than this may produce more informative images.

Z axis sectioning interval

In order to study the three-dimensional structure of a specimen, images are collected at a series of focal levels at intervals determined by the commands sent to the focus motor. The most straightforward way to ensure that the reconstructed images have correct proportions in the *x*, *y*, and *z* axes is to collect optical sections at *z* axis intervals equal to the *x*,*y* pixel dimension. However, the interfocal plane interval needed to adequately sample the specimen in the *z* axis is not as small as the *x*,*y* pixel dimension because the axial resolution is poorer than the lateral resolution (see Table 4.5.1). The optimal interfocal plane interval (according to the Nyquist Sampling Theorem) is equal to the axial resolution divided by 2.3. Collecting images at shorter intervals results in oversampling with an increased risk of photobleaching.

Illumination intensity

Fluorescence emission increases linearly with illumination intensity up to a level at which emission saturates. Optimal signal-to-background and signal-to-noise ratios are obtained with illumination levels well below saturation (Tsien and Waggoner, 1995). The illumination intensity on a laser-scanning microscope can be adjusted by inserting neutral-density filters into the light path and/or by operating the laser at submaximal power. In general, the best images are obtained with illumination levels that are as high as possible without producing unacceptable rates of photobleaching.

PMT black level and gain

The contrast and information content of confocal images are influenced by the black level and gain of the photomultiplier tube (PMT) amplifiers. To obtain maximal information, the black level and gain should be adjusted to take advantage of the full dynamic range of the PMTs. The appropriate black level setting can be found by scanning while the light path to the PMT is blocked. The image that appears on the display monitor should be just barely brighter than the background, which is black (gray level = 0). To set the gain, scan the specimen and adjust the gain so that the brightest pixel in the image is slightly below white (gray level = 255). Selecting black level and gain settings which ensure that all signals fall within the dynamic range of the PMT is important for quantitative imaging experiments. The software provided with many confocal microscopes includes a pseudocolor image display mode that facilitates selection of appropriate black level and gain settings by highlighting pixels with intensity values near absolute black and absolute white.

Averaging

Confocal images of dimly fluorescent specimens captured at typical scan rates (1 to 2 sec/frame for a slow-scan confocal microscope) appear noisy because of the small numbers of photons collected from each spot. In some instances, it may be possible to improve the signal-to-noise ratio by scanning the specimen at slower rates. Another way to obtain a better image is by summing and averaging the signals obtained in multiple scans (frame averaging). Some confocal microscopes provide a second averaging method (line averaging), in which individual lines are repeatedly scanned and averaged. Line averaging generally produces sharper images than frame averaging (which averages full frames) because there is less risk of blurring due to movements or changes in the specimen.

Image display

Commercial confocal microscope packages provide software for some types of image enhancement and display. The display options for three-dimensional datasets typically include "*z* projections" (see Fig. 4.5.1B), which are two-dimensional displays formed by superimposition of stacks of optical sections, and stereoscopic views, which are made by combining two image stacks, one aligned in the *z* axis and the other with a displacement between successive images. Many systems also have the capability to compute cross-sections and projections of the specimen from varying angles. Computed projections for a sequence of view angles can be played as a movie in which the specimen appears to rotate around an axis. Such movies give the viewer a striking impression of the three-dimensional geometry of the specimen. Additional display options are available in various integrated software/hardware packages specifically designed for visualization and analysis of three-dimensional images.

Anticipated Results

Fluorescence in fixed specimens protected with an antifade agent is often sufficiently bright and resistant to photobleaching to make it possible to reconstruct three-dimensional images using imaging parameters that provide optimal resolution. Superb three-dimensional views may be obtained of structures as small and complex as a cell's cytoskeleton or the terminal arbor of an axon. The maximum depth in the specimen at which adequate images can be obtained depends on a number of factors (e.g., the match in refractive indexes of the immersion and mounting media, the wavelength of light, and the extent of scattering and absorption by the specimen). Under optimal conditions, it may be possible to image structures at depths near the limit allowed by the working distance of the objective; in practice, image quality usually deteriorates at depths in the range of a few hundred micrometers or less.

Although confocal microscopy on living cells is more difficult and damage to the tissue may preclude extensive three-dimensional reconstruction, the added time dimension and confidence in the reality of the images makes it well worth the effort. In addition, it is possible to study dynamic processes lasting for hours by collecting sequences of time-lapse images. Robust fluorophores such as certain variants of GFP (S65T, EGFP) can be imaged repeatedly with minimal loss of fluorescence (see, for example, Ellenberg et al., 1997). In addition, modern laser-scanning confocal microscopes provide a versatile optical bench and sophisticated specimen positioner which permit a wide range of experiments with the controlled application of laser light to living tissues. Current examples of these approaches are photobleaching (Cole et al., 1996; Wedekind et al., 1996) and release of caged compounds (Callaway and Katz, 1993; Svobodoa et al., 1996). These are only the harbingers of many future applications of light probe physiology made possible by the versatility of the confocal microscope.

Resources Available via Internet

NIH Image, a powerful image analysis program for Macintosh computers developed by W. Rasband (Research Services Branch, National Institute of Mental Health, NIH), has many useful tools for analysis of confocal images. It can be downloaded from *http://rsb.info.nih.gov/nih-image/* or obtained via FTP from *zippy.nimh.nih.gov*. A version of NIH Image modified for operation under Windows also is available. Much information about fluorescent probes can be obtained from the Molecular Probes Web Site at *http://www.probes.com/*.

Many topics of interest to confocal microscopists are discussed on the confocal e-mail listserver network. To subscribe to the list, send the message "subscribe confocal<your name>" to *listserv@ubvm.cc.buffalo.edu*.

Immunoperoxidase Methods for Localization of Antigens in Cultured Cells and Tissues

This unit describes the localization of intracellular antigens by the immunoperoxidase staining technique at the electron microscopic (EM) level. These methods provide a potentially valuable alternative, or in some cases a complementary approach, to immunogold labeling. Labeling with immunogold provides a higher level of antigen resolution and can be made reasonably quantitative. However, immunogold labeling is usually best conducted on ultrathin, frozen sections, which requires a special microtome and an extremely high degree of specialized technical skill. In contrast, immunoperoxidase labeling methods are relatively simple in that no special equipment or skills are needed beyond those required for standard transmission EM of plastic-embedded samples. Furthermore, they provide the opportunity for enzymatic amplification of what might otherwise be weak immunoreactive signals. The immunoperoxidase method is limited by its inherently qualitative nature and by the potential for diffusion of the immunoreactive signal from the site of antigen location. These advantages and limitations make immunoperoxidase labeling particularly valuable for localizing intracellular antigens that are contained within membrane-bounded organelles. Under certain circumstances, however, the method can also be successfully applied to cytoplasmic and extracellular antigens.

The immunoperoxidase methods described here are typically referred to as preembedding labeling methods, meaning that the antibodies bind to antigens before the cells or tissues are embedded for sectioning. The methods are also of the indirect type, meaning that the antigen is localized by a two-step antibody binding protocol: antigens are first bound by primary antibodies, which are in turn bound by a secondary antibody that is covalently coupled with horseradish peroxidase (HRP). An electron-dense immunoreaction product at the sites of antigen-antibody binding is then generated in two steps: first, the bound HRP-conjugated secondary antibody catalyzes the formation of oxidized and polymerized diaminobenzidine (DAB) using H_2O_2 as an electron donor, and second, the oxidized and polymerized DAB is rendered electron dense by binding to reduced osmium tetroxide (OsO_4). Labeled cells are then embedded in plastic resin and sectioned for standard transmission EM.

This unit describes two protocols for immunoperoxidase staining: one specific for adherent, cultured cells (see Basic Protocol 1) and one specific for cells within tissue sections (see Basic Protocol 2). Three embedding methods are described for adherent cultured cells. (1) For antigens located anywhere in the cell except the endoplasmic reticulum (ER), cells can be easily detached using propylene oxide and embedded with a standard plastic embedding resin in a microcentrifuge tube (see Basic Protocol 1). (2) For antigens located in the ER, cells can be detached by scraping in ethanol before embedding (see Alternate Protocol 1). (3) Alternatively, to prepare sections through the full depth of the cultured monolayer, cells can be embedded while they are still attached to the culture dish (see Alternate Protocol 2).

STRATEGIC PLANNING

Preliminary Light Microscopy Experiments

Immunoelectron microscopy, by either immunogold or immunoperoxidase labeling, is generally a labor-intensive and time-consuming enterprise. The rate-limiting step is thin sectioning, which is required for EM observations. Therefore, it is strongly recommended that several preliminary studies establishing near-optimal staining parameters be carried

Contributed by William J. Brown
Current Protocols in Cell Biology (1999) 4.6.1-4.6.17

at the light microscopic (LM) level, first by immunofluorescence staining (*UNIT 4.3*) and then by LM-level immunoperoxidase localization. Immunofluorescence is relatively rapid and simple, and it can be used to optimize a number of potentially important variables. For example, one can easily screen by immunofluorescence to optimize fixation time, detergent concentration for cell permeabilization, antibody concentrations, and incubation times. Experience has shown that experimental conditions (for these variables) that generate a bright immunofluorescence signal can generally be applied directly to the immunoperoxidase labeling protocol. Once these conditions are established, a few preliminary immunoperoxidase labeling experiments should be conducted at the LM level. This second series of experiments is valuable for establishing the optimal concentration of HRP-conjugated secondary antibody and the optimal DAB reaction time.

A large amount of time can be saved by optimizing conditions through these preliminary immunofluorescence and immunoperoxidase LM experiments rather than at the EM level. Also, the results obtained by the LM methods can serve as an invaluable comparison for those obtained by EM, either providing increased confidence that the antibodies are accurately localizing the antigen of interest or providing cause for concern. In other words, the results should be consistent irrespective of the method used. Finally, preliminary screening by immunofluorescence or LM immunoperoxidase labeling should be used to ensure that the primary antibody is of sufficiently high quality to generate a high signal-to-noise ratio. Meeting this goal may require production of an IgG fraction, affinity purification of the antibodies, or production of a high-titer ascites fluid for monoclonal antibodies. A successful immunoperoxidase localization at the EM level is very unlikely to be realized if the antibodies cannot first generate an easily detectable immunofluorescence and LM immunoperoxidase signal.

Monitoring the DAB Reaction

Monitoring development of the DAB reaction can easily be done with an upright light microscope and a low-power or long-working-distance objective lens (so it won't get wet), or with an inverted microscope. If using a standard upright microscope, place the petri dish on a microscope slide on the microscope stage to move the dish around. The development of the DAB reaction is best viewed by plain brightfield optics, rather than by phase contrast, because the formation of the contrasting brown/black reaction product is more easily detected.

For most antigens, by the time the reaction looks really good by LM, it will probably be overdone for EM, because the DAB reaction product may have diffused away from the immediate area of the antigen-antibody complexes. This is especially true for antigens contained within membrane-bounded organelles (e.g., the Golgi complex and endosomes), which can lyse following formation of extensive amounts of reaction product. However, antigens contained within the endoplasmic reticulum are sometimes more difficult to detect at the EM level and, therefore, require that the reaction product be quite dark and obvious at the LM level. Thus, it is sometimes difficult to know exactly how far to let the reaction go at the LM level in order to generate a well-contained signal by EM. Therefore, for each experimental condition, two to three dishes should be carried through the fixation and antibody steps, so that each can be subjected to the DAB reaction for a different period of time. The following sequence is suggested: first, react one dish until the reaction product is robust and obvious, then react another dish until the brown/black DAB reaction product is just barely visible by LM, and react a third dish to a point somewhere in between the first two. With experience, two dishes will usually suffice for each experimental condition. The optimal length of time for the DAB reaction can vary greatly from 2 to 30 min. Generally, if the reaction has not developed by ~30 min, something may have gone wrong.

Some special considerations apply to DAB reactions in tissue sections. The length of reaction time can be quite variable. It is best to not have an explosive reaction, as this leads to DAB diffusion in the tissue. It is better to have the reaction proceed slowly (typically, 5 to 30 min at room temperature). If reactions proceed very quickly (e.g., within 1 to 2 min), place the tubes on ice to chill the DAB substrate before adding H_2O_2, and perform the reaction on ice. During the reaction time, the tissue will probably turn brown or black, depending upon the antigen and antibody. Affinity-purified or monoclonal antibodies will often not turn sections as dark as those incubated with crude antiserum, but they give less background and the localization will be better. Monitor the reaction with a dissecting microscope. Some experience is required to know when the sections are dark enough. In the beginning, however, it is better to err on the side of excess so that there is some kind of signal. Therefore, react several sections until they are noticeably dark, and several others for a shorter period of time.

IMMUNOPEROXIDASE STAINING OF CULTURED CELLS

BASIC PROTOCOL 1

This protocol describes a method for the localization of antigens in cultured cells at the EM level by the immunoperoxidase staining procedure. The protocol has been specifically developed for adherent, monolayer cell cultures of established cell lines. However, cultured cells that grow in suspension can, in many cases, be attached to poly-L-lysine-coated dishes and then processed as described in this section. The protocol can also be easily applied to primary cells. In either case, specific conditions for culturing cells are left to the investigator (see *UNIT 1.1*).

Many of these steps can be modified to meet specific experimental needs (e.g., dish size and incubation times). All steps are conducted at room temperature unless otherwise indicated. This protocol describes one of three methods for removing the cells from the culture dishes. Selection of the appropriate method depends on whether (1) the antigen is located anywhere within the cell except the ER (this protocol), (2) the antigen is located in the ER (see Alternate Protocol 1), or (3) sections through the intact monolayer are desired (see Alternate Protocol 2).

Materials

Cells of interest
PLP fixative (see recipe), freshly prepared
PBS, pH 7.4 (*APPENDIX 2A*)
0.005% to 0.05% (w/v) saponin (Sigma)/PBS
Primary antibody in saponin/PBS with 0.1% (w/v) ovalbumin
HRP-conjugated secondary antibody: horseradish peroxidase–conjugated Fab fragments of anti–rabbit IgG or anti–mouse IgG (Biosys) in saponin/PBS with 0.1% (w/v) ovalbumin
Glutaraldehyde fixative: 1.5% (v/v) glutaraldehyde in 5% (w/v) sucrose/100 mM sodium cacodylate, pH 7.4
7.5% (w/v) sucrose/100 mM sodium cacodylate, pH 7.4
0.2% (w/v) DAB solution (see recipe), freshly prepared
3% (v/v) H_2O_2, freshly prepared from 30% H_2O_2 stock solution
1% (w/v) reduced OsO_4 solution (see recipe), freshly prepared and ice cold
100 mM sodium cacodylate, pH 7.4, ice cold
70%, 95%, and 100% (v/v) ethanol
100% propylene oxide, EM grade
1:1 (v/v) propylene oxide/plastic embedding resin (e.g., Spurr's)
100% plastic embedding resin (e.g., Spurr's)

35-mm disposable plastic petri dishes
Horizontal reciprocating shaker

NOTE: The propylene oxide detachment method of embedding can be somewhat tricky. It is advisable to practice on cells before attempting the immunoperoxidase staining (see step 18).

Prepare cells

1. Grow cells of interest to ~75% confluency in 35-mm disposable plastic petri dishes. Prepare two to three dishes for each experimental condition (see Strategic Planning and step 13).

   It seems best to not do the immunoperoxidase protocol soon after trypsinization and replating. It is better to plate the cells at lower density and wait 2 to 4 days for them to repopulate the dish before immunoperoxidase staining.

   Other dishes can be used for this procedure, but 35-mm dishes yield a reasonable number of cells for thin-sectioning, and larger dishes require more antibody.

2. Fix cells on the dish by replacing medium with 1 ml PLP fixative, taking care to prevent cells from drying out. Incubate 2 to 3 hr with gentle shaking on a horizontal reciprocating shaker.

   Rotary shakers are acceptable; however, they may cause the center of the dish to dry out if small volumes of fluid are used (e.g., during antibody incubations).

3. Remove fixative and wash cells three times, 5 min each, with 1 to 2 ml PBS.

4. Permeabilize cells by removing PBS and adding 1 to 2 ml of 0.005% to 0.05% saponin/PBS. Incubate for 5 min with gentle shaking.

   The minimal concentration of saponin required to allow antibody penetration should be determined by preliminary immunofluorescence experiments (see Strategic Planning). This concentration may vary depending upon the source of saponin and the type of cells. Nearly all cell types can be rendered optimally permeable using a concentration between 0.005% and 0.05%.

   NOTE: *The saponin concentration used here should also be used in all subsequent antibody incubations and washes.*

Expose cells to primary antibody

5. Remove saponin/PBS and apply ≥0.5 ml primary antibody in saponin/PBS. Incubate ≥l hr with gentle shaking.

   For 35-mm dishes, ~0.5 ml is the minimal volume needed to cover and keep the cells from drying out. An appropriate antibody concentration should be determined by preliminary immunofluorescence experiments (see Strategic Planning).

   Alternatively, cells can incubated in primary antibody for ~30 min at room temperature, and then shifted to 4°C for overnight incubation. Dishes should be covered and placed in a sealed, humidified chamber (e.g., a Tupperware-type container). Overnight incubation is especially useful if the day has been long. The peroxidase signal also tends to be improved, but sometimes with increased background.

6. Wash cells three times, 5 min each, with 1 to 2 ml saponin/PBS.

Expose cells to secondary antibody

7. Remove wash solution and apply 0.5 to 0.7 ml HRP-conjugated secondary antibody. Incubate ≥1 hr with gentle shaking.

   An appropriate dilution of the secondary antibody should be determined by preliminary immunoperoxidase staining experiments (see Strategic Planning). For the Biosys secon-

dary antibody, a good starting point is a 1:400 to 1:800 dilution. The Fab-HRP antibodies from Biosys are particularly good reagents. Their small size, relative to whole IgG-HRP or F(ab′)$_2$-HRP conjugates, allow lower concentrations of saponin to be used for membrane permeabilization.

If importing the Biosys antibody into the U.S., it is necessary to obtain a Permit for Importation and Transportation of Controlled Materials and Organisms and Vectors (VS Form 16-6A) from the USDA. To obtain this permit, an Application for Permit to Import Controlled Material or Import or Transport Organisms and Vectors must be submitted. This application can be obtained from and submitted to USDA, APHIS, VS, Federal Building, Hyattsville, MD 20782 (Fax no. 301-436-8226).

8. Wash cells three times, 5 min each, with 1 to 2 ml saponin/PBS.

9. Wash cells three times over a period of 5 to 10 min with 1 to 2 ml PBS (each wash) to rinse out the saponin.

   This is an important step because removal of saponin lessens the amount of DAB diffusion during the peroxidase reaction.

10. Fix cells by removing PBS, applying 1 ml glutaraldehyde fixative, and incubating for 30 to 60 min with gentle shaking.

11. Wash cells three times, 5 min each, with 1 to 2 ml of 7.5% sucrose/100 mM sodium cacodylate, pH 7.4.

Perform DAB reaction

12. Remove wash solution and apply 1 ml of 0.2% DAB solution.

    CAUTION: *DAB is carcinogenic. Wear gloves and work in fume hood when handling. Treat all DAB-containing solutions and contaminated supplies with bleach, and dispose according to institutional guidelines for hazardous chemicals.*

13. Start the DAB reaction by adding 3.3 µl of 3% H_2O_2 to the dish. Quickly swirl to mix the H_2O_2 and DAB. Start timing and monitoring the reaction using an upright or inverted light microscope (see Strategic Planning). React one dish until the reaction product is robust and obvious, one dish until the brown/black DAB reaction product is just visible, and one to a point somewhere in between.

    Start with a reaction taken to yield a robust product, and then scale back the time to give lesser amounts. The optimal length of time for the DAB reaction can very greatly from 2 to 30 min. A nearly-optimal reaction time can be established by preliminary immunoperoxidase staining experiments (see Strategic Planning). With experience, this procedure can be reduced to two dishes/experimental condition.

14. Stop the reaction by removing DAB solution and quickly rinsing cells three times with 1 to 2 ml of 7.5% sucrose/100 mM sodium cacodylate, pH 7.4.

Osmicate the cells

15. In a fume hood, remove wash solution and osmicate cells with 1 ml ice-cold, 1% reduced OsO_4 solution. Cover petri dishes and place in a Tupperware-type container. Seal well and incubate for 1 hr at 4°C with gentle shaking.

    CAUTION: *Wear gloves when handling osmium. Perform this step in a fume hood to avoid osmium vapors. Be sure that the Tupperware-type container is well sealed—use Parafilm if unsure. Dispose of used osmium according to institutional guidelines for hazardous chemicals.*

16. Return cells to the fume hood, remove osmium solution, and rinse cells quickly three times with 1 to 2 ml ice-cold 100 mM sodium cacodylate, pH 7.4. Allow cells to reach room temperature.

17. Dehydrate cells with a graded series of ethanol (70%, 95%, 100%) as typically done for conventional plastic embedding. Perform three or four quick rinses with ~2 ml of each ethanol solution.

Detach cells and embed in plastic

18. Remove ethanol and quickly add ~0.5 to 1.0 ml of 100% propylene oxide with a glass Pasteur pipet.

    CAUTION: *Perform embedding procedure in the fume hood.*

19. Quickly score the bottom of the dish in a crude checkerboard pattern with the tip of the pipet. Immediately pipet the propylene oxide up and down to dislodge cells from the dish as the plastic dissolves.

    The bottom of the dish starts to turn mottled in appearance and then turns white, and sheets of cells should be seen detaching from the dish.

20. Collect cells and place in a microcentrifuge tube.

    If desired, the cells can be pooled from the dishes that were subjected to varying DAB incubation times to yield a single cell pellet. The advantage of combining cells is that only one pellet needs to be sectioned, giving a sampling of all reaction times in a single section. To identify which DAB reaction time gave the best EM-level staining, the cells from each dish should be placed in separate microcentrifuge tubes.

21. Microcentrifuge to obtain a tight pellet, using a horizontal-type rotor (e.g., Beckman model 11 microcentrifuge) for 2 to 3 min at the highest setting.

    CAUTION: *Be sure that the tubes are tightly capped because propylene oxide fumes are explosive.*

22. Remove propylene oxide and wash the cell pellet twice with ~1 ml of 100% propylene oxide. Microcentrifuge again if pellet becomes disrupted.

23. Remove propylene oxide and replace with ~1 ml of 1:1 propylene oxide/plastic embedding resin. Incubate with gentle rotation for 30 min.

24. Remove 1:1 mixture and wash pellet twice with ~1 ml of 100% plastic embedding resin. Incubate overnight in 100% plastic embedding resin with gentle rotation.

25. Replace with fresh resin mix and polymerize according to manufacturer's specifications for the plastic.

Section and view the cells

26. Cut silver/gold sections by standard ultramicrotomy methods.

27. Stain thin sections with lead citrate only. Omit uranyl acetate to generate a good ratio of signal (DAB-OsO_4 deposits) to noise (rest of the cytoplasm). For details, see Brown et al. (1984).

28. Visualize the sectioned material by standard transmission EM.

    Contrast of the electron-dense product can also be slightly increased by operating the EM at lower accelerating voltages (e.g., 60 versus 80 kV).

DETACHMENT AND EMBEDDING OF CULTURED CELLS FOR ANALYSIS OF ER ANTIGENS

ALTERNATE PROTOCOL 1

This protocol is specifically designed to remove dehydrated cells from the dishes and embed them in plastic when antigens are localized to the ER. It avoids the use of propylene oxide, which tends to extract the DAB reaction product from the ER.

1. Expose the cells to primary and secondary antibody, fix the cells, stain them with OsO_4, and dehydrate them (see Basic Protocol 1, steps 1 through 17).
2. With 100% ethanol still in the dishes, scrape cells from the dish with a small rubber policeman or cell scraper. Collect the detached cells and transfer them to a microcentrifuge tube.

   If desired, the cells from each of the two to three DAB treatment times can be combined in one tube to prepare a single pellet containing cells from each of the treatment groups. To identify which DAB reaction time gave the best EM-level staining, keep the cells from each dish in separate microcentrifuge tubes.
3. Microcentrifuge the cells to obtain a tight pellet, using a horizontal-type rotor (e.g., Beckman model 11 microcentrifuge) for 2 to 3 min at the highest setting.
4. Remove the ethanol and embed directly in 100% plastic embedding resin with several changes of resin, including one overnight incubation. Polymerize the plastic according to the supplier's instructions.

   CAUTION: *Perform embedding procedure in a fume hood.*
5. Cut silver/gold sections by ultramicrotomy, stain with lead citrate, and visualize the sections (see Basic Protocol 1, steps 26 through 28).

EMBEDDING OF CULTURED CELLS FOR ANALYSIS OF MONOLAYER SECTIONS

ALTERNATE PROTOCOL 2

This protocol is used to prepare sections that span the full depth of the monolayer, allowing cells to be embedded, and thus antigens to be localized, while maintaining the attached cellular morphology. This method can be used whether or not the antigen is located in the ER.

Additional Materials *(also see Basic Protocol 1)*

Epon 812 resin
Embedding molds

1. Expose the cells to primary and secondary antibody, fix the cells, stain them with OsO_4, and dehydrate them (see Basic Protocol 1, steps 1 through 17).
2. Rinse the cells twice more with 100% ethanol.
3. Remove the ethanol and rinse the cells three times with 100% Epon 812 resin.

   CAUTION: *Perform embedding procedure in fume hood.*

   For this method, Spurr's formulation should not be used because it is difficult to separate from the petri dish. The Epon 812 equivalent resin is recommended.
4. Incubate cells overnight in unpolymerized plastic resin.
5. Remove the resin, apply a thin layer (1 to 2 mm) of fresh 100% resin, and polymerize the resin according to the supplier's instructions.
6. Separate the hardened plastic resin from the dish using pliers or a hammer.

7. Use a razor blade to cut small squares (~5-mm^2) of the plastic resin.

   The squares should be small enough to fit in the embedding mold.

8. Place a square of the polymerized plastic into an embedding mold with the cell side facing upward.

9. Cover the square with a thin layer of unpolymerized plastic resin. Place another square with the cell side facing downward to make a sandwich.

   If the polymerized plastic is thin enough, three to four layers can be sandwiched together.

10. Carefully overlay the sandwich with unpolymerized plastic resin to fill the mold and polymerize the resin according to the supplier's instructions.

11. Cut silver/gold sections by standard ultramicrotomy methods, orienting the resin blocks so the sections are cut perpendicular to the plane of the monolayer. Stain with lead citrate and visualize the sections (see Basic Protocol 1, steps 27 and 28).

BASIC PROTOCOL 2

IMMUNOPEROXIDASE STAINING OF TISSUE SECTIONS

This protocol describes a method for immunoperoxidase staining of cells in tissue sections, and is useful for resolving both intracellular and extracellular antigens. Localizing antigens in cells within tissues can provide a valuable complementary data set to that obtained by immunoperoxidase localization in cultured cells (see Basic Protocol 1), because often a large number of different cell types can be examined. However, this method differs in several significant ways from that applied to cultured cells due to the inaccessibility of cells contained within tissues. A primary difference is that tissues must be sectioned prior to labeling, in order to allow antibody penetration into the cells. All steps are done at room temperature unless otherwise noted. This protocol requires expertise with a Cryostat-type tissue sectioner.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Animal tissue of interest
PLP fixative (see recipe), freshly prepared
PBS, pH 7.4 (*APPENDIX 2A*)
10% (v/v) dimethyl sulfoxide (DMSO) in PBS, 4°C
Isopentane (2-methylbutane)
Liquid nitrogen
Tissue-Tek OCT compound (Baxter)
0.1% (w/v) ovalbumin/PBS
Primary antibody in 0.1% ovalbumin/PBS with 0.02% (w/v) sodium azide (NaN_3)
HRP-conjugated secondary antibody: horseradish peroxidase–conjugated Fab fragments of anti–rabbit IgG or anti–mouse IgG (Biosys) in 0.1% ovalbumin/PBS
Glutaraldehyde fixative: 1.5% (v/v) glutaraldehyde in 5% (w/v) sucrose/100 mM sodium cacodylate, pH 7.4
7.5% (w/v) sucrose/100 mM sodium cacodylate, pH 7.4
0.2% (w/v) DAB solution (see recipe), freshly prepared
3% (v/v) H_2O_2, freshly prepared from 30% H_2O_2 stock solution
1% (w/v) reduced OsO_4 solution (see recipe), freshly prepared and ice cold
100 mM sodium cacodylate, pH 7.4, ice cold

70%, 95%, and 100% (v/v) ethanol
100% propylene oxide, EM grade
1:1 (v/v) propylene oxide/plastic embedding resin (e.g., Spurr's)
100% plastic embedding resin (e.g., Spurr's)

Large styrofoam box or container
Cryostat-type tissue sectioner
10 × 75–mm test tubes
Slow-moving shaker or mixer
Flat embedding molds

Fix tissue

1. Fix animal tissues by perfusion (if possible) with PLP fixative for 5 min.
2. Remove tissues from animal, immerse in ~5 ml PLP fixative, and carefully slice into small pieces of workable size (~2 mm^3). Prepare extra pieces of tissue (at least three or four per tissue sample).

   If desired, obtain and fix a variety of tissues from the animal to establish a tissue bank. Once they are frozen in liquid nitrogen (see step 15), tissues can be stored almost indefinitely and used when needed.
3. Continue to fix tissue pieces by immersion for 4 to 6 hr.
4. Wash tissue pieces four times, 15 min each, in ~5 ml PBS.

Freeze tissue

5. Cryoprotect the tissue pieces by placing in ~5 ml cold 10% DMSO in PBS for 1 hr at 4°C.
6. Fill a small (~50-ml) metal beaker or cup ~¾ full with isopentane.
7. Bore a "seat" slightly less than the diameter of the cup in the bottom of a large styrofoam box or container. Place the cup in the container so that it fits snugly in the seat.
8. Fill the container with liquid nitrogen just up to the level of the isopentane and wait for the isopentane to freeze (~10 to 20 min).
9. With a small metal probe (e.g., spatula blade), melt a small well in the frozen isopentane until it is large enough to hold a piece of tissue.
10. Wait a few seconds for the isopentane to cool (but not freeze). During this time, place a piece of tissue on the end of a wooden applicator stick.
11. Rapidly plunge the end of the stick with tissue into the well of liquid isopentane.

    Within seconds, the tissue will turn white and be frozen throughout.
12. Leave in the isopentane for 5 to 10 sec.

    Do not leave the tissue in longer or the isopentane will freeze with the tissue in it.
13. Remove the stick and place in the liquid nitrogen bath.

    Tissues can be left there until all of the pieces have been frozen in a similar fashion. It may be necessary to occasionally remelt the frozen isopentane if doing several pieces.
14. With a scalpel equilibrated in liquid nitrogen, cut the tissue off the stick while immersed in liquid nitrogen being careful to keep fingers out of the liquid nitrogen.
15. Punch several small holes in a cryovial so that liquid nitrogen will bathe the tissue during storage.

16. With cold forceps, pick up the frozen tissue pieces and place in the cryovial. Store in liquid nitrogen.

    Tissue frozen in this manner can be stored indefinitely in liquid nitrogen. This is a handy stopping point.

Cut sections on a Cryostat

17. Retrieve frozen tissue and keep in a liquid nitrogen bath until sectioned.

18. Remove one piece of tissue, mount in Tissue-Tek OCT compound, and assemble the chuck of a Cryostat-type tissue sectioner. Equilibrate the tissue to −18° to −20°C.

19. Cut ~10- to 20-μm-thick sections according to manufacturer's instructions.

    Thinner sections provide better antibody penetration, but very thin ones are difficult to handle and tend to curl. For most tissues, 10 to 20 μm seems to be fine. Thicker sections are required for some tissues. For example, glomeruli tend to fall out of thin kidney sections, so kidneys should be cut at ~30 μm.

    For the subsequent immunoreactions, three to five good sections per tissue sample are normally sufficient; however, the beginner might want to cut seven to nine because some may be lost along the way.

20. Place sections into 10 × 75–mm test tubes (two to four per tube) containing 2 to 3 ml of 0.1% ovalbumin/PBS, and allow sections to come to room temperature.

Carry out antibody incubations

21. Allow the sections to sink to the bottom of the tube, carefully aspirate the ovalbumin/PBS, and gently add 200 to 300 μl primary antibody, avoiding any physical damage to the sections.

    The approximate starting antibody concentration can be determined by preliminary immunofluorescene experiments using cultured cells (see Strategic Planning) or on 2- to 4-μm-thick cryostat sections. Good immunoperoxidase signals can be achieved in sectioned material by doubling the antibody concentration that gives a good immunofluorescence signal.

22. Seal tube with Parafilm and incubate overnight with gentle shaking or mixing.

    Care must be taken to ensure that all sections remain immersed in the fluid and do not dry out.

23. Wash sections six times, 15 min each, with 1 ml of 0.1% ovalbumin/PBS with gentle shaking.

24. Remove wash solution and apply 200 to 300 μl HRP-conjugated secondary antibody. Incubate for 2 hr with gentle shaking.

    An appropriate dilution of the secondary antibody should be determined by preliminary immunoperoxidase staining experiments (see Strategic Planning). For the Biosys secondary antibody, a starting point is a 1:400 to 1:800 dilution. The Fab-HRP antibodies from Biosys are particularly good reagents (for import information for this antibody, see Basic Protocol 1, step 7).

25. Wash sections four times, 15 min each, with 1 ml of 0.1% ovalbumin/PBS with gentle shaking.

Fix sections

26. Fix sections by removing ovalbumin/PBS, applying 1 to 2 ml glutaraldehyde fixative, and incubating for 60 min with gentle shaking.

27. Wash sections four times, 10 min each, with 1 ml of 7.5% sucrose/100 mM sodium cacodylate, pH 7.4, with gentle shaking.

Carry out DAB reaction

28. Remove wash solution and apply 1 ml of 0.2% DAB solution. Incubate for 1 min.

    CAUTION: *DAB is carcinogenic. Wear gloves and work in fume hood when handling. Treat all DAB-containing solutions and contaminated supplies with bleach, and dispose according to institutional guidelines for hazardous chemicals.*

29. Start the DAB reaction by adding 3.3 µl of 3% H_2O_2. Quickly swirl to mix the H_2O_2 and DAB. Start timing and monitor the reaction using a dissecting microscope. React several sections until they are noticeably dark, and several other sections for a shorter period of time.

    The reactions can be carried out in the tubes and inspected with a dissecting microscope, or the sections can be transferred to a dish for viewing with an inverted microscope.

    The optimal length of time for the DAB reaction should be between 5 and 30 min for tissue sections. A nearly-optimal reaction time can be established by preliminary immunoperoxidase staining experiments (see Strategic Planning).

30. Stop the reaction by removing DAB solution and rinsing sections four times quickly with 7.5% sucrose/100 mM sodium cacodylate, pH 7.4.

Osmicate the tissue

31. Place tubes on ice in a fume hood. Remove wash solution and osmicate tissue sections with 200 to 300 µl of ice-cold, 1% reduced OsO_4 solution. Seal tubes with Parafilm and incubate for 1 hr at 4°C with gentle shaking.

    CAUTION: *Wear gloves when handling OsO_4. This step must be done in a fume hood to avoid osmium vapors. Use a small volume of osmium to reduce osmium waste. Dispose of used osmium according to institutional guidelines for hazardous chemicals.*

32. Return tubes to the fume hood, remove osmium solution, and wash sections three times quickly with 1 to 2 ml ice-cold 100 mM sodium cacodylate, pH 7.4. Allow sections to reach room temperature.

33. Dehydrate sections with a graded series of ethanol (70%, 95%, 100%) as typically done for conventional plastic embedding. Perform three or four quick rinses with 2 to 3 ml of each ethanol solution.

Embed sections

34. Replace ethanol with two 1-vol changes of 100% propylene oxide.

    CAUTION: *Perform embedding procedure in a fume hood.*

35. Replace propylene oxide with 1 vol of 1:1 propylene oxide/plastic embedding resin (e.g., Spurr's). Incubate with gentle mixing for 30 min.

36. Remove 1:1 mixture, add 1 vol of 100% unpolymerized plastic embedding resin, and gently mix overnight.

37. Replace resin with at least two 1-vol changes of fresh resin.

38. Transfer sections to flat embedding molds. Fill mold with resin and polymerize according to manufacturer's specifications for the resin.

    Several sections can be stacked in one mold and then thin sections can be made through the entire depth of all sections for greater sample size.

39. Cut silver/gold sections, stain with lead citrate, and visualize the sections (see Basic Protocol 1, steps 26 to 28).

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers see* ***SUPPLIERS APPENDIX****.*

Diaminobenzidine (DAB) solution, 0.2% (w/v)

0.2% (w/v) 3,3′-diaminobenzidine tetrahydrochloride
7.5% (w/v) sucrose in 100 mM sodium cacodylate buffer, pH 7.4

Dissolve the appropriate amount of DAB in ~90% of the final desired volume of sodium cacodylate/sucrose buffer. Mix vigorously on a magnetic stirring plate in the dark (put a box over the stirring plate). Use 1 N NaOH to readjust the pH to ~7.2 to 7.4, checking by continuous monitoring with a pH meter. Bring to the final desired volume with sodium cacodylate/sucrose buffer. Filter by passing through a 0.2-µm filter. Keep in the dark until use.

The DAB should dissolve in several minutes and the solution should appear clear if slightly brownish. The pH will drop to ~6.5.

CAUTION: *DAB is carcinogenic. Wear gloves and work in fume hood when handling. Treat all DAB-containing solutions and contaminated supplies with bleach, and dispose according to institutional guidelines for hazardous chemicals.*

Periodate/lysine/paraformaldehyde (PLP) fixative

Solution A: 0.2 M lysine·HCl/phosphate buffer

Dissolve 1.83 g lysine·HCl in 50 ml H_2O. With continuous monitoring with a pH meter, add 0.1 M Na_2HPO_4 dropwise until pH 7.4 is reached. Bring solution to 100 ml with 0.1 M sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*). Store up to several weeks at 4°C.

Solution B: 8% (w/v) paraformaldehyde

Add 8 g paraformaldehyde to 80 ml H_2O while mixing on a magnetic stirring plate. Heat slowly with stirring until temperature reaches 60°C. Add 1 N NaOH dropwise until solution clears (~3 to 5 drops/100 ml). Bring to 100 ml with H_2O. After cooling, filter with Whatman no. 1 paper. Store up to several weeks at 4°C.

Fixative

Combine 3 parts solution A with 1 part solution B. Add sodium periodate ($NaIO_4$) to a final concentration of 0.01 M (21.3 mg/10 ml). Use the complete fixative at room temperature within 1 to 2 hr.

CAUTION: *Prepare the paraformaldehyde in a fume hood and wear protective gloves.*

Reduced osmium tetroxide (OsO_4) solution, 1% (w/v)

4% stock solution: Prepare 4% (w/v) OsO_4 in water and place in a glass container free of any organic contaminants. Store indefinitely at 4°C.

Working solution: Prepare a solution of 1% (w/v) OsO_4 in 100 mM sodium cacodylate, pH 7.4, by mixing one part 4% (w/v) OsO_4, two parts 200 mM sodium cacodylate, pH 7.4, and one part H_2O in a disposable plastic centrifuge tube. Chill on ice. Add solid $K_4Fe(CN)_6$ (potassium ferrocyanide) to a final concentration of 1% (w/v) and mix vigorously until it is dissolved and the solution has turned brown/black. Prepare fresh before use.

CAUTION: *Osmium solutions must be contained in a properly vented fume hood, and protective gloves should be worn. Dispose of osmium and contaminated supplies according to institutional guidelines for hazardous chemicals.*

COMMENTARY

Background Information

The ability to localize antigens, usually proteins and glycoproteins, at the EM level by immunocytochemical labeling methods has had a tremendous impact on our understanding of the subcellular and molecular organization of cells and on the dynamic processes carried out within them. Moreover, understanding the function of gene products is often aided by, and in many cases dependent on, knowing the subcellular location of the RNA or protein of interest. Not surprisingly, numerous immunocytochemical methodologies have been developed to couple the tremendous specificity of antibodies with staining methods that render antigen-antibody complexes detectable by either light or electron microscopy.

In order to be generally applicable for cell biological studies, all immunocytochemical protocols must overcome three common challenges: (1) allowing antibodies access to the intracellular environment, (2) preserving antigenicity, and (3) maintaining cellular morphology. Frustratingly, it is usually the case that solving one of these challenges only leads to problems with the others. For example, methods for maintaining excellent cellular morphology (e.g., glutaraldehyde fixation) are often counter-productive for preserving antigenicity. The protocols detailed in this unit strike a compromise that combines excellent morphological preservation with the power of antibody specificity and the signal amplification provided by enzyme cytochemistry via the peroxidase reaction (Graham and Karnovsky, 1966; Novikoff and Goldfischer, 1969; Novikoff, 1980).

Immunoperoxidase labeling at both the LM and EM levels has evolved over many years with important advances made by many laboratories (e.g., McLean and Nakane, 1974; Broadwell et al., 1979; Novikoff et al., 1979; Courtoy et al., 1980, 1982; Tougard et al., 1980; Louvard et al., 1982; Brown and Farquhar, 1984). The protocols detailed here derive from these efforts, and are useful for quite a variety of antigens. Not surprisingly, however, there are many variations of the immunoperoxidase labeling method, and it may be that some variations work better for particular antigen/antibody combinations. A few alternative procedures that readers might find useful or interesting are found in Brown and Farquhar (1989), Norgren and Lehman (1989), Saraste et al. (1995), Li et al. (1997), and Todd (1997). Conversely, DAB cytochemistry remains little changed since its early development and modification (Graham and Karnovsky, 1966; Novikoff and Goldfischer, 1969; Novikoff, 1980) and the application of ferrocyanide-reduced osmium to enhance electron density (Karnovsky, 1971).

Immunoperoxidase labeling at the EM level provides several important advantages over other methods. First, it is highly sensitive because the immunolabeled signal can be enzymatically amplified during the DAB reaction, and therefore it is quite useful for the detection of sparse antigens such as membrane receptors. Second, the morphological preservation of intracellular organelles and structures by PLP fixation (McLean and Nakane, 1974) can reach that of conventional glutaraldehyde-fixed samples. In this regard, the PLP fixative is particularly versatile for immunoperoxidase labeling at the EM level. Third, the method is fairly simple and does not require any special equipment or skills beyond those needed for standard transmission EM (TEM) of plastic-embedded samples. These three characteristics are in contrast to immunogold labeling of cryosections, which requires a special and expensive cryoultramicrotome and a high degree of specialized skill and training to generate frozen thin sections, does not provide for amplification of the immunolabeling signal, and typically generates samples in which membranes are negative images, making interpretation of results sometimes difficult.

Nevertheless, immunoperoxidase labeling has three important disadvantages when compared to immunogold. First, immunoperoxidase labeling is, by its nature, not quantitative. It gives only a qualitative picture (like immunofluorescence) of where an antigen is located in the cell. Immunogold labeling can, by rigorous statistical methods, provide important quantitative information about antigen distribution. Second, immunoperoxidase suffers from potential diffusion of the DAB reaction product away from the site of antigen-antibody binding. This diffusion leads to lower resolution than with immunogold labeling, possibly leading to erroneous conclusions about the actual site of antigen location. Third, double immunolabeling by immunoperoxidase is not generally possible, although one method for doing this has been described (Norgren and Lehman, 1989). For discussions of the limita-

tions of DAB cytochemistry see Novikoff (1973, 1980) and Courtoy et al. (1983).

Given its attractions and limitations, immunoperoxidase labeling at the EM level can be particularly useful for localizing molecules contained within intracellular membrane-bounded organelles, where antigens might be sparse (e.g., membrane receptors), but where they are sequestered within a compartment that prevents diffusion of the DAB reaction product into the cytoplasm. However, immunoperoxidase labeling can also be productively applied to antigens not contained within membranes, including both extracellular antigens (such as those in the extracellular matrix; Courtoy et al., 1980, 1982), and cell-surface antigens (Kerjaschki and Farquhar, 1983; Brown et al., 1984). In addition, immunoperoxidase can be useful for localizing certain cytoplasmic antigens, especially if they are localized to a specific region of the cell or if a low level of resolution is required (for example, when attempting to identify a particular cell type in a complex tissue or organ).

Critical Parameters and Troubleshooting

The most common problems with immunoperoxidase staining are the lack of a DAB reaction product signal or a reaction that leads to inappropriate diffusion of reaction product away from the sites of antigen-antibody binding. Without question, the DAB reaction is the most tricky step in this procedure. For this reason, two to three dishes of cultured cells (or multiple tissue sections) should be processed per experimental condition, using a range of DAB reaction times within each sample. However, with a little experience the reaction can become quite reliable and reproducible. A lack of signal at the EM level can virtually always be avoided by conducting the preliminary experiments for LM and fluorescence microscopy (see Strategic Planning). It cannot be over-emphasized how much time can be saved by spending a week or two on these preliminary experiments to establish important initial parameters.

Nevertheless, a weak or undetectable signal at the LM or EM level may result from one or more problems listed in Table 4.6.1. These problems are typically easy to diagnose and rectify by LM-level screening. When testing a new antibody for immunoperoxidase staining, be sure to include a few dishes for a known positive control antibody to distinguish between potential problems with the new primary antibody and other subsequent steps. This positive control is especially important because occasionally an antibody may work particularly well by immunofluorescence on methanol- or formalin-fixed cells but will not give an immunoperoxidase signal on cells fixed with PLP.

Inappropriate diffusion of the DAB reaction product may be harder to avoid in the beginning because it is usually only detected by EM (Fig. 4.6.1). If the preliminary experiments indicate that the antigen under investigation is contained within a membrane-bounded organelle, then all the reaction product should be sequestered within that compartment. Diffusion of reaction product out of the organelle and into the cytoplasm may indicate one of several possible problems detailed in Table 4.6.1.

Once good reaction product is obtained at the EM level, photographic documentation should be obtained. Although EM film is relatively expensive, do not cut corners here. Expose a number of negatives to have many good choices when it comes time to picking the best, most-representative image. Also, if there is a particularly good image that really demonstrates the point you want to make, take several pictures, perhaps slightly altering the focus on a few, in case something happens to one of the negatives. It is usually much easier to find an EM negative than it is to find that same cell again.

Anticipated Results

At the EM level, the DAB reaction product should be noticeably electron dense—more so than any cellular structure including membranes, ribosomes, or heterochromatin (Fig. 4.6.1). The reaction product may have a slightly mottled appearance if filling a large membrane-bounded compartment. Oxidized DAB has an affinity for membranes, so even if an antigen is present throughout the lumen of a vacuolar organelle, the reaction product may not be uniformly distributed within that lumen. Rather, the DAB reaction product may diffuse and bind to the inner surface of the limiting membrane yielding a dark rim of staining. At the LM level, the DAB reaction product appears a brown/black color.

Time Considerations

Immunoperoxidase staining of cultured cells

The labeling protocol from the beginning of fixation to the start of embedding can be done in a single day; however, it will take at least 8

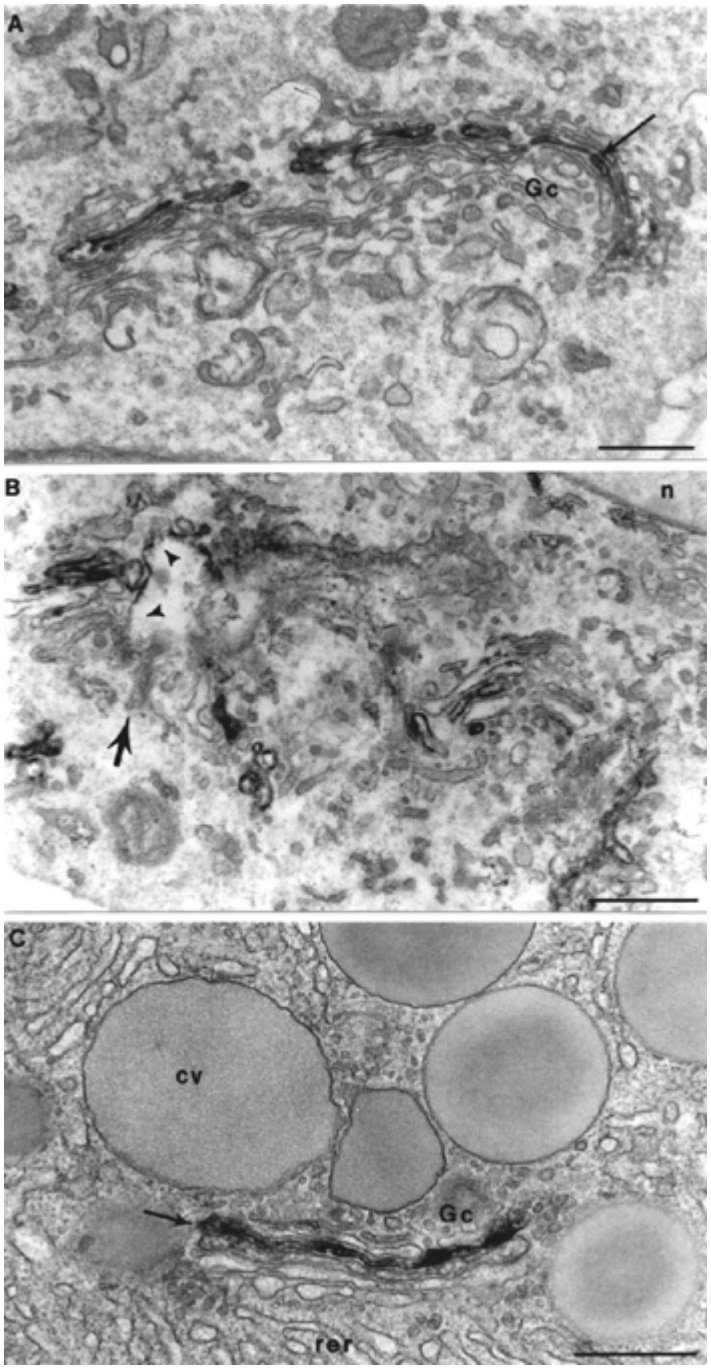

Figure 4.6.1 Immunoperoxidase localization of resident Golgi-complex enzymes in cultured cells and cells from tissue sections. (**A** and **B**) Rat clone 9 hepatocytes stained by the methods described in Basic Protocol 1 for cultured cells with antibodies to the medial Golgi enzyme α-mannosidase II. In (**A**), the very electron-dense DAB reaction product (arrow) stands out in sharp contrast to the rest of the cytoplasm and fills mainly one or two cisternal elements of the Golgi stack. This example illustrates a well-preserved, immunolabeled cell whose reacted organelle membranes are morphologically intact. Note that the DAB reaction product remains sequestered within the lumen of the cisternae. In (**B**), another clone 9 cell, reacted with the same antibody, shows significant damage resulting from cisternal elements that have become extremely dilated ("exploded") and broken (arrowheads). As a consequence, the DAB reaction product leaks into the cytoplasm (arrow). In (**C**), a portion of a rat pancreatic acinar cell is shown. The cell was labeled with antibodies against sialyltransferase, a *trans* Golgi enzyme, by the methods described in Basic Protocol 2. In this cell, the DAB reaction product also stands in sharp contrast to the cytoplasm and is sequestered within an intact cisternae (arrow). Abbreviations: cv, condensing vacuole; Gc, Golgi cisternae; n, nucleus; rer, rough endoplasmic reticulum. Scale bars, 0.5 μm.

Table 4.6.1 Troubleshooting Guide for Immunoperoxidase Localization Protocol

Problem	Possible cause	Solution
Poor general morphology	Inadequate fixation time	Fix longer
	Fixative made incorrectly	Follow recipe carefully; ensure that paraformaldehyde goes into solution
Organelles appear to be exploded, leaving holes in the cytoplasm (Fig. 4.6.1B)	DAB reaction too long or rapid	React for shorter period of time and/or slow the reaction down on ice
Weak or no DAB reaction product	Antibody titer and/or affinity low	Prepare IgG fraction or affinity purify antibodies
	Cells not well permeabilized	Increase saponin concentration or incubation time
	HRP-conjugated antibody no longer active	Check HRP activity by testing with small amount of DAB and H_2O_2
	H_2O_2 not good	Use fresh H_2O_2; check H_2O_2 in a test tube with DAB solution and 1-2 µl HRP-conjugated antibody to see if substrate turns dark brown/black
DAB reaction product diffused away from primary site of reaction and/or from membrane-bounded organelles that appear to have exploded (see above)	Samples over-reacted for DAB deposition	React for shorter period of time; lower concentration of primary or secondary antibody
	Saponin not sufficiently washed out	Increase number of washes in PBS
Immunofluorescence indicates that antigen is a membrane protein, but immunoperoxidase results in a diffuse cytoplasmic stain near an organelle but not within the lumen	DAB has possibly leaked out through a compromised membrane (see above), or worse, the epitope recognized is on the cytoplasmic face of membranes	Not much can be done if the epitope is cytoplasmically oriented; try reacting for a shorter period of time and/or on ice
DAB reaction product seen by LM but not EM	OsO_4 not properly reduced	Follow recipe for reduced osmium
General background staining	Used antiserum or antibody that is not specific	Use IgG fraction or affinity-purified antibodies; try increasing ovalbumin concentration to 1% when diluting antibody to reduce nonspecific binding
DAB not soluble	Used 3,3′-DAB free base	Use 3, 3′-DAB tetrahydrochloride
Cells will not detach from dish	Inferior quality propylene oxide	Use EM-grade propylene oxide

to 9 hr even in experienced hands and can be quite fatiguing. Also, keep in mind that this timeframe does not account for any experimental manipulations that might have been done to the cells before fixation. Therefore, the author recommends that on day 1 (following any experimental procedures) cells be fixed and processed up to and including incubation in the primary antibody, at which point the cells can be kept overnight as described in the protocol. The time from fixation to addition of the primary antibody will take minimally ~3 to 4 hr. The author does not recommend incubating cells overnight in the secondary antibody, because this gives a slightly higher nonspecific background labeling. Thus, on day 2, cells are processed through incubation with the secondary antibody, the DAB reaction, osmication, and the start of embedding. This process will take minimally ~4 to 5 hr. Infiltration of embedding plastic will proceed overnight and all the next day (day 3), and another overnight incubation is required for heat-activated polymerization. Thus, cells are ready for thin sectioning, staining, and visualization on day 4.

Immunoperoxidase staining of tissue sections

Immunoperoxidase labeling of tissue sections can conveniently be done in five days.

Day 1: Fix and freeze tissues. This will take anywhere from 6 to 8 hr depending on how many tissue samples are being processed. Tissues can be stored frozen indefinitely, until used to complete the protocol.

Day 2: In the afternoon, cut the cryostat sections. Apply the first antibody and incubate overnight. These steps can take anywhere from 1 to 4 hr depending on the level of experience with microtomes and the number of samples being processed. With experience, days 1 and 2 can be combined.

Day 3: Complete the procedure from application of secondary antibody to start of embedding sections (4 to 6 hr). Allow embedding to proceed overnight.

Day 4: Continue embedding during the day and perform heat-activated polymerization overnight.

Day 5: Thin section and stain tissue for visualization.

Cryo-Immunogold Electron Microscopy

INTRODUCTION

Subcellular localization of gene products, such as mRNA, miRNA, proteins, as well as (glyco)lipids, and other antigens using high-resolution cryo-immunogold electron microscopy allows for topological biochemistry at the ultrastructural level (Basic Protocol). This is the most sensitive procedure for immunodetection of several antigens simultaneously on ultrathin sections prepared from chemically fixed cells or tissues, because aldehyde fixation (Support Protocols 1 and 2) is the only denaturation step. The omission of harsh organic solvents (such as those used for plastic embedding) ensures better preservation of antigenicity. The fixed material is embedded in gelatin (Support Protocol 3), cryosectioned (Support Protocol 4), and mounted on Formvar-coated grids (Support Protocol 5). The basic principles and variations are described in the protocols below and illustrated in the accompanying videos.

IMMUNOGOLD LABELING

BASIC PROTOCOL

The precise reaction conditions used for immunogold labeling may vary depending on the antibody, and this is determined by trial and error (a useful reference is Raposo et al., 1997). This is a typical labeling protocol during which the sectioned material is exposed first to antibodies and then to protein A–gold particles. If the primary antibody does not bind to protein A, incubation with a secondary antibody that does bind protein A can be added. All procedures are carried out at room temperature. Note that for murine tissue, a secondary anti-mouse antibody can cause false positive artifacts. This antibody will also detect endogenous Ig of the mouse if present in the tissue. An alternative would be to use primary antibodies or Fab's directly coupled to ultrasmall gold and silver enhancement (see Alternate Protocol) (see *http://www.aurion.nl*) or to biotin with a rabbit anti biotin followed by protein A gold.

Materials

Cells or tissue of interest, fixed (Support Protocol 1 or 2), embedded (Support Protocol 3), cryo-sectioned (Support Protocol 4), and mounted on Formvar-coated grids (Support Protocol 5)
2% (w/v) gelatin-coated 2.5-cm Petri dishes
PBS (*APPENDIX 2A*) containing 0.15 M glycine
PBS containing 1% (w/v) BSA
Primary antibody diluted in PBS/1% BSA
PBS/0.1% (w/v) BSA
Secondary antibody in PBS/1% BSA (optional)
10-nm protein A–gold particles at OD 0.1 (commercially available from Cell Biology, Medical School, Utrecht University, The Netherlands) in PBS/1% BSA
PBS containing 1% (v/v) glutaraldehyde
Uranyl oxalate solution (see recipe; optional)
Methyl cellulose/uranyl acetate solution (see recipe)
Parafilm M
Whatman no. 50 filter paper
37°C incubator
Forceps
Stainless steel loop slightly larger than grids attached to P1000 (blue, 1000-μl) pipet tips (see Video 1 at *http://www.currentprotocols.com*).

Contributed by Peter J. Peters, Erik Bos, and Alexander Griekspoor
Current Protocols in Cell Biology (2006) 4.7.1-4.7.19

Prepare the sample

1. Place the grid containing cryosections on cold 2% gelatin plates and leave for 30 min at 37°C.

   The 2% gelatin will melt and the grids will float on top of the liquified gelatin. The 12% gelatin that was introduced into the sample during the embedding step is melted away at this point into the 2% gelatin.

2. Lift the floating grid with a pair of fine forceps and transfer it onto 100-µl droplets of PBS/0.15 M glycine laid out on a sheet of Parafilm M, keeping the upper part of the grid dry at all times (see Video 2 at *http://www.currentprotocols.com*).

   The bottom part of the grid should always remain wet during transfer to the next droplet.

3. Wash five times, each time by floating the grid for 2 min on fresh 100-µl droplets of PBS/0.15 M glycine.

   All subsequent treatments (washings and incubations) involve the transfer of the grid onto fresh droplets of medium that are laid out on Parafilm M. About 100-µl droplets should be used for all solutions except the antibody and protein A–gold, for which 5-µl droplets are used. Grids receiving the same antibody treatments can be washed together on a single drop of washing solution.

4. Wash grid once, by floating for 3 min on a 100-µl droplet of PBS/1% BSA.

Expose the sample to antibody

5. Incubate grid for the appropriate period of time at room temperature on a 5-µl droplet of primary antibody diluted to an appropriate concentration in PBS/1% BSA.

   The appropriate dilution and incubation times vary with the antibody used. Incubation time ranges from 30 to 100 min. Antibody titer is usually in the range of 0.2 µg/ml but must be tittered for each antibody in order to find the best specific signal-to-background signal ratio.

6. Wash the grid five times, each time by floating for 3 min on 100-µl droplets of PBS/0.15 M glycine, and then perform a final wash on PBS/0.1% BSA.

7. *Optional:* When a primary antibody is used that does not react with protein A (Table 7.2.1), incubate grid with a secondary (bridging) antibody that binds protein A, diluted in PBS/1% BSA, for 20 min and rinse five times for 2 min on PBS/0.15 M glycine.

Expose the sample to protein A gold

8. Incubate grid for 20 min on 10-µl droplets of 10-nm protein A–gold particles (at an OD of 0.1) in PBS/1% BSA.

9. Wash grid three times with rapid changes and then with six 3-min changes, each time by floating on 100-µl droplets of PBS.

Fix the sample

10. Incubate grid for 5 min on 100-µl droplets of PBS/1% glutaraldehyde in chemical hood.

    For double immunogold labeling, after this step wash the grids with PBS/0.15 M glycine (step 2) and repeat the entire procedure from that point on with the second primary antibody. For double-labeling experiments, use protein A with different sizes of gold particles (e.g., 10 and 15 nm).

11. Wash grid ten times, each time by floating for 2 min on 100-µl droplets of distilled water.

12. *Optional:* Incubate grid for 5 min on 100-µl droplets of uranyl oxalate solution and rinse by floating for 1 min on a 100-µl droplet of water to prevent possible artifacts introduced by uranyl acetate.

Embed the sample

13. Quickly wash grid by floating for 1 min on 100-µl droplets of methyl cellulose/uranyl acetate solution, then floating 5 min on fresh 100-µl droplets of methyl cellulose/uranyl acetate solution on ice.

14. Retrieve the grid with a stainless steel loop of diameter slightly larger than the grid, glued into a P1000 pipet tip.

15. Drain away excess methyl cellulose/uranyl acetate solution by touching the loop at an angle of 90° to a filter paper (Whatman no. 50) and tracking the loop from left to right for 2 cm. Stop and lift the loop from the paper just before the remaining volume gets absorbed by the paper (see Video 3 at *http://www.currentprotocols.com*).

16. Air dry grid at room temperature by placing the pipet tips upside-down in a pipet tip rack.

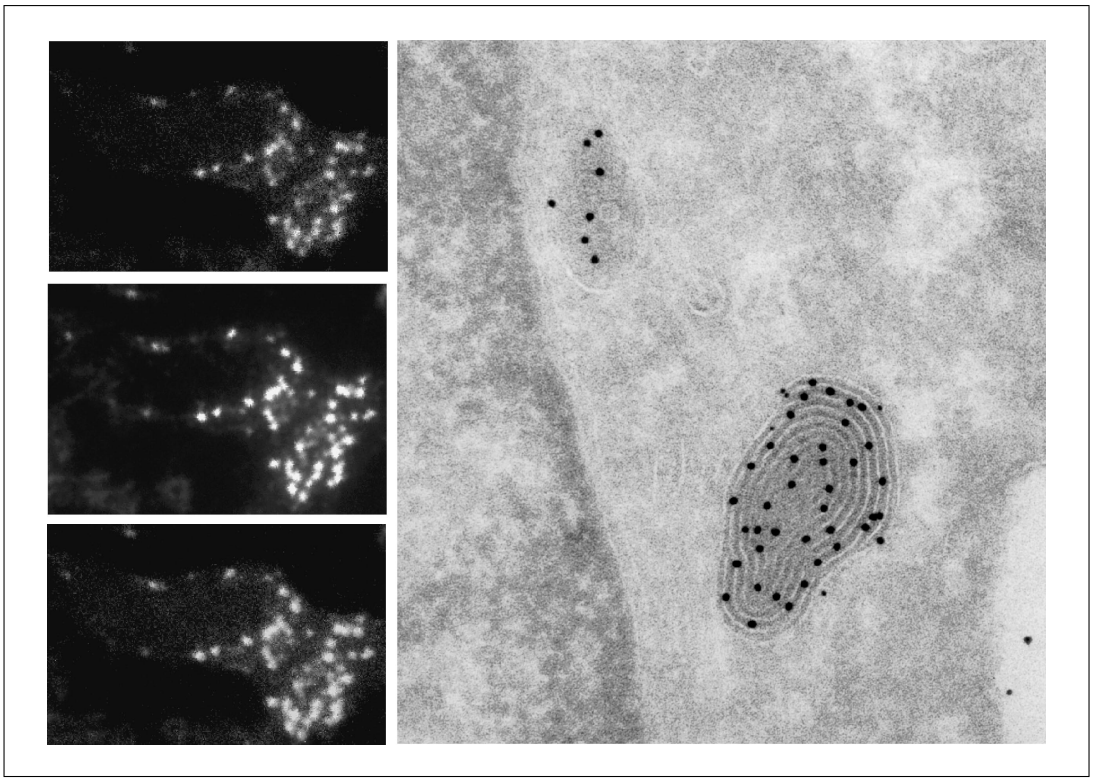

Figure 4.7.1 Light microscope and electron microscope micrographs of two adjacent ultrathin cryosection of a dentritic cell. **LM** MHC class II was detected together with CD1b by immunofluorescence on semithin cryosections of 280 nm. The CD1b is presented in the upper left panel; MHC class II in the lower left panel and a merge of the pictures is shown in the left bottom panel. CD1b and MHC class II molecules are located intracellular in the lysosomal MHC class II compartments (MIIC; see Peters et al., 1991a). Note that details of immunofluorescence pattern is comparable if not better then confocal laser scan microscopy. **EM** micrograph (right panel) of a 50-nm section. Immunogold labeling of CD1b (small gold) and MHC class II (large gold) within MIIC. Please note that by EM one can see a differential distribution of CD1b versus MHC class II within the MIIC not seen by LM. The CD1b molecules reside on the outer membrane while class II molecules are on the internal membranes of the MIIC. For the color version of this figure go to *http://www.currentprotocols.com*.

A film of methyl cellulose/uranyl acetate is left on the grid after drying. This is important to give optimal contrast and to preserve the integrity of membrane structures. The film should be slightly thicker than the sections and can be assessed by the interference colors viewed under a stereomicroscope. A gold-colored film is optimal for 50- to 70–nm sections. Currently the authors prefer one-slot grids for creating uniform thickness of cellulose and evaluating serial sections.

Examine the sample

17. Examine grid by electron microscopy at 80 kV with a small aperture.

    See Figure 4.7.1 for an example of results.

ALTERNATE PROTOCOL

IMMUNOGOLD LABELING WITH SILVER ENHANCEMENT

When ultrasmall gold–coupled antibodies or protein A is used as a reagent, silver enhancement is employed to make the ultrasmall gold particles visible in the electron microscope.

Additional Materials *(also see Basic Protocol)*

Gelatin storage plates containing grids with cryosections
PBS containing 0.5% (w/v) cold fish skin gelatin (CFG)
Fab fragments of the primary antibody conjugated to Aurion ultrasmall gold particles
Ultrasmall gold silver enhancement kit (Aurion)

Prepare the sample

1. Place the gelatin storage plates containing the inverted grids with the cryosections in an incubator maintained at 37°C for 20 min.

   The gelatin will melt and the grids that are on top will float as the gelatin changes from a solid underground to a liquid. Also, residual 10% gelatin that was introduced into the sample during the embedding step is melted away at this point. The upper part of the grid should always remain dry.

2. Lift the floating grid with a pair of forceps and transfer onto 100-µl droplets of PBS/0.15 M glycine laid out on a sheet of Parafilm M.

3. Wash five times, each time by floating the grid for 3 min on fresh 100-µl droplets of PBS/0.15 M glycine.

   All subsequent treatments (washings and incubations) involve the transfer of the grids onto fresh droplets of medium that are laid out on Parafilm. 100-µl droplets should be used for all solutions except the antibody and gold, for which 5- and 7-µl droplets are used, respectively.

4. Wash grid by floating for 3 min on 100-µl droplets of PBS/1% BSA or PBS/0.5% CFG.

Expose the sample to antibody conjugated to gold

5. Incubate grid for the appropriate period of time at room temperature on 5-µl droplets of antibody Fab fragments conjugated to Aurion ultrasmall gold diluted to an appropriate concentration in PBS/1% BSA.

   The appropriate dilution and incubation times vary with the antibody used. Incubation time ranges from 30 to 100 min. Antibody titer is usually in the range of 0.2 µg/ml but must be titered for each antibody, at the EM level, in pilot experiments.

   One can use any Fab for proper custom service coupling. See Mironov et al. (2003) for good results.

6. Wash grid six times, each time by floating for 3 min on 100-µl droplets of PBS.

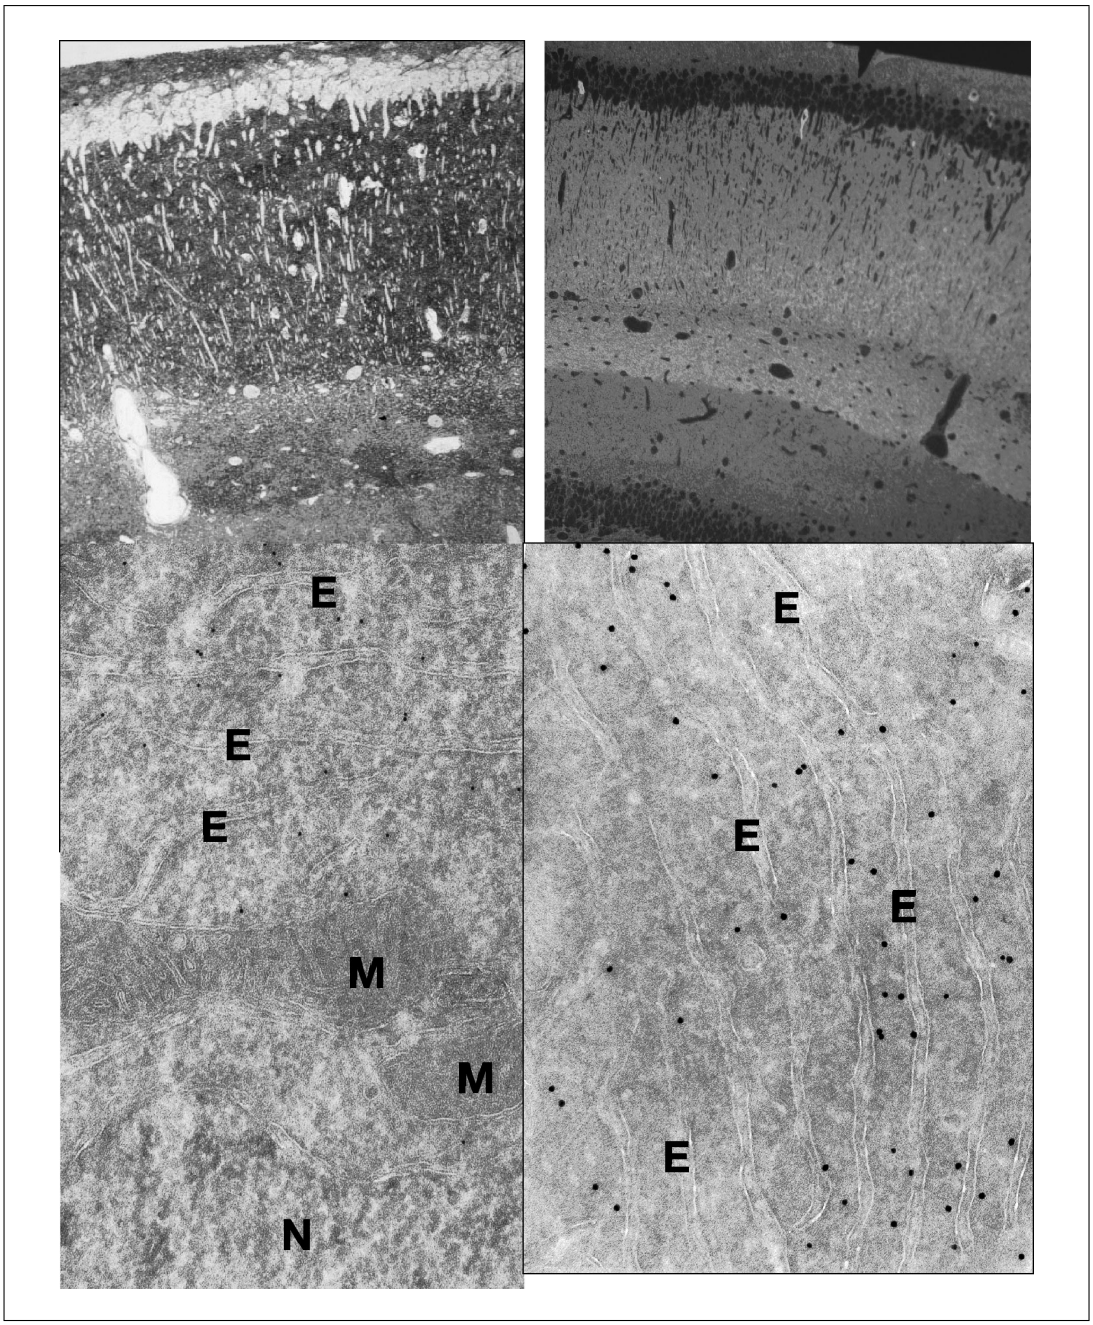

Figure 4.7.2 **LM** Hippocampal semithin cryosections labeled for PrP^C with Fab D18. Labeling is concentrated in the stratum oriens (o), stratum radiatum (r) and lacunosum-moleculare (lm); cell bodies of pyramidal (p) and granule (g) layers are free of labeling with the exception of a few cells. Upper left: Fab D18 was used with a secondary polyclonal antibody and protein A–gold (5 nm) that was subsequently visualized by silver enhancement (Aurion). Upper right: Fluorescent labeling shows a labeling pattern similar to panel A. **EM** PrP is concentrated in the cytosol in a subpopulation of neurons. Lower left: protein–A gold particles label PrP. Lower right: Direct immunolabeling with Fab D18-ultrasmall gold (Aurion) and silver enhancement demonstrates the same cytPrP abundance. For the color version of this figure go to *http://www.currentprotocols.com*.

Fix the sample

7. Incubate grid for 5 min on 100-µl droplets of PBS/1% glutaraldehyde.
8. Wash grid ten times, each time by floating for 2 min on 100-µl droplets of distilled water.

Enhance the staining

9. Prepare the enhancement mixture by adding 20 drops of the silver enhancer solution to 1 drop of the developer solution. Incubate grid for 30 min at room temperature on 100-µl droplets of the enhancement mixture.

   IMPORTANT NOTE: *This incubation procedure is temperature dependent. If the temperature is increased, then the incubation time must be decreased!*

10. Wash grid ten times, each time by floating for 2 min on 100-µl droplets of distilled water.
11. Incubate grid for a maximum of 2 min on 100-µl droplets of uranyl oxalate solution.

    Incubation >2 min will interfere with the silver deposits!

Embed the sample

12. Quickly wash grid on one 100-µl droplet of distilled water and one 100-µl droplet of methyl cellulose/uranyl acetate solution, then float the grid 2 min in a fresh 100-µl droplets of methyl cellulose/uranyl acetate solution on ice.
13. Retrieve the grid with a stainless steel loop of diameter slightly larger than the grid, attached to a P1000 pipet tip.
14. Drain away the excess of methyl cellulose/uranyl acetate solution by touching the loop at an angle of 90° to a filter paper (see Video 3).
15. Air dry grid at room temperature by placing the pipet tips upside-down in a pipet tip rack.

    A film of methyl cellulose/uranyl acetate is left on the grid after drying. This is important to give optimal contrast and to preserve the integrity of membrane structures.

Examine the sample

16. Examine grid by electron microscopy at 80 kV with a small aperture.

    See Figure 4.7.2 for an example of material stained with Aurion ultra small gold silver enhancement kit.

SUPPORT PROTOCOL 1

ALDEHYDE FIXATION OF CELLS FOR CRYO-IMMUNOGOLD LABELING

The chemical fixation step is critical for cryo-immunogold electron microscopy. The purpose of fixation is to cross-link and immobilize all subcellular structures and antigens in their most native form and maintain maximum antigenicity. Two different fixatives are commonly used: formaldehyde (FA), or a combination of FA and glutaraldehyde (GA). It is good practice to use these fixatives side by side so that later it can be determined which one is most suitable for the antigens that are being studied. (See Video 4 at *http://www.currentprotocols.com*.)

Materials

Cultures of adherent cells (from a 10-cm dish) or cells in suspension
Culture medium appropriate to the cell type
2× fixative, pre-warmed to 37°C: 2× FA (see recipe) *or* 2× FA/GA (see recipe)
Storage solution (see recipe)
PBS containing 0.15 M glycine, 37°C
PBS containing 1% (w/v) gelatin

Cell scraper
Glass Pasteur pipets (do not use plastic since several cell types may adhere to plastic)
Table-top centrifuge
1.5-ml microcentrifuge tubes
15-ml tubes (Falcon)

1. Add fresh medium to cells the day before the experiment.

   Cells should have been growing for more then 1 day (routinely 3 days) on the dish.

   At the time of fixation adherent cells should be ~ 75% confluent; the density of cells in suspension should be ~1 × 10^6 cells/ml. The total volume of growth medium should be 5 ml.

   Alternatively, the cells can be grown on an EM grid to permit analysis of the living cells by light and/or epifluorescence microscopy, microinjection of the cells, and then sectioning of the grid for EM analysis. To grow cell on an EM grid, place Formvar-coated golden grids on the bottom of a plastic Petri dish with the film side up. Add prewarmed PBS/1% gelatin to cover the entire dish. Let stand for 10 min at 37°C. Rinse with prewarmed PBS and add PBS/1% glutaraldehyde to cover the dish and allow to stand for 10 min. Rinse with sterile PBS/0.15 M glycine and then air dry. Place a droplet of cell suspension on top of each grid without floating the grids. Allow the cells to settle for 15 min and then add culture medium. Incubate for 12 to 36 hr at 37°C and evaluate the cell density by light microscopy (Stoorvogel et al., 1996).

2. Add 5 ml of 2× fixative (pre-warmed) to 5 ml of a suspension of cells that have just come out of the incubator or to a 10-cm plate of adherent cells. Incubate the cells horizontally for 24 hr (FA) or 2 hr (FA/GA) at room temperature. Do not disturb (shake or vortex) cells during fixation period.

   CAUTION: *Fixatives are corrosive to the skin, nose, and eyes. Therefore, it is advisable to work in the chemical hood with a double set of gloves and safety goggles.*

   Don't wash or centrifuge cells in PBS or any other medium before fixation, in order to avoid artifacts.

For adherent cells

3a. Replace the fixative with PBS/0.15 M glycine and wash 2 times with PBS/0.15 M glycine. Replace PBS/0.15 M glycine with 5 ml of pre-warmed PBS/1% gelatin and leave for 30 min at 37°C.

   Adherent cells can become severely damaged by air-drying. Wash cell cultures one by one and replace solutions quickly. Always leave the plates in a horizontal position!

   Using gelatin to scrape the cells produces a greater yield of cells and protects the cells from mechanical damage.

   Cells may detach after fixation. Therefore, keep the fixative and rinsing solutions, centrifuge the floating cells from these solutions and resuspend them replacing the fixative with PBS/0.15 M glycine. Pool these recovered cells later with the scraped cells. Under several experimental conditions (e.g., transfection, RNAi) cells may detach from the surface of the culture dish, go into suspension during culture, and may be missed. In this case, add an equal volume of 2× fixative to the collected medium and pellet the cells. Add the pelleted cells to the other fixed cells.

   Resuspend cells gently with a Pasteur pipet (do not use a vortexer, because this may damage ultrastructural details). Take up small volumes in the pipet when resuspending, so that cells do not get trapped on glass surface.

4a. Scrape the cells with a cell scraper. Transfer to a 1-ml tube.

5a. Centrifuge the cells 3 min at 1000× *g*, room temperature. Resuspend cells in 1 ml PBS and transfer to 1.5-ml microcentrifuge tube.

For some cells higher centrifugation speed is required.

If the samples are to be shipped to another laboratory by air, ship them in a room-temperature Styrofoam storage box to prevent freezing of the samples during flight. Frozen samples are useless!

For suspension cells

3b. Transfer suspension of fixed cells to 15-ml tube and centrifuge 3 min at 1000× *g*, room temperature.

For some cells a higher centrifugation speed is required.

4b. Resuspend cells in 1 ml PBS/0.15 M glycine and transfer to 1.5-ml microcentrifuge tube. Rinse twice in PBS/0.15 M glycine.

If fixed cells have to be stored, replace fixative with storage buffer. Make sure that the tube is filled to the top with storage buffer; this will prevent drying of cells in the tube. Cells scraped in gelatin should be rinsed in PBS/0.15 M glycine before storage buffer is added (aldehyde fixative also cross-links gelatin). Store microcentrifuge tubes that contain the fixed cells indefinitely in storage solution at 4°C in an airtight container (e.g., a 50-ml centrifuge tube).

If the samples are to be shipped to another laboratory by air, ship them in a room-temperature Styrofoam storage box to prevent freezing of the samples during flight. Frozen samples are useless!

SUPPORT PROTOCOL 2

FIXATION OF TISSUE FOR CRYO-IMMUNOGOLD LABELING

Pieces of tissue biopsy, dissected organs, or embryos can be fixed for cryo-immunogold labeling.

Materials

Tissue of interest
1x fixative: 1× FA (see recipe), *or* 1× FA/GA (see recipe)
Storage solution (see recipe)
Razor blades, acetone cleaned
Glass vials with screw caps
Fine forceps

1. Add one piece of freshly dissected tissue from an anesthetized mouse, biopsy tissue, dissected organ, or embryo immediately to 2 ml of 1× FA fixative and one to 2 ml of 1× FA/GA fixative in a glass vials with screw caps. For perfusion fixation, use a very short perfusion pulse with warm culture medium (e.g., DMEM or PBS) before perfusing with fixative.

Within 1 min after oxygen deprivation or temperature loss, cells alter dramatically at the ultrastructural level and in antigen distribution!

CAUTION: *Fixatives are corrosive to the skin, nose, and eyes; therefore it is advisable to work in the chemical hood with a double set of gloves and safety goggles.*

Perfusion fixation of tissue is preferable for achieving good morphology. The authors routinely use this for mice.

2. Cut tissue into 3-mm thick pieces using clean acetone-rinsed, air-dried razor blades and fine forceps.

Use of a dissecting microscope aids careful handling and reduces mechanical damage to the tissue. Perform this operation in a chemical hood.

3. Fix FA-fixed tissue at room temperature for 24 hr and GA/FA-fixed tissue for 2 hr, except fix GA/FA perfusion–fixed brains overnight.

   Fixing longer will result in difficulties when sectioning.

   For studies on GPI-anchored proteins that only label on FA-fixed tissue, the authors prefer to fix cells in the cold to avoid redistribution of the protein.

4. After fixation, transfer tissue to storage solution in glass vials. Store at 4°C in an airtight container.

   Once in storage solution, in preparation for embedding, the authors routinely place brain and other tissue in PBS and cut 0.5-mm slices with a vibratome for proper micro-anatomical examination of the tissue used for EM. For further storage, slices are then transferred back into storage solution.

EMBEDDING SAMPLES FOR CRYO-IMMUNOGOLD LABELING

SUPPORT PROTOCOL 3

Cells and tissues are embedded in gelatin to facilitate easy handling during the rest of the procedure. It is advisable to have a dissecting microscope with cold-light optics permanently present in a cold room. Care should be taken to prevent the samples from drying out. Gelatin allows solidification of a cell suspension and loose tissue at low temperature, so that it becomes a piece of material that can be handled relatively easily. The gelatin will melt once the ultrathin cryosections are prepared for immunolabeling. Sucrose infiltration prevents the material from ice-crystal damage during freezing in liquid nitrogen.

Materials

Fixed cells (see Support Protocol 1) or tissue (see Support Protocol 2) in storage solution
PBS
PBS containing 0.15 M glycine
12% (w/v) gelatin in 0.1 M sodium phosphate buffer (see recipe), 37°C
2% and 5% (w/v) gelatin in 0.1 M sodium phosphate buffer (see recipe), 37°C (for tissue)
2.3 M sucrose in 0.1 M sodium phosphate buffer, pH 7.4
Parafilm M
Glass Pasteur pipets
Razor blades, acetone-rinsed and air-dried
Dissecting microscope with cold-light optics
1-ml plastic vials
10-ml vials
Table-top centrifuge
End-over-end rotator (~10 sec per rotation)
Fine forceps
Greiner analyzer cup 14/24-mm, 1.5-ml, and caps (Greiner Bio-One)
Aluminum specimen holders, or steel pins, roughened with sandpaper and acetone-cleaned, dust-free
15-ml aluminum cryo tubes with two holes punched in the top
Liquid nitrogen

For fixed cells

1a. Centrifuge fixed cells 3 min at 1000 × *g*, room temperature. Remove supernatant. Resuspend cells in PBS/0.15 M glycine and centrifuge again. Repeat once more.

2a. Resuspend cells in 1 ml of 12%, 37°C gelatin, then incubate 5 min at 37°C.

3a. Centrifuge cells for 3 min at 11,180 × *g*, room temperature. Let stand on ice for 10 min to allow the gelatin to solidify.

4a. Cut the microcentrifuge tubes just above the cell pellet and cut in halves. Transfer to a 10-ml vial containing pre-cooled PBS, and keep on ice (see Video 5 at *http://www.currentprotocols.com*).

The microcentrifuge tube should be opened before cutting to avoid pressure inside the tube which will squeeze out the gelatin from the cut end.

Cold PBS prevents the gelatin from melting.

These steps are best carried out in a cold room, to ensure that the gelatin does not melt and that the sample does not dry out, as well as for easy handling with sucrose.

5a. Transfer the pellet halves to a droplet of cold PBS using forceps, but without exerting any pressure on the cells, and cut the cells/gelatin into slices of 0.5 mm. Then cut the slices into 0.5-mm cubic blocks, using clean (acetone rinsed, air dried) razor blades, under a dissecting microscope.

For fixed tissues

1b. Wash tissue two times, each time for 5 min, in PBS/0.15 M glycine.

2b. Incubate 30 min each in 2%, 5% gelatin, and twice, 30 min each, in 12% gelatin in an end-over-end rotator (13 rotations/min) at 37°C.

3b. Place the tissue in a small drop of gelatin on top of a piece of Parafim M and remove excess gelatin by pushing the piece of tissue along the Parafilm surface when the gelatin is still liquid. Put the Parafilm on ice so the remaining gelatin covering the tissue solidifies. Cover the gelatin-infiltrated piece of tissue with a drop of cold PBS. Then, proceed to step 6.

6. Transfer the cubic blocks to a Greiner cup with a cap and containing 2.3 M sucrose.

7. Rotate sample in sucrose for at least 4 hr in an end-over-end rotator in the cold room.

8. Working under the dissecting microscope and using fine tweezers with a minimum of force, transfer the sample, along with a minimum of sucrose, from the vial to very clean aluminum specimen holder that has been roughened with sandpaper or scratched with a sharp steel pin.

Roughening or scratching increases the surface of the specimen holder, which ensures better attachment of the sucrose.

9. Remove excess sucrose using clean filter paper, and transfer holders to small aluminum cryo containers filled with liquid nitrogen (see Video 6 at *http://www.currentprotocols.com*). Store in liquid nitrogen.

Sample blocks can be stored in liquid nitrogen for years and are ready for ultrathin cryosectioning repeatedly (see Support Protocol 4).

SUPPORT PROTOCOL 4

CRYOSECTIONING FOR CRYO-IMMUNOGOLD LABELING

The procedure for ultrathin cryosectioning is demanding, it requires training and practice; learning this skill is comparable to learning a musical instrument for professional performance.

Materials

Sample blocks that are stored in liquid nitrogen (see Support Protocol 3)
Section retrieval solution (see recipe), freshly prepared

Ultramicrotome (Leica) with cryochamber and antistatic devices (Diatome)
Diamond knife (Diatome; cryo-immuno 35°)
Trimming knife (Diatome; cryo-trim 45° or 20°)

Eyelash; undamaged, clean and mounted on a wooden stick (see Video 7 at *http://www.currentprotocols.com*).

3-mm diameter loop made of twisted 0.3-mm romanium wire (Winkelstroeter Dentaurum) on a 15-cm wooden stick (see Video 1 at *http://www.currentprotocols.com*)

Carbon- and formvar-coated copper grids (see Support Protocol 5)

1. Cool the ultramicrotome to −100°C. Insert and secure specimen, trimming knife, and knife for ultrathin sectioning in the ultramicrotome as described by the manufacturer.

2. Trim the front face of the block with a trimming knife by making sections of 200-nm thickness, at a speed of 100 mm/sec.

   Trimming of the sample is a prerequisite for making ribbons of ultrathin sections. The end result is a perfectly trimmed rectangular block from which ultrathin cryosections are made.

3. Trim the edges of the block by making sections from the short side of the sample block, and stop sectioning when the counter on the control unit of the microtome indicates 100 to 120 μm. Leave the block <0.25 mm wide.

4. Rotate the sample at 90° angles and trim along each side to end up with a shiny rectangular block of 0.25 × 0.50–mm or smaller. Rotate the sample back to the original position.

   At this step, it is advisable to check whether the trimmed block is suitable for further sectioning, by cutting a few 0.25-μm thin cryosections. These can then be picked up (step 6) and evaluated by light microscopy. Methylene blue staining or immunocytochemistry (UNITS 4.3 & 4.6) may be performed on these sections. If necessary, the specimen can be trimmed further after the light microscope examination. Also, sections for LM evaluation can be used to chose the proper area of interest for further trimming. This works best with the 20° Diatome trimming knife.

5. For ultrathin sectioning, set and maintain the temperature of the cryochamber, knife holder, and specimen holder of the microtome at −120°C.

6. Cut ultrathin sections of 70-nm thickness with a gold color (for FA-fixed material) or 50-nm with a light yellow color (for FA/GA-fixed material) at a speed of 1 to 2 mm/sec using a clean diamond knife (see Video 8 at *http://www.currentprotocols.com*).

   The Cryo Immuno diamond knife is preferred to the Ultrathin 35 diamond knife because it makes section manipulation easier and reduces the potential for damage to the sections. Sections are less likely to curl or fly away as they move from the diamond knife to a diamond platform, and they are less likely to twist or crumple on transfer to the pick up drop. Also it is easier to clear frost and ice crystals from the diamond surface, again reducing the potential for section damage.

   Usually an antistatic device in the chamber is used to facilitate sectioning.

   Sections should be lined up adjacent to each other so as to form a ribbon 0. 25-mm wide made up of 7 to 10 sections (depending on compression). During sectioning, sections should be manipulated with an eyelash mounted on a wooden stick in order to carefully bring the ribbon down the knife as sections are added, and to flatten out any curled up or wrinkled sections if needed.

7. Retrieve sections from the cryo chamber using a droplet of pick-up solution created on a 3-mm stainless steel loop attached to a 15-cm wooden stick. Press the droplet onto the face of the ribbon of sections and quickly remove the loop carrying the sections from the cryo chamber (see Videos 9 and 10 at *http://www.currentprotocols.com*).

   Keep the retrieval solution cup always covered with a cap to avoid evaporation and place the retrieval solution cup (Greiner Bio-One) on ice. The curvature of the droplets used for picking up should not be too great.

Avoid contact of the metal loop with the knife-edge, because this can severely damage the edge.

Successful pick-up depends on correct timing (i.e., the droplet should be applied to the section when the pick-up solution is cold but before ice crystals appear in the droplet), which is difficult to indicate and should be found by experience. Once the correct timing is found, perfectly flat sections can be obtained.

8. As soon as the sections are thawed, place them immediately onto Formvar- and carbon-coated copper grids, ensuring that the entire usable surface of the grid is covered by methyl cellulose/sucrose. Store sections up to several weeks in a closed box at 4°C. See Griffiths and Posthuma, 2002 for a study of storage conditions.

9. Before finishing the cryo-microtomy session, clean the diamond knives before the sections dry on the knife. See the Diatome webpage for instructions on cleaning diamond knives (Handling and Use Manual at *http://www.emsdiasum.com/diatome/diamond%5Fknives).*

SUPPORT PROTOCOL 5

PREPARATION OF CARBON- AND FORMVAR-COATED COPPER GRIDS

Formvar- and carbon-coated copper grids are used for mounting sections.

Materials

6% (w/v) ammonium hydroxide solution
Acetone
Formvar (Merck)
Chloroform, analytical grade

100-mesh copper grids or one-hole grids
100-ml glass-stoppered Erlenmeyer flask
Glass microscope slides
Coplin jar
Adhesive paper, e.g., address labels for envelopes
Formvar/carbon-coating device (BOC Edwards or equivalent)

Prepare the grids

1. Add 1 ml of 6% ammonium hydroxide solution to 200 copper grids (100 mesh) in a glass tube. Stir on a vortex and stop the reaction when the ammonium hydroxide solution appears slightly green when held next to a white surface. Rinse grids exhaustively in tap water (at least 10 rinses) and subsequently dry in acetone.

Prepare the Formvar solution

2. Dissolve 1.1 g Formvar in 100 ml chloroform in a glass-stoppered Erlenmeyer flask with stirring. When Formvar is dissolved stop stirring and let the solution stand overnight.

3. Rub the surface of a glass microscope slide with a soft cotton cloth and then with lens paper. Make sure that the slide is very clean and dust free.

4. Transfer the Formvar solution gently into a separating funnel with straight sides.

Prepare the Formvar film

5. Place the slide for 70% of its length into Formvar solution for 1 min (see Video 11 at *http://www.currentprotocols.com*).

6. Let the Formvar drain by opening the valve and then allow the slide to air dry in the funnel for 1 min.

The rate at which the Formvar solution drains from the container (e.g., ~5mm/sec) will determine the thickness of the Formvar coat (optimum thickness ~50 nm). A regulator can be used to control the flow rate.

7. Rub the edges of the glass slide with lens paper and scrape a thin strip of Formvar from the bottom side with a razor blade to split the film.
8. Fill a glass container completely with distilled water and level off the surface with a glass pipet. Breathe on the slide, then immediately hold the slide vertically and insert it slowly into the water, allowing the film to float on the surface.

   Formvar film will float on the surface and should have a grayish (interference color) appearance (due to the 50-nm thickness).

Coat the grids with Formvar

9. Using fine forceps place up to about 40 clean 100-mesh copper grids onto the Formvar film, with the rough surface of the grid facing the film. Avoid the edges of the film and any areas that do not appear regular.
10. Remove the Formvar film plus grids from the water surface using an ethanol-cleaned glass slide covered with a white address label on one side. Put the slide onto the Formvar film and push it into the water so that the grids adhere to the paper on the slide.
11. Let the grids air dry.
12. Evaluate the quality of the Formvar-coated grids by viewing one or two in an electron microscope.

    The film should be dust free, without significant crevices, holes, or tears, and should not break under a high-energy beam (80 kV without objective aperture).

Carbon coat the grids

13. Following the equipment manufacturer's instructions, coat the grids at least 1 day later with a layer of evaporated carbon under high vacuum. Store coated grids for up to 2 months and if needed, glow discharge them if they repel water.

    The desired thickness is critical and can be judged by evaluating the color of the address label relative to a noncoated address label. There should be only a minor change in color (the coated address label should be slightly darker in color).

    If the retrieval solution does not completely cover the grid when the loop is removed, it is necessary to glow discharge the grid. Freshly made carbon support films tend to have a hydrophobic surface which inhibits the spreading of solutions. After glow discharge treatment with air, the carbon film becomes hydrophilic and negatively charged, thus allowing easy spreading of aqueous droplets (Aebi and Pollard, 1987).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

BSA stock solution, 10% (w/v)

Prepare 10% (w/v) bovine serum albumin (BSA, fraction V; Sigma) in 0.1 M sodium phosphate buffer containing 0.02% (w/v) sodium azide. Stir slowly at 4°C until BSA dissolves. Adjust pH to 7.4 and centrifuge 1 hr at 100,000 × *g*, 4°C. Retain supernatant and store in 1-ml aliquots at 4°C in closed tubes.

The BSA fraction V is prepared by heat treatment and organic solvent precipitation.

Formaldehyde (FA) fixative, 2×

Thaw a 5-ml aliquot of 16% (w/v) formaldehyde (FA) stock solution (see recipe) in 60°C water. When solution is very clear and particles of FA are dissolved completely, mix the following:

10 ml 0.4 M PHEM buffer (see recipe; 0.2 M final)
5 ml 16% FA stock (see recipe; 4% w/v final)
5 ml H_2O
Prepare immediately before use

For fixation of tissues, this solution should be diluted further (1:1) to 0.1 M PHEM buffer and 2% PFA (1×)

Formaldehyde (FA) stock solution, 16% (w/v)

Dissolve 32 g paraformaldehyde in 200 ml water. To help dissolve the FA, gradually add about 3 drops of 10 N NaOH and stir on a hotplate until the solution is clear. Do not heat above 60°C. Divide formaldehyde solution into aliquots in 10-ml tubes. Store up to several years at −20°C in a sealed box.

CAUTION: *FA is toxic, so it is necessary to prepare the solution in a fume hood.*

Once dissolved, paraformaldehyde becomes formaldehyde.

Never use formalin (37% formaldehyde in a solution that contains 10% methyl alcohol) to prepare this fixative. The methyl alcohol in formalin destroys cell ultrastructure.

Formaldehyde/glutaraldehyde (FA/GA) fixative, 2×

Thaw a 5-ml aliquot of 16% formaldehyde stock solution (see recipe) in 60°C water. When solution is very clear and particles of FA are dissolved completely, mix the following:

10 ml 0.4 M PHEM buffer (see recipe; 0.2 M final)
5 ml 16% (w/v) FA stock solution (see recipe; 4% w/v final)
1 ml 8% (v/v) glutaraldehyde (GA; 0.4% v/v final)
4 ml H_2O
Prepare immediately before use

For fixation of tissues, this solution should be diluted further (1:1) to 0.1 M PHEM, 2% FA and 0.2% GA (1×).

Gelatin, 1%, 2%, 5%, and 12% (w/v)

Prepare gelatin (Merck) solutions in 0.1 M sodium phosphate buffer, pH 7.4, containing 0.02% (w/v) azide. Store months at 4°C in aliquots of 2 to 10 ml. Store 2% gelatin to be used for labeling in small petri dishes in a closed box at 4°C to avoid drying.

Methyl cellulose/uranyl acetate

Methyl cellulose stock: Add 2 g methyl cellulose (Sigma, 25 centipoise), while stirring, to 98 ml distilled water prewarmed to 90°C. Cool on ice while stirring, until temperature has dropped to 10°C. Stir overnight at low speed in the cold room. Let the solution stand for 3 days in the cold room. Centrifuge 95 min at 97,000 × *g*, 4°C, then divide the supernatant into 10-ml aliquots and store for up to 2 months at 4°C.

To prepare methyl cellulose/uranyl acetate: Carefully mix 1 ml of 4% uranyl acetate (see recipe) and 9 ml of methyl cellulose stock. Store up to a few weeks at 4°C in a dark container.

CAUTION: *When working with radioactivity and heavy metal, take appropriate precautions to avoid contamination of yourself and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by the local radiation safety officer.*

PHEM buffer, 0.4 M

Dissolve 72.5 g PIPES (240 mM final) in 600 ml 0.375 N NaOH with stirring. Then, still stirring, gradually add 15.2 g EGTA (40 mM final). Dissolve 23.8 g HEPES (100 mM final) in 200 ml water and add this to the other mixture. Add 1.63 g $MgCl_2$ (8 mM final). Adjust pH to 6.9 with 1 N NaOH and adjust volume to 1000 ml. Store up to several years at −20°C.

Section retrieval solution

Prepare a 1:1 mixture of 2.3 M sucrose in 0.1 M sodium phosphate buffer, pH 7.4, and 2% (v/v) methyl cellulose in distilled water. Mix on an end-over-end rotator in the cold for 20 min. Prepare fresh.

Storage solution

Thaw a 5-ml aliquot of 16% formaldehyde stock solution (see recipe) in 60°C water. When solution is clear, mix the following:

5 ml 0.4 M PHEM buffer (see recipe)
0.6 ml 16% FA stock solution (see recipe), thawed and clear
14 ml H_2O
Store months at 4°C

The final concentrations are 0.1 M PHEM and 0.5% FA.

Uranyl acetate, 4% (v/v)

Prepare a 4% stock of uranyl acetate in distilled water and adjust pH to 4 with 0.1 N HCl if necessary. Store in the dark for up to 1 month at 4°C; filter through 0.22-μm Millipore filter before use.

CAUTION: *When working with radioactivity, take appropriate precautions to avoid contamination of yourself and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by the local radiation safety officer.*

Uranyl oxalate solution

Mix 1 vol of 4% uranyl acetate (see recipe) and 1 vol of 0.15 M oxalic acid. Carefully adjust pH to 7 with 25% (v/v) ammonium hydroxide, stirring well after adding each drop to ensure that any precipitate that forms can dissolve. Store up to several months in the dark at 4°C.

COMMENTARY

Background Information

The pioneers in ulltrathin cryosectioning were Fernandez-Moran, Bernad, Luduc, Appleton, and Christensen. Kent Christensen was the first to devise a cryosectioning bowl attachable to a conventional ultramicrotome (Christensen, 1971). These pioneers were able to show some structural details in ultrathin cryosections.

However, rapid strides in the field of ultrathin cryosectioning came from the work of K. Tokuyasu, who developed a cryosectioning technique that is also referred to as the Tokuyasu method (Tokuyasu, 1973). He introduced a high-molar sucrose solution to infiltrate aldehyde-fixed specimens as a way to prevent ice-crystal formation and to provide the frozen specimens plasticity suitable for ultrathin sectioning. In addition, he introduced a new method of retrieving ultrathin cryosections lying on a dry knife. This was done by approaching the section with a droplet of high-molar sucrose that was about to freeze, and then quickly attaching the sections on the droplet to retrieve them from the cryochamber.

Tokuyasu faced still another problem: negative staining was effective in protecting cryosections from air drying damages, but the background was often too dense to allow recognition of immunolabeling markers, particularly ferritin which was the only marker available then. One of his solutions

was to embed the sections in a mixture of a heavy metal compound and an oganic material (Tokuyasu and Singer, 1976; Tokuyasu, 1978). This procedure is now widely applied to examination of cryosections.

The pioneers in immunogold labeling were Romano and Romano (1977), Roth et al. (1978), and Batten and Hopkins (1979). They developed procedures to couple *Staphylococcal* protein A–coated colloidal gold particles for use in localization of antigens at the EM level.

Slot and Geuze (1981) devised a simple procedure to produce a wide range of sizes of gold particles, which allowed detection of more than one signal. A comprehensive review on the history of colloidal gold in EM is the article by J. Roth (1996).

Quantitative EM immunocytochemistry was first carried out on plastic sections by Roth et al. (1978). In EM immunocytochemistry, plastic sections are advantageous over cryosections in some aspects (e.g., Roth et al., 1981; Roth and Berger, 1982) but generally it is a disadvantage because antigenicity is not as well preserved and detection is not as sensitive as with cryosections.

It was Slot and Geuze (1981) who introduced the immunogold labeling procedure on ultrathin cryosections and laid the basis for the procedure outlined in this unit. The use of different sizes of gold particles made the technique very powerful for localizing multiple antigens at the EM level (Slot et al., 1991). Griffiths et al. (1982) used a uranyl acetate and methyl cellulose mixture to stain and embed cryosections to improve the delineation of cellular structures. Major improvements in ultrothin cryosectionin were brought about by the commercial development of a high-quality cryo-ultramicrotome and cryospecific diamond knives. Cryosectioning of cells and tissues was simplified by embedding them in gelatin and cutting them into blocks after solidifying them in the cold room before sucrose infiltration (Peters et al., 1991b). Today, it is possible to localize three different antigens on ultrathin cryosections using glutaraldehyde as a blocking step between labeling procedures (Slot et al., 1991). More recently, Liou et al. (1996) showed that the structural integrity of cryosections was greatly improved by substituting a mixture of methyl cellulose and sucrose for the sucrose initially introduced by Tokuyasu. This procedure has now become first choice for high-resolution detection of antigens at the subcellular level. The methodology of amtigen localization at the EM level in epithelial cells grown on polycarbonate filters has been described (Peters and Hunziker, 2001). Recently, improved methods for quantitative immunogold EM have been formalized. Terry Mayhew and colleagues (Mayhew et al., 2002) described very useful methods for random sampling, stereological estimation, and inferential statistics that underlie them. For current immunogold EM this methodology is a must for tackling many questions.

Critical Parameters and Troubleshooting

In immunogold staining of ultrathin cryosections, there are many steps where things can go wrong. Unfortunately, whether this has happened can be determined only at the end of the procedure, by electron microscopy. The most commonly encountered problems are: low-quality sections, absence of specific labeling, high background labeling, co-label artifacts, dirty grids, and weak contrast.

Poor sections are often due to unsuitable preparation of the specimen, bad quality of knife, or instability in the cryomicrotome. Dilutions of fixatives must be prepared just before they are used for specimen fixation. Specimens that have dried out during preparation, or the presence of residual sucrose around the gelatin block, may cause sectioning problems. Also, loose attachment of the specimen holder or knife holder to the cryomicrotome will cause problems. Contamination of specimen and knife, which can result from condensation of ice crystals, must be avoided.

Nonspecific labeling is encountered mainly because the antibody does not recognize the antigen after aldehyde fixation. This can be tested by evaluating the antibody on aldehyde-fixed material by FACS (fluorescence cell sorter analysis) or immunofluorescence microscopy (*UNIT 4.3*), prior to testing the antibody at the EM level.

Overexpression of the antigen (protein) in a control cell that does not express the antigen endogenously or the use of RNAi or knockout mice are the best quality controls for specificity.

Background labeling is often the result of an excessive concentration of protein A gold or because the antibody titer was too high. For the protein A gold concentration, it is best to follow the instructions of the manufacturer. For most applications, the antibody titer is used in the range of 0.2 to 2 μg/ml.

It is best to try different dilutions and evaluate the specific signal-to-background ratio. Polyclonal, monoclonal, and recombinant Fab antibodies can be successfully employed. It is important to use a bridging antibody that binds specifically and efficiently to protein A gold as an intermediate step if the primary antibody does not bind protein A efficiently.

When double-labeling procedures are carried out, co-label artifacts are often encountered. In this case, the two sizes of gold particles are always adjacent to each other, at ~20 nm apart, and this is often mistaken for colocalization. The cause of colabeling is not understood, but often the antibody that is used for the detection of the second antigen binds to the antibody that was used to detect the first antigen. Also, protein A gold that is used in the second step may still bind to the antibody used in the first step. Glutaraldehyde incubation after the first immunolabeling should overcome the later problem. It is important to always check using a single label first.

Dirt on the grid is usually caused by phosphate contamination of the upper surface of grids or if phosphate becomes mixed with uranyl solutions before drying. Also, partial drying out of droplets during the immunolabeling incubation can result in dirty grids. Always keep the grids under a Petri dish during incubation and never touch the Parafilm where droplets are being applied.

A screening of antibodies by FACS or light microscopy before and after aldehyde fixation, and an evaluation of antibody specificity by immunoblots (*UNIT 6.2*) and immunoprecipitation (*UNIT 7.2*) may speed successful labeling on cryosections. Control cells that are transfected with or without the specific protein are very instrumental as a positive control.

Protein A gold particles of 10 and 15 nm are routinely used. The authors do not favor Ig-coated gold particles. Detection of antigen on murine tissue with monoclonal antibodies results in false positive label if a mouse Ig secondary antibody is used as a bridging step. In that case the use of monoclonal antibodies or Fab's coupled to ultrasmall gold (Aurion) with subsequent silver enhancement (kit from Aurion) is the best option (Mironov et al., 2003). The authors have recently discovered that protein A gold binds directly to prion proteins on live but not on fixed cells (Peters et al., 2003).

Transmission electron microscopy is carried out at 80 kV with the smallest objective aperture. Exposure time of film is between 0.5 and 1 sec. Damage to sections can be reduced by never evaluating sections without objective aperture.

Anticipated Results

Successful immunogold labeling should allow the detection of specific antigens at the subcellular level. Figure 4.7.1 shows light and electron micrographs of a dendritic cell labeled with anti-MHC and CD1b. Both LM and EM studies of two adjacent sections can easily be applied (van der Wel et al., 2003, 2005; Swanson and Peters, 2005).

Quantitative analysis

This aspect, which is very critical for electron microscopy work, is beyond the scope of this protocol. For a recent review see Mayhew et al., 2002. For an application of their methodology see Mironov et al., 2003; Touret et al., 2005.

Electron tomography of cryosections

The next great challenge will clearly be to understand the three-dimensional architecture of the cell in terms of the spatial arrangement of its protein components, and to describe quantitatively how this arrangement alters as the cells respond to stimuli.

Electron tomography is a powerful method to determine the three-dimensional structures of large macromolecular assemblies in cells where crystallographic methods are not applicable. The essence of this approach is to obtain a series of projection images in an electron microscope by tilting the specimen relative to the electron beam and combining the images computationally to reconstruct the three-dimensional structure. The authors have recently, in collaboration with Sriram Subramaniam (NCI) and Helmut Gnaegi (Diatome), used electron tomographic imaging to determine the molecular architecture of *E.coli* cells. By placing individual molecules into the density map derived from tomography, it was possible to construct a three-dimensional molecular model for a membrane protein network. The current excitement in this field arises from the expectation that the ongoing advances in cryo-sectioning, diamond knife developments, microscope instrumentation and computational methods may ultimately make it possible to routinely obtain resolutions in the range of 20Å, potentially good enough to locate individual proteins in a cell. The method used builds from the methodology described here, but the details are beyond the scope of this unit. For further reading see Lefman et al. (2004).

Recently the authors have developed a new "sandwich" pick-up technique that allows better preservation and less extraction of the cryosection. In addition cryo-sections are vitrified after pickup and thawing in a "vitroblot" to optimize vitrification to permit cryo-electron tomography (P.J. Peters, unpub.observ.).

Time Considerations

On average, it takes ~1 week to test and evaluate newly fixed cells with a new antibody. Often, however, multiple antibodies need to be tested at varying dilutions and under varying experimental conditions.

Acknowledgement

The methods outlined in this protocol could not have been developed without the input of former colleagues at the EM Laboratory in Utrecht. The authors are also grateful for the outstanding help of Elly van Donselaar, Nicole van der Wel, Diane Houben, and Sue Godsave.

Correlative Video Light/Electron Microscopy

BASIC PROTOCOL

This unit describes newly developed methods that allow the examination of living cells by time-lapse analysis with the subsequent identification of the just-observed organelle under an electron microscope.

Many cellular functions, such as intracellular traffic, cytokinesis, and cell migration crucially depend on rapid translocations and/or shape changes of specific intracellular organelles. To understand how such functions are organized and executed in vivo, it is important to observe in real time in living cells such dynamic structures as a budding transport carrier, an elongating microtubule, or a developing mitotic spindle, but to have the degree of spatial resolution afforded by electron microscopy (EM). Most suitable for this is a conceptually simple, yet powerful, method called correlative video light/electron microscopy (CVLEM), by which observations of the in vivo dynamics and the ultrastructure of intracellular objects can indeed be combined to achieve the above-mentioned result. This unit describes this methodology, illustrates the type of questions that the CVLEM approach was designed to address, and discusses the expertise required for successful application of the technique.

The CVLEM procedure includes several stages: (1) transfection of living cells with an appropriate green fluorescent protein (GFP) fusion protein, (2) observation of structures labeled with GFP in living cells, (3) fixation, (4) immunolabeling for EM, (5) embedding, (6) identification of the cell in the resin block, (7) sectioning, and (8) EM analysis. During the first step, cells have to be transfected with the cDNA encoding the GFP fusion protein whereby the structure of interest can be discovered in living cells (Lippincott-Schwartz and Smith, 1997). In this way, it is possible to gain information about the structure, including its dynamic properties (i.e., motility, speed and direction, changes in size and shape) and life cycle. At the end of this stage, it is necessary to stabilize the cell structure by addition of a fixative, allowing one to capture the fluorescent object at the moment of interest. As GFP is not visible under an electron microscope, immunostaining is required to identify the GFP-labeled structure at an EM level. This protocol uses immunogold and immunoperoxidase protocols to perform staining for EM. Usually the immunogold protocol (Burry et al., 1992) is suitable for labeling the vast majority of antigens; the immunoperoxidase protocol should be used only to label antigens residing within small membrane-enclosed compartments, because the electron-dense products of the peroxidase reaction tend to diffuse from the place of antibody binding (Brown and Farquhar, 1989; Deerinck et al., 1994). Once stained, the cells must be prepared for EM by traditional epoxy (or other) embedding techniques, and the cell and the structure of interest must be identified in EM sections. Finding an individual subcellular structure in a single thin section can be complex, and sometimes impossible, simply because most of the cellular organelles are bigger than the thickness of a routine EM section and may lie in a plane different from the plane of a random section. Analysis of serial EM sections of the whole cell is thus required to identify the structure previously observed in vivo. An example of such an identification is shown in Figure 4.8.1. Finally, EM analysis of serial sections can be supported by digital three-dimensional serial reconstruction or high-voltage EM tomography.

Current Protocols in Cell Biology (2001) 4.8.1-4.8.9

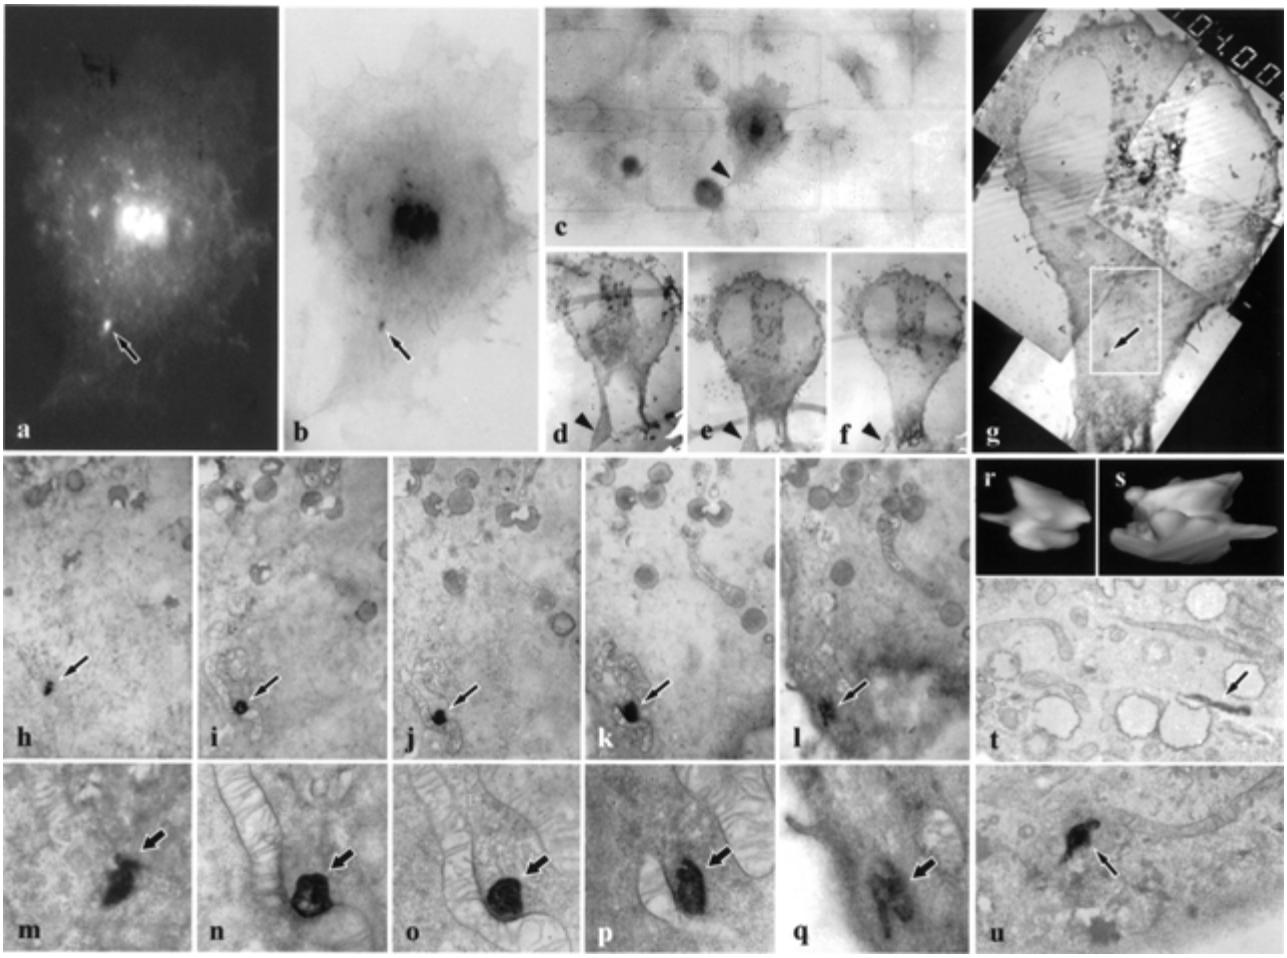

Figure 4.8.1 In vivo dynamics and ultrastructure of an individual Golgi-to-plasmalemma carrier (GPC) studied using CVLEM. The GPC in (**a**) (arrow) was observed in vivo using time-lapse confocal microscopy. After fixation, the cells were immunoperoxidase labeled and embedded in epoxy resin. The structure in (**b**) (arrow) was identified as the fluorescent GPC shown in panel **a** by the computer-aided superimposition of the two images using the CELLocate coordinates [an example of which is shown in (**c**)]. The general pattern of immunoperoxidase labeling in (**b**) coincided with the fluorescent pattern of vesicular stomatitis virus glycoprotein–GFP (VSVG-GFP) in (**a**). Serial sections of the cell were then produced (**d** through **f**), and the first section displaying the transport intermediate [(**g**); arrow] was captured at low magnification (**f**, **g**). Note that the sections contain structures that are helpful for identification [e.g., protrusion in (**c** through **f**); arrowheads]. (**h** through **q**) represent a series of consecutive 200-nm sections containing the GPC (arrow). The field shown in (**h** through **l**) is the area of the cell identified by a white box in (**g**). Three-dimensional reconstruction characterizes the GPC as an elongated saccules with a short tubular protrusion (**r**, **s**). Other GPCs identified using the same approach appeared either as tubules [(**t**); arrow] or saccules with short tubules [(**u**); arrow]. The bar in panel **u** represents the following lengths in the other panels: 9 μm (*a*, *b*), 31 μm (*c*), 12.2 μm (*d-f*), 6 μm (*g*), 2.1 μm (*h-l*), 700 nm (*m-q*), 320 nm (*r*, s), 1.2 μm (*t*, *u*).

Materials

Cells of interests
cDNA encoding an appropriate GFP fusion protein
Fixative A (see recipe)
Fixative B (see recipe)
PBS (*APPENDIX 2A*)
Blocking solution (see recipe)
Primary antibody to label structure of interest
Monovalent Fab fragments of secondary antibody conjugated with horseradish peroxidase (HRP; Rockland) or Nanogold (Nanoprobes)
1% (w/v) glutaraldehyde in 0.2 M HEPES buffer, pH 7.3

Gold enhancement mixture (see recipe)
DAB solution (see recipe)
2% (w/v) OsO_4 (Electron Microscopy Sciences) in water
3% (w/v) potassium ferrocyanide in 0.2 M cacodylate buffer
0.2 M cacodylate buffer, pH 7.4 (see recipe)
50%, 70%, 90%, and 100% (v/v) ethanol
Epoxy resin (see recipe)
8-mm resin cylinder prepared in advance from a cylindrical mold

35-mm MatTek petri dishes with CELLocate coverslip and map of CELLocate grid (MatTek)
Inverted fluorescence microscope
Multiphoton microscope, laser-scanning confocal microscope, or digitalized fluorescence inverted microscope capable of acquiring a time-lapse series of images by computer
60°C oven
Ultramicrotome with sample holder, glass knife, and diamond knife
Eyelashes
Pick-up loop (Agar)
Adjustable-angle laboratory clamps
Slot grids covered with carbon-formvar supporting film (Electron Microscopy Sciences, Agar)
Electron microscope
Software for three-dimensional reconstruction from serial sections

Additional reagents and equipment for transfection (*APPENDIX 3A*)

Transfect cells

1. Plate cells of interest at 50% to 60% confluence on a 35-mm MatTek petri dish with the CELLocate coverslip attached to its bottom.

   The CELLocate coverslip contains an etched grid with coordinates that allow the localization of the cell of interest at any step in the preparation.

   To facilitate the process of locating the visualized cell of interest in the resin block, the cells should be plated at 50% to 60% confluence.

2. Transfect cells with cDNA encoding an appropriate GFP fusion protein using any method described in *APPENDIX 3A*.

   If electroporation is used, steps 1 and 2 should be reversed.

   The authors have successfully used procollagen I–mannosidase II–, and vesicular stomatitis virus glycoprotein (VSVG)–GFP constructs for transfection.

Observe labeled structures in living cells

3. Place the dish under an inverted fluorescence microscope, select a transfected cell of interest, and identify its position relative to the coordinates of the CELLocate grid.

4. Draw (or photograph) the position of the cell on the map of the CELLocate grid.

5. Observe the dynamics of the GFP-labeled structures in the selected living cell using a multiphoton microscope, laser-scanning confocal microscope, or digitalized fluorescence inverted microscope that allows acquisition of a time-lapse series of images by a computer.

Fix cells

6. At the moment of interest, while still acquiring images, add fixative A to the cell culture medium at a ratio of 1:1 fixative/medium.

   Fixation usually induces the fast fading of GFP fluorescence and blocks the motion of labeled structures in the cell.

7. Stop acquiring images and keep cells in fixative for 5 to 10 min.

   During this time it is useful to acquire a Z series of images of the cell.

8. Wash with 2 ml fixative B and leave the cells in this fixative for 30 min.

Immunolabel cells for EM

For EM with Nanogold:

9a. Wash cells three times for 5 min with 2 ml PBS.

10a. Incubate cells 30 min in 2 ml blocking solution.

11a. Incubate cells overnight with primary antibody diluted in blocking solution.

   The dilution depends on the antibody; in general, the concentration of antibodies for EM should be 5- to 10-fold higher than for immunofluorescence.

12a. Wash cells six times for 2 min with 2 ml PBS.

13a. Dilute Nanogold-conjugated Fab fragments of the secondary antibody 1:50 (v/v) in blocking solution and add it to the cells; incubate 2 hr.

14a. Wash cells six times for 2 min with 2 ml PBS.

15a. Fix cells 5 min with 1 ml of 1% glutaraldehyde in 0.2 M HEPES buffer, pH 7.3.

16a. Wash cells three times for 5 min with 2 ml PBS and then again three times with distilled water.

17a. Incubate cells 6 to 10 min with 0.5 ml gold enhancement mixture.

18a. Wash cells three times for 5 min with 2 ml distilled water.

For EM with HRP:

9b. Wash cells three times for 2 min with 2 ml PBS.

10b. Incubate cells 30 min in 1 ml blocking solution.

11b. Incubate cells overnight with primary antibody diluted in blocking solution.

   The dilution depends on the antibody; in general, the concentration of antibodies for EM should be 5- to 10-fold higher than for immunofluorescence.

12b. Wash cells six times for 2 min with 2 ml PBS.

13b. Dilute HRP-conjugated Fab fragments of the secondary antibody 1:50 (v/v) in blocking solution and add it to the cells; incubate 2 hr.

14b. Wash cells six times for 2 min with 2 ml PBS.

15b. Fix cells 5 min with 1 ml of 1% glutaraldehyde in 0.2 M HEPES buffer, pH 7.3.

16b. Wash cells three times for 5 min with 2 ml PBS.

17b. Incubate the cells with 1 ml DAB solution.

18b. Wash cells three times for 2 min with 2 ml PBS.

Embed cells

19. Incubate cells in 0.5 ml of a 1:1 (v/v) mixture of 2% OsO_4 and 3% potassium ferrocyanide in 0.1 M cacodylate buffer on ice for 1 hr.
20. Wash cells with 2 ml distilled water.
21. Dehydrate cells in a series of ethanol solutions: 50% (10 min), 70% (10 min), 90% (10 min), and three times in 100% (10 min each).
22. Incubate cells 1 to 2 hr in 1:1 (v/v) epoxy resin/ethanol, room temperature.
23. Incubate cells in pure epoxy resin for 1 hr at room temperature and then overnight (≥12 hr) in a 60°C oven.

Isolate cell of interest in the resin block

24. Put a droplet of fresh epoxy resin on the block where the examined cell is located. Use the fresh resin as glue to attach the block of embedded cells to the flat base of an 8-mm resin cylinder. Return the assembly to the 60°C oven for an additional 16 hr.
25. Carefully lift the resin from the petri dish and cover glass.

    It is easiest to remove the resin by gently bending the cylinder to and fro.

    If the CELLocate cover glass cannot be detached from the embedded cells, incubate the sample in a plastic tube with hydrofluoric acid (HF; Sigma) for 30 to 60 min to dissolve the glass. Do not use a glass tube, as it wll be dissolved by the HF. Wash with water and monitor the completeness of glass dissolution under a stereomicroscope. If glass is not dissolved, repeat treatment with HF and wash again with water. Incubate sample 60 min in 0.1 M PBS or 0.2 M HEPES buffer, pH 7.3, to neutralize the HF, wash with water, and dry.

    If desired, embedded specimens can be stored for an unlimited time at room temperature before sectioning and analysis.

Prepare EM sections

26. Trim the resin block to give a pyramid of ~3 × 3 mm size with the cell of interest in its center.
27. Put a sample holder into an ultramicrotome so that the segment arc of the ultramicrotome is in the vertical position. Secure a glass knife in place.
28. Bring the sample as close to the knife as possible.
29. Rotate the knife stage to align the bottom edge of the pyramid parallel to the knife edge.
30. Tilt the segment arc and the knife to adjust the gap between the knife edge and the surface of the sample.

    The gap is visible as a bright band if all three lamps of the ultramicrotome are switched on. It must be identical in width during the up and down movements of the resin block to ensure that every point of the sample surface containing the cell of interest is at the same distance from the knife edge.

31. Turn the specimen holder 90° to the left or to the right and trim the edges of the resin block to leave a narrow pyramid (≤100 µm wide) with its long axes parallel to the knife edge.

    The pyramid should be as narrow as possible and the cell of interest should be in its center. An experienced person can trim a pyramid directly with a razor blade.

32. Turn the specimen holder 90° back and lock it in exactly the same position as before.

    This is very important.

33. Replace the glass knife with a diamond knife and position the latter towards the pyramid.

34. Make serial sections according to the instructions for the ultramicrotome.

35. Stop the motor. Use two eyelashes to divide the band of the sections into pieces suitable in size for collection with a pick-up loop.

    Each piece should be small enough to fit completely inside the inner circle of the loop without touching it.

36. Pick up a band of sections by touching the pick-up loop to the surface of water containing the band, making sure the band is completely inside the inner circle of the loop and does not touch it.

37. Raise the loop with the sections on it, and fix the loop inside the lab clamps near the stereomicroscope of the microtome.

    The loop should be visible under the stereomicroscope of the ultramicrotome.

38. Take a formvar-coated slot grid and gently touch sections on the water (do not touch the loop) with the carbon-coated surface of the grid.

39. Very slowly move the slot grid away from the loop.

    If the movement is slow enough, the water is eliminated from the surface of the supporting film, and only a very small droplet of water remains on the grid, which does not hinder the placement of the grid directly into the grid container. Grids can be stored an unlimited time at room temperature.

Perform EM analysis

40. Place the slot grid under the electron microscope and identify the cell, using the traces of the coordinated grid filled with the resin on the first few sections.

41. Take consecutive photographs (or acquire the images with a computer using a video camera) from the serial sections until the organelle of interest (just observed by light microscopy) is no longer seen.

42. Using software designed for three-dimensional reconstruction, align the images and make a three-dimensional model according to the instructions for the software.

REAGENTS AND SOLUTIONS

*Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Blocking solution

100 ml PBS (*APPENDIX 2A*) containing:
0.5 g BSA
0.1 g saponin
0.27 g NH_4Cl
Store up to 3 months at 4°C

Cacodylate buffer, 0. 2 M

2.12 g sodium cacodylate
100 ml water
Adjust to pH 7.4 with 1 N HCl
Store up to 6 months at 4°C

Diaminobenzidine (DAB) solution

10 mg DAB
20 ml 0.1 M Tris·Cl, pH ~7.6 (*APPENDIX 2A*)
Prepare fresh
Just before use add 13.3 µl of 30% H_2O_2

Epoxy resin

Combine 20 g epoxy embedding resin (Fluka), 13.0 g dodecenylsuccinic acid (DDSA), and 11.5 g methylnadic anhydride (MNA) in a test tube. Heat in a 60°C oven for 2 to 3 min and then vortex well to mix the components. Add 0.9 g 2,4,6 Tris (dimethylaminomethyl) phenol (DMP-30) and immediately vortex again. Store 1-ml aliquots up to 6 months at –20°C.

Fixative A (0.1% glutaraldehyde, 4% paraformaldehyde)

Add 1.25 ml of 8% (w/v) glutaraldehyde to 100 ml of fixative B (see recipe). Store up to 2 to 3 days at 4°C.

Fixative B (4% paraformaldehyde)

Dissolve 4 g paraformaldehyde powder in 100 ml 0.2 M HEPES buffer, pH 7.4, while stirring and heat to 60°C. Add a few droplets of 1 N NaOH to form a clean solution. Store up to 3 months at 4°C.

Gold enhancement mixture

Mix equal volumes of solutions A (enhancer; green cap) and B (activator; yellow cap) of a Gold-enhance kit (Nanoprobes) and wait 5 min. Add equal volumes of solution C (initiator; purple cap) and then solution D (buffer; white cap) and mix. Prepare ~400 µl final reagent per dish.

A convenient method is to use equal numbers of droplets from each bottle.

COMMENTARY

Background Information

Correlative light/electron microscopy (CLEM) was developed several years ago, and has been used when the analysis of immunofluorescently labeled structures required higher resolution than can be achieved using light microscopy (Tokuyasu and Maher, 1987; Powell et al., 1998). In spite of its potential, CLEM has not been used very often, probably because the possibility of correlating two static images–one fluorescent and one electron microscopical–is of interest only in a limited number of situations. The real gains from CLEM come from its combination with the kind of dynamic observations obtainable from GFP video microscopy in living cells (i.e., from its use in CVLEM). The CVLEM approach is potentially valuable in any area of cell biology where elucidating the three-dimensional ultrastructure of individual dynamic cellular objects at times of choice can be informative (Mironov et al., 2000). For example, the growth of a subset of microtubules can be visualized in vivo (Perez et al., 1999). By CVLEM, it is now possible to study at EM resolution the environment in which they are growing, as well as the interactions of the microtubule tips with other cytoskeletal elements or intracellular organelles, at various stages of tip growth. In addition to cytoskeletal dynamics, CVLEM could also be useful for studying cell division and cell-cell interactions (although the specific questions to be addressed are best left to the specialists). CVLEM has been applied successfully to characterize the ultrastructure of membrane carriers transporting secretory proteins from the Golgi complex to the cell surface (Polishchuk et al., 2000).

One limitation, and, at the same time, attraction, of CVLEM is its complexity. The use of this technique is demanding, and to master its various steps requires a whole array of skills. However, microscopy is developing fast both in the field of live-cell imaging and in the field of EM, and new powerful technologies are rapidly becoming available in user-friendly versions. This should make the use of CVLEM appealing to a number of cell biologists. Through the use of fluorescent proteins of different colors, two or more marker proteins can

be observed simultaneously (Ellenberg et al., 1999). This will allow analysis of the interactions between different organelles and organelle subdomains (Ellenberg et al., 1999; Pollok and Heim, 1999). Combining these and other methods with the quickly developing electron microscope tomography (Ladinsky et al., 1994) will increase the subtlety and range of the questions that can be answered by CVLEM. While we wait for the microscopy of the future, endowed with the magical power to show cellular structures with EM resolution in vivo in real time, CVLEM offers a useful chance to look deeper inside living cells.

Critical Parameters

Taken together, all the steps of CVLEM represent quite a long procedure (see Time Considerations) and require significant effort by a researcher or technician. Hence, it would be especially disappointing to loose such tour-de-force experiments due to small problems in specimen handling. To apply CVLEM successfully, several important parameters should always be taken into account by the experimenter.

Fixation/labeling protocol. Preliminary experiments should be carried out to understand whether the antibodies selected for labeling of a GFP–fusion protein work with the immuno-EM protocol. Many antibodies that give perfect results for immunofluorescence do not work for immuno-EM staining, because the glutaraldehyde used in most EM fixatives tends to cross-link amino groups of antigen epitopes, therefore decreasing the antigenicity of the target protein and restricting the penetration of antibodies across the cytosol. However, a decrease or an absence of glutaraldehyde in the fixative can result in poor preservation of ultrastructure of the intracellular organelles. If immuno-EM labeling is not successful, it may be possible to optimize the concentration of glutaraldehyde in the fixative, or to use the periodate/lysine/paraformaldehyde fixative described by Brown and Farquhar (1989). In addition, it is important to select an immunoperoxidase or immunogold protocol to label the structure of interest. To label epitopes of a GFP–fusion protein located in the cytosol, only the immunogold protocol should be used; for other epitopes, HRP labeling is also suitable.

Locating the cell of interest. It is extremely important to be able to find the cell of interest at any step in the CVLEM procedure. Only cells located on the grid of the MatTek petri dish can be selected for time-lapse observations. The position of the cell of interest on the grid should be noted, otherwise the cell will be difficult to locate again. Low-magnification images showing the field surrounding the cell of interest can greatly help when trimming the resin block around the cell and when locating the cell under the electron microscope. In this case, neighboring cells can be used as landmarks to identify the cell of interest. It is more convenient to work with cells that are plated at a lower confluence (e.g., 50% to 60%). It is also useful to have fluorescent and phase-contrast images of the target cell, because particular structures (e.g., microvilli, pseudopodia, inclusions) can also be used to help find both the cell and the structure of interest.

Section thickness. The thickness of serial sections should be ~50 nm (or less) for very precise three-dimensional reconstruction, ~80 nm for routine work, or ~250 nm for electron microscope tomography.

Anticipated Results

Once considerations for specific localization of the cell and the organelle have been optimized, the precise three-dimensional structure of the organelle and its connections with other organelles at different moments of its life cycle can be identified.

Time Considerations

The entire CVLEM procedure requires 4 to 5 days. During the first day, cells must be transfected with cDNA. The next day, it is possible to make observations in living cells, fix them, and start the immunolabeling. The third day is required to complete the immunolabeling and resin embedding of the cells. During the fourth experimental day, the cell of interest is identified in the resin block and cut into serial sections. On the fifth day, EM analysis is performed. If desired, it is possible to store embedded specimens indefinitely before sectioning and analysis.

Polarization Microscopy

INTRODUCTION

Polarization microscopy, also called polarized light microscopy, allows one to nondestructively follow dynamic, anisotropic organization of living cells and tissues at the microscopic as well as submicroscopic levels.

Since, in polarization microscopy, light waves are used to probe the specimen, spatial resolution of the image is limited to ~0.2 µm, even using objective and condenser lenses with numerical apertures approaching 1.4. Nevertheless, the brightness of each resolved area in the image measures the polarization optical property, most commonly birefringence, of the corresponding minute area in the specimen. The birefringence directly reflects the anisotropic organization of the microscopically unresolvable, fine structure—namely, the submicroscopic, molecular, and atomic lattice arrangements of the specimen within each diffraction-limited image area.

Thus, e.g., the assembly and disassembly dynamics of spindle microtubules and the developmental changes in sperm chromatin could be revealed, and the arrangement of the atomic lattice in developing biocrystalline spicules, as well as the packing arrangement of DNA molecules in sperm chromosomes, could be unveiled with polarization microscopy at levels even finer than those conventionally seen with electron microscopy.

Examples in this unit were chosen mostly from those particularly familiar to the author and which have been used successfully by many generations of students and co-workers. Beyond the biological material mentioned below, or those that are commonly used for studying living cell behavior and fine structure of their organelles, a treasure trove of suggestions for other living cells appropriate for study can be found throughout an article by Belar (1928).

The first part of this unit touches on some general procedures, and outlines the background optical theory and relevant literature sources for polarization microscopy. The unit then examines several basic examples for using the polarizing microscope, emphasizing the study of living cells or products, starting with those that can be carried out with relatively simple equipment and proceeding to examples that require more advanced instruments. For instructions on setting up and operating a polarization microscope see Murphy (2001), Oldenbourg (1999), and manufacturer's instructions.

For more comprehensive discussions and an annotated list of references on polarized light and birefringence phenomena, see Inoué (1986, especially Appendix 3). For additional information, see Bennett (1950), Jenkins and White (1957), Hartshorne and Stuart (1960), and Hecht (1998).

Types and Transmission Axis of Polars

Polarizers, or polars, range from plastic-sheet "Polaroids" to calcite polarizers of many designs. Although very expensive and fragile, the calcite polarizers provide the theoretically maximum transmission (i.e., nearly 50% of the incoming nonpolarized light) over a wide wavelength range. Their extinction factor (EF; see in Example 5 below) also tends to be an order of magnitude better than the sheet Polaroids. On the other hand, light transmitted through the calcite polars has to be collimated into parallel beams in order to avoid astigmatism. They are used in expensive polarization optical systems requiring the highest EF and minimum loss of light. Some new sheet polarizers such as "Polacolor" and those available from Spindler and Hoyer are reported to have both high transmission for white light and high EFs.

Sheet Polaroids generally contain a stretched sheet of polyvinyl alcohol, a long-chain polymer whose backbone can be aligned by heating and stretching the polymer sheet that has been cast from an aqueous solution. Commonly they are stained with polyiodide micelles, whose conjugated backbones lie parallel to the aligned polyvinyl alcohol chains. It is the conjugated backbone of the polyiodide that gives rise to the *dichroism* of these Polaroid sheets (Inoué, 1986). They can be made into large sheets and can easily be cut into various shapes with a pair of scissors. This is the material used for Polaroid sunglasses. As polars in microscopes, their soft and somewhat wavy surfaces are protected by mounting them with index-matched cement between antireflection-coated glass cover plates.

The transmission axis (E-vector direction of the transmitted polarized light) for Polaroid sunglasses is oriented vertically in order to reduce the glare from horizontal surfaces, such as the road, water, or hood of a car. Light

Current Protocols in Cell Biology (2002) 4.9.1-4.9.27

reflected from such (nonmetallic) horizontal surfaces contains a high proportion of polarized light whose E- (electric-) wave oscillates horizontally and hence is cut out by the Polaroid sunglasses. Thus, the Polaroid sunglasses become convenient, quick references for establishing the E-vector transmission direction of other polars.

Birefringence

Light traveling inside a birefringent material is split into two waves that travel at different speeds. The slower wave suffers greater refraction than the faster wave since the refractive index experienced by each wave is inversely proportional to its velocity of propagation.

The two waves vibrate in planes that lie perpendicular to each other, as dictated by the material's optical axes, and to the direction of propagation of the light ray. For a ray traveling in a particular direction through a birefringent material, the electric (E-) vector direction encountered by the slow wave is called the slow axis, and that of the fast wave the fast axis.

Optical Axes and Optic Axis

Broadly speaking, crystals can be classified into six groups depending on their axes of symmetry. All crystals, except those in the cubic group (e.g., NaCl, KCl), are birefringent, that is, they transmit light whose E-vectors, oscillating in different planes, travel at different velocities (Hartshorne and Stuart, 1960; Inoué, 1986). However, each crystal type has a unique single axis, or two axes, along which light is transmitted at equal speeds regardless of the direction of the E-vector. In other words, light propagating along such an axis does not suffer birefringence. Such an axis is called the optic axis of the crystal or the birefringent material.

In addition to the optic axis, a crystal generally has three principal optical axes (one of which may correspond to the optic axis). Between crossed polars, when the optical axes of a crystal come to lie parallel to the polarizer or analyzer, the entering polarized light is not split into two components, thus encountering no birefringence, and so the crystal appears dark. This extinction is seen intermittently in a swimming pluteus larva of a sea urchin, when the long axis of one of the biocrystalline, skeletal spicules comes to lie along the polarizer or analyzer transmission direction (see Example 1; Fig. 4.9.1).

In the younger, gastrula-stage sea urchin embryo, the triradiate precursor of the spicule may appear not to be birefringent unless viewed from its side. That is because the optic axis of these biocrystals, made of calcite, lies perpendicular to the plane of the triradiate spicule.

With the background between crossed polars made gray by turning a compensator from its extinction orientation, regions of the birefringent specimen whose axes coincide with the transmission axes of the polars appear with similar brightness to the background, i.e., neither brighter nor darker than the background. Four such regions are commonly seen, e.g., on the fertilization envelope, asters at the spindle poles, and starch grains (see Examples 3 and 4 and Fig. 4.9.4).

Sign of Birefringence and Coefficient of Birefringence

Depending on the crystal type, light may travel faster or slower along the optic axis compared to other axes. The former type of crystal is known to be positively birefringent (e.g., quartz, collagen fiber), and the latter negatively birefringent (e.g., calcite, DNA thread; Inoué, 1986). In addition to its sign, each crystal type exhibits a unique amount of birefringence, the coefficient of birefringence, which is the *retardance*-per-unit thickness of crystal (see discussion of Retardance, below). In fact, the signs of birefringence and refractive indices for light traveling along the axes of pure crystals are so unique that they are used in crystallography for identifying their composition and lattice type.

Traditionally, in biological polarization microscopy, the expressions positive and negative birefringence are used relative to some obvious frame of reference (see Examples 3 and 4) rather than to the crystal axis of the object. For example, the fertilization envelope is said to be positively birefringent relative to its tangent, meaning the E-wave oscillating parallel to the tangent of the fertilization envelope (the obvious outline seen outside the equator of the egg; Fig. 4.9.4) is retarded (refracted) more than the E-wave oscillating perpendicular to the envelope. Since the fertilization envelope is a hollow sphere, the axis of symmetry (and, hence, optic axis for any unit area of the envelope) should be its radius rather than its tangent. So, according to the crystallographic definition, the envelope has a negative birefringence. On the other hand, if one were to make a thread of the material that makes up the envelope, the axis of symmetry would be along the length of the thread, so that the traditional nomenclature commonly used in biology does have its utility.

Retardance

Light waves traveling through a birefringent specimen are split into two orthogonally polarized components, one being refracted more, or traveling slower, than the other (Bennett, 1950; Inoué, 1986). The phase difference between these two waves as they emerge from the specimen is known as their retardance, or birefringence retardation. The retardance (Δ) is, in fact, the difference in refractive indices ($n_e - n_o$) experienced by the "extraordinary" and "ordinary" waves multiplied by the thickness (d) of the specimen. Thus $\Delta = (n_e - n_o) \times d$.

The retardance can be expressed in fractions of wavelengths or in nanometer units; e.g., $\lambda/4$, or 136.5 nm (= 546 nm/4), for a quarter-wave plate for the mercury green line. A mitotic spindle may show a retardance of 2.7 nm, or only 1/200 wavelength for the mercury green line.

Intrinsic, Form, and "Accidental" Birefringence

Birefringence of a specimen may arise from anisotropy (difference in physical property exhibited for different directions in the same material) of structural organization at various submicroscopic levels that are all too fine to be resolved with the light microscope. If the ultrastructure of the specimen is anisotropic at a level usually detectable with the electron microscope, but not with the light microscope (e.g., stacks of cell membranes, such as in the Schwann sheaths of nerve or the outer segments of the retina, parallel-oriented filament systems such as the F-actin thin filaments in muscle, microtubules in flagellar axonemes, and spindle fibers), they exhibit an optical anisotropy known as form birefringence. Form birefringence arises from the parallel array of filaments or membranes whose refractive index differs from that of the imbibing medium and therefore, disappears when the refractive indexes of the two match. For filaments, the sign of form birefringence is positive, whereas for membranes it is negative.

When the birefringence arises from anisotropy within the molecules themselves, it is not altered by the refractive index of the imbibing medium, and the material is said to possess intrinsic birefringence. The regularly aligned polypeptide chain in collagen fibers and in the myosin filaments of muscle A-bands, the regularly aligned DNA protein in mature sperm head, and the biocrystalline calcite in the skeletal spicules of sea urchin embryos are some examples of material that exhibit intrinsic birefringence.

While intrinsic birefringence tends to be considerably stronger than form birefringence, the two may contribute more or less equally in some biological structures, either with the same or opposite signs of birefringence. For example, the positive intrinsic birefringence of lipid molecules, or of membrane proteins, may overcome the negative form birefringence introduced by the lipid bilayers when the refractive index of the imbibing medium approaches that of the bilayers (Ambronn and Frey, 1926; Schmidt, 1935, 1937; Frey-Wyssling, 1953).

In addition to the naturally observed intrinsic and form birefringence, one may encounter birefringence induced by flow or by external forces such as stretch or compression or by the application of electrical, magnetic, or other fields. The induced birefringence, in turn, may reflect the intrinsic or form birefringence of the aligned molecules or submicroscopic particles, or may reflect distortion of the electron orbits within the substance itself. In this last regard, strain birefringence can be induced even in naturally isotropic substances such as glass, isotropic crystals, or well annealed plastics. In fact, the strain birefringence in the objective and condenser lenses can be high enough to interfere with observation of small specimen retardances, and special strain-free objectives (designated with P or Pol) are sometimes supplied to minimize such effects.

Edge Birefringence

The edges of objects, viewed with polarization microscopy using high-NA objective lenses, may display what appears to be a double birefringent layer. While in some cases these may represent the birefringence due to membrane fine structure or its molecular organization, in other cases they can be caused merely by the presence of a sharp refractive index gradient at the edges of the object. The object can be purely isotropic; the only condition required is that there exist a sharp gradient of refractive index at the boundary between the object and its surrounding. Such birefringence is called "edge birefringence."

As detailed by Oldenbourg (1991), with edge birefringence the inner, thin "birefringent layer" shows a slow axis (axis with greater refractive index) parallel to the boundary and an outer thin "birefringent layer" with its slow axis perpendicular to the boundary when the refractive index of the object is greater than its surroundings. When the refractive index of the object becomes equal to its surroundings, the edge birefringence disappears. When the re-

fractive index of the object becomes less than its surroundings, the directions of the slow axes are reversed.

As with edge birefringence, form birefringence also disappears when the refractive index of the rodlets or platelets matches that of the imbibing medium. But the sign of form birefringence does not change below and above the matched index. The slow axis direction is unchanged (relative to the specimen axis) above and below index match point. In contrast, with edge birefringence the signs of birefringence (in the two layers on both sides of the optical boundary) are reversed in media whose refractive index is greater than the index match point compared to the situation in media below the match point. In contrast to both edge and form birefringence, the retardance due to intrinsic birefringence is unaffected by the refractive index of the imbibing medium.

It is important to distinguish edge birefringence from form or intrinsic birefringence since edge birefringence reflects an optical effect that has nothing to do with the molecular or fine structural anisotropy that we are probing.

COLOR IN POLARIZED LIGHT

Interference Colors

Many crystals that are normally colorless, including the biocrystalline spicules of sea urchin plutei, show in vivid color when observed in white light between crossed polars (Fig. 4.9.2). The color reflects the birefringence retardation (or retardance, i.e., the phase difference) that the two components of the orthogonally polarized light components suffered in passing through the crystal. For example, if the retardance were 550 nm, or a full wavelength for green light, the two orthogonal components would add back together to form the initial state (i.e., of plane polarized light as before entering the crystal) upon exiting the crystal. Thus, green light is extinguished by the analyzer. Wavelengths other than 550 nm are elliptically polarized and are partially transmitted by the analyzer. Thus, the complementary color of green, i.e., red, is seen through the analyzer (Inoué, 1986).

Similarly, for an object giving a retardance of 490 nm, full wavelength for blue light, blue is extinguished and its complementary color yellow is seen through the analyzer. For a retardance of 568 nm, full wavelength for yellow light, yellow is extinguished and its complementary color blue is seen through the analyzer. For a retardance of 600 nm, full wavelength for red light, red is extinguished and its complementary color green is seen through the analyzer. These interference colors thus measure the retardance of the specimen.

For a cylindrical object like the pluteus skeletal spicule, light would travel the furthest distance across its middle and suffer the most retardation, so that the axis of the spicule would appear with the highest-order interference color. Thus, the axis may appear green, surrounded by blue, then red, then yellow, then gray, etc., as light travels through decreasing thickness towards the outer margin of the cylindrical biocrystal and is thus retarded, proportionately, less and less.

Dichroism

In addition to optical anisotropy that is manifested as birefringence (difference of refractive index for light waves whose E-waves are oscillating in different planes), one may also encounter dichroism (difference of absorbance, or of absorption spectrum, for light waves whose E-waves are oscillating in different planes). Whereas a birefringent material simply changes the phase of polarized light, a dichroic material transmits light to different degrees, depending on the wavelengths and the angle between its axes and the plane of the entering polarized light.

Polaroid films serve as effective polars by taking advantage of the aligned polyiodide chains that show a strong dichroism for most wavelengths in the visible spectrum. The conjugated electrons that make up the backbone of the polyiodide chains strongly absorb the (E-) component of the visible light waves that are polarized parallel to that direction, whereas they absorb little of the component that is polarized at right angles to the backbone.

The dichroism of Polaroid sheets that extends over much of the visible wavelength range is, however, an exception. Most dichroic materials (or pleochroic materials, i.e., many-colored instead of showing two different colors, depending on the vibration direction of the polarization of light) exhibit two different absorption curves depending on the orientation of their chromophores relative to the plane (of the E-wave) of polarized light.

DNA in mature sperm is a biological material that shows prominent dichroism in ultraviolet (UV) light. The conjugated bonds in the purine and pyrimidine bases of B-form DNA, regularly oriented at right angles to the DNA backbone as in steps of a spiral staircase, give

rise to a UV dichroism with a dichroic ratio of 4, spanning the wavelength range of ~250 to 380 nm. This dichroism is present because the conjugated bonds in the bases (that resonate in the UV range) lie at right angles to the B-form DNA backbone. So the UV polarized at right angles to the backbone is absorbed four times more effectively than UV that is polarized parallel to the DNA backbone (Wilkins, 1951; Inoué and Sato, 1966). This gives rise to the UV dichroism that has a negative sign (i.e., greater absorbance perpendicular to the backbone compared to parallel to the backbone).

The same conjugated bonds give rise to the much greater polarizability of the electrons, and, hence, to higher refractive indexes for visible light waves whose E-fields lie in the plane of the bases compared to fields along the backbone of DNA. That gives rise to the strong negative birefringence of B-form DNA in the visible wavelength range (Inoué and Sato, 1966; Inoué, 1986). The author took advantage of this dichroism and birefringence, which are both abolished upon polarized UV microbeam irradiation (possibly by dimerization of the thymidine bases), to analyze the detailed packing arrangement of DNA and to uniquely visualize chromosomes, taking advantage of a needle-shaped head of an insect sperm (Fig. 4.9.7; Inoué and Sato, 1966).

Chromophores with such high dichroic ratios can be recognized by a change in light transmittance or absorbance, or of color, as the orientation of a single polar (a polarizer in the absence of an analyzer, or an analyzer in the absence of a polarizer) is changed.

Cell inclusions with regularly oriented natural chromophores—e.g., retinal rods and cones (Schmidt, 1935), sickled blood cells (Perutz and Mitchison, 1950; Hárosi, 1981), and chloroplasts (Breton et al., 1973; Hsu and Lee, 1987)—may also show some degree of dichroism. Cell inclusions, or products with regularly oriented fine structure that have been stained with dyes, may likewise be dichroic.

When the dichroic ratio is low, as in these latter examples, it may require a sensitive spectrophotometer to detect a change in color, or wavelength dependence of light transmittance, as the specimen orientation is changed relative to the orientation of the polarized light (Hárosi and MacNichol, 1974). In such cases, the dichroism may still be detected visually if one uses both a polarizer and an analyzer and orients one of the two a few degrees from the crossed position. The complementary dichroic colors can then be seen visually by turning the polar or compensator in opposite directions from the extinction orientation.

Using the dichroic fluorescence of tetramethylrhodamine that was used to sparsely decorate actin filaments, Kinosita and coworkers were able to demonstrate, and measure, the speed of rotation of individual actin filaments around their own axis as the filaments are propelled by myosin molecules coated on the surface of a microscope coverslip. Through video contrast enhancement of the fluorescence microscope images taken in polarized light, they were able to show the cyclic brightness change in the dichroic fluorescent dye as the single actin filament, <10 nm in diameter, glided along the lawn of myosin heads (Kinosita, 1999).

The sensitivity for measuring the orientation of a dichroic fluorescent molecule, such as green fluorescent protein, can be increased several fold by using parallel polars instead of a single polarizer or analyzer (Inoué and Goda, 2001).

Colloidal Gold, Pinholes

Spindle microtubules in *Haemanthus* endosperm cells decorated with 20 nm-diameter colloidal gold appear as dark black lines when observed in a compensated field between crossed polars in monochromic light. These same microtubules show in striking colors ranging from red to purple, green, orange, and gold when they are observed in white light with the polars off-crossed by a few degrees and the compensator orientated to different directions (Inoué and Spring, 1997, Color Plate III). These colors are attributed to anisotropy of Tyndall light scattering (or di-Tyndallism) by the linear array of colloidal gold particles that are arranged quite densely (not contacting each other, yet acting as an effective conductor, or antenna, for the high-frequency electromagnetic light waves) along the lengths of each microtubule.

Examined at high magnification, pinholes in thin metal film, evaporated on coverslips that are used to test the performance of microscope objective lenses, can also each appear with striking saturated colors when examined in polarized white light. Light from the pinholes becomes alternately extinguished as the microscope stage is rotated. In other words, each pinhole is acting as a polarizer that appears to have a narrow transmission wavelength. No doubt, each pinhole is not completely circular but must be elongated, since they are generally produced by some random dust particle or impediment to sputtering or high-vacuum depo-

sition of the metal film. Thus, each "pinhole" acts as an anisotropic nonconductor in the thin metal film.

In fact, a very narrow crack in a thin metal film preferentially transmits light that is polarized with its E-vector oriented perpendicular to the narrow crack and whose wavelength reflects the local width of the submicroscopic crack (S. Inoué, unpub. observ.). The situation is somewhat the converse of the aligned polyiodide chains or of the colloidal gold-decorated microtubules, in that instead of a submicroscopic thread-shaped conductor, one has a thread-shaped non-conductor surrounded by a conducting film.

Anomalous Birefringence

Stained or colored biological tissue and cell components often exhibit "anomalous birefringence," i.e., the color observed in white light between crossed polars actually changes with adjustment of the compensator. In other words, the birefringence, or the retardance observed, is a function of the wavelength of light. Such a color change, or "anomalous birefringence," is observed even when the retardance of the object is a small fraction of the wavelength of light (Perutz and Mitchison, 1950).

Colorless objects, on the other hand, generally show birefringence that changes only slightly with variation of wavelengths. What color is observed for a colorless object is primarily due to interference colors when the retardance approaches a wavelength or more, as described earlier (Fig. 4.9.2).

On the other hand, with strongly absorbing materials such as a dye or stain, the refractive index drops sharply on the shorter wavelength side and rises precipitously on the longer wavelength side of the absorption peak ("anomalous dispersion"; Jenkins and White, 1957; Hecht, 1998). Since the wavelength-specific absorption of light in a dye or stain is commonly brought about by conjugated ring structures, the birefringence associated with such an anisotropic structure would also be expected to show a strong dispersive character (wavelength dependence). The anisotropic dispersive character would then give rise to anomalous birefringence. Objects exhibiting anomalous birefringence would also be expected to show some dichroism as well.

These several wavelength-dependent polarization optical effects (as with polarization of fluorescence, a topic not covered here) are of considerable potential interest as potent tools for analyzing dynamic changes within, or interactions among, biological molecules and fine structures. Further studies on the physical optical bases of these phenomena should lead to their wider application in cell biology.

OPTICAL ROTATION

Optical rotation (also known as circular birefringence) is a polarization optical effect that may (rarely under the microscope) induce an object to become bright between crossed polars. Unlike (linear) birefringence, the brightness due to optical rotation does not depend on the regular alignment of the molecules but on their internal asymmetry and thus is observed even in solutions of the particular molecules. Optical rotation may also be seen in certain crystalline substances, such as quartz and other material viewed along the helical axes of the molecules that make up the crystal.

An object exhibiting optical rotation does not undergo extinction between crossed polars as the microscope stage revolves. Instead, the object can be made darker by turning the polarizer or analyzer away from their crossed orientation. Except in pure monochromatic light, as a polar is turned, these "optically active" objects or solutions acquire a brownish or bluish hue instead of undergoing complete extinction. The color reflects a high degree of wavelength dependence that is characteristic of optical rotation. Such wavelength dependence of optical rotation is known as optical rotatory dispersion. The infrared optical rotatory dispersion, e.g., of myosin and related proteins in solution, has been used to determine the degree of helix content of protein molecules (Szent-Györgyi et al., 1960).

VIDEO MICROSCOPY

As in many other modes of microscopy, the capabilities of polarization microscopy have been substantially enhanced by the application of video and electronic image processing, analysis, and device control. As described in Allen et al. (1981) and Inoué (1981b) and summarized, e.g., in Shotten (1993), and Inoué and Spring (1997), video microscopy can effectively enhance image contrast, subtract background, reduce noise, and allow image capture with better corrected higher-NA objective lenses and even with relatively short exposures.

The new LC PolScope introduced by Oldenbourg, provides striking, high-contrast images of weakly birefringent cellular regions and does so independently of specimen axis orientation. The recent system introduced by N. Allen and co-workers selectively enhances (or

suppresses) contrast in differential interference contrast (DIC) microscopy and should also be applicable for bringing out birefringent regions of the specimen.

Oldenbourg's LC PolScope

Oldenbourg's LC PolScope (which can be adapted to most research-grade microscopes outfitted for polarization microscopy) provides striking, high-contrast images of weakly birefringent objects. Furthermore, the system has the unique attribute of providing maps of birefringence distribution that is independent of orientation of the specimen axis within the focal plane.

The new system uses circularly, instead of linearly polarized light and two electronically controlled liquid crystal compensators instead of a mechanically driven conventional compensator (Oldenbourg and Mei, 1995; Oldenbourg, 1996). Four video images are acquired into computer memory in rapid succession. In acquiring each of these four images, the computer provides appropriate voltages that adjust the retardances of the two compensators. The LC PolScope uses no mechanically moving compensators and records the images in perfect register. From the set of four images, the retardance map is immediately calculated by the computer and displayed on the monitor.

The calculated image generated with the LC PolScope is, in fact, a map of birefringence distribution whose intensity is directly proportional to the retardance of each specimen point. In contrast, with images obtained by standard polarization microscopy, the intensity of each image point is proportional to the square of the retardance of the specimen point. The LC PolScope can also display a map of slow-axis orientations for pixels for each image point.

The LC PolScope has been used to display the dynamic distribution of microtubules in newt lung epithelial cells undergoing mitosis (see on-line video accompanying Inoué and Oldenbourg, 1998) and the highly dynamic behavior of actin filaments and network in cultured growth cones of *Aplysia* neurons (Katoh et al., 1999) with unprecedented clarity.

The LC PolScope system is available from CRI (Cambridge Research and Instrumentation).

Nina Allen's Compensator

In another recent development, Holzwarth et al. (1997, 2000) also use a voltage-driven liquid-crystal compensator for DIC observations with video microscopy. They use crossed linear polars rather than circular polarizers as in Oldenbourg's system. Appropriate voltages, applied by a computer to the compensator, generate an additive and a subtractive shift to the phase difference introduced by the Wollaston or Nomarsky prism. Each of these images is stored in computer memory and subtracted from each other. The difference image displays the DIC effect alone, while subtracting away stationary background noise and image features that did not originate from interference between the two sheared rays.

Although designed for use in DIC and still retaining the orientation-dependent contrast characteristic of images observed between crossed linear polarizers, Allen's new compensator applied to polarization microscopy should also effectively bring forth contrast in weakly birefringent regions of the specimen. Conversely, the modified system could selectively suppress contrast due to birefringence by adding (rather than subtracting) the two images stored in computer memory and selectively bring forth image features not based on optical anisotropy.

Centrifuge Polarizing Microscope

Living cells centrifuged on an isopycnic gradient at several thousand $\times g$ (earth's gravitational field) tend to stratify with their lighter components packed at the centripetal pole and heavier inclusions packed at the centrifugal pole of the cell (Harvey, 1940; Zalokar, 1960). In the process, cytoskeletal elements, membranes, and organelles tend to become aligned or deformed. To study the fine structure and function of stratified cell components and to learn about the mechanical linkages of the organelles to the membranes and cytoskeletal elements, the author of this unit has developed a centrifuge polarizing microscope (CPM; Inoué et al., 1998, 2001a).

The CPM allows video-rate polarization microscope observations of the spinning specimen, with image resolution of 1 μm, in living cells suspended in an isopycnic solution or crawling on a glass substrate. Birefringence retardations can be detected and measured down to 1 nm in cells that are exposed to up to $10{,}500 \times g$.

With the CPM, the author has found striking changes in the conformation of endoplasmic reticulum immediately following fertilization of sea urchin eggs, has followed the process of Ca^{2+}-induced nuclear-envelope breakdown and meiotic spindle formation in a marine annelid egg, measured the climbing forces generated

by myosin mutants of slime mold amoebae, and observed the enigmatic formation and rapid precipitation of dense "comets" in a concentrated solution of a thread-shaped virus (Inoué et al., 2001b).

APPLICATIONS OF POLARIZATION MICROSCOPY

Example 1: Examining Biocrystals

Hard tissue generated in living organisms often contains, or is made up of, biocrystals. Biocrystals are indistinguishable (in terms of their atomic lattice and, hence, intrinsic optical properties) from inorganic crystals, yet their morphology is primarily determined by their biological function and seldom reflects the habits (e.g., cleavage faces) of the natural crystal.

A common form of biocrystal, such as the skeletal spicules found in embryonic sea urchins (or the plates of their adult forms), is based on calcite, a highly birefringent, negative uniaxial material that is the main ingredient of chalk.

The birefringence, growth, and morphogenesis of calcareous biocrystals, such as the skeletal spicules generated by the mesenchyme cells in the gastrula- and pluteus-stage sea urchin larvae, can be studied with a simple polarizing microscope that can be easily assembled.

All one needs is a polarizer, inserted in the illumination path before the condenser of the microscope, and an analyzer (crossed relative to the polarizer) placed after a low (10× or 20×) power objective lens. In fact, both of these "polars" may already be present on the microscope. If the microscope is equipped for DIC, simply slide out the Nomarsky prism and set the condenser turret to the bright-field position. Close down the condenser iris so that the condenser NA becomes just below half that of the objective NA. Make sure the polars are carefully crossed so that, with the lamp brightness turned up, the blank field becomes completely (or very) dark in Köhler illumination (see *UNIT 4.1*).

When live gastrula or pluteus larvae are observed between crossed polars, the pair of triradiate or skeletal spicules should alternately twinkle like stars as the ciliated embryo swims about (see Fig. 4.9.1). The thicker parts of the skeletal spicule may show brilliant interference colors when observed in white light (see Fig. 4.9.2).

One can even make these observations using a dissecting microscope of the type that allows transillumination of the specimen. Simply attach a polarizer below the specimen-support glass plate and an analyzer below the objective lenses. The polars can be sheet Polaroids, perhaps those cut to appropriate shape from plastic Polaroid sunglasses. With the analyzer transmission axis oriented horizontally (i.e., turned 90° with respect to the way Polaroid sunglasses would normally be oriented), the polarizer mounted below the glass specimen support plate can be oriented vertically (north-south) by rotating the support plate to achieve extinction. Note that it is important to observe the specimen in a glass container, not in a plastic Petri dish, since most plastic lab ware exhibits very strong birefringence that can overwhelm the specimen birefringence.

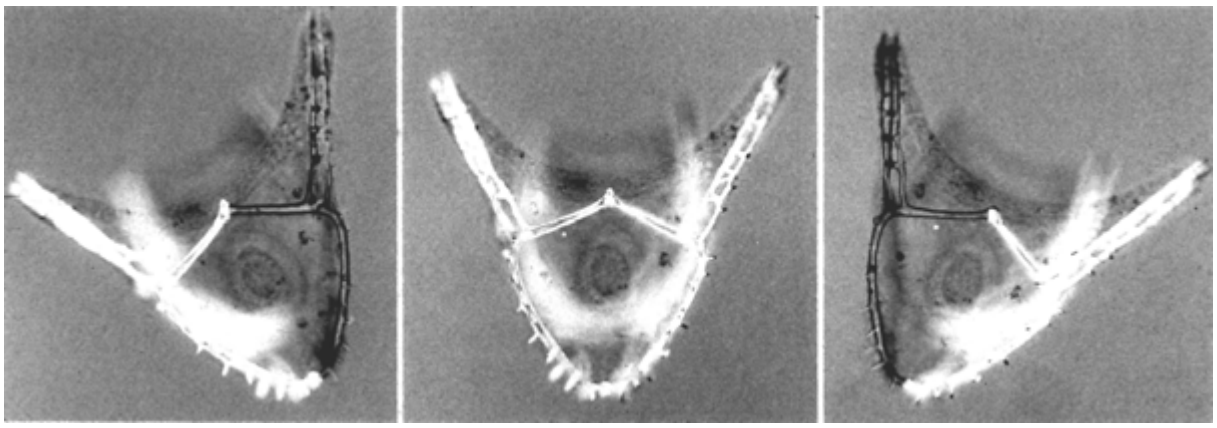

Figure 4.9.1 Pair of skeletal spicules in sea urchin pluteus larva. As the ciliated pluteus swims about in the field of the polarizing microscope, the skeletal spicules alternately shine and become extinguished. Despite its complex shape, the whole of each spicule is extinguished at once when its (calcite) crystal axes come to lie parallel to the axes of the crossed polars. Such extinction pattern is characteristic of biocrystals (from Okazaki et al., 1980).

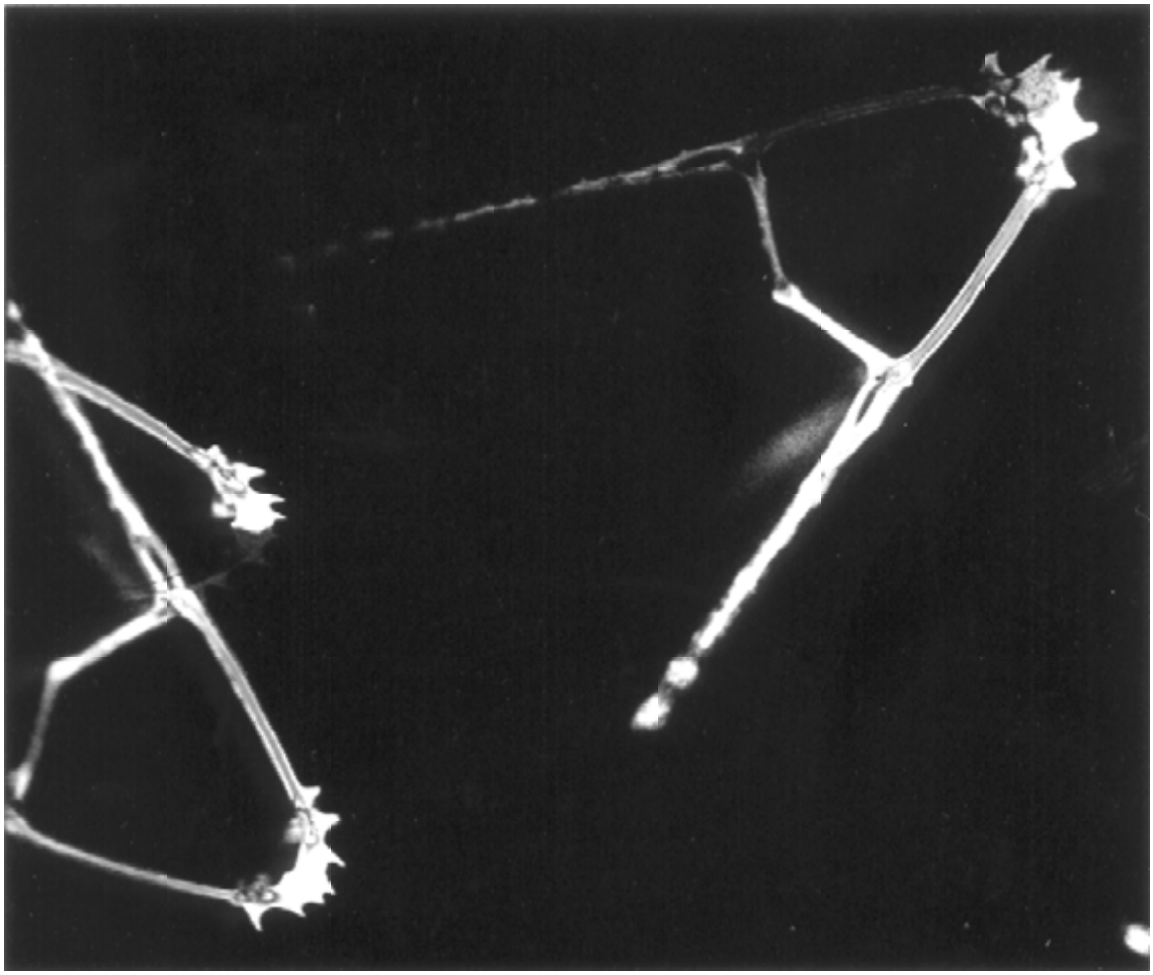

Figure 4.9.2 Skeletal spicules isolated from sea urchin pluteus larvae observed between crossed polars in white light. The calcite spicule is so strongly birefringent (coefficient of birefringence = –0.172) that a region just over 3-μm thick already introduces a 580-nm retardation. In that region, yellow light exiting the spicule is extinguished by the analyzer so the spicule takes on a bluish hue. Figure courtesy of Jan Hinsch, Leica. **See color plate.**

While appearing to be a rudimentary exercise, consideration of the polarization optics and close observations of the image of the specimen can, in fact, reveal the directions and homogeneity of optical axes of the biocrystals, yield their sign and coefficient of birefringence, relate the growth of the biocrystal to the activity of the mesenchyme cells, and produce other useful information (Okazaki and Inoué, 1976).

In addition to the calcareous skeletal spicules that consist of a single biocrystal in echinoderm embryos, most bone and teeth contain an array of biocrystals (Schmidt, 1924).

Example 2: Examining Collagen, Muscle, and Histological Preparations

Many transparent organisms and tissue sections exhibit birefringent regions that can be seen with simple polarizing microscopes. The wavy collagen fibers and cross-striated muscle in animal tissues (see Fig. 4.9.3), and cellulose fibrils in the walls of plant cells (e.g., see Green, 1963), stand out prominently sometimes amidst bright crystalline inclusions. Likewise, the keratin layers in hair (which can vary with animal species) and synthetic fibers show strong birefringence.

Some of the crystalline inclusions seen in the background were formed in life, while other randomly scattered crystals could have developed in the medium in which a fixed specimen is embedded. Others, which at first glance may appear to be simple crystals (with simple optical axes as in biocrystals), upon closer inspection may turn out to have complex (more or less radially symmetric) extinction patterns. These may be starch grains with concentric lamellar structures that show characteristic extinction

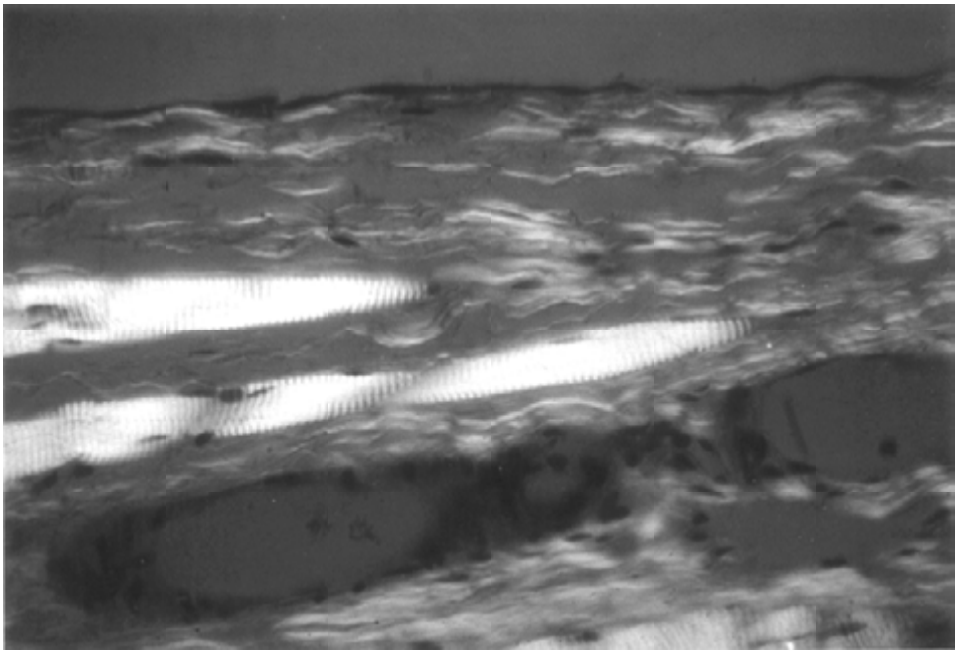

Figure 4.9.3 Tissue section showing birefringent cross-striated muscle and collagen fibers. A typical H & E–stained tissue section observed between crossed polars in the presence of a Brace-Köhler compensator. The birefringent A-bands of the cross-striated muscle fibrils and the wavy axes of the birefringent collagen fibers stand out. **See color plate.**

patterns (see Frey-Wyssling, 1953). On a larger scale, a more or less similar pattern can be seen in the shells of embryonic gastropods (Schmidt, 1924).

Example 3: Preparing to Study Spindles and Asters

In contrast to the structures described above, which may show interference colors between crossed polars and tend to show retardances of the order of many hundreds of nanometers, other structures in living cells display a very weak birefringence retardation that amounts to only a few to a fraction of a nanometer. These include the arrays of microtubules that make up the spindle fibers, astral rays, and flagellar and ciliary axonemes, the arrays of actin and intermediate filaments, various membrane systems, and chromatin in sperm heads.

Unlike the examples mentioned above, whose birefringence is mostly based on the anisotropy of their intramolecular bonds (intrinsic birefringence), many of the intracellular filament and membrane arrays exhibit form birefringence that is based on their ultrastructural geometry.

In order to detect and study the weak birefringence common to intracellular structures, one needs a polarizing microscope equipped with polars yielding a high extinction factor (see Example 4), strain-free optics, a Brace-Köhler compensator, and a bright light source (Swann and Mitchison, 1950; Inoué and Dan, 1951).

While the test specimen and protocol described below are useful for checking the performance of a polarizing microscope equipped with the highest-NA lenses, in this protocol for observing fertilization and spindle and aster formation in marine eggs, it is recommended that one use a 10× to 20× objective lens with the condenser iris partly closed so that $NA_{cond} = 0.3 \times NA_{obj}$.

To see whether a microscope has been adequately equipped and adjusted for studying weak birefringence of intracellular structures, one can try out a convenient test specimen prepared as follows. On a clean microscope slide place a few drops of saliva. Place a clean coverslip on top and observe in Köhler illumination (see *UNIT 4.1*) using a bright light source. Make sure the polars are fully crossed and that the microscope is equipped with a Brace-Köhler compensator.

If the microscope is adequately equipped and adjusted, the buccal epithelial cells (the so-called "spit cells" that are present in the saliva) should appear brighter or darker than the gray background depending on the orientations of the cell and the compensator. The gray back-

ground is introduced by the compensator and varies with the orientation of its axes between the crossed polars, as described below.

If the spit cells show up in this fashion, both brighter and darker than the gray background depending on their orientation, the polarizing microscope should be ready for other applications. However, before removing the test slide, go through the following exercises, which will give further insight into the submicroscopic structure of the cell structure that is being examined.

When a spit cell in focus is brighter than the background, the retardances of the cell and the compensator are added together and introduce a greater phase difference, thus making the specimen appear brighter. Since the slow axis of the birefringent spit cells (i.e., the long axis of their keratin fibrils) is generally oriented along the long axis of the cell, they appear bright when that axis lies in the same quadrant as the slow axis of the compensator.

When the slow axes of the specimen and compensator lie in opposite quadrants, their retardances cancel (subtract from) each other, so that the specimen appears darker than the background field.

Using these criteria, record which quadrant of the compensator contains its slow axis. Some cells appear bright in some regions and dark in others. There the keratin fibrils are not uniformly aligned parallel to the long axis of the cell, but in different directions depending on the part of the cell.

Note also that the cells (or cell regions) in certain orientations appear neither brighter nor darker than the field. With the compensator removed (or brought to its extinction orientation), those cell regions should appear as dark as the extinguished background. Those are cells, or cell regions, in which the keratin fibrils are oriented exactly parallel or perpendicular to the polarizer and analyzer axes. Verify this explanation by revolving the microscope stage or by observing a cell that is flowing and changing its orientation slowly.

Just as the specimen becomes dark when its optical axes, in the absence of a compensator, coincide with those of the polars, the background for the whole field becomes dark when the compensator optical axes are oriented parallel to the axes of the polars. These extinction orientations show the optical axes, respectively of the compensator or specimen, which relate directly to the orientations of their atomic bonds or fine structure.

In testing for the adequacy of the polarizing microscope through these exercises, the apparatus is also set up to establish the optical axes and signs of birefringence of the weekly birefringent specimen. Through such an exercise, we can interpret the nature and alignment of the submicroscopic molecular or fine-structural arrays that are themselves much too small to be resolved with the light microscope.

Example 4: Examining Fertilization, and Spindle and Aster Formation, in Egg Cells

Elevation and hardening of fertilization envelope

Collect eggs and sperm from appropriate species of gravid sea urchins or sand dollars (Costello et al., 1957; Schroeder, 1986; Lutz and Inoué, 1986). Use species with optically clear eggs such as Lytechinus variegatus, *Lytechinus pictus*, or *Echinarchnius parma*.

Wash the eggs in filtered seawater three times, each time by allowing the eggs to settle, changing the seawater above the layered eggs, and again letting the eggs settle. Add a dilute suspension of sperm to a portion of the washed, unfertilized eggs (save some unfertilized eggs in a larger dish). Then, quickly make a preparation using a clean slide and coverslip (with a coverslip fragment or small piece of Scotch tape placed under one edge to prevent squashing the egg). Observe the elevation of the fertilization envelope with the polarizing microscope. In the first 3 to 5 min after fertilization, note how the fertilization envelope elevates and becomes increasingly birefringent.

Note also that the parts of the envelope that lie in the same quadrants as the slow axis of the compensator become quite bright while parts of the envelope in the other quadrants become darker than the gray background (Fig. 4.9.4). In other words, the slow axis for the envelope lies parallel to its surface, or the envelope shows a "tangentially positive birefringence." As the birefringence of the envelope rises, the middle (crescent-shaped) region of the darker part of the envelope may become brighter. For that region, the birefringence retardation of the envelope has become greater than that of the compensator. This effect is more pronounced the smaller the retardance introduced by the compensator. In fact, with the compensator oriented in its extinction orientation, all four quadrants of the envelope will shine equally brightly.

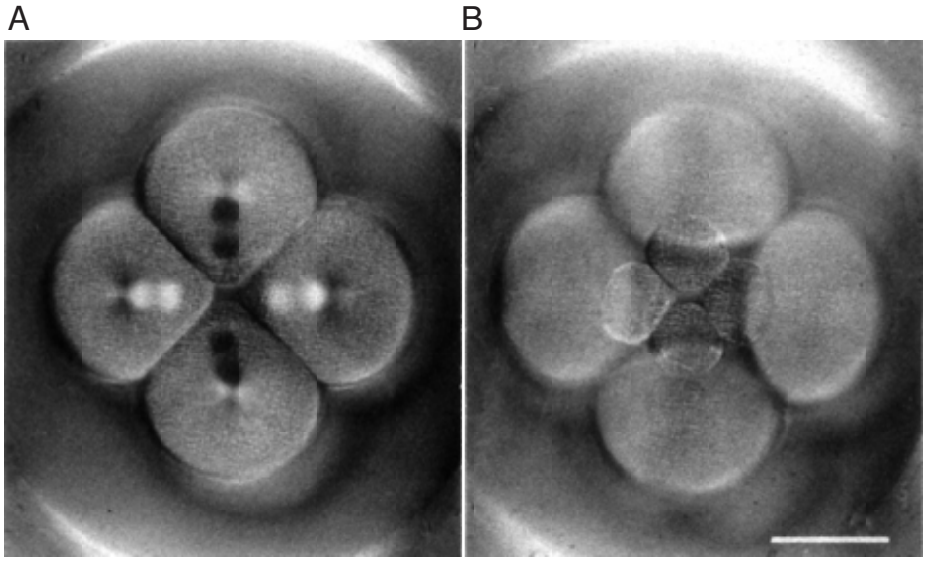

Figure 4.9.4 Birefringence of fertilization envelope and fourth-division mitotic spindles in a sand dollar egg. (**A**) The tangentially positive birefringence of the fertilization envelope and the radially positive birefringence of the mitotic spindle and aster microtubules show clearly in this transparent cleavage stage egg of *Echinarchnius parma.* The egg is viewed near its vegetal pole, to which the vegetal fourth-division spindles have converged. (**B**) The asymmetric location of the vegetal pole spindles has given rise to four small micromeres, whose descendants give rise to the gametes and the mesenchyme cells that pattern the pair of skeletal spicules. Compensator slow axis is oriented horizontally.

This rise in positive birefringence of the fertilization envelope reflects the deposition of a fibrous inner layer that strengthens the envelope. In fact, it is possible to strip off the envelope by passing the fertilized eggs through a fine-meshed bolting cloth, within 3 to 4 min after fertilization, after the fertilization envelope has risen sufficiently, but before it has hardened (as judged by its strong birefringence).

Mitotic spindle and asters: Assembly and disassembly of mitotic microtubules

Make a fresh preparation ~40 min to 2 hr after fertilization (~15 to 20 min before the onset of first cleavage, depending on the species and temperature). In this preparation made at the appropriate time, one should see the birefringent asters and the mitotic spindle gradually appearing.

Note how both the asters and spindle initially appear as small, weakly birefringent structures that may be barely detectable.

Depending on the orientation of their fibrillar components (microtubules) and the compensator setting, portions of the asters and spindle may appear bright or dark. In fact, each aster will generally appear as a radial structure with two dark and two bright quadrants since the microtubules radiate out from the centrosome.

Over the next several minutes, the asters and spindle gradually grow in size and birefringence, until the spindle reaches full metaphase. At anaphase, the clear gap in birefringence that develops between the two half spindles by full metaphase gradually increases in length as the chromosomes are moved polewards.

Starting with the first appearance of the tiny spindle and asters, make time-lapse video records of the events every 5 to 15 sec apart, making sure that a time-of-day signal and audio records of any comments are included. Keep a record of room temperature near the microscope. If possible, record also the orientation of the compensator that just extinguishes the darkest part of the spindle. Choose spindles whose long axes lie in the plane of focus and that are oriented at 45° to the transmission axes of the polars. This exercise may be easier if observations are made on eggs in their second division where two spindles should be oriented parallel to the first cleavage plane.

Depending on the species being used and on the microscope, the chromosomes themselves may or may not be visible. Switching to DIC or phase contrast may help see the chromosomes in favorable cases (see Figure 1 in Salmon and Segal, 1980).

As the spindle approaches telophase and the half-spindle birefringence diminishes, the asters

generally grow to their maximum size and birefringence. Shortly thereafter, the cell cleaves in a plane bisecting the anaphase spindle.

The astral rays and fibers in the spindle display a positive birefringence along the length of their fibrils or of their microtubules. Since virtually all of their birefringence can be accounted for by the form birefringence of their constituent microtubules (Sato et al., 1975), the rise and fall and distribution of their birefringence directly reveals the change in concentration and distribution of oriented microtubules, which themselves are too small to be resolved with the light microscope.

Observation with a polarizing microscope of changes in the spindle and astral birefringence, associated with the natural progress of cell division or in cells exposed to cold or mitosis-inhibiting chemicals such as colchicine, have laid an important foundation for our present understanding of the submicroscopic organization and events in mitosis, as well as the assembly properties of the mitotic, and other labile, microtubules (Inoué, 1952a, 1952b, 1964, 1981a; Inoué and Sato, 1967; Inoué and Salmon, 1995).

Example 5: Using Polarization Microscopy at Maximum Resolution

So far, these examples have dealt with observations and measurements of weak birefringence that could be made with lower-power microscope objective lenses. In order to gain more image resolution, one must not only use higher-power objective lenses, but objective and condenser lenses with higher numerical apertures (NAs). That is because the minimum distance (d) between two small points that can just be resolved is given by the following relationship (see *UNIT 4.1* for further detail):

$d = 1.22 \times$ (wavelength of light)/(NA of objective + working NA of condenser).

While the exercises described in Examples 1 to 4 can be carried out with a simple polarizing microscope equipped with objective lenses that have relatively low NAs, they become difficult or impossible when one attempts the same procedures with lenses that have NAs of >0.5. That is because a considerable amount of background light leaks through the crossed polars at high NAs, no matter how carefully the system is adjusted. The extinction factor {EF = (Intensity with parallel polars)/(Intensity with crossed polars)} that may be as high as 10^4 for low-power objectives which are clean and free of strain birefringence, may drop to as low as 10^2 for some highest-NA objectives. It takes place even with carefully selected strain-free lenses and is generally caused by two factors: the differential transmission of the polarized components of light in and perpendicular to the plane of incidence and their phase differences, both introduced at oblique optical interfaces that lie between the polarizer and analyzer.

In simple terms, light must be refracted at high angles of incidence by the objective and condenser lenses, and the slide and coverslip surfaces, in order to gain the high NA needed for obtaining the high image resolution. In polarization microscopy, that very fact makes the EF drop precipitously at higher NAs. In other words, without some special remedies as described below, the detection of very weak birefringence and generation of very high image resolution are mutually incompatible.

Fortunately, there are a few remedies, although these are somewhat difficult to implement, that can help alleviate these problems. To understand these remedies, first observe the appearance of the back aperture of the objective lens. This can be done by replacing the ocular of the microscope with a telescope used for adjusting a phase-contrast system. Or, if your microscope is equipped with a Bertrand lens, insert and focus the Bertrand lens so that it, together with the ocular, makes up a telescope that images the back aperture of the objective lens. Alternatively, remove the ocular and peek down directly at the back aperture of the objective lens.

Confirm that you have indeed focused on the back aperture plane. There you should see the image of the condenser iris, whose size changes as the condenser iris is opened and closed. With proper Köhler illumination, if you open and close the field diaphragm rather than the condenser iris, only the brightness of the back aperture and not the size of the iris image should change.

In the absence of a compensator, observe the objective lens back aperture as the polarizer and analyzer are crossed and slightly off-crossed. If the lenses are free of strain birefringence and birefringent dirt or dust particles, the objective back aperture should show a dark cross flanked by brighter quadrants between the arms of the cross when the polars are exactly crossed. The arms of the dark cross lie along the transmission axes of the polars (Fig. 4.9.5A).

When the polarizer or analyzer is slightly off-crossed, the dark arms of the cross turn into two dark V shapes located in opposing quad-

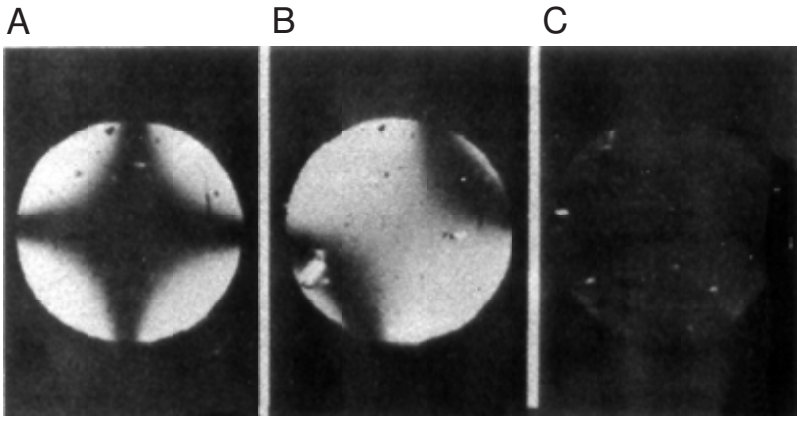

Figure 4.9.5 Patterns observed at the back aperture of polarizing microscope equipped with high-NA (×97/1.25) strain-free, matched condenser and objective lenses. (**A**) The back aperture shows a dark cross between crossed polars in the absence of a birefringent specimen or a compensator, if the objective and condenser lenses are free from *lateral* strain birefringence. The lenses may, however, still be introducing *radial* birefringence! (**B**) As the analyzer (or polarizer) is turned, the cross opens up into two dark Vs that should remain dark up to the edge of the aperture if there is no contributing birefringence. Turning the polar in the opposite direction reverses the quadrant in which the Vs appear. (If the Vs do not move out to the periphery of the aperture but fade rapidly as a polar is turned, the contrast of the Vs can generally be restored by adjusting a compensator. That region of the aperture is then introducing elliptically polarized light, either because a lens suffers radial strain birefringence or because of the nature of the anti-reflection coating used on the lens.) (**C**) Extinction pattern of the same lens pair shown in A and B, but equipped with a polarization rectifier. The whole back aperture (up to the maximum NA), as well as the microscope field, is now well extinguished. (From Inoué and Hyde, 1957.)

rants of the back aperture (see Fig. 4.9.5B). Those V-shaped regions are where the plane of the incident polarized light has been rotated (by lower transmission of the polarized light vector vibrating normal to the plane of incidence compared to that vibrating parallel to the plane of incidence).

As the polars are further off-crossed, the V-shaped regions move further out, but may become faint and no longer be very dark. At this point a Brace-Köhler compensator inserted at the appropriate orientation can restore the darkness of the Vs. In other words, light rays traversing the objective and condenser lenses (and slide and coverslip), at angles and directions corresponding to those regions that have now become darkened at the back aperture of the objective lens, act as though those particular rays experienced birefringence or had suffered a phase difference and become elliptically polarized. This elliptical polarization is commonly due to the anti-reflection coating applied to the lens surfaces. As with the rotation of polarized light, it also increases with the angle of incidence and the departure of the plane of incidence from the vibration plane of the polarized light incident at each air-glass interface.

The net result of all of these polarization-altering effects at the lens (and slide and coverslip) surfaces is the dark cross at extinction and the two sets of Vs that move further out into opposing quadrants.

The polarized light modified in this fashion (in the four quadrants between the arms of the dark cross) is transmitted by the analyzer crossed with the polarizer and, hence, gives rise to the large amount of background "stray light" found with high-NA lenses.

To minimize this stray light that drowns the low-contrast image of weakly birefringent specimens, a simple, quick fix is to close down the condenser iris and use an objective lens with a lower NA. However, one loses image resolution as well as the amount of image brightness needed to see or record the images. Also, the depth of field can become unacceptably deep and make for a confusing image.

Oil-immersion objective and condenser lenses tend to depolarize the light less and hence, introduce less stray light compared to "high dry" objective lenses that have the same NA. That is because up to four air-glass interfaces, where the rays suffer the steepest angle of incidence, are essentially eliminated by oil immersion between the objective lens and coverslip, and condenser lens and slide.

Video enhancement can also help to a certain degree. By analog or digital processing, the

unwanted background stray light can be offset (suppressed) and the image contrast can be raised so that the optical problems can be overcome to some degree (Allen et al., 1981; Inoué, 1981b; Inoué and Spring, 1997).

A proper remedy for the depolarization of light is accomplished by using objective and condenser lenses equipped with polarization rectifiers. By using "rectified" lenses, one can, in fact, restore much of the polarization states of the light passing each region of the objective lens back aperture (Fig. 4.9.5C) and thus achieve high extinction for the full aperture even when using high-NA lenses (Inoué and Hyde, 1957).

In addition to allowing the detection and measurement of very weakly birefringent minute objects, rectification gets rid of the diffraction anomaly that is introduced in images of weakly birefringent objects. The diffraction anomaly, which arises from the different states of polarization in different quadrants of the aperture plane, can even reverse the contrast of weakly birefringent minute objects and prevent proper interpretation of the specimen's fine structure (Inoué and Kubota, 1958; Inoué and Spring, 1997).

Unfortunately, rectified lenses, which used to be available from American Optical, and from Nikon, are currently not commercially available. However, the following two alternative approaches can provide some relief of the problems discussed.

The first uses two opposite-handed circular polarizers instead of crossed linear polarizers to extinguish the field (Huxley, 1960). An advanced version of this type of polarizing microscope is Oldenbourg's "LC PolScope."

As a final alternative, one can gain some improvement of image resolution combined with elevated extinction by using an appropriate mask at the aperture plane. The mask, placed at the back aperture of the objective lens and/or at the plane of the condenser iris diaphragm, would be shaped so as to transmit light along the dark arms of the cross, while cutting out the modified polarized light that would have passed through the rest of the aperture.

Such masks would definitely raise the EF, making the background much darker and allowing detection of very low birefringence retardances. Such masks would also effectively provide high NAs in two orthogonal directions, thus yielding high resolution for objects that diffract light in those directions. The accompanying modifications of the point-spread function may be a slight penalty to pay in order to gain high extinction and freedom from anomalous diffraction at very high NAs.

Example 6: High-Resolution Polarization Microscopy of Meiotic Mitosis and Spermiogenesis

Using a polarizing microscope as described in Example 5, it is possible to use high-NA objective lenses (combined with high effective NA of the condenser) to examine the detailed distribution of birefringence as in the mitotic spindle of a dividing cell or the coil-of-a-coil packing arrangement of DNA in certain chromosomes.

Some cell types are more suited for such observations: such as single-layered tissue cells that remain flat instead of rounding up during mitosis (McIntosh et al., 1975), cells without excessive light scattering or birefringent inclusions, cells with large and clearly visible chromosomes, and cells in which different mitotic and developmental stages are well synchronized. Some examples include: newt lung epithelial cells (Rieder and Hard, 1990; Oldenbourg, 1999), endosperm cells of the African blood lily (Inoué and Bajer, 1961), some symbiotic protozoa in the wood-eating cockroach (Inoué and Ritter, 1978), spermatocytes of crane flies (Forer, 1965), grasshopper spermatocytes (Fig. 4.9.6 and Zhang and Nicklas, 1996), and maturing spermatids (Fig. 4.9.7 and Inoué and Sato, 1966). The extensive article (in German) by Belar (1928) is a treasure trove of cell sources available for observing various features of cells in the living state as well as after fixation and staining.

The following describes a method for preparing grasshopper spermatocytes and spermatids for high-resolution polarization microscopy. The following materials are required:

Healthy male grasshoppers, preferably of *Dissosteira*, *Chortophaga*, or related species that fly well for several meters at a time, rather than those that only hop or fly for short distances (for some reason, the spermatocyte mitochondria, which are birefringent, are better aligned in the former group of grasshoppers and interfere less with detailed observation of spindle birefringence);

Grasshopper Ringer's solution (see Table 4.9.2 and preparation instructions below);

Clean Syracuse watch glasses;

Bio-cleaned slide and coverslips (see Table 4.9.1 and instructions for bio-cleaning below);

A pair of sharp iridectomy scissors;

A sharp pair of stainless-steel watchmaker's forceps;

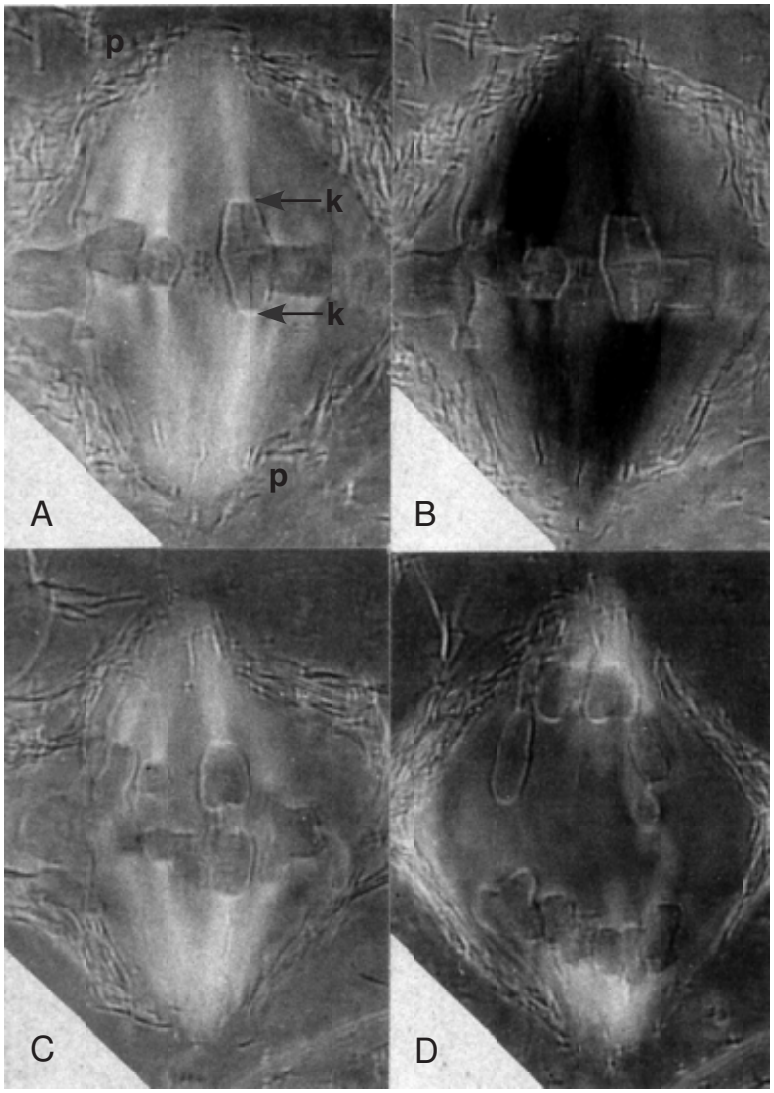

Figure 4.9.6 Meiosis-1 spindle of grasshopper spermatocyte observed with rectified optics. The positive birefringence of the bundle of microtubules that make up the chromosomal spindle fibers shows prominently. The kinetochores (k) also appear to show the same sign of birefringence as the microtubules, but it has not yet been established whether this reflects fine-structural anisotropy of the kinetochore, or primarily the edge birefringence of the chromosome at the kinetochore. The mitochondria also show a longitudinally positive birefringence with overlapping edge birefringence. The compensator slow axis lies parallel to the spindle fibers in panels (**A**), (**C**), and (**D**), so that the positively birefringent microtubule bundles appear brighter than the background. (**C**) The compensator orientation is reversed so that the microtubule bundles appear in reverse contrast. (From Nicklas, 1971.) For online version of time-lapse series of this and other cells in mitosis, see *http://www.molbiolcell.org* and Inoué and Oldenbourg (1998).

Sharp, stainless-steel dissecting needles;
A sharp hypodermic needle mounted on a wooden handle;
Pasteur pipets with rubber bulbs;
Small balls of absorbent cotton;
6- to 8-mm-wide strips of filter paper;
Mineral oil or other innocuous oils such as Halocarbon oil 27;
Valap (see *UNIT 13.1*);
70% ethanol;
Dissecting microscope with trans-illumination.

Preparation instructions for several of these items, along with some parameters critical to performing the experiments described here, are included in the discussion of Ensuring that Cells are "Happy" While They Are Being Observed Under the Microscope, below.

Let the male grasshopper hold onto a small wad of absorbent cotton or a small piece of tissue, so as to absorb the brown fluid expelled

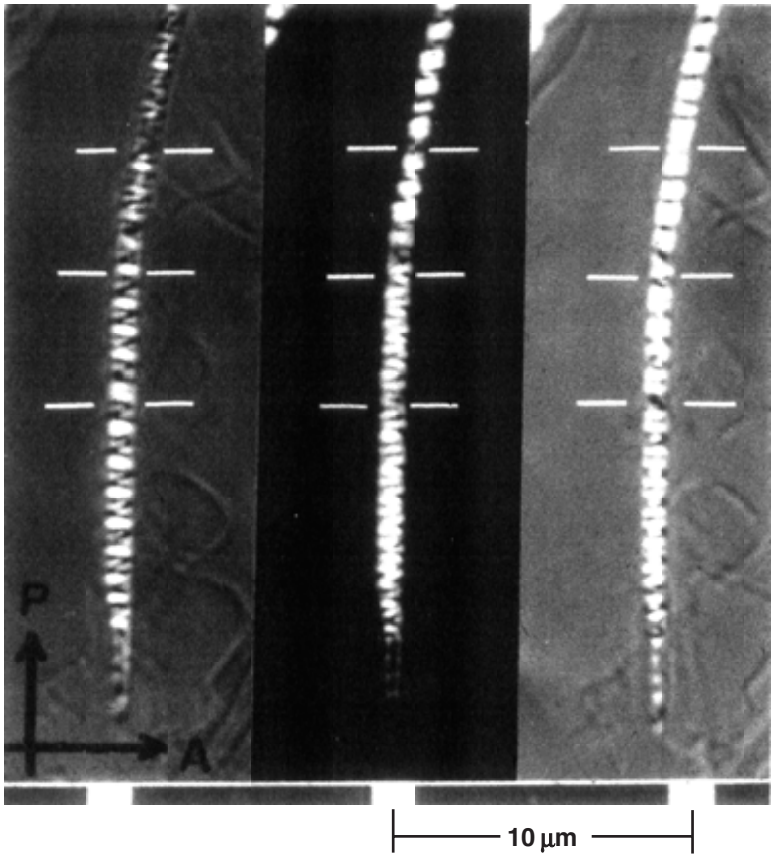

Figure 4.9.7 Live sperm head of cave cricket viewed with a high-resolution polarizing microscope. The sperm head immersed in DMSO (dimethyl sulfoxide) is viewed at three compensator settings using rectified optics (×97/1.25 NA). P, A: transmission axes of the polarizer and analyzer. The compensator slow axis is oriented perpendicular to the sperm axis in the middle panel, turned ~5° clockwise in the left panel and ~4° counterclockwise in the right panel. The helical regions of the DNA, wound in a coil of coil within the chromosomes, appear bright or dark depending on their slow axis orientations relative to that of the compensator. Bars indicate junctions of chromosomes that are packed in tandem in the needle-shaped sperm head. This is the first (and virtually only) mode of microscopy by which the packing arrangement of DNA and the chromosomes have been clearly imaged in live sperm of any species. From Inoué and Sato (1966).

from its mouth. Lift and clip off the wings at their bases. Then, holding onto the grasshopper with his hind legs folded under the abdomen, insert one blade of the iridectomy scissors pointing up and forward at around the third or fourth from the last abdominal segment as shown in Figure 4.9.8. Make an incision that covers four or five segments along the back of the abdomen. Then gently squeeze the lower part of the abdomen until the pair of testes (Fig. 4.9.9; usually colored bright yellow, orange, or red) pop out from the incision. Cut the ducts and place the testes in the saline (grasshopper Ringer's) solution in a watch glass.

Under the dissecting microscope, use a watchmaker's forceps and sharp needle to peel off the colored layer of fat and the Malpigian tubules that surround the testes. They can be toxic to the isolated spermatocytes if not removed from the final preparation. Freed from the covering material, the whitish lobes of the testes should now look like a bundle of bananas. With a piece of absorbent cotton moistened with 70% ethanol, wipe clean the iridectomy scissors, forceps, and needle used, and then transfer the lobe bundles of the testes to a clean Syracuse watch glass containing fresh saline solution.

Again, under the dissecting microscope, use sharp dissecting needles to separate a testis into small bundles containing three to four intact lobes. Cut apart the bundles where they bunch together, i.e., at the proximal end of the lobes where they share a common sperm duct.

Using the Pasteur pipet, transfer one small bundle of lobes together with a small drop of

saline onto a clean slide. Place a clean coverslip on top and remove excess solution with a small piece of filter paper or tissue paper until the lobes are just starting to be flattened.

Observe the preparation under the polarizing microscope using a low-power (10×) objective lens. In each intact lobe, there should be located, from the duct end towards the distal end, more or less in the following order, bundles of mature sperm heads, immature sperm heads, and sperm tails, then follicles containing spermatids, secondary spermatocytes, primary spermatocytes, and, finally, spermatogonial cells (Fig. 4.9.10). The birefringence of the heads of the mature and immature sperm, as well as of some of the spermatid, and perhaps of the bundle of sperm tail, should be quite prominent.

By using a Brace-Köhler compensator, establish the sign of birefringence (direction of

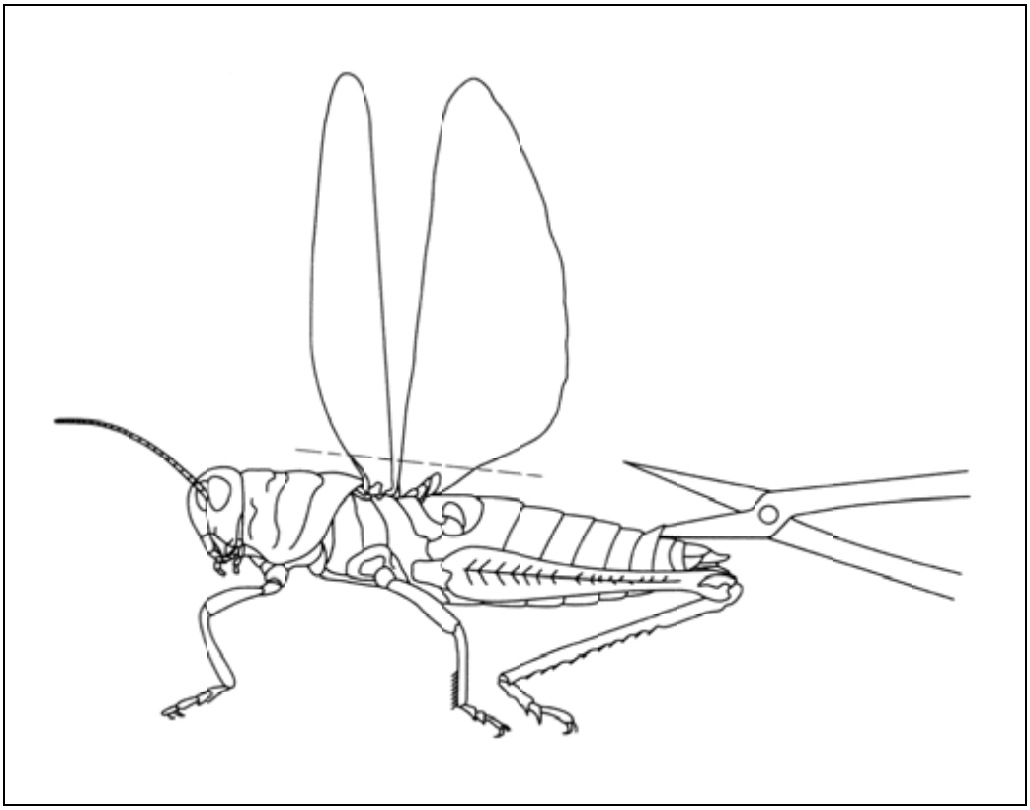

Figure 4.9.8 Dissecting a male grasshopper to expose testes (also see Fig. 4.9.9 and instructions in text).

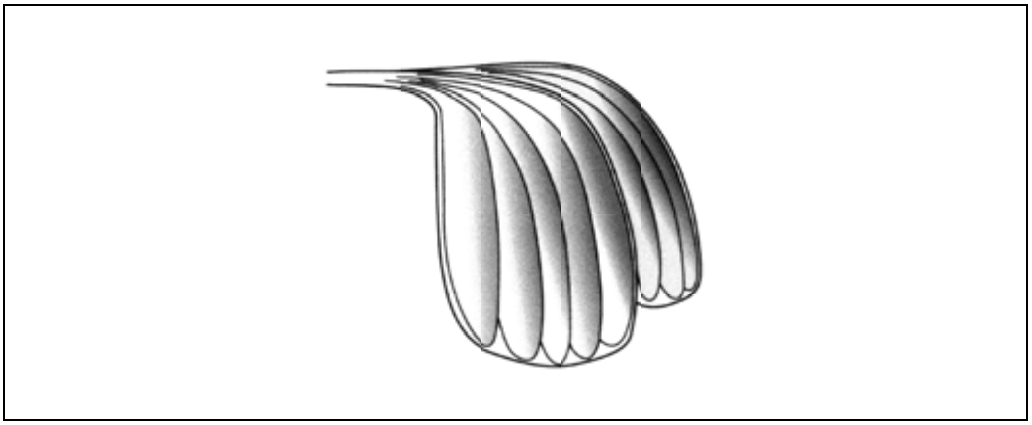

Figure 4.9.9 The pair of testes extracted from a grasshopper. The bundle of lobes in each testis, made like a bunch of bananas and held together where they share a common sperm duct, are covered by a brightly colored sheath. The distal ends of the lobes splay apart when the testicular sheath is peeled off.

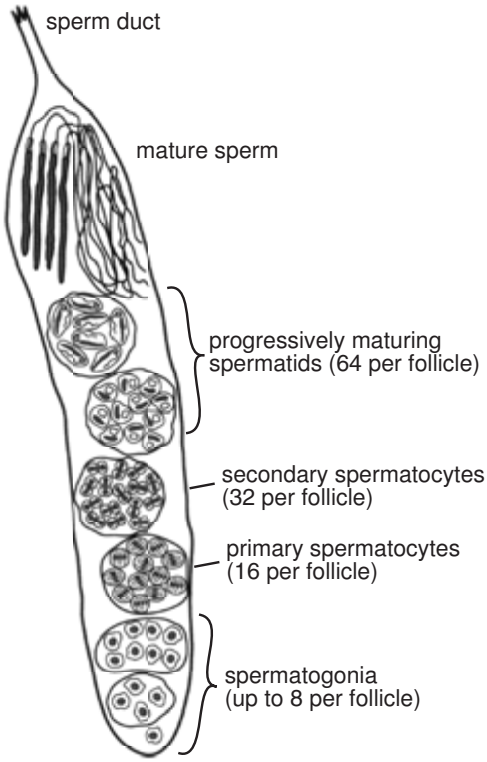

Figure 4.9.10 Arrangement of follicles and cells (not to scale) in the lobe of a grasshopper testis. This highly schematic diagram illustrates one of the many lobes, which are arranged like a bunch of bananas, in a grasshopper testis. The cells, developing synchronously within each follicle in the lobe, are progressively more mature from the distal end of the lobe to the proximal end where the lobes are joined by the sperm ducts. For a photograph of section of fixed lobes, see Figure 1 in Belar (1929).

the slow axes of these structures relative to their long axes). Note that the contrast due to sperm tail birefringence, which is mostly due to the form birefringence of their axonemal microtubules, is reversed from that of the sperm head, which is almost exclusively due to the intrinsic birefringence of the DNA molecules aligned parallel to the length of the sperm head.

Next, make a fresh preparation for observing the spindle fibers and chromosomes and individual sperm with greater resolution. This exercise may require some practice, since a combination of care and speed of preparation is important. Also, do not be frustrated if, at first try, primary spermatocytes at just the right stage of meiotic mitosis are not found. There are a number of follicles at different stages of spermiogenesis in each testicular lobe, and the divisions of the 16 primary spermatocytes in each follicle are synchronized, but you may not come across a lobe that contains a follicle at the right stage. Usually, it is not necessary to try more than two or three lobes.

Using a pair of watchmaker's forceps, transfer a bundle of three to four testicular lobes onto a bio-cleaned microscope coverslip. The coverslip should be resting on a clean microscope slide or some other appropriate holder that lifts it off from the lab bench or other surfaces, which may be a source of lint or other birefringent dust. In making the transfer, be sure to hold onto the duct ends of the lobes and not the other, free end. During the transfer, touch the lobes gently to the clean, dry rim of the watch glass to remove much of the saline solution.

Using a hypodermic needle with a very sharp tip as a knife, cut the lobes (now resting on the coverslip) near their free ends. Then, holding onto the duct end of the lobes with a watchmaker's forceps, draw the lobes in a spiral a few millimeters in radius, making sure that their free, cut ends trail on the surface of the coverslip. As you draw the spiral, cells should flow out together with the testicular fluid, from the cut ends of the lobes onto the surface of the

coverslip. Those near the cut end flow out first, then those closer to the ducts that you are holding onto. Pick up and discard the residue of the lobes. The result is a spiral-shaped thin film of cells, more or less arranged in order from least differentiated cells to mature sperm (see Fig. 4.9.10).

Quickly place a drop of oil (Halocarbon 27 or light mineral oil) on the spiral, invert the coverslip, and cover the preparation by contacting onto a clean slide. Do not use any spacers. Remove the excess oil by contacting a strip of filter paper to the rim of the coverslip, then seal the preparation with Valap.

The slide is now ready for observation of the spindle and chromosomes in meiotic divisions and different stages of sperm maturation. The observations can be carried out on the same live cells for many hours. Not only are the cells arranged and clustered, more or less in the order of stages of spermiogenesis, but they should also lie in reasonably flat monolayers making them suitable for observations with high-NA lenses using polarization microscopy, phase contrast, or DIC.

Note, however, that the testicular lobes, from the time they are removed from the saline medium, and especially the very thin spread of cells in the spiral, could almost instantly lose water by evaporation before being covered by the Halocarbon oil. Thus, some practice and speed of operation becomes important for the last phases of the preparation described above.

In successful preparations observed in high-extinction polarization microscopy, one finds meiosis-I spindles (which are considerably larger than those in meiosis-II) with a moderate degree of positive birefringence, somewhat rounded spindle poles (in contrast to being very pointed), and chromosomal spindle fibers that appear somewhat fluffy (rather than too sharp as though drawn as a line). Such cells can be expected to complete meiosis-I as well as meiosis-II in several hours (see Inoué, 1964).

The process of sperm maturation, on the other hand, is very slow, so that one is not likely to see the actual transition of single spermatids from one stage to the next. The successive stages of sperm maturation, including the rise of negative birefringence in the spermatid nucleus associated with their dehydration and shape changes, should, however, be neatly displayed in chronological order on the slide, so that it should not be difficult to visualize the sequence of events.

Example 7: Examining Meiotic Spindles and Chromosomes

Note that in grasshopper spermatocytes, it can take several hours between the time when an apparently mature spindle is formed and the beginning of anaphase. During that interval, known as prometaphase, chromosomes oscillate back and forth to both sides of the metaphase plate (Deitz, 1969). Concurrently, the associated spindle fibers change the strength of their birefringence. With time-lapse cinematography or video, one can also observe considerable fluctuation of the spindle birefringence (the so-called "Northern Lights Phenomenon"; Inoué, 1964), reflecting the dynamic growth and shortening of their constituent microtubules (Mitchison and Kirschner, 1984; Walker et al., 1988).

The sex chromosomes, in particular, may be found to travel all the way form one spindle pole to another. The oscillatory behavior of these prometaphase chromosomes, and the associated stretching and contraction of their kinetochores to which the chromosomal spindle fibers are attached, may be observed more clearly by switching from polarization to DIC or phase-contrast microscopy (Salmon and Segal, 1980; Nicklas et al., 1995).

Once full metaphase is established, and all of the chromosomes have lined up on the metaphase plate, a signal is released and the chromosomes synchronously enter anaphase (Nicklas et al., 1995). Note the change in distribution and strength of birefringence of the spindle fibers and astral rays as anaphase progresses. What can one infer about the behavior of the microtubules from these observations?

Note also, as anaphase progresses, that another bundle of thread-shaped, birefringent elements lines up along the long axis and surrounding the spindle, to be pinched apart into two as the cell cleaves. Note the sign of birefringence of these mitochondrial threads.

In each daughter cell that results from the division of the spermatocytes, the mitochondria come together to form a dense, round body, the Nebenkern, which has a diameter similar to the reconstituted daughter nucleus and is often mistaken for the latter. The Nebenkern shows a higher refractive index than their surrounding cytoplasm, whereas the daughter nuclei themselves tend to have a lower refractive index than the surrounding cytoplasm. Using DIC optics, verify these refractive index differences by observing the shadow-cast appearances at the edges of these structures.

Example 8: Examining The Sperm and Maturing Spermatids

The needle-shaped, mature sperm heads in grasshoppers show a very strong birefringence whose character is reversed from that of the sperm tail and the acrosome at the tip of the head. Establish the sign of birefringence of these three regions.

Also note that, unlike the nuclei in spermatocytes (and many other cells), the refractive index of the sperm head is very high, reflecting the loss of water and condensation of its chromatin during spermatid maturation.

Choose a series of spermatids starting with those that are nearly mature to very young ones. As maturation progresses, the sperm nucleus becomes more and more elongated, while its birefringence increases. The coefficient of birefringence of the mature sperm is, in fact, extremely high, amounting to -2×10^{-2}, approximately that of a thread of pure DNA (Schmidt, 1941; Wilkins, 1951; Inoué and Sato, 1966).

Note that before the spermatid starts to lose water and become elongated, the nucleus is almost nonbirefringent. Most cell nuclei show very little birefringence (with the exception of those in sperm and in certain Dinoflagellates; Schmidt, 1932, 1937; Cachon et al., 1989), despite the fact that they contain a large quantity of DNA.

In maturing spermatids, note also that the axis of birefringence of the sperm head is tipped this way and that and is not totally parallel to the elongated axis of the head, as in the fully mature sperm. In some insects, such as the cave cricket, the axes of negative birefringence, even of the mature sperm head, can still be resolved and seen not to be uniform. Instead, they are disposed more or less in a zigzag fashion (Fig. 4.9.7), reflecting the packing arrangement of their DNA backbone and chromosomes. The detailed packing arrangement of the DNA bases, including at levels far smaller than the resolution limit of the polarizing microscope, was determined by irradiation of the live sperm head with a microbeam of polarized UV and by quantitatively measuring changes in the birefringence and their axes for each resolvable area (Inoué and Sato, 1966).

Ensuring that Cells Are "Happy" While They Are Being Observed Under the Microscope

To observe the behavior or fine structure in living cells under a microscope, there are several factors that demand special attention. This is especially true when observations are to be made for extended periods of time and under conditions that require brilliant illumination, as in polarization microscopy, to visualize weakly birefringent objects. On the other hand, birefringence can be an especially effective monitor for the physiological state, and "happiness," of the cell.

Biological material

Start with healthy organisms and cells. Clearly, one cannot expect to gain healthy cells from diseased or necrotic plants or animals or gain normal fertilization and development when the gametes are not fully ripe.

Culture medium

Be alert to toxic contaminants, especially those that can affect the cells at low concentrations. Heavy metals such as copper, zinc, and silver, which can be present in trace amounts even in conventional reagent-grade sodium chloride, can be sources of trouble since NaCl is used in high concentrations in artificial seawater and physiological saline. Likewise, for making culture media, distilled water made in glass or quartz stills (with adequate vapor, i.e., water droplet, suppression) is preferred over that from metal stills. Deionizers remove trace metals, but one should be careful that the water is not contaminated by mold or bacteria (which can grow in the columns or tubing) and their products including surfactants (which show up as long-lasting foam after the water is shaken or bubbled).

Slide and coverslips

Cells prepared between a slide and coverslip are exposed to a large area of the glass surface relative to the volume of the medium bathing the cell. In addition, the cells are likely to be contacting the glass surface directly. Thus, slight contaminants on the glass surface can disproportionately affect the cells being observed. Eliminate surfactants and heavy metals that may affect the well-being of the cells as well as birefringent contaminants that may interfere with observations by polarization microscopy (see below).

Oxygen supply

In addition to changes in pH of the medium, anoxia (and hyperoxia in the case of some obligatory anaerobes; Ritter et al., 1978) can interfere with proper health and division of cells grown in the confined space between the slide and coverslip. Tissue culture cells are commonly observed through special flow-through microscope chambers where the culture me-

dium is appropriately oxygenated and its pH and temperature are monitored or controlled. Alternatively, developing marine embryos and dividing protists can be observed continuously for many hours using a micro-chamber containing an equilibrated gas phase formed between a slide and coverslip (see Inoué and Spring, 1997). Microscope preparation of cells covered with a layer of nontoxic oil (even under the coverslip) can survive for many hours since many oils, especially silicone and fluorocarbon oils, dissolve gases, including oxygen, very effectively. Halocarbon oils, such as Kel F-10, FC-47, and Voltalef that previously were used to cover cultured cell smears, e.g., of insect spermatocytes, are no longer available. Instead, the Halocarbon oils 27 or 200 (Halocarbon Products; see *SUPPLIERS APPENDIX*), used for immersing developing *Drosophila* embryos, would appear to be reasonable, currently available alternatives. The manufacturer recommends that fresh oils be bubbled with air before use for a day or two to replenish the oxygen that was evacuated during manufacturing.

Temperature

While slides containing cultured cells of mammalian origin generally require heating, most invertebrate cells may need to be kept cool, i.e., no warmer than moderate room temperature. For observing such cells, be especially careful with the illumination used for polarization microscopy. A source with high brightness is needed in order to see or record the weak birefringence in the cell. But most high-brightness sources (not just quartz halogen or other tungsten filament lamps, but also mercury and xenon arc lamps) produce a huge quantity of infrared. Be sure to use a good quality heat-cut filter, and, if practical, a high-transmission (>65%) narrow-band-pass (±15 nm) green interference filter. That is because the preparation can be heated up with the infrared and far red portions of the spectrum, and cells can react adversely to the blue end of the spectrum (Langford and Inoué, 1979).

In addition, use Köhler illumination and keep the illuminated area to the smallest practical size by adjusting the opening of the field diaphragm. Even using a laser beam, it is not easy to heat up a portion of the specimen with a diffraction-limited small spot of light because water carries away the heat very effectively. On the other hand, the light from an unfiltered incandescent or arc source can rapidly heat up the specimen under the microscope if the illumination covers a large area of the specimen.

The birefringence of the mitotic spindle (as well as its shape) can be a sensitive thermometer that reflects the temperature of the specimen, which is otherwise quite difficult to monitor closely. At lower temperatures, the spindle birefringence drops, while at higher (physiologically compatible) temperatures the birefringence rises (showing enhanced polymerization of tubulin) following a remarkably reproducible curve (Inoué et al., 1975; Nicklas, 1979).

Drying

With cells mounted between slide and coverslip in an aqueous medium be especially alert to drying and increased tonicity of the medium. Valap (see *UNIT 13.1*) is an effective material that can be applied to seal cells mounted in aqueous solutions between the slide and coverslip. The distribution of birefringence in the spindle can indicate the tonicity of the medium. In hypertonic media the chromosomal spindle fibers tend to appear as sharp pencil-drawn lines that converge sharply to the spindle poles (a sign of poor health, although partially reversible), while in less concentrated media, they appear fluffier.

Bio-clean slides and coverslips

In preparing cells for long-term observations under a microscope, one needs to be especially careful to prepare media with the appropriate pH and degree of oxygenation, free of heavy metals. It is especially important to use glassware that is "biologically clean." Since the cells being observed under a microscope are bathed in a very small volume of medium and their surfaces contact a disproportionately large area of the glass surface (and the concentration of any contaminant can become exceptionally high), the slide and coverslips in particular must be bio-clean.

Bio-clean glassware should be free from soap and detergent in addition to even minute amounts of heavy metal, fixatives, and other toxic contaminants or residues that may have been left or adsorbed onto the glass surface. Glassware (including slides and coverslips) and plasticware that have been acquired new from suppliers (except specially packaged pipet tips and capped centrifuge tubes, etc.) should not be assumed to be bio-clean. Table 4.9.1 shows the sequence of procedures used in the author's laboratory for preparing bio-clean glassware and slides and coverslips (Lutz and Inoué, 1986).

Glassware once used with fixatives should be separated by marking with clear, indelible F

Table 4.9.1 Procedures for Bio-Cleaning Glassware (after Lutz and Inoué, 1986)

Step	Procedure
1	Fill 500-ml beaker with hot tap water and enough detergent to make the solution sudsy.
2	Drop 30 to 50 slides or coverslips *individually* into the beaker. Try to position the slides in a criss-cross arrangement in the beaker.
3	Soak for 15 to 30 min.
4	Place beaker in ultrasonic washer for 3 to 5 min.
5	Rinse many times in tap water to remove the majority of the detergent.
6	Using stainless-steel forceps, transfer slides or coverslips individually into another beaker containing tap-distilled water. Repeat this individual transfer/rinse ten times. Sonicate beaker 3 to 5 min before the last transfer.
7	Individually transfer slides or coverslips into a beaker containing glass-distilled water. Repeat this ten times. Sonicate beaker for 3 to 5 min before the last transfer.
8	Individually transfer slides or coverslips into bioclean storage jars filled with 80% ethanol for storage.
9[a]	Before use, remove slide or coverslip from alcohol using clean forceps and wipe dry with a Kimwipe folded twice (four thicknesses). Do not rub.

[a]If possible, use a centrifuge ("Spin Dry" available from Technical Video) to avoid the possibility of lint associated with Step 9.

marks, and not mixed with bio-clean glassware, since it may be very difficult to get rid of some ingredients of fixatives.

In addition to preparing bio-clean slides and coverslips, keep their surfaces, as well as optical surfaces of the microscope that lie between the polarizer and analyzer, free from birefringent dirt and dust particles. In particular, be careful to prevent pieces of lint (including cellulose fibers, which often have birefringence retardations close to a wavelength or more) from falling on to, or becoming attached to, the surfaces of slides and coverslips. Such fibers can drastically lower the EF of the whole polarization optics and completely interfere with observation of weak birefringence of intracellular structures. Since clean glass surfaces tend to attract lint particles electrostatically, avoid laying your slide or coverslip directly on a bench top, or on the surface of the glass plate that supports the specimen on a dissecting microscope. Instead, place the slide and coverslip on a spacer, such as a fresh applicator stick bent into a V shape, or prop it up by supporting one end by a couple of millimeters off the surface. Note that Kleenex and lens tissue used to wipe the slide or coverslip can also be a source of cellulose fibers. To avoid wiping, use a centrifuge to spin off the alcohol used for the final rinse of the slide and coverslip (see Figures 3 to 11 in Inoué and Spring, 1997).

Grasshopper Ringer's solution

Table 4.9.2 provides the composition of saline solutions that can be used for preparing the grasshopper testes and for observing meiosis in their spermatocytes for many hours (Nicklas et al., 1979). Note that the final tonicity of the medium (plus testicular fluid) may vary somewhat, depending in part on the atmospheric humidity at the time the contents of the testicular lobe are streaked onto the coverslip. Thus, Belar advises either breathing onto the preparation with one's mouth wide open or blowing with lips nearly closed, depending on whether the preparation should be made more or less dilute before sealing the preparation. As noted before, the morphology and birefringence distribution in the spindles are, in fact, sensitive indicators of the cell's health and whether the preparation is or is not appropriate for long-term observation of the division events.

Valap

Valap is a low-melting-point, nontoxic, waxy material used for sealing coverslips. Valap is made by simmering a 1:1:1 mixture of vaseline, lanolin, and paraffin (using indirect heat to prevent overheating or catching on fire) for several hours (also see *UNIT 13.1*). Use of beeswax instead of paraffin, or Valab, yields a somewhat more adhesive sealant. A major advantage of these sealants is that they can be applied directly to seal the edges of coverslips covering wet specimens.

Valap and Valab can be applied either from a melt using a small brush or with a warm spatula or heating wire made by passing current (e.g., from a low-voltage-microscope lamp transformer) through an ~5-inch length of U-

shaped nichrome wire fastened to an insulated holder such as an electric plug fixture (Fig. 4.9.11). Be careful not to pass too much current through the heating wire (if it smokes, it is too hot) since the sealant can spit, and small droplets of this highly birefringent aggregate that land on the coverslip can ruin the extinction of the polarization optical system.

After applying the sealant, examine all four sides of the coverslip with a dissecting microscope or magnifying glass to make sure that there are no imperfect seals or pinholes, since water evaporates rapidly from even a very small hole in the seal.

Effect of fixation

Polarization microscopy, carried out on living cells that continue to divide, develop, or otherwise undergo normal physiological or developmental activities, provides a good

Table 4.9.2 Composition of Insect Ringer Solution[a]

Stock solution[b]
500 mM PIPES
27 mM KCl
67.5 mM $CaCl_2$
2.5 mM $MgCl_2$
Adjust pH to 6.8 to 6.9 with 10 N NaOH[c]

[a]This is the solution currently recommended by Nicklas et al. (1979) and supercedes the earlier formula of Niklas (Nicklas and Staehly, 1967) as well as those of Belar (1929, footnotes on pp. 364 and 387). In his 1929 artcile, Belar describes and illustrates with photographs of live cells the appearance of pseudopodia, chromosomes, and mitochondria of spermatocytes exposed to media with different degrees of tonicity. He also warns that the preparation be kept from being heated by (the infrared rays from) the light source. See Inoué, 1952b, for effect of temperature on the birefringence of spindle fibers (polymerization of spindle microtubules), which serves as a sensitive intracellular thermometer.

[b]Prepare fresh in glass-distilled water each month and store in refrigerator.

[c]On day of use, dilute 5 ml of stock solution to between 27 and 38 ml (start with 32 ml) with glass-distilled water. The final optimum concentration depends on the extent of evaporation during culture preparation and the physiological state of the animals; the required dilution usually does not change over a period of a week or two.

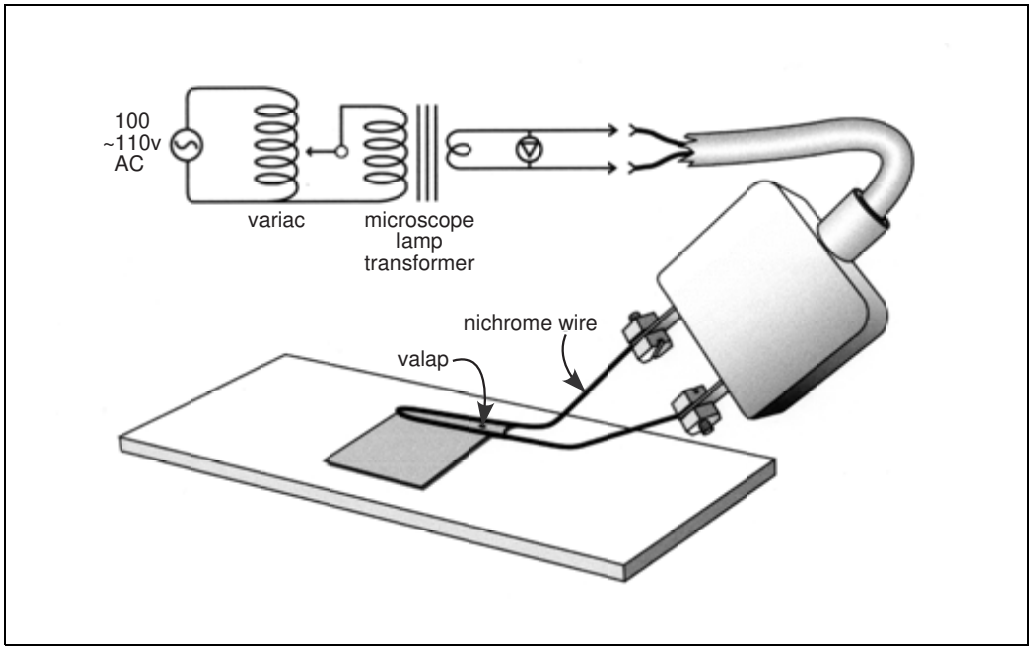

Figure 4.9.11 Electric heater for sealing coverslips with Valap. A 5-in.-long piece of ~20-G nichrome wire is bent as shown and attached, via a convenient handle (e.g., a two-pronged AC plug), to a variable voltage transformer (e.g., one used to power a low voltage microscope lamp). The melted Valap, that has formed a bridge by capillarity between the arms of the nichrome wire loop, is transferred to and painted along the edges of the cover slip.

baseline for understanding the submicroscopic organization and its changes in these cells. That baseline is an important yardstick to heed in considering whether the fine structure of the cell has remained intact when one fixes a cell, or tissue, in preparation for electron microscopy, cytochemistry, or other technique.

When the same cell loses, gains, or changes its birefringence appreciably upon fixation, one needs to wonder whether the fixation itself may not have abolished, created, or altered the fine structure of the cell component. Note that the refractive index of the medium in which the fine structure is immersed also affects the form birefringence of the structure.

For example, prior to introduction of glutaraldehyde as a fixative, spindle and other labile microtubules tended to disappear with standard osmium fixation (Inoué, 1993). Even with glutaraldehyde fixation, there is the possibility that not all of the labile microtubules are preserved (Sato et al., 1975). Given the preparative techniques used for electron microscopy today, we may still be unaware of the loss in fine structural organization encountered by some of the cell's labile filament or membrane systems (e.g., see Burgos et al., 2000).

Acknowledgments

The author is grateful to: Dr. Bruce Nicklas of Duke University for providing updated information on grasshopper Ringer's solutions and on Halocarbon oils, Jan Hinsch of Leica for providing the original for Fig. 4.9.2 and for help with locating references, Drs. Rudolf Oldenbourg and Michael Shribak of the Marine Biological Laboratory for comments on a draft version of the article, Drs. Edward D. Salmon, Nina Allen, and Sid Shaw for help in locating references, the Woods Hole Oceanographic Institution Graphics Services Group for expert help in preparing the figures, and Jane MacNeil of the Marine Biological Laboratory for her tireless help in preparing this article.

Fluorescent Speckle Microscopy (FSM) of Microtubules and Actin in Living Cells

This unit describes the execution of an epifluorescent microscopic method, fluorescent speckle microscopy (FSM), that allows visualization of assembly/disassembly dynamics, movement, and turnover of macromolecular assemblies in vivo and in vitro. Microinjection or expression in living cells of fluorophore-conjugated proteins followed by their incorporation into cellular structures and visualization by fluorescence microscopy has yielded much information about protein localization and dynamics (Wang, 1989; Prasher, 1995). However, this method has been limited by high-background fluorescence from unincorporated and out-of-focus incorporated fluorescent proteins and difficulty in detecting movement of fluorescent structures because of their uniform labeling. These problems have been partially alleviated by use of more cumbersome methods of laser photobleaching and photoactivation of fluorescence in which a portion of molecules in a structure is marked and the behavior of the molecules in the marked region is monitored (Wolf, 1989; Mitchison et al., 1998). In contrast, FSM uses a very low concentration of fluorescent subunits that co-assemble with endogenous unlabeled subunits giving a structure with a speckled appearance in high-resolution fluorescence images (Waterman-Storer et al., 1998; Fig. 4.10.1). The appearance, disappearance, and movement of speckles stand out to the eye in time-lapse FSM. These changes in fluorescent speckle pattern correspond to the assembly, disassembly, and movement of the structure and can be quantitated (Waterman-Storer et al., 1999). FSM images are captured using conventional wide-field fluorescence light microscopy and digital imaging with a low-noise, cooled charge-coupled device (CCD) camera. FSM provides information about protein dynamics throughout the field of view, as opposed to within a small marked region of the cell as is the case for laser photobleaching and photoactivation of fluorescence techniques. FSM also significantly reduces out-of-focus fluorescence and greatly improves visibility of fluorescently-labeled structures and their dynamics in thick regions of living cells (Waterman-Storer et al., 1998). Finally, the low level of fluorescent protein used in FSM is much less likely to perturb cellular protein balance thereby reducing the chances of artifactual changes in cell behavior due to the effects of protein "overexpression."

This unit will focus on the utilization of FSM for observing microtubule and actin cytoskeletal dynamics in vivo. For microtubules, which can easily be distinguished in fluorescence light microscopy as single filaments both in vivo and in vitro, the fiduciary marked filaments seen in FSM will allow one to unequivocally distinguish between microtubule translocation as powered by motor proteins and microtubule treadmilling, in which one end of the polymer assembles concomitant with polymer disassembly at the other end (Waterman-Storer and Salmon, 1997). Microtubule FSM also allows observation of microtubule behavior within mitotic spindles containing many hundreds of microtubules and in the central regions of interphase cells. For actin, FSM can be used for studying the assembly dynamics and retrograde movement of actin meshworks in the leading lamella of migrating cells (Waterman-Storer et al., 1998).

STRATEGIC PLANNING

General

Successful FSM requires knowledge and experience in high-resolution epifluorescence microscopy, basic tissue culture and biochemistry skills, and considerable skill in single-cell microinjection and handling of cells for live-cell imaging. This unit provides detailed information in basic protocols for designing a digital microscope system for obtaining

Current Protocols in Cell Biology (2002) 4.10.1-4.10.26

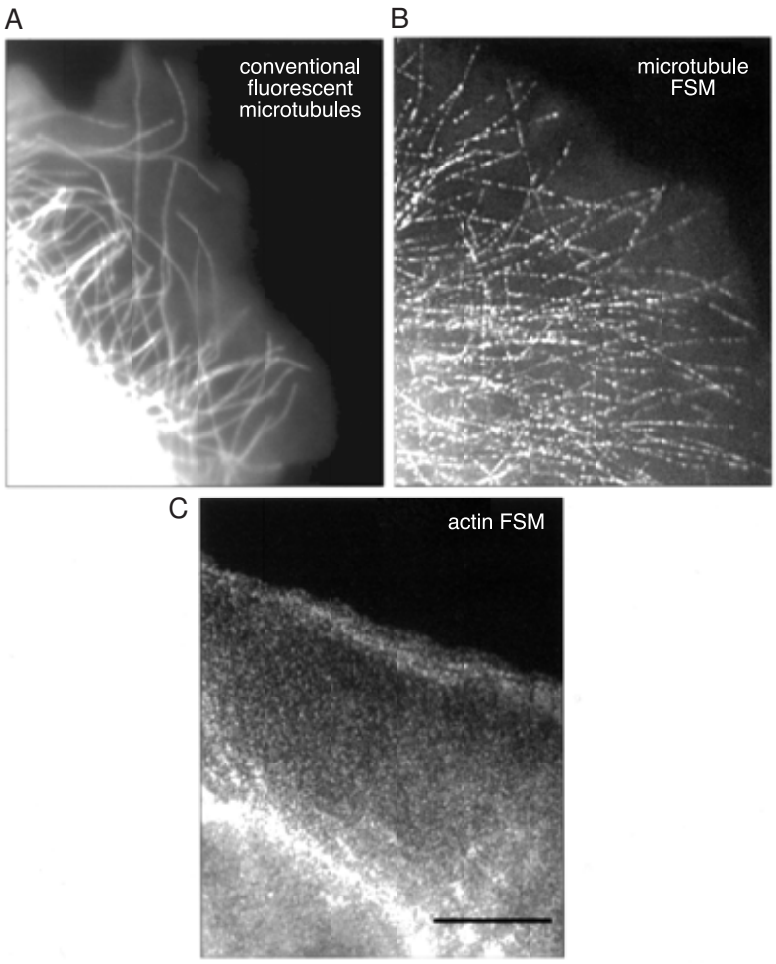

Figure 4.10.1 FSM images of actin (**C**) and microtubules (**B**) in the lamellae of living epithelial cells. A comparison of conventional image of fluorescent microtubules (**A**), labeled with X-rhodamine tubulin, in which labeled tubulin makes up ~10% of the cellular tubulin pool with microtubule FSM (**B**), X-rhodamine tubulin, in which labeled tubulin makes up 0.5% of the tubulin pool. In the conventional image (**A**), there is a high background fluorescence that masks details in the central regions of the cell, and the microtubules are continuously labeled along their lengths, devoid of fiduciary marks. In the FSM image (**B**), the background fluorescence is low, there is no loss in the ability to see the full length of the individual microtubules, and they are covered with fiduciary marks. The images were taken on the same imaging system with the same objective lens. The exposure time for (**A**) was ~200 msec while that for (**B**) was 1500 msec. (**C**) FSM image of a cell injected with low level of X-rhodamine labeled actin. Note the speckled appearance of the lamella, which is made up of a very dense meshwork of cross-linked actin filaments. Bar = 10 μm, all images are at the same magnification.

time-lapse FSM images (see Basic Protocol 1), tips for success in live-cell fluorescence microscopy (see Basic Protocol 2), and basic quantitative analysis of FSM images (see Basic Protocol 3); and support protocols for fluorescent labeling of tubulin (see Support Protocol 1) and actin (see Support Protocol 2). Please refer to *UNIT 4.2* for information on basic fluorescence microscopy, *UNIT 1.1* for cell and tissue culturing, and details of how to carry out single-cell microinjection.

Prior to performing FSM imaging, good quality fluorescently labeled protein must be prepared. Labeled proteins that have given good results in FSM applications can be obtained commercially from Cytoskeleton, Inc.. However, if imaging cytoskeletal dynamics is going to be ongoing in the laboratory, it is much more economical to prepare the proteins oneself. For making fluorescent tubulin, unlabeled tubulin must first be made.

Tubulin purification requires a source of fresh pig or cow brains, and can be prepared by the method described in *UNIT 13.1*, Support Protocol 3. Fluorescent labeling of actin requires a source for muscle acetone powder. Although the powder is available from Sigma, better quality acetone powder can be obtained from a laboratory that specializes in actin biochemistry (generally, these laboratories store large quantities in freezers), or alternatively, it can be prepared by the method of Pardee and Spudich (1982).

Choice of Fluorophore

Support Protocols 1 and 2 describe preparation of tubulin and actin, respectively, that is covalently bound to a succinimidyl ester derivative of the fluorophore of choice. The Molecular Probes catalog is an excellent source of information about the chemistry of fluorophores. Succinimidyl ester derivatives react with lysine residues that are accessible on the surface of the protein. For both tubulin and actin, there is more than one lysine available for reaction, thus, there is the opportunity for higher dye-to-protein ratios, and therefore, brighter fluorescence. For tubulin labeling, succinimidyl esters have, historically, given the greatest success in yield and functional product capable of polymerization and depolymerization (Hyman et al., 1991). Actin labeled with 5-iodoacetamide, which reacts with a single cysteine residue (cys374) on actin, has been well characterized (Wang and Taylor, 1980), however, the dye-to-protein ratio is lower than labeling on lysines.

In choosing the "color" (excitation and emission spectrum) of the fluorophore for FSM imaging, there are two things to keep in mind—the phototoxicity effects on cells of particular wavelengths and endogenous cellular auto-fluorescence. Cells are sensitive to and damaged by short wavelengths; these effects are manifested as retraction of the cell edge, rounding up, and eventually death. Thus, fluorophores that excite at <450 nm (e.g., Coumarin, pyrene) should not be used. Even wavelengths between 450 and 500 nm that excite fluorescein-like dyes (e.g., FITC, Oregon green, Bodipy FL, Alexa 488, or Cy-2) can produce phototoxicity. However, excitation wavelengths beyond the visible (>700 nm, infrared) should be avoided, as well, due to heating effects. The best choice in terms of minimizing phototoxic effects are yellow/orange (570 to 600 nm, tetramethylrhodamine, TAMRA, Cy-3, Bodipy TMR, Alexa 546), orange/red (600 to 630 nm, Lissamine rhodamine, X-rhodamine, Alexa 568, Texas red), or far-red emitting dyes (>630 nm, Cy-5). Of these, the longer wavelength exciters are better, although emission of dyes such as Cy-5 are very difficult, if not impossible, to see by eye, and thus, are problematic to work with. The author's best success with FSM has come from using the X-rhodamine, Alexa 568, or Texas red fluorophores.

Cellular auto-fluorescence is caused by flavo-proteins that excite in the UV and blue, and emit in blue and green (450 to 550 nm) wavelengths. This auto-fluorescence contributes to background when using fluorescein (FITC) or fluorescein-like dyes, and it "dilutes" the speckle contrast. The author has found this effect to be particularly problematic for actin FSM, in regions of the cell where actin filaments make up cross-linked meshworks that appear as uniform, dense fields of speckles in FSM images (Fig. 4.10.1). If the use of green emitters is unavoidable, as is the case in the author's laboratory where microtubules and actin are labeled with spectrally distinct fluorophores and monitored by dual wavelength FSM, green emitters can be used with some success for microtubule FSM.

From this discussion, it is apparent that low-level expression of green fluorescent protein (GFP) fusion proteins are not optimal for FSM. First, there is the problem of cellular autofluorescence. Second, the large size (23 kDa) of the GFP moiety, often results in a sizable proportion of the expressed fusion protein losing its ability to functionally incorporate into the cytoskeleton, contributing to background fluorescence. A third problem is the lack of a suitable method for preventing photobleaching of GFP. Finally,

the brightness (quantum efficiency) of the GFP fluorophore is much lower than chemical fluorophores. For studying a microtubule-binding protein, the author has alleviated this last problem to a large degree by fusing multiple (3 to 5) GFP molecules in tandem, joined by short flexible linkers, to the microtubule binding domain of the protein and selecting cells for imaging that express very low levels of the fusion protein (Faire et al., 1999). However, this approach would be unadvisable for actin or tubulin, which would surely be rendered dysfunctional by the incorporation of a 75- to 125-kDa attachment.

BASIC PROTOCOL 1

DESIGNING A MICROSCOPE SYSTEM FOR TIME-LAPSE DIGITAL FSM

As opposed to a step-by-step protocol, in this section, the basic components needed to set up an FSM system are discussed, giving the recommendations for critical elements required in each type of component (Fig. 4.10.2). It is *imperative* that one reads the Background Information on the theory of FSM image formation before one attempts to understand how and why particular components are chosen for the imaging system.

After reading the discussion of FSM image formation (see Background Information), it is clear that there are three key elements of the microscope imaging system to ensure successful FSM imaging. First, the epifluorescent microscope should be as efficient as possible at collecting photons and should be capable of high-resolution, high-magnification imaging. This is achieved with high-quality, 1.4-NA oil-immersion objective lenses with minimal lens elements. Additionally, this requires a simple optical path between the specimen and camera with as few intervening components as possible. Second, the camera should be highly sensitive, low noise, and should have high enough spatial resolution to match the resolution of the microscope. These properties are met by several cooled CCDs available on the market today. Finally, since fluorophores are subject to photobleaching, light exposure to the specimen should be kept to a minimum. This is accomplished through the use of an electronically controlled shutter on the epi-illuminator that only opens during the time of camera exposure. In addition, a computer with a digital image acquisition board and software for controlling the shutter and image acquisition timing are needed to integrate the system.

Materials

Upright or inverted epi-fluorescent microscope and optics including:
- Epi-illuminator
- High-magnification objective lens (e.g., 60×, 63×, or 100×)
- Excitation filter, emission filter, and dichromatic mirror
- Electronically controlled shutter
- Cooled CCD camera
- Computer, digital image acquisition board, and software for control of shutter and image acquisition

Microscope stand

Upright or inverted epi-fluorescent microscope and optics

1. The microscope stand should be of biological research quality, with a substantial mass that resists vibration and is not subject to temperature-induced expansion and contraction.

   If possible, the microscope should be mounted on a vibration isolation table. The focusing system should be of high quality, with a means by which to lock focus during long-term time-lapse imaging, since slight shifts in focus result in changes in speckle intensity that can be artifactually interpreted as cytoskeletal dynamics.

2. The microscope should be equipped with a high quality epi-illuminator including a 100-W HBO mercury arc lamp, and a lamp housing with a parabolic mirror that

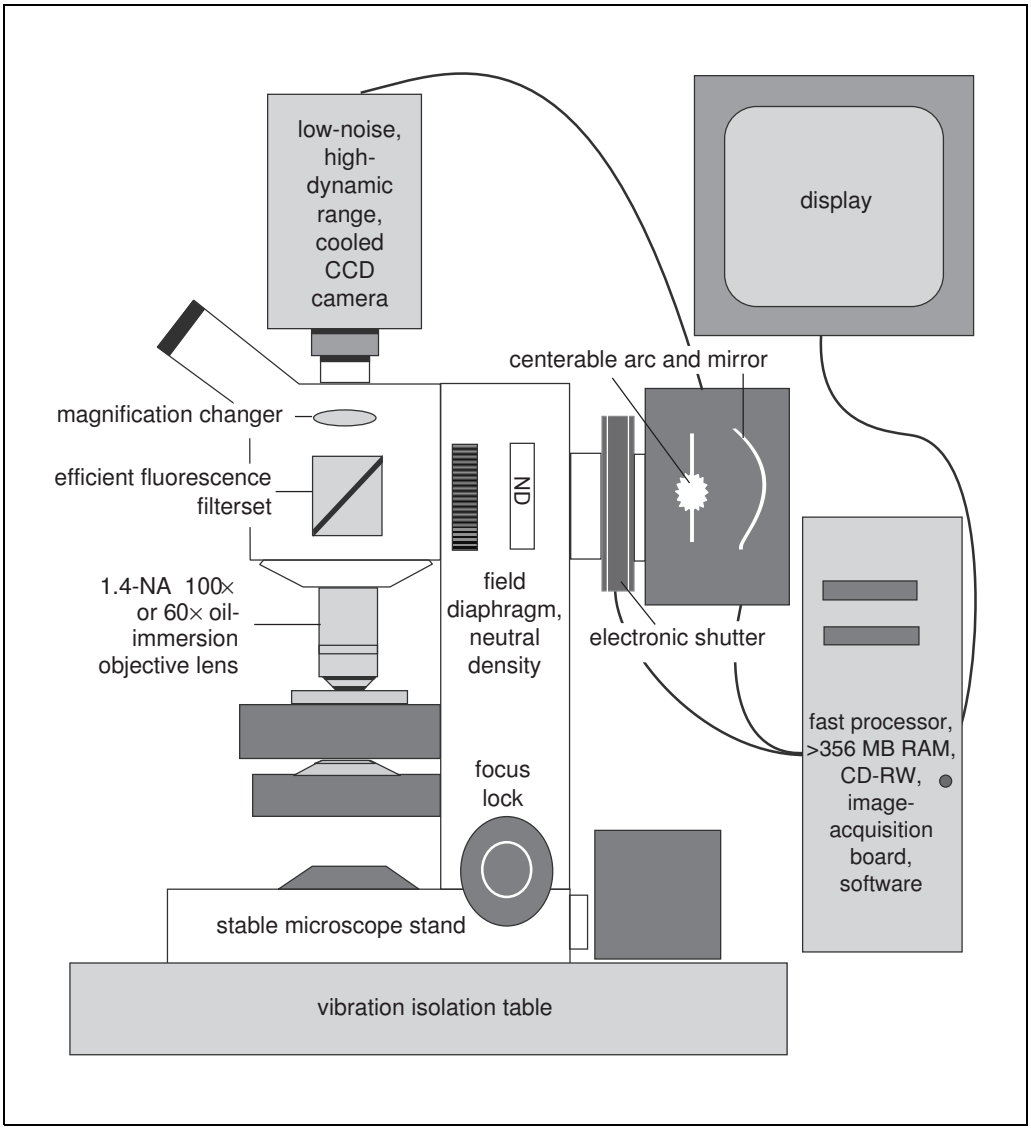

Figure 4.10.2 Diagrammatic view of the components of an upright FSM imaging system. See Basic Protocol 1 for details.

allows manual control of bulb and mirror centration for proper alignment of Köehler epi-illumination.

It is very helpful, though not necessary, to have manual control of centration and size of the field diaphragm of the epi-illuminator. Closing down the field diaphragm to just the area of the specimen being imaged reduces photo-damage to the whole specimen and reduces out-of-focus fluorescent flare in the image. Similarly, it is helpful if the epi-illuminator is equipped with slots in which to insert neutral density filters to control specimen illumination. An infrared blocking filter can also be included in the illumination path to minimize exposure of the specimen to damaging heat.

3. The objective lens (which also acts as the condenser in epi-illumination) should allow the highest resolution possible, thus, one with the highest numerical aperture available, i.e., 1.4-NA oil-immersion; and magnification of 60×, 63×, or 100×, the choice being dependent on the spatial resolution of the camera detector (see Matching Microscope and Detector Resolution below).

Keep in mind that 60× or 63× lenses are often more efficient at transmitting light than 100× lenses. However, never sacrifice system resolution for this small gain in light detection. The

lens should not contain contrast-forming elements such as phase rings that block transmission of photons. The lens should be corrected for chromatic aberration (apochromatic) and should be highly efficient at passing the wavelengths of light being imaged, which depends on the choice of fluorophore. Ask the manufacturer for information on the spectral efficiency of the lens.

When imaging a small specimen, it is not necessary that the lens be flat-field corrected (plan-corrected). Indeed, often objectives specifically designed for efficient epi-fluorescence (Super Fluor-, Nikon; Fluor-, or Fluar- lenses) are not plan-corrected because this correction adds glass elements to the lens, and the more glass elements, the more places to lose photons. However, for a flat, wide–field view, the author has had good luck using DIC-grade plan apochromat objectives.

4. The excitation and emission filters and a dichromatic mirror should be as efficient as possible for exciting the fluorophore, separating the excitation from emission, and collecting the emission of the fluorophore of choice. The use of long-pass filters rather than band-pass filters may maximize this efficiency.

5. The path from the objective to the detector should be simple and contain as few intervening components as possible to allow maximum photon collection. Remove analyzers, wave plates, and Wollaston prisms that are used for various modes of polarization microscopy. Optovars or magnification changers should be optimally removed; however, if needed to match the microscope resolution to the detector resolution (see below), this is a source of light loss that will have to be tolerated.

6. The camera port should utilize the most direct path from the specimen. For an upright microscope, this would be the one port directly over the objective, and for an inverted configuration, a bottom or "Keller" port underneath the microscope is best. Remove prisms from the light path that split the image between the ocular and camera port.

   The bottom port requires a hole in the table upon which the microscope is seated, in order to accommodate the camera. If this is not possible, a side camera port, which requires one mirror to direct the image to the camera is better than a front port that requires at least two mirrors.

Electronically-controlled shutter

7. The electronically-controlled shutter should be mounted with proper adapters in the light path between the lamp-house and the epi-illuminator.

8. The shutter should be mirrored on the surface facing the lamp to reflect heat away from the specimen.

9. The shutter should operate quietly, quickly, reliably, and without excessive vibration. Obtain a shutter that can be actuated from a software triggered pulse via the serial or parallel port of the computer.

Cooled CCD camera

10. The camera should be a scientific-grade slow-scan cooled CCD camera; a video-rate CCD camera equipped with a cooling device cannot be substituted. The choice of camera will be discussed in terms of the choice of the CCD chip itself and then the electronics of the camera in which the chip is housed. Various combinations of the two are available from different camera manufacturers. For a general introduction and in-depth discussion of CCD cameras, see Inoué and Spring (1997).

The CCD chip

11. *Spatial resolution.* The spatial resolution is determined by the physical size of the silicon photodiodes or "pixels" on the CCD chip. These currently range in size from ~6 × 6– to 30 × 30–μm. The larger the pixel size, the more magnification from the

microscope will be needed to ensure resolution-limited images. Thus, smaller pixel size is better for FSM as it will not require photon-robbing magnification changers or Optovars in the light path. The total number of pixels making up the CCD and the pixel size will determine the imaging area.

12. *Spectral sensitivity.* Different types of CCD's have specific probabilities at any given wavelength of converting a photon to a photoelectron that is counted as signal by the camera, i.e., quantum efficiency (QE). For example, a Sony HyperHad CCD has ~45% chance of converting a green photon to a photoelectron (45% QE for green light) and a ~25% QE for red light. Thus, this CCD is much more efficient at detecting green fluorescence than red. Manufacturers supply graphs of the wavelength versus QE for their available CCDs. A CCD should be chosen that has spectral sensitivity for the fluorophore of choice.

13. *Illumination geometry.* CCDs can be illuminated from their front or back sides. Illumination from the front requires that the light pass through substrate materials to reach the photosensitive area, reducing QE. Back-illuminated CCDs are physically thinned to allow illumination directly on the back side of the photosensitive surface, making them much more sensitive (also much more fragile and expensive). However, because of the thinning process, there are limits to the size of the pixels, usually around ~25 × 25–μm, with the smallest currently available at 13 × 13–μm. Thus, one has to weigh whether the increased sensitivity is worth the loss in having to put an Optovar in the image path, as well as whether one can afford the expense. For FSM applications, sensitive front-illuminated CCDs have worked quite well.

14. *Readout geometry*. Once photons are converted to charge in the array of pixels, the charges must be read out to an image acquisition board so that the image can be reconstructed in the computer by assigning a gray value to the relative charge at each pixel position. Charges are transferred out of the CCD in three basic ways. Full-frame readout occurs as each row of pixel charges is transferred serially out of the CCD one row after another. This type is the slowest and introduces the most noise into the image, although, this type of readout is still acceptable for FSM if other camera electronics do not introduce sources of noise. In contrast, in frame-transfer and interline-transfer CCDs, either the entire pixel charge array or whole rows of pixels are rapidly transferred to an array of pixels that are masked from light. The charges are then read out from the masked area while the imaging area is being exposed to light again. These types are much faster and less noisy than the full-frame readout. Frame-transfer CCDs tend to be more expensive and interline-transfer CCDs suffer from lower resolution, although this problem has been overcome in recent years. Thus, all three geometries are acceptable for FSM, although the increased speed of the interline-transfer CCD may offer an advantage for increasing image-acquisition rate to observe actively ruffling cells or microtubule motor activity.

Camera electronics

15. A CCD with the lowest temperature cooling system within the means of one's budget should be chosen. Heat on the CCD can be interpreted by the photodiodes as light, thus, contributing to image noise. Different camera manufacturers will house the same CCD in cameras with different degrees of cooling ranging from 20°C below room temperature to −50° or −60°C. Do not choose the least expensive CCD because heat is an avoidable source for noise that can easily mask the very faint FSM signal.

16. *Readout speed.* In general, the faster the readout speed, the more error is introduced during charge transfer, which translates to noise in the image. Speeds in modern cameras range from 100 kHz in some low-noise back-illuminated cameras, to 14 to

15 MHz in interline- and frame-transfer cameras. For quantitative FSM imaging of cytoskeletal dynamics, image acquisition rates of 1 to 2 images/sec may be required, which cannot be accomplished by the slower cameras. Here, a reasonable compromise of speed and low noise must be sought, but it is recommended not to buy a camera much slower than 1 mHz.

17. *Dynamic range.* Although the total number of photons that can be absorbed by each pixel before it is saturated with charge is set for a given CCD, the number of gray levels this amount of charge is divided up into for display is not fixed. It can be represented by 8, 10, 12, 14, or 16 bits of information per pixel, corresponding to 256, 1024, 4096, 16,384, or 65,536 (2^8, 2^{10}, 2^{12}, 2^{14}, or 2^{16}) gray levels, respectively. For FSM imaging of very dim specimens, it is important to have the biggest dynamic range possible (again, within a reasonable budget). This is required so that there will be finer gradations of gray within the very small portion of the dynamic range that is utilized. Successful FSM has been achieved using 10-bit cameras, although ≥12 bits/pixel is recommended.

18. *Subarraying and binning.* Being able to read out only a specified portion of the CCD (subarraying) can increase image acquisition speed for imaging small areas of a cell, but it is not necessary. Binning, in which the charges in a group of pixels are combined and read out as a single pixel to increase sensitivity should not be done in FSM, as this effectively increases pixel size and decreases CCD resolution.

Computer, digital image acquisition board, and software for control of shutter and image acquisition

19. A computer with the fastest processor and most random access memory (RAM) affordable should be used. Time-lapse FSM image series are large files often on the order of ≥100 MB, and computer "horsepower" is necessary to view and manipulate these.

    The author recommends ≥356 MB of RAM.

20. *File storage.* A compact disc read/write (CD R/W) device is the most economical choice recommended to archive the large files generated by time-lapse FSM. The fastest write speed available within budget should be chosen.

21. Use the image acquisition board recommended by the camera and software manufacturer, making sure that the board can handle the bit depth of the camera. Many cameras come with their own boards.

22. Software should be capable of time-lapse digital image acquisition and triggering the shutter during camera exposure. The software should allow easy viewing of time-lapse series as movies, with control of play-back rate and adjustment of brightness and contrast in the entire image series. Basic image processing including the ability to perform low-pass filtering and image arithmetic (subtraction, multiplication, etc.) is required. The software should provide the ability to perform quantitative analysis of intensity, position, and distance.

    The author has used MetaMorph (Universal Imaging) with outstanding success. However, NIH-Image freeware (http://rsb.info.nih.gov/nih-image/) is also very versatile and many free macros are available.

Matching microscope and detector resolution

23. The key to actually achieving resolution-limited images of fluorescent speckles is matching microscope and detector resolution. Magnifying the diffraction-limited spot to the size of 3 pixels on the CCD is required so that the CCD does not limit

imaging system resolution or produce aliasing between pixels. This is called the Nyquist sampling criterion. Any magnification over this value does not contain any more information and simply reduces the area of the specimen that is imaged. The magnification (M) required to achieve this is given by

$$M = 3(P_{width})/r$$

where P_{width} is the width of a pixel on the CCD and r is the size of the diffraction-limited spot. Thus, for red fluorescence with a resolution limit of 0.27 μm (for red fluorescence, see Background Information) and a camera with 6.7-μm pixels, the magnification required to satisfy the Nyquist criterion is 74.4×. Thus, either a 100× objective or a 60× with a 1.25× Optovar should be used, whichever transmits more light.

TIME-LAPSE FSM IMAGING OF THE CYTOSKELETON IN LIVING CELLS

BASIC PROTOCOL 2

This protocol describes how to handle living cells for FSM imaging. Included are basic recommendations for microinjection, detailed instructions for prevention of photobleaching, and image acquisition. Photobleaching of chemical fluorophores (not GFP) is dependent on dissolved oxygen in the medium. Thus, photobleaching can be substantially prevented by removal of dissolved oxygen, in this case, with a commercial product, Oxyrase, and by then sealing the imaging chamber from contact with air (Waterman-Storer et al., 1993).

Materials

~0.5 mg/ml labeled cytoskeletal protein (tubulin or actin, see Support Protocols 1 or 2, respectively)

Cultured tissue cells grown on 22 × 22–mm glass coverslips in small plastic petri dishes

Valap (*UNIT 13.1*)

Buffered filming medium (see recipe)

Oxyrase EC (Oxyrase Inc.)

Microultracentrifuge (Optima TL or TLX, Beckman Instruments; or Discovery M120, Sorvall)

0.6-ml microcentrifuge tubes

Swinging bucket rotor for microultracentrifuge with adapters for holding 0.6-ml microcentrifuge tubes (for the Beckman TLS-55 rotor, the standard thick-walled 1.4-ml polycarbonate tubes are used; and for the Sorvall, custom adapters are needed)

Microinjection needles (see recipe)

Microloader pipet tips (Eppendorf or equivalent) or narrow-gauge syringe (narrow enough to fit in the bore of the microinjection needle, Hamilton Company)

Single-cell microinjection system capable of controlled backpressure of 0.1 to 20 psi and with a precision micromanipulator for injection of single cells, mounted on an inverted microscope equipped with a long-working-distance phase-contrast condenser and a 40× dry phase-contrast objective lens with a working distance long enough to focus through the plastic petri dish and coverslip.

Microscope stage incubator (optional)

1 × 3–in. glass microscope slides

Scotch double-stick tape (3M)

Cotton swabs

FSM imaging system (see Basic Protocol 1)

Prepare labeled cytoskeletal protein

1. Cool the microultracentrifuge and rotor to 4°C.
2. Rapidly thaw and immediately place on ice a 3-µl aliquot of ~0.5 mg/ml labeled cytoskeletal protein.
3. Pellet insoluble protein in the sample. Cut off the lid of the 0.6-ml microcentrifuge tube containing the labeled protein and place the tube in the polycarbonate adapter for the swinging bucket rotor. Make sure to place a balance tube in the opposite bucket. Microultracentrifuge 20 min at 77,000 × *g* (Beckman TLS-55 rotor at 30,000 rpm), 4°C.

   Do not microultracentrifuge any faster, as this will crush the microcentrifuge tube.
4. During the microultracentrifugation, locate the cultured tissue cells to be injected on the microscope stage using a 40× phase-contrast objective lens.

   All manufacturers correct their high-resolution optics for the thickness of a no. 1.5 coverslip.

   Cell choice is obviously dependent on the biological question; however, it is advisable to choose flat, large, well-spread cells as these are better for microinjecting and imaging. PtK1 are a favorite for mitosis studies, while Swiss 3T3 are a favorite for cell locomotion studies.
5. Following microultracentrifugation, promptly remove the sample from the microultracentrifuge and transfer to ice.

Microinject cells with labeled protein

6. Backload a microinjection needle with ~0.5 µl of protein solution using either a microloader pipet tip or a narrow-gauge syringe.

   Be careful not to touch the insoluble pellet when retrieving the solution from the microcentrifuge tube.
7. Microinject several cells in the center of the coverslip using ~0.5 to 1.5 psi constant pressure.

   The constant flow from the needle helps to keep it from clogging.

   It is not recommended to transiently increase the pressure during microinjection, as this will result in too much fluorescent protein in the cells, ruining the speckle effect.
8. Return the cells to a 37°C, 5% CO_2 incubator for 1 hr to recover from microinjection and to allow incorporation of labeled protein into the cytoskeleton.
9. During this time, place filming medium in a 37°C water bath, melt Valap on a hot plate set on low; and turn on the microscope, camera, and stage incubator to allow temperatures to equilibrate.

   A microscope stage incubator is only required for cells from warm-blooded species. An incubator can be as simple as a home hair blow dryer custom-fitted with a rheostat for control of the heating coils and a thermometer taped to the stage.

Mount cells for imaging

10. Just prior to mounting the specimen, prepare 1 ml of buffered filming medium containing 20 to 30 µl Oxyrase EC.

   The amount of Oxyrase the specific cell type can tolerate must be determined empirically. Some cells are more sensitive to oxygen deprivation than others. For sensitive cells (such as PtK1), make sure the filming medium is prepared with high glucose medium, so that extra glucose will be available for anaerobic metabolism.

11. Prepare a filming chamber by placing two 3 × 30–mm strips of double-stick tape side by side 1 cm apart and parallel with the long axis onto a 1 × 3–in. glass microscope slide to form a channel where the cells will be.

12. Retrieve the coverslip containing the injected cells from the dish of medium, dry the back side and the edges that will be placed on the tape strips, and place the coverslip, cell-side down onto the tape so that the area containing the injected cells lies between the strips of tape.

    Press the coverslip into place to form a good seal with the tape.

13. Add Oxyrase-containing filming medium to the cell "chamber" by pipetting it against the edge of the coverslip between the strips of tape. Exchange the medium several times by wicking away medium with filter paper from the opposite open end of the chamber while pipetting.

    Be sure not to introduce any bubbles into the chamber during pipetting as the presence of air in the chamber will cause problems with photobleaching.

14. Carefully dry the edges of the specimen chamber (do not introduce bubbles) and use a cotton swab to apply melted Valap along all edges of the coverslip to seal it completely to the slide.

Observe mounted cells

15. Allow the slide to equilibrate to the proper temperature on the microscope stage for 10 to 15 min. Turn the room lights off to allow one's eyes to adapt to the dark.

16. Use epifluorescent illumination to locate the fluorescent-injected cells.

    The cells should be quite dimly fluorescent and may not be visible with a low-power, low-NA objective lens, therefore, one may have to search with an oil-immersion lens. After locating the cells, switch to high-magnification, high-NA objective lens. At this point, be careful about illuminating the specimen and causing photobleaching—look only as long as needed to get a cell in focus and centered in the field of view then quickly shutter the light. Use of neutral density filters to attenuate illumination during focus and centration may also be helpful in preserving the fluorescence in the specimen.

    Cytoskeletal polymers are excluded from the nucleus; cells with fluorescent nuclei are likely dead. Dimly fluorescent individual microtubules should be visible by eye, while fluorescent actin should be rather diffuse throughout the cell and perhaps brighter in stress fibers.

17. Pick a dim cell to start with because microinjection will result in cells of varying fluorescent brightness.

    With practice, one will be able to judge by eye the brightness required for good FSM.

18. Illuminate only the area of interest by adjusting the field diaphragm of the epi-illuminator.

Optimize camera conditions and acquire time-lapse images

19. Optimize exposure time. First, make sure the camera is set to the maximal dynamic range possible and set the image display to "autoscale." Without autoscaling, the image will likely appear black since the FSM image is expected to use a very small portion of the low end of the dynamic range of the camera. Then, take a 500-msec "dark image" image with the illuminating light shuttered to get a measurement of the background gray level of the camera. Next, be sure the illumination shutter is set to synchronize with the camera exposure. Then, take images of the fully illuminated specimen (no neutral density filters), trying to get the specimen signal to ~10% higher in gray level value than the background.

For example, if the background gray level in a 14-bit (16,384 gray level) camera is 500, try for an exposure that will give the specimen a gray level of ~550. The sample should be dim enough that this very small amount of signal above the noise should require a rather long exposure time. A good starting point is 500- to 1000-msec exposures, but upwards of 2000 msec may be required.

The time of exposure will vary depending on the camera used, the brightness of the sample, the age of the arc lamp, and the tolerance of the specimen to light. Signs of photo-damage include cessation of cell motility, retraction of cell lamellipodia, or blockage of mitotic progression.

20. Optimize focus. Take exposures while slightly adjusting the fine focus until the best focused–fluorescent speckles can be seen. Then, lock the focus.

    If the actin network does not appear speckly, or if individual microtubules do not appear discontinuously labeled along their lengths, there is too much labeled protein in the cell. Find another, more dimly labeled cell.

21. Acquire time-lapse image series. For following actin movement, acquire images every 10 to 30 sec. For following microtubule dynamics and movement, acquire images at 3- to 10-sec intervals. Image as long as is needed or until the sample is photobleached.

BASIC PROTOCOL 3

QUALITATIVE AND QUANTITATIVE ANALYSIS OF TIME-LAPSE FSM IMAGE SERIES

Methods are presented to extract measurements of speckle movement and lifetime to determine polymer velocities and turnover times.

Materials

Stage micrometer (Fisher)
Image analysis software

1. Calibrate the pixel-to-distance conversion factor. Take an image of a 10–μm stage micrometer using the objective lens used for image acquisition.

   The number of pixels in 10–μm is used to calculate the pixel-to-distance conversion factor. Most software packages will allow this factor to be input so that measurements made are automatically reported in micrometers as opposed to pixels.

2. Adjust the brightness and contrast of the image series to maximize the speckle appearance.

3. Play the time-lapse series as a movie, paying attention to the movement, appearance, and disappearance of fluorescent speckles.

4. To enhance FSM images, perform an "unsharp mask" filter on each image in the time-lapse series (Waterman-Storer et al., 1999).

   This consists of performing a 9 × 9– or 10 × 10–low-pass filter on the image and then multiplying by a constant of 0.5. This low-passed, scaled image is then subtracted from the original image, and the result is multiplied by a constant to scale it to the same average gray level as the original image. This series of operations greatly enhances speckle appearance.

5. To measure speckle movement rates in complex fields of speckles such as the mitotic spindle or the actin-rich lamella of a migrating cell, perform kymograph analysis (Waterman-Storer et al., 1999; Fig. 4.10.3).

   There are two ways to make kymographs of speckle motion in an image series. In the first method, a narrow rectangular cursor is drawn on the image stack, with the long axis of the

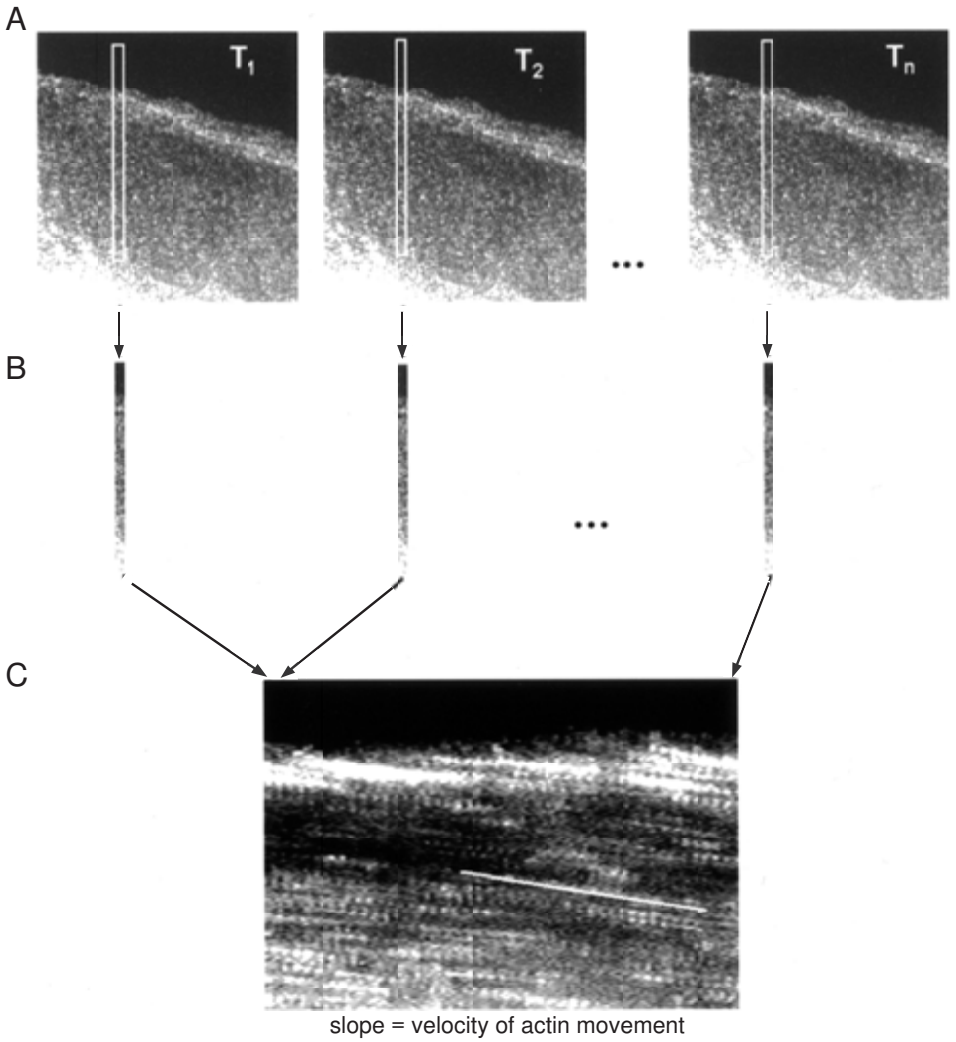

Figure 4.10.3 Construction of a kymograph. (**A**) A long thin rectangular region whose long axis is parallel to the direction of speckle movement is selected in each image in a time-lapse series (T_1- T_n). (**B**) This region is extracted from each image and pasted side-by-side in a montage to form the kymograph (**C**). As speckles move along the axis of the rectangular region in the original image series over time, they appear as oblique streaks on the kymograph, the slope of which correspond to the velocity of speckle movement (see Basic Protocol 3).

rectangle aligned with the direction of speckle movement determined by viewing the series as a movie. The rectangle should be 2 to 4 pixels in width and the length of the area desired for motion analysis. This region of interest is then copied from each image in the time-lapse series, and pasted side-by-side in a montage to form the kymograph picture. By eye, the speckles within the rectangular region that are moving along its long axis produce oblique white lines in the kymograph, the slope of which yields the velocity of motion. The disadvantage of this method is that it only measures speckle movements in either horizontal or vertical directions.

The second method requires the image processing software to possess a "kymograph function." The MetaMorph system is used as an example. The point-to-point line drawing function in MetaMorph is used to draw a line in any direction along the direction of movement for motion analysis on the first image in the time-lapse series. This has the advantage that the line can curve with the curvature of motion. The "kymograph" routine in MetaMorph samples pixel intensity values along this line for each image in a series and

montages these values into an image where the horizontal direction is the pixel values measured along the line, and the vertical direction is lines from subsequent images in the time series. Measurements of distance in the horizontal direction are calibrated in micrometer units. Measurements of distance in the vertical direction must be calibrated to the total time of the number of images in the series. For example, if the images are recorded at 10-sec intervals and there are 50 images in the series, then the vertical distance of the kymograph corresponds to 500 sec. Velocities are determined by the slopes of the oblique trajectories of speckle movements in the kymographs.

6. Use single-speckle motion tracking to track the movement of single cytoskeletal polymers.

   Currently, this can only be done by hand, but software for automated tracking is being developed. Commercially available automated tracking software is incapable of tracking single speckles in a dense field of similar speckles, which in addition are often fuzzy, ill-defined, tiny, and subject to intensity changes due to slight shifts in focus. Hand tracking is done by measuring the distance of the speckle from its origin at time zero in each frame of the time-lapse series. This can often be done semi-automatically using software functions such as "track points" in MetaMorph. The distance over time can be used to calculate instantaneous velocities (change in distance from frame n to frame n + 1) or average velocities by performing regression analysis of the distance versus time data.

7. Measure speckle lifetime to give a value for the lifetime of the cytoskeletal filament, i.e., its rate of turnover.

   In theory, the intensity value of a single pixel at the center of a fluorescent speckle could be recorded at every point in time and the lifetime of the speckle determined from this "fluorescent life history." However, this is currently very difficult in practice because of problems with photobleaching, shifts in focus that affect speckle intensity, and minute movement of speckles in living specimens. Again, image analysis software that takes these problems into consideration is currently being developed.

SUPPORT PROTOCOL 1

PREPARATION OF FLUORESCENTLY LABELED TUBULIN FOR FSM

This is a modification of a protocol developed by Hyman et al. (1991; also see the Mitchison laboratory Web page, *http://iccbweb.med.harvard.edu/mitchisonlab/Pages/label.html*). In this method, tubulin is first polymerized to bury the sites of tubulin dimer-dimer interactions to mask them from being labeled, then polymerized tubulin is reacted with fluorophore. The succinimidyl ester derivative of the fluorescent dye reacts with lysine residues at a high pH. Tubulin is readily denatured at high pH, so the longer the labeling reaction is allowed to proceed, the lower the yield, therefore, do not exceed the recommended reaction time. The reaction is then quenched by lowering the pH, and the tubulin is cycled for a temperature-dependent round of depolymerization and repolymerization (see *UNIT 13.1* for more information on the biochemistry of tubulin) to select for the assembly competent labeled tubulin dimers before finally being depolymerized in microinjection buffer and frozen for storage. This method takes ~7 hr and should yield ~10 mg of labeled tubulin, which should be useful for 6 to 8 months frozen at −80°C.

Materials

10-ml aliquots of phosphocellulose-purified tubulin in column buffer (CB; totaling 40 to 60 mg of tubulin; *UNIT 13.1*)
CB/BRB-80 conversion buffer (see recipe)
100 mM GTP (see recipe)
Glycerol
Labeling buffer (see recipe)
High-pH cushion (see recipe)
Quench (see recipe)

Low-pH cushion (see recipe)
Succinimidyl-ester derivative of fluorescent probe of choice
Anhydrous DMSO
Injection buffer (IB; see recipe)
1× BRB-80 (see recipe for 10×)
1 M $MgCl_2$ (*APPENDIX 2A*)

37°C water bath
100- and 10-ml graduated cylinder
Parafilm
Ultracentrifuge (with a Beckman 70.1 Ti rotor; or equivalent)
13.5-ml ultracentrifuge screw-cap polycarbonate tubes
Manual pipet-pump type pipettor (VWR or equivalent)
1.6-ml microcentrifuge tubes
Microultracentrifuge (Beckman Optima TLX with TLA-100.4 rotor or Sorvall RC M120 GX with S100AT4 rotor)
5.1-ml microultracentrifuge polycarbonate tubes
7-ml dounce homogenizer with "B" pestle
Spectrophotometer with a small-volume quartz cuvette
0.6-ml UV-impermeant microcentrifuge tubes

Prepare tubulin

1. Thaw three to four 10-ml aliquots of phosphocellulose-purified tubulin (frozen off the column in CB; *UNIT 13.1*) by immersing tubes in a 37°C water bath and agitating gently and continuously until they are fully thawed. As soon as the solutions are fully thawed, transfer tubes to ice and pool the aliquots into a 100-ml graduated cylinder on ice.

2. Add 1/20 vol CB/BRB-80 conversion buffer and add 100 mM GTP for a final concentration of 1 mM. Allow tubulin to bind GTP for 5 min on ice.

3. Add 1/3 vol glycerol, cover the cylinder with Parafilm, and mix very well by gentle inversion.

4. Incubate 40 min in a 37°C water bath to allow tubulin to polymerize, gently mixing every 10 min.

   Make sure the water level in the bath is as deep as the liquid level in the cylinder so that the temperature is constant throughout the whole solution.

5. During this incubation prewarm the ultracentrifuge with a Beckman 70.1 Ti rotor, labeling buffer, high-pH cushion, Quench, low-pH cushion, and several 13.5-ml ultracentrifuge screw-cap polycarbonate tubes to 37°C.

   The rotor can be prewarmed by putting it in a watertight plastic bag and submersing it in warm water (in a separate 37°C water bath from the polymerization reaction). The centrifuge may only warm up to ambient temperature. If this is the case, so long as the rotor is at the proper temperature, the microtubules should be intact.

Isolate microtubules

6. At the end of the incubation, add 3 ml warm high-pH cushion to each warm 13.5-ml ultracentrifuge tube. Slowly layer the polymerized tubulin onto the cushion by using a manual pipet-pump to slowly drip the tubulin solution down the side of the ultracentrifuge tube, being careful not to mix the tubulin with the dense cushion. Divide the microtubule solution evenly among the ultracentrifuge tubes. Balance pairs of filled ultracentrifuge tubes to within 0.01 g, and remember to include the centrifuge cap.

7. Ultracentrifuge the microtubules 1 hr at 185,000 × *g* (Beckman 70.1 Ti rotor at 52,000 rpm), 37°C.

8. During the ultracentrifugation, make up 100 mM succinimidyl-ester derivative of fluorescent dye of choice in anhydrous DMSO in a 1.6-ml microcentrifuge tube. Warm to 37°C and vortex it well to get as much as possible into solution.

9. Just before microtubule ultracentrifugation is over (step 7), microcentrifuge the insoluble fluorescent dye solution for a few minutes at maximum speed, room temperature. Promptly collect the supernatant and transfer it to a new 1.6-ml microcentrifuge tube.

10. After the ultracentrifugation, note the position of the clear/pearlescent pellet in each tube. Aspirate the supernatant to half the height of the cushion, and wash the cushion with 1 to 2 ml of warm labeling buffer. Then, completely aspirate the supernatant off, rinse the pellet gently with 1 ml warm labeling buffer, and aspirate again. Immediately add 500 µl warm labeling buffer to each tube, and return the tubes to the 37°C water bath.

11. Resuspend each pellet by pipetting up and down in warm labeling buffer. While resuspending one pellet, keep the remaining tubes in the 37°C water bath, and use the same pipet tip for all tubes.

    Careful and thorough resuspension is key to high labeling efficiency.

    The pellets are dense and sticky. Use a cut-off tip (cut ~5 mm off the end) on a 1-ml pipetman, starting with the 500 µl in each tube. Dial the pipetman in to 300 µl, and pipet liquid up and down over the pellet until it is fully resuspended with no chunks present. Be patient, avoid frothing the solution, and do not poke the tip into the pellet as chunks of the pellet will get stuck inside the tip and will be lost.

12. After the first 500 µl, pool the resuspended pellets in one tube in the 37°C water bath, and go back and rinse each tube thoroughly with another 300 µl of warm labeling buffer. Pool all together, a total of 2 to 3 ml, and keep in the 37°C water bath.

Label microtubules

13. Add fluorophore dye solution (step 9) to the resuspended microtubules to 10 mM final concentration, mix well by gentle vortexing, and incubate 30 min at 37°C. Gently vortex every few minutes throughout the labeling reaction, being careful not to froth the solution.

14. During the labeling incubation, warm up the microultracentrifuge with rotor and several 5.1-ml microultracentrifuge polycarbonate tubes to 37°C.

15. Stop the labeling reaction by adding an equal volume of Quench.

16. Put 1 ml of low-pH cushion into each 5.1-ml microultracentrifuge tube, and layer 2 ml of the labeled polymer on top. Microultracentrifuge microtubules 30 min at 200,000 × *g* (Beckman TLA-100.4 rotor at 70,000 rpm), 37°C.

17. During the centrifugation, cool a 7-ml dounce homogenizer, pestle, and 10 ml of injection buffer (IB) on ice and warm up a few milliliters of distilled water to 37°C.

18. After centrifugation, aspirate the supernatant to 1/2 cushion volume, wash the cushion with a few drops of warm distilled water, and then aspirate the remaining cushion.

Depolymerize labeled microtubules

19. Immediately add 500 µl cold IB to each tube. Incubate 10 min on ice to let depolymerization initiate before beginning to resuspend the pellets. Pool resuspended

pellets into the dounce homogenizer on ice, rinse each tube with an additional 200 µl of cold IB, pool all.

This pellet will be horribly sticky. Do not attempt to fully resuspend the pellet in the microultracentrifuge tube, but instead try to partially resuspend as much solids as possible and transfer them into the homogenizer. As always, be patient and do not introduce bubbles into the solution.

20. Allow the microtubules to depolymerize for 30 min on ice, slowly raising and lowering the pestel in the homogenizer the entire time, being careful not to introduce bubbles and keeping the homogenizer immersed in ice.

21. During depolymerization, chill the microultracentrifuge, a few 5.1-ml microultracentrifuge tubes, and the rotor to 2°C.

22. Transfer the resuspended pellets to cold 5.1-ml microultracentrifuge tubes and clarify the depolymerized tubulin by microultracentrifuging 10 min at 415,000 × *g* (Beckman TLA-100.4 rotor at 100,000 rpm), 2°C.

Polymerize labeled microtubules

23. Collect the supernatants and pool in a 10-ml graduated cylinder at room temperature. Add 1/10 vol of 10× BRB-80, 1 M $MgCl_2$ to a final concentration of 4 mM, 100 mM GTP to a final concentration of 1 mM, and finally 1/3 vol glycerol. Mix well by inversion.

24. Polymerize microtubules by incubating the graduated cylinder, covered with Parafilm, for 45 min in a 37°C water bath, with occasional mixing.

25. During the incubation, warm up the rotor, microultracentrifuge, and two 5.1-ml microultracentrifuge tubes to 37°C.

26. Just prior to termination of incubation, put 0.5 ml of low-pH cushion in each warm 5.1-ml microultracentrifuge tube. After the incubation, layer the polymerized microtubules on each low-pH cushion.

27. Microultracentrifuge microtubules 30 min at 200,000 × *g* (in the TLA-100.4 rotor at 70,000 rpm), 37°C.

28. During this microultracentrifugation, chill 5 ml IB on ice and warm 5 ml of 1× BRB-80 to 37°C.

29. After the microultracentrifugation, aspirate the supernatant to 1/2 cushion volume, wash the cushion two times with a few drops of warm 1× BRB-80, then aspirate the supernatant completely, wash the pellet very gently two times with warm 1× BRB-80 to remove all residual glycerol (which is toxic if microinjected into cells).

30. Cover pellets with 200 µl of cold IB and incubate 5 min on ice before resuspending the pellets. During this time, chill the microultracentrifuge and rotor to 4°C.

31. Resuspend the pellets in a total of 300 µl per tube by pipetting, using the second 100 µl as a rinse. Pool the resuspended pellets in a clean, chilled microultracentrifuge tube and cover it with Parafilm.

These pellets should not be as sticky as the last ones and should be fairly easy to resuspend by pipetting.

Depolymerize microtubules

32. Depolymerize the resuspended microtubules by incubating 30 min on ice.

33. Clarify the depolymerized microtubules by microultracentrifuging for 5 min at 415,000 × *g* (in the TLA-100.4 rotor at 100,000 rpm), 4°C.

34. After microultracentrifugation, transfer the supernatant to a new 1.6-ml microcentrifuge tube on ice.

Calculate concentration of tubulin and fluorophore

35. Calculate concentration of tubulin, the fluorescent dye-to-protein ratio, and the percent yield of the preparation. Measure the absorbance of a 1:100 dilution (in water) of the tubulin solution at 278 nm (A_{278}) and at the excitation maximum of the fluorophore in a quartz cuvette, using water to blank the spectrophotometer. Calculate the concentration of tubulin using the extinction coefficient for tubulin ε = 115,000 M^{-1} cm^{-1} at 278 nm and Beer's law:

$$\text{Concentration} = \text{dilution factor} \times A_{278}/\varepsilon$$

36. Calculate the concentration of fluorescent dye similarly, using the extinction coefficient supplied by the fluorescent dye manufacturer (contact technical service for information).

The fluorescent dye-to-protein ratio is simply the ratio of the molar concentrations. For calculation of the percent yield, determine the total amount of labeled tubulin obtained from the concentration and volume and use the molecular weight of the dimer, 110 kDa to convert to milligrams to compare to the original amount of tubulin labeled.

37. Adjust the concentration of labeled tubulin to 20 to 30 mg/ml with IB, and drop freeze 3-µl aliquots in 0.6-ml UV-impermeant microcentrifuge tubes in liquid nitrogen for storage at –80°C.

38. For use for microinjection, rapidly thaw an aliquot of concentrated labeled tubulin and transfer immediately to ice. Dilute to 0.5 mg/ml with cold IB, and drop freeze 3-µl aliquots for use within 2 weeks.

SUPPORT PROTOCOL 2

PREPARATION OF FLUORESCENTLY LABELED ACTIN FOR FSM

This is a modification of a protocol developed by J.S. Sanger and J.W. Sanger (Turnacioglu et al., 1998). In this protocol, actin is labeled on lysines with a succinimidyl ester derivative of the fluorescent dye of choice. The labeling is carried out on actin filaments, so that the dye does not bind to regions of the actin monomer that are involved in filament formation, and then the labeled actin is taken through rounds of depolymerization, polymerization, and depolymerization to select for functional labeled molecules, similar to the protocol for labeling tubulin. However, actin polymerization is not temperature dependent like tubulin, but salt dependent with polymerization driven by high-salt concentrations and depolymerization occurring at low-salt concentrations (Pardee and Spudich, 1982). Thus, the depolymerization portion of the cycle occurs very slowly (i.e., over 3 days) by dialysis to remove salt, and should not be rushed. This protocol takes a total of 7 days and should yield 20 to 30 mg of labeled actin, which is good for >1 year when stored at −80°C.

Materials

Muscle (rabbit psoas or chicken breast) acetone powder
1 M KCl (*APPENDIX 2A*)
1 M $MgCl_2$ (*APPENDIX 2A*)
100 mM ATP (see recipe)
Succinimidyl ester derivative of the fluorescent probe of choice, pre-equilibrated to room temperature
Anhydrous DMSO

1 M sodium bicarbonate (see recipe), freshly prepared
1 M NH_4Cl (see recipe)
G-buffer, 4°C (see recipe; ATP should be added just prior to use)

50-ml beaker
Refrigerated ultracentrifuge with rotor (e.g., Beckman 70.1 Ti rotor)
13.5-ml screw-cap ultracentrifuge tubes
50-ml and 1-liter graduated cylinder
Spectrophotometer and quartz cuvette
1.6-ml microcentrifuge tubes
Aluminum foil
Refrigerated centrifuge with rotor (e.g., Sorvall SS-34 rotor)
50-ml open-top polycarbonate centrifuge tubes (or equivalent)
7-ml dounce homogenizer with type "B" pestle
Pretreated glycerol-free cellulose dialysis tubing (see recipe), ~2 cm diameter, 20,000 MWCO (i.e., Spectra/Por 6, Fisher)
Dialysis tubing clips
0.6-ml UV-impermeant microcentrifuge tubes

Extract and polymerize actin monomers from muscle

1. Add 1 g of muscle acetone powder to 25 ml chilled deionized, distilled water in a 50-ml beaker. Extract the actin monomers by mixing 30 min at 4°C. During extraction, cool the ultracentrifuge and rotor to 4°C.

   Use a magnetic stirrer and stir plate in the cold room.

   Muscle acetone powder is commercially available from Sigma, but actin preparations from commercial sources will not give the best yields. A better source is from a laboratory that purifies actin regularly (generally, these laboratories store large frozen quantities) or to prepare the powder oneself using the method of Pardee and Spudich (1982).

2. Transfer to 13.5-ml ultracentrifuge tubes and clarify the extract by ultracentrifuging 1 hr at 185,000 × *g* (Beckman 70.1 Ti rotor at 52,000 rpm), 4°C.

   Be sure to balance paired tubes by weight to within 0.01 g.

3. After the centrifugation, carefully collect supernatant in a 50-ml graduated cylinder. Determine the initial amount of actin monomers by measuring the absorbance at 290 nm (A_{290}) of a 1:10 dilution and using the extinction coefficient of actin $\varepsilon = 0.62\ M^{-1}\ cm^{-1}$ in the equation for Beer's law (see Support Protocol 1, step 35).

4. Polymerize the actin by adding 1 M KCl (final 0.1 M), 1 M $MgCl_2$ (final 2 mM), and 100 mM ATP (final 1 mM). Transfer to a 50-ml beaker and stir 30 min at room temperature.

5. During the polymerization, dissolve the fluorophore in anhydrous DMSO to a concentration of 100 mM in a 1.6-ml microcentrifuge tube. Warm fluorescent dye solution for 10 min to 37°C and vortex vigorously.

6. Clarify the dye solution by microcentrifuging 5 min at maximum speed, room temperature. Promptly transfer the supernatant to a fresh 1.6-ml microcentrifuge tube and keep at room temperature.

7. After polymerization, raise the pH of the actin solution to ~pH 9 for the labeling reaction by adding 1/5 vol of 1 M sodium bicarbonate.

Label actin

8. Add fluorescent dye solution to the protein solution at a ratio of 5 mole fluorophore to 1 mole actin. Add a stir bar to the beaker, cover the beaker completely with aluminum foil, and stir 45 min at room temperature.

9. After 45 min, add a second aliquot of fluorophore, equal to the amount of the first addition, re-cover the beaker, and continue stirring for an additional 45 min, room temperature.

   During this time, chill the super-speed centrifuge and rotor to 4°C.

10. Following labeling, quench the reaction by adding 1 M NH_4Cl to a final concentration of 50 mM. Stir 10 min, 4°C.

11. Transfer the solution to 50-ml super-speed centrifuge tubes and pellet large aggregated material by centrifuging 10 min at 12,000 × *g* (Sorvall SS-34 rotor at 10,000 rpm), 4°C.

12. Collect the supernatant and transfer to new 50-ml screw-cap ultracentrifuge tubes. Balance the tubes to within 0.01 g and ultracentrifuge the F-actin 60 min at 185,000 × *g* (Beckman 70.1 Ti rotor at 52,000 rpm), 4°C.

13. Note the position of the pellet in the ultracentrifuge tube and aspirate the supernatant. Resuspend pellet in 5 ml of G-buffer.

14. Pool pellets in a 7-ml dounce homogenizer and homogenize slowly on ice to resuspend, being careful not to introduce bubbles; then thoroughly rinse the ultracentrifuge tubes with an additional 1 ml of G-buffer.

Depolymerize the F-actin

15. Transfer the resuspended pellets into pretreated dialysis tubing (clipped at one end to form a bag) that has been rinsed with G-buffer. Squeeze out the bubbles and seal the opposite end with another clip. Place the dialysis bag in a 1-liter graduated cylinder containing 1 liter G-buffer and a magnetic stir bar. Cover the entire cylinder with aluminum foil, and stir for 3 days in a cold room, changing the buffer once every day.

16. Collect the dialyzed actin, transfer it to 13.5-ml ultracentrifuge tubes, and clarify the actin solution by ultracentrifuging 1 hr at 185,000 × *g* (Beckman 70.1 Ti rotor at 52,000 rpm), 4°C.

17. Collect the supernatant containing G-actin into a small beaker and discard the pellet.

Polymerize G-actin to F-actin

18. Polymerize G-actin into F-actin by addition of 1 M KCl (final 0.1 M), 1 M $MgCl_2$ (final 2 mM), and 100 mM ATP (final 1 mM); and mix 60 min at 4°C.

19. Transfer the solution to an ultracentrifuge tube and pellet the F-actin by ultracentrifuging 60 min at 185,000 × *g* (Beckman 70.1 Ti rotor at 52,000 rpm), 4°C.

20. Aspirate the supernatant and resuspend the pellet in 1 to 2 ml of cold G-buffer in the dounce homogenizer. Transfer to a dialysis bag.

21. Dialyze the resuspended pellet in 1 liter G-buffer in a graduated cylinder covered with aluminum foil for 3 days, 4°C, changing the buffer once every day.

    Add ATP fresh to each change of dialysis buffer

22. Following dialysis, transfer the dialysate to an 13.5-ml ultracentrifuge tubes and clarify the G-actin by ultracentrifuging 1 hr at 185,000 × *g* (Beckman 70.1 Ti rotor at 52,000 rpm), 4°C.

Analyze actin

23. Collect the supernatant and determine the concentration, total protein, percent yield, and fluorophore-to-actin ratio of the final product (see Support Protocol 1, step 35 for tubulin labeling).

    The extinction coefficient for actin at 290 nm is 0.62 M^{-1} cm^{-1}, the molecular mass of actin monomer is 45 kDa, and the extinction coefficient for the fluorophore is supplied by the manufacturer.

24. Drop-freeze the labeled actin in 10-µl aliquots in 0.6-ml UV-impermeant microcentrifuge tubes and store at −80°C.

25. For use for microinjection, rapidly thaw an aliquot of concentrated labeled actin and transfer immediately to ice. Dilute to 0.5 mg/ml with cold IB, and drop freeze 3-µl aliquots for use within 2 weeks.

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ammonium chloride (NH_4Cl), 1 M

5.35 g NH_4Cl
100 ml distilled H_2O
Store up to 6 months at room temperature

ATP, 100 mM

8.5 ml H_2O
0.55 g Na_2ATP
pH to ~7.0 with NaOH
Bring to final volume to 10 ml with H_2O
Dispense into 200-µl aliquots
Store up to 1 year at −20°C

BRB-80, 10×

400 mM K PIPES, pH 6.8 (see recipe)
5 mM $MgCl_2$ (*APPENDIX 2A* for 1 M)
5 mM EGTA (*UNIT 13.1*)
Store up to 1 year at 4°C

Buffered filming medium

14.8 g/liter Leibovitz L-15 medium powder lacking phenol red (Sigma)
7 mM HEPES, sodium salt
1× antibiotic/antimycotic (100×, Life Technologies; penicillin/streptomycin/amphotericin B)
10% (w/v) fetal bovine serum (FBS, *APPENDIX 2A*)
Adjust pH to 7.2 and sterile filter
Store up to 3 months at 4°C

CB/BRB-80 conversion buffer

1.18 M K PIPES, pH 6.8 (see recipe)
11 mM $MgCl_2$ (*APPENDIX 2A* for 1 M)
Store up to 6 months at room temperature

G-buffer

2 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
0.2 mM $CaCl_2$ (*APPENDIX 2A*)
Add just before use:
0.2 mM ATP (see recipe for 100 mM)
0.5 mM 2-mercaptoethanol
Store up to 1 day at 4°C

Glycerol-free cellulose dialysis tubing, pretreated

Boil 10 min in 10 mM EDTA. Store in sealed jar for up to 1 year at 4°C. Rinse well with water before use.

GTP, 100 mM

Check molecular weight of GTP lot to determine the amount required for 10 ml of a 100 mM solution
8.5 ml distilled H_2O
1 ml of 1 M $MgSO_4$ (*APPENDIX 2A*)
Adjust pH to 7.0
Distilled H_2O to 10 ml
Dispense into 200-µl aliquots, store up to 1 year at −20°C

HEPES, 1 M (pH 8.6)

119.15 g HEPES (free acid)
Distilled H_2O to 400 ml
Add solid KOH a few pellets at a time while mixing until the pH is ~8.4
Add concentrated KOH dropwise to achieve pH 8.6
Distilled H_2O to 500 ml
Sterile filter and store up to 1 year at 4°C

High-pH cushion

0.1 M HEPES, sodium salt, pH 8.6 (add from 1 M stock; see recipe)
1 mM $MgCl_2$ (*APPENDIX 2A*)
1 mM EGTA (*UNIT 13.1*)
60% (w/v) glycerol
Store up to 6 months at room temperature

Injection buffer (IB)

50 mM potassium glutamate
0.5 M $MgCl_2$ (*APPENDIX 2A*)
Store up to 2 years at −20°C

Labeling buffer

0.1 M HEPES, sodium salt, pH 8.6
1 mM $MgCl_2$ (*APPENDIX 2A*)
1 mM EGTA (*UNIT 13.1*)
40% (w/v) glycerol
Store up to 6 months at room temperature

Low-pH cushion

1× BRB-80 (see recipe for 10×)
60% (w/v) glycerol
Store up to 6 months at room temperature

Microinjection needles

For Eppendorf systems, standard femtotip microinjection needles work well. For home-pulled needles, a blunt-tipped needle with a ~0.5- to 1.0-μm i.d. tip opening should be used. Either needle type should be pre-coated inside and out with hexamethyldisilazane (HMDS, Pierce Chemical). This is done by propping the needles on a piece of modeling clay in a petri dish, putting a couple of drops of HMDS on the bottom of the dish, quickly covering the top, and putting the dish in the fume hood overnight to allow the HMDS to vaporize and coat the needles. This treatment greatly reduces needle-clogging problems. Needles may be tested by watching flow of a 1 mg/ml fluorescent dextran solution from a needle immersed in culture medium using a 40× lens and epifluorescent illumination. At 1- to 2-psi needle pressure, the solution should flow *very* slowly from the needle, i.e., a small "cloud" of fluorescence as big as ~1/4 the field of view should take 2 to 4 sec to form.

PIPES, 1.5 M (pH 6.8)

226.8 g PIPES (free acid)
H_2O to 400 ml
Add solid KOH a few pellets at a time while mixing until the pH is ~6.6
Add concentrated KOH dropwise to achieve pH 6.8
Distilled H_2O to 500 ml
Sterile filter and store up to 1 year at 4°C

Quench

2× BRB-80 (see recipe for 10×)
100 mM potassium glutamate
40% (w/v) glycerol
Store up to 6 months at room temperature

Sodium bicarbonate, 1 M

8.40 g $NaHCO_3$
100 ml distilled H_2O
Make up fresh and keep at room temperature

COMMENTARY

Background Information

Principles of FSM image formation

FSM was originally characterized for imaging fluorescent microtubules, thus it is important to understand the basics of microtubule assembly and structure in order to understand FSM images of microtubules. Similar principles apply to FSM images of actin.

Microtubules dynamically assemble in cells from a cytoplasmic pool of α/β tubulin dimers (reviewed by Desai and Mitchison, 1997). Dimers of 8 × 5–nm are oriented head-to-tail along the 13 protofilaments that comprise the 25-nm diameter cylindrical wall of a microtubule (Fig. 4.10.4). There are 1625 dimers in 1 μm of microtubule length. Microtubules grow by dimer association with their ends. Thus, microtubules can be fluorescently labeled by attachment of chemical fluorophores to purified tubulin dimers, then incorporation of the fluorescent dimers into the ends of a microtubule polymer. As seen in Figure 4.10.1, microtubules assembled from a low fraction (~0.5%) of fluorescent tubulin appear speckled in high-resolution images, while microtubules assembled from higher fractions (~10%) of labeled tubulin appear continuously labeled along their lengths.

The resolution of fluorescent microtubules in the light microscope depends on the emission wavelength of the fluorophore (Inoué and Spring, 1997). Resolution limit in wide-field fluorescence microscopy is given by

$$r = 0.61\lambda/NA_{obj}$$

where λ is the wavelength of emission light and NA_{obj} is the numerical aperture of the objective lens. In practice, this equation means that the image of a single fluorophore will be the same

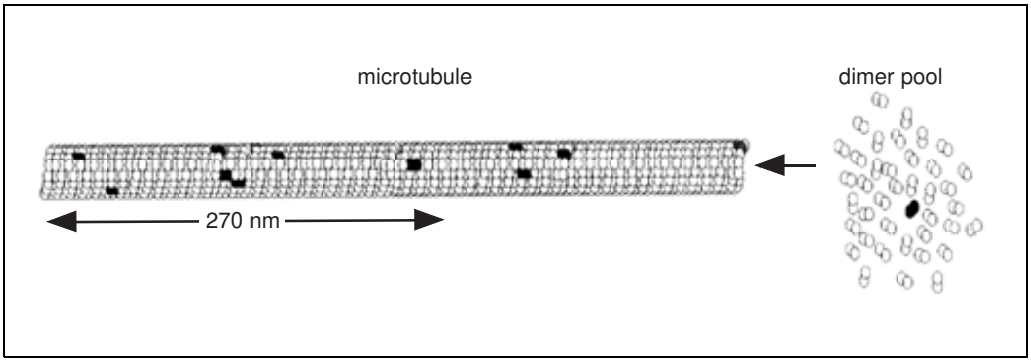

Figure 4.10.4 Stochastic growth model for how microtubules get fluorescent speckles. See Background Information. R (red fluorescence) = $0.61\lambda/NA_{obj}$ = 270 nm = 440 tubulin dimers; $M = FN = 4.4$ for 1% labeled tubulin; SD = $[Nf(1-f)]^{0.5} = 2.15$; C = SD/M = 0.48; as mean, M, decreases, standard deviation, SD, increases, and speckle contrast, C, increases.

size as the image of however many fluorophores that can fit in a resolution-limited spot, only the single fluorophore will be much dimmer than the group. For example, resolution is ~270 nm for the 620-nm fluorescence from tubulins conjugated to the X-rhodamine fluorophore. Thus, the image of a linear, 25-nm wide, red fluorescent microtubule is a linear series of resolution-limited 270-nm-wide fluorescent spots along the microtubule, with the intensity of the resolution-limited spots related to the number of fluorophores within each spot.

Analysis of the assembly of purified tubulins in vitro (Waterman-Storer and Salmon, 1998) has shown that fluorescent speckles in microtubule FSM images are generated by the normal stochastic association of fluorescently labeled and unlabeled tubulin dimers with growing microtubule ends (Fig. 4.10.4). Each time a dimer is added to the microtubule end, the probability that it will be a dimer with a fluorophore depends on the fraction (f) of labeled dimers in the tubulin pool. If, for example, f = 1%, then each time a dimer is added to a microtubule end, there is a 1 in 100 chance it will have bound fluorophore. Over many microns of microtubule length (1625 dimers/μm), the mean number of fluorescent dimers (M), in 270 nm, the size of the resolution-limited spot, is:

$$M = fN$$

where f is the fraction of labeled fluorophores and N is the number of dimers in 270 nm of microtubule, or 440 dimers. For a situation in which f = 1%, the average number of fluorescent dimer per 270 nm is M = 4.4. In FSM images, the speckle pattern along the microtubule is produced by variations from the mean in the number of fluorophores per resolution-limited spot. The standard deviation (SD) for a stochastic process is

$$SD = (Nf(1\text{-}f))^{0.5}$$

which is approximately the square root of the mean for small values of the fraction of labeled tubulin. For a mean value of 4.4, SD = 2.1. This high standard deviation relative to the mean explains how microtubules get fluorescent speckles as a result of a high variability in the number of fluorescent tubulin subunits per resolvable unit distance along the microtubule. The author defines speckle contrast (C) as:

$$C = SD/M$$

At low fractions of fluorescent dimer, the standard deviation is high relative to the mean, producing more contrasting speckles. For the microtubule FSM image seen in Figure 4.10.1, the fraction of labeled tubulin of ~0.5% or less is estimated. At this concentration, the number of fluorophores per diffraction-limited spot has been calculated to be between 0 and 7 (Waterman-Storer and Salmon, 1999).

The above analysis also does not consider the effects of background fluorescence on speckle contrast. As the fraction, f, of fluorescently labeled tubulin decreases, background fluorescence also decreases, giving less out-of-focus fluorescence and higher speckle contrast in the FSM images.

Critical Parameters and Troubleshooting

The critical parameters for setting up a time-lapse FSM imaging system will not be discussed here as Basic Protocol 1 dealt with this in detail. Similarly, troubleshooting hardware and software problems is virtually impossible without knowledge of the specific components

of the imaging system. These problems are best dealt with by consultation with the manufacturer as problems arise.

For successful live-cell FSM imaging, the most critical components are proper fluorescent protein concentration, successful suppression of photobleaching, and high quality, well labeled, fully functional protein. Fluorescent speckles cannot be detected if the concentration of fluorescent protein in the cell is too high. Although, the needle concentrations recommended have been used successfully, the amount of protein that gets incorporated into the cell depends on the microinjection technique. Tubulin can be diluted with IB and actin can be diluted with G-buffer to alleviate problems of overly bright cells. Conversely, if there is not enough labeled protein, the camera exposures required to capture an image will be excessively long and may result in motion artifacts in the image. This can easily be solved by increasing the needle concentration.

Photobleaching problems can occur if the imaging chamber is not fully sealed, if there are air bubbles present in the chamber, or if the potency of the Oxyrase is wearing out. Make sure the edges of the coverslip are dry when attaching it to the tape and use Oxyrase that is stored for <1 year at −80°C. Labeled tubulin or actin that is incompetent for polymerization due to denaturation or blockage of protein-protein interaction sites by dye binding will not contribute to forming fluorescent speckles by incorporating into microtubules or actin filaments, but it will surely contribute to soluble background fluorescence, making the dimly fluorescent speckled structure difficult to detect above the background. If the background is too high and the protein is not incorporating into polymers, the labeling will have to be carried out again.

The points to pay attention to during labeling of fluorescent tubulin to increase yield and produce well-labeled, functional protein is to not over-label the protein by extending the labeling reaction time, to save time by having solutions and centrifuges pre-equilibrated to the proper temperatures, and to be meticulous in resuspending pellets and collecting supernatants. After the first microtubule polymerization and centrifugation, when resuspending the microtubules for labeling, keeping the pellets warm and using warm buffer for resuspension is essential. This is a step where much tubulin can be lost if it is allowed to depolymerize prior to labeling. After centrifuging the labeled microtubules, resuspension of the labeled microtubule pellet and depolymerization is another step where yield can be reduced. If the pellet is not completely resuspended, the microtubules will not depolymerize and will be lost in the subsequent clarification step—thus, be patient and homogenize slowly during the entire depolymerization incubation. A final key point to note is that small amounts (<15 mg) of starting material when carrying out these protocols should not be used. Yield for the protocols is knowingly very low, and if small amounts are used to start with, one may end with no labeled product.

Actin labeling is quite easy because one begins with such a large amount of material and actin is such a stable protein that it is difficult to be unsuccessful. One key parameter is the quality of the acetone powder. Actin will not be readily extracted from poor powder. Use the most finely powdered or "fluffiest" powder within the supply. Do not include hard chunks or dark-colored particles in the starting material for the prep as these will not have been fully acetone extracted. It is not recommended to speed the depolymerization steps by decreasing dialysis time. This will cause large losses of protein, which will fail to depolymerize and subsequently be lost in the pellet of the clarification centrifugation. One may change dialysis buffers more often, but do not decrease dialysis time. In fact, one may increase the dialysis for up to 5 days if necessary. When changing dialysis buffers, always add the ATP fresh to the buffer.

The labeling efficiency of tubulin or actin should not have dramatic effects on imaging. However if a very poor labeling is achieved (<0.5 dye per protein), the large amount of protein microinjected to get good images may have some effects on the balance of polymer/monomer in the cell.

Anticipated Results

When live cells are injected with low levels of well-prepared fluorescently labeled cytoskeletal proteins and imaged on an efficient epifluorescent microscope at high resolution with a sensitive, low-noise cooled CCD that is matched in resolution to the microscope optics, FSM images like those in Figure 4.10.1 should be obtained. In time lapse, microtubule FSM should reveal the assembly dynamics of speckled microtubule ends at the cell periphery as microtubules undergo dynamic instability, growing at 1 to 10 μm/min and shortening at 5 to 20 μm/min, with frequent switching between these states. The speckles on microtubules

should remain constant in pattern and only change after depolymerization and repolymerization. In this regard, keep in mind that very slight shifts in focus can change the intensity of speckles dramatically. For time-lapse actin FSM, actin speckles should appear along the leading edges of migrating cells and move towards the cell center at 0.1 to 2 μm/min. In addition, within the lamella actin network, fluorescent speckles should appear and disappear as actin within the meshwork turns over. Actin in stress fibers and bundles will appear as linear arrays of speckles, and contractility can be seen as speckles move within these bundles.

Time Considerations

Relative to preparing fluorescent proteins, performing time-lapse FSM of living cells requires little time and is dependent on the biological process of interest. The cells will need to be microinjected, to recover for ~1 hr after microinjection, to be mounted for live-cell microscopy, and then to be imaged on the microscope for as long as is required by the biological process of interest. Fluorescent labeling of tubulin requires 1 full day, provided tubulin has already been purified according to *UNIT 13.1*, Support Protocol 3. Fluorescent labeling of actin takes 7 days with the first day, in which the labeling is carried out, being the most labor intensive, with ~6 hr required. Day 2 and 3 need 10 min each, 4 hr on day 4, 10 min on both days 5 and 6, and 2 to 3 hr on day 7. The method should yield 20 to 30 mg of labeled actin. Both of these fluorescent proteins are good stored at −80°C for a reasonably long time, although labeled actin appears to be more stable (>1 year) than tubulin (6 to 8 months).

Two-Photon Excitation Microscopy for the Study of Living Cells and Tissues

The effective sensitivity of fluorescence microscopy, especially with thick samples, is limited by out-of-focus flare. This limitation is greatly reduced in a confocal microscope (*UNIT 4.5*; White et al., 1987), which uses a confocal pinhole to reject out-of-focus background and produce unblurred imaging of thin (<1 μm) optical sections. Alternatively, deconvolution microscopy, using a conventional microscope, digitally reconstructs an image using the measured point spread function of the optics (Agard et al., 1989; Carrington et al., 1990; Holmes et al., 1995; McNally et al., 1999). Two-photon excitation microscopy (also known as nonlinear optical microscopy or two-photon laser scanning microscopy; Denk et al., 1990) is another alternative to confocal and deconvolution microscopy that provides clear advantages for three-dimensional imaging. In particular, two-photon excitation excels at imaging of living cells, especially within intact tissues such as brain slices, embryos, whole organs, and even animals. This unit will describe the basic physical principles of two-photon excitation and discuss the advantages and limitations of its use in laser-scanning microscopy. Practical considerations for this technique will be highlighted in order to illustrate the utility of this technique and demonstrate some of its physical limitations. Finally, selected applications of two-photon excitation microscopy will be discussed, in order to illustrate how this technique has made possible experiments that could not have been performed otherwise.

Before performing any optical-sectioning experiment, careful consideration should be given to selecting the technique that is best suited to answer the biological question. For fluorescence microscopy on relatively thick samples, two-photon excitation often provides the most attractive solution, although complementary three-dimensional fluorescence microscopy methods each have particular benefits that make them better suited for certain experiments.

Confocal microscopy uses a pinhole to reject out-of-focus background fluorescence. Thus, this technique allows three-dimensional sectioning into thicker tissues. However, the excitation light generates fluorescence, and thus photobleaching and phototoxicity, throughout the specimen, but it only collects signal from within the plane of focus. This can cause significant photobleaching and phototoxicity problems, especially in live samples. Also, the penetration depth in confocal microscopy is limited by absorption of excitation energy throughout the beam path and by sample scattering of both the excitation and emission photons.

Deconvolution techniques often provide the best solution for samples with relatively low out-of-focus background or for samples with low signal levels (McNally et al., 1999). Since deconvolution methods use conventional wide-field microscopes for image acquisition, the excitation intensity is generally kept low. Thus, deconvolution is usually effective for imaging monolayers of living cells. It is important to realize, though, that many so-called deconvolution methods are simply nonlinear data filters that do not generate quantitative data. Only true, constrained, iterative deconvolution methods provide quantitative data that can be used for further analysis. However, deconvolution on wide-field fluorescence microscopes provides limited penetration into thick samples, as a result of increased out-of-focus background and light scattering. Also, because of the heavy computation required, the deconvolved images cannot give immediate feedback during the experiment.

Two-photon excitation provides three-dimensional sectioning without absorption (and thus photobleaching and phototoxicity) above and below the plane of focus. Consequently, it offers increased depth penetration over confocal microscopy and can be less phototoxic to live samples. Thus, two-photon excitation microscopy is used, in preference to these other techniques, for experiments that require deep penetration into live tissue or intact animal samples. However, because the photophysics involved with two-photon excitation is different from conventional fluorescence excitation, deleterious effects are occasionally observed with two-photon excitation of certain fluorophores, which in turn limits the applicability of this method for optical sectioning in thin samples.

TWO-PHOTON EXCITATION

Principles of Two-Photon Excitation

Two-photon excitation is a relatively old concept in quantum optics. It was first proposed theoretically by Maria Göppert-Mayer in her doctoral dissertation (Göppert-Mayer, 1931) and observed experimentally shortly after the invention of the laser (Kaiser and Garrett, 1961). Thus, much of the theoretical and experimental background is well understood. Two-photon excitation arises from the simultaneous absorption of two photons in a single quantitized event. Since the energy of a photon is inversely proportional to its wavelength, the two photons should be about twice the wavelength required for one-photon excitation. For example, a fluorophore that normally absorbs ultraviolet light (~350 nm) can also be excited by two red photons (~700 nm) if they reach the fluorophore at the same time (Fig. 4.11.1). In this case, "the same time" means within ~10^{-18} sec. Because two-photon excitation depends on simultaneous absorption, the resulting fluorescence emission depends on the square of the excitation intensity. This quadratic dependence gives rise to many of the significant advantages associated with two-photon excitation microscopy (see Two-Photon Excitation in Laser-Scanning Microscopy). To obtain a significant number of two-photon absorption events (where both photons interact with the fluorophore at the same time), the photon density must be approximately a million times what is required to generate the same number of one-photon absorptions. This means that extremely high laser powers are required to generate significant two-photon-excited fluorescence. These powers are easily achieved by focusing mode-locked (pulsed) lasers, where the power during the peak of the pulse is high enough to generate significant two-photon excitation, but the average laser power is fairly low (Denk et al., 1995). In this case, the resulting two-photon-excited state from which emission occurs is the same singlet state that is populated during a conventional fluorescence experiment. Thus, fluorescent emission after two-photon excitation is exactly the same as generated in normal one-photon excitation (Denk et al., 1995).

Another nonlinear optical process, three-photon excitation, may also prove useful for biological experiments (Maiti et al., 1997). Three-photon excitation works in much the same way as two-photon excitation, except that three photons must interact with the fluorophore at the same time. Because of the quantum-mechanical properties of fluorescence absorption, the photon density required for three-photon excitation is only about ten-fold greater than what is needed for two-photon absorption (rather than another million-fold greater). This makes three-photon excitation attractive for some experiments. For instance, an infrared laser (~1050 nm) can bring about three-photon excitation of an ultraviolet-absorbing fluorophore (~350 nm) and simultaneously produce two-photon excitation of a green-absorbing fluorophore (~525 nm). Three-photon excitation can also be used to extend the region of useful imaging into the deep ultraviolet (i.e., by use of 720-nm light to excite a fluorophore that normally absorbs at 240 nm). This can be useful, since ultraviolet wavelengths below ~300 nm are very problematic for regular microscope optics. Higher-order nonlinear effects are also possible and have been experimentally demonstrated (e.g., four-photon absorption), although it is unlikely that they will find any immediate application in biological research.

Two-Photon Excitation in Laser-Scanning Microscopy

The powerful advantages of using two-photon excitation in laser-scanning microscopy arise from the basic physical principle that the absorption depends on the square of the excitation intensity. In practice, focusing a single

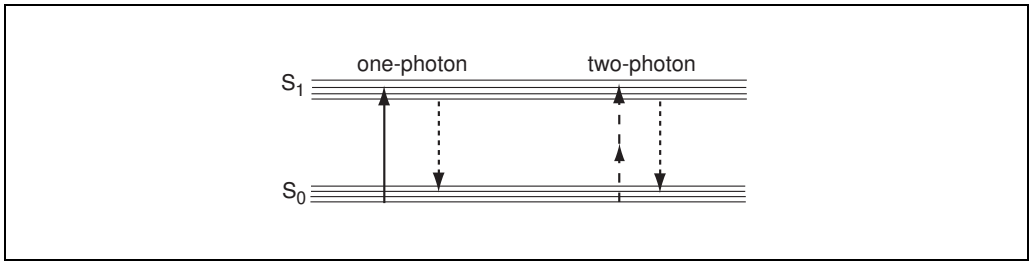

Figure 4.11.1 Jablonski diagram of a single light blue photon (solid black arrow) being absorbed to generate an excited state (left). Simultaneous absorption of two photons of red light (dashed arrows) can produce the identical excited state.

pulsed laser through the microscope optics generates two-photon excitation. As the laser beam is focused, the photons become more crowded, and the chance of two of them interacting simultaneously with a single fluorophore increases. In fact, the focal point is the only place where the photons are crowded enough to generate an appreciable amount of two-photon excitation. This is illustrated in Figure 4.11.2. Above the focal point, the photon density is not high enough for two photons to be within the absorption cross-section of a single fluorophore at the same time. However, at the focal point, the photons are so crowded that it is possible to find two of them within the absorption cross-section of a single fluorophore simultaneously. In practice, two-photon excitation microscopy is made possible not only by crowding the photons spatially (by focusing in the microscope), but also by concentrating the photons in time (by using the pulses from a mode-locked laser). This gives the needed excitation intensities for two-photon excitation, but the pulse duty cycle (the duration of the pulse divided by the time between pulses) of 10^{-5} limits the average input power to <10 mW, which is just slightly greater than what is used in confocal microscopy. The pulse durations are considered ultrashort, typically from ~100 femtoseconds to ~1 picosecond (10^{-13} to 10^{-12} sec), but from the perspective of the fluorophore (where the absorption event is on the 10^{-18} sec time scale), they appear to be quite long in duration.

The localization of two-photon excitation to the focal point provides most of the advantages over confocal microscopy. In a confocal microscope, fluorescence is excited throughout the sample, but only signal from the focal plane passes through the confocal pinhole, so background-free data can be collected. By contrast, two-photon excitation only generates fluorescence at the focal plane, so there is no background, and no pinhole is required. This dramatic difference between confocal and two-photon excitation microscopy can be demon-

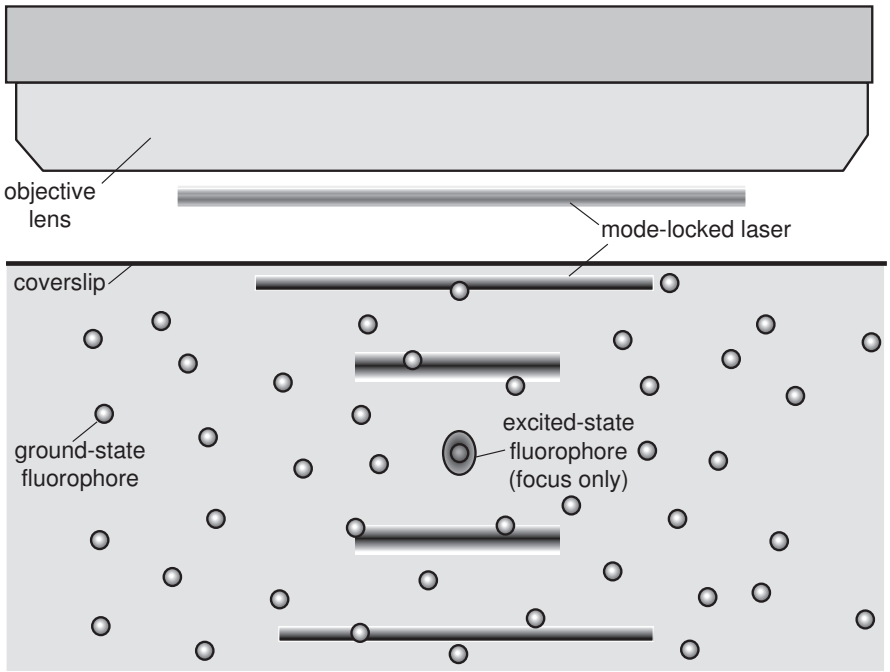

Figure 4.11.2 Demonstration of photon crowding that occurs at the focus of a microscope. As the pulses of red laser exit the objective lens and pass through a sample containing fluorophores (small circles), there is nearly zero probability of two photons passing simultaneously within the cross-section of a single fluorophore located outside the focal point. This is true even during the peak of each laser pulse. However, because of the extremely high photon density at the focal point, it is possible for two photons to interact simultaneously with a fluorophore, which becomes excited. To reach a sufficiently high concentration, the light is crowded both spatially (to the focus of the objective lens) and temporally (through the pulses of the mode-locked laser).

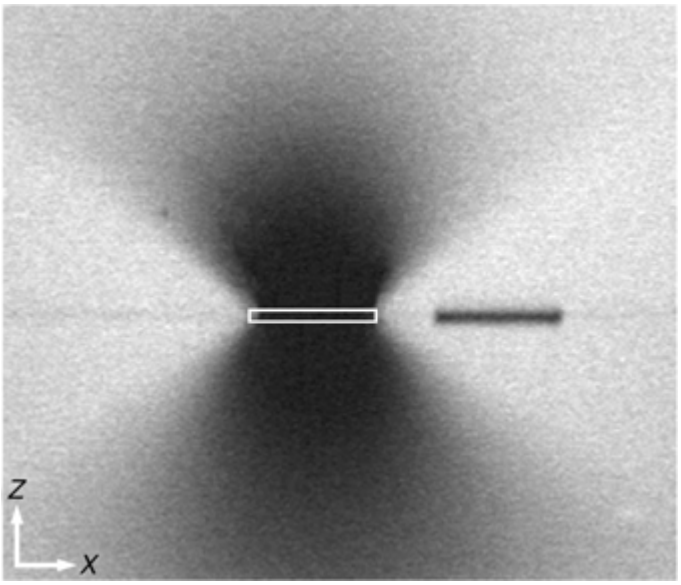

Figure 4.11.3 Photobleaching (*x-z*) profiles caused by one-photon and two-photon excitation. The *x-z* profile of the excitation pattern in a confocal microscope (left side pattern) formed by repeatedly scanning a single *x-y* optical section in a thick film of fluorescein-formvar until fluorescence was completely bleached. The white box represents the focal plane or the region from which data was collected by the confocal microscope. Nearly uniform bleaching occurred both above and below the focal plane. The same excitation pattern is shown for two-photon excitation (right side pattern). Two-photon excitation causes no photobleaching (excitation) outside the focal plane.

strated by imaging the photobleaching patterns of each method. Figure 4.11.3 shows the *x-z* photobleaching pattern that arises from repeated scanning of a single *x-y* plane (or the image plane) in a fluorescein-stained formvar film. The confocal microscope laser excites fluorophores above and below the focal plane (shown by the white box); hence bleaching is observed in these areas (Fig. 4.11.3; left). In contrast, two-photon excitation only occurs at the focal plane and confines bleaching to this area (Fig. 4.11.3; right).

The localization of excitation yields many advantageous effects. First, the three-dimensional resolution of a two-photon excitation microscope is identical to that of an ideal confocal microscope. Second, because there is no out-of-focus absorption, more of the excitation light penetrates through the sample to the plane of focus. This can lead to greatly increased sample penetration—generally at least two to three times deeper than is possible with confocal microscopy (Centonze and White, 1998). Third, as shown in Figure 4.11.3, use of two-photon excitation minimizes photobleaching and photodamage, two of the most important limitations in fluorescence microscopy of living cells and tissues. Although damage to cells owing to interactions with light is poorly understood, decreasing photodamage will lead to extended viability of the biological samples under investigation. Since practical experience indicates that the red excitation light alone does not affect cell viability, it is likely that most of the photodamage is associated with two-photon absorption and thus occurs only at the focal plane.

Two-photon excitation microscopy does not require a pinhole to obtain three-dimensional resolution, which allows flexible detection geometries. The geometries for both descanned- and nondescanned-detection two-photon excitation are shown in Figure 4.11.4. In the descanned geometry, the emitted light (represented by the dotted pattern) returns through the same path as the excitation light hitting the scanning mirrors before passing through the confocal pinhole to the detector. In confocal microscopy, this geometry is necessary to block the detection of out-of-focus emission. Nondescanned beam paths provide more alternatives: (1) a dichroic mirror, located directly after the objective lens, reflects the emitted light through a transfer lens to a detector placed in a plane conjugate to the objective rear aperture ("conjugate plane detector" in Fig. 4.11.4); (2) the

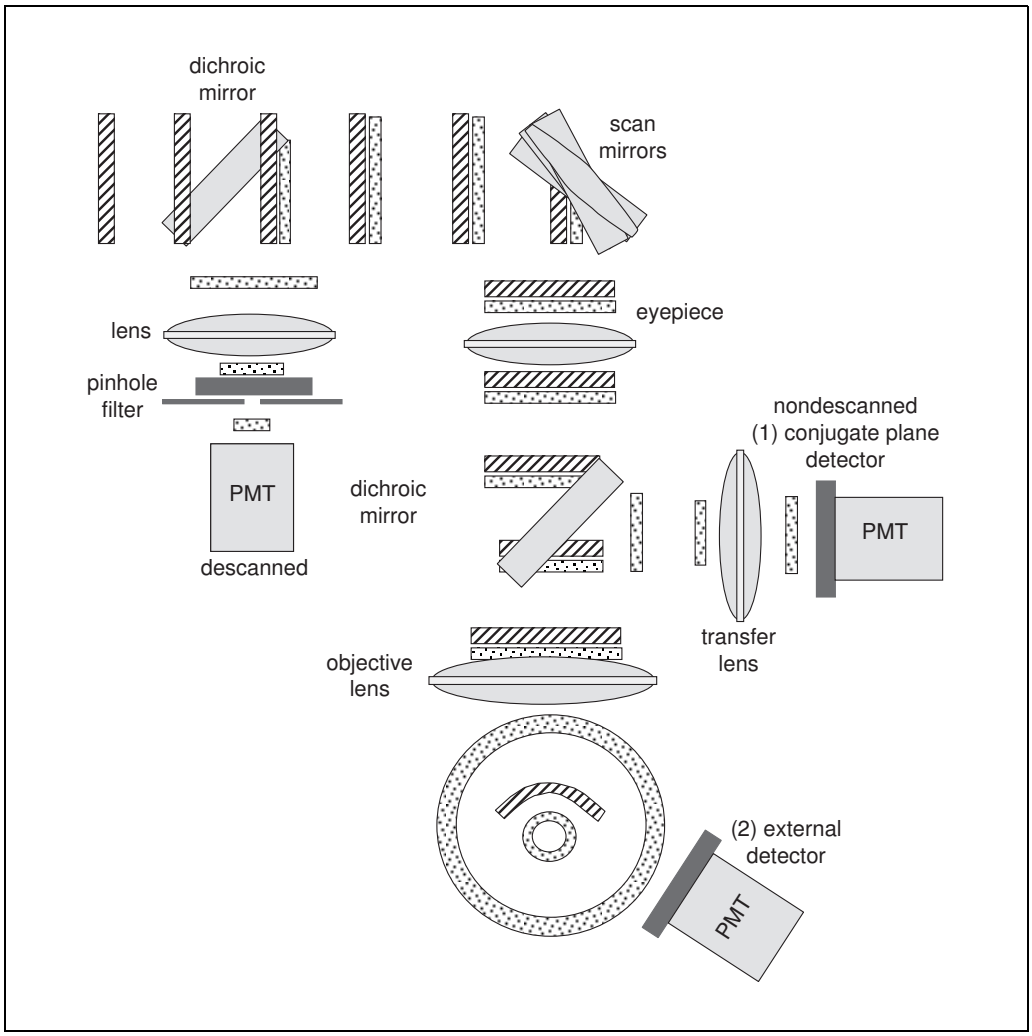

Figure 4.11.4 Descanned and nondescanned detection geometries used with two-photon excitation microscope. The incoming laser light is raster scanned (*x* and *y* scan mirrors), and is focused onto the sample by the objective lens. The descanned detection path returns through the excitation beam path, passing back through the scanning mirrors, and it is focused through the confocal pinhole to the photomultiplier tube (PMT). With nondescanned detection, the fluorescence: (1) returns through the objective lens and then is reflected by a dichroic mirror through a transfer lens that focuses the light so that the back aperture of the objective is conjugate to the front face of the PMT, or (2) is detected directly from the sample using an external PMT.

emitted light is collected, without passing through the objective lens, directly from the sample using an external detector ("external detector" in Fig. 4.11.4); or (3) the emitted light is reflected by a dichroic mirror to a charged-coupled device (CCD) camera at the intermediate image plane, in order to collect the wide-field image (not shown in Fig. 4.11.4). This last type of geometry is used for fast data acquisition systems using two-photon excitation. Although it is possible to use descanned detection for two-photon excitation, using a nondescanned alternative (listed as 2 above) is recommended to fully utilize the depth penetration of this technique. The nondescanned path allows for collection of more scattered photons, requires fewer optical elements (e.g., mirrors, lens), and reduces the distance over which dust particles in the air will interfere with the fluorescence signal. Therefore, using nondescanned detection with two-photon excitation dramatically increases collection efficiency and is a must for maximal depth penetration into living tissue.

PRACTICAL CONSIDERATIONS FOR TWO-PHOTON EXCITATION MICROSCOPY

Mechanism of Deep Sectioning

As mentioned above, the most powerful advantage of two-photon excitation microscopy

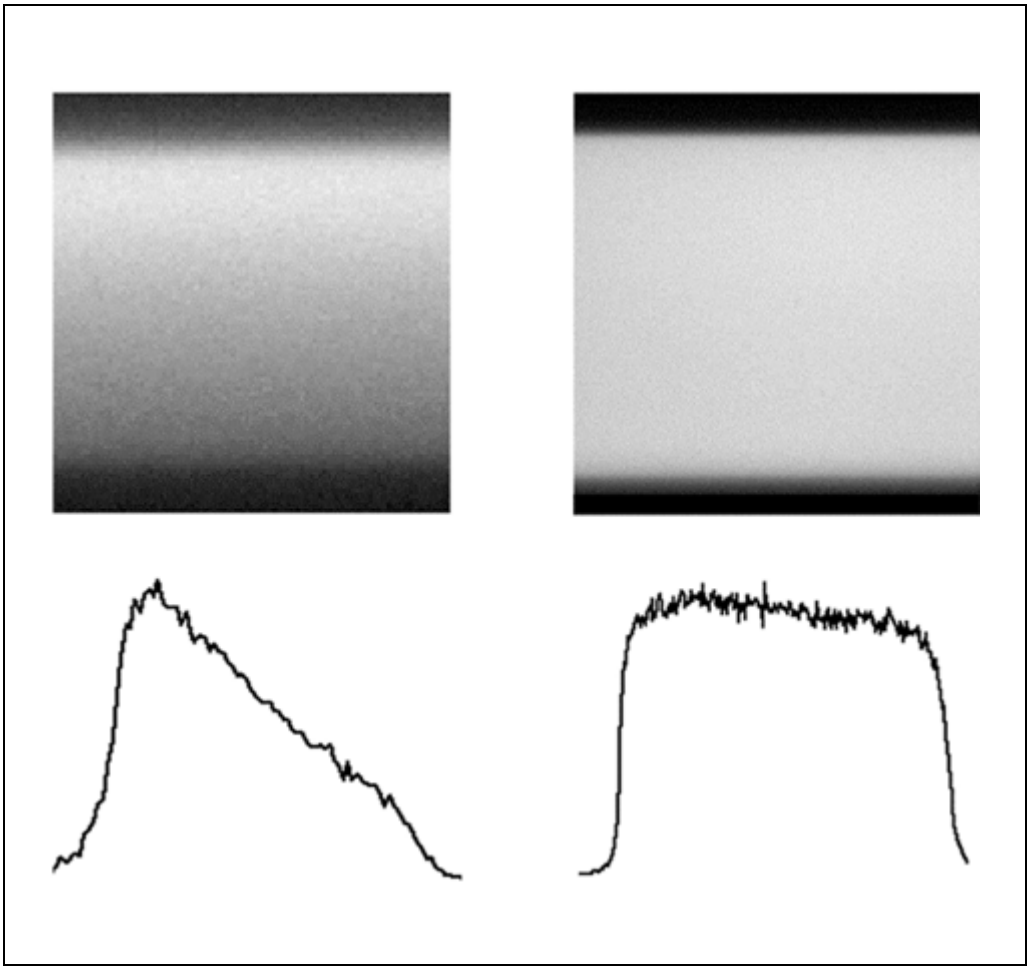

Figure 4.11.5 Top: *x-z* images of fluorescence and *z*-profiles from a rhodamine-stained polymer film (no scattering). Bottom: Intensity profiles from *z*-scan of *x-z* scan. Because there is no out-of-focus absorption in two-photon excitation, much more excitation light reaches deep into the sample so the signal is brighter and the imaging depth larger.

is its ability to provide superior optical sectioning deep into thick samples. Thus, it is important to understand how this increased depth of penetration is achieved. There are three physical mechanisms that combine to allow this increased effectiveness in thick samples: (1) lack of out-of-focus absorption allows more of the excitation light to reach the sample; (2) the red and infrared light used in two-photon excitation is scattered less than bluer light; and (3) the effects of light scattering are less detrimental to two-photon microscopy than confocal microscopy. These three points can be considered separately.

The first point is that the lack of out-of-focus absorption in two-photon excitation microscopy allows more of the excitation light to reach the focal plane. In a confocal microscope, excitation photons are absorbed by any fluorophores along the excitation light path, so fewer photons reach the focus, thus decreasing the signal. This effect becomes worse if the sample contains fluorophores throughout, as shown in Figure 4.11.5. The polymer sample shown in this figure is nonscattering but contains a uniform distribution of a high fluorophore concentration. In this figure, the top of the *x-z* scan is closest to the objective lens, and the fluorescence intensity is plotted as a function of depth into the sample (*z* distance) for each *x-z* scan. In the case of one-photon excitation (confocal microscopy), the intensity shows a steady decrease with penetration depth as the excitation light is absorbed before it reaches the deeper focal planes. In contrast, two-photon absorption only occurs in the focal plane, so there is no absorption of excitation light by fluorophores between the objective lens and the focal plane. Thus, all of the excitation reaches the focal plane, which keeps the fluorescence signal constant throughout the depth of the polymer. This dramatic difference between confocal and two-photon excitation is shown on the right in Figure 4.11.5, where the intensity is relatively stable with penetration depth.

The second point is that the redder excitation light used in two-photon excitation microscopy is less scattered by the sample than is bluer excitation light used in conventional excitation. Biological tissue can be considered as a medium with a nonuniform index of refraction. Light traveling through such a medium is scattered off in various directions. In fluorescence microscopy, the incoming excitation light can be scattered away before it reaches the focal plane, and the resulting fluorescence can also be scattered as it passes back through the sample before it reaches the detector. Both of these effects will reduce the collected fluorescence signal. Because of the irregular distribution of material within biological samples, it is not possible to calculate the scattering behavior precisely. However, the simplest approximation, Rayleigh scattering, gives a minimal estimate of the fraction of light scattered in such a system. For this case, the amount of scattered light is inversely proportional to the fourth power of the light's wavelength ($1/\lambda^4$). Using this estimate, 488-nm (one-photon) light would be expected to scatter ~7-fold more than 800-nm (two-photon) light. Thus, even more of the two-photon excitation laser light can reach the focal plane, which further increases the depth of penetration into the sample. In practice, scattering from tissue structures is always greater than is predicted by the Rayleigh approximation, but it is always the case that longer (redder) wavelengths are scattered less than shorter (bluer) wavelengths. On the detection arm of the microscope, the emitted fluorescence is identical regardless of whether it was generated using one- or two-photon excitation, so scattering of fluorescence emission affects both methods equally.

The third point is that any scattering of the excitation or fluorescence light does not affect signal collection as significantly as it does in confocal microscopy. This is due simply to the physics of image formation in two-photon excitation microscopy. While the lack of out-of-focus absorption and the differences in scattering both allow for increased excitation light to reach the focal plane deep within intact tissue, this third point actually allows for increased image contrast with two-photon excitation. The

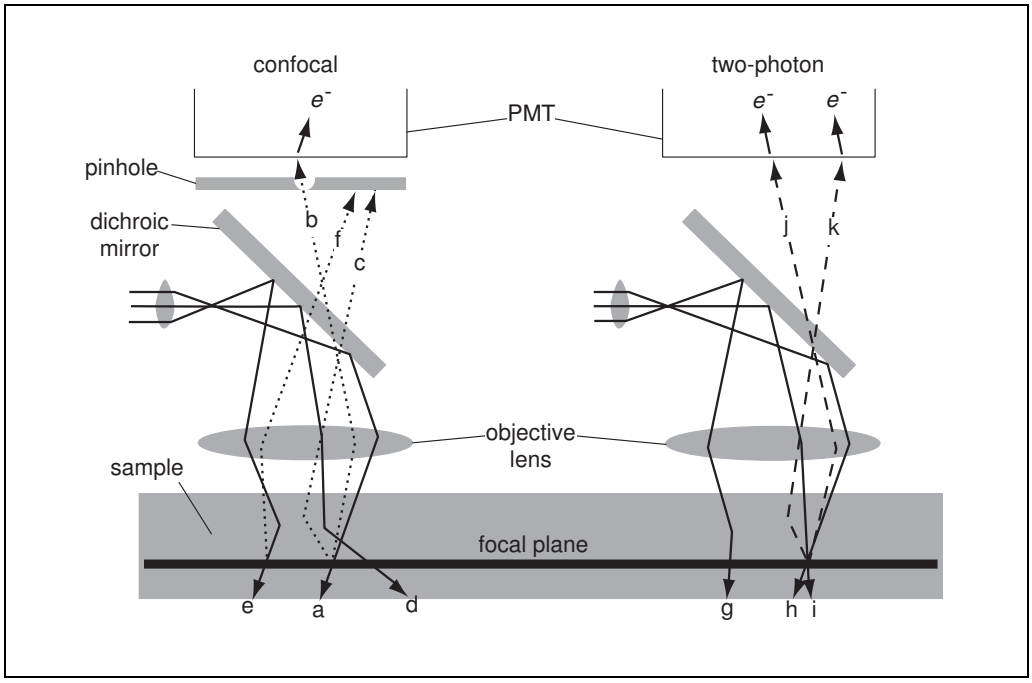

Figure 4.11.6 In confocal microscopy (shown on the left), excitation light reaches the focus (a), and fluorescence from the focus is collected and passes through a pinhole (b). Fluorescence that is scattered (c) does not pass through the pinhole, thus reducing signal. Any scattering of the excitation beam (d and e) can cause fluorescence (f), which may add background to the image. This fluorescence is inefficiently collected but can cause a background fog. For two-photon excitation microscopy (shown on the right), any scattering of a single excitation photon (g) will not cause background, since the chance of two photons scattering to the same place at the same time is essentially zero. Scattering and out-of-focus absorption are reduced with two-photon excitation, resulting in an increase in the amount of excitation light reaching the focus (h and i). Unscattered fluorescence is collected by the PMT (j). Further, because no pinhole is needed, any scattered fluorescence photons can still be collected, thus greatly increasing the collected signal (k).

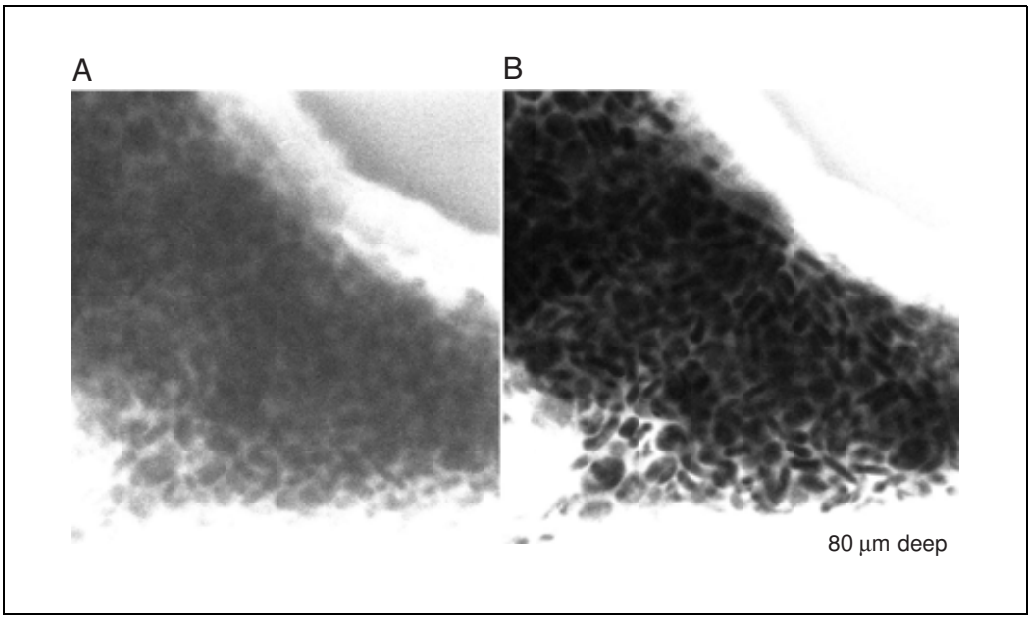

Figure 4.11.7 A shark choroid plexus stained with fluorescein. These images were collected 80 mm into the sample, where the image quality of the one-photon microscope is minimally acceptable. In contrast, using two-photon excitation at this same focal plane allows the collection of an image with excellent intensity contrast.

reasons behind this point are illustrated in Figure 4.11.6 (Denk and Svoboda, 1997).

In a confocal microscope, the excitation light (blue) is focused into the sample (a, in Fig. 4.11.6), and the fluorescence (green; represented by dotted lines) from that focal spot is captured by the objective lens, passes cleanly through the pinhole, and reaches the detector (b). This fluorescence light is the desired signal, but some of it can be scattered as it passes back through the sample (c). This scattered fluorescence does not pass through the pinhole and is therefore lost and not detected. These losses greatly reduce the detected fluorescence signal. As the excitation light passes through the sample, it may be absorbed (d) or scattered before it reaches the focus (e). If it is absorbed, it can generate fluorescence. Since this fluorescence does not arise from the focal spot, it does not pass through the pinhole, so it is not efficiently detected. However, a small portion of out-of-focus fluorescence can be scattered into the pinhole and then be detected. This fluorescence will create a background fog that will be roughly constant across the image, as shown in the examples below. This fog reduces the dynamic range of the image, thus reducing the image contrast. Likewise, the scattered excitation can generate fluorescence (e), and this fluorescence can also contribute to the background fog (f).

In the case of two-photon excitation, the excitation photons (red; represented by dashed lines in Fig. 4.11.6) can also be scattered (g). However, the chance of two photons being scattered simultaneously to the same place is essentially zero, so that the background fog that plagues confocal microscopy in thick samples is not generated in two-photon excitation. Also, more of the excitation light reaches the focal plane (h and i) due to the two points discussed above—i.e., the reduced out-of-focus absorption and the decreased scattering of the redder two-photon excitation light. Importantly, the generated fluorescence (green) has an increased chance of being detected by the photomultiplier tube (PMT) even if scattered (j) because no pinhole is present to block it (k). This insensitivity to scattering effects and lack of out-of-focus absorption allow for the preservation of the full image contrast from deep within samples.

A comparison of confocal and two-photon microscopy imaging quality is shown in Figure 4.11.7 of a shark choroid plexus stained with fluorescein. These images were collected 80 μm into the sample, which is the maximal depth for sufficient image contrast from confocal microscopy for this sample. While the signal level of the brightest features can easily be matched between the two methods, the background fog seen in the confocal image greatly reduces the image contrast. The two-photon excitation image, on the other hand, shows excellent intensity contrast. However, because scattering of the fluorescence is significant in thick biologi-

cal samples, the use of descanned detection and an open pinhole is not enough to gain the advantages of two-photon excitation (Centonze and White, 1998). To gain the full advantage, a nondescanned detection scheme (Fig. 4.11.4, where the fluorescence does not pass back through the scanning system as it must in a confocal microscope) must be used to increase the fluorescence collection efficiency (Piston et al., 1994). Using the same shark sample shown in Figure 4.11.7, a comparison of imaging using descanned (pinhole-open) and nondescanned detection is shown in Figure 4.11.8. In each detection geometry, the same imaging optics (i.e., dichroic mirror, barrier filter, and PMT detector) were used. The sample was first imaged using descanned detection at approximately the largest depth (140 μm) that allowed some intensity contrast (Fig. 4.11.8A). Keeping all settings constant and switching to nondescanned detection, the image shown in Figure 4.11.8B was collected. This image is clearly saturated in many regions of the image, demonstrating the improved signal collection with this detection geometry. Because the excitation was identical in both cases, this 8-fold increase in signal is due solely to the collection of scattered fluorescence photons. To obtain a nonsaturated image, the PMT voltage was reduced from 1000 to 750 V (Fig. 4.11.8C). Clearly, this sample can now be scanned even more deeply using the nondescanned detection. In fact, the depth of penetration in this sample was not limited by the tissue but by the working distance of the objective lens.

Image Resolution

The resolution of two-photon excitation is no better than that achieved with a well-aligned confocal microscope. In fact, the use of longer excitation wavelengths (i.e., red or infrared, instead of ultraviolet or blue) results in a larger resolution spot for two-photon excitation (Sheppard and Gu, 1990). If a biological structure cannot be resolved in the confocal microscope, it will not be resolved in a two-photon excitation laser-scanning microscope either. This point is well understood by experts in the field, but it is often missed by prospective users in the biomedical research community.

Imaging Thick Samples

As mentioned above, there are three reasons why two-photon excitation is more effective in thick samples: lack of out-of-focus absorption allows more of the excitation light to reach the sample, the red exciting light is less scattered, and the effects of fluorescence scattering are less detrimental to two-photon microscopy than to confocal microscopy. When utilizing long-working-distance optics and a nondescanned detection mechanism, the depth of penetration and image quality is often limited by the ability to effectively label the tissue—i.e., with increasing depth it becomes increasingly difficult to introduce fluorescent labels into tissues. The expression of green fluorescent protein (GFP) in transgenic animals is likely to enhance the usefulness of two-photon excitation in vivo imaging. Transgenic animals promise enormous opportunity for the ability to fluorescently label specific organs and pro-

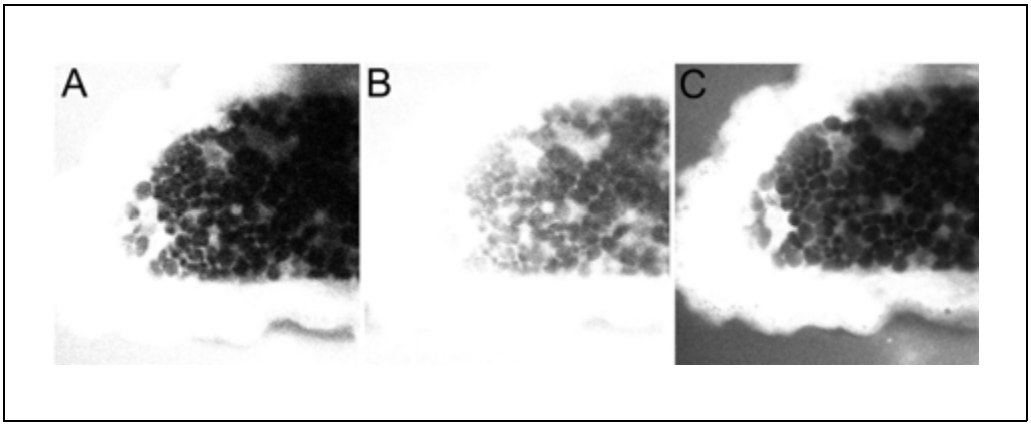

Figure 4.11.8 A comparison of descanned and nondescanned two-photon scanning depth. The sample was first imaged using descanned detection at approximately the longest depth (140 mm) that allowed achieving some intensity contrast (**A**). Keeping all settings constant and switching to nondescanned detection, the image shown in (**B**) was collected. This image is clearly saturated in many regions of the image demonstrating the improved signal collection with this collection geometry. In order to obtain a non-saturated image, the photomultiplier tube gain was changed from 1000 to 750 V (**C**).

teins of living animals for detection using two-photon excitation. Alternatively, tissue characteristics may also limit depth of the penetration. This is especially a concern in either heavily pigmented tissue, such as liver, or highly scattering tissue, such as skin.

Imaging Thin Samples

For imaging of thin samples, two-photon excitation might not offer significant advantages over conventional confocal microscopy. This is because of slightly increased photobleaching in the focal plane (the total photobleaching in a thick sample is still much reduced, though; see Fig. 4.11.3; Patterson and Piston, 2000). One example where two-photon excitation is beneficial, even for thin preparations, is the imaging of ultraviolet-excited fluorophores such as NADH (see Examples of Two-Photon Excitation Microscopy). In such experiments, ultraviolet light appears to be more harmful than the two-photon induced photobleaching. To determine if two-photon excitation would be beneficial, it is always worthwhile attempting the experiments on a confocal microscope first. Once it is known what the limitations of the confocal microscope are for the measurements, it can easily be determined whether the use of two-photon excitation would be advantageous for completing the experiments.

Absorption Spectrum

Two-photon absorption spectra can bear little resemblance to the corresponding single-photon spectra (Birge, 1986). Experience so far indicates that most fluorophores work pretty well with two-photon excitation at twice the wavelength of their one-photon absorption peak. For reasons beyond the scope of this unit, fluorophores with a nonsymmetric chemical structure tend to follow this rule more closely than symmetric ones. For example, fluorescent proteins (e.g., CFP, GFP, and YFP) have a nonsymmetric fluorophore and absorb well at twice their one-photon excitation. However, to take full advantage of two-photon excitation microscopy, these absorption spectra must be measured, which is considerably more difficult than measuring conventional one-photon absorption spectra. Only a few sources for this information exist (Birge, 1986; Xu et al., 1995, 1996; Albota et al., 1998; Neu et al., 2002), although, as this technique becomes more widespread, it is likely that two-photon absorption spectra will become more generally available.

Localized Photochemistry

Two-photon excitation also allows the initiation of photochemical reactions in the focal region. These chemistries involve ultraviolet light–induced reactions for which two-photon excitation can be substituted. For example, the uncaging of a dye, photochemically inducing a nonfluorescent molecule to become fluorescent, can be initiated in individual cells of a tissue using two-photon excitation. Alternatively, biological stimulators or suppressants can also be uncaged. Methods for two-photon-excited uncaging have not been fully developed, largely because the photoreactions can be quite slow (from milliseconds to seconds). Thus, the compound might diffuse over several micrometers within the sample between the time when it is excited and the time it becomes active. Nonetheless, this technique holds the promise of interesting biological applications, some of which will be discussed below.

Laser Sources

While the instrumentation requirements for two-photon excitation microscopy are largely indistinguishable from those for confocal microscopy, the laser excitation source is considerably different. Two types of ultrafast mode–locked laser systems are in general use today: Ti-sapphire lasers and Nd-YLF lasers. These systems do not require water cooling and plug in to regular electrical outlets, but they are considerably more expensive than the small air-cooled lasers used in confocal microscopy. The wavelength tunability of the Ti-sapphire laser (700 to 1100 nm) makes it more versatile than the single-wavelength Nd-YLF laser (1047 nm). Currently, computer-controlled Ti-sapphire lasers cover the wavelength range of 720 to 900 nm in an automated fashion. Further improvements in the ease of use and versatility of these systems are likely to continue in the near future.

Laser Power

The power necessary to excite a fluorescent sample has an optimal limit. Fluorescence intensity increases with increasing power, but the fluorophore eventually becomes saturated. Saturation occurs at laser powers that cause a significant proportion of the fluorescent molecules to exist in their excited rather than ground state (~1 mW at the sample for one-photon excitation, ~50 mW at the sample for two-photon excitation; Denk et al., 1990); therefore, more photons simply are unable to excite more molecules. Any additional excitation energy

beyond saturation contributes to increased photodamage and photobleaching. For each experimental setup, one needs to assess the damage imposed during beam scanning; it should be noted that trivial cell-viability tests (such as esterase activity or dye exclusion) do not always accurately reflect cellular photodamage. Often, a more rigorous functional test is more informative. For example, the viability of hamster embryos was confirmed by their continued development (Squirrell et al., 1999), and the viability of pancreatic islets was confirmed by their maintenance of normal glucose-stimulated NAD(P)H response (Bennett et al., 1996).

EXAMPLES OF TWO-PHOTON EXCITATION MICROSCOPY

This section will highlight some of the available literature to illustrate common situations where two-photon excitation is preferable to confocal imaging. These examples will focus on the benefits of two-photon excitation due to its reduced phototoxicity, increased tissue imaging depth, and ability to initiate localized photochemistry. The details of these experiments will be left to the specified references.

Two-photon excitation is generally less phototoxic than confocal microscopy. This is well demonstrated by time-lapse imaging of hamster embryo development (Squirrell et al., 1999). In this study, the embryo's development was monitored continuously for more than 10 hr using two-photon excitation of a vital mitochondrial dye. Conversely, normal embryo development ceased after only a few minutes of confocal laser exposure. It was thought that the two-photon excitation laser (1047 nm) greatly increased the embryo's viability. These researchers also used two-photon excitation microscopy to assess the effects of inorganic phosphate on hamster embryo development (Ludwig et al., 2001). In this study, the mitochondrial distribution of living hamster embryos cultured in varying amounts of inorganic phosphate was imaged at 6 hr of culture using two-photon excitation microscopy. The embryos were developed further prior to morphological assessment at 27 and 51 hr of culture. It was clear from these studies that the two-photon illumination was nonperturbing to the development of these embryos, while parallel confocal imaging damaged the embyros.

The nontoxic nature of two-photon excitation has allowed in vivo imaging of human skin (Masters et al., 1997). This work involved detailed spectroscopy of the autofluorescent signals from skin at various depths (0 to 50 and 100 to 15 μm) using excitation wavelengths ranging from 730 to 960 nm. When used in conjunction with reflected-light confocal microscopy, two-photon excitation microscopy nondestructively provides detailed white light and autofluorescent images of skin layers from the same region of skin (Masters and So, 1999).

Two-photon excitation is also used to avoid the phototoxic effects of ultraviolet irradiation. This feature is especially useful for the imaging of the naturally occurring reduced pyridine nucleotides—NAD(P)H—as an indicator of cellular respiration. NAD(P)H has a small absorption cross-section and a low quantum yield and absorbs in the ultraviolet. Thus, it is difficult to measure, and its imaging has the potential to cause considerable photodamage. NAD(P)H imaging has proven useful for studying the pathophysiology of cultured partially differentiated L6 myotube cells (Perriott et al., 2001). In cellular NAD(P)H images, the autofluorescence pattern reflects primarily NADH in mitochondria as spotted regions over a diffuse cytoplasmic signal. In differentiated cells, the fluorescence is evident as columns of mitochondria between muscle fiber striations. With increasing glucose concentration, an increase in fluorescence was readily apparent. Overall, this study showed that the kinetics of glucose utilization in real time can be defined in a single cell or averaged over several cells, and that there is homogeneity in glucose metabolism.

Quantitative two-photon imaging of NAD(P)H has also been done on individual β cells within the pancreatic islet (a quasi-spherical micro-organ consisting of ~1000 cells; Bennett et al., 1996). Furthermore, the spatial resolution of this technique allows the separation of both the cytoplasmic and mitochondrial NAD(P)H signals (Patterson et al., 2000). Figure 4.11.9 is a typical image of β cell NAD(P)H autofluorescence within an intact islet, displaying a signal from both the cytoplasm and mitochondria. The outlines of single cells are visible, as are the nuclei, both of which appear dark. The separation of cytoplasmic and mitochondrial signals allowed detailed examination of the metabolism of glucose and pyruvate in these regions of pancreatic islet β cells. Current models for glucose-stimulated insulin secretion (GSIS) suggest that metabolites further along the signal-transduction pathway should cause a similar cascade of signaling events and lead to insulin secretion. However, pyruvate potentiates GSIS but does not induce insulin secretion on its own. Using two-photon imaging of NAD(P)H and separation of cyto-

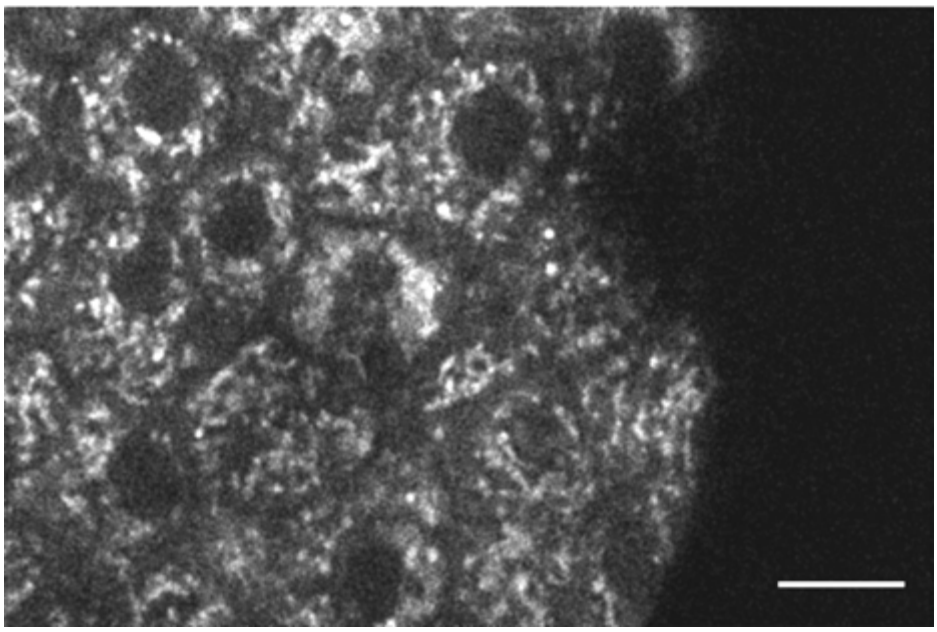

Figure 4.11.9 Optical section of NAD(P)H autofluorescence from an intact pancreatic islet. NAD(P)H signal arises from both the cytoplasm and mitochondria, the latter being brighter and somewhat punctate. Cell outlines and nuclei—where there is little or no NAD(P)H—appear dark. Bar, 10 μm.

plasmic and mitochondrial signals, it was shown that β cells metabolize pyruvate, although transiently (Rocheleau et al., 2002). This transient mitochondrial response suggests two separate models, which are currently under study: either mitochondrial pyruvate transport is inhibited during late pyruvate metabolism or the tricarboxylic cycle is inhibited during late pyruvate metabolism. In these studies, living pancreatic islets were repetitively scanned at sampling rates that are unobtainable by biochemical methods. Such repetitive imaging simply cannot be performed using confocal microscopy, owing to the limitations imposed by photobleaching and ultraviolet-induced photodamage.

Because two-photon microscopy uses mode-locked (pulsed) lasers, it is ideal for extension into fluorescence lifetime imaging (Piston et al., 1992; French et al., 1998). Imaging of the nanosecond fluorescence decay times gives information that is independent of fluorophore concentration. For instance, lifetime imaging can give an unambiguous value for fluorescence resonance energy transfer (FRET) efficiency between two probes (Harpur et al., 2001). Recently, two-photon-excited lifetime imaging microscopy of NAD(P)H has been used to quantify the NAD(P)H concentration in different subcellular compartments. Free NADH levels in the nucleus regulate the corepressor CtBP, involved in cell-cycle regulation and transformation transcriptional pathways. Using two-photon NAD(P)H microscopy and lifetime imaging, it was shown that the free NADH levels in the nucleus closely correspond to the half-maximal concentration for CtBP binding (Zhang et al, 2002).

The technique of two-photon excitation is also useful with other established biophysical techniques, such as fluorescence correlation spectroscopy (FCS; Schwille et al., 1999) and fluorescence recovery after photobleaching (FRAP; *UNITS 13.5 & 21.1*; Brown et al., 1999). Both techniques generally utilize stationary one-photon (continuous-wave) lasers. FCS determines the occupation number and diffusion characteristics of fluorescent probes inside the focal volume of the stationary beam, and it has proven useful in molecule-interaction and diffusion studies. FRAP, through photobleaching of fluorescence in the focal area and observation of fluorescence recovery, has been used to study macroscopic diffusion of fluorescent molecules. These techniques have both been used extensively to examine the diffusion char-

acteristics of fluorescent probes on cultured cell membranes. Currently, the complexity of these two techniques has limited the utility of these techniques to in vitro systems and cell culture models. The well defined excitation volume in two-photon microscopy is useful for quantitative FCS and FRAP. Furthermore, these techniques are likely to show great utility in studying bimolecular dynamics in thick living tissues using two-photon rather than one-photon excitation.

Deep penetration with two-photon excitation allows in vivo imaging, although a number of complexities need to be overcome when imaging living animals. In vivo fluorescent imaging involves two-photon excitation imaging of a living animal through the skin, through surgical openings, or through coverslip windows placed onto the animal. When working with live animals, it is often more difficult to fluorescently label the sample. Specific labeling of neurons in living mice, using a Ca^{2+} indicator, has been done to monitor neural function using two-photon excitation (Svoboda et al., 1997). The expression of green fluorescent proteins (GFP) in transgenic animals to fluorescently label specific organs and proteins is likely to permit new applications of two-photon excitation in vivo imaging (Potter et al., 2001). Another complexity when working with living animals is that the samples can move during the imaging process. Currently, in vivo studies are done with anesthetized animals, and imaging rates are increased in order to limit the effect of this movement. In the future, it is likely that technological advances such as the miniaturization of two-photon microscopes for attachment directly to the animal (Helmchen et al., 2001) will allow in vivo imaging of freely moving animals.

The microcircuitry of neurons in brain slices has been mapped using two-photon imaging (Kozloski et al., 2001; Peterlin et al., 2001). These researchers used bulk loading of calcium indicator combined with two-photon imaging. They triggered a signal neuron and then mapped the calcium signal initiated in connecting (follower) neurons. It was determined that the neocortex is composed of precise circuits. The followers belonged to a few selective anatomical classes and their positions were determined between animals (Kozloski et al., 2001).

A final and potentially very powerful application of two-photon excitation microscopy is three-dimensionally resolved photorelease of caged compounds (uncaging). For example, techniques have been developed for quantitative two-photon uncaging of calcium (Brown et al., 1999). As discussed previously, the photochemical reactions involved are generally quite slow (from milliseconds to seconds), which allows the compound to diffuse over several micrometers within the sample between the time when it is excited and the time it becomes active (Kiskin et al., 2002). Diffusion is not a problem when this technique is used to mark cells by uncaging membrane-impermeant fluorescent molecules. This technique has been successfully used to track the development of sea urchin embryo cell lineages (Piston et al., 1998). Faster-uncaging molecules have been successfully used in studies of uncaging stimulants using two-photon excitation to map neuron receptors (Denk, 1994; Matsuzaki et al., 2001). These studies utilized the three-dimensional nature of two-photon excitation to photochemically uncage stimulants in the imaging medium. When the stimulant was uncaged near the membrane, it stimulated receptors in close proximity, which was detected through a patch clamp of the cell. In this type of imaging, excitatory response, rather than photons, maps the image. In particular, a study utilizing uncaging of MNI-glutamate in conjunction with a whole-cell clamp for detection of signal was successfully used to map glutamate receptors on cultured hippocampal neurons and hippocampal CA1 pyramidal neurons in acute slice preparations (Matsuzaki et al., 2001). These researchers were able to obtain excellent lateral and axial FWHM diameters of 0.6 and 1.4 μm, respectively, in the slice preparations, indicating fast uncaging chemistries. These researchers determined that α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors are abundant in mushroom spines and that the distribution of these receptors is tightly correlated with spine geometry.

CONCLUSIONS

Two-photon excitation microscopy shows great utility for dynamic imaging of living cells in thick samples, such as intact tissue. This often makes possible experiments where conventional imaging cannot be performed. Using a mode-locked (pulsed) laser and photon crowding at the focal point, two-photon excitation only occurs at the focal plane. Localized excitation results in emission from only the focal region, providing sectioning ability without the use of a pinhole, and it reduces phototoxicity because photodamage is largely limited to the focal volume. Although two-photon

excitation microscopy does not generate images with higher resolution than confocal microscopy, it does allow for increased depth penetration into samples. This increased depth penetration is possible due in part to the open pinhole geometry of the two-photon microscope, lack of out-of-focus absorption of the excitation light, and decreased scattering of the excitation light. In order to take full advantage of the depth of penetration, it is necessary to use nondescanned detection geometries because of the dramatic increase in collection efficiency of scattered photons. Clearly, the advantages of two-photon excitation have allowed for experiments that would not be possible using confocal microscopy, and, as this technique gains popularity and the technology gets less expensive, it is expected that more and more exciting experiments will be achieved.

Total Internal Reflection Fluorescence Microscopy for High-Resolution Imaging of Cell-Surface Events

The wavelength of light imposes a physical limit of ~400 nm on the maximum resolution that can be achieved using light microscopy. This unit will describe the use of total internal reflection fluorescence microscopy (TIR-FM), or evanescent wave microscopy, an approach that partially overcomes this physical limit and permits one to selectively image just those fluorophores in the optical plane (along the *z* axis) within 50 nm of the cell surface. TIR-FM works by means of limiting the depth of penetration of the excitation light within this narrow region. This narrow excitatory plane not only provides a high signal-to-noise ratio but also minimizes the photodamage to the cell.

Basic through-the-objective TIR-FM setups are now commercially available from Olympus and Nikon, and these can be used for most generic applications. The Basic Protocol, however, outlines a procedure for setting up a TIR-FM microscope in the laboratory using a through-the-prism configuration, and the Alternate Protocol outlines a modification of this procedure for a through-the-objective configuration. These outlines are intended to serve as a starting point; the exact details of any home-made setup will ultimately be decided based on the exact application.

SETTING UP A THROUGH-THE-PRISM TIR-FM SYSTEM

BASIC PROTOCOL

A prism can be used to direct the excitation beam to the samples above the critical angle for total internal reflection. Based on the relative position of the prism, coverslip and the objective there are various ways to set up the prism based TIR setup. These variants are described in the Background Information and in Figure 4.12.3. This section describes the protocol used for setting up the basic prism based setup in which the prism is adjacent to the objective (Fig. 4.12.3C).

Materials

40- to 100-nm fluorescent polystyrene beads (Molecular Probes)
0.05× phosphate-buffered saline (PBS; *APPENDIX 2A*)
Immersion oil appropriate for objective (see Critical Parameters)

Wide-field epifluorescence microscope, upright or inverted (*UNIT 4.1*) with appropriate excitation and emission filters
Prism (see Background Information; Edmund Scientific)
Laser (see Critical Parameters; Spectrum Physics, Coherent, Melles-Griot, and others), with single-mode laser optical fiber or system of mirrors and focusing lens
Sykes-Moore chamber (Bellco Glass) or other coverslip mounting chamber
Laser-safety goggles

Set up microscope, prism, and laser

1. Use a conventional wide-field fluorescence microscope (upright or inverted). Mount the prism either on the holder for the condenser or build a stable mounting that has the option of vertical motion.

   The choice of prism shape (e.g., cubic, rectangular, equilateral, or trapezoidal) depends on the desired configuration of the setup—i.e., whether the prism is adjacent or opposite

Contributed by Jyoti K. Jaiswal and Sanford M. Simon
Current Protocols in Cell Biology (2003) 4.12.1-4.12.15

to the objective. In this protocol, a through-the-prism system where the prism is adjacent to the objective is described (see Background Information and Fig. 4.12.3C).

The prism should have the freedom to move parallel to the optical axis with its surface in contact with the coverslip. For a microscope that focuses by moving the stage up and down, a micromanipulator that can hold a prism could be fixed to the microscope stage.

2. Direct the laser light to the prism by using either a single-mode laser fiber or a system of mirrors and focusing lens with adjustable angle mounts fixed to the table. Include a suitable shutter in the laser light path to permit switching between the epifluorescent illumination from the arc lamp and the TIR-FM illumination.

Establish area of TIR using fluorescent beads

3. Prepare a 1:1000 dilution of 40- to 100-nm fluorescent polystyrene beads in 0.05× PBS. Mount a coverslip on the microscope in the same manner as for the actual experiment (e.g., mounted using a Sykes-Moore chamber or any other coverslip mounting chamber). Add sufficient volume of solution to cover the entire coverslip.

4. Use the arc lamp illumination to focus on the fluorescent beads that are immotile (attached to the coverslip).

5. Place a small droplet of immersion oil directly on the prism. Carefully translate the prism vertically so that it touches and spreads the oil, but does not inhibit the lateral sliding motion.

   Beading up of the oil around the edges of the prism should be prevented by using little oil and by wicking away the excess, as it could interfere with the illumination path.

6. Wearing the laser safety goggles, with the help of mirrors (and without any focusing lens in place), adjust the collimated laser beam position so that it is directly in line with the objective's optical axis (see Background Information).

   The beam can be observed by the scattering of the laser light as it traverses the prism, oil, and oil-glass interface.

7. Insert the focusing lens and focus the beam roughly at the region of the interface in line with the objective. Using the focusing lens mount, adjust the lateral position of the lens (not the mirrors controlling the raw laser beam) so that the laser beam hits the interface between the coverslip and the aqueous solution directly in line with the objective. To guide this adjustment, look directly at the beam path for three closely aligned spots of scattered light, corresponding to where the focused beam first crosses the immersion oil layer, where it totally reflects off the sample surface, and where it exits by crossing the oil again.

8. Using the epifluorescence excitation, ensure that the immotile fluorescent beads are still in focus.

   In epifluorescence, the motile beads will appear as a diffuse fluorescent blur. If TIR is achieved, the immotile beads (attached to the glass) should always be visible, but the motile fluorescent beads will appear to be constantly bouncing in and out of the evanescent field and hence in and out of the field of view. If this "bouncing" of beads is not clearly visible, then readjust the incident angle of the laser beam.

9. Once the conditions described under step 8 are obtained, use the focusing lens to center the area of TIR within the field of view.

   The focusing lens can be moved forward or backward along the laser optical path to achieve the desired size of the total internal reflection area on the coverslip.

Examine specimen

10. Once the optics are correctly aligned for total internal reflection, translate the prism vertically to remove the sample with fluorescent beads and replace it with the experimental sample. Translate the prism back to the same position to make optical contact.

    Although the total internal reflection region will not be in exactly the same spot because of irreproducibility in the prism height, it will be close enough to make final adjustments with the focusing lens while observing fluorescence from the new sample.

SETTING UP A THROUGH-THE-OBJECTIVE TIR-FM SYSTEM

ALTERNATE PROTOCOL

An objective with a high numerical aperature (>1.45 NA, see Table 4.12.1) can be used to bring the excitation beam to the sample above the critical angle for total internal reflection. The same objective can be used to collect the resulting emission from the sample (Fig. 4.13.4A). This section will describe how this can be achieved. See Background Information for further details and Critical Parameters for choosing the proper objective for your purpose.

Additional Materials *(also see Basic Protocol)*

Optical mounts including mirrors, optical fiber couplers, and fiber optics or lenses for coupling the laser beam expander to the microscope port (Olympus, TILL Photonics)
Plano-convex lens of short radius of curvature *or* hemispherical or triangular prism and converging lens with focal length of several centimeters
High-numerical-aperture objective (see Critical Parameters)

1. Set up microscope and laser, and prepare bead suspension (see Basic Protocol).

   For ease of switching back and forth between TIR-FM and epifluorescence illumination, the optics used to combine the arc lamp and TIR light sources should include a movable mirror that is easily reached and that can be used to switch between the two light paths. This can be achieved by making the laser beam perpendicular to the arc-lamp beam, and inserting a retractable mirror at an angle of 45° to both the beams at the place where the two meet. Depending on whether the mirror is inserted or not, one can choose between the arc lamp and the laser beam.

Steer the laser beam into the center of the objective

2. Place a triangular or hemispherical prism or a plano-convex lens (flat side down) on a coverslip and place this assembly on the microscope stage.

3. Add immersion oil between the objective and the coverslip and focus on the upper surface of the coverslip using the halogen lamp illumination.

   Usually dust and defects on the coverslip can be easily seen, to assess the focus.

4. Allow the raw collimated laser beam to enter the standard epi-illumination port and field diaphragm along the optical axis. Steer the beam such that removing all the obstructions between the coverslip sample and the room ceiling produces a large area of laser illumination on the ceiling, roughly straight up.

Obtain and confirm TIR illumination

5. Reposition the beam so that it enters the center of the field diaphragm at an angle that is no longer parallel to the optical axis. Slowly increase the angle until the laser illumination on the ceiling, moving to an ever-lower position on the side wall, just disappears (at this angle, the beam is just blocked by the internal aperture of the objective). Reduce the entrance angle so that half the illuminated area is visible.

6. In order to focus the raw beam at the back focal plane of the objective place the converging lens about 20 cm up-beam from the field diaphragm. This will cause the illuminated region on the wall to become smaller.

7. Move the converging lens longitudinally (along the axis of the laser beam) towards the field diaphragm.

   The back-focal plane can be seen by removing the eyepiece. Some microscopes (e.g., Olympus 1 × 70) have a toggle switch near the eyepiece that permits visualizing the back focal plane without removing the eyepiece.

   This will continuously minimize the illuminated region on the wall until the focal point of the lens falls exactly at the objective's back focal plane. At this position, the beam emerging from the objective lens is roughly collimated and would be propagating upward along the inner periphery of the objective.

8. Verify that total internal reflection is achieved by moving the coverslip horizontally to a new spot that is not under the prism.

   Almost no light should emerge, except for some scattering, because of total internal reflection at the glass coverslip–air interface.

9. Replace the bare coverslip with an identical one containing a solution of fluorescent beads and again verify that no light emerges, even at the glass-water interface.

   If the light does emerge, then change the angle of the incident beam using the steering mirrors just until the point when no light emerges.

10. Confirm that TIR excitation is indeed achieved by focusing the epifluorescence excitation on the fluorescent beads, then switching to TIR illumination.

    When TIR is achieved, the diffuse background fluorescence from the beads will be lost. Instead there will be two populations of beads. A small number of immotile beads (attached to the glass) will always be visible and a larger population will bounce in and out of view. If this bouncing of beads is not apparent, adjust the incident angle of the laser beam until it is.

11. Fine tune the mirrors and converging lens to center the total internal reflection field.

    The size of the total internal reflection fluorescence area on the sample is directly proportional to the laser-beam size at the field diaphragm. To change this size, replace the converging lens with another one of different focal length but always keep its focal point at the objective's back focal plane, which is at a fixed position up-beam from the microscope.

Examine specimen

12. Replace the fluorescent beads with the actual sample.

    When the cells are in focus, the total internal reflection optics should be perfectly aligned without need for further adjustment.

SUPPORT PROTOCOL

MEASURING THE INCIDENT ANGLE OF THE EXCITATORY BEAM

While for the prism-based setup the angle of the incident beam can be measured directly. However, the following indirect method can be used to measure the angle of incidence for both through-the-prism and through-the-objective types of setup.

For materials, see Alternate Protocol.

1. Follow steps 1 to 9 of the Basic Protocol or 1 to 11 of the Alternate Protocol to obtain TIR.
2. Without disturbing the optical setup of the excitation beam, replace the coverslip containing the beads with a coverslip containing a hemispherical prism or a plano-convex lens (see Alternate Protocol, step 2).
3. Place a screen on the wall adjacent to the microscope to mark the position of the beam exiting the prism.
4. Carefully mark the position on the screen that corresponds to the vertical position of the coverslip on the stage.
5. Measure the horizontal positions of these two spots with relation to their points of exit from the coverslip.
6. Using the above values draw a triangle connecting these three points, and calculate the angle between the TIR beam and the base (abscissa) of the triangle.
7. Determine the angle of incidence of the excitatory beam by subtracting the calculated angle from 90°.

COMMENTARY

Background Information

The earliest recorded demonstration of the phenomena of total internal reflection was by John Tyndall on May 19, 1854. Tyndall, who is credited for explaining why the sky is blue, presented a demonstration entitled "On Some Phenomena Connected with the Motion of Liquids." His lecture covered the properties of thin streams of water. At the end, he presented a demonstration in which light, leaving a water tank through a hole in its side, would follow the water as it fell to the ground (Fig. 4.12.1). The light hit the interior sides of the water stream at an angle steep enough that it was completely reflected. No light was observed to leave the water stream and, instead, the water served as a light pipe (Pepper, 1860; Greenslade, 1997).

The fundamental principle of TIR-FM is based on one additional observation. Total internal reflection of the light means that there is no energy propagated on the opposite side of the interface. However, a standing field is generated at the interface, into the medium of lower refractive index on the side opposite the incident wave. This field, called the evanescent field or evanescent wave, decays exponentially with increasing distance from the interface (Fig. 4.12.2A). The characteristic distance for decay of the evanescent-wave intensity is a function of the incident angle of the light beam, its wavelength, and the difference in the refractive index of media on either side of the interface. For most biological applications, altering these parameters the field of illumination can be adjusted to any depth between 50 and 200 nm. Thus, the predominant excitation of fluorophores is within this distance from the interface.

In 1965, Hirschfeld developed this as a method for selectively illuminating a surface at a solid-liquid interface. However, it was not until 1981 that this approach was adopted for use in biology to image cell-substrate contact (Axelrod, 1981, 1983; Axelrod et al., 1981; Gingell, 1981). Although TIR-FM has been applied for a variety of biological applications over the past two decades, very recent technical advances in fast imaging and image analysis, as well as the availability of commercial TIR fluorescence microscopes, are opening up possibilities for wider and easier application of this technique (Axelrod, 1989, 2001). As a result, TIR-FM has been used for a variety of live-cell applications, including study of cell-surface contact, diffusion of proteins and lipids in the plasma membrane, submembrane actin dynamics, and vesicular exocytosis (Schmoranzer et al., 2000; Sund and Axelrod, 2000; Wagner and Tamm, 2000; Amann and Pollard, 2001; Steyer and Almers, 2001; Toomre and Manstein, 2001).

Theory of TIR-FM

When a beam of light encounters a medium with lower refractive index, it changes its path such that the resulting beam is refracted (bent away) from the path of the incident beam. For TIR-FM, the incident angle, θ, (as measured from the plane normal to the incident surface) has to be large enough for the beam to totally internally reflect back into the medium with the higher refractive index (Fig. 4.12.2B). This con-

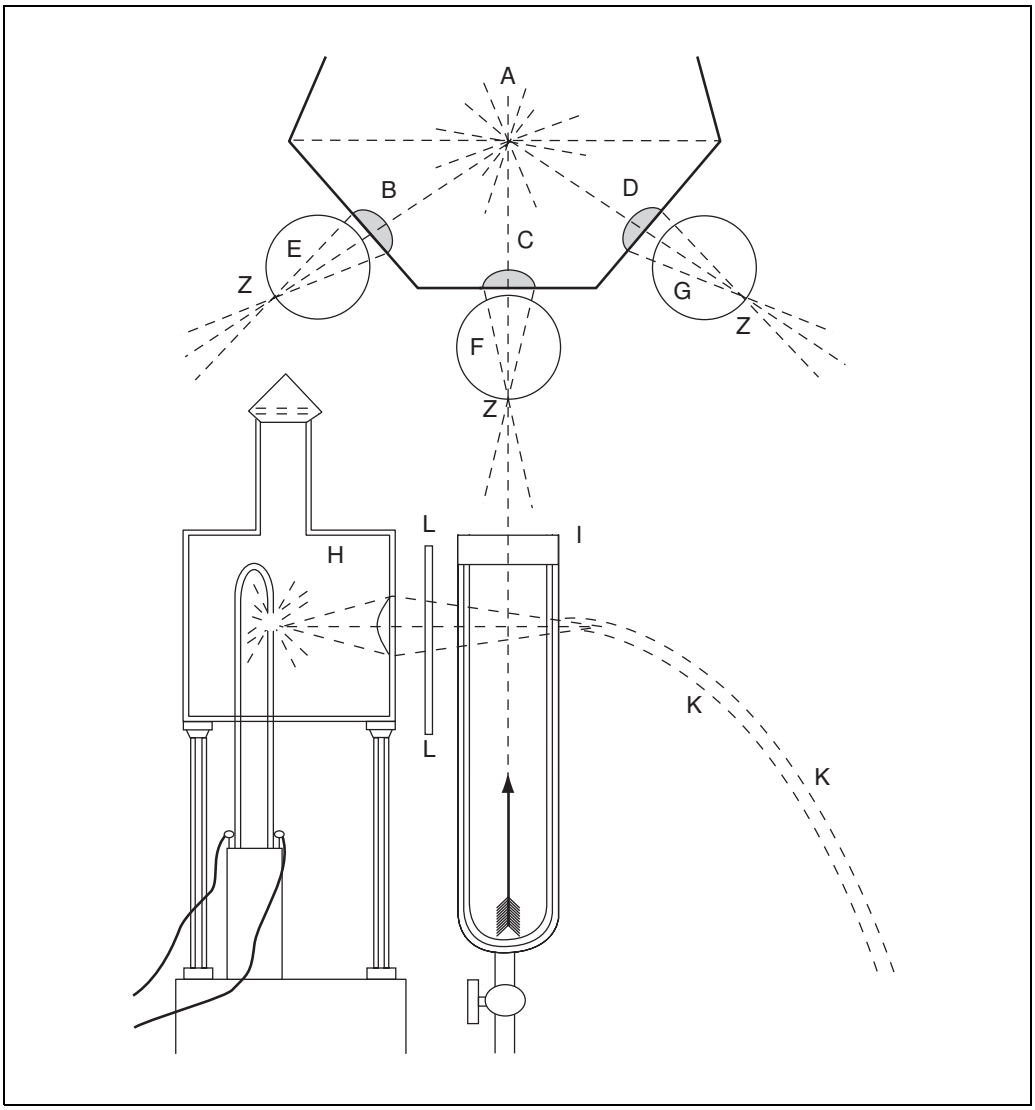

Figure 4.12.1 Illustration of the classic experiment ("The Liquid Vein") demonstrating total internal reflection. The apparatus (viewed from the top in the upper part of the figure and from the side in the lower) consists of a Duboscq lantern with an electric arc light (A), three sides of which are furnished with lenses (E, F, and G). Outside the lantern are three cylinders of water, each with a circular glass window and orifices at (Z) from which the water and the rays of light pass out. In the lower diagram, a section is seen of one side of the Dubosoq lantern (H) and one cylinder of water (I), with the water entering from below through the stopcock. The stream of illuminated water is labeled K, and L represents a bit of colored glass held between the lantern and the cylinder of water to impart color to the light. From Pepper (1860).

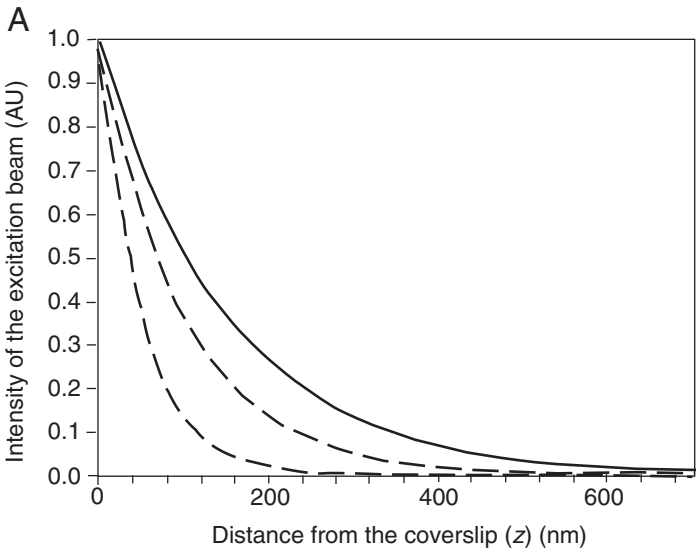
dition occurs above a critical angle. For a light beam that is traveling from a medium with high refractive index (n1), such as oil, glass, or silica, into a medium with lower refractive index (n2), such as water or air, the critical angle (qc) is:

$$\theta_c = \sin^{-1}\frac{n_2}{n_1}$$

Equation 4.12.1

For TIR to occur, the ratio n2/n1 must be <1, and the value of q should be > qc. For all values of q < qc, the light beam propagates through the interface, leading to a wide-field illumination. Glass coverslips typically used to grow tissue culture cells have a refractive index (n1) of 1.515, while the cytosol and the medium surrounding the cells have refractive indices (n2) ranging from 1.33 to 1.38. To obtain total internal reflection at the higher end of the cellular refractive index (1.38), the angle of incidence must be larger than the critical angle of [sin-1 (1.38/1.515) = 65.64°].



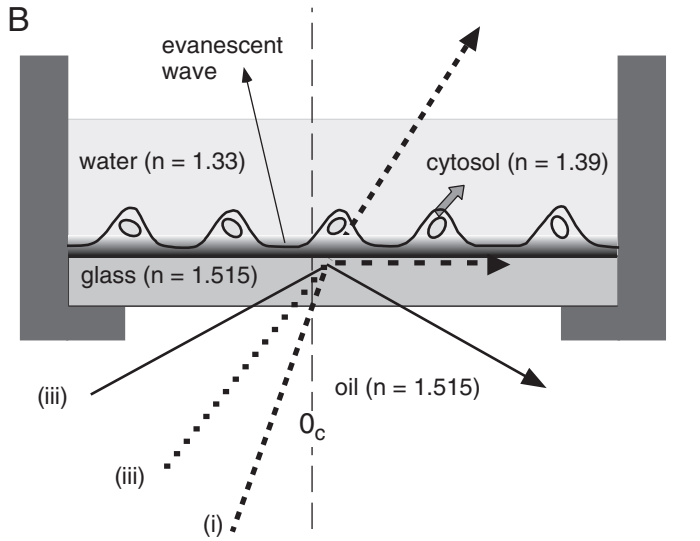


Figure 4.12.2 (**A**) Exponential decay of evanescent field. The intensity of the evanescent field in the aqueous medium is plotted over the distance from the coverslip/water interface for typical decay lengths (dotted line, $d = 50$ nm; dashed line, $d = 100$ nm; and solid line, $d = 150$ nm) used in most experiments. (**B**) Illustration of Snell's law, refraction, and total internal reflection. Beams that are (i) refracted, (ii) incident at the critical angle, and (iii) totally internally reflected are illustrated at a glass-water interface. The evanescent field is indicated as a gradient of gray at the interface that falls exponentially with distance from the interface.

If, instead of intact cells, permeabilized or fixed cells are used, the effective refractive index is that of aqueous buffer (n2 = 1.33), and the critical incidence angle is reduced to 61.39°.

For values of q > qc, the resulting electromagnetic evanescent field has the same frequency, wavelength, and polarity as the incident light. For an infinitely wide beam, the intensity of the evanescent wave (measured in units of energy/area/sec) decays exponentially with perpendicular distance from the interface between the two media (Fig. 4.12.2A). The intensity (I) at any given point z is related to the intensity at the interface [$I(0)$] by:

$$I(z) = I(0)e^{-\frac{z}{d}}$$

Equation 4.12.2

where for a light of wavelength λ, which is incident at the interface at an angle θ, the depth of penetration (*d*) is given by:

$$d = \frac{\lambda}{4\pi}\left(n_1^2 \sin^2 \theta - n_2^2\right)^{-\frac{1}{2}}$$

Equation 4.12.3

At $\theta > \theta_c$ evanescent wave intensity is equal to the intensity of the incident beam, but the intensity approaches zero as θ approaches 90°.

Methods for achieving total internal reflection

The necessary and sufficient criterion for obtaining total internal reflection is that the excitation light be introduced on the surface of the coverslip at an angle greater than the critical angle. This can be achieved in a variety of different ways, and, as detailed below, each of these have their advantages and limitations.

Excitation through a prism: In the prism-type TIR-FM setup, the excitatory beam is coupled into the coverslip via a prism (Fig. 4.12.3A, B, and C). At the first interface between the air and the prism, the angle of the excitatory beam is narrow enough that most of it enters the prism with minimal refraction. The prism and the coverslip are in contact with the oil, whose refractive index matches that of the glass. Thus, the excitation beam passes through this interface with minimal reflection or refraction. However, changing the angle of incidence of the beam on the prism allows alteration of the angle at which the beam hits the interface of the coverslip and the cell. At a steep enough angle, the excitation beam is totally internally reflected at this interface, resulting in excitation

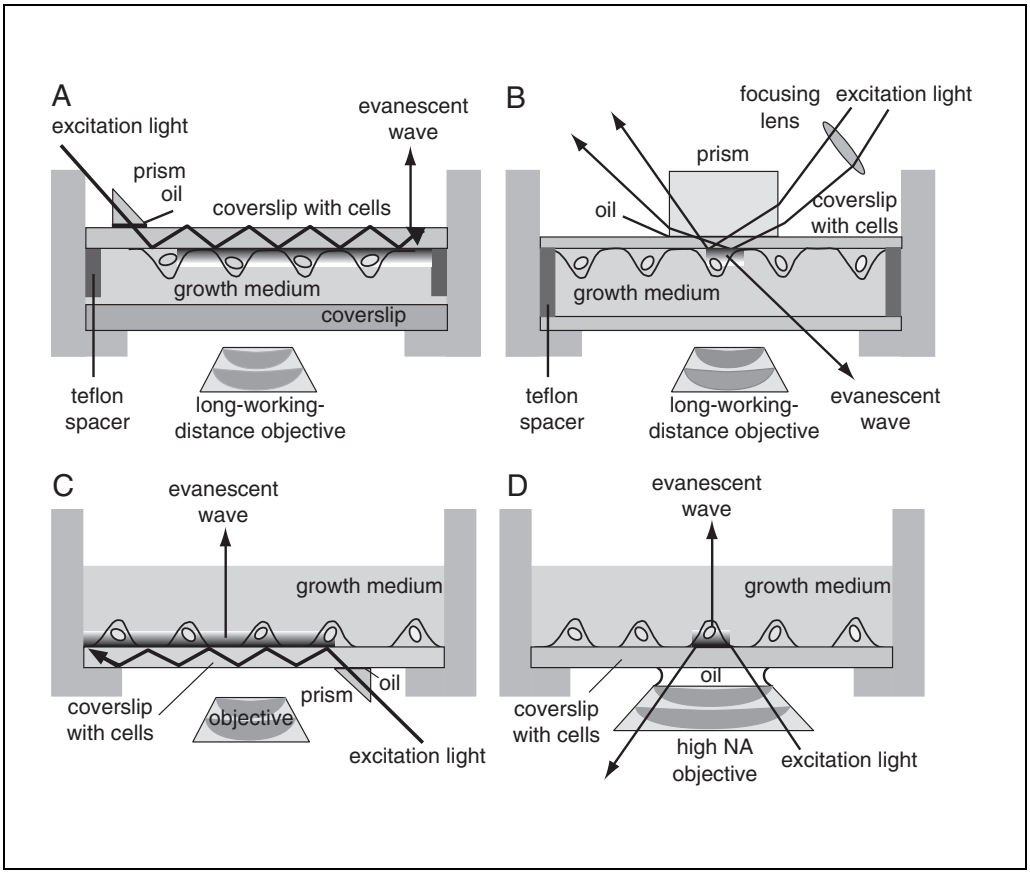

Figure 4.12.3 Possible arrangements for setting up total internal reflection fluorescence microscope. In (**A**) and (**B**), the excitation beam is passed through the prism opposite the objective. Unlike (A), a narrow field of TIR illumination is achieved in (B) with the use of a bigger prism that allows the internally reflected light to pass through the prism instead of being reflected back into the coverslip. In (**C**), the excitation beam passes though the prism adjacent to the objective, and in (**D**), excitation takes place through the objective.

of a narrow region of the cell near the coverslip. The resulting fluorescence from the cell is collected by an objective lens.

An advantage of the prism-based approach is that it allows separation of the excitation and emission light paths. This reduces the background fluorescence caused by scattering of the excitation light in the objective. This setup also reduces the need for elaborate optics necessary to prevent the bleed-through of the excitation light into the emission channel. However, there are many limitations to this approach. First, once the sample has been focused, the prism must be carefully positioned on the coverslip and maintained such that it does not lose the coupling with the coverslip. Second, the oil used to couple the prism to the coverslip must be kept very clean throughout an experiment; any dust will cause scattering of the excitation light. Third, during positioning of the prism on the surface, the oil must not be allowed to spread on the coverslip, since TIR will be lost from places where the oil spreads on the surface of the glass.

Depending on the position of the prism used to target the excitation light, with respect to the objective lens, there are two basic types of prism-based setup, as described in the following paragraphs.

Excitation through the prism opposite to the objective: As described in Figure 4.12.3A and B, in this setup the fluorescence emission is collected through an objective from the side opposite to that of the prism. Depending on the prism used, cells on the entire coverslip can be illuminated (Fig. 4.12.3A) or the excitation light can be limited to a small region under observation (Fig. 4.12.3B). The relatively large distance between sample and objective limits this application to an objective with a long working distance and a low NA (typically 0.75 or less). Thus, this technique is less sensitive and not suitable for low-light applications.

Excitation through the prism adjacent to the objective: In this setup, the prism is on the same side of the coverslip as the objective, while the specimen is on the opposite side (Fig. 4.12.3C). The specimen can be translated while the prism remains laterally fixed. The advantage of this approach is that it allows the use of objectives with higher NA than can be used with the prism on the opposite side of the objective. A disadvantage of this configuration is that oil- or glycerol-immersion objectives cannot be used. If oil/glycerol were used at the interface of the prism and coverslip and any of it were to smear, it would lead to loss of total internal reflection. Thus, the choice of objectives is limited to air- or water-immersion objectives. This puts an upper limit to the numerical aperture of the objective, thus reducing the sensitivity of the detection. Depending upon how the coupling is done, this could lead to a fairly wide field of excitation which could be an advantage or disadvantage depending upon the experimental interest.

Excitation through the glass support setup: This approach, which is useful for large-scale evanescent wave excitation, is a slight variation on the excitation-through-the-prism approach. Here the excitation beam is directly coupled to a thin glass surface with the specimen on it. The laser has to be introduced at an angle such that, after refraction in the glass support, the light impinges upon the sample at an angle > qc, thus generating an evanescent wave. This can be done by making an appropriate angle at the edge of the glass surface. This allows the use of any objective of choice; at the same time it does not restrict the accessibility to the sample. However, due to the larger field of evanescent illumination, it leads to photobleaching even outside the field of view. Also, if the coupling between the laser and the coverslip is not robust, it could lead to fluctuations or even a total loss of evanescent field.

Excitation through the objective: In the objective-type TIR-FM setup, the supercritical angle on the coverslip-cell interface is reached by focusing the excitatory beam on the periphery of the back focal plane of the objective (Fig. 4.12.4A). In this way, the beam is refracted by the objective and directed through the refractive index–matched media: the objective, the immersion liquid, and the coverslip. The objective thus functions both as the prism, delivering the exciting beam, and as the optics, collecting the emission. The main advantage is that objective-type TIR-FM employs high-numerical-aperture, short-working-distance objectives, resulting in collection of much higher fluorescence emission compared to the prism-type approach. This results from the relationship whereby light collection is approximately equal to the square of the NA; thus, a 1.65 NA objective used in the objective-type TIR will collect 90% more light than a 1.2 NA water objective required for the prism-type TIR. Moreover, such a setup makes the sample fully accessible for other manipulations such as microinjection, patch

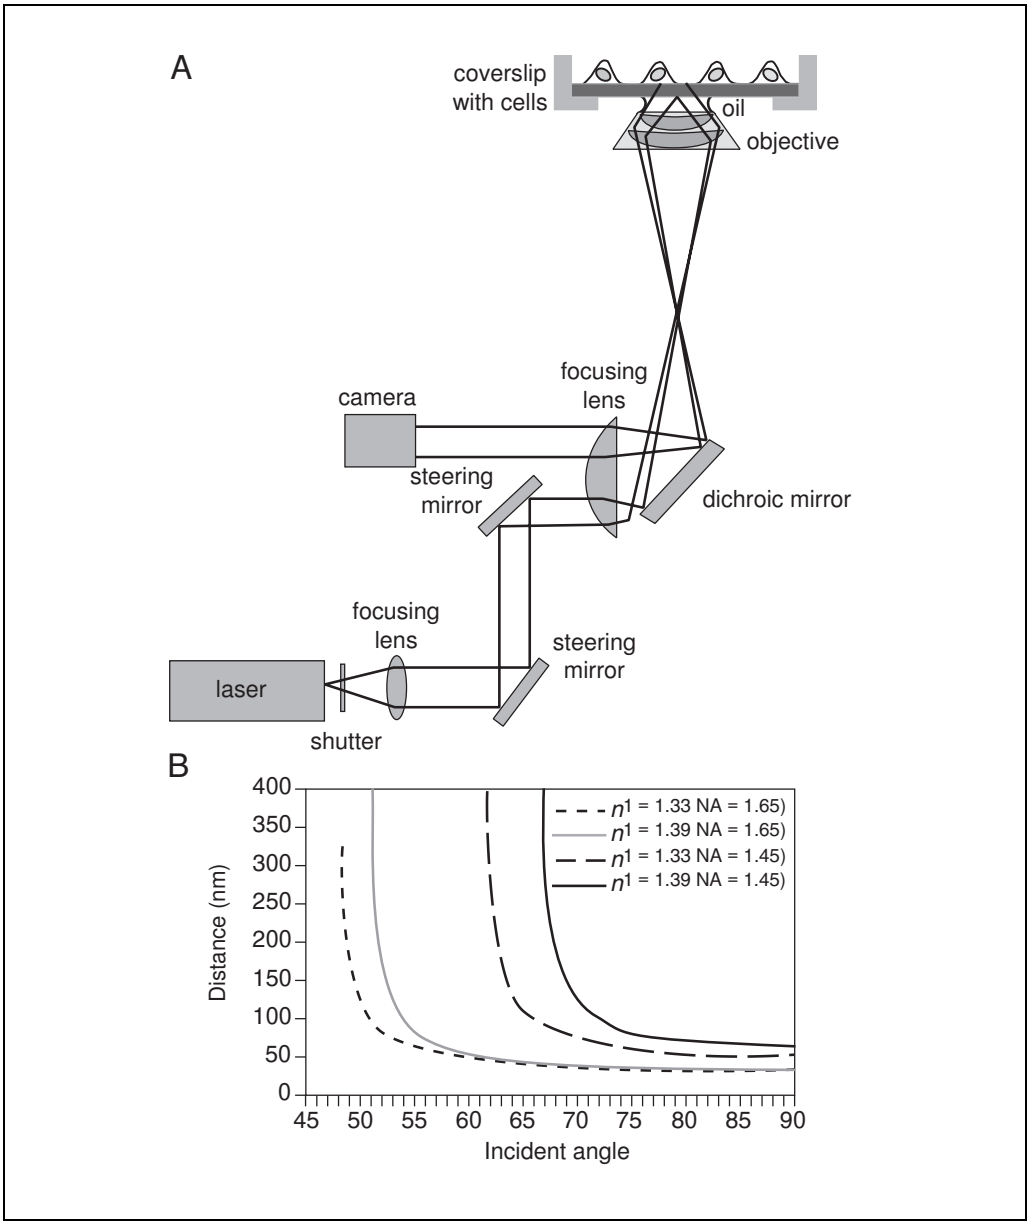

Figure 4.12.4 Through-the-objective TIR-FM setup. (**A**) Excitation and emission light path. (**B**) Relationship between incident angle of the beam and its evanescent depth. The spatial decay constant for the evanescent field is plotted for both the NA 1.45 and 1.65 objectives according to Equation 4.12.2 for refractive indices (n_1) of 1.33 and 1.39, typical of water and cytosol, respectively.

clamping, and atomic force microscopy. Another advantage of this approach is that it permits the use of both a laser-based and an arc lamp–based excitation light source for TIR. Finally this approach is easier and more reproducible in terms of setup: it does not require oil to couple the prism to the objective; it does not require a careful positioning of the prism on the coverslip; and from experiment to experiment, there is less variability in alignment of the excitatory beam. This approach has some limitations. First, since the excitation light has to pass through the same optics as are used to collect the emission, dichroics and filters must be used to minimize inadvertent detection of the excitation light. Second, if the excitation is not properly aligned, it is possible to get scattering within the objective, which would lead to loss of TIR-FM.

Critical Parameters

Depending on which of the methods is used to achieve TIR, the optics used (prism or high-NA objective, or edged glass) to target the

excitation light need to be altered, but the rest of the setup is similar in all cases.

Epifluorescence microscope

Both an upright or an inverted epifluorescence microscope can be used for an TIRF microscope. For applications that require access to the sample for other manipulations such as microinjection, atomic force microscopy, patch clamping etc. use of inverted microscope with the objective-type setup (Fig. 4.12.3D) or with a "prism adjacent to the objective" setup (Fig 4.12.3C) is recommended. However, an upright microscope with long working distance objective can also be used in conjunction with "prism opposite to the objective" setup to provide a limited access to the sample.

Light source

In principle, it is possible to employ conventional tungsten halogen or mercury/xenon arc lamps to conduct TIR-FM experiments. However, using an arc lamp requires generation of a sharp-edged shadow image of an opaque circular disc at the back focal plane of the objective. Although the arc lamp provides the convenience of selecting any excitation wavelength from the UV to the visible spectrum just by changing the excitation filters, a majority of the investigations reported in the literature are performed using laser illumination. The reason for this is that laser light is brighter, coherent, polarized, and well collimated. Hence, it is easier to direct into the objective or prism using standard beam expanders, mirrors, and focusing lenses. Collimation of the light emitted by the arc lamp results in severe (>90%) reduction of intensity, making it difficult to use the commercial arc lamps as light sources for TIR-FM. Another advantage of the laser source is that it can be used to illuminate an area of a defined geometry that can be easily adjusted to accommodate experimental variations. However, a limitation of laser illumination is the unavoidable interference fringing on the specimen. These fringes can be somewhat reduced by meticulously cleaning the optical surfaces. Additionally, a field with a uniform concentration of fluorophore can be used to generate an image that can then be used to normalize for the spatial inhomogenities in illumination. Alternatively, for experiments requiring highly uniform illumination, the fringing can be eliminated by using a commercially available laser fiber phase scrambler.

For most applications, a laser with a single-wavelength output of ≥20 mW should be adequate. However, for applications requiring short exposure time, e.g., FRAP (*UNITS 13.5 & 21.1*), lasers with output of 100 mW should be used. In either case, the laser should provide an option for regulating its output externally. If the laser source does not provide the means to regulate the power output, then an acousto-optic modulator (AOM) or a set of neutral-density filters should be introduced in the laser light path. Note that AOMs provide a continuous control of the intensity from zero to the maximum, but they tend to lose up to 50% of the input light. Hence, use of AOMs necessitates lasers with higher power.

For any of the types of TIR-FM setup described above, excitation light from a laser source can be introduced either through an optical fiber or as a free-standing beam. However, the exact optical arrangement is dependent upon the setup used to obtain TIR-FM. For through-the-prism setup, use of optical fiber minimizes the risk of accidental direct exposure to the laser beam. Depending on the position of the prism (with respect to the sample), the fiber has to be placed either above or below the microscope stage and positioned to target the beam into the prism at an appropriate angle for TIR. Similarly a fiber-based setup should be used for the through-the-glass-support-based setup. For the objective-based setup, the laser light could be introduced using a fiber in the same port as the epifluorescence light from the arc lamp; the two light sources can thus be coupled. There are commercially available adaptors from Olympus, Nikon, and TILL Photonics (see *SUPPLIERS APPENDIX*) that permit coupling the light sources for a variety of microscopes. Alternatively the free-standing laser light can also be steered into the microscope using mirrors and focused on the back focal plane of the objective using a set of focusing lens (Fig. 4.12.4A).

Objectives

As described in Equation 4.12.1, in order to collect maximum amount of light emitted by the sample (and hence obtain brighter images) it is necessary to use an objective with as large a numerical aperture (NA) as possible. Any long-working-distance objective can be used for a prism-based TIR-FM setup with the prism on the opposite side (Fig. 4.12.3A and B). However, for a setup with the prism on the same

side of the sample as the objective (Fig. 4.12.3C), the choice is an air objective (preferably with a high NA). The choice of objective for through-the-objective TIR-FM setup is crucial. This can be achieved reliably only with oil-immersion objectives having an NA of 1.45 or larger.

As can be deduced from Equation 4.12.1, for an objective lens with refractive index of 1.515 and a NA of 1.40, the maximum angle at which the light can be incident on the sample is [$\sin^{-1}(1.4/1.515) = 67.53°$]. For viewing live cells using an objective with n = 1.515, the critical angle is 65.63° (Table 4.12.1; Fig. 4.12.4B). This leaves a very small region of the objective that can be used to obtain TIR. Because the refractive index of the cell is not uniform along all of its surface, and because even a small extent of scattering of excitation light could lead to a loss of total internal reflection, use of objectives with NA of 1.4 or lower is not practical for obtaining through-the-objective TIR. Development of objective lenses with NA of 1.45 by Olympus, Nikon, and Zeiss, and with NA of 1.65 by Olympus, has made it possible to reliably obtain TIR through the objective (Table 4.12.1).

The 1.65 NA objectives: In contrast to all other objectives that make use of glass with a refractive index of 1.515, the 1.65 NA Apo 100× objective by Olympus uses glass with a refractive index of 1.788. The higher refractive index of the glass, together with the high numerical aperture of the objective, has a few consequences for TIR microscopy. First, there is a relatively wide range of angles over which TIR can be achieved (Terakawa et al., 1997; Kawano et al., 2000; Table 4.12.1, Fig. 4.12.4B). Second, the higher refractive index makes the TIR field much less sensitive to variations in the refractive index of the cell, resulting in a uniform evanescent field all along the cell surface. At an angle of 63° (typical for this objective) the space constant ranges from 44 nm (n_2 = 1.33) to 48 nm (n_2 = 1.37). As the angle is varied for n_2 = 1.33, the space constant for this field ranges from 49 nm (for 60°) to 42 nm (for 66°). The main disadvantages of this objective are the requirement for a special high-refractive-index immersion liquid (n = 1.78) and high-refractive-index coverslips (n = 1.788). The currently available immersion liquid is volatile and slightly toxic, leaving a crystalline remnant on the objective after a few hours in a heated environment. The high-refractive-index cover slips supplied by Olympus (composed of Ohara glass LAH64, thickness 0.150 mm) are very expensive, fragile, and acid- and base-labile, and hence difficult to reuse. An acid-resistant alternative for this coverslip is the Schott-glass type SF11, available in 0.150 mm thickness for one-third the price of the Olympus coverslips from VA Optical (see *SUPPLIERS APPENDIX*). However, SF11 is slightly more autofluorescent than LAH64 and causes higher chromatic error. It is therefore only usable for bright and single-color fluorescent samples.

The 1.45 NA objectives: Most of the problems associated with the 1.65 NA objective are overcome by the recent introduction of 60× 1.45 NA objective (Olympus; Nikon) and the 100× 1.45 NA objective (Zeiss; Nikon), which use regular immersion oil and coverslips. The decay constant of the evanescent field for the 60× 1.45 NA objective is also larger (d = 90 to 200 nm) than for the 100× 1.65 NA objective (d = 50 to 100 nm). The range of incident angles for TIR is smaller for the 1.45 NA objectives compared to the 1.65 NA objective (Table 4.12.1). Also, since the 1.45 NA objective uses standard glass with a refractive index of 1.515, the decay distance is more sensitive to local variations in the refractive index of the cell (Table 4.12.1).

Immersion oil

For the objective-type TIR-FM setup it is crucial that the immersion oil being used is refractive index matched with the objective and the cover glass. While use of low autofluorescence immersion oil is desired, most commercially available oil do not have refractive indices suitable for use with the available high NA objectives. Thus the refractive index of the immersion oil should be carefully examined before its use in TIR-FM.

Filters and mirrors

Special excitation and emission filters and dichoric mirrors need to be used with the TIR setup. Due to the higher intensity of the laser light sources, instead of the conventional excitation filters (which are appropriate for blocking light from an arc lamp), excitation filters with higher optical density (>4) should be used. The emission filters must also be carefully chosen so that they are blocked for light outside of the desired wavelength range. Also, the higher laser intensity necessitates use of di-

Table 4.12.1 Total Reflection Angles and Maximum Angles for Objective Lenses

NA of objective	n_1	n_2	Critical angle (θ_c)	Maximum angle of incidence (θ)	Least depth of penetration, d (nm)
1.40	1.515	1.38	65.63° (NA = 1.38)	67.53° (NA = 1.40)	168
1.45	1.515	1.38	65.63° (NA = 1.38)	73.15° (NA = 1.45)	89
1.65	1.788	1.38	50.51° (NA = 1.38)	67.34° (NA = 1.65)	55

chroic mirrors with better antireflective coating, so as to minimize the reflection off the back surface of the mirror. These measures are necessary because leakage of even small amounts of scattered excitation light of different wavelength or of light reflected from the back surface of the dichroic mirror (hence traveling at an angle different from that of the primary beam) would decrease the signal-to-noise ratio.

Troubleshooting

Beam path

If total internal reflection cannot be achieved, make sure that the beam path is not obstructed and that it is still being targeted to the sample. Follow the steps in the Basic and Alternate Protocols to achieve TIR and confirm the existence of TIR using the fluorescent beads. An alternative approach to confirm the existence of TIR involves the use of two dyes, e.g., Fluorescein (green) and Dil (red). A procedure for using these dyes to test for the TIR is as follows.

1. Treat the surface of the cover glass for 10 min with a solution of DiI dissolved at 0.5 mg/ml in ethanol.
2. Rinse off the coverslip with water and add a 0.1mg/ml solution of carboxyfluorescein.
3. Illuminate the sample with 488 nm epifluorescent light. This should lead to both red and green emission.
4. Now switch to TIR illumination. If the TIR setup is not optimal, fluorescence emission of both the dyes will still be visible. Adjust the angle of the incident beam to the point where most of the emission is red, while the green emission is minimal. By shifting the excitatory beam back and forth, one can identify the critical point at which the emission sharply shifts from green (epi) to red (TIR); this will be the point at which the beam is incident on the sample at the critical angle.

Image homogeneity

Often the TIR-FM image of cells that appear homogeneous in epi-illumination appear heterogeneous in TIR illumination. This heterogeneity could be due to dirt and defects on the surface of the coverslip or to the fact that the cells have not adhered well enough to the coverslip. Either of these factors would cause the cell to be illuminated nonuniformly all along the bottom surface of the cell. Since TIR excitation decays exponentially with distance from the coverslip, even slight undulations in the cell membrane due to improper adherence or due to dirt and defects on the coverslip could cause illumination artifacts. To ascertain whether the heterogeneity is due to the illumination artifact of TIR, label the cell membrane using a membrane-specific dye (e.g., DiI) and observe using TIR. If the cell is not attached uniformly to the glass surface, then the fluorescence will be nonuniform. This problem can be remedied by coating the surface of the coverslip with suitable matrix molecules, such as fibronectin or collagen, that will promote better adherence of cells to the coverslip surface. However, cells that do not adhere well to the coverslips might not be suitable for carrying out TIR-FM.

Anticipated Results

As with any form of optical sectioning microscopy, TIR-FM minimizes the out-of-focus fluorescence, and hence it has a high signal-to-noise ratio for the images. This is essential for imaging fluorescently tagged molecules that are present throughout the cell but that carry out their function only in a very narrow region near the cell membrane. For example, actin bundles present near the cell surface are those that are involved in cell adhesion and migration. While wide-field fluorescence imaging of cells expressing fluorescently tagged actin collects fluorescence from actin both near the cell sur-

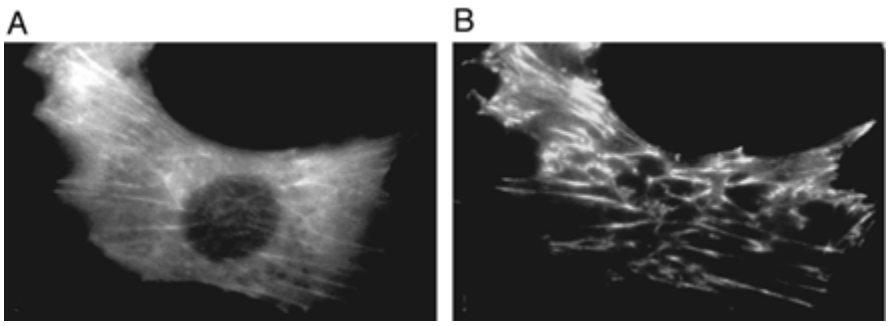

Figure 4.12.5 Imaging the distribution of GFP-labeled actin in live cells. Basal surface of normal rabbit kidney (NRK) cells stably expressing the actin-EGFP was imaged using (**A**) epifluorescence illumination and (**B**) TIR-FM illumination. While the fluorescence of G actin from the entire cell body makes it difficult to resolve the presence of the F actin bundles using epifluorescence, TIR-FM allows visualizing these bundles by illuminating only a narrow region of the cell adjacent to the membrane-coverslip interface.

face and deeper inside the cell, TIR-FM allows imaging of only the actin near the cell surface (Fig. 4.12.5). This allows visualization of changes in actin dynamics as the cells attach and migrate on the coverslip.

Time Considerations

The sample preparation procedure for TIR-FM is just the same as for conventional fluorescence imaging. Hence, once the microscope is set up for operating in the TIR-FM mode, the only additional time needed for carrying out TIR-FM imaging is that involved in ensuring that the TIR beam is properly aligned (<15 min).

Fluorescent Labeling of Yeast

Fluorescence microscopy techniques for yeast cells are fairly similar to those used with mammalian tissue culture cells. As with mammalian cells, fluorescent dyes can be used to identify organelles, GFP fusion proteins can be used to track the localization and dynamics of a specific protein, and membrane trafficking pathways can be evaluated using pulse-chase methods with fluorescent markers. This unit is designed to present a range of fluorescent techniques commonly used for the baker's yeast *Saccharomyces cerevisiae*.

One major difference between fluorescent labeling in mammalian cells versus yeast cells is size. Mammalian cells can range from 10 to 100 μm, compared to ~3 to 5 μm for a yeast cell, making identification of some subcellular structures and clear colocalization determinations somewhat challenging. Using larger, diploid cells for imaging can sometimes help with this problem. In addition, newer confocal microscopes (*UNIT 4.5*) have been designed with more precise control over pinhole size and *z*-axis movements, allowing slices as thin as 0.4 μm, which is thin enough to image multiple planes inside a yeast cell. For reference, most publications involving yeast cell light microscopy use a range of confocal, deconvolution (McNally et al., 1999) and standard fluorescence microscopy and are presented at ~1000× magnification.

The focus of this unit is fluorescence labeling for localization of a specific protein as well as techniques for tracing the movement of molecules through the endocytic pathway. The protocols begin by describing a few of the basic techniques commonly used to label the vacuole (see Basic Protocol 1 and Alternate Protocol 1), which is the degradative compartment of a yeast cell (equivalent to the lysosome of mammalian cells) and is among the more easily identified organelles in yeast. Following this method are assays of the endocytic pathway, which generally leads to delivery to the vacuole, using fluorescent labels (see Basic Protocols 2 and 3, and Alternate Protocol 2). The unit also describes both live and fixed cell imaging techniques for specific proteins as well as techniques to label the filamentous actin cytoskeleton in yeast cells (see Basic Protocols 4 to 6, and Alternate Protocols 3 and 4). Finally, the authors have included a simple technique for identifying budding patterns in haploid and diploid yeast cells (see Basic Protocol 7).

This is by no means a comprehensive list of the methods available for fluorescent techniques in yeast cells. In this unit, the authors have tried to focus on methods that have been tested repeatedly in their laboratory to provide as much insight as possible. The internet is a great resource for additional and alternate yeast protocols that laboratories are willing to share. Entering "yeast protocol" in most search engine queries will provide numerous options. In addition, methods describing flow cytometry/cell sorting of fluorescently labeled yeast (Vida and Wendland, 2002), as well as vital fluorescent dyes to label mitochondria and other structures (Erdmann and Gould, 2002; Nunnari et al., 2002) are also available. The Molecular Probes catalog is another great resource for many useful reagents.

STRATEGIC PLANNING

For each of the protocols, the first step requires the ability to prepare growing yeast cells in medium. See *UNIT 1.6* for a description of liquid culture growth protocols for yeast cells (also see *UNIT 3.8*). Unless otherwise stated, either rich or selective/minimal medium is acceptable. Measure the concentration of yeast cells by an OD_{600} reading in a spectrophotometer expressed as an OD_{600} per milliliter culture. For *most* of the protocols (i.e., unless specifically stated otherwise), it is acceptable to dilute cells back from a semisatu-

Current Protocols in Cell Biology (2003) 4.13.1-4.13.28

rated/saturated culture in the morning as long as the cells double in concentration at least once (after the dilution in the morning) before beginning the assay.

When pelleting yeast cells, it is important to centrifuge at low speeds to preserve the shape and structure of the yeast cells and organelles. For small volumes (≤1.5 ml), use a microcentrifuge and pellet cells at 300 to 800 × *g* for 1 to 5 min. For larger volumes, use a clinical centrifuge and 15- to 50-ml tubes, but pellet cells for 5 to 10 min at 300 to 800 × *g*. If the cells are deformed in any way, decrease the centrifugation speeds. Also, cells in minimal/synthetic medium often do not pellet as well as cells in rich medium (e.g., YEPD). To improve recovery, it may be necessary to pellet the cells, remove ~80% to 90% of the medium, and then centrifuge again before removing the remaining medium. As noted in each protocol, safe centrifugation speeds are normally in the range of 300 to 800 × *g* for live yeast cells.

Most of the methods prescribe the use of concanavalin A (con A)–coated coverslips (22 × 22–mm) to help immobilize yeast cells. The production of con A–coated coverslips is described in Reagents and Solutions.

Yeast strains that are *ade2* mutants (grow as pink or red colonies) accumulate a fluorescent intermediate in the vacuole. If an ADE2$^+$ strain cannot be used, it will be necessary to take special measures to reduce or prevent accumulation of this interfering signal. To do so, add adenine (from a concentrated stock) to a final concentration that is five times normal (i.e., 0.1 mg/ml) to the medium at all times (even to rich/YEPD medium), including the overnight growth medium.

BASIC PROTOCOL 1

LABELING THE VACUOLE IN LIVE CELLS WITH CDCFDA

5(6)-Carboxy-2′-7′-dichlorofluorescein diacetate (CDCFDA, Molecular Probes) is a vacuole-specific vital dye. Briefly, when incubated with cells, it passively diffuses through membranes because of its neutral state. When the dye reaches the vacuole, esterases cleave CDCFDA to form a charged, fluorescent molecule. The charge prevents subsequent diffusion of the fluorescent label from the vacuole. Cells can be viewed by fluorescence microscopy under a FITC filter.

Materials

Yeast cells (see Strategic Planning)
0.5 M sodium citrate, pH 4.0 (see recipe)
10 mM 5(6)-carboxy-2′-7′-dichlorofluorescein diacetate (CDCFDA; Molecular Probes) in anhydrous DMSO (store in the dark for 3 months to 1 year at −20°C)
PBS (pH 7.4)/2% (w/v) glucose (see recipe)

Shaking incubator set to appropriate growth temperature
Con A–coated coverslips (see recipe)
FITC filter

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

1. Culture yeast cells overnight to log phase (~0.3 to 1.0 OD_{600}/ml; *UNIT 1.6*) and transfer 900 µl into a room temperature 1.5-ml microcentrifuge tube.
2. Add 100 µl of 0.5 M sodium citrate, pH 4.0, and 1 µl of 10 mM CDCFDA in anhydrous DMSO.
3. Incubate 15 min at growth temperature with shaking.
4. Centrifuge gently 3 to 5 min at 300 × *g*, room temperature. Aspirate supernatant.

5. Resuspend in 100 µl PBS (pH 7.4)/2% (w/v) glucose.
6. Mount 2 to 3 ml onto con A–coated coverslips and observe using a FITC filter (*UNIT 4.2*).

LABELING ACIDIC ORGANELLES WITH QUINACRINE IN LIVE CELLS

ALTERNATE PROTOCOL 1

6-Chloro-9(4-diethylamino-1-methylbutylamino)-2-methoxyacridine dihydrochloride (quinacrine) is a vital dye that can be used to label acidic compartments in cells (i.e., it gives more general information about the state and function of the vacuole). The unprotonated form can diffuse across cell membranes, allowing labeling of intact live cells. Upon encountering an acidic environment, the molecule becomes protonated, restricting its ability to diffuse across membranes and enhancing its fluorescent signal, making quinacrine an effective tool for specific labeling of acidic organelles. When the dye is used in excess, the quinacrine signal is quenched, so if the fluorescent signal is low, try decreasing the amount of quinacrine used as well as increasing it. The labeled cells are viewed by fluorescence microscopy under a FITC filter.

Additional Materials *(also see Basic Protocol 1)*

Rich medium (*UNIT 1.6*)
1 M HEPES, pH 7.6: adjust to pH 7.6 with KOH (store up to 1 year at room temperature)
20 µM quinacrine (Sigma) in 1 M HEPES, pH 7.6 (store in the dark for 3 months to 1 year at −20°C)
100 mM HEPES (pH 7.6)/2% (w/v) glucose (see recipe), ice cold

1. Culture yeast cells overnight to log phase (0.3 to 1.0 OD_{600}/ml; *UNIT 1.6*). Transfer 1 ml cells to a 1.5-ml microcentrifuge tube and centrifuge 3 to 5 min at 300 × *g*, room temperature. Aspirate medium and cool pellets on ice (~ 2 to 5 min).
2. Resuspend in 0.9 ml rich medium. Add 100 µl of 1 M HEPES, pH 7.6, and 10 µl of 20 µM quinacrine in 1 M HEPES, pH 7.6.
3. Incubate 5 min at growth temperature with shaking.
4. Gently pellet cells by centrifuging 3 to 5 min at 300 × *g*, room temperature. Remove medium and cool pellets on ice (~ 2 to 5 min).
5. Resuspend in 50 µl ice-cold 100 mM HEPES (pH 7.6)/2% (w/v) glucose. Keep on ice.
6. Mount 2 to 3 ml onto con A–coated coverslips and observe using a FITC filter (*UNIT 4.2*).

The quinacrine signal is often faint, so be prepared to take images for up to 10 sec.

LABELING THE ENDOCYTIC PATHWAY IN LIVE CELLS WITH FM4-64

BASIC PROTOCOL 2

N-(3-triethylammoniumpropyl)-4-(6-(4-(diethylamino)phenyl)hexatrienyl) pyridinium dibromide (FM4-64; Molecular Probes), is an amphipathic fluorescent molecule that inserts into lipid membranes, fluorescing only when in this hydrophobic environment. Its charged polar head prevents passive diffusion through membranes, thus it labels only the exoplasmic leaflet of the bilayer. This property makes FM4-64 an excellent marker of the endocytic pathway. Briefly, cells are labeled with dye for a short pulse, then uninternalized dye, including that inserted into the plasma membrane, is washed away. The dye is then chased in live cells for 40 to 60 min, allowing it to reach a steady state localization. In wild-type cells, the FM4-64 accumulates at the vacuolar membrane. The total amount of cell-associated fluorescence represents the approximate rate of internalization over the pulse time, such that differences in intensity can reflect differences in internalization rates.

If cells labeled with this method exhibit an altered fluorescent pattern, this suggests a block or kinetic delay in transit through the intermediate compartments of the endocytic pathway. Cells are viewed by fluorescence microscopy using a rhodamine/TRITC filter.

Materials

Yeast cells (see Strategic Planning)
Rich medium (*UNIT 1.6*) at growth temperature
FM4-64 (see recipe)

Heat block at assay temperature
Water bath with shaker set at assay temperature
Con A–coated slides (see recipe)
Rhodamine/TRITC filter

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

1. Culture yeast cells overnight to log phase (~0.3 to 1.0 OD_{600}/ml *UNIT 1.6*). If cells are not already in rich medium, transfer them into rich medium at growth temperature by centrifuging 3 to 5 min at ~300 to 800 × *g*, room temperature, pouring off the supernatant, and resuspending in rich medium.

2. *Optional:* If the assay temperature is different than the growth temperature (e.g., when testing a temperature sensitive mutant at its restrictive temperature), shift cells to the assay temperature for 10 min to 1 hr.

   From this point on, keep all medium and cells at the assay temperature as much as possible (use a heat block at assay temperature to hold microcentrifuge tubes while aspirating and washing).

3. Transfer 1 ml cells to a 1.5-ml microcentrifuge tube and centrifuge gently 0.5 to 5 min at 300 × *g*, room temperature. Aspirate medium and add 50 µl FM4-64.

   Using shorter centrifugation times to pellet the cells will reduce the time they are not at the assay temperature.

4. Incubate cells 15 to 20 min at growth temperature with gentle shaking.

5. Add 1 ml prewarmed medium to each tube, then centrifuge gently as described in step 3. Remove supernatant and add 1 ml prewarmed medium. Repeat this wash two more times (for a total of three), incubating cells in medium for 15 to 60 sec between centrifugations.

   These wash steps are necessary to extract uninternalized dye from the exoplasmic leaflet of the plasma membrane. FM4-64 has an off rate of ~2 sec.

6. Incubate 30 to 60 min in shaking water bath at assay temperature.

   Use longer chase times for lower assay temperatures.

7. Pellet cells gently as described in step 3 and aspirate medium. Gently resuspend pellets in 50 to 100 µl medium. If testing a temperature sensitive (ts) allele, store samples on ice until mounted on coverslips.

   Storage on ice will prevent further trafficking of the dye in the nonrestrictive environment, particularly in the case of ts alleles that recover at permissive temperature.

8. Mount 2 to 3 µl onto con A–coated coverslips and observe immediately under a rhodamine/TRITC filter (*UNIT 4.2*).

INTERNALIZATION TIME-COURSE ASSAY USING FM4-64

ALTERNATE PROTOCOL 2

In order to better evaluate the location of a block or decreases in the rate of endocytosis through endosomes, a time-course assay can be used. Briefly, cells are labeled on ice rather than at growth temperatures, washed quickly to remove uninternalized dye from the medium while leaving the plasma membrane labeling in place, and then allowed to internalize dye for 0 to 20 min (or longer) in a chase at assay temperatures. Cells are collected and kept cold until placed on coverslips for viewing. See Figure 4.13.1 for an example of wild-type endocytosis patterns over 0 to 20 min chase time.

Additional Materials *(also see Basic Protocol 2)*

FM4-64 (see recipe), ice cold
Rich medium with and without a carbon source (*UNIT 1.6*), ice cold

1. Culture yeast cells and incubate at restrictive temperatures (if appropriate) as described (see Basic Protocol 2, steps 1 and 2). Gently pellet four or more separate 1-ml aliquots of each strain in microcentrifuge tubes (see Basic Protocol 2, step 1), aspirate, and cool the pellets on ice. Resuspend each tube in 50 µl FM4-64, prechilled on ice.

   Use a 1:50 dilution of stock FM4-64 (see recipe).

2. Label the plasma membrane by incubating tubes 15 to 20 min in an ice bath with sufficient water to make a slush.

3. To one tube from each strain (zero time point), add 1 ml ice-cold rich medium without a carbon source and centrifuge 3 min at ~300 × *g*, 4°C. Aspirate and repeat this wash once more. Resuspend pellets in 50 to 100 µl rich medium with no carbon source. Keep these cells on ice at all times from this point forward.

4. Wash the remaining three (or more) tubes of each sample two times with cold rich medium containing a carbon source as described in step 3, but do not incubate between washes. Resuspend in 1 ml rich medium containing a carbon source.

   Do not wash more than this, otherwise it is possible to lose too much plasma membrane labeling.

5. Place the tubes into a water bath at assay temperature with shaking. After 5 min, remove 1 tube for each sample and wash cells twice with ice-cold rich medium without a carbon source. Resuspend as in step 3 (keep as the 5 min time point).

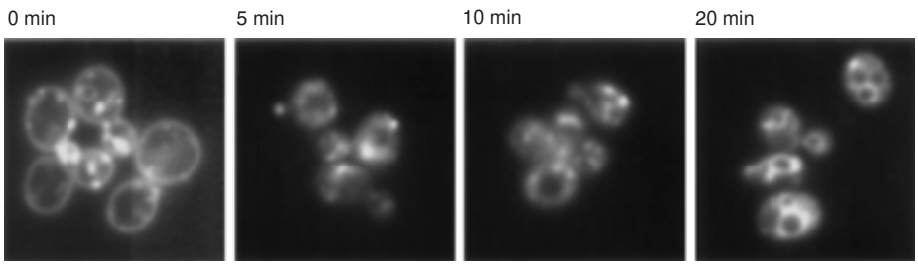

Figure 4.13.1 Wild-type behavior in an FM4-64 time-course assay. Cells were treated as described (see Alternate Protocol 2) with an assay temperature of 30°C and imaged using a Zeiss fluorescence microscope and 100× objective with a rhodamine/TRITC filter. Shown are wild-type images from time points 0, 5, 10, and 20 min. Note that at the zero time point, labeling is almost entirely on the plasma membrane, and by the 20 min time point, the label is mostly on the vacuolar membranes (one to five circular organelles that are ~1/5 to 1/2 of the yeast cells).

Continue to incubate remaining tubes, collecting time points as described at 10, 15, and 20 min.

Longer time points can be collected as well by starting with more tubes for each sample in step 1 and continuing the assay. For lower assay temperatures, it may be necessary to collect chase time points for as long as 90 min.

6. Mount 2 to 3 µl onto con A–coated coverslips and observe with a rhodamine/TRITC filter (*UNIT 4.2*).

BASIC PROTOCOL 3

ENDOCYTIC RATE MEASUREMENT BY LUCIFER YELLOW UPTAKE IN LIVE CELLS

Lucifer yellow (LY) is a fluorescent fluid-phase dye that does not pass through membranes. It is taken into cells by endocytosis of bulk fluid-phase material from the extracellular space. It is delivered to the vacuole, where its accumulation is an indicator of general rates of internalization. This technique requires a few tricks, so on the first attempt be sure to follow the method and troubleshooting notes carefully. Note that it is unclear whether LY is completely stable for long-term storage. If the experiment doesn't work, try using a fresh batch of LY.

Materials

Yeast cells (see Strategic Planning)
Culture medium, preferably rich (*UNIT 1.6*)
Rich medium (*UNIT 1.6*)
40 mg/ml lucifer yellow (see recipe)
Phosphate/azide/fluoride buffer (see recipe), ice cold

16-G needle
Incubator with orbital shaker set at assay temperature
Con A–coated coverslips (see recipe)
FITC filter

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

1. Culture yeast cells in culture medium (preferably rich) overnight to 1×10^7 cells/ml (~0.1 OD_{600}/ml depending on strain) at growth temperature (*UNIT 1.6*).

   The overnight culture should be sufficiently dilute such that the density never exceeds this value—i.e., if the cells grow to a density greater than ~0.1 OD_{600}/ml, it is recommended that a new culture be started for this assay. The cells should not be diluted to a lower density and regrown until they have doubled.

   For some strains, it is very important that the cells have never exceeded this density in liquid culture (see Critical Parameters); however, some labs have reported using cells that are ~0.5 OD_{600}/ml with success. The variability may be dependent on strain and LY batch/lot. The authors have found that SEY6210 does not work at all for LY-uptake experiments; however, the Research Genetics wild-type strain BY4741 has worked very well in the authors' experience.

2. Gently pellet 1 ml cells by centrifuging 2 min at 300 to 800 × *g*, room temperature. Aspirate the medium.

3. Resuspend cells in 90 µl rich medium and add 10 µl of 40 mg/ml lucifer yellow. Mix well by pipetting carefully. Do not vortex.

4. Close the tube and poke a hole in the lid with a 16-G needle to allow gas exchange.

   Gas exchange is very important.

5. Incubate tubes at growth or assay temperature with orbital mixing for 1.5 to 2 hr in the dark (e.g., covered with aluminum foil). Try to use an air incubator to avoid contamination of the sample through the hole in the lid.

   It is important that cells be continuously aerated during this process through the hole in the lid. Also, mixing the tubes by snapping or flicking the tube periodically may help maintain proper aeration.

6. Add 1 ml ice-cold phosphate/azide/fluoride buffer and centrifuge as in step 2. Repeat this wash three times, resuspending the pellet between washes.

   If cells are not forming tight pellets, remove only 80% to 90% of the medium from the pellet, then centrifuge again and remove the remaining medium for each wash.

7. Resuspend the final pellet in 30 µl phosphate/azide/fluoride buffer and keep cells on ice.

8. Mount cells on con A–coated coverslips and view by fluorescence microscopy using a FITC filter (*UNIT 4.2*).

   LY is stable for up to 4 hr in cells if kept cold, wet, and dark, so it is best to store cells in the ventilated tubes used for the assay on slushy ice that is kept covered. The signal may be faint, so be prepared to take images for up to 10 sec under the FITC filter.

   Very bright vacuoles indicate cells that are dead or are about to die. This accumulation is due to a transporter in the vacuolar membrane that concentrates LY by a nonendocytic mechanism after the plasma membrane has become permeable.

LOCALIZATION OF PROTEINS IN LIVE YEAST CELLS WITH GFP-FUSION PROTEINS

BASIC PROTOCOL 4

A common technique for in vivo localization of a specific protein in any cell type is to create a chimera between the protein and the fluorescent protein GFP, or any of its variants. Described below is a method for viewing these fusion proteins in live yeast cells. This method was developed for use of fusion proteins with EGFP (Tsien, 1998), so keep in mind that use of different mutant forms of GFP may have slight differences in pretreatment of cells. In this assay, Tris buffer is added and incubated with cells briefly to achieve a slightly basic pH, which increases fluorescence of EGFP. In addition to this protocol, an alternate method (see Alternate Protocol 3) is described for viewing GFP fusion proteins in cells labeled with a rhodamine-phalloidin-labeled actin cytoskeleton.

Materials

Yeast cells expressing GFP-protein chimeras (*APPENDIX 3A*; also see Strategic Planning)
1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
PBS (pH 7.4)/2% (w/v) glucose (see recipe)

Incubator set to appropriate growth temperature
Incubator set to assay temperature
Con A–coated coverslips (see recipe)
FITC filter

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

1. Culture yeast cells expressing GFP-protein chimeras overnight to mid-log phase (~0.3 to 0.8 OD_{600}/ml) at growth temperature (*UNIT 1.6*). If doing a temperature shift assay, incubate (i.e., shift) cells 15 to 60 min at assay temperature.

   Use selective medium if the fusion protein is carried on a plasmid.

2. Add 1 M Tris·Cl, pH 7.5, to cultures to a final concentration of 10 mM.
3. Incubate cells ~5 min at assay temperature with shaking.
4. Centrifuge 1 ml cells in a 1.5-ml microcentrifuge tube 3 to 5 min at 300 to 800 × *g*, room temperature. Aspirate medium.
5. Resuspend cells in 50 to 200 µl PBS (pH 7.4)/2% (w/v) glucose.
6. Mount cells on con A–coated coverslips and view by fluorescence microscopy under a FITC filter (*UNIT 4.2*).

BASIC PROTOCOL 5

LABELING THE ACTIN CYTOSKELETON WITH RHODAMINE-PHALLOIDIN IN FIXED CELLS

The filamentous actin cytoskeletal network in yeast cells displays a dynamic polarized pattern throughout the cell cycle (Amberg, 1998). In cells about to bud and in small budded cells, filamentous actin cortical patches are polarized to the site of the newly emerging or emerged bud. Cytoplasmic filamentous actin cables are aligned along the mother-bud axis. As the yeast cell switches from polarized to isotropic growth, the actin patches and cables reorient throughout the mother and bud. At cytokinesis, the actin patches recongregate to the mother-bud neck and the cables orient in both mother and bud towards the neck as well. Mushroom toxins, such as phalloidin, bind filamentous actin with high specificity. Attachment of fluorescent tags, such as rhodamine, to phalloidin allows the use of this toxin as a label in yeast cells for the filamentous actin cytoskeleton. Briefly, cells are fixed in mid-log phase to ensure a mixed population of early budded, late budded, and cytokinesing cells. The cells are then permeabilized and incubated with toxin. DAPI (Molecular Probes) is included in the toxin incubation to stain nucleic acids. This assists in determining cell cycle stage (see Lew and Reed, 1995). Cells are washed to remove unbound dye and viewed under fluorescence microscopy with rhodamine/TRITC and UV/DAPI filters. See Figure 4.13.2 for an example of F-actin patterns in early budded cells as well as those undergoing cytokinesis. In addition, see Figure 4.13.3 for the depolarized, chunky F-actin pattern in mutant cells.

Materials

Yeast cells (see Strategic Planning)
Rich or selective medium (*UNIT 1.6*)
In-medium fixation cocktail (see recipe)
Overnight fixation cocktail (see recipe)
PBS, pH 7.4 (see recipe)
0.2% (v/v) Triton X-100 in SHA buffer (see recipe)
PBS containing phalloidin and DAPI (see recipe)
DABCO antifade (see recipe)

Water bath with shaker set at assay temperature
End-over-end rotator
Con A–coated coverslips (see recipe)
Rhodamine/TRITC and UV/DAPI filters

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

Prepare cells

1. Incubate 10 ml yeast cell cultures overnight to early- to mid-log phase (0.3 to 0.7 OD_{600}/ml) in rich or selective medium (*UNIT 1.6*).

Try to keep the final concentration (step 3) below 0.7 OD_{600}/ml.

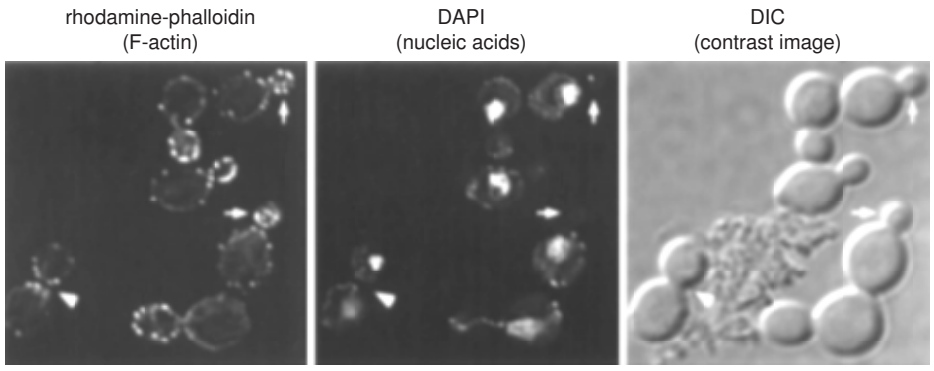

Figure 4.13.2 Filamentous actin in fixed wild-type yeast cells. Cells were treated as described (see Basic Protocol 5) with an assay temperature of 37°C and a temperature shift to 37°C 90 min before fixing. Cells were imaged using a Zeiss fluorescence microscope and 100× objective with a rhodamine/TRITC filter, DAPI optics, and differential interference contrast (DIC). The F-actin and nucleic acid images were deconvolved using a Deltavision deconvolution microscopy program. Arrows in all three panels show polarized F-actin patches in the growing bud of yeast cells in the early bud stage. The small number of patches in the mother cell are sometimes seen but indicate a slight depolarization, which may be due to incomplete recovery from the temperature shift. Arrow heads in all three panels delineate the mother-bud neck in cells undergoing cytokinesis. The large spots in the DAPI images are nuclei, and the smaller spots are nucleoids in mitochondria.

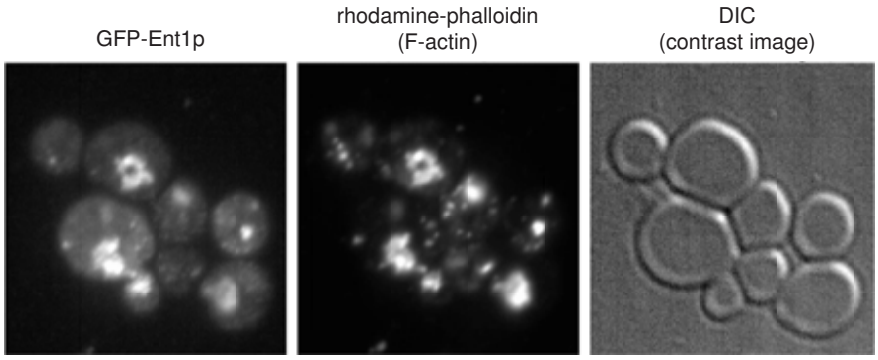

Figure 4.13.3 GFP-Ent1p and F-actin colocalization in mutant cells. Cells were treated as described (see Alternate Protocol 3) with an assay temperature of 30°C. Cells were imaged using a Zeiss fluorescence microscope and 100× objective with a FITC filter, a rhodamine/TRITC filter, and DIC. Note that the F-actin is both depolarized (not localized to growing small buds) and found in large clumps rather than small punctae. The GFP-Ent1p is localizing to these mislocalized F-actin clumps. Reprinted from Watson et al. (2001) with permission by the American Society for Cell Biology.

2. If the assay temperature is different than the growth temperature, shift the cells to the assay temperature when their concentration is in early-log phase (0.2 to 0.4 OD_{600}/ml), so that by the end of the shift (≥90 min) they will still be in the correct range.

   Even wild-type yeast cells respond to heat shock by temporarily reorganizing their actin cytoskeleton to a depolarized state. A prolonged exposure (90 min) to the elevated temperature is required to allow cells to re-establish their normal actin polarity; therefore, cells must be shifted for ≥90 min prior to fixation.

Fix cells

3. Record the final concentration (OD_{600}/ml) of each sample. Then, in a ventilated hood, add 2.5 ml in-medium fixation cocktail to each 10 ml cell culture, adding directly to the culture (i.e., do not pellet cells).

4a. *For nonshifted cells:* Place cells back into a water bath with shaker and incubate 1 to 2 hr.

4b. *For temperature-shifted cells:* Keep cells in fix at the elevated temperature for at least the first 20 min out of a total 1 to 2 hr fixation period (see step 4a).

   Once cells have begun to fix, temperature should no longer matter.

5. After at least 1 hr of fixation, prepare cells for further fixing overnight. Pellet cells (i.e., centrifuge 5 min at 1500 ×*g*, room temperature), aspirate, and resuspend in 1 ml overnight fixation cocktail per sample. Transfer to a 1.5-ml microcentrifuge tube.

6. Incubate overnight at room temperature, with agitation (end-over-end rotator), at room temperature.

7. Centrifuge 5 min at 1500 to 2000 × *g*, room temperature. Wash once by resuspending in 1 ml water (use this resuspension to transfer cells to 1.5-ml microcentrifuge tubes if they are not in them already), then pelleting cells and aspirating. Wash twice with 1 ml PBS, pH 7.4.

   Because cells are fixed, faster centrifugation (as denoted above) is okay.

Permeabilize cells

8. Resuspend cells in 1.0 ml of 0.2% (v/v) Triton X-100 in SHA buffer and incubate 10 to 15 min at room temperature.

   There is no need to agitate.

9. Wash three times in 1 ml PBS to remove detergent. Resuspend cells to 10 OD_{600}/ml in PBS (using final OD_{600}/ml from step 3). Remove 100 µl (i.e., 1 OD_{600}) to a new tube, pellet cells and aspirate liquid.

   It is important to wash out the detergent well. Remaining detergent will increase the level of background signal.

Label cells

10. Label cells by resuspending in 30 to 50 µl PBS containing rhodamine-phalloidin and DAPI. Incubate in the dark 1 hr at room temperature.

    Alternative fluorescent labels conjugated to phalloidin are available and should work with this method.

    It is also possible to label cells overnight at 4°C in the cold room. This works quite well. If this is done, wash at least two additional times.

11. Wash 3 times in 0.5 ml PBS.

    To avoid losing the pellet in this step, remove the PBS from the pellet during each wash by pipetting rather than aspirating.

12. Resuspend final pellet in 30 to 50 ml DABCO antifade. Mount 2 to 3 ml of cells on con A–coated coverslips and view with rhodamine/TRITC and UV/DAPI filters (*UNIT 4.2*).

LABELING OF LIVE CELLS WITH RHODAMINE-PHALLOIDIN FOR COLOCALIZATION WITH GFP FUSION PROTEIN

ALTERNATE PROTOCOL 3

Fixation is sometimes deleterious to GFP localization, in particular for some peripherally associated membrane proteins. The following method is used to label unfixed cells with rhodamine-phalloidin, which allows GFP localization to be maintained. Instead of fixing cells, they are simultaneously permeabilized and labeled with rhodamine-phalloidin. It is assumed that the actin cytoskeleton and associated proteins are immobilized during the process of labeling due to the ability of phalloidin to stabilize actin filaments (Cooper, 1987). With this method, GFP localization is often preserved; however, this should be confirmed by comparison to a control in the same experiment. This control should consist of nonpermeabilized live cells containing the same GFP-fusion protein but not stained with phalloidin (see Basic Protocol 4). See Figure 4.13.3 for an example of a GFP-tagged protein that colocalizes with F-actin in mutant cells.

Additional Materials *(also see Basic Protocol 5)*

Yeast cells expressing GFP-fusion constructs (*APPENDIX 3A*; also see Strategic Planning)
Permeabilization/staining solution (see recipe)
FITC and rhodamine/TRITC filters

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

1. Culture yeast cells expressing GFP-fusion constructs overnight to early- to mid-log phase (~0.3 to 0.8 OD_{600}/ml; *UNIT 1.6*).

   Use selective medium if the fusion protein is carried on a plasmid.

2. Harvest 1 to 5 ml cells (less if the OD_{600} is at the upper value). Centrifuge 5 min at 300 to 600 × *g*, room temperature. Resuspend in 50 to 100 µl permeabilization/staining solution.

3. Incubate 10 min in the dark, then place on ice an additional 10 to 15 min, also in the dark.

4. Mount 2 to 3 µl cells on con A–coated coverslips and view under FITC and rhodamine/TRITC filters (*UNIT 4.2*).

   For unknown reasons, many cells will exhibit either one fluorescent label or the other, so be patient in looking for cells with both labels. It is generally better to use the FITC channel to choose an area of cells, then switch to the rhodamine channel to check for phalloidin labeling.

BASIC PROTOCOL 6

LOCALIZATION OF A PROTEIN IN FIXED YEAST CELLS WITH IMMUNOFLUORESCENCE

Methods for the use of immunofluorescence in yeast are very similar to methods for labeling mammalian cells, although the small size of yeast cells can make detailed localization slightly more difficult. However, many organelles have characteristic localization or available marker proteins so that double-labeling experiments with a specific protein can be effective. For choosing and pretesting antibodies for immunofluorescence, refer to *UNIT 4.3* on mammalian cell immunofluorescence. In brief, yeast cells are fixed, made into spheroplasts to remove the cell wall (which is necessary for antibody access to intracellular compartments), and permeabilized before they are attached to coverslips or slides using polylysine. The cells are then blocked, labeled with primary antibody, labeled again with fluorescently conjugated secondary antibodies, and viewed using a fluorescence microscope.

Materials

Yeast cell cultures (see Strategic Planning)
1× and 5× fixation cocktail (see recipe)
SHA buffer (see recipe)
Spheroplasting solution (see recipe)
1% (v/v) Triton X-100 in SHA buffer
2 mg/ml poly-L-lysine (Sigma; store up to 3 months to 1 year at −20°C)
WT buffer (see recipe)
Primary and secondary antibodies
Fixed or spheroplasted cells from a strain with the target antigen deleted (optional)
1 mg/ml DABCO antifade (see recipe)
Nail polish

Incubators set at growth temperature and 30°C
Standard slides or slides coated with Teflon to form wells (Polysciences)
Pipet tip connected to an aspirator
Moisture chamber (see recipe)
Weight (e.g., book)
Fluorescence filters

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

NOTE: It is recommended that 1× AEBSF or similar protease inhibitors be added to all prepared solutions used in this protocol. This reduces loss of rare antigens due to activity remaining from vacuolar proteases.

Fix cells

1. Incubate 10 ml yeast cell cultures overnight to mid- to late-log phase (~0.5 to 1.0 OD_{600}/ml; *UNIT 1.6*).
2. Add 2.5 ml of 5× fixation cocktail to each 10 ml of culture. Shake for 1 to 2 hr at growth temperature.
3. Centrifuge 5 min at 300 to 800 × *g*, room temperature. Pour off medium and resuspend in 1 ml of 1× fixation cocktail. Transfer to 1.5-ml microcentrifuge tubes. Fix cells for 12 to 24 hr with gentle mixing at room temperature.
4. Pellet cells as described in step 3 and aspirate the supernatant. Resuspend in a small amount of SHA buffer for storage at 4°C (up to 1 to 2 days) or continue directly to step 6 for immediate use.

Make spheroplasts and permeablize cells

5. If cells have been stored, pellet as described in step 3. Aspirate the supernatant.

6. Resuspend in 1 ml spheroplasting solution. Incubate 30 min at 30°C (or lower temperature if assay/growth temperature was below 30°C, but increase time of incubation by 5 to 10 min for every 2°C less) flicking tubes every 10 min or so to mix.

7. Centrifuge 5 min at 300 × *g*, room temperature. Aspirate supernatant and resuspend in 0.5 ml of 1% (v/v) Triton X-100 in SHA buffer. Incubate ~10 min at room temperature.

   As an alternative, 1% (w/v) SDS can also be used to permeabilize, but since it is a harsher detergent, it may damage cells.

8. Wash twice in 1 ml SHA buffer and resuspend in SHA buffer to ~1.2 OD_{600} per 50 µl (~24 OD_{600}/ml).

Prepare for incubation on slides

9. Prepare slides by applying 10 to 20 µl of 2 mg/ml poly-L-lysine. Spread the solution with a pipet tip over the area of the slide where the cells should stick (usually a ~3- to 4-mm diameter circle). Incubate 15 min at room temperature

   There are two types of slides that can be used. The first alternative is to use standard slides. After the cells settle, the area of interest will be visible on the slide. The second alternative is to use slides precoated with Teflon to form wells (e.g., Polysciences slides). This nicely contains the liquid on the slide during incubations and doesn't put pressure on the cells when the coverslips are applied, but it can lead to unflattened cells with multiple out-of-focus layers.

10. Aspirate polylysine by placing a pipet tip connected to an aspirator at one edge of the puddle to draw off the fluid. Wash three times by dripping water over the area and aspirating as with the polylysine.

11. Add 15 µl fixed spheroplasts (step 8) dropwise as in step 10 to each slide and let settle 15 to 30 min in a moisture chamber. Aspirate excess liquid as described above (step 10).

    From now until mounting coverslips, be careful not to let the cells dry out on the slide and keep the slides inside the moisture chamber. Keep liquid on the cells at all times, aspirating just before adding a new solution.

12. Block cells by dropwise addition of 15 to 30 µl of WT buffer and incubation for at least 15 min at room temperature. Aspirate immediately before antibody treatment.

13. *Optional:* Incubate primary and secondary antibodies with fixed or spheroplasted cells from a strain with the target antigen deleted. Pellet the deletion cells out of the blocked antibody solutions (i.e., 5 min at ≥10,0000 × *g*, room temperature) and use the supernatant (which will already be diluted) for steps 14 (primary) and/or 17 (secondary).

    Try to use the same dilutions and incubation times as will be used in the assay (it is often convenient to set this up during step 12). This can help reduce background, if needed. In addition, microcentrifuging all antibodies (even those not preincubated with deletion cells) can help by removing precipitates. After diluting the antibodies in WT buffer (both primary and secondary), pellet precipitates by microcentrifuging 5 min at maximum speed, room temperature.

Incubate in primary antibody

14. Add 15 µl primary antibody diluted in WT buffer to the blocked cells on the slide. Incubate 60 to 90 min at room temperature or overnight at 4°C in the moisture chamber.

    The dilution concentration depends on the antibody but typically ranges from 1:10 to 1:500. A good rule of thumb is to use ten times the concentration used for successful immunoblotting.

15. Wash five times with 15 to 30 µl WT buffer by dripping liquid over the cells and then aspirating for each wash.

Incubate in secondary antibody

16. Add 15 µl secondary antibody diluted in WT buffer. Incubate 45 to 90 min in the dark at room temperature or overnight at 4°C in the moisture chamber.

    Longer incubations will give higher backgrounds.

    Signal can be increased by using a nonconjugated secondary antibody and a fluorescently conjugated tertiary antibody. For example, use primary antibody raised in a rabbit that recognizes the protein, followed by secondary antibody goat anti-rabbit IgG, then tertiary antibody FITC-conjugated donkey anti-goat IgG. For each antibody after the primary, follow the secondary antibody incubation times and wash conditions in this step.

17. Wash five times as described in step 15.

Mount the samples

18. Aspirate the liquid and add 3 to 5 µl of 1 mg/ml DABCO antifade to the cells. Place the coverslip over the cells on the slide (or overturn the coverslip with the cells attached onto a slide). For gentle flattening of the cells for viewing, cover the entire slide (with coverslip already present) with a folded Kimwipe (to absorb excess mounting solution) and press down firmly and evenly with a weight (e.g., a book) for 1 to 2 min.

    Paraphenylenediamine (PPD) is sometimes used for antifade, but it has been found to cleave some fluorophores off the antibody. DABCO does not cause this problem.

19. To seal the coverslip and prevent drying of cells, paint the edges of with nail polish. Let dry in the dark.

    Be careful not to use too much or the polish will seep under the coverslips and obscure the cells.

20. View cells under the appropriate fluorescent filters, which depends on the fluorophore conjugated to the final antibody (*UNIT 4.2*). To store cells for viewing on another day, keep the already sealed slides at 4°C (or −20°C) in the dark (up to 2 weeks).

ALTERNATE PROTOCOL 4

LOCALIZATION IN SPHEROPLASTED THEN FIXED CELLS WITH IMMUNOFLUORESCENCE

Although the method described above (see Basic Protocol 6; i.e., fixation followed by spheroplasting cells) generally works well, this alternative method works better for labeling some proteins. The best method may depend on the antigen or antibody, and needs to be determined empirically; however, for proteins localized to cortical actin patches, the cells need to be fixed before spheroplasting to maintain polarized localization.

Materials

Yeast cell cultures (see Strategic Planning)
Softening medium: 0.1 M Tris·Cl, pH 9.4 (*APPENDIX 2A*)/10 mM DTT (freshly prepared)
Spheroplasting medium (see recipe)
37% (v/v) formaldehyde
SHA buffer (see recipe)
SHA buffer/1% LDAO (see recipe)

Incubator set to growth temperature
30°C incubator with orbital shaker

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and permeablizing and staining cells for proteins (see Basic Protocol 6, steps 9 to 20)

NOTE: It is recommended that 1× AEBSF or similar protease inhibitors be added to all solutions prepared for this protocol. This reduces loss of rare antigens due to activity remaining from vacuolar proteases.

1. Incubate 10 ml yeast cell cultures overnight to mid- to late-log phase (~0.5 to 1.0 OD_{600}/ml).
2. Centrifuge an amount of cells equivalent to an OD_{600} of 10 for 5 min at 300 to 800 × *g*, room temperature. Aspirate and resuspend in 2 ml softening medium. Incubate 10 min at room temperature.
3. Pellet cells gently as described in step 2, aspirate, and resuspend in 2 ml spheroplasting medium. Mix by vortexing on low. Incubate 10 min with orbital shaking at 30°C.
4. To fix cells, add 37% formaldehyde to a final concentration of 4%. Incubate 1 hr at 30°C.
5. Pellet cells gently as described in step 2, aspirate, and resuspend in 1 ml SHA buffer. Transfer to a 1.5-ml microcentrifuge tube.
6. Pellet cells gently as described in step 2, aspirate, and resuspend in 0.5 ml SHA buffer/1% LDAO to permeabilize. Incubate 10 min at room temperature.
7. Wash cells twice with 1 ml SHA buffer, pelleting, aspirating, and resuspending each time.
8. Resuspend final pellet in 400 µl SHA buffer. Visualize proteins as described (see Basic Protocol 6, steps 9 to 20).

LABELING CELL WALL CHITIN DEPOSITION WITH CALCOFLUOR WHITE

BASIC PROTOCOL 7

Bud scars are enriched in the polysaccharide chitin and can be observed as rings on the cell walls of yeast. In haploid cells, the normal pattern of budding is axial (the next bud forms adjacent to the site of the previous bud), whereas in diploid cells it is bipolar (occurs from either end of the elongated cell). When cells are defective for processes such as endocytosis or for actin cytoskeletal structure, budding patterns often become random in the diploid cell, resulting in rounder, less football-shaped diploids. By labeling cells with calcofluor white (CfW), which binds irreversibly to chitin in the cell wall, improper budding can be seen as nonbipolar patterns of rings on diploid cells (e.g., bud scars are found at the equator). See Figure 4.13.4 for an example of normal and mutant diploid bud scars stained with calcofluor white.

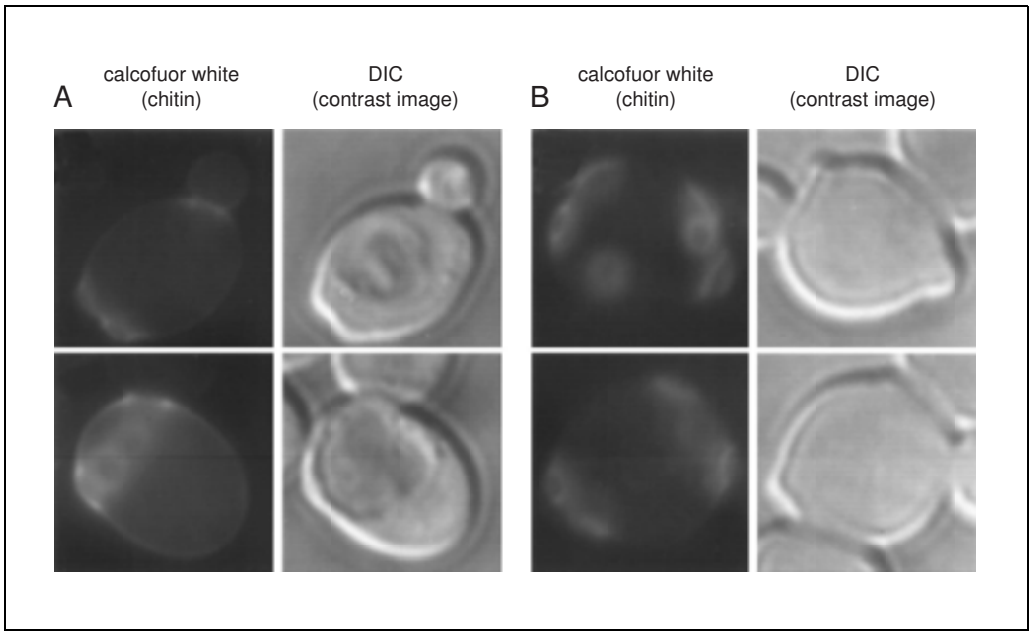

Figure 4.13.4 Bud scars in wild-type and mutant cells. Diploid cells were treated as described (see Basic Protocol 7). Cells were imaged using a Zeiss fluorescence microscope and 100× objective with DAPI optics and DIC. (**A**) Two cells exhibiting normal bud scars at each of the elongated ends of these diploid cells. (**B**) Two mutant cells, exhibiting randomly arranged bud scars. It is also clear that these diploid cells do not have a normal elongated shape.

Materials

Yeast cells (see Strategic Planning)
1 mg/ml CfW (see recipe)

Incubator set to growth temperature
Con A–coated coverslips (see recipe)
UV/DAPI filter

Additional reagents and equipment for yeast cell culture (*UNIT 1.6*) and fluorescence microscopy (*UNIT 4.2*)

1. Culture yeast cells overnight to a high density (>1.0 OD_{600}/ml; *UNIT 1.6*).

   This increases the population of cells that are old enough to have budded multiple times.

2. Using an amount of cells equivalent to an OD_{600} of 2 to 5, centrifuge 5 min at 300 to 800 × *g*, room temperature. Aspirate medium.

3. Resuspend cells to 5 OD_{600}/ml in 1 mg/ml CfW solution.

4. Incubate 5 min at room temperature with gentle agitation.

5. Centrifuge as described in step 2 and aspirate medium. Resuspend in 1 ml water, centrifuge again, and aspirate medium. Repeat this wash twice more.

6. Resuspend final pellet in 100 to 500 µl water.

   Use more for a larger cell pellet.

7. Mount cells on con A–coated coverslips and view under a UV/DAPI filter (*UNIT 4.2*).

REAGENTS AND SOLUTIONS

Use deionized or distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

CfW, 1 mg/ml

Dissolve calcofluor white (CfW; Sigma) to 1 mg/ml in water. CfW takes a long time to dissolve; however, dissolution may be aided by the addition of 0.1 N sodium hydroxide dropwise with mixing until the solution clears. Store up to 3 months to 1 year in the dark at 4°C.

CfW is also known as Fluorescent Brightener 28.

Con A–coated slides

Prepare a 2 mg/ml stock solution of concanavalin A (con A; Sigma) in water (store up to 1 year at −20°C). Pipet 5 µl con A onto each 22 × 22–mm coverslip, spread with the side of a clean pipet tip, and allow to air dry in a dust-free room (if possible). Con A–coated coverslips can be made a few days in advance, but it is preferable to make them the same day of use. Store at room temperature.

Poly-L-lysine can also be used to immobilize yeast cells for microscopy (see Basic Protocol 6). Be sure to keep track of which side of the coverslip is coated.

DABCO antifade

Dissolve 1,4-diazabicyclo[2.2.2]octane (DABCO; Molecular Probes) in 90% glycerol to 1 mg/ml. Protect from light as much as possible during preparation. Store in the dark at −80°C for long term storage (i.e., up to 1 year), or store smaller aliquots at −20°C for short term use (i.e., up to 3 months).

PPD (paraphenylenediamine) is sometimes used for antifade, but it has been found to cleave some fluorophores off the antibody. DABCO does not cause this problem.

DAPI, 1 mg/ml

Dissolve sufficient 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI; Molecular Probes) in water to prepare a 1 mg/ml (1000×) solution. Store in the dark for up to 3 months to 1 year at −20°C.

Fixation cocktail, 5×

0.5 M potassium phosphate, pH 6.5 (see recipe)
20% (v/v) formaldehyde (from 37% stock)
Prepare fresh

All 37% (v/v) formaldehyde should be used within 3 months of opening.

FM4-64

Stock solution: Prepare a 1 mg/ml solution of FM4-64 (Molecular Probes) in DMSO. Store in small aliquots up to a few months at 20°C.

Working solution: Freshly dilute 1 mg/ml FM4-64 stock (see above) 1:50 for assay temperatures ≤30°C or 1:100 for assay temperatures >30°C in rich medium (*UNIT 1.6*). Once the dye is diluted in rich medium, prewarm to assay temperature.

IMPORTANT NOTE: *Do not prepare diluted FM4-64 more than 30 min prior to use.*

Repeated freeze thaws may decrease lifetime (see Critical Parameters).

HEPES/100 mM/ 2% (w/v) glucose

Dilute 1 M HEPES, adjusted to pH 7.6 with potassium hydroxide, 1:10 in water. Freshly add glucose from a concentrated stock (i.e., 50% w/v) to 2% (w/v). Store up to 24 hr at room temperature.

In-medium fixation cocktail

Combine 1.15 ml of 1 M potassium phosphate buffer, pH 6.5 (see recipe), and 1.35 ml of 37% (v/v) formaldehyde for every 10 ml cells to be fixed. Prepare fresh.

All 37% (v/v) formaldehyde should be used within 3 months of opening.

Lucifer yellow, 40 mg/ml

Dissolve the dilithium salt of lucifer yellow CH (LY; Molecular Probes or Sigma) to 40 mg/ml in water. Store at 4°C for short periods (weeks) or –20°C for long periods (months).

It is unclear whether LY is completely stable for long-term storage (see Critical Parameters). If the experiment doesn't work, try using a fresh batch of LY.

Moisture chamber

A moisture chamber is used for keeping the cells on the slides/coverslips from drying out during incubations; they should be kept moist and in the dark. One recommended method is to use a tissue culture dish (15 cm or 6 well) with a damp paper towel pressed into the lid (it shouldn't fall if it is damp, but not soaked, and pressed firmly) and aluminum foil covering the entire lid and base.

Overnight fixation cocktail

For every 10 ml needed, mix 7.9 ml water, 1.0 ml of 1 M potassium phosphate, pH 6.5 (see recipe), and 1.1 ml of 37% formaldehyde. Prepare fresh.

All 37% (v/v) formaldehyde should be used within 3 months of opening.

PBS, pH 7.4

10 mM sodium phosphate buffer, pH 7.4 (*APPENDIX 2A*)
150 mM NaCl
Filter, sterilize, and store up to 6 months at room temperature.

PBS containing phalloidin and DAPI

Dilute 200 U/ml rhodamine-phalloidin stock (see recipe) 1:10 and 1 mg/ml DAPI (see recipe) 1:1000 in PBS, pH 7.4 (see recipe). Make fresh within 1 hr of use and keep dark.

PBS (pH 7.4)/2% (w/v) glucose

Add glucose fresh from a concentrated stock (i.e., 50% w/v) to PBS, pH 7.4 (see recipe), at a final concentration of 2% (w/v). Prepare fresh.

Permeabilization solution

In PBS, pH 7.4 (see recipe) prepare:
1 M sorbitol
0.1% (w/v) saponin
0.1 mg/ml RNase
5 mM $MgCl_2$
Prepare fresh

Permeabilization/staining solution

Add 50 µl of 200 U/ml rhodamine-phalloidin stock (see recipe) per 1 ml permeabilization solution (see recipe). Make fresh within 1 hr of use and keep dark.

Phosphate/azide/fluoride buffer

50 mM potassium phosphate buffer, pH 7.5 (*APPENDIX 2A*)
10 mM NaN_3 (add fresh from concentrated stock)
10 mM NaF (add fresh from concentrated stock)
Prepare fresh

Some methods use sodium rather than potassium phosphate buffer.

Potassium phosphate, 0.04, 0.5, and 1 M (pH 6.5)

For a 1 M solution, mix 2 parts 1 M dibasic potassium phosphate (K_2HPO_4) with 1 part of 1 M monobasic potassium phosphate (KH_2PO_4). Store up to 1 year at room temperature. To prepare a 0.5 M solution, dilute 1:1 with water. For a 0.04 M solution, dilute 1:25 in water.

Rhodamine- or Texas red–phalloidin, 200 U/ml

Dissolve sufficient rhodamine- or Texas red–phalloidin in 1.5 ml methanol to prepare 200 U/ml as directed by manufacturer (see instructions on tube). Store in the dark for 3 to 6 months at −20°C.

Alternative fluorescent labels conjugated to phalloidin are available and should also work.

SHA buffer

1 M sorbitol
0.1 M HEPES, pH 7.5 (adjust pH with NaOH)
5 mM sodium azide
Prepare fresh from stock solutions

SHA buffer/LDAO, 1% (w/v)

Freshly prepare 1% (w/v) lauryldimethylamine oxide from a concentrated (i.e., 10% w/v) stock solution in SHA buffer (see recipe). Prepare fresh.

Sodium citrate, 0.5 M (pH 4.0)

Prepare a 0.5 M solution of citric acid and adjust the pH to 4.0 with sodium hydroxide. Store up to 1 year at room temperature.

Spheroplasting medium

Prepare the following 10 to 50 ml (depending on the number of samples) synthetic growth medium (i.e.,YNB/SD) containing amino acids and 2% glucose:
1 M sorbitol
0.04 M potassium phosphate buffer, pH 6.5 (see recipe)
10 µg/ml zymolyase
Make fresh within 1 hr of use.

Spheroplasting solution

In SHA buffer (see recipe) prepare:
0.2% (v/v) β-mercaptoethanol
45 µg/ml zymolyase (Seikagaku Corp.)
Make fresh within 1 hr of use.

WT buffer

50 mM HEPES, pH 7.5 (adjust pH with NaOH)
150 mM NaCl
0.1% (v/v) Tween-20
1 mM sodium azide
5% (w/v) IgG-free BSA
Prepare fresh if possible, but can be stored up to 2 days at 4°C during the course of assay.

COMMENTARY

Background Information

Imaging in yeast cells is constantly improving due to advances in microscopy techniques, and also as a result of the development of new and better microscopes and organelle-specific labels (Kohlwein, 2000).

Elucidating pathways

Saccharomyces cerevisiae is best known for its genetic malleability, allowing easy creation and identification of mutant phenotypes. The membrane trafficking pathways in yeast cells have been extensively investigated and characterized over the last few decades, leading to identification of the molecular components of the secretory pathway (Novick et al., 1980), the endocytic pathway (Chvatchko et al., 1986; Raths et al., 1993; Munn and Riezman, 1994; Wendland et al., 1996), and the organelles involved in these two important transport pathways and movement between them (Wendland et al., 1998; D'Hondt et al., 2000; Antonny and Schekman, 2001). This unit provides a few of the methods that have been developed to easily, and sometimes quickly, identify defects in endocytic and vacuolar sorting pathways. In addition to these vital microscopic techniques are, of course, a complementary set of biochemical techniques to study many of these same molecular structures (Conibear and Stevens, 2002; Sipos and Fuller, 2002).

GFP-fusion proteins

The use of GFP-fusion proteins in both mammalian and yeast cells has exploded in the last decade or so. Roger Tsien provides a detailed and careful review of the many achievements since the discovery of this useful protein and its applications (Tsien, 1998). In genetically malleable yeast cells, creation and introduction of GFP-fusion proteins is fairly straightforward. Shuttle vectors are available that allow simple cloning of a specific gene directly into promoter- and GFP-containing vectors at polylinkers designed to allow in-frame insertions. In addition, GFP tags can be fused to the C terminus of a protein behind its endogenous promoter. Reviews on the creation and use of GFP-fusion proteins are also available (Rines et al., 2002; Tatchell and Robinson, 2002).

Labeling cells using rhodamine-phallodin

Early work on yeast actin and tubulin led to the discovery of a distinct pattern in the distribution and structure of these two cytoskeletal elements (Adams and Pringle, 1984). In *Saccharomyces cerevisiae*, the actin cytoskeleton can be recognized in two distinct forms, actin cortical patches and actin cables. Each structure corresponds to bundles of filamentous actin, but they are structurally distinct and believed to perform different functions. The stereotyped localization pattern of actin cytoskeletal elements during the cell cycle is required for normal polarized bud growth and cytokinesis. Early methods for visualization of filamentous actin in yeast cells using the mushroom toxin phalloidin are still very similar to those used today (Adams and Pringle, 1991), although the protocol described in this unit includes a permeabilization step that the authors have found increases the percentage of labeled cells dramatically.

Immunofluorescence

Immunofluorescence techniques have been applied in yeast cells with much success, and several suggestions and methodologies have been described previously (Pringle et al., 1989, 1991). The development of confocal microscopes that allow optical sections thinner than 0.4 μm have aided in the creation of better, more precise immunofluorescence images. In addition, colocalization images can be more definitive. The methods described here are only two of many possible immunofluorescence preparations available, although most methods used are simply variations on the two basic methods provided. Removal of the cell wall to allow antibody access to internal structures is an essential step to any immunofluorescence protocol using yeast, but because spheroplasting (cell wall removal) can be stressful to living yeast cells, many methods include this step after fixation is completed.

Labeling chitin in the yeast cell wall

Chitin is a minor component of the yeast cell wall in content, but it is essential for yeast cell survival. Its role in septum formation at the mother-bud neck in cytokinesis is believed to be this essential function (Cabib et al., 1982, 2001). Chitin is deposited in a ring at the site where a bud emerges. These chitin rings represent the major concentration of chitin in the cell wall, although minor amounts of chitin are distributed throughout to provide strength and rigidity. The action of three chitin synthases, Chs1p, Chs2p, and Chs3p, are required for

different functions in the synthesis and deposition of chitin during the cell cycle. Chs3p exhibits a unique form of regulation that requires the recycling endocytic pathway for delivery to sites of chitin synthesis (Ziman et al., 1996; Holthuis et al., 1998). In this assay, deposition of chitin in rings is visualized to examine cells for a polarized pattern of bud site selection. Loss of this polarized pattern correlates with defects in polarized cell growth in general and actin cytoskeletal defects (Casamayor and Snyder, 2002).

Critical Parameters

Labeling the vacuole in live cells with CDCFDA

CDCFDA must be made in anhydrous DMSO to prevent premature hydrolysis and maintain the neutral, diffusible form. For this assay (see Basic Protocol 1), the cells do not need to be at a precise concentration, but using cells in early- to mid-log phase at the time of assay and centrifuging as gently as possible will increase the likelihood of visualizing pretty yeast cells with vacuoles that are larger and fewer in number. Haploid yeast cells that are rounded rather than elongated or bent, with vacuoles visible as solid circles are desired.

Labeling acidic organelles with quinacrine in live cells

This is a fairly simple method (see Alternate Protocol 1), but the signal is often faint. As with labeling vacuoles (see Basic Protocol 1), it is preferable to have the yeast cells in early- to mid-log phase, but it is not required for the assay to work.

Labeling the endocytic pathway in live cells with FM4-64

FM4-64 is fairly stable in DMSO, but the authors have found that repeated freeze-thawing cycles will decrease its fluorescence. It is best to dissolve the compound in DMSO and aliquot small amounts for storage at −20°C. In addition, once the FM4-64 is diluted into medium, it will lose activity slowly, so do not prepare diluted FM4-64 too far in advance (see Reagents and Solutions). In this assay (see Basic Protocol 2), it is *very* important to treat the cells gently, because this will increase the likelihood of obtaining pretty yeast cells and vacuoles; therefore, pellet cells as gently as possible and resuspend them by pipetting or inverting tubes gently, never vortex. It is also easier to measure pixel intensity of larger vacuolar membranes because there are fewer overlapping membranes through the yeast cell, so use cells that are closer to early- to mid-log if possible. Finally, it is important to wash the cells in medium thoroughly after the pulse incubation to make sure that all plasma membrane labeling is removed. Leftover FM4-64 on the plasma membrane may mask any dim phenotypes because the cells will have plenty of time during the chase to internalize this label.

Internalization time course with FM4-64

Follow many of the critical parameters described for labeling the endocytic pathway (see Basic Protocol 2) for this method (see Alternate Protocol 2) as well; however, it is important *not* to wash cells thoroughly after labeling. In this method, plasma membrane labeling is necessary since no internalization should have occurred during the label period on ice. Wash cells gently and briefly by spinning immediately after resuspension, keeping them cold. For better temperature control during the labeling and washing process, keep microcentrifuge tubes sitting in slushy ice. Finally, keep in mind that chase time assay temperatures <30°C will require longer time points than 20 min, and may take up to 60 to 90 min before cells exhibiting a kinetic delay (i.e., mutants) will show vacuolar labeling.

Endocytic rate measurement by LY uptake in live cells

Endocytic measurement by lucifer yellow (LY) uptake (see Basic Protocol 3) often requires strict adherence to several critical parameters, and in some strains lucifer yellow uptake will not work at all. In particular, for this fluid to be internalized successfully in many strains, the cells must be grown overnight from inoculation to very early- or early-log phase only. To achieve this most conveniently, it is often easier to inoculate a dilution series of the cells for overnight cultures, allowing use of whichever culture is at the best concentration when ready to begin the assay. Some other laboratories, however, have found that their strains can be at mid-log concentrations and still internalize lucifer yellow at high rates. Thus, after the described method has been found to work, it may be desirable to experiment with different growth concentrations to see if mid-log phase cells work for the strain in question.

While cells are incubated with the lucifer yellow label, it is *essential* that they be allowed proper gas exchange with the outside air. Closed microcentrifuge tubes do not allow this, so it is best to use a needle (~16 to 18 G) to poke a hole in the top of each of the sample tubes. Do not invert the tubes after this. It is also very important that the lucifer yellow be kept in the dark at all times. Cover the tubes with aluminum foil whenever possible and keep them in the dark on ice until they are mounted onto slides. Finally, lucifer yellow has been reported to work after storage at both 4° and −20°C. Once the assay is working with fresh stocks, it may be a good idea to try several different storage conditions to see which one works best for the particular lucifer yellow stock being used.

Localization of proteins in live yeast cells with GFP fusion proteins

Viewing GFP-fusion proteins can be very easy, or a terrible ordeal, but this depends much more on the fusion protein than on the GFP viewing method. The method described in this unit (see Basic Protocol 4) is fairly simple, and the only critical parameter is that if the GFP-fusion protein is not integrated into the genome of the yeast strain being used, selection for the plasmid carrying it must be maintained at all times. Also, if the medium is already neutral/slightly basic, it is not necessary to add the Tris buffer. The best way to determine this is a side-by-side comparison.

Labeling the actin cytoskeleton with rhodamine-phalloidin in fixed cells

There are several critical parameters for labeling the actin cytoskeleton properly, but most of them involve proper preparation of cells before fixation. In order to achieve a nice mix of cell cycle stages at the end of this assay (see Basic Protocol 5), it is vital that the cells be either in early- or mid-log phase. Even late-log phase will result in a much lower percentage of early budded and cytokinesing cells. To this end, if cells are diluted in the morning, make sure that they have doubled *more* than one time to get all of the cells back into the early- to mid-log stages. In addition, even in wild-type cells, heat shock (i.e., a temperature shift from the overnight growth temperature), will result in complete depolarization of the actin cytoskeleton (as does centrifugation at excessive speeds), followed by a repolarization. Repolarization is a 90-min process, so if cells are shifted, they need to be at the assay temperature for ≥90 min before fixation. During this shift, keep in mind that the concentration is still important because the cells will continue to grow during this shift, and often grow faster at the higher temperature. During the assay, it is important to wash the cells well between each major step (fixation to permeabilization, permeabilization to dye labeling, dye labeling to viewing) to prevent the accumulation of background fluorescence.

Labeling of live cells with rhodamine-phalloidin for colocalization with GFP fusion proteins

This is a pretty simple method (see Alternate Protocol 3) that, if it works, can be very informative. The main critical parameter is to prepare GFP-labeled only cells (see Basic Protocol 4) alongside this assay to make sure that permeabilization or treatment with the toxin does not affect the GFP pattern.

Localization of a protein in fixed yeast cells with immunofluorescence

Immunofluorescence techniques are all fairly similar and have a few standard critical parameters. The most important is to use a very specific primary antibody. Polyclonal antibodies are often used, but they need to be tested thoroughly for their specificity. This is usually done by immunoblot, which is described in *UNIT 6.2*. Washes between antibody incubations are necessary to remove nonspecifically bound antibodies, and it is also important to make sure the cells are kept moist at all times. In addition, it is important to make sure that the protocol instructions (see Basic Protocol 6) and incubation times are followed carefully. Finally, when doing colocalization, always test the fluorescent tags for bleed-through in both fluorescent channels/filter sets by preparing two extra sets of cells, each with one of the two labels being used.

Localization in spheroplasted, then fixed cells with immunofluorescence

The same critical parameters apply for this protocol (see Alternate Protocol 4) as for localization of proteins in fixed yeast cells with immunofluorescence (see Basic Protocol 6). If it is not known what localization pattern is expected, it is a good idea to try both this protocol and Basic Protocol 6, to determine which label works best, as well as to verify that the pattern of fluorescence is the same with both methods.

Labeling cell wall chitin deposition with calcofluor white

This method (see Basic Protocol 7) is fairly simple. To make sure that most cells will be old (i.e., have undergone multiple divisions), it is necessary to have a cell population that is saturated. This decreases the percentage of newly formed daughter cells that will have only the birth scar.

Troubleshooting

With all fluorescent methods, the first thing to try if there is little to no fluorescent signal is a fresh batch of the fluorescent compound. Also, *always* include a wild-type control in all assays in case the lack of signal is from a mutant strain. Finally, make sure that the correct filter sets for the compound being visualized are being used on the microscope (spectra for dyes are usually available from the suppliers).

Labeling the vacuole in live cells with CDCFDA

If a fresh batch of CDCFDA is being used and a good signal is still not achieved, try adjusting the concentration of CDCFDA in the incubation. Too much may be causing quenching of the signal, so try starting with a range from ~5 μM to ~20 μM to check for improvement in signal. Also, try adjusting the pH or concentration of sodium citrate in case the content of the medium is affecting the assay.

Labeling acidic organelles with quinacrine in live cells

If a fresh batch of quinacrine is being used and a good signal is still not achieved, try decreasing the concentration of quinacrine by setting up four tubes of the same strain and using final concentrations of 1, 1.5, 2, and 2.5 μM. If a better signal is obtained, it may be desirable to try a series of concentrations around the best signal until the optimum concentration for the strain is obtained. If the signal is still too low, try increasing the incubation time with the dye.

Labeling the endocytic pathway in live cells with FM4-64

If a fresh batch of FM4-64 is being used and a good signal is still not achieved, try using the FM4-64 at a higher concentration/lower dilution (i.e., 1:50 or 1:75 if 1:100 is currently being used). If a higher concentration of FM4-64 is already being used, try using a lower concentration (more dilute), because high concentrations of FM4-64 can quench the signal. If the amount of fluorescent signal is high enough, but the wild-type yeast vacuoles are unusually fragmented, try using cells closer to early log phase. If the cells are not rounded and pretty, centrifuge at lower speeds and resuspend as gently as possible to improve their structure.

Internalization time course with FM4-64

If the fluorescence is too dim in the wild-type cells in this assay, troubleshooting will depend on which time point is giving the low signal. If the zero time point is missing plasma membrane labeling, most likely the washing is too thorough. Decrease the number, time of incubation, and/or volume of washes for all of the samples (so that later time points also maintain this PM label to have dye to internalize), and try to resuspend cells more gently. If the first time point after zero is too faint, but the zero time point and later times were okay, it may be that the assay temperature and strain being used require more time to internalize before the first time point is taken. If all of the time points after zero are too faint, these samples may be being washed more thoroughly than the zero time point. Try to make washes as close to equal as possible. Finally, if the final time point does not show mostly vacuolar staining in at least the wild-type cells, it is necessary to extend the assay to later time points until it does. Keep in mind that the number of samples to view under the microscope later increase rapidly with this assay, so rather than including additional time points, it may be desirable to spread the time points evenly over the extended time.

Endocytic rate measurement by LY uptake in live cells

If a fresh batch of lucifer yellow is being used, and a good signal is still not achieved, first try borrowing or getting a few different background strains and testing them out. As a positive control, the Research Genetics strain, BY4741 has worked most robustly and reliably for the authors. If none of the other wild-type strains give a visible/measurable signal, then start troubleshooting the method. If some of these strains give a signal, but the laboratory background strain does not, it may be that the strain will not work with this assay (for example, the authors have never seen lucifer yellow uptake in the wild-type strain SEY6210). To troubleshoot the method, start by making sure that all of the details of the protocol are being

followed, then try some of these suggested modifications to improve the signal.

1. Use one or two strains at several different starting concentrations and see if any one concentration works better.
2. Try altering the lucifer yellow concentration during the internalization incubation.
3. Try increasing the size of the gas exchange hole in the microcentrifuge tube, or increasing or decreasing the agitation rate during the dye incubation.

Keep in mind that this signal is often very low even when the assay works, so if vacuolar labeling is visible in the wild-type at all, this may be the maximal signal. Also remember that an extremely brightly stained vacuole, as noted in the method, is a sign of a dying yeast cell and is not due to endocytosis.

Localization of proteins in live yeast cells with GFP fusion proteins

If a good signal is not being achieved for the fusion protein, start by trying a GFP-fusion protein that is known to work (e.g., borrow from another laboratory or obtain one for which details on construction and strain are published so it will be known that nothing is being missed). If neither works, try changing to a different medium in case the experimental medium is too acidic or contains fluorescence quenchers. If the tester GFP-fusion protein works, then it is likely to be a problem with the fusion protein. First confirm that the fusion protein is stably produced by immunoblotting (*UNIT 6.2*). Also, many GFP-fusion proteins give a faint signal when a non-GFP version of the same protein is already available in the cell. Try integrating the GFP fusion in place of the genomic copy (or deleting the genomic copy and using the GFP fusion as the only copy on a plasmid). If this doesn't work, try using a high-copy-number vector, but keep in mind that increasing the levels of the fusion protein can harm the cell and/or result in altered localization due to high protein levels. Sometimes fusing GFP to the protein affects its folding/fluorescence, localization, or function, so it is possible to try creating an N-terminal fusion if previously a C-terminal fusion was created. Keep in mind that any fusion proteins used should be tested for functionality by rescue of mutant phenotypes wherever possible.

Labeling the actin cytoskeleton with rhodamine-phalloidin in fixed cells

If a fresh batch of rhodamine-phalloidin is being used and a good signal is still not achieved, it may be that the cells are not being sufficiently permeabilized. Try using about half the total OD_{600} amount of cells and make sure to use a full 1 ml of 0.2% Triton X-100 for the permeabilization step. If the actin is not properly polarized, the cells may be becoming distressed before or at the beginning of fixation. Be extra careful to treat cells gently until they have been in the fixation solution for at least 1 hr. If the cells are deformed or otherwise ugly in structure, the formaldehyde being used during fixation may be bad or the centrifugation used during preparation may be too fast. Try using fresh formaldehyde first. Finally, if a high background level of fluorescence is being observed, try adding extra washing steps after both the permeabilization (high background often comes from residual detergent when phalloidin is added) and phalloidin incubation steps. All of these washes make it easy to lose the pellet; remember that it is better to remove wash solutions with a pipet than an aspirator.

Labeling of live cells with rhodamine-phalloidin for colocalization with GFP fusion proteins

If a fresh batch of rhodamine-phalloidin is being used and a good signal for the actin is still not being achieved, try decreasing the total amount of cells taken and increasing the volume of permeabilization/staining solution to give each individual cell better access to both detergent and toxin label. If the GFP signal is too low in the actin-labeled cells, but not in the nonpermeabilized GFP-labeled-only cells, check the pH of the permeabilization solution and make sure that it is still around 7.4 (acidic pH decreases EGFP signal).

Localization of a protein in fixed yeast cells and in spheroplasted, then fixed cells with immunofluorescence

If the fluorescent signal is too low, try increasing the primary antibody concentration (it may be desirable to do a series of dilutions), or the time or temperature used when incubating with primary antibody. If doing colocalizations and both fluorescent signals are low, try adjusting the permeabilization or spheroplasting methods to give the antibodies better access to their targets. If the background signal is too high, try decreasing the secondary antibody incubation time or concentration, increasing the number of washes between antibody treatments, or changing the primary antibody.

Labeling cell wall chitin deposition with calcofluor white

Calcofluor white staining is usually very bright. If this signal is low, make sure the calcofluor white has dissolved into solution before use. If too much background is present, decrease the concentration of CfW. If not enough bud scars per cell are being achieved to assess budding patterns, try adjusting the growth conditions used in preparing the cells for the assay.

Anticipated Results

Labeling the vacuole in live cells with CDCFDA

CDCFDA evenly labels the entire lumen of any compartment exhibiting esterase activity. In wild-type cells one to five filled circles of fluorescence should be observed, taking up ~1/3 to 1/2 of the total cell volume. Mutant cells with defective delivery of hydrolases to the vacuole could exhibit normal structure but severely decreased fluorescence or abnormal structure including fragmented vacuoles and/or a Class E compartment, an enlarged late endosome–like structure adjacent to the vacuole (Raymond et al., 1992).

Labeling acidic organelles with quinacrine in live cells

Quinacrine labels the entire lumen of acidic membrane-enclosed compartments. In wild-type cells one to five filled circles or fluorescence should be observed, taking up ~1/3 to 1/2 of the total cell volume. Mutant cells may exhibit many of the defects described for CDCFDA.

Labeling the endocytic pathway in live cells with FM4-64

FM4-64 labels membranes only, and in wild-type cells should accumulate on the vacuolar membrane after the chase. In wild-type cells approximately one to five rings of fluorescence should be observed, each with a dark interior, taking up ~1/3 to 1/2 of the total cell volume. Mutant cells with a defect in endocytosis could exhibit abnormal fluorescence patterns such as endosomal labeling (punctate spots around the vacuole or adjacent to the plasma membrane) as well as decreased total cell-associated fluorescence. This can be measured by a cell sorter or approximated by measuring pixel intensity of vacuolar membranes from microscopy images taken under the same exposure conditions.

Internalization time course with FM4-64

In an internalization time course, the zero time point should exhibit a single ring of fluorescence for each cell corresponding to the plasma membrane. If the zero time point cells show some endosomal label, they may be getting a little warmer during the labeling or washing steps than they should. Make sure the centrifugation is performed at 4°C. When looking through time points after zero, endosomal membrane labeling should be visible (several punctate spots near the plasma membrane), then late endosomal labeling (punctate spots farther in the interior of the cell), then finally vacuolar labeling (one to five rings of fluorescence, taking up ~1/3 to 1/2 of the cell interior). See Figure 4.13.1 for an example of wild-type internalization at 30°C. Mutant cells defective for endocytosis could exhibit a delay in the progression of the dye through these stages, as well as decreased signal in the time points after zero (where all samples should have approximately equal label) due to removal of plasma membrane label in the postchase washes.

Endocytic rate measurement by lucifer yellow uptake in live cells

Lucifer yellow is a fluid-phase dye; therefore, in wild-type cells it should accumulate in approximately one to five filled circles of fluorescence, taking up ~1/3 to 1/2 of the interior of the cell. Mutant cells defective for endocytosis should exhibit decreased or absent fluorescence signal.

Localization of proteins in live yeast cells with GFP fusion proteins

The anticipated localization pattern for this assay will depend completely on the GFP-fusion protein being observed.

Labeling the actin cytoskeleton with rhodamine-phalloidin in fixed cells

Filamentous actin will be found in two forms, cortical actin patches and extended actin cables. As described, these two structures exhibit a distinct pattern throughout the cell cycle. In cells with small buds under DIC, ~90% of the cortical actin patches should be in the small daughter bud. Actin cables should extend along the axis from the bud into the mother cell, perpendicular to the bud neck. In cells with large buds, if DAPI staining shows the nucleus near the mother-bud neck, the nucleus is about to divide and the actin cytoskeleton should be randomly distributed in both cells. If the DAPI staining shows two separate nuclei, one in each

cell, then the actin cortical patches should be at the mother-bud neck and cables should extend outward from this neck in both directions. Figure 4.13.2 shows an example of these wild-type patterns. Mutants may be defective for polarization, for formation of cables or actin patches, or may have defects in regulating actin dynamics—e.g., few large actin clumps rather than several small patches, which may be depolarized. See Figure 4.13.3.

Labeling of live cells with rhodamine-phalloidin for colocalization with GFP fusion protein

Filamentous actin should follow the same patterns described for Basic Protocol 5, but again, GFP-fusion protein patterns will depend on the fusion protein used. Keep in mind that the protein might localize to cortical patches that are distinct from cortical actin patches. Figure 4.13.3 shows an example of GFP-Ent1p, which does localize to actin patches, but in these mutant cells actin patches are chunky and depolarized.

Localization of a protein in fixed yeast cells and in spheroplasted then fixed cells with immunofluorescence

The anticipated localization pattern for these assays will depend completely on the protein being observed.

Labeling cell wall chitin deposition with calcofluor white

Calcofluor white binds to chitin deposits in the yeast cell wall. Because there are low levels of chitin throughout the cell wall, with heavier deposits at scars formed at previous bud sites, the CfW pattern is usually characterized by a barely visible outline of the yeast cell, with several small rings of bright fluorescence on the outside edges/surface of the cell. Each individual ring is usually <1/10 the size of the yeast cell, and in wild-type diploid cells, one to several rings will usually be found on each end of the elongated cell. The middle third of each diploid yeast cell should be dark (devoid of chitin rings) in wild-type cells. In cells defective for recycling endocytosis, chitin deposition is decreased and rings will be absent or barely visible. In mutant cells defective for polarized cell growth, including actin cytoskeletal defects, the chitin rings will be found randomly over the surface of the diploid cells, and the cells themselves are usually not elongated but instead are round. Examples of both wild-type and depolarized chitin deposition are shown in Figure 4.13.4.

Time Considerations

For all of the protocols, there is an initial time investment required to prepare the cells for the assay. Inoculation of a culture the day before the assay is required to obtain a liquid culture ready for staining. Most of these assays require log-phase cells which may take up to 5 hr the next day to prepare if cells are saturated in the morning and must be diluted to bring the cells back to log phase. Remember that not all assays can use the cells diluted in the morning.

Labeling the vacuole in live cells with CDCFDA

Preparation of CDCFDA-labeled cells should take <1 hr once cells are in log phase. For an experienced fluorescence microscopist, viewing time should take 10 to 15 min per sample.

Labeling acidic organelles with quinacrine in live cells

Preparation of quinacrine labeled cells should take <30 min once cells are in log phase. For an experienced fluorescence microscopist, viewing time should take 10 to 15 min per sample.

Labeling the endocytic pathway in live cells with FM4-64

The FM4-64 assay should take anywhere from 1 to 3 hr once cells are in log phase. Once cells are ready for viewing, they should be observed as soon as possible but preferably not more than 1 hr after preparation. For an experienced fluorescence microscopist, viewing time should take 10 to 20 min per sample.

Internalization time course with FM4-64

The FM4-64 time course should take anywhere from 1 to 2 hr once cells are in log phase. Prepare the solutions just before harvesting the cells, making sure that all media are completely prechilled. For an experienced fluorescence microscopist, viewing time should take 10 to 20 min per sample (remember that this is per strain multiplied by the number of time points).

Endocytic rate measurement by lucifer yellow uptake in live cells

The lucifer yellow assay should take ~3 hr once cells are in early log phase. For an experienced fluorescence microscopist, viewing time should take 10 to 20 min per sample.

Localization of proteins in live yeast cells with GFP-fusion proteins

Preparation of GFP-fusion protein cells for viewing is very simple. Other than additional time for a temperature shift, once cells are in log phase they can be ready for viewing in as little as 5 min. For an experienced fluorescence microscopist, viewing time should take 10 to 15 min per sample.

Labeling the actin cytoskeleton with rhodamine-phalloidin in fixed cells

Preparation of F-actin labeled cells could take as little as 4 to 5 hr once cells are in log phase, but it can also be stretched out over 3 days. For an experienced fluorescence microscopist, viewing time should take 10 to 20 min per sample.

Labeling of live cells with rhodamine-phalloidin for colocalization with GFP fusion protein

Preparation of colabeled F-actin and GFP cells should take <1 hr once cells are in log phase. For an experienced fluorescence microscopist, viewing time should take 15 to 25 min per sample because it may take more time to find cells with both labels.

Localization of a protein in fixed yeast cells with immunofluorescence

Preparation of yeast cells with immunofluorescence requires an overnight fixation step after cells are in log phase. Once cells are fixed, the preparation could take as little as 5 hr, but often requires additional overnight incubation with the primary antibody as well. It is best to plan well and plan ahead for this assay, reading the method thoroughly before beginning the preparation. For an experienced fluorescence microscopist, viewing time should take 10 to 15 min per sample.

Localization in spheroplasted, then fixed, cells with immunofluorescence

This method for preparation of yeast cells with immunofluorescence can be done in 1 long day (~7 hr of preparation once cells are in log phase) but is likely to require at least 2 days for proper preparation of cells. As with Basic Protocol 6, make sure to read the method thoroughly before beginning the assay. For an experienced fluorescence microscopist, viewing time should take 10 to 15 min per sample.

Labeling cell wall chitin deposition with calcofluor white

Preparation of calcofluor white labeled cells should take <15 min starting from a dense overnight culture. Prepare the CfW solution a few days prior to beginning the assay since it may take over 24 hr to dissolve in solution. For an experienced fluorescence microscopist, viewing time should take 10 to 15 min per sample.

Fluorescence Lifetime Imaging Microscopy

Nowadays, fluorescence microscopy plays a central role in the fields of biology, biophysics, and in the life sciences in general. Its utility for imaging tissues, subcellular compartments, and even single molecules with high contrast is expanded by the possibility to investigate different properties of fluorescence like intensity, polarization, lifetime, and other spectroscopic parameters. The fluorescence lifetime in particular is a molecular property that offers a clearer fluorochrome signature than intensity spectra, and it contains information on the local molecular environment and chromophore photophysics of fluorescent labels. For these reasons, fluorescence lifetime imaging microscopy (FLIM) is used to enhance the image contrast of biological samples and to study molecular interactions of fluorescently labeled biomolecules by Förster resonance energy transfer (FRET). This unit will mainly focus on the second possibility. FRET is a photophysical phenomenon that allows the investigation of biochemical reactions in living cells. Under physiological conditions, FRET occurs exclusively between interacting molecules labeled with suitable fluorescent dyes with proper optical characteristics.

FRET imaged by FLIM exhibits the normal diffraction-limited spatial resolution offered by the light microscopical system used, but it maps interaction events that are on the 10- to 100-Å scale. Fluorescence microscopy flourished in the last decade with the advent of different detection techniques and the discovery of the green fluorescent protein and its different spectral variants. FRET imaging by FLIM contributed to the recent increase in sensing possibilities in cells.

Both the phenomena of energy transfer and lifetime are described theoretically and practically in this unit. Theoretical aspects that are usually neglected but are connected with the practical limitations of these techniques are also discussed. The limitations, pitfalls, and crucial considerations for FLIM and FRET will be demonstrated using experimental and simplified theoretical frameworks.

STRATEGIC PLANNING

FLIM—Fluorescence Lifetime Imaging Microscopy

Fluorescence emission is a property of molecules that can absorb photons and re-emit the accepted energy as photons with lower energy, i.e., at higher wavelengths. This process is described by the energy level (Jabłoñksy) diagram presented in Figure 4.14.1. Thicker horizontal lines represent different electronic energy levels with their associated vibrational states (thinner lines). These are ordered with energy increasing from bottom to top of the graph. Transitions are plotted with straight lines for radiative processes and with wavy lines for non-radiative phenomena.

Only considering the ground state, the first two excited states, and the first triplet state, the number of possible transitions between different electronic states is quite variable:

(1) photon absorption: $S_0 \rightarrow S_1$, $S_1 \rightarrow S_2$, $S_0 \rightarrow S_2$

(2) radiative de-excitation between singlet states (fluorescence processes)

(3) non-radiative de-excitations (quenching)

(4) radiative transition $T_1 \rightarrow S_0$ (phosphorescence).

Each transition is associated with a rate constant, a molecular property that could eventually be perturbed by the environment. In fluorescence microscopy, usually, interest is in the fluorescence transition $S_1 \rightarrow S_0$.

Contributed by Alessandro Esposito and Fred S. Wouters

Current Protocols in Cell Biology (2004) 4.14.1-4.14.30

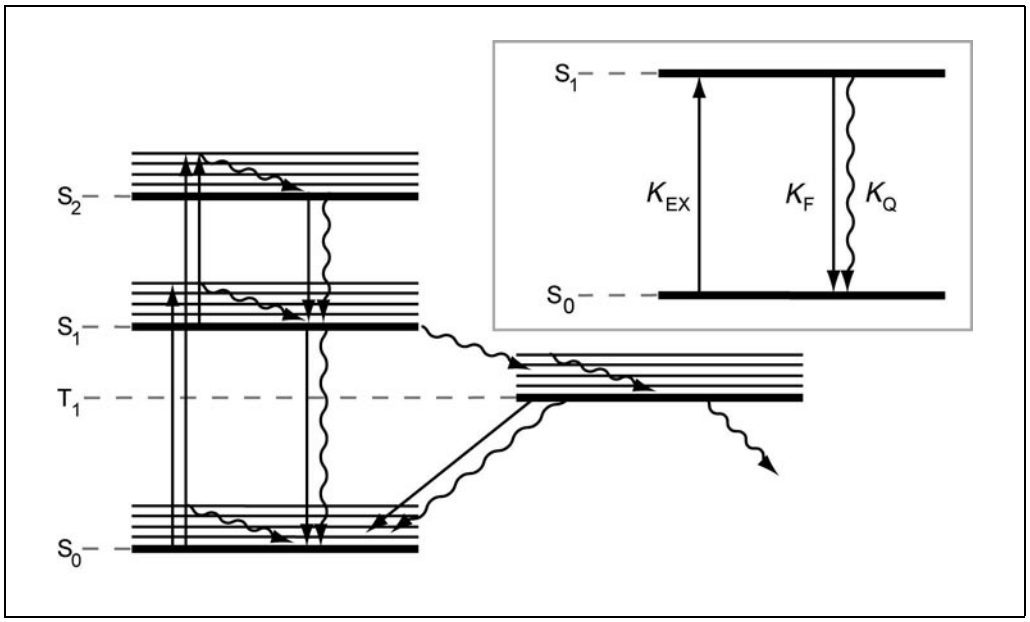

Figure 4.14.1 Typical depiction of fluorochrome photophysics (Jabłoñksy diagram). Plotted are the first three singlet and the first triplet electronic states (a more detailed description can be found in Strategic Planning). Top inset: simplified Jabłoñksy diagram, with photon absorption (K_{EX}), fluorescence (K_F), and internal conversion (K_Q, quenching) transitions indicated. Straight lines represent radiative transitions, wavy lines indicate non-radiative transitions.

The excited state S_1 has a defined lifetime, which depends on the rate constants of the different de-excitation pathways. After a photon is absorbed, a fluorescence photon is emitted after a certain delay. Thus, one definition of lifetime is the average time that a molecule spends in its excited state.

Average time means that the time decay is stochastic and follows a distribution that, in general, is exponential:

$$p(t) = \frac{1}{\tau} e^{-\frac{t}{\tau}}$$

Equation 4.14.1

The exponential decay constant τ of this probability distribution $p(t)$ also represents the lifetime and it is easy to find that the two definitions match when one considers the *average* lifetime.

The lifetime depends on equilibrium of the different rate constants:

$$\tau = \frac{1}{K_F + K_{NR}}$$

Equation 4.14.2

where K_F is the rate of photon emission, while K_{NR} is the rate of non-radiative de-excitation that could represent collisional quenching and/or energy transfer. An increase of these non-radiative processes due to interaction with the environment thus reduces the lifetime of a fluorochrome, which could be used by FLIM to probe these environmental influences. If the interactions with the environment are negligible or invariant, the lifetime represents a more reliable marker for a fluorescent species than its spectra. In fact, lifetime distributions are considerably narrower than intensity spectra.

FLIM has been used successfully for the separation of different fluorophores in multiple-stained samples (Figure 4.14.5; Pepperkok et al., 1999; Neher and Neher, 2004) to map endogenous autofluorescent cellular metabolites like NADH (Lakowicz et al., 1992) or to measure ratiometric probes like the high-affinity calcium indicator dye Indo-1 (Szmacinski et al., 1993). FLIM, performed on tissues, presents a growing and interesting diagnostic tool in the medical sciences (Tadrous et al., 2003). A recent investigation (Eliceiri et al., 2003) using FLIM on tissues stained with conventional histological dyes also demonstrated improved contrast and information content. In conclusion, FLIM is a well-established microscopy technique in the fields of biology, physics, and medicine. This unit will mainly focus on the lifetime-based detection of FRET because of its direct relevance for, and promising applicability in, the rapidly developing and converging fields of modern cell biology and biophysics.

FRET—Förster Resonance Energy Transfer

FRET is the phenomenon by which a donor fluorochrome transfers energy to an acceptor molecule in a non-radiative manner (Förster, 1965; Clegg, 1996). This phenomenon can be better understood by a quantum physical model but is easier explained by the classical concept of coulombic dipole-dipole interactions, although without emission and consequent re-absorption of a real photon. The simplified Jabłoñksy diagram in Figure 4.14.2 presents the transitions between the donor and acceptor ground and excited states. The energy transfer transition is given by:

$$(D,a) \overset{K_{ET}}{\rightarrow} (d,A)$$

Equation 4.14.3

where D, A denote excited states and d, a ground states of donor and acceptor, respectively. Consider the FRETting donor-acceptor pair as a system with four quantum states (Fig. 4.14.2):

1. *da*, both donor and acceptor, respectively, are in the ground state;
2. *Da*, only the donor is excited;
3. *DA*, both donor and acceptor are excited;
4. *dA*, only the acceptor is excited.

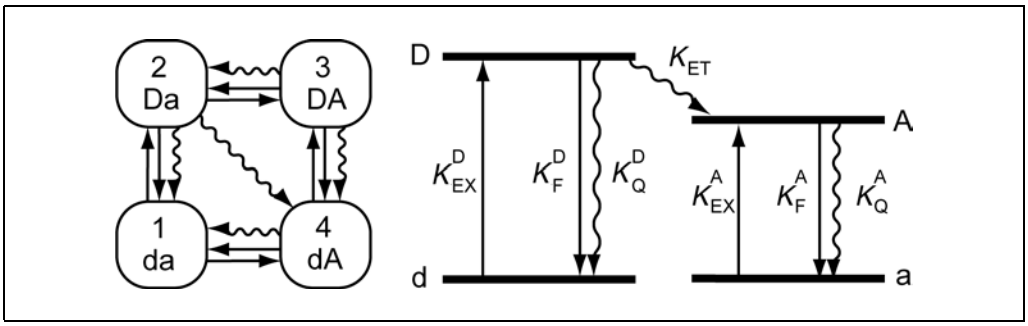

Figure 4.14.2 Four-state transition diagram. The simplified energy level diagram (right) illustrates transitions between ground and excited state of donor (*D*) and acceptor (*A*) fluorophores. The donor-acceptor pair can be considered as a unique photophysical system with four states (left) in which the diagonal radiation-less transition represents energy transfer. Lower-case letters indicate ground state and capital letters indicate excited state.

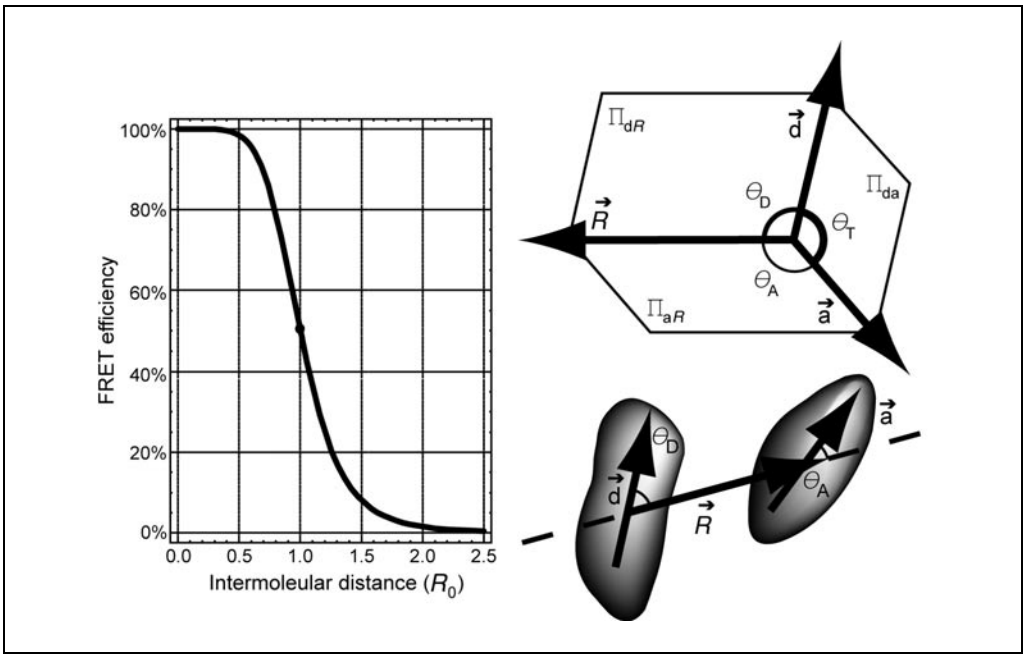

Figure 4.14.3 Spatial degrees of freedom in a FRET pair. The energy transfer phenomenon is a dipole-dipole interaction that depends on the intermolecular distance (R) and on the relative orientation of the two molecular dipole moments. The FRET efficiency increases with the sixth power of the intermolecular distance (left graph). The Förster radius, the distance at which the donor transfers energy to the acceptor with 50% efficiency, is a characteristic of the pair. Two interacting molecules are depicted (bottom-right) with their electrical dipole moment and the intermolecular distance vectors. The angle definitions of the three vectors are drawn in the upper-right scheme. Π indicates the plane defined by the different vectors and θ represents the angles (defined in Strategic Planning) that are most commonly used as coordinates for the orientational factors.

The energy or excitation transfer (ET) transition adds a de-excitation pathway to the single fluorochrome diagram (Figure 4.14.1 inset) and hence reduces the lifetime of the donor excited state in accordance with Equation 4.14.2, as it increases the probability per time unit of excited state depopulation. The quantum yield of this transition is called the FRET efficiency (ε). When the FRET efficiency is maximal (100%), i.e., when K_{ET} is much greater than the other rate constants, all absorbed energy is transferred from donor to acceptor.

FRET is often called fluorescence resonance energy transfer. Because this name is ambiguous and could lead to the assumption that there is emission of a fluorescence photon by the donor or that the acceptor should be a fluorescent molecule, it is preferable to associate the first letter with the name Förster, the discoverer of this phenomenon. For the same reason, FRET is also referred to simply as RET or ET (energy transfer or excitation transfer) in literature.

One of the most interesting aspects of ET is its extreme dependence on the intermolecular distance. An ET event occurs typically between distances of 10 and 100 Å, in the order of magnitude of protein size. Molar concentrations are required to reach these intermolecular distances in the absence of a specific interaction mechanism, a meaningless range under physiological conditions. This implies that if two molecules are FRETting in a biological system, they are also interacting. The second interesting aspect is that the FRET efficiency falls with the sixth power of the intermolecular distance (Figure 4.14.3):

$$K_{ET} = \frac{1}{\tau_D}\frac{R_0^6}{R^6};\ R_0^6 = \frac{\kappa^2}{n^4}Q_D J;\ \varepsilon = \frac{R_0^6}{R_0^6 + R^6}$$

Equation 4.14.4

Equation 4.14.4 illustrates the parameters of interest in this unit. R_0 is called the critical or Förster distance (or Förster radius). This parameter is a property of the FRET pair and is linked to the overlap integral J of the donor emission and acceptor absorption spectra, the donor quantum efficiency Q_D, the refractive index of the medium n and an orientational factor κ. R_0 is the distance at which the two molecules transfer energy with 50% efficiency. The sixth-power dependence of FRET on a fluorochrome separation distance causes FRET to sense only short (<10 nm) distance interactions, which prevents false-positive detection of interactions. It also allows high sensitivity for intermolecular distance variations over a scale of a couple of nanometers where the efficiency goes from all to none.

κ is an orientational parameter whose most common definition is shown in Equation 4.14.5:

$$\kappa^2 = (\cos\theta_T - 3\cos\theta_D \cos\theta_A)^2$$

Equation 4.14.5

As represented in Figure 4.14.3, θ_T, θ_D, and θ_A are the angles between donor-acceptor dipole moments, the donor dipole moment–intermolecular distance vector, and the acceptor dipole moment–intermolecular distance vector, respectively. Another useful definition is:

$$\kappa^2 = \cos^2\omega(1 + 3\cos^2\theta_D)$$

Equation 4.14.6

in which ω is the angle between the acceptor dipole moment and the electric field originating from the donor transition moment. This second relation illustrates that the FRET efficiency depends on two angular degrees of freedom and an intermolecular distance degree of freedom. κ^2 assumes a maximum value of 4 only when the donor and acceptor dipoles and the intermolecular distance vector are parallel or antiparallel as shown in Table 4.14.1. This happens when the acceptor transition dipole is parallel or

Table 4.14.1 Extreme Orientational Parameter Configurations[a]

κ^2	θ_T	θ_D	θ_A
4	0	π	0
	0	0	π
	π	0	0
	π	π	π
0	$\pi/2$	$\pi/2$	θ_A
	$\pi/2$	$3\pi/2$	θ_A
	$3\pi/2$	$\pi/2$	θ_A
	$3\pi/2$	$3\pi/2$	θ_A
	$\pi/2$	θ_D	$\pi/2$
	$\pi/2$	θ_D	$3\pi/2$
	$3\pi/2$	θ_D	$\pi/2$
	$3\pi/2$	θ_D	$3\pi/2$

[a]The orientational parameter κ^2 can be represented as a function of three angles that define the relative orientation between the donor and the acceptor as shown in Figure 4.14.3. There are only four discrete values at which κ^2 is maximal while there are continuous distributions of angles for which κ^2 is zero. In the latter case, it is sufficient that the donor *or* the acceptor dipole is orthogonal to the intermolecular distance while orthogonal to each other. For this reason, the probability to obtein high κ^2 values is very much lower than for lower values.

antiparallel ($\omega = 0, \pi$) to the donor electrical field. κ^2 assumes the minimum value of zero in more configurations, namely when these two vectors are orthogonal ($\omega = \pi/2, 3\pi/2$) and at least one is perpendicular to the intermolecular distance vector. For this reason, the relative orientation of two fluorochromes plays a crucial role in the yield of energy transfer.

A complete description of this aspect of ET is given by Lakowicz (1999) and van der Meer (1999). The latter work shows that the probability to obtain a maximum value for κ^2 is almost negligible compared to other, lower values. In any case, the probability on a particular value of κ^2 decreases with increasing values. The FRET efficiency between two rigidly connected chromophores will most probably be reduced by an unfavorable orientation of the two dipole moments. κ^2 is equal to 3/2 when complete rotational freedom between the two molecules can be assumed. This might hold true for small, conjugated organic fluorophores, but it is likely not the case for genetic fusions with the visible fluorescent proteins (VFPs). In this case, the chromophore mobility is restricted inside the β-barrel of the VFP structure and the VFPs are likely to bury into the surface of the fused protein. The orientation factor must therefore be optimized in the design of FRET-based biosensors by linker mutagenesis strategies to avoid the most probable but less optimal relative donor-acceptor orientation outcome.

Another important parameter is the refractive index of the medium. The energy transfer efficiency depends on the inverse of the fourth power of the refractive index. Some problems can arise when changing the mounting medium or buffer solution. Mounting cells in mowiol or glycerol, for example, causes an increase of the refractive index up to 1.48 to 1.49, which is considerably higher than the refractive index of cytoplasm, which is estimated to be 1.38. At very low FRET efficiency, this can cause a significant reduction of energy transfer. The possible effect of the refractive index should be considered critically under experimental conditions where the refractive index is varied over a broader range.

Theory: Energy Transfer, Energy Migration, and Lifetimes

Energy migration (EM) is the radiative migration of energy between molecules, i.e., the re-absorption of emitted photons. This phenomenon could dominate over longer distances where EM is relevant because it only falls with the second power of the intermolecular distance. Although EM can be considered as a distinct phenomenon, there are theoretical frameworks in which the two processes are explained as different manifestations of the same phenomenon (Juzeliûnas and Andrews, 1999). As only the non-radiative energy transfer couples the donor-acceptor photophysics such that the donor lifetime is reduced, EM does not affect FLIM-based FRET measurements.

For these reasons, a lifetime map obtained by fluorescence lifetime imaging microscopy represents the distribution of Förster resonance energy transfer. By application of Equations 4.14.2, 4.14.3, and 4.14.4, a quantitative FRET image can be retrieved from the following relation:

$$\varepsilon = 1 - \frac{\tau}{\tau_0}$$

Equation 4.14.7

in which τ is the observed reduced lifetime of the donor while τ_0 is the non-FRETting lifetime that, as reported before, is a donor property.

FRET, FLIM, and molecular biological tools together offer a powerful toolset for the investigation of protein function in the physiological setting of the intact living cell or tissue. In the current proteomics era, there is a demand for identification of molecular activity of identified gene products and elucidation of their interplay in the signalling network of the cell. These questions demand a screening approach to obtain a proteome-wide diagram of protein-protein interactions, modifications, and activities, all of which can be addressed by FRET. This static picture of interactions needs to be complemented with spatiotemporal information, thus requiring measurements in living cells.

Time and Frequency Domain (TD/FD) FLIM

Fluorescence lifetime imaging microscopes are classified into two main categories depending on the detection technique used. Time domain FLIM uses a pulsed-light source and detects the time decay distribution of the emitted fluorescence. Frequency domain FLIM typically uses sinusoidally modulated excitation light and senses the lifetime-dependent demodulation and phase-delay of the emission signal. Pulsed excitation can also be applied in the frequency domain. Both kinds of detections can be implemented on wide-field or scanning microscopes, but presently, the most common setups are wide-field FD-FLIM and laser-scanning TD-FLIM.

TD-FLIM: Excitation Light

A flash of light is required to time resolve the sample lifetime. This flash causes the transient population of the first excited state of the fluorochrome, and the detectors will follow the decay distribution of the emitted fluorescence. Pulsed lasers with pulse widths in the pico- or femtosecond range are the best light sources for the time domain. These lasers provide delta-like excitation, causing the time response of the system to depend primarily on the fluorescence characteristic of the fluorochrome and from the timing properties of detectors. A typical TD-FLIM takes advantage of a Ti:Sapphire-pulsed laser usually employed for two-photon (TP) microscopy (*UNIT 4.11*). The TP excitation regime can be used conveniently to generate lifetime images with the optical sectioning capabilities and the typical resolution of this technique. Single-photon excitation (SP) is usually achieved by regeneration of the near infrared (NIR) Ti:Sapphire emission using crystals that double the light frequency by second harmonic generation. Today, picosecond solid-state lasers are also available that allow a simpler setup to be built and that eliminate the need for expensive, yet more flexible and tuneable lasers like those used for TP excitation.

TD-FLIM: Common Scanning Setup

A common setup consists of a two-photon laser scanning microscope (TPLSM) or confocal laser scanning microscope (CLSM) configuration because the most suitable detectors capable of retrieving the fast decay distributions are point-detectors like photo-multiplier tubes (PMTs), multi-channel plate photo-multiplier tubes (MCP-PMTs), and single-photon avalanche diodes (SPADs). The laser beam is scanned over the sample and the sub-nanosecond light pulses transiently populate fluorochromes, which immediately relax to the ground state with a time-decay distribution that is typical for each fluorochrome. The distribution of the decay times is sampled at each pixel location.

A TD-CLSM has some advantages over the TD-TPLSM FLIM configuration. It is well known from literature that the confocal microscope has an intrinsically higher resolution than a TP microscope (Denk et al., 1995). Moreover, the pinhole could be removed to use the microscope in normal scanning mode to allow the acquisition of more photons from a thicker focal plane. This is sometimes beneficial to collect sufficient photons under demanding biological applications albeit at the cost of spatial resolution. When exciting specific fluorochromes, SP excitation exhibits a clear advantage over TP as

the absorption spectra of the latter are considerably broader. It is possible to excite multiple fluorochromes simultaneously in a sample by TP excitation and this is usually an advantage (Esposito et al., 2004), but it could present a problem in FRET measurements because direct excitation of the acceptor should generally be avoided. In any case, if sectioning is required or when lifetime detection is used for contrast enhancement between different fluorochromes, TPLSM regains its advantages.

TD-FLIM: Detection with TCSPC or TGSPC

Time-correlated single photon counting (TCSPC) and time-gated single photon counting (TGSPC) are the two most frequently used techniques for time-domain detection. TCSPC (O'Connor and Phillips, 1984; Becker et al., 2004) detects the time-delay between a single laser pulse and the first photon emitted from the sample. The presence of detector dead time prevents the detection of further photons that are emitted after the ones that have been counted, which can cause a loss of detectable signal at high-emission rates. A time-correlated system builds the distribution of arrival times from the first emitted photon per pulse from which, through pixel-by-pixel fitting routines, a lifetime image is retrieved. Usually, the reversed start-stop configuration is applied with high-repetition rate pulses. In this case, the time-delay between a detected photon and the next laser pulse is measured to avoid pulse-pileup. Time-gated detectors perform single photon counting by integration of fluorescent signals in two (Wang et al., 1991; Buurman et al., 1992; van der Oord et al., 2001) or more time windows (de Grauw and Gerritsen, 2001). These detectors collect almost all photons that emerge from the sample and can be gated after a sub-nanosecond initial delay to suppress the contribution of short-lifetime background signals to the measurement. Data collected in two windows can be simply analyzed according to Equation 4.14.8 to obtain an average lifetime estimator without the need for time-consuming and computationally expensive fitting procedures. Gating systems with multiple time windows can also resolve multi-exponential decays.

TD-FLIM: Wide-Field Microscopes

Typical time-domain FLIM setups are based on scanning microscopes but wide-field versions (Wang et al., 1991; Siegel et al., 2001b; Webb et al., 2002) are also interesting because they can be operated faster. The classical TD wide-field FLIM is built around a multi-channel plate with gated sampling of decay fluorescence intensities at defined time-delays. A minimum of two images acquired at different time delays are needed to retrieve a lifetime image. Recently, a more efficient wide-field gated system has been developed (Agronskaia et al., 2003) that projects two time-delayed images of the sample side-by-side onto the same multi-channel plate (MCP). The emitted fluorescence is split into two separate optical paths with different lengths, corrected for different magnification factors and focussed on the gated device. The two recorded images can be spatially matched and their ratio is a good lifetime estimator for mono-exponential decays. The rapid lifetime determination (RLD) formula (Ballew and Demas, 1989) can be used to retrieve sample lifetime:

$$\tau = \frac{\Delta\tau}{\ln(I_1/I_0)}$$

Equation 4.14.8

where I_0, I_1 are the non-delayed and delayed image, respectively, and $\Delta\tau$ is the gating time width. This is the same formalism that is also used for two-window time-gated scanning microscopes. This wide-field setup was reported to reach a maximum acquisition speed of 100 Hz, compared to other systems where speed seems to be limited to 1 Hz.

FD-FLIM: Excitation Light

A frequency domain microscope commonly uses a sinusoidally modulated light source whose intensity is described by the following equation:

$$I = I_0\left[1 + m_0 \cos(\omega t + \varphi_0)\right]$$

Equation 4.14.9

where I_0 is average light intensity, m is modulation depth, ω is circular frequency, and φ_0 is a phase bias. The donor emission follows this sine wave but, if periodicity is in a time scale comparable to donor lifetime, emitted fluorescence is demodulated and delayed by the lifetime itself. After proper calibration of the system with a reference sample, it is possible to determine these two parameters which are linked to the sample lifetimes with the following equation:

$$m = \sqrt{\frac{1}{1 + \omega^2 \tau^2}};\ \varphi = \arctan(\omega\tau)$$

Equation 4.14.10

Because typical biologically interesting fluorescent probes exhibit nanosecond-lifetimes, the excitation intensity is modulated at several tens of megahertz. This is achieved by use of acousto-optic modulators (AOM), transparent crystals in which an ultrasonic wave field creates a refraction index grid (Piston et al., 1989). A coherent beam passing through such a crystal is diffracted and the first-order diffraction spot is almost completely modulated. Pulsed-light sources can also be used in the frequency domain (Gratton et al., 2003).

FD-FLIM: Wide-Field Detection

The most common setup for frequency domain imaging is based on a wide-field microscope. The coherence of the modulated laser beam is removed by a spinning ground-glass disc or a continuously vibrated optical fiber to suppress speckle noise and then expanded on the input port of a conventional fluorescent microscope.

To detect demodulation and phase delay of fluorescence emission, fluorescence signal is cross-correlated with the excitation signal by homodyning or heterodyning techniques (Spencer and Weber, 1969; Gadella et al., 1994; also see Lakowicz, 1999). The former technique is simpler and current electronics are sufficiently fast to perform homodyming. Whatever solution is adopted, a device with spatial resolution that can multiply an electronical reference signal with a light signal is needed because it is currently not possible to directly multiply (cross-correlate) two light signals. These devices are the multi-channel plates that are also used for gating in wide-field time-domain implementations. They can be gated to $<$100 psec, which is more than sufficient for typical systems that are operated in the 50- to 100-MHz region. The fluorescence photons arrive at the photocathode of the MCP and generate photoelectrons. The probability that a photon is detected, i.e., a photoelectron is emitted, is proportional to the voltage on the photocathode. This is modulated with voltages proportional to the excitation signal to achieve cross-correlation in the homodyning technique. The number of photoelectrons is subsequently amplified and imaged onto a phosphor screen. The response of the former is slow (milliseconds) and integrates the signal. The resulting image is projected onto a CCD camera. The MCP-CCD ensemble behaves as a phase-sensitive camera (Lakowicz and Berndt, 1991). If the frequency of the gain-modulation is different from the modulated excitation, cross-correlation is performed in heterodyning mode. Here, phase shift and modulation are transferred to a signal at a difference frequency. This passes through the low-pass filter (slow response)

phosphor screen to be sampled by a CCD camera in time. In the homodyning technique, several images are acquired at different, relative phase delays injected into the MCP gain. This image phase stack is compared with the reference measurement and then analyzed by a pixel-by-pixel Fourier analysis algorithm or sine function fitting routine. The demodulation and phase-lag maps are inverted to obtain two lifetime estimations. Multi-component lifetime systems are usually considered non-resolvable with frequency domain techniques, but they can be resolved in the time-domain by multi-exponential fitting routines. Recent works show how at least a two-component lifetime system can also be resolved in the frequency domain by global analysis (Verveer and Bastiaens, 2003). Global analysis has been previously applied to investigate multi-component lifetime systems (Verveer et al., 2000; Squire et al., 2000) using multi-frequency FD-FLIM data.

The authors recently developed an alternative analysis method for resolving lifetime heterogeneity in general and for a two-component (FRETing) system in particular (Esposito et al., unpub. observ.).

FD-FLIM: Phase-Fluorimeters and IMS

The principle by which lifetimes are measured with an FD-FLIM microscope has a history in cuvette-based phase fluorimeters. These systems are commercially available and some solutions are very simple and compact. They are fast and precise and their only limitation is that they perform single-spot measurements. This implies that only an average lifetime can be obtained from a sample. A simple and inexpensive compromise between microscopes and phase fluorimeters is possible and suitable for a large number of biological questions that do not strictly rely on spatial resolution; such a system has been reported (Herman et al., 2001). Here, a LED was driven by a phase fluorimeter to excite a sample in a region of interest. The emitted fluorescence, collected by the microscope, is focussed on the phase-fluorimeter PMT to allow detection of an average lifetime over a whole cell. The intensity modulated multiple-wavelength scanning (IMS) microscopy technique is equivalent to phase fluorimeters, which rely on lock-in amplification. Lifetime imaging by IMS has been reported (Carlsson and Liljeborg, 1998). The main parts of the system are a lock-in amplifier and a scanning head. Scanning is performed at a frequency that is typically several orders of magnitude slower than the frequency of the modulated light. Therefore, a lock-in amplifier sees the scanning mirrors of the microscope frozen in time, enabling it to perform a lifetime estimation. This adaptation of phase fluorimetry for use in microscopy, although interesting, did not find considerable application in the literature.

LEDs and New-Generation Detectors

Although there is no real commercial effort to produce new light sources and detectors specifically for lifetime detection, technology is certainly advanced enough to deliver new potential tools for this field. Both light-emitting diodes (LED) and photodiode detectors have seen tremendous improvements in the past few years thanks to intense industrial research for the purpose of optical data transmission. Very high brightness (up to 10 cd) and rapidly modulatable (up to 200 MHz) LEDs are currently available (Harms et al., 1999; Herman et al., 2001; Landgraf, 2001; O'Hagan et al., 2002). For detectors, there is no immediate commercial perspective for bi-dimensional integration of fast detectors that could store phase- or time-delayed images onto the same chip and with higher resolution than an MCP. However, current state-of-the-art technology did produce interesting detectors like SPDA sensors (Mitic et al., 2003) or CMOS and CCD cameras with ever increasing yield and speed. CCDs were also recently used as fast-gating devices by directly modulating their gain (Mitchell et al., 2002a,b). The production of all-solid-state detectors that store gated images at different time or phase delays on the same chip is realistic and eagerly awaited in the field. The authors are currently exploring the applicability of one such experimental design for lifetime detection.

Other FLIM Techniques

In recent years, several new FLIM techniques were designed. ϕFLIM (van Munster and Gadella, 2004a) is a slightly modified FD-FLIM setup where one of two signal generators is phase modulated, and a different acquisition protocol is adopted. In this setup, steady-state, cosine and sine transforms that are required for Fourier analysis are directly grabbed (see Basic Protocol 1 and Anticipated Results; Eq. 4.14.13) rather than measuring an image phase stack. This speeds up the standard FD-FLIM method and avoids systematic errors that could occur when only a few images are acquired per phase stack. Although ϕFLIM presents a sensible and potentially useful variation on the frequency-domain theme, it is currently more sensitive to noise and further development is required before it becomes a practical alternative.

A standard FD-FLIM setup can also be modified by use of polarized excitation light and detection through parallel or orthogonal polarization analyzers. This technique, called "dynamic fluorescence anisotropy imaging microscopy in the frequency-domain" or rFLIM (Clayton et al., 2002), allows determination of rotational correlation time and fluorochrome lifetime on a pixel-by-pixel basis. rFLIM provides access to information on the environment of the fluorochrome and allows for detection of FRET between spectrally identical FRET pairs, called homoFRET. When energy is transferred from a donor to an identical acceptor species, the depolarization that usually occurs due to rotation of the fluorochrome is emphasized because of the different relative orientations of two homo-transferring fluorescent molecules.

A standard TD-FLIM can be modified with the addition of a second TCSPC detector spectrally separated from the first one. Two acquisitions can be used to determine both lifetime and a spectral maximum estimator at each sample location. This technique is called "spectrally resolved fluorescence lifetime imaging microscopy" or sFLIM and has been successfully used for the detection of single RNA molecules in living cells (Knemeyer et al., 2003).

An FD-FLIM can be operated with more than one acousto-optic modulator (AOM), injecting more than one harmonic component into the fluorescence signal. This system called multi-frequency FLIM or mfFLIM has been developed (Squire et al., 2000) to resolve multi-lifetime samples without the need for taking sequential lifetime images at different modulation frequencies. The same investigation can be performed by injecting a broader harmonic content in the emitted-fluorescence signal by pulsed-laser excitation.

Finally, a pump-probe microscope with lifetime imaging capabilities has been developed (Dong et al., 1995). A pump-laser pulse populates the donor excited state while a probe-laser pulse delayed with respect to the pump pulse, stimulates photon emission. By sampling the emitted fluorescence at different pump-probe time delays, sample lifetimes can be estimated.

Choosing a FLIM Setup

A theoretical figure of merit has been derived (Draaijer et al., 1995; Gerritsen et al., 2002; Carlsson and Philip, 2002; Philip and Carlsson, 2003), which allows comparison between different lifetime detection methods. It is clear that frequency- and time-domain methods converge to ideal performances under optimal conditions. In a recent study (Gratton et al., 2003), frequency-domain and time-domain FLIM were compared on the same scanning setup. It was shown that FD-FLIM performance is better with realistic biological samples. However, TD-TCSPC-lifetime imaging can achieve a time resolution close to 25 psec and exhibits an ideal photon collection efficiency at low photon-counting rates, although under these conditions, acquisition times are very long (1 to 30 min). TD-TGSPC allows increased acquisition and post-processing speeds, above all with the use of two-gate

systems, albeit at the cost of lower photon efficiencies. The IMS frequency–domain technique compares with time-domain systems. All these techniques are mostly performed with two-photon excitation and using confocal, laser-scanning microscopes. Wide-field detection requires use of gated image intensifiers and consequently suffers from a lower spatial resolution and overall photon collection efficiency. However, poor photon counts usually generated by biological samples sometimes require a non-confocal light collection scheme, thereby sacrificing spatial resolution to obtain sufficient fluorescence detection. For these reasons and the simpler hardware required, wide-field FD-FLIM represents a good compromise for lifetime imaging.

The selection of the FLIM system is also strictly dependent on its application. TD-TCSPC can give the most accurate results, and it excels when detailed investigation of photophysical processes is required. TD-TGSPC can be more efficient for biological applications, and a wide-field FD-FLIMs can, in general, be faster and easier to operate but with lower spatial resolution. Specific lifetime detection variants, briefly described previously, can also offer particular advantages.

Commercially available TD and FD systems, also in their simplified versions, can give sufficiently reliable lifetime estimations to be used as quantification instruments for detection of molecular interactions and protein biochemical states by FRET. These systems also offer less-expensive and easier-to-use solutions when compared with the typical custom-built FLIM setups.

In the following section two protocols are described for the operation of wide-field frequency-domain and a laser-scanning two-photon TCSPC time-domain lifetime microscope. A more detailed description of the hardware and some typical results are in Anticipated Results. With information given in the first section and the Literature Cited, the adaptation of these protocols to wide-field TD and scanning FD is straight-forward.

Sample preparation protocols are available in other Current Protocols books, in this chapter, and regarding FRET application, specifically *UNIT 17.1*.

BASIC PROTOCOL 1

OPERATING A WIDE-FIELD FD-FLIM SETUP

Proper calibration of the microscope setup is required to obtain reliable quantitative lifetime estimations. The optical path, hosted on an adequately vibration-isolated optical table, should be aligned and maintained periodically and checked before each use. Without a proper calibration, FD-FLIM systems are vulnerable to systematic errors. This does not affect the qualitative meaning of the measurements, but a fine calibration can be necessary for more quantitative estimations (Hanley et al., 2001). The present protocol describes the standard alignment and calibration procedure for a frequency-domain wide-field system. Furthermore, the acquisition of an image phase stack and its post-processing for estimation of sample lifetime are illustrated. Although there are several possibilities for building and operating a frequency-domain lifetime microscope, this protocol describes the most common and robust setup.

Materials

Single-exponential decaying fluorochrome with a well-defined lifetime (e.g., Rhodamine-6G)
Basic components of a wide-field FD-FLIM (see Commentary)
Positive-intrinsic-negative (PIN) diode connected to an oscilloscope (bandwidth up to 100 MHz)
Mirror, reflective foil, homogenous flat fluorescent or scattering sample

CAUTION: Protective goggles matching the used laser wavelength and power are recommended when aligning the optical path. Lasers can be harmful and standard laser safety rules should always be followed. Moreover, handle the optics with cotton gloves to avoid dirty or scratched optical surfaces.

Tune and align laser

1. Tune and peak laser at the desired frequency.

   This is straightforward with lasers typically used in the frequency domain. Every time the light wavelength is changed, the optical path requires subtle re-alignment because the optics focus light in slightly different positions.

2. Align acousto-optic modulator (AOM) to obtain a diffraction pattern (see Figure 4.14.4, top panel). Drive AOM with proper frequency.

   The AOM modulates the laser beam when it passes almost longitudinally, but it is slightly tilted through the radio frequency (RF)-driven crystal.

3. Get the laser beam to pass longitudinally through its optical window. Slightly tilt the AOM.

   If no diffraction pattern is detected, change the driving frequency and iteratively adjust the crystal position until a clear diffraction pattern appears.

4. Align and tune the AOM to reach the best modulation performance. Monitor light intensity of the first-order spot of the diffraction pattern with the PIN diode connected to the oscilloscope. Sweep frequency to obtain maximum light modulation. Adjust voltage on the AOM to reach maximum modulation with minimum possible distortion. Re-align the AOM in a fine manner to optimize light modulation.

5. Select the first-order spot, attenuate, and de-speckle the laser light.

   The first-order spot can be selected by an iris. A neutral density filter wheel can be used to attenuate the laser light when required. The laser beam, before being expanded, can be de-speckled by focusing it on a multi-mode fiber optic cable that is continuously vibrated (50 Hz provided by the mains are enough). Speckle noise can also be removed by a spinning ground-glass disk, but a vibrating optical fiber is the best choice for simplicity and user safety.

6. Couple laser beam with microscope.

   The laser beam can be expanded by a lens of proper focal length onto one of the input ports of the microscope.

7. Align laser beam with microscope optics by imaging a flat and homogeneous sample like a reflective foil, a mirror, a scattering or a fluorescent solution. Move the coupling optics to try to obtain the most homogeneous and bright field. Close, if available, the field iris aperture of the microscope and, with a focussed sample, move optics so that the iris shape is focussed together with sample. Repeat all previous adjustments iteratively to find the best compromise between brightness, homogeneity, and focus of the excitation light source.

8. Calibrate microscope with a reference lifetime by placing a reference sample like a zero-lifetime sample (reflective foil or scatterer) or a solution of a well-known and characterized single-exponential lifetime fluorochrome on the stage. Measure modulation and phase-lag of the reference according to steps 9 to 15 and use these parameters to calibrate a lifetime imaging (Equations 4.14.13 to 4.14.15).

   A pixel-by-pixel calibration can be necessary if the detector response is not spatially homogeneous.

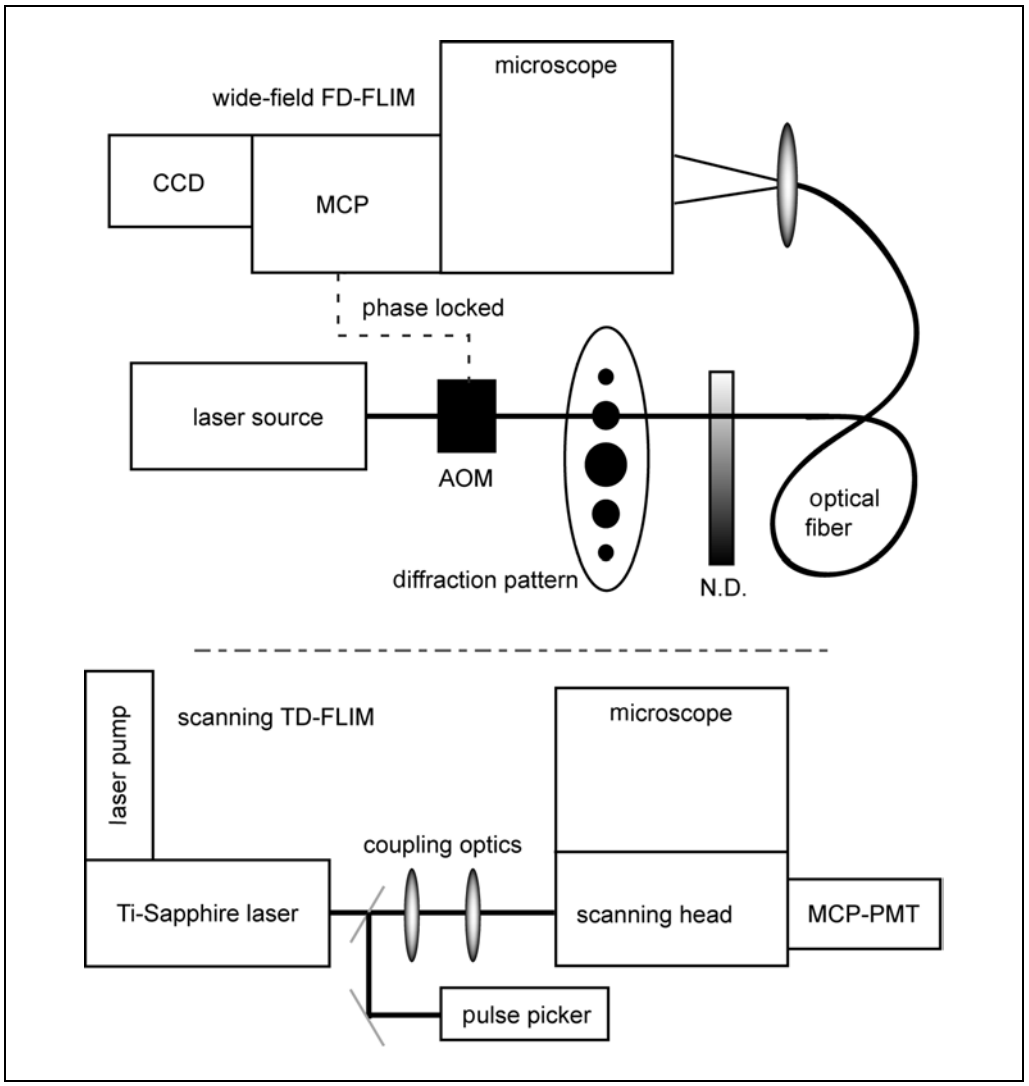

Figure 4.14.4 Typical setup diagrams of wide-field FD-FLIM and two-photon laser scanning TD-FLIM. In wide-field frequency-domain lifetime microscopy, a continuous-wave laser is usually sinusoidally modulated by an acousto-optic modulator. The first order spot is selected, attenuated, and subsequently focussed into a continuously vibrated optical fiber. The laser beam is then expanded onto an input port of a wide-field microscope. The fluorescence emission is focussed on the MCP photocathode and its phosphor screen output is imaged by a CCD camera. In laser scanning TCSPC time-domain FLIM, a pulsed-light source, like a green laser, pumps a Ti:Sapphire NIR laser coupled to the scanning head of a microscope. The laser beam is split and monitored by a photodiode to provide the trigger for the TCSPC timing. The emission fluorescence is focussed on the single-photon counting detector. A detailed description of the setup is given in Anticipated Results.

Acquire a lifetime image

9. Initialize imaging parameters. Place sample on the stage. Once the field-of-view to be imaged is selected, set exposure time, gain, and laser intensity of the system avoiding saturation of the detector during phase stack acquisition.

   This can be done by adjusting the phase delay to get maximal fluorescence emission from the focussed sample and increasing gain or laser power below the detector saturation level.

10. Set the microscope to zero-phase delay.

    To speed-up phase stack post-processing, it is useful to remove system phase bias so that acquisition of images starts at the phase at which a zero-lifetime reference is in phase with the source light. The images need to be recorded at equal phase-delay steps over the complete period of excitation light modulation in a number greater than or equal to three.

For fast measurement, a two-image counter-phase acquisition schema can also be used as proposed by Schneider and Clegg (1997).

11. Acquire phase stack by initializing the system and opening the excitation light shutter. Grab an image and close the excitation light shutter. Change the relative phase of the detector and complete phase stack acquisition.

    Appropriate time-delays in the acquisition protocol could be necessary. The use of motorized shutters avoids photobleaching during dead time of phase stack acquisition. Their use can be limited to the start and end of acquisition to decrease acquisition time.

12. (Optional) Correct phase stack for photobleaching. Acquire a second image phase stack with a reverse-phase protocol.

    The two stacks can be averaged to compensate for photobleaching. In this manner, all the images are acquired with the same cumulative light dose and the phase stack is corrected at the first-order approximation allowing lifetime estimation also in presence of significant photobleaching (in practice, up to 50%).

13. Compute Fourier coefficients (Equation 4.14.13).

    The image phase stack can be summed to obtain a standard fluorescent image (F_0) and summed after the multiplication of each image by the cosine (F_{cos}) or sine (F_{sin}) of the phase at which they are acquired (see Anticipated Results: Wide-field FD-FLIM). The resulting images are the sine and cosine transforms of the phase stack and together with the stack average, they represent the zeroth (steady-state fluorescence image) and first Fourier coefficients.

14. Compute a mask for lifetime images by applying a threshold to the DC image. Compute the lifetime using the mask to avoid unnecessary computation and possible numerical errors.

15. (Optional) Compute phase delay and demodulation factors according to Equation 4.14.14.

    This step is necessary during the acquisition of a reference. Skipping this step for the phase lifetime estimation saves a significant amount of computational time.

16. Compute sample lifetimes by Equation 4.14.15.

    The algorithm implementation of Equations 4.14.13 through 4.14.15 is used to retrieve two lifetime estimations of the sample. Step 15 can be skipped by substituting Equation 4.14.14 in 4.14.15. The images should always be masked to remove background and possibly computed only on unmasked pixels to reduce processing time.

17. Analyze lifetime estimations.

    Controls with single fluorochromes without interaction with the environment should appear flat in contrast to a typical steady-state fluorescence image. Lifetime distributions can be analyzed to detect lifetime subpopulations and bi-dimensional histograms of phase lifetime versus modulation lifetime (or vice-versa) allows the detection of lifetime subpopulations and heterogeneities.

OPERATING A TD-FLIM BASED ON TPLSM

BASIC PROTOCOL 2

A time-domain FLIM based on a two-photon microscope requires certain know-how for daily maintenance and regular realignment of the system. Although significant advances were made in recent years in production of user-friendly systems, like picosecond all-solid-state lasers and self-tuneable Ti:Sapphire light sources, use of laser sources like the Tsunami (Spectra Physics) and the Mira (Coherent) is still more common in most microscopy facilities. This protocol describes alignment of a typical scanning microscope with a manually operated Ti:Sapphire light source. These near infrared (NIR) lasers possess emission powers that are harmful to the eyes and, depending on the tuned wavelength,

are not visible to the naked eye. For this reason, the following protocol needs to be followed with particular care and respect to user safety regulations for systems with open optical paths. The present protocol describes how to align and perform daily maintenance of a two-photon system and explains its use for lifetime imaging.

Materials

Homogenous flat fluorescent sample
Basic components of a scanning TD-FLIM (see Strategic Planning and Critical Parameters)
Infrared viewer

CAUTION: Wear protective goggles matching near-infrared radiation when aligning the optical path. Lasers can be harmful and standard laser safety rules should always be followed. Moreover, handle the optics with cotton gloves to avoid dirty or scratched optical surfaces.

Tune and align laser

1. Check the laser pump alignment.

   A Ti:Sapphire laser is pumped by a green laser. This pump should be optically aligned. Its alignment is not part of daily maintenance but a lasing failure of the NIR laser could be caused by loss of proper positioning and focusing of the pump beam on the Ti:Sapphire crystal.

2. Tune and peak Ti:Sapphire laser at the desired frequency. Peak the power of laser by iteratively moving main mirror adjustment controls and adjust positioning of the cavity prism or prisms to obtain laser mode locked. Tune light wavelength at 10- to 20-nm steps adjusting peak power and prism position at each step. Once operational wavelength is reached, fine peak the power and check for mode-locking.

   A manually operated two-photon laser cavity needs to be properly tuned and aligned before every use. If lasing fails, it might be necessary to clean the optical components from dust. Non-vacuum cavities can require opening, adhere to the user manual of the laser supplier in this case.

3. Align optics for coupling of laser with microscope scanning head. Couple a femtosecond-pulsed laser with the scanning head of a microscope by air because fiber optics ruin the pulse-shape and consequently the efficiency of the TP excitation. Align all optics, especially after changing the wavelength over broad ranges. Align mirrors from the laser source towards the scanning head, centering each optic element with iterative use of positioning controls. When the scanning head is reached, center the laser on the scanning mirrors through the input optics.

4. Fine align microscope scanning head by placing a homogeneous and bright fluorescent sample on the microscope stage and then scanning the sample with sufficiently high power, under fast scanning conditions and without zoom.

   Increasing power, gain, integration time, and sweeping the focus position could be necessary to detect a fluorescent signal. If no signal is detected, coarsely reposition the laser beam at the scanning head input until a signal appears, avoiding sudden and long saturation of detectors. Find a compromise between homogeneity and brightness of the field of view by iteratively adjusting the last mirror of coupling and positioning of the scanning head. For rough alignment, it is sometimes necessary to remove the objective. It is relatively easy to detect the presence of a misaligned laser beam by placing a white paper in the microscope optical path. It is now straightforward to center the beam and start with fine alignment.

5. Operate the microscope.

   Once a laser source is focussed on the sample, FLIM is ready for operation. Usually a lifetime reference is not required because time response of the system can be retrieved directly from the data fit, but particular systems could require further calibrations. For instance, use of a picosecond—rather than a femtosecond—pulsed laser requires measurement of the laser pulse shape to deconvolve time distributions and retrieve more quantitative and reliable measurements. If time-domain electronics lose synchronization with laser pulses, check (if available to inspection) the position of the photo-diode that provides the timing trigger.

Acquire a lifetime image

6. Initialize imaging parameters. Set sample on stage and once the field of view is selected and focussed, select an adequate image pixel resolution.

   Imaging with more than 512 × 512 pixels is not recommended because of poor photon counts that can be reached. The expert user will find a good compromise in choosing a proper image dimension. In any case, the image can be spatially binned in the post-processing stage. Find a balance between laser power and detector gain. Increasing light intensity will cause more photodamage and photobleaching of the fluorescent dye, but a low excitation rate requires longer integration times to reach suitable photon counts. Two-photon excitation, although reducing photobleaching over three dimensions, increases loss of fluorescent probes and sample damage in the single focal plane with second- or higher-order intensity dependence. In this case, but not for single-photon excitation, lower laser power and longer integration times reduce photobleaching.

7. Acquire an image by starting acquisition and allowing the electronics to store a time stack for an appropriate integration time.

   It is not rare to collect photons for ≥1 min although only experience can suggest a correct time window.

8. Analyze the time stack by fitting the time-decay distribution with the most appropriate model. Fit pixel by pixel the time stack with a simpler function that models the investigated photophysical system (commonly, a single-exponential fit). Analyze residuals and check for particular correlations or trends.

   After a good fit, the residuals represent only noise and are randomly distributed around zero. If this is not the case, a different model is required.

9. Analyze lifetime image.

   The simpler fit procedure obtained by a mono-exponential decay results in an intensity image, a lifetime map, and a χ^2 output that represents, pixel by pixel, the goodness of fit. The lifetime map needs to be masked based on tresholded intensity and χ^2 images. Pixels with a total amount of photons <100 have an uncertainty >10%. An intensity threshold minimly between 10 (>30% uncertainty) and 100 counted photons is suggested. Also, mask out pixels that exhibit high χ^2 values.

10. (Optional) Fit more complex decay distributions.

    If analysis of residuals or χ^2 values suggests fitting with more complex functions, repeat step 8 with a different model. Addition of more fit parameters also allows the fit to adapt better to a noisy distribution. Only apply different models if χ^2 values reduce consistently. A multi-exponential decay fit typically results in images representing the population size of each time component, the lifetime images, and a χ^2 map.

11. Analyze lifetime distributions.

    Once the time stack is processed and converted into lifetime maps, analysis of the lifetime distribution allows detection of different lifetime populations. Inspection of the intensity image segmented by the corresponding lifetime values allows detection of possible different populations or presence of artifacts.

COMMENTARY

Background Information

Fluorescence lifetime detection has been available from the 1920s when E. Gaviola built the first phase fluorimeter. The main developments and biological applications of lifetime detection were carried out by Gregorio Weber and colleagues. It should be noted that fluorescence lifetime measurements and FRET, although known for a long time, could only recently be implemented in microscopy by development of technologies that were necessary to construct the first FLIM systems capable of quantitative FRET determinations. In the 1980s, significant advances in both phase-sensitive detection (Gratton and Limkeman, 1983; Gratton et al., 1984) and time domain (O'Connor and Phillips, 1984) led to the implementation of lifetime detection in microscopy. The first FLIM microscopes were wide-field frequency (Wang et al., 1989; Morgan et al., 1990; Lakowicz and Berndt, 1991; Gadella et al., 1993) and time-domain (Wang et al., 1991) setups. Soon after, time-correlated (Ghiggino et al., 1992) and time-gated (Buurman et al., 1992) single photon counting techniques were adapted to scanning microscopes, followed by the combination of FLIM and two-photon excitation (So et al., 1995). A third class of lifetime detection was introduced later (Dong et al., 1995) based on stimulated emission imaging induced by pump and probe excitation.

Due to its high value for biology, FRET imaging by FLIM took only a few years to be applied (Oida et al., 1993; Gadella et al., 1995). Especially together with advances in molecular biology and the availability of visible fluorescent proteins (Lippincott-Schwartz et al., 2001; Zhang et al., 2002), FLIM became one of the most quantitative tools available for detection of protein-protein interactions and protein biochemical status inside cells (Bastiaens and Pepperkok, 2000; Wouters et al., 2001; Elangovan et al., 2002; Bunt and Wouters, 2004).

In less than two decades, FLIM has been continuously improved and today presents a mature technique that, thanks to burgeoning technologies, is continuously developing into more sensitive and user-friendly systems.

Critical Parameters and Troubleshooting

FRET efficiency

Several aspects should be considered in the selection of a FRET pair. First, the donor needs to be a fluorescent (or luminescent) molecule with a high quantum yield and should be excitable in the range of available excitation wavelengths. The acceptor absorption spectrum should overlap significantly with the donor emission spectrum, and its extinction coefficient should be high in order to increase the Förster distance. There are no particular requirements for the quantum yield of the acceptor that could also be a non-fluorescent molecule. The FRET efficiency can also be increased by optimizing the rotational parameter κ^2 by modification of the linker between the fusion protein and the donor/acceptor fluorescent protein. The contribution of a rotational effect to FRET in a biosensor construct can be evaluated by swapping donor and acceptor. If FRET efficiencies change, κ^2 optimization should be considered to increase the energy transfer efficiency.

Spectra

Narrow spectra are commonly required for multi-staining experiments. When using FLIM to image FRET, it is preferable or necessary to avoid spectral contamination. Even though lifetime measurements are less susceptible to spectral contamination and multi-component lifetime systems can, in principle, be resolved by multi-exponential fitting in the time domain or by multi-frequency measurements in the frequency domain, acceptor fluorescence bleed-through can inject artifacts in FRET estimation, and direct acceptor excitation can reduce or suppress the energy transfer process. Nevertheless, the strictest spectral requirement for FRET is to maximize donor emission and acceptor absorption spectral overlap, but not at the cost of significant spectral contamination.

If acceptor bleed-through in the donor channel is impossible to remove, the acceptor lifetime can be detected as signature of sensitized emission. This technique has been used in the frequency domain (Harpur et al., 2001) and can probably also be implemented in the time domain. In fact, although time domain measurements resolve multi-exponential decays, low photon counts or the use of a two-window time-gated system could require such detection when non-negligible spectral contamination is present. The use of a low-quantum-yield (or dark) acceptor completely eliminates the spectral contamination problem in FRET experiments.

Photobleaching

Photobleaching is the photo-inactivation of a chromophore and can affect both donor and

acceptor. Both phenomena can, in fact, be exploited in specific intensity based FRET detection methods (Wouters et al., 1998). In all other FRET detection measurements, photobleaching should be minimized. Even though lifetimes are intensity independent, lifetime imaging could also suffer from photobleaching artifacts. The most evident problem is degradation of the signal-to-noise ratio. In scanning time domain, which usually requires longer acquisition times, a good compromise is needed between excitation light intensities and acquisition times. Furthermore, TCSPC is less efficient at very high photon counts (Gratton et al., 2003). Reducing laser power, i.e., emitted photons, while increasing acquisition time, avoids saturation effects. This is also effective to reduce photobleaching when using two-photon excitation. TPE, in fact, reduces bulk photobleaching, but photobleaching in the focal plane is increased and usually even exceeds the excitation rate because of the intrinsic non-linear photophysics of TP absorption (Patterson and Piston, 2000). Prolonged exposure times also increase the collection of autofluorescence especially when high photobleaching occurs. Autofluorescence can thus inject more heterogeneity in the measurement, preventing adequate data fitting and typically reducing measured lifetimes. Time-gated systems can cancel out short-lifetime autofluorescence contribution by use of an initial gate-off time. More photostable fluorochromes, higher concentrations of fluorophores, and anti-bleaching agents can be used to reduce this problem.

The wide-field frequency domain lifetime imaging (and wide-field time domain) method is based on the sequential acquisition of images to create an image phase stack (time stack). Photobleaching can modify the phase time stack, injecting artifacts in the lifetime estimation. Up to 15% of photobleaching can be tolerated. Photobleaching tolerance can be further increased by correcting the phase stack by acquisition of a second phase stack with a reverse phase delay protocol. More recently, the randomization of phase-image acquisition was shown to significantly reduce photobleaching artifacts without the need of the reverse-phase decay protocol (van Munster and Gadella, 2004b). The average of the forward and reverse phase stacks is then used for a lifetime estimation. This correction relies on a first-order approximation of photobleaching which holds up to 50% of signal loss (Gadella et al., 1994). Furthermore, the phase-shift and demodulation lifetime estimations diverge due to photobleaching. Their averaged value is, therefore, also quite stable at non-negligible levels of photobleaching.

In conclusion, donor photobleaching can be afforded both in time domain and frequency domain by wide-field and by scanning setups. In contrast, FLIM estimations of FRET can seriously suffer from acceptor photo inactivation. Acceptor photobleaching can be caused by direct excitation and by energy transfer itself. The result is a loss of FRET and concomitant recovery of donor fluorescence. Therefore, when the energy transfer is reduced by acceptor bleaching, FLIM detects increasing amounts of non-FRETting donor lifetimes. In this case, increased exposure times cause a dilution, and eventually a loss, of the FRET signal.

This problem can be minimized by avoiding direct excitation, e.g., by the choice of adequate FRET pairs, use of fluorophores that exhibit a large Stoke's shift, and use of an acceptor with considerably lower photobleaching susceptibility than the donor, e.g., photostable and/or low-quantum-yield dyes.

The commonly used FRET pairs GFP-YFP and Cy3-Cy5 suffer from such an unfavorable bleaching susceptibility. Also, the new combination of GFP and monomeric RFP is affected. Good combinations are GFP-Cy3 and pairs that use the photostable Alexa dyes as acceptor.

Furthermore, it should be noted that for donor-acceptor systems that are free to diffuse and contain an excess of acceptor molecules, photobleaching by FRET generally does not present a problem as bleached acceptors are quickly replenished.

Fluorochrome lifetimes

Contrast enhancement by lifetime imaging is also applicable when the fluorochromes are spectrally similar but exhibit separable lifetimes. This method is very useful as lifetime distributions are generally sharper than spectra, allowing experimental designs where spectrally mixed emissions are resolved by lifetime (Pepperkok et al., 1999). Furthermore, it is possible to combine lifetime and spectra data (Siegel et al., 2001b) to unmixed emissions from multiple fluorescent species (Carlsson and Liljeborg, 1997; Neher and Neher, 2004).

Fluorochromes can have multi-exponential or complex fluorescence decays. CFP, for instance, exhibits a double-exponential decay. Furthermore, lifetimes of this GFP mutant are dependent on excitation wavelength. Lifetime heterogeneities, whenever possible, should

be avoided because these decays require more photons to be resolved, and the lifetime distributions will be broader. The recently published Cerulean CFP mutant (Rizzo et al., 2004) was reported to exhibit improved lifetime characteristic and a 2.5-fold increase in brightness, which could potentially alleviate this problem associated with the use of CFP in FLIM.

In a FRET experiment, it is advisable to select longer lifetime donor fluorophores as the determination of FRET using subnanosecond lifetime dyes becomes more difficult and uncertain. With respect to FRET efficiency, there are no particular requirements to the acceptor lifetime other than the practical consideration of acceptor photobleaching prevention by selection of short lifetime dyes. The latter also carry the advantage that the generation of a considerable acceptor-excited population is avoided. As acceptor fluorophores in the excited state cannot accept another quantum of energy from a nearby excited donor molecule, an excited population represents a FRET-incompetent fraction that frustrates the FRET phenomenon (Schönle et al., 1999; Jares-Erijman and Jovin, 2003.).

False negatives and false positives

With the exception of instrumental errors and improper use, FRET imaged by FLIM cannot practically detect false-positive interactions. In contrast, false-negative detection can be caused when the distance or orientation between fluorophores on interacting molecules is beyond the limit for efficient FRET detection. For this reason, FRET-resolved interactions are reliable but absence of FRET only carries information in a very limited number of cases like in biosensors based on linked FRET pairs. The two rotational and one distance degrees of freedom play a crucial role in the detection of FRET. Both factors can be optimized by finding the proper location for positioning of chromophore conjugation or by optimizing linkers. Without detailed structural information, however, this optimization will have to be performed empirically.

Acquisition times and signal-to-noise ratio

The acquisition time of a lifetime image can vary over a broad range from fractions of seconds up to several minutes depending on the adopted system and on the sample brightness. A high-speed time-gated time-domain FLIM has been developed (Agronskaia et al., 2003) that reaches a sampling frequency of 100 Hz. Similar implementations can probably be designed for frequency domain setups. In general, standard FD and TD setups usually acquire images at ~1 Hz. The most sensitive TCSPC-based TD-FLIM, using a MCP-PMT detector, can rarely be operated with exposure times <1 min for a reasonably sized image, and when multi-exponential decays or FRET are detected, the acquisition times can increase up to 30 min (Becker et al., 2004). Other time-domain systems can limit the integration time to some seconds (Gerritsen et al., 2002). A standard wide-field FD-FLIM is usually operated on time scales well under 1 min and can easily approach 1-Hz acquisition rates independent of image size. These systems also exhibit shorter processing times thanks to the very efficient Fourier analysis algorithm implementation. TCSPC is computationally expensive because of the fitting procedure while a two-window time-gated system also reaches fast post-processing speeds due to the rapid RLD algorithm. The use of faster acquisition protocols and algorithms has been described; these allow a wide-field FD-FLIM (Schneider and Clegg, 1997) and a scanning TD-FLIM (Trabesinger et al., 2002) to operate in real-time.

Acquisition time is a crucial parameter, not only for the detection of short-lived events or motile structures in living cells, but also in connection with problems described for photobleaching. The lower limit of exposure times is set by the requirement for sufficient signals for a reliable lifetime determination. For single photon counting, in which poissonian noise dominates, error in the intensity image is equal to the inverse of the square root of the photon count. The error in lifetime estimation is larger. For time-domain detection, depending on the system, the error can become twice as large. Therefore, care should be taken that acquisition times always produce photon counts that exceed a tolerable uncertainty threshold. More than 200 counts, for example, are required for a reliable mono-exponential decay fit and 1000 counts give ~5% of statistical error in the lifetime estimation, while a bi-exponential fit requires at least 10,000 counts (Köllner and Wolfrum, 1992).

The selection of acquisition times in other FLIM systems relies more on the experience of the user. In any case, the error in a lifetime estimation for different intensities can be verified by the analysis of the standard deviation of the retrieved lifetime in samples with homogeneous lifetimes, e.g., fluorophore solutions.

Anticipated Results

Scanning TD-FLIM

The time-domain FLIM setup that was used (Figs. 4.14.5 and 4.14.7) is an upgraded TSC-SP2 AOBS laser scanning confocal microscope (Leica Microsystems) equipped with a Ti:Sapphire Mira900 two-photon laser pumped by a Verdi-V8 laser (both from Coherent) in the mode-locked femtosecond-pulsed regime (Fig. 4.14.4, bottom). The laser was tuned at 820 nm or 900 nm for proper TP excitation of CFP and GFP, respectively (Chen and Periasamy, 2004). A custom-made emission filter wheel is placed between the output port of the scanning-head and the TD-FLIM detector, an MCP-PMT (R3809U-50 by Hamamatsu Photonics) that allows high sensitivity and sub-nanosecond time resolution. Fluorescence emission of CFP without YFP contamination was detected using a band-pass filter centered at 480 ± 15 nm and a 520 ± 15 nm filter was used for GFP detection. The time-resolved fluorescence decays are reconstructed by TCSPC. The acquisition board (SPC830) and software (SPCImage) were from Becker & Hickl.

Figure 4.14.5 shows a TD-TCSPC image of two constructs that were expressed simultaneously in HeLa cells. This preparation shows how FRET reduces donor lifetimes and how lifetimes enhance contrast. The first construct consists of a tandem fusion of CFP and YFP that exhibits efficient FRET. This construct is too large to enter the nucleus passively and, accordingly, the signature of ET, i.e., reduced CFP lifetime, is detected in the cytoplasm. The average lifetime in this region is 1.75 ± 0.13 nsec (mean ± standard deviation), which is significantly reduced compared with 2.28 ± 0.05 nsec reported for CFP in the literature (Elangovan et al., 2002; Becker et al., 2004). In the spectral window used, the CFP-YFP construct is spectrally completely equivalent to the second construct, CFP fused to a nucleolar targeting signal. The lifetime measurement shows a clear contrast between the nucleoli and the cytoplasm that identifies the two different constructs. This is shown in Figure 4.14.5 where the intensity image (Fig. 4.14.5A) is segmented according to the lifetime map (Fig. 4.14.5B). A lifetime threshold of 2 nsec allows the clean discrimination between two differently stained areas (Fig. 4.14.5C,D). The mean lifetime values over the nucleoli were equal to 2.20 ± 0.07 nsec, in full agreement with the reported lifetime of CFP and equal to measurements on cytoplasmically targeted CFP alone (not shown). The nucleolar CFP signal presents an intrinsic non-FRETting lifetime reference that allows the quantification of the FRET efficiency: 20 ± 6% (errors computed by error propagation). This reference can also be created by photobleaching YFP in a defined region of the cell (not shown).

The CFP exhibits a bi-exponential excitation wavelength-dependent lifetime by itself. The use of this fluorescent protein for FLIM is possible but its lifetime heterogeneity can limit its quantitative use. This is more relevant to FRET analysis because the number of photons that should be collected to quantify the multi-exponential decay of CFP FRETting and non-FRETting fractions is difficult to achieve in biological samples.

In general, the analysis of the χ^2 values (Fig. 4.14.5E,F) is crucial for data interpretation because they represent goodness of fit. In particular, the time stack needs to be fitted pixel by pixel with the proper model. Very often, it is necessary to spatially bin images in order to achieve suitable counts for either mono- or bi-exponential decay fits. For these reasons, it is necessary to fit only those pixels where an adequate number of photons are collected. At the end of the fitting procedure, the χ^2 (the authors always refer to χ^2 normalized to degrees of freedom) should be close to unity. A detailed overview of χ^2 analysis is presented by Lackowicz (1999). The χ^2 maps for single and bi-exponential fits of this data set are shown in Figure 4.14.5E,F. It is clear that the bi-exponential fit, although not ideal, is more reliable than the single-exponential fit. Furthermore, the average χ^2 value in nucleolar areas is 1.05 and 1.02 for mono- and double-exponential decay but 2.01 and 1.26, respectively, for cytoplasmic regions. Fits are less precise in these areas because of increased lifetime heterogeneity due to some conformational freedom in the CFP-YFP construct. This also increases the heterogeneity in FRET efficiencies, i.e., measured lifetimes. Another important consideration is demonstrated in Figure 4.14.5E, where the χ^2 values in dimmer regions are lower. This is a misleading artifact caused by the fact that the fitting algorithm (Eq. 4.14.11) tolerates more noise in regions with low intensity:

$$\chi^2 = \sum_i \frac{\left(N_i^{(\mathrm{fit})} - N_i^{(\mathrm{obs})}\right)^2}{N_i^{(\mathrm{obs})}}$$

Equation 4.14.11

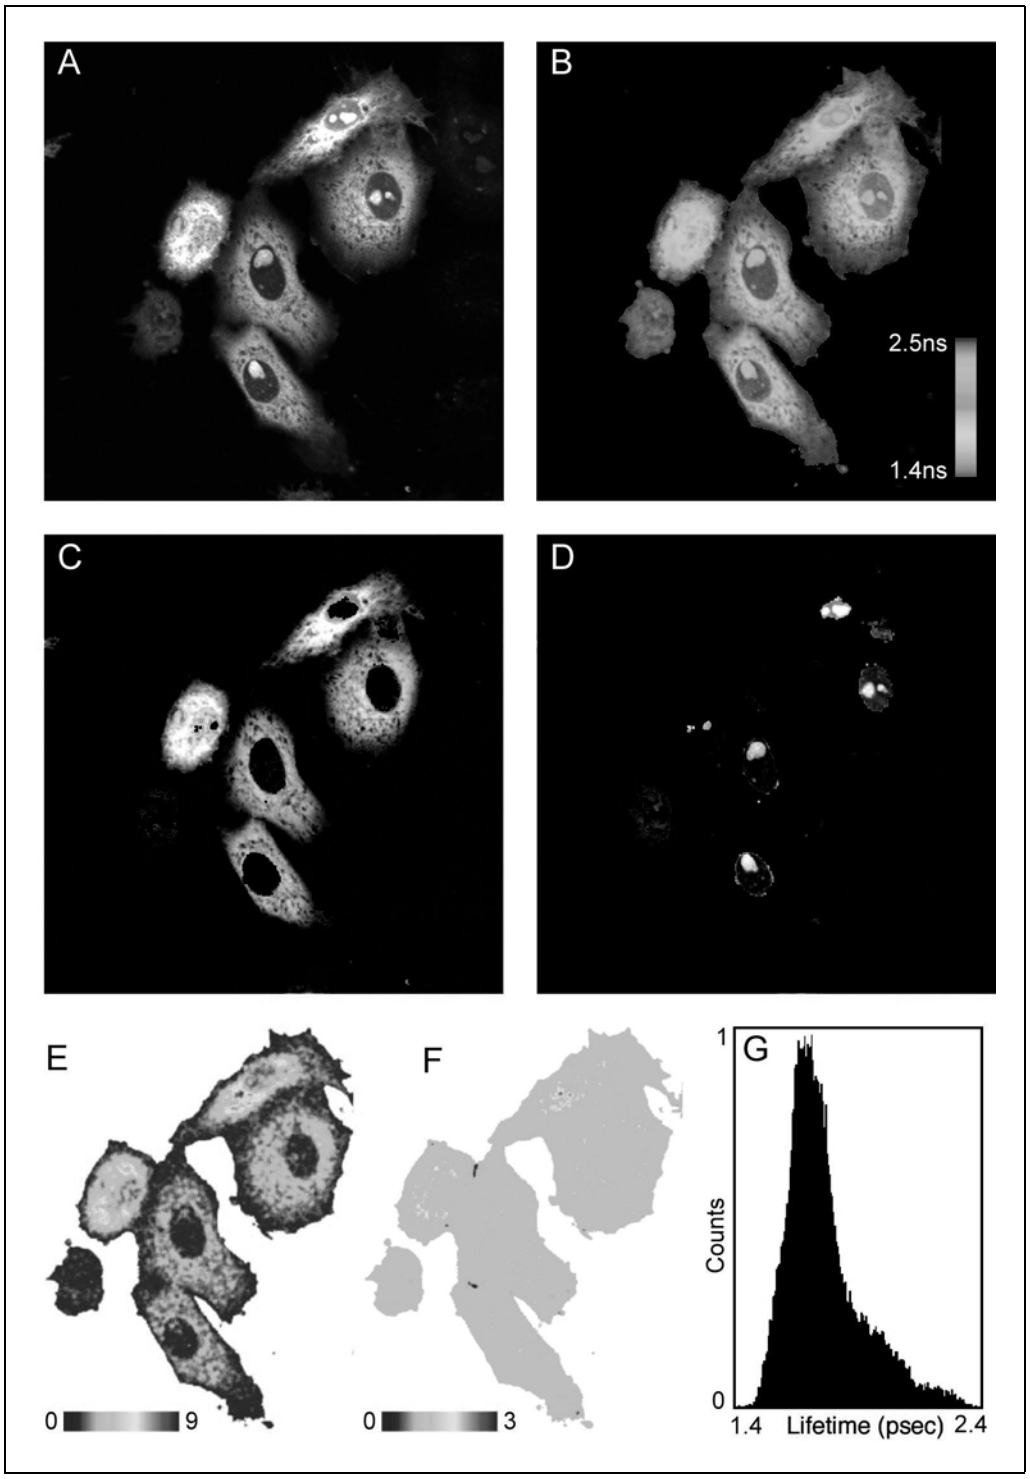

Figure 4.14.5 HeLa cells expressing nucleolar CFP and a cytosolic CFP-YFP (Venus) fusion construct. The two-photon laser scanning single-photon counting image (**A**) is acquired through a band-pass filter centered at 480 ± 15 nm in the CFP spectral band. The spectrally undistinguishable emission from the two cyan constructs is adequately segmented in a cytoplasm (**C**) and nucleolar (**D**) staining by tresholding the lifetime map (**B**) at 2 nsec. Chi square analysis is required to judge the reliability of the lifetime estimations and the fitting model (**E,F**). (**G**) shows the sample lifetime distribution. The long-lifetime shoulder corresponds to the non-FRETting CFP in the nucleoli. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

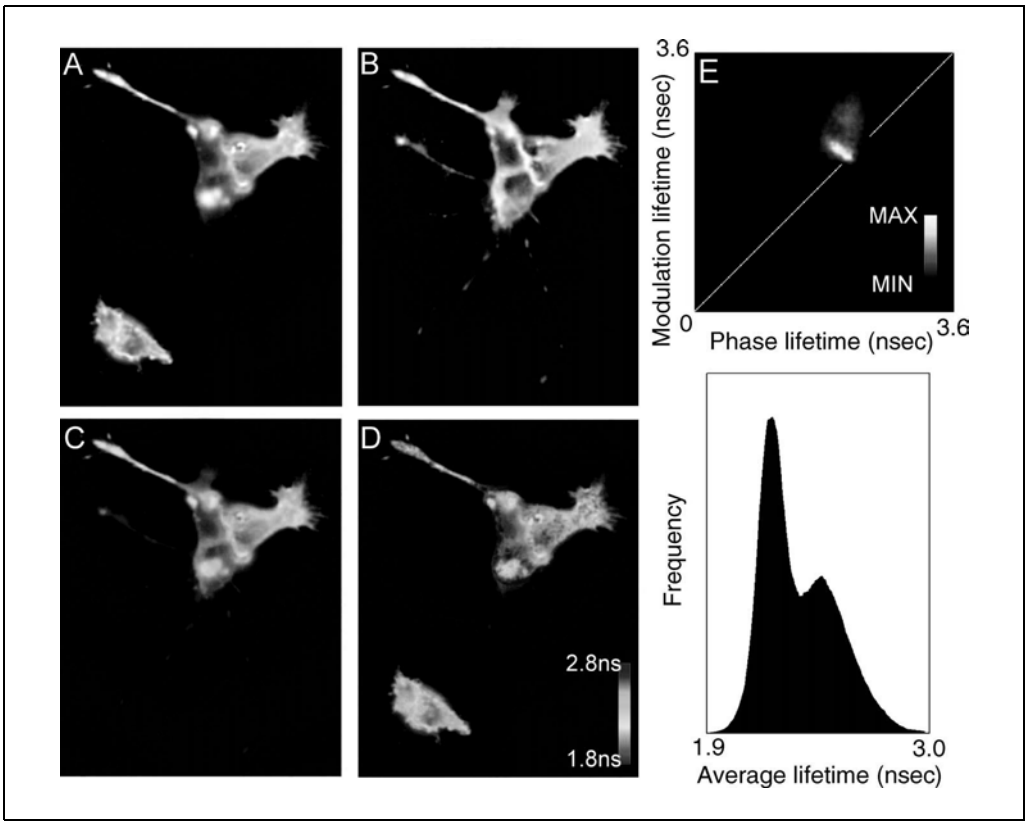

Figure 4.14.6 Human SHSY-5Y neuroblastoma cells expressing a GPI-GFP construct (**A**) simultaneously stained with cholera toxin–Alexa594 (**B**). The images are acquired by a wide-field microscope and the overlay (**C**) of the GFP and Alexa594 reveal most extensive colocalization in the top right cell that extends one process to the upper left of the image. The lifetime map (**D**), acquired by wide-field FD-FLIM, reveals the locations where the donor and acceptor are interacting. A control cell is shown in the inset in **A** and **D**. The bi-dimensional histogram (**E**) shows the two populations of pixels corresponding to the non-FRETting (upper right) and FRETting (lower left) fractions. The bottom-right panel shows the bi-dimensional distribution of the average lifetimes. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

In fact, each squared difference between the experimental data points and the fit (squared residuals) is normalized to the variance of the measured (obs = observed) number of photon that, for the photon counting technique, is equal to the observed number of photons itself. In dimmer regions, an inappropriate model can fit a noisy measurement and the χ^2 determination tolerates larger errors. Since it is not always possible to fit the right model with adequate photon counting statistics and because systematic errors can increase the χ^2 value, χ^2 analysis is always required but should not be over-interpreted. Analysis of the residuals can help to judge the reliability of the hypothesized model. Residuals should be distributed around zero, representing only noise. Non-random residual distributions are an indication to change the fit model. The use of a stretched exponential fit (Eq. 4.14.12) seems to be a good compromise for analysis of time-domain data (Siegel et al., 2001a):

$$I_0 e^{-\left(\frac{t}{\tau}\right)^{\frac{1}{h}}}$$

Equation 4.14.12

with the addition of only one parameter (h) to the single exponential decay, heterogeneous distributions can be suitably fitted. This is because stretched exponential fits consider a continuous distribution, rather than discrete lifetimes.

Wide-field FD-FLIM

The frequency domain FLIM (Fig. 4.14.4, top) is custom-built around a fully automated Axiovert200M inverted fluorescence microscope (Zeiss) and an LSTEP (Märzhäuser

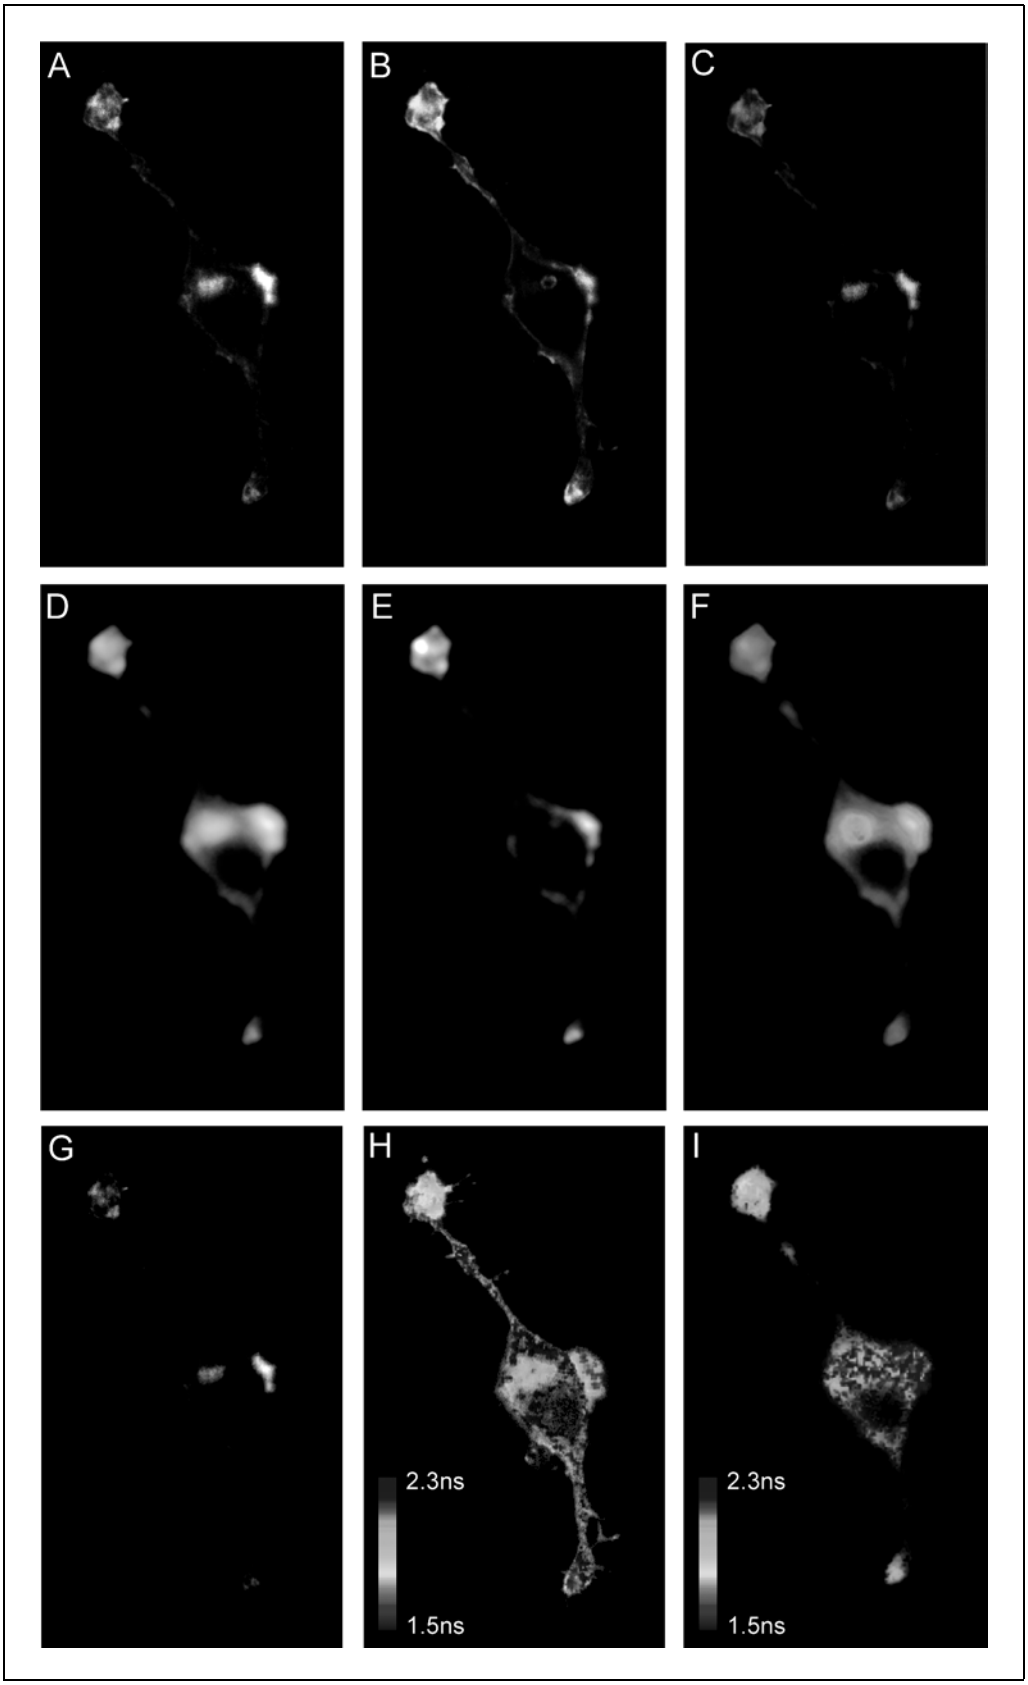

Figure 4.14.7 Legend at right.

Wetzlar) x-y stage equipped with a customized controller. The microscope is completely remote-controlled to allow automatic positioning of sample, shutter operation, and selection of focus, filter, and light source. The excitation light is provided by an Innova 300C Argon laser (Coherent). The 488-nm laser line was selected for excitation of the GFP. The laser beam height is maintained by beam-steering optomechanics and is directed through the crystal of a standing-wave acousto-optic modulator ME405 (IntrAction). The first-order sine-like-modulated spot of the diffraction pattern emerging from the AOM is selected by an iris and is attenuated by a variable neutral density filter wheel. The beam is then focussed onto a multi-mode optical fiber that is continuously vibrated at 50 Hz. The emanating laser beam is expanded by a concave lens onto the back input port of the microscope. Fluorescence emission of the sample is detected by an ImagerQE CCD connected to the output phosphor screen of an HRI multi-channel plate intensifier, both by Lavision. Two phase-locked signal generators IFR2023A (IFR System) provide the electrical signals for the MCP reference (~80 MHz in the presented measurements) and to drive the AOM.

Figure 4.14.6 shows a typical image set acquired by this microscope. SHSY5Y human neuroblastoma cells were transfected with GPI-GFP and were incubated with Alexa594-labeled cholera toxin B subunit (CTB). The GPI-GFP locates to lipid microdomains, called rafts, by virtue of its acylation, the CTB binds to raft-resident GM1 gangliosides. Both raft markers are expected to interact and give rise to FRET when recruited to the same type of raft. Figure 4.14.6A and B show the GPI-GFP donor and CTB acceptor images, respectively. A phase stack of 16 images was collected with forward and reverse phase delays, and averaged to correct for photobleaching (Gadella et al., 1994). The zeroth and first two Fourier coefficients were computed for each pixel. They can be calculated by Equation 4.14.13 (Clegg and Schneider, 1996):

$$F_0 = K^{-1} \sum_{k=1}^{K} D_k$$

$$F_{\cos} = \sum_{k=1}^{K} D_k \cos\theta_k$$

$$F_{\sin} = \sum_{k=1}^{K} D_k \sin\theta_k$$

Equation 4.14.13

where D_k are single images of the phase stack, K is the number of images, and θ_k the phase delays. F_0 corresponds to a normal steady-state fluorescence image (also called the DC image) and $F_{\cos}$, $F_{\sin}$ are the cosine- and sine-transforms, respectively, of the stack by which, using Equation 4.14.14, the pixel-by-pixel modulation and phase of the emitted fluorescence is retrieved:

$$m = \frac{\sqrt{F_{\sin}^2 + F_{\cos}^2}}{F_0}$$

$$\varphi = \arctan\left(\frac{F_{\sin}}{F_{s\cos}}\right)$$

Equation 4.14.14

Figure 4.14.7 *(at left)* Human SHSY-5Y neuroblastoma cell expressing GPI-GFP and stained with cholera toxin–Alexa594 (see Fig. 4.14.6). The same cell was imaged by a laser scanning time-domain (**A,B,C,G,H**) and a wide-field frequency domain (**D,E,F,I**) FLIM. **A** and **D** show GFP staining, **B** and **E** the Alexa594, and **C** and **F** the respective overlays and colocalizations. The comparison between the confocal (upper row) and the wide-field (middle row) images reveals the intrinsic difference in resolution between a CLSM and an image intensifier (MCP). For the same reason, the time-domain lifetime map (**H**), overlaid with the intensity two-photon TCSPC image, shows a better spatial resolution compared to the lifetime distributions imaged by the wide-field microscope in the frequency-domain setup. The main advantage of the latter technique is its speed in imaging of dim sample (<30 sec) compared to longer time exposure (20 min) required by a sensitive TCSPC system equipped with an MCP-PMT detector. The differences in lifetime are explained by different imaged focal plane position and thickness, but both systems detect molecular interactions between markers (25% and 35% FRET maximum for FD and TD, respectively). Note that interactions are found in the cellular extremities and part of the somal plasma membrane. Intracellular GPI-GFP, which was not exposed to the CTB does not give rise to FRET. Even though significant colocalization can be seen in a membrane patch to the right of the cellular soma, the markers there do not physically interact. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm.*

To retrieve the phase- and modulation-lifetime estimation using Equation 4.14.10, the microscope was previously calibrated with a reflecting foil in the sample focal plane as a zero-lifetime reference. This allows the computation of the absolute phase delay and the demodulation factor between the excitation light and emitted fluorescence for each pixel. The lifetime images were computed according to Equation 4.14.15:

$$\tau_\phi = \omega^{-1} \tan(\phi - \phi_0)$$

$$\tau_m = \omega^{-1} \sqrt{\left(\frac{m_0}{m}\right)^2 - 1}$$

Equation 4.14.15

where the subscript 0 denotes a zero-lifetime reference phase and modulation.

Figure 4.14.6D shows an overlay of the average lifetime and fluorescence image of the donor. Modulation lifetime is always greater than the phase estimation and the true lifetime lies between these retrieved values. The average of the apparent lifetimes (Lakowicz, 1999) is the best estimator for the true sample lifetime. FD-data can be masked according to χ^2 values if a fitting routine is applied instead of the Fourier analysis or if a statistical estimator is available (Gadella et al., 1994).

This experiment was selected to demonstrate the detection of FRET in a demanding research sample. The choice for membrane-bound components limits the fluorescence emitted from the sample and is not optimal for wide-field detection. From the overlay of the donor and acceptor intensities (Fig. 4.14.6C), it is clear that the two signals correlate more in the cell at the top-right whose processes extend to the top-left corner. The lifetime map reveals a clear FRET signature in only this cell. In contrast to the colocalization information, the FRET analysis shows interaction between the two raft markers in defined regions of the cell. This finding reflects the presence of rafts containing only one of the markers in the entire cell, but rafts containing both only in select areas of the cell. Colocalization of the two fluorochromes is not sufficient to demonstrate their interaction. The analysis of the bi-dimensional histogram of phase- versus modulation-lifetime estimations, color-coded by the frequency of their occurrence and the distribution of average lifetimes, discriminates two populations of pixels correlating to FRETting and non-FRETting donors. In general, the analysis of the lifetime distributions offers an index to identify sample heterogeneity. The two apparent lifetimes, in fact, should be equal for single exponential decaying fluorochromes, but they tend to diverge at increasing sample heterogeneity (Lacowicz, 1999; Murata et al., 2000), e.g., caused by FRET.

Wide-field and scanning detection

The presented Anticipated Results offer more than a comparison between frequency- and time-domain configurations, it also allows comparison between wide-field and scanning detection.

Figure 4.14.7 shows images of the same cell acquired by two different microscopes that were previously described. The images in the top row show the GPI-GFP (Fig. 4.14.7A) and the cholera toxin–Alexa594 (Fig. 4.14.7B) fluorescence emission acquired by the confocal microscope and their overlay (Fig. 4.14.7D). These images represent the practical limits of spatial resolution in these samples. The middle row shows the same signals acquired by a wide-field microscope with an image intensifier. The difference in spatial resolution caused by the resolution limit of the MCP is evident. As a consequence, the lifetime map obtained with the two-photon laser scanning microscope (Fig. 4.14.7F,G) has an intrinsically higher spatial resolution than the lifetime image acquired by wide-field detection. Both systems reveal FRET but the latter method detects lower overall energy transfer efficiencies because the reduced lifetime FRET signal is diluted by donor fluorescence emanating from components in the intrinsically thicker focal plane and out-of-focus volume that have not been exposed to extracellularly applied CTB.

The advantage of wide-field detection arises when faster acquisition times are needed. This particular sample was imaged with an integration time of 25 min in the scanning microscope while the phase stack was built in <30 sec by the wide-field microscope. This sample was quite demanding and required the upper limit of acquisition time that is used in practice for scanning and wide-field microscopes.

Conclusions

Lifetime imaging presents an important and powerful tool for cell biology and biophysics. Its use will certainly spread as more user-friendly and less-expensive commercial solutions become available. Lifetimes can be used to enhance the contrast in biological and medical imaging and can be used to screen for

intermolecular interactions and molecular activities in living cells. Lifetime images are quantitative and intuitive, but particular attention should be given to data analysis and interpretation. Even though false-positive interactions are practically impossible to obtain by lifetime imaging of FRET, over-interpretation of data and instrumental errors are always possible. Proper reliability analysis is required to certify FLIM findings and to estimate their noise content. Nowadays, optical techniques present a pillar of cellular biophysics. With the advent of quantitative techniques like FLIM and FRET, it is revolutionizing the life sciences. FLIM by itself, but above all its capability to measure FRET, will play a fundamental role as a medical diagnostic tool, a sensitive instrument to probe the photophysics behavior of optically active molecules, a tool for studying the behavior of biomolecules, and it will provide support in the proteomics challenge to understand cellular proteins performing their tasks in the cell. This demands an interdisciplinary effort of cell biology, microscopy, and physics.

Time Considerations

The limiting step in any FLIM experiment is the preparation of the biological sample. Time considerations for expression of fluorescent fusion proteins and immunocytochemistry can be found in *UNIT 17.1.* The practical time aspects of FLIM measurements are not different from those of any other fluorescence microscopy experiments, with the exception of the necessity to acquire multiple images (see Acquisition Times and Signal-to-Noise Ratio).

Acknowledgments

The authors would like to express their gratitude to Mika Ruonala and Mišo Mitkovski for providing the biological samples.

Biological Second and Third Harmonic Generation Microscopy

This unit describes how higher harmonic generation microscopy (HHGM) is applied to detect native, nonstained cell and tissue structures that were previously only accessible after immunohistochemical or immunofluorescent labeling.

Nonlinear optical microscopy by multiphoton excitation has developed into a popular, and powerful approach that combines different excitation and emission techniques for the three-dimensional (3-D) reconstruction of biological specimens (Denk et al., 1990; Konig, 2000). The specific approaches include detection of two- and three-photon excited fluorescence, two-photon excited fluorescence lifetime (FLIM), and the second and third harmonic generation. Specimens amenable to multiphoton microscopy include fixed and live samples, thin and thick slices or samples with transparent or relatively opaque properties, as well as intravital microscopy in anesthetized animals (see *UNIT 4.11*). The most obvious advantages of multiphoton microscopy include: (1) greater tissue penetration up to the millimeter range due to near-infrared excitation and consequently, less scatter; (2) reduced phototoxicity imposed onto cells and tissues due to the inherent confocality exciting only fluorophores in the focal plane and the lack of a detector pinhole resulting in improved optical detection efficiency; (3) the broader excitation range of fluorophores, compared to single photon excitation, allowing multicolor imaging using the same excitation wavelength; and (4) the possibility of combining fluorescence microscopy with other detection modes, including HHGM and FLIM. Therefore, nonlinear imaging is being used for nearly any application in cell biology that requires multicolor imaging, deep tissue penetration, low phototoxicity, and high resolution, similar to confocal microscopy.

Two-photon or multiphoton excited HHGM has become one of the most popular and powerful techniques for the reconstruction of intrinsic structural and molecular properties of cells, extracellular matrix, and bone without the use of dyes or stains (Campagnola et al., 2002; Friedl, 2004). Two modalities of HHGM are presently being used for biomedical applications, the second (SHG) and third (THG) harmonic generation imaging (the principle and theoretical basis for these imaging modalities are detailed in the Commentary). SHG and THG imaging provides structural and molecular information that is complementary to two-photon fluorescence (TPF) imaging and can be simultaneously combined with other two-photon excited modalities, including two-photon photoactivation, two-photon correlated spectroscopy, two-photon single-particle tracking, and two-photon lifetime microscopy. HHGM is most useful in the imaging of connective tissue, collagen fibers and fascia, as well as striated muscle, inflammatory cells, blood vessels, and hair at a resolution near the diffraction limit of visible light.

This unit will provide details on the experimental setup and some biological applications of HHGM, including 3-D connective tissue reconstruction and dynamic imaging of cell motility in 3-D tissues. In the commentary, the physical basics of HHGM are described, additional examples for HHGM are given, and there is a discussion on how to detect and minimize multiphoton-excited phototoxicity.

STRATEGIC PLANNING

Materials detectable by SHG and THG

The first step is to consider whether the molecular structure of interest can be detected by HHGM. Because this is a young technique, progressive use of this technology will lead

Table 4.15.1 Second and Third Harmonic Imaging of Cell and Tissue Structures

Compound	Excitation wavelength (nm)[a]	Molecular property	Reference	Technical comments; substrates
SHG				
Fibrillar collagen	700–1064	Triple coil of coiled α-helices	Stoller et al., 2002; Cox et al., 2003; Yasui et al., 2004	Dermis, vessel walls, peritumoral stroma; diminished signal during proteolytic degradation
Tubulin	760–880	Coil of whole protein units forming tube with polarized ends	Dombeck et al., 2003	Brain slices; dynamic imaging of mitotic spindles at 880 nm
Myosin		Two α-helix polymer proteins coiled in a left hand	Both et al., 2004; Plotnikov et al., 2006	
Styryl dyes FM4-64 RH 237	 1064 880	Forms anisotropic scaffold along plasma membrane the orientation of which is voltage-dependent	Dombeck et al., 2005; Sacconi et al., 2005	Suitable for backward detection; scanning in the msec range; no photobleaching
Cellulose	840–880; 1230	Structural symmetry of β 1:4-linked glycans	Cox et al., 2005	Low S/N[b]
Starch (in chloroplasts)	840–880; 1230	Structural symmetry of α 1:4-linked glycans	Cox et al., 2005	High S/N[b]
DNA	730–800	Unknown	Gauderon et al., 2001	
THG				
Lipids and lipid bodies	1050–1250	High comparative third order susceptibility, $\chi^{(3)}$	Debarre et al., 2006	Good backward S/N[b] THG in weakly absorbing tissue
Myosin	1230	High comparative third order susceptibility, $\chi^{(3)}$	Chu et al., 2004	
Collagen	1050–1300	Unknown	Kao, 2004	
Hydroxyapatite crystals in tooth enamel	1050–1300	Unknown	Kao, 2004	
Inorganic crystals ($CaCO_3$) in cytolyths, mouse bone, and spincules	1500	High comparative third order susceptibility, $\chi^{(3)}$	Oron et al., 2004	
Oxyhemoglobin	1260–1470	High comparative third order susceptibility, $\chi^{(3)}$	Schaller et al., 2000	Low S/N[b]

[a]Detection at $\lambda_{ex}/2$ for SHG and $\lambda_{ex}/3$ for THG.
[b]Abbreviation: S/N, signal-to-noise ratio.

to rapid growth of the materials list, therefore a database search on molecular structures and optimum wavelength characteristics should be performed before starting a higher harmonic generation imaging (HHGI) project.

Biological Second and Third Harmonic Generation Microscopy

Structures to be detected: Second harmonic generation is caused by materials that are structured in crystalline-like lattices that are noncentrosymmetric on length scales on the order of the excitation light wavelength called the coherence length (Chu et al., 2002; Mohler et al., 2003; see Table 4.15.1). Besides metal and ion crystals, several

biological materials contain repetitive or symmetric structural units, including coiled-coil structures and polymeric proteins (Table 4.15.1). Third harmonic generation is a much weaker process, however elicited by different types of materials, particularly phase transitions, such as water-lipid interfaces (Table 4.15.1).

Combination with fluorescence: Because HHGI can be combined with fluorescence microscopy and other imaging modalities, it is necessary to consider which excitation and detection wavelengths are required to excite the fluorophores together with SHG or THG (Gauderon et al., 2001; Mempel et al., 2004b). The combination of higher harmonic and fluorescence microscopy has allowed for versatile combinations of cell and tissue imaging in cell biology, histology, and tissue engineering (Table 4.15.1).

Sample type: For the imaging of live thick tissue samples (>100 μm thick) of strong light-scattering properties, including connective tissues and lymph nodes, near-infrared excitation offers increased penetration depth in thicker light-scattering samples at a relatively low degree of cellular phototoxicity and thus, is superior to single-photon excitation. The properties of HHGM to reconstruct 3-D ECM structures and cell membranes together with fluorescence show particular promise in the assessment of tissue morphogenesis during development and pathological remodeling, including wound repair and neoplasia.

DESIGNING A MICROSCOPE SYSTEM FOR HHGM

BASIC PROTOCOL 1

The hardware setup for HHGM (Fig. 4.15.1) follows, in principle, that of a laser-scanning microscope for visible wavelength emission and detection (see *UNIT 4.5*) and a two-photon excitation microscope using pulsed near-infrared laser sources (see *UNIT 4.11*). Any two-photon microscope already includes the capability of HHGI, therefore the setup description here will address specific features only. Besides higher harmonic generation imaging, the setup allows the excitation and detection of fluorophores (see *UNIT 4.11*), and using additional laser and detector hardware, coherent anti-Stokes Raman scattering (CARS) microscopy, fluorescence lifetime imaging (FLIM; see *UNIT 4.14*) in parallel and without crosstalk.

The laser beam is generated by a titanium-sapphire laser, either alone or in combination with a synchronously pumped optical parametric oscillator (OPO; Table 4.15.2). Using a cascade of mirrors, the laser beam is directed into the microscope by a computer-controlled *xy*-scanner consisting of one or two galvanometer-driven mirrors (Table 4.15.3) coupled to an upright or inverted microscope stage. The reconstruction of 3-D specimens requires serial *z*-sectioning and thus, a computerized *z*-positioning of sample stage or

Table 4.15.2 Laser Sources and Wave-lengths

Laser type	Wave length (nm)	Comments
Titanium:Sapphire	700–1040	Popular and broadly used laser type, but cost-intense; modern systems include computer-automated wavelength tuning and user-friendly maintenance
Fianium fiber	1064	Useful for measurements of membrane potential
Chromium fosterite	1230	Greatly reduced tissue autofluorescence at very long excitation wave length; low photodamage
Optical parametric oscillator (OPO)	1000–1600	Requires a Ti:Sa pump laser at fixed wavelength (e.g., 775 nm); computer-automated tuning available

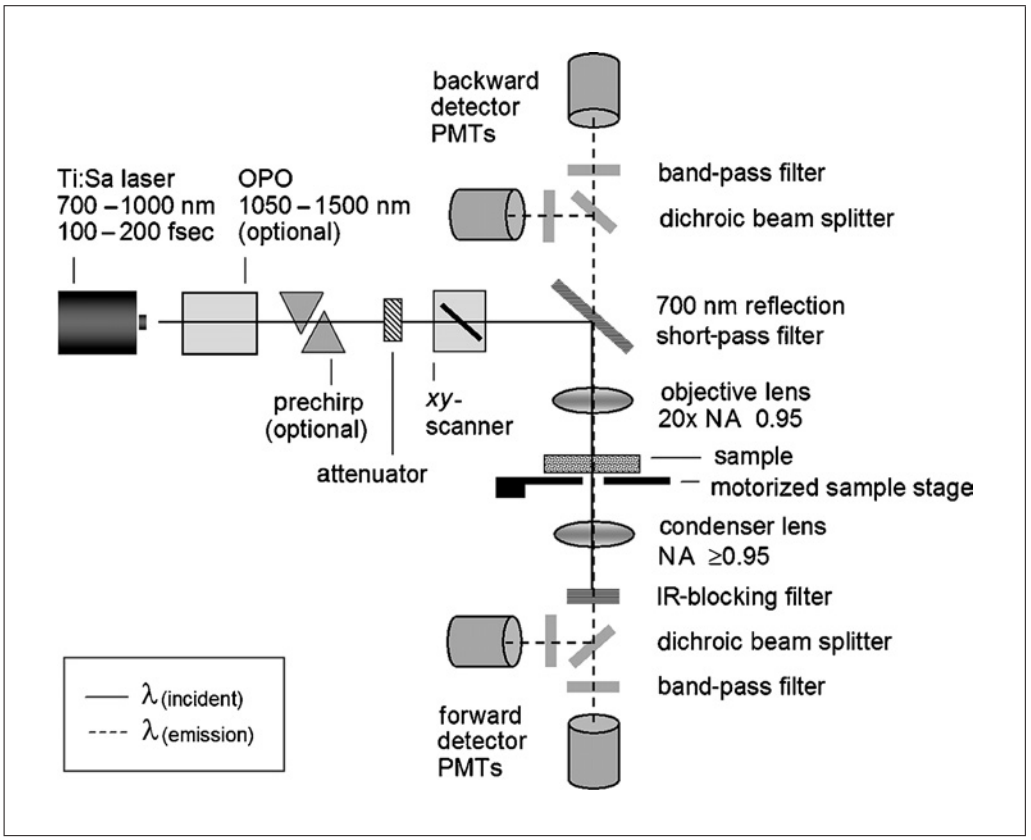

Figure 4.15.1 Set-up of a photomultiplier-based multiphoton microscope for higher harmonic generation microscopy. The beam of a mode-locked Ti:Sa laser is passed through an optional prechirp path consisting of two prisms to compensate for shifts in pulse width, followed by an attenuator of the beam intensity, and one or two galvanomirrors for scanning. For tuning of the incident beam above 1 μm, an optical parametric oscillator (OPO) pumped by the Ti:Sa laser is required. After reflection by a dichroic mirror, the beam is focused by the objective lens into the sample. Emission signals elicited in the focal plane of the sample are detected in forward direction by the condenser lens and in backward direction through the objective lens, spectrally separated by a dichroic filter and passed through a band-pass filter for each individual signal-adapted bandwidth before the detector photomultipliers (PMTs). In both directions, the transmitted or reflected laser light is blocked by band pass filters.

Table 4.15.3 Commercially Available Multiphoton Systems

System	Website	Technical details
Zeiss HLSM 510 MP	*http://www.zeiss.de*	4 non-descanned PMTs (2 forward, 2 backward), up to 6 descanned PMTs; includes 3-D and 4-D reconstruction software
Leica TCS MP	*http://www.leica-microsystems.com*	4 non-descanned PMTs (2 forward, 2 (4) backward), up to 6 descanned PMTs; includes 3-D and 4-D reconstruction software
LaVision Biotech	*http://www.lavisionbiotec.de/start_product.html*	8 non-descanned PMTs (4 forward, 5 backward); includes optional multibeam CCD camera-based version
Prairie Technologies	*http://www.prairie-technologies.com/ultima.htm*	4 non-descanned PMTs in the backward direction

Table 4.15.4 Software Packages for 3-D and 4-D Data Reconstruction and Analysis

System	Website	Technical details	Comments
Imaris (Bitplane)	*http://www.bitplane.com*	3-D and 4-D multicolor reconstruction, cell tracking, colocalization, microfilament tracing	Fast reconstruction; user-friendly software handling
Volocity (Improvision)	*https://www.improvision.com/*	3-D and 4-D multicolor reconstruction, cell tracking, colocalization, angiogenesis tool	64 bit version available, user-friendly platform; limitations with large datasets
Amira	*http://www.amiravis.com/*	3-D multicolor reconstruction, volume rendering	Not able to reconstruct 4-D stacks, limited export functions, limitations with large data stacks
NIH Image	*http://rsb.info.nih.gov/nih-image/Default.html*	Mac and PC version available, fast and powerful tool for data handling and manual tracking; good video manipulation tools	Open-access shareware platform; large number of plug-ins generated by users available; no automated tracking or 3-D surface rendering

objective, as is available for most high-quality microscopes. The detection unit includes beam splitters and band-pass filters designed for the wavelength-resolved detection of emitted light using photomultipliers (PMTs).

The operation of the system including scan-head control and image acquisition is controlled by acquisition routines provided by the manufacturer of the scanning system. Because image acquisition will generate large amounts of data, the hardware and software design should be optimized for maximum throughput and storage capability as well as fast processor speed. These rules are described in detail in *UNIT 4.10*. However, appropriate image reconstruction and analysis often require the use of additional software designed to handle large data stacks (Table 4.15.4). These data analysis software packages can retrieve primary files generated by most major confocal and multiphoton systems and if required, custom-designed input can be obtained from the manufacturer on demand.

Materials

Upright or inverted microscope and optics suitable for epifluorescence detection including:
- Epi-illuminator (bright field)
- High numeric aperture objective (NA > 0.7)
- Detector unit using photomultipliers, beam splitters and band-pass filters
- Sample stage including computer-driven *z*-position control (alternatively *xyz*-position control)
- Heating system to maintain 37°C (optional)

Multiphoton laser including:
- Diode-pump laser coupled to titanium-sapphire laser (Table 4.15.2)
- Incoupling of the laser beam into the scan head via mirrors (beam path)

Laser scanning unit including computer-controlled operation system for scanning conditions, signal acquisition, primary image reconstruction and storage (Table 4.15.3)

Software for 3-D and 4-D image reconstruction (Table 4.15.4)

Vibration isolation table designed for stable mounting of optical instruments

Powermeter to measure laser light intensities along the beam path, including infra-objective level

Adjust beam path and optics

1. Place all optical and electronic components including the microscope, except for the computer, on a vibration isolation table.

   All optical and electronic components including the microscope need to be of the highest quality.

2. Obtain specific information from the microscope and scan-head manufacturers, which should include the parameters of all mirrors, lenses, and the objective. To reduce absorption or scattering of light, use silver coatings for mirrors.

   To provide sufficient sensitivity for weak signals, the optical transparency of the total beam path (from laser source to the location of the sample) should be >30%.

   For excitation above 1200 nm, the optical elements of most systems (mirrors, tube lens, and scan lens) must be custom-designed for increased infrared transparency.

   Upon request, most manufacturers will provide an appropriate alternative system design for microscope, scan head, and detectors.

3. Set up epifluorescence detection, which is not mandatory, but it is useful for initial sample screening and positioning.

4. Select objectives that allow high resolution (indicated by high NA) and maximum transparency.

   For intravital microscopy in living animals, long working-distance objectives of NA 0.80 to 0.95 (usually 20× magnification) are popular because of their versatility and deep tissue penetration capabilities (up to 2 mm) and high light sensitivity; however they often do not provide sufficient detailed resolution for cytoskeletal structures or the subcellular distribution of membrane components. Objectives of higher NA are usually limited by their short working distance (≤250 μm); however they provide better subcellular detail, which can be important for imaging of cell and tissue cultures. The choice for oil- versus water- or multi-immersion objective depends upon the type of sample used. For intravital and live-cell microscopy, water-immersion dipping objectives are preferred because they can be directly introduced into the sample medium. For further details on objectives see UNIT 4.11.

5. Detect HHG using photomultipliers in either forward/transmission or backward direction. To avoid loss of signal, use a collection lens in the forward direction with a NA the same or higher, compared to the illumination NA determined by the objective (Fig. 4.15.1).

   Whereas fluorescence intensities detected in the backward or forward direction are often equal, SHG transmission often shows a 5- to 10-fold stronger intensity, compared to the backward detection, yet using a sensitive objective, the backward detection will still deliver sufficient signal for the detection of collagen and myosin in native state (Fig. 4.15.2).

   Because of the inherent confocality achieved by multiphoton excitation, the detectors do not require a pinhole, thus are nondescanned (i.e., do not go again through the scanhead). Besides PMTs, a CCD camera may be placed to detect higher harmonic signals in the forward direction, but not in the backward direction, because the reflected signal mostly comprises scattered photons and consequently, gives low signal-to-noise ratio at the focal plane of the CCD chip. For third harmonic imaging, at least in theory, emission is nonisotropic and might be detected by CCD camera-based systems in the forward and backward direction.

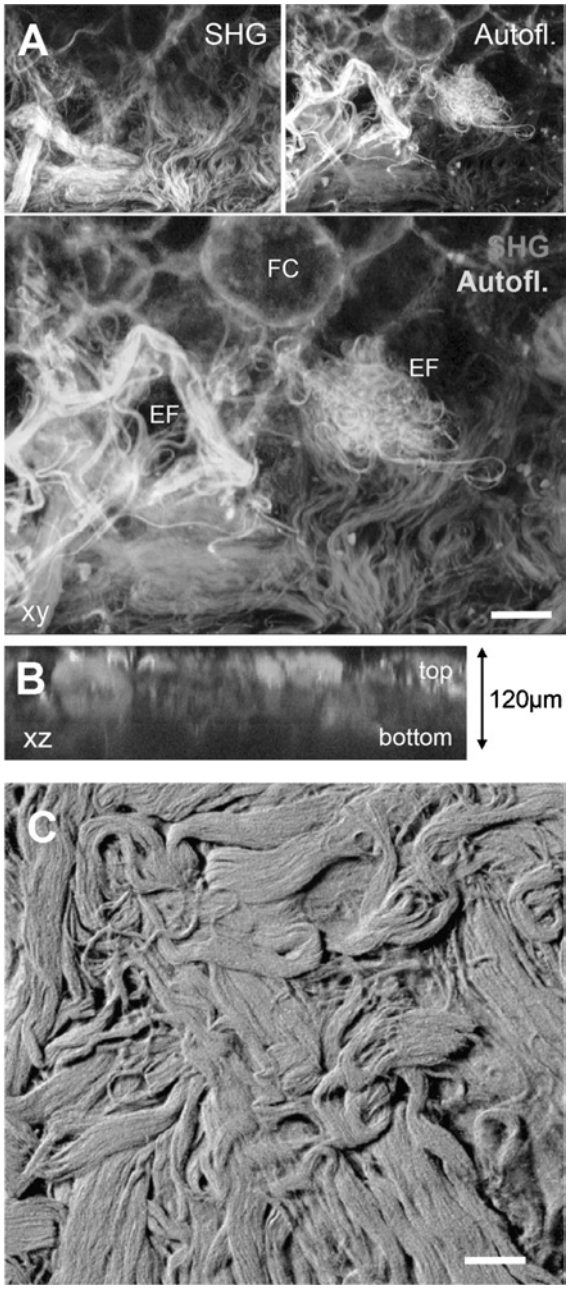

Figure 4.15.2 Three-dimensional reconstruction of collagen bundles from human dermis. Non-labeled 3-mm thick samples from human dermis were fixed in 4% buffered paraformaldehyde and sliced tangentially. The wavelength of the incident beam was 880 nm, the polarization vertical and horizontal, and the band-pass filters 440/20 (SHG) and 515/30 (autofluorescence). Images were acquired using a 20× N.A. 0.95 water immersion objective, resulting in an optical transverse resolution of 500 nm and a pixel resolution of ∼400 nm. The axial resolution was 4 to 5 μm. Images show (**A**) SHG together with autofluorescence in *x-y*, (**B**) the reconstructed *x-z* projection, and (**C**) topographic reconstruction of SHG only. EF, elastic fiber; FC, fat cell. Bar = 20 μm. For color version of this figure see *http://www.currentprotocols.com*.

Select lasers

6. As a laser source, select a tunable titanium-sapphire laser generating femtosecond pulses of laser light to provide maximum flexibility for HHGI in biological applications (Table 4.15.2). Adjust the wavelength within a tuning range from 700 to ∼1000 nm. Alternatively, use lasers generating a fixed wavelength (Table 4.15.2).

In general, short-pulse lasers allow smaller spot size and higher resolution. For excitation above 1000 nm, fixed-stage lasers for specific wavelength or a tunable OPO deliver wavelengths up to 1600 nm (Table 4.15.2).

Select detectors and filters

7. In contrast to fluorescence emission, the SHG (THG) emission is near exactly half (one-third) the introduced wave-length. Set conditions so that SHG and THG are spectrally separated from other spectra of the emission signal by dichroic mirrors and relatively narrow band-pass filters spanning 10 to 20 nm. The aim is to block the incident laser beam at least twice at the level of the high-pass and band-pass optical filters. All filters and dichroic mirrors should block the wavelengths at which the laser operates (i.e., up to 1000 nm for Ti:Sapphire laser; up to 1500 nm for an OPO-based system). Further set up details are described in *UNIT 4.11*. As alternative to a cascade of dichroic filters, spectral separation can be achieved by a prism and dynamic range mirrors or an optical array detector, as used in the descanned beam path of Leica or Zeiss confocal systems, respectively (Table 4.15.4). As detectors, very high sensitivity PMTs that have a narrow dynamic range or PMTs with lower sensitivity but higher dynamic range may be used, depending on the application.

   For most applications in ex vivo samples and intravital microscopy, an overlapping spectrum of emitted HHG and fluorescence spectra at different intensity will be present, which requires a broad dynamic range of the PMT detectors at the expense of sensitivity at the ultra-low signal strength. For applications that include very low SHG and THG and relatively limited intensity, such as the detection of small numbers of multimers, a high sensitivity PMT or avalanche photodiodes to count single photons might be required.

BASIC PROTOCOL 2

DETECTION OF FIBRILLAR COLLAGEN IN CONNECTIVE TISSUE EX VIVO

Fibrillar collagen is a very bright second harmonic generator at excitation range above 800 nm; it is suitable for the quantitative reconstruction of ex vivo and in vivo tissue samples (Fig. 4.15.2). Vertically oriented collagen fibers scatter mostly in the forward direction, whereas horizontally oriented fibers scatter bidirectionally (Zipfel et al., 2003), thus, imaging of horizontally positioned fibers should be attempted by adjusting the orientation of the sample.

For 3-D reconstruction of thick specimens of low optical transparency detection of the backward scatter is required, such as thick slices of human skin ex vivo (Fig. 4.15.2) or murine skin during intravital microscopy (Fig. 4.15.3). Other collagenous tissues that require SHG backward detection due to low transparency are bone and parenchymatous organs.

Materials

Freshly excised piece of tissue or organ
Medium of choice (e.g., RPMI, DMEM, or PBS; *APPENDIX 2A*)

Additional reagents and equipment for designing a microscope system for HHGM (Basic Protocol 1)

1. Place freshly excised piece of tissue or organ directly into liquid nitrogen (−196°C).
2. Retrieve the sample and position it onto a microscope slide and add 200 to 1000 µl of medium compatible with the cell or tissue type being used (e.g., RPMI, DMEM, or PBS).
3. Position sample at the microscope and dip the objective directly into the medium.

   If the interface between sample and objective loses water, the immersion depth can be increased by using a polyethylene ring or placing the sample within a petri dish.

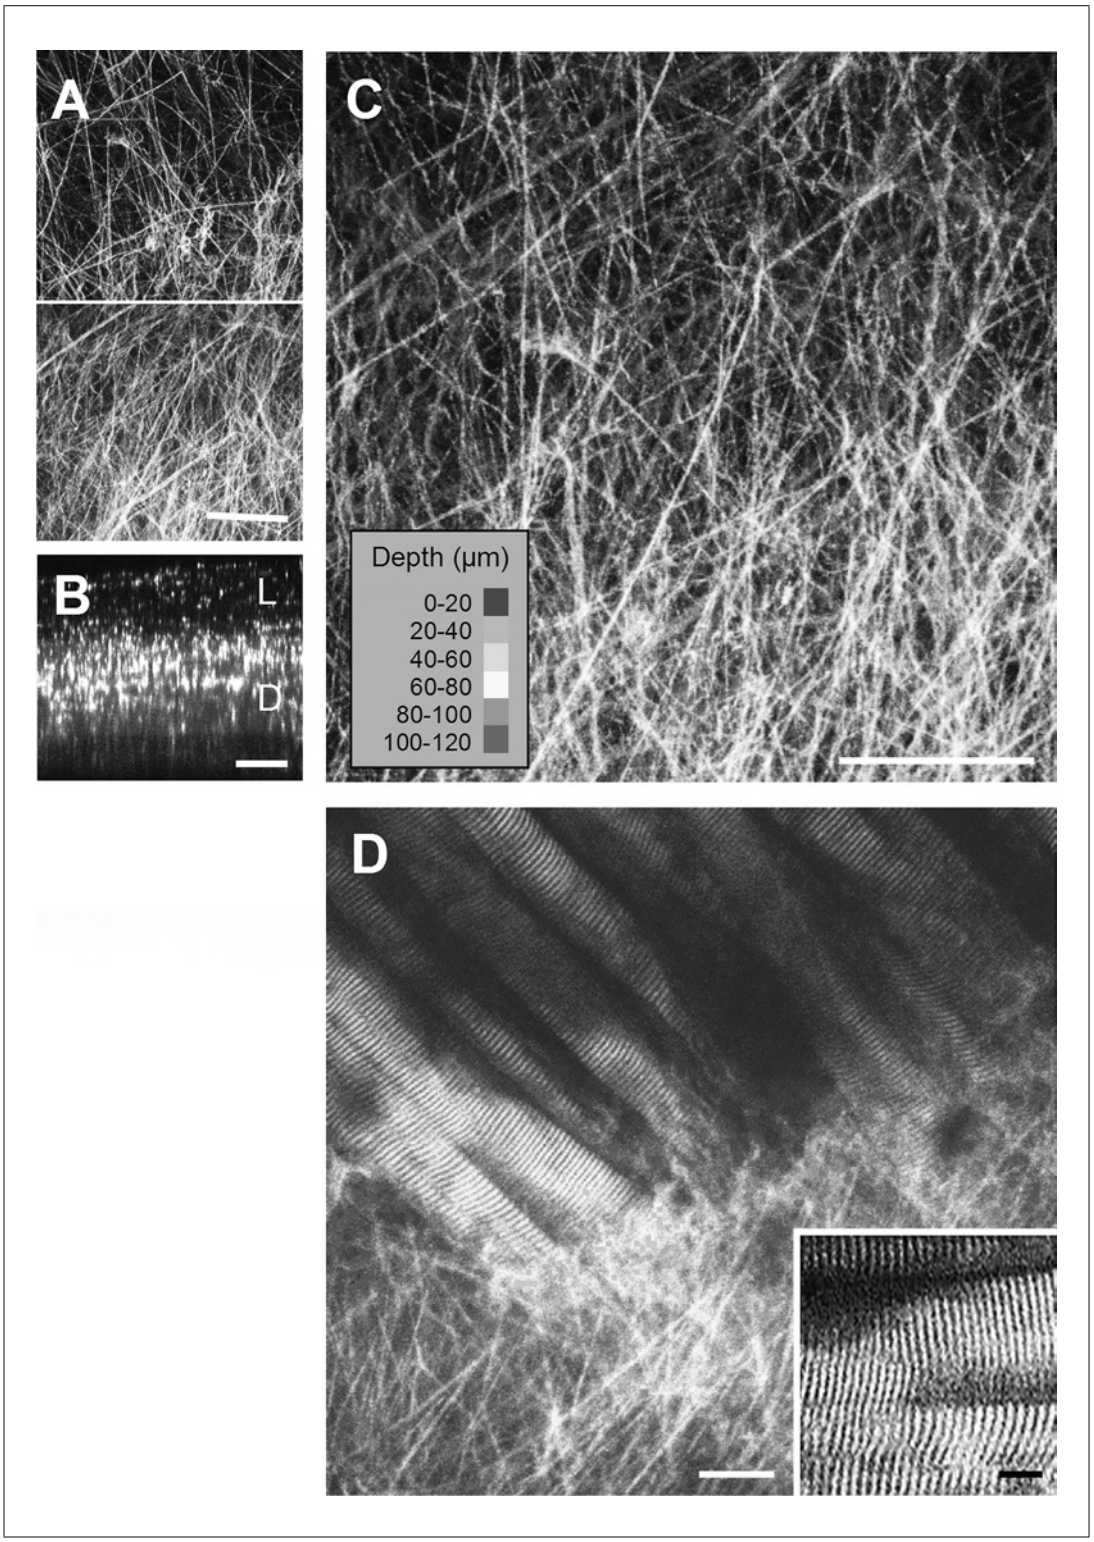

Figure 4.15.3 Intravital SHG microscopy of individual collagen fibers and striated muscle in the mouse dermis. The epidermis of live anesthetized BL6 mice was horizontally removed and *z*-sectioning up to 400 nm in depth was performed using 800-μm excitation and a 20× N.A. 0.75 water immersion objective, as described (Wolf et al., 2003). SHG was detected using an upright microscope at 400/20 nm in backward direction for both *x-y* (**A, C**) and *x-z* sectioning (**B**). (**A**) Depth-encoded reconstruction of collagen fibers. (**B**) Vertical reconstruction showing the loose ("L") and dense ("D") dermal connective tissue, and (**C**) false-color encoded horizontal representation of penetration depth. (**D**) Intravital SHG detection of striated muscle and collagen-rich fascia. Bars = 50 μm (A to C), 30 μm (D) and 10 μm (D, inset). For color version of this figure see *http://www.currentprotocols.com*.

4. Scan sample at 880 nm. To separate SHG at 440 nm from other signals, use a 440/15 or 440/20 band-pass filter before the PMT.

   The autofluorescence emission of native tissues covers the ranges from 480 to 650 nm, thus a dichroic 480-nm beam splitter or below will be useful. Whereas the emission peak of SHG signal shifts with the wavelength of the incident beam, the fluorescence spectrum remains fairly stable.

   For the multimodal reconstruction of human skin, SHG is readily combined with green or red autofluorescence, representing mostly elastic fibers, elastolytic (denatured) collagen fibers, and fat cells (Konig et al., 2005). The combined detection of SHG and autofluorescence was used in the reconstruction of human and mouse skin (Campagnola et al., 2002; Wolf et al., 2003), native arterial vessels (Zoumi et al., 2004; Boulesteix et al., 2006), heart valves (Konig et al., 2005), native mouse lymph node (Mempel et al., 2004a), and lung (Debarre et al., 2006).

5. If necessary, increase the intensity of the SHG signal by altering the polarization of the incident laser beam. Alternatively, try rotating the sample. If signal intensity is very low, increase laser power to 50 to 100 mW to lead to sufficient SHG excitation.

   The SHG signal elicited by collagen stems from the crystalline-like triple-helical structure whose cross-section has rotation symmetry but not inversion symmetry. The signal stems from surface layers of the collagen fibril but not from inner structures (Williams et al., 2005), and its intensity strongly depends on the tertiary and quaternary fibril structure, as well as ionic strength of the surrounding medium. Dissociation of the fibrillar structure and thus second order susceptibility tensor χ by a hyperosmotic agent, such as glycerin which is used as transparency-enhancing clearing agent in transcutaneous microscopy, leads to the denaturation and hence reduction of SHG signal of fibrillar collagen which is reversible upon rehydration (Yeh et al., 2003). Structural changes caused by air-drying leads to a 4-fold reduction of SHG (Yasui et al., 2004), denaturation by heating to 50° to 75°C increases the SHG signal by up to 2.5-fold, whereas higher temperature causes complete disintegration and loss of signal (Tan et al., 2005). Conversely, chemical cross-linking reduces effects caused by denaturation (Yeh et al., 2003). For future work, the susceptibility of structural changes in collagen to SHG imaging will be useful to study collagen assembly and remodeling in morphogenesis and disease state.

6. To calibrate the penetration depth of the system, define the top and bottom of the tissue volume and reconstruct the volume by acquiring sequential scans at different *z*-positions.

   In human skin using 880-nm excitation, which has a lower absorbance and scattering than lower wavelengths, sensitive reconstruction of autofluorescence is achieved up to a depth of 120 μm (Fig. 4.15.2B), whereas the decay of the SHG signal is apparent earlier. In contrast to fibrillar collagens, nonfibrillar collagen, basement membranes, epidermal keratin, and fibrin are not known to elicit SHG (Yasui et al., 2004).

BASIC PROTOCOL 3

DETECTION OF SHG IN MOUSE TISSUES BY INTRAVITAL MICROSCOPY

Whereas in histology and most immunofluorescence applications, samples are processed by fixation and slicing, intravital microscopy in small animal models is based upon minimum change to the specimen observed. Emission thus is preferably endogenous and includes SHG, autofluorescence, and light emitted by endogenously expressed fluorophores in transgenic cells or animals. Here, SHG detection results in an anatomically correct reconstruction of extracellular matrix and certain cell types, such as striated muscle cells.

Materials

Mouse sample

Additional reagents and equipment for preparing mouse samples for intravital microscopy (*UNIT 4.11*), acquiring a *z*-stack (Basic Protocol 2) and, designing a microscope system for HHGM (Basic Protocol 1)

1. Prepare the mouse sample for intravital microscopy, as described in *UNIT 4.11*. The location of interest needs to be stably positioned and fixed on the microscope stage, e.g., using needles or custom-designed holders.
2. Acquire a *z*-stack as described in Basic Protocol 2.
3. Reconstruct the 3-D stack from several individual scans by optical superimposition to generate an extended focus in depth representation. Alternatively, use *x*-*z*-reconstruction to obtain information about the total depth and signal intensity changes relative to penetration depth.

   In contrast to human skin, mouse dermis is less densely textured and consists of loosely oriented individual rather than densely packed collagen fibers (Fig.4.15.3A, B). Particularly due to the low scattering of light, high resolution reconstruction of individual fibers by SHG is achieved up to a depth of 400 μm (Fig. 4.15.3).

4. Using the same setup, detect striated muscle cells in vivo, using SHG. If the signal intensity is low, try rotating the sample slightly around the vertical axis to increase signal strength. For maximum SHG, orient the polarization of the incident beam to 45°, not 0° or 180° to the length orientation of the myosin filaments.

   The sarcomeres are 2- to 3-μm long contractile actomyosin units in striated muscle and cardiomyocytes that generate strong SHG (Fig. 4.15.3D; Both et al., 2004) and moderate THG (Chu et al., 2004). The signal is induced by the α-helical structure of the coiled rod region of the myosin filament, not by myosin heads and actin filaments (Plotnikov et al., 2006). In contrast to SHG, THG is much less angle-dependent (Chu et al., 2004).

SIMULTANEOUS DETECTION OF CELLS AND COLLAGEN FIBERS IN VITRO AND IN VIVO

BASIC PROTOCOL 4

Dynamic imaging of cell-ECM interactions in 3-D in vitro collagen lattices represent a useful, in vivo-like model to reconstruct molecular cell functions in the 3-D tissue-like context (Abbott, 2003). To simultaneously visualize the collagen fibers and the shape and position of live cells, SHG is combined with two-photon excited fluorescence microscopy (Figs. 4.15.4 and 4.15.5).

Materials

Cells expressing GFP or labeled with fluorescent dye (Support Protocol 1)
Collagen lattice containing fluorescent cells (Support Protocol 2)

Additional reagents and equipment for designing a microscope system for HHGM (Basic Protocol 1)

1. No specific cell label is required if the cells endogenously express GFP and thereby provide an intrinsic fluorescent signal for detecting their morphology. Alternatively, the cytoplasm or compartment of interest may be labeled with a fluorescent dye, such as Calcein AM or CFSE which label the cytoplasm (see Support Protocol 1).
2. Incorporate the cells within a 3-D collagen lattice (see Support Protocol 2).
3. Select a wavelength between 800 and 880 nm for excitation and 400 and 440 nm (λ/2) for detection of SHG of collagen fibers (e.g., 440/10). For fluorescence, use a dichroic filter below 510 nm and a band-pass filter suitable for the spectrum of FITC to detect the cells (e.g., 515/30) or a long-pass filter (e.g., LP515).

   Because absorption of light by 3-D collagen lattices is much weaker than by dense human tissues, the excitation wavelength of 800 nm has the advantage of strong excitation and emission strength.

4. To detect SHG and TPF in live samples, use simultaneous two-channel scanning. To determine the number of adjacent sections required for complete volume

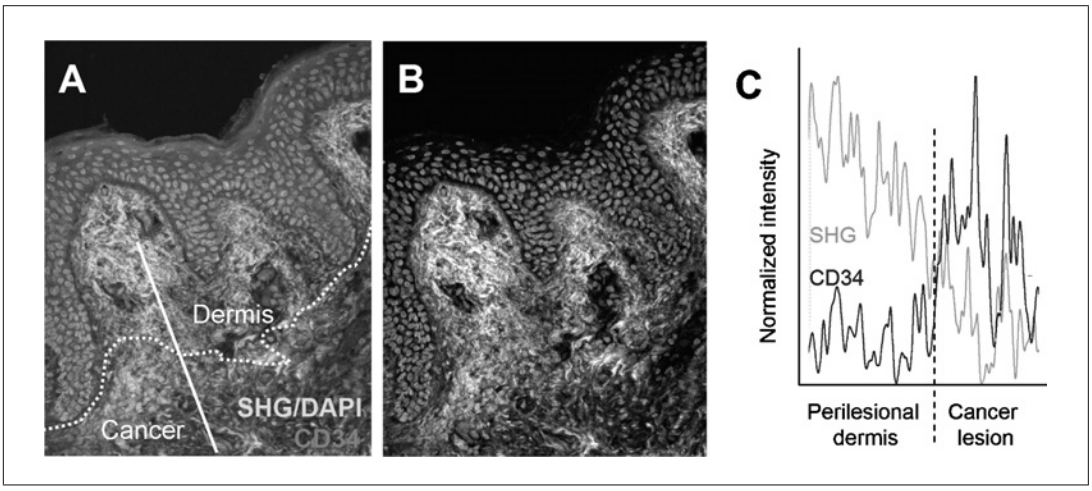

Figure 4.15.4 Multimodal SHG and fluorescence microscopy of invasive cancer lesion. Frozen section (10 μm) of human dermatofibrosarcoma protuberans was stained with anti-CD34 antibody (staining cancer cells) and secondary Alexa 543–conjugated secondary antibody and DAPI and analyzed as described in Figure 4.15.3. The emission of SHG and DAPI was detected at 440/20 and Alexa 543 was detected at 620/40. (**A**) Two-color representation of SHG and fluorescence in epidermis, dermis, and cancer lesion. (**B**) SHG of collagen and DAPI signal alone, showing strongly reduced SHG in the cancer lesion. (**C**) Normalized intensity curves for normal and cancerous tissue show the loss of SHG at the border and within the cancer lesion, as reconstructed along the solid line in (A). For color version of this figure see *http://www.currentprotocols.com*.

reconstruction, run a preliminary *z*-stack and perform a frame-to-frame review of the images. If the same horizontal collagen fiber is present in at least one but no more than two adjacent sections and if diagonally sectioned fibers continuously "run" from frame to frame without jumps, sufficient overlap is present to achieve loss-less 3-D image acquisition. If the axial resolution is known, calculate the number of sections required. A stack depth of 20 μm requires at least five consecutive *z*-sections for an axial resolution of 5 μm (20× objective) or 11 for an axial resolution of 2 μm (63× objective) for loss-less reconstruction.

The aspect and resolution of SHG from collagen matches to great extent the reconstruction using confocal reflection microscopy (Fig. 4.15.5; see UNIT 4.5; Wolf et al., 2003). Using intravital microscopy in anesthetized mice, the combination of fluorescence and SHG allows the dynamic reconstruction of lymphocyte migration and interaction with antigen-presenting cells in the lymph node (Mempel et al., 2004b) and the dissemination of cancer cells in the mammary fat pad towards blood vessels and the immigration therein (Wang et al., 2002).

Quantitative reconstruction of the data set by xyz tracking shows both the fate of migrating cells in cell-cell communication and reverse transmigration in vivo and its relation to existing tissue structures, such as migration in between and along collagen fibers (contact guidance; Wang et al., 2002; Mempel et al., 2004a). Other approaches to image live cells include the tracking of intracellular vesicles in hepatocytes using THG (Debarre et al., 2006) and time-lapse reconstruction of the sarcomere shortening in striated muscle cells in vitro and in vivo (Plotnikov et al., 2006). In all cases, a fast enough acquisition of 3-D data stacks (up to 100 individual slices) requires relatively strong SHG and fluorescence signals in the backward direction and 4-D image reconstruction by a software independent of the scanning routine. Presently available shareware and commercially available software packages for 3-D reconstruction and data analysis are shown in Table 4.15.4.

5. Run a time series by serially acquiring *z*-stacks at defined time intervals, such as one frame per 15 sec for fast leukocytes or one frame per 5 min for slow tumor cells.

Observation periods may vary from a few minutes to several days, depending on the magnitude of migration dynamics.

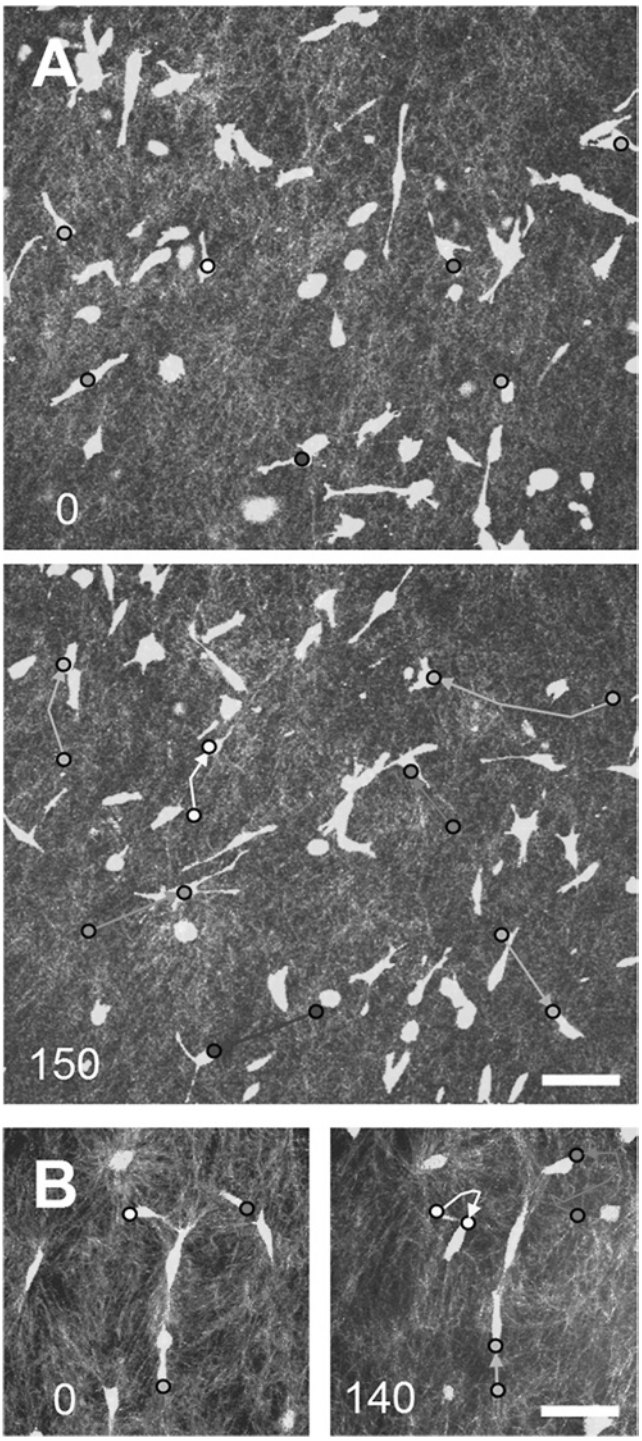

Figure 4.15.5 Real-time reconstruction of cancer cell migration in 3-D collagen lattices using simultaneous multiphoton SHG and fluorescence detection (**A**), compared to confocal reflection and fluorescence microscopy (**B**). HT-1080 fibrosarcoma cells were labeled with Calcein-AM (green), incorporated into 3-D collagen lattices and monitored by either multiphoton (A) or single-photon excited confocal microscopy (B). *Z*-stacks of 16-μm scanning depth (4 sections) were obtained at 15 (A) and 5 (B) min time intervals and superimposed. Position changes of selected cells during the observation interval are highlighted by start and end point as well as migration path. Collagen is equally well reconstructed by SHG, compared to confocal reflection microscopy (Friedl et al., 1997). Preserved cell elongation and position change during the entire observation indicate the absence of photodamage in both settings (incident light power in (A) was 15 mW). Bars = 80 μm. Time (min) is indicated in the lower left corner. For color version of this figure see *http://www.currentprotocols.com*.

SUPPORT PROTOCOL 1

CYTOPLASMIC STAINING OF LIVE CELLS

This procedure is used to stain the cells in 3-D collagen cultures to differentiate the cells from the collagen fibrils.

Materials

Cultured cells in culture flask or petri dish
Calcein-AM (Molecular Probes)
DMSO (Invitrogen)
Dulbecco's modified Eagle's medium (DMEM) *or* other medium (e.g., PBS; *APPENDIX 2A*); may contain serum and antibiotics

1. Add a small aliquot of Calcein-AM from stock solution (1 mM; in DMSO) to the medium of the culture in a collagen lattice to obtain a final concentration of 1 μM.
2. Incubate the culture for 60 min at 37°C.
3. Remove the supernatant and wash the culture twice using medium or PBS.
4. Proceed with Basic Protocol 4.

SUPPORT PROTOCOL 2

ESTABLISHMENT OF 3-D COLLAGEN CULTURES

3-D collagen lattices represent a simple yet biologically meaningful alternative to 2-D liquid culture approaches to measure cell functions, such as proliferation, survival, differentiation, and migration (Friedl et al., 1997; Friedl, 2004). This procedure describes how cells are incorporated into the 3-D lattices so they are embedded from the onset of the culture.

Materials

Adherent cells
2 mM EDTA solution in PBS, pH 7.4
Dulbecco's modified Eagle's medium (DMEM) or other medium; may contain serum and antibiotics (*APPENDIX 2A*)
10× concentrated minimal essential Eagle's medium (MEM; Flow Laboratories) or other 10× concentrated medium
7.5% (w/v) sodium bicarbonate solution (Life Technologies)
3.0 mg/ml collagen stock solution, acidified (e.g., bovine dermal collagen; Vitrogen; Nutacon BV or rat tail collagen; Becton Dickinson)
Migration chamber (see recipe)

1. Detach adherent cells (e.g., 2×10^5) by incubating in 2 mM EDTA for 2 to 5 min, 37°C. Wash twice with 1 to 10 ml of medium, centrifuging 10 min at 300 × *g*, 4°C each time. Decant the supernatant and resuspend the cells in 500 μL medium.

   EDTA is preferred over trypsin/EDTA because it does not lead to alterations in surface protein composition caused by the enzymatic removal of adhesion receptors.

2. Add 100 μl of 10× MEM to 50 μl sodium bicarbonate in a small sterile tube. Check that the indicator color changes from yellow (acidic) to purple (basic).
3. Add 750 μl cell-free collagen stock solution and mix until homogenous slightly purple color is obtained.

   Avoid air bubbles while mixing.

4. Add 450 μl cell suspension in medium and mix until homogenous bright pink color is reached. Again, avoid generating air bubbles.

   The pH should now be 7.8 to 8.0. To verify the pH use a pH indicator strip.

5. Add the cell-containing collagen solution into the incubation chamber.
6. Place the incubation chamber into the incubator (37°C, 5% CO_2) for 15 to 30 min for collagen polymerization and equilibration of the gas conditions. The final pH should be 7.4 to 7.5.

   If a commercially available climatized incubator is used with the video microscope, steps 1 to 6 can be modified for ECM culture in conventional petri dishes or microtiter plates.
7. Fill the chamber with warm and previously equilibrated medium.

   This medium can contain chemokines or other factors, such as antibody or pharmacological inhibitors.
8. Close the migration chamber, place it on the microscope stage and proceed with Basic Protocol 4.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Migration chamber

A migration chamber is a cell incubation chamber, either from commercial sources or self-constructed (Friedl and Bröcker, 2004). Most microscope manufacturers provide small chambers for a small petri dish or specialized incubation chambers for extra small volumes. Alternatively, an incubation chamber can be self-constructed. An example for a self-constructed migration chamber is detailed in Friedl and Bröcker (2004).

COMMENTARY

Background Information

Physical principle of two-photon and multiphoton effects

Two-photon excitation occurs by the near-simultaneous absorption of two or more photons by a molecule normally excitable by one photon of twice the energy and occurs the moment two lower energy photons are simultaneously absorbed by the same molecule (Fig. 4.15.6A). The first photon generates a virtual state of the electron and the second must be absorbed before the virtual state is de-excited (i.e., within the Heissenberg approximation of 10^{-15} sec). Together, both photons result in an excitation of nearly the same impact as a single higher energy photon excitation of the same molecule. In order to achieve a high enough photon density for two-photon excitation, the irradiant laser light needs to be phase-(mode)-locked and pulsed.

The pulse width of the irradiant beam is determined from an autocorrelation (in time) experiment in which the full-width at half-maximum of the pulse is in the range of 2 to 10 psec (for picosecond lasers) or 100 to 300 fsec (for femtosecond lasers) interrupted by an illumination-free interval of several nanoseconds, which results in a repetition rate of 76 to 96 MHz (Fig. 4.15.6A). Because of the high photon density during the pulse, high probabilities for two-photons or multiple photons to become near-simultaneously absorbed by a molecule is high, provided minimum of tens of milliwatts (for fsec pulses) are present in the focal plane under the objective (corresponding to an overall intensity ranging from MW/cm^2 up to GW/cm^2).

Two-photon excitation is quadratically related to the illumination intensity at the focal point, and only at the focal point is a significant number of photons achieved. Consequently, signal arises only from the scanned focal volume, and thin optical sections are being generated in 3-D samples, whereas little excitation and photodamage occurs outside the focal plane. Therefore, multiphoton excitation lacks photobleaching and phototoxicity in regions above or below the focal plane.

Higher harmonic generation (HHG)

HHG includes SHG and THG (Fig. 4.15.6B). SHG results from the sum frequency doubling to produce a narrow band of half the excitation wavelength and twice the energy (Fig. 4.15.6B). THG results from the sum frequency tripling to produce emission at a third of the excitation wavelength and triple

the energy (Fig. 4.15.6B). HHG occurs only in the focal plane providing sufficiently high photon density and, similar to multiphoton fluorescence microscopy, represents an inherently confocal approach allowing 3-D reconstruction from *z*-slices (Fig. 4.15.6C). Emitted HHG signals are commonly detected by photomultipliers (Fig. 4.15.6C). In contrast to fluorescence, most cases of HHG do not involve the absorption of light, thus relatively little heat is produced. Therefore, pure harmonic generation imaging tends to be much less phototoxic than two-photon or multiphoton fluorescence microscopy.

SHG

SHG is a nonlinear coherent scattering process that conserves energy. The summation of the light rays into the second harmonic frequency results from phase matching of the incident light with an environment that encourages summation of frequencies. The resulting signal

$$\mathrm{SHG} \propto \frac{(p \cdot \chi^{(2)})^2}{\tau}$$

is dependent on the square of the input laser power, p, a susceptibility coefficient, χ, and the width of the laser pulse, τ. As the light rays pass through this environment the electric field of the light exerts forces on the electron charge distribution and consecutive changes in a dipole moment, referred to as the electric polarization. The electric polarization (P) is linear, but for high-energy electric fields, such as an incident laser pulse (E) of high energy, P becomes a summation of linear and nonlinear terms. SHG is sensitive to structural molecular alterations caused by external factors such as temperature, folding, osmolarity, and ionic strength; biological structures may vary in their proportion of linear and nonlinear properties. Therefore, SHG should be tried out for each sample and contains an empiric component. The electric polarization is further determined by a susceptibility factor (χ) which depends on the environmental and molecular structure and polarization angle with respect to the light rays, as defined by

$$P^{(2)}_{\mathrm{SHG}} = \chi^{(2)} E \cdot E$$

The intensity of emitted light is nonlinearly proportional to the input light frequency but has a quadratic dependence, which means that below a certain threshold at low excitation energy no signal will be obtained whereas a near linear emission is achieved above the threshold. In the linear range, intensity changes can thus be used for quantitative image analysis.

The strength of SHG is further dependent on the size scale to which the noncentrosymmetric (NCS) medium is effective, called the coherence length, L_c, $\Delta k \cdot L_c \approx \pi$, where Δk is the difference in wavevectors,

$$k = \frac{2\pi}{\lambda}$$

between the fundamental and second harmonic waves of wavelength, λ. The coherence length is dependent on the incident wavelength and must be in the order of the NCS period size.

SHG is an anisotropic process and mainly propagates in the same direction of the incident light, whereas only a minor fraction is backscattered (Fig. 4.15.6C). The ratio of SHG signal for forward to backward direction often ranges above 5:1 (tubulin, fibrillar collagen; Dombeck et al., 2003), thus forward detection is required for low S/N ratio.

THG

THG is based on the "third order susceptibility" which means that its signal has a cubic dependence on input intensity:

$$P^{(3)}_{\mathrm{THG}} = \chi^{(3)} E \cdot E \cdot E$$

Unlike the physical and geometrical rules of SHG, all materials potentially possess properties to elicit THG to a varying degree, but the THG signal intensity is more sensitive to and requires high average powers and small pulsewidths,

$$\mathrm{THG} \propto \frac{(p \cdot \chi^{(3)})^3}{\tau^2}$$

Similar to SHG, the susceptibility factor, $\chi^{(3)}$ in THG is variable and also changes vastly from material to material, thus extensive spectral examination is required for each individual sample type. Near-infrared input elicits third harmonic generation of ultraviolet light of relatively lower penetration depths in scattering samples, whereas the use of excitation above 1200 nm reaches TGH signals in the visible range. THG is an isotropic process, therefore emission signal intensities are equally strong in forward and backward directions.

Although the above theoretical considerations predict ubiquitous THG for most biological samples, empirical evidence suggests that TGH signals, which are intrinsically weak,

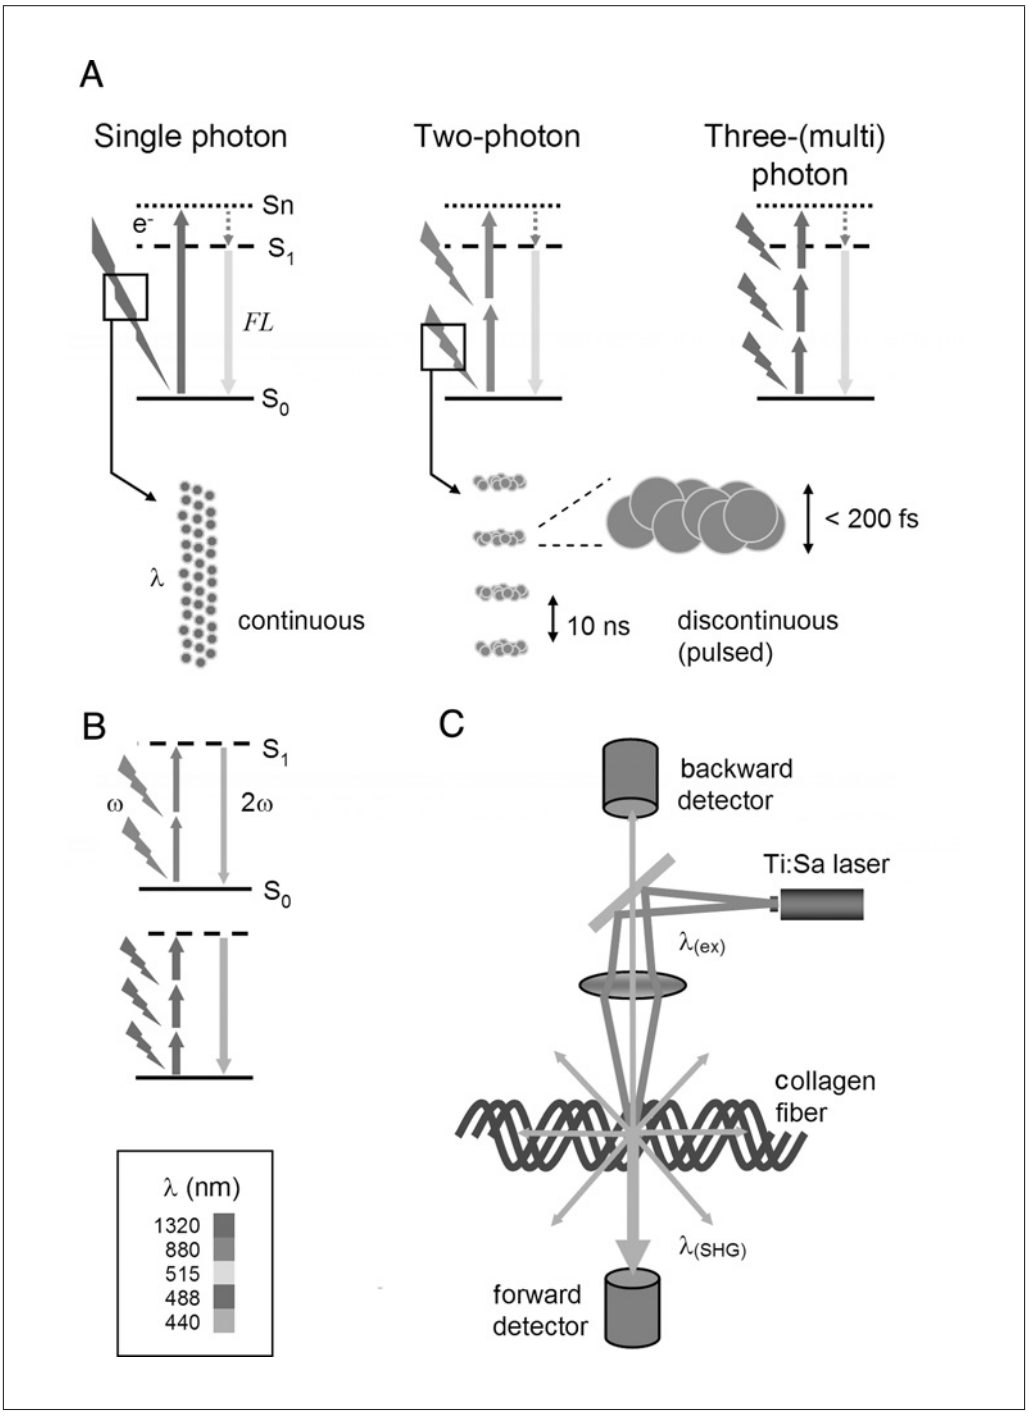

Figure 4.15.6 Principles of single-, two-, and three-photon excited fluorescence (**A**), compared to second and third harmonic generation (**B, C**). (**A**) Excitation of fluorescence. Single-photon excitation results from a continuous photon flux, generating continuous emission. Two- and three-photon excitation are caused by high-energy pulses of light of longer wavelengths. In both cases, the emission spectrum is near identical. (**B**) Excitation of second and third harmonic generation. Two (top) or three photons (bottom) of pulsed high-energy light are converted to one photon of two- or three-fold energy, respectively, corresponding to half or a third of the wavelength. (**C**) Beam path of forward and backward SHG induced by triple-helical collagen. Abbreviations: *FL*, fluorescence emission; S_0, nonexcited state of an electron; S_1, excited state of an electron; S_n, short-lived excited state of higher energy level; ω, frequency of the light; $\lambda_{(ex)}$, wavelength of excitation beam; $\lambda_{(SHG)}$, wavelength resulting from SHG. For color version of this figure see *http://www.currentprotocols.com*.

are further dampened by homogeneous out-of-focus regions just above and below the focal point that interfere destructively and delete the net signal.

Critical Parameters and Troubleshooting

Photodamage in live samples

The maximum photon flux and thus signal-to-noise ratio is limited by photodamage which varies for different sample types. Even though the use of (near-)infrared light causes less photodamage to live cells and tissues than visible or UV light excitation, the use of too high peak power required for enhancing weak two-photon and multiphoton effects can severely compromise cell function and integrity. The mechanisms of laser-induced cell damage are not resolved, however a combination of local heat, absorption of incident illumination, and toxic photoproducts of chromophores are plausible explanations. A reliable net indicator of photodamage is the generation of gas bubbles in the sample causing the loss of specific signal of both SHG and fluorescence (Fig. 4.15.7).

As a rule of thumb for the tuning range from 700 to 1000 nm, intensities of up to 7 mW, as measured by a powermeter below the objective, will not cause photodamage and intensities up to 15 mW can be tolerated by live cells over several hours if the lag phase between scanning is sufficiently long (Fig. 4.15.6). Much higher excitation intensities up to 100 mW or more in the focal plane can be used for detecting weak signals of the tissue microarchitecture without signs of photodamage or denaturation, such as collagen and elastin in fixed samples (Dombeck et al., 2005; Boulesteix et al., 2006; Debarre et al., 2006). At illumination >1000 nm, higher intensities are well tolerated. Long-term continuous-time scanning in living *Xenopus* embryos using excitation at 1280 nm and a power of 75 mW is required to generate strong SHG and THG signals yet lacks apparent toxicity (Sun, 2005). Likewise, excitation of membrane potential dyes at 1064 nm up to 80 mW is tolerated by neuronal cells, suggesting that long-term real-time microscopy by multiphoton excitation will develop towards better tolerability using excitation wavelengths above 1 μm.

Anticipated Results

Other structures detected by HHGI

Microtubules In cells, polymerized tubulin forms the filamentous microtubule network important in cell polarity, vesicle trafficking, and mitosis. Microtubules in the polymerized state, but not after depolymerization by nocodazole, generate relatively weak SHG signals in brain slices (Dombeck et al., 2003). Mitotic spindles can be detected in living cultured cells (Dombeck et al., 2003) or intact embryos (Sun, 2005).

DNA. Condensed chromosomes during mitosis, but not interphase DNA, after extraction and fixation and mounting on a glass slide can be detected by SHGI, using 800-nm excitation wavelength (Gauderon et al., 2001). By contrast, no published example has monitored SHG or THG of nonlabeled DNA in live cells and tissues, suggesting that the sample preparation contributes to the noncentrosymmetry and spatial arrangement of the chromosome structure.

Bone and teeth. Mineralized bone matrix and developing central bone marrow cavity in the mouse embryo is detected by THG up to penetration depths of several hundred microns (Oron et al., 2004). Despite progressive mineralization, both loose and compact bone regions are resolved in detail. In sections from teeth, linear SHG and even stronger THG signal is generated by dentin, most likely originating from the underlying collagen fiber scaffold (Kao, 2004). Particularly inorganic crystals and inorganic complexes in tissue display an abrupt change in refractive index at their surfaces, relative to the surrounding tissue, which is strongly susceptible to THG.

Membrane potential. Styryl dyes are elongated molecules with large hyper-Rayleigh scattering efficiency that get aligned in roughly perpendicular order along the plasma membrane to form anisotropic scaffolds, the orientation of which is sensitive to the transmembrane electric field. Alterations of the membrane potential, as during depolarization, cause electro-optic realignment and thus, anisotropy that is exploited as increased SHG for membrane potential measurements (Pons et al., 2003; Dombeck et al., 2004; Millard et al., 2004; Sacconi et al., 2005). Live-cell studies indicate that the dyes RH 237, FM4-64, and JPW1114 show sufficient signal-to-noise ratio and little toxicity (Dombeck et al., 2005) and can be combined with conventional fluorescent indicators, including Ca^{2+}- and Na^{+}-sensitive dyes. The absolute change in signal intensity amounts to 5% to 20% per 100 mV which is linear to the amount of depolarization and can be calibrated by voltage-gated patch clamp technique (Dombeck et al., 2005; Sacconi et al., 2005). Differences of absolute

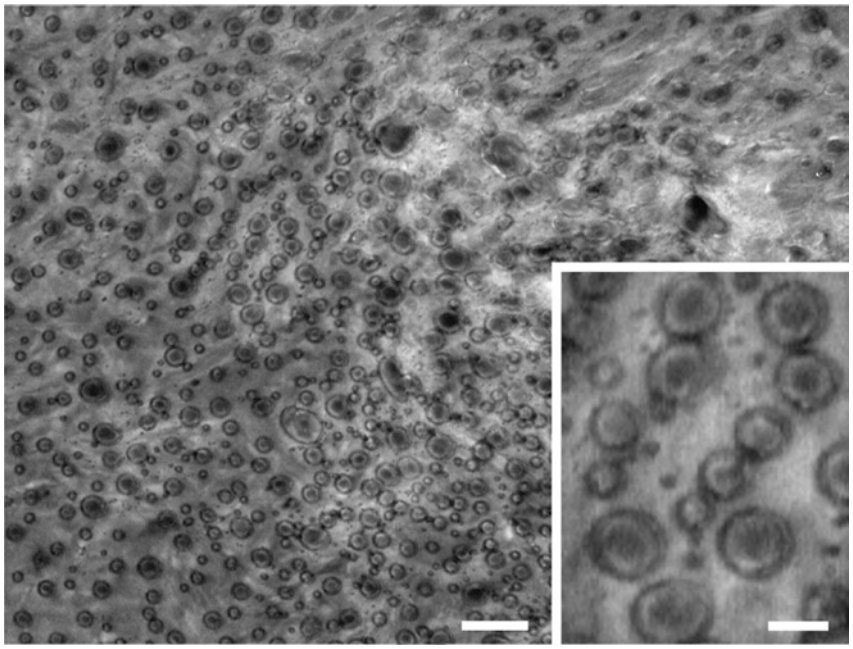

Figure 4.15.7 Multiphoton-induced photodamage and loss of SHG signal in native section of the dermis. Excitation was obtained at 880 nm, the incident light power was 160 mW (~10 scans). Photodamage was apparent from gas bubbles and the loss of both SHG (blue) and autofluorescence (green and red). Bars = 20 μm and 10 μm (inset). For color version of this figure see *http://www.currentprotocols.com*.

SHG sensitivity are specific for each dye, cell type, and subcellular location of the region of interest, and transformed cells appear to develop stronger signals than nontransformed cells (Dombeck et al., 2005; Sacconi et al., 2005). Forward detection in transparent cell culture as well as backward detection (at 80% lower efficiency) from thick tissue slices at high temporal (<1 msec) and spatial resolution can be achieved (Dombeck et al., 2005). Thus, SHG imaging will be an important approach to intravital reconstruction of fast-voltage transients in cell membranes during cell-cell signaling at minimum interference with the electrophysiological properties of the membrane.

Plants. Cellulose and starch are both polymers of glucose. Cellulose is composed of a polymer of β-1,4 linkages and starch of α-1,4 linkages. Individual polymer chains are cross-linked and arrange in a crystal-like order to form fibrils of high tensile strength that are susceptible to SHG. Starch, because of its open helical structure, causes higher SHG intensity than cellulose, which is more linear in structure (Cox et al., 2005).

Lipid bilayers. Although all materials have the susceptibility for THG, lipid membranes contained in aqueous medium have a comparatively high third-order susceptibility due to the formation of water-lipid interfaces. Strong THG signals are generated by lipid membrane and lipid bodies in tissues and in vitro systems, including lipid bodies and vesicles in live hepatocytes (Debarre et al., 2006).

SHG and THG probes. Several extrinsically applied labels exhibit strong SHG signals, either based on their own structure, or after their interaction with cell and tissue components. These include gold nanoparticles for immunological staining (Jumah et al., 2004; Lippitz et al., 2005) and polyhydroxybutyrate (PHB) polymers that generate biodegradable fibrillar structures used for tissue engineering (Deng et al., 2003).

Time Considerations

The acquisition of a single image frame takes 0.2 to 5 sec, depending on the scanning frequency and resolution. Image stack acquisition from the reconstruction of a 3-D volume requires a few up to several hundred images, thus may take several seconds up to minutes for a single data point. Whereas a single microscopy experiment is complete within a few minutes to hours, sample preparation, as well as image reconstruction and data analysis, may take up to days and weeks.

Analyzing Real-Time Video Microscopy: The Dynamics and Geometry of Vesicles and Tubules in Endocytosis

In recent years there has been a rapid increase in the use of real-time video microscopy of cellular processes. Typically, a protein of interest is fluorescently tagged, and a sequence of images is obtained at regular time intervals. To date, the analysis of the movies has been largely qualitative, with a protein of interest being observed to be transported between locations, noting general changes in morphology over time, and occasionally making dimensional measurements. But real-time imaging offers many more opportunities to make systematic measurement of quantities such as volume, surface area, and flux, and their changes over time. As well as allowing quantitative comparisons between systems when, for instance, a protein is modified, this approach can lead to a better qualitative understanding by refining thinking about the systems observed. With the use of three-dimensional real-time video microscopy becoming more common (Rietdorf and Zimmermann, 2000), quantitative geometric analysis will only increase in importance.

One approach to analyzing real-time cellular processes is to model the structures as geometric objects in order to estimate quantities such as surface area and volume, and their changes over time. A fundamental assumption is that membrane is conserved, i.e., any membrane entering or leaving a system can be accounted for. For example, in the case of the vesicle-tubule systems this corresponds to the assumption that for any decrease in the membrane area of a vesicle there is a corresponding increase in membrane in a tubule. Whether membrane area conservation holds in an experiment depends strongly on the cellular system and the observation methods, but once the assumption is made or has been shown experimentally to be true, it is possible to infer many quantities not directly observable in the images.

Generally, it may be true that there are membrane transport events that are not being observed in individual live-cell video microscopy experiments. But, by making assumptions or estimations about them, mathematically testable hypotheses can be generated. The measurements obtained from the experimental data will then either confirm what is expected, or the hypotheses will have to be revisited.

The following sections demonstrate how to apply geometric and conservation principles to experimental data using endosomal membrane tubulation following endocytosis as an example. Each section first describes a general principle, shows how the principle has been applied to an example, and concludes with the observations and conjectures that the analysis has yielded.

DATA AND MEASUREMENT

The following example uses tubulation of a vesicle during endocytosis. Some typical images are shown in Figure 4.16.1 from a sequence of 90 images taken at 10-sec intervals, giving a total time span of 900 seconds (15 min; Kerr et al., 2006). For the purposes of this example, this sequence will be referred to as The Movie. In The Movie (see Video 1 at *http://www.currentprotocols.com*) the vesicle is initially irregular in shape (Fig. 4.16.1A), but it is observed to rapidly become circular as tubulation is initiated (Fig. 4.16.1B). In the center left of Figure 4.16.1B a roughly spherical vesicle with multiple tubules radiating out from it can be seen. Over 900 sec the vesicle decreases in radius from ~2.5 μm to 1.25 μm. There is an initial burst of tubule activity with many long and branched tubules formed. After ~250 sec (25 frames), tubule activity significantly decreases, with only a few short tubules observed and little or no branching (Fig. 4.16.1C). Faster frame rate movies of up to 1 frame per second have been taken, and in these the tubules are observed to grow, break off, and be transported away from the vesicle (Kerr et al., 2006).

The real-time video microscopy images are recorded as a sequence of TIFF format images with a fixed time interval between each frame. Using software such as ImageJ (see Internet Resources), each frame may be examined individually and measurements obtained. ImageJ enables the user to measure common geometric properties such as length, fit circles and ellipses to structure in the images, and record measurements over a

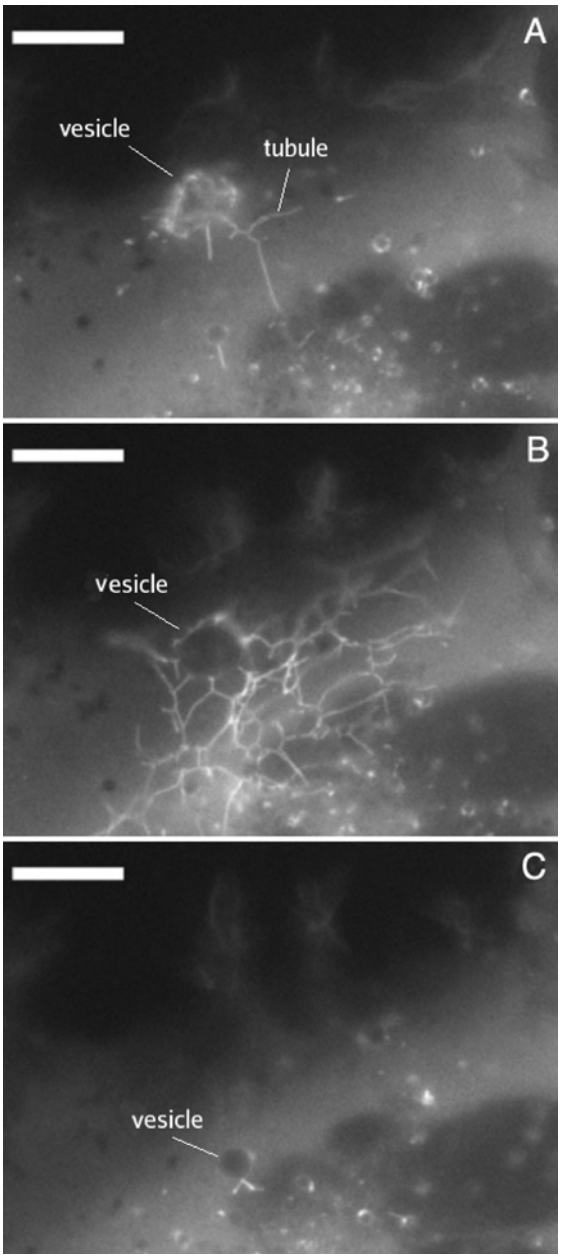

Figure 4.16.1 Tubule formation on a vesicle during endocytosis. Flp-In HEK293 cells stably expressing GFP-SNX5 were generated as described in Merino-Trigo et al. (2004). HEK-GFP-SNX5 cell monolayers were serum-starved overnight before being exposed to 100 ng/ml recombinant EGF ~1 min before the movie was started. Time-lapse movies were recorded using an Olympus IX71 inverted microscope equipped with an Olympus 60X oil objective. Images were captured with an IMAGO Super VGA 12 bit 1280 × 1024 pixel CCD camera (T.I.L.L. Photonics). Imaging control and post-capture image analysis are performed using TILLvisION software and ImageJ v1.31 (see Internet Resources). The delay between image capture was 10 sec. A single macropinocytic event heavily decorated with GFP-SNX5 shortly after its formation at the plasma membrane is presented. GFP-SNX5 is evident on tubular extensions of the limiting membrane of the macropinosome, within the cytosol and on smaller perinuclear puncta reminiscent of early endosomes. Image (**A**) shows the irregularly shaped vesicle and tubules at time 0. Image (**B**) is 210 sec later. Significant tubulation has occurred: many long and branched tubules are apparent, and the vesicle appears circular. Image (**C**) is taken at 780 sec. The vesicle has decreased significantly in area and only a few short tubules are apparent. Bars represents 10 μm. Time-lapse movie available as Video 1 at *http://www.currentprotocols.com*.

sequence of frames. Knowing the time interval between frames, the rates of change of measured quantities over time may then be calculated. Measurements of vesicle surface area over time in The Movie are shown in Figure 4.16.2. Measurements from other movies show that the tubules range in length from 1 μm to 12 μm, and a typical value for rate of longitudinal growth is 0.5 μm/sec (Kerr et al., 2006). Fixed cell electron micrographs show the tubules having average radii of ~18.36±4.42 nm (M. Lindsay and R. Parton, unpub. observ.).

The question arises of whether the geometric and membrane conservation assumptions are reasonable. Because only the proteins that are marked are captured in the images, it is possible that membrane is being added or removed from the vesicle system unobserved. However, experiments using nocodazole, which blocks tubule growth, show the vesicles exhibiting relatively little decrease in size (Kerr et al., 2006); this suggests that the majority of membrane being transported into or out of the vesicle is via tubule growth. Further, cell membranes can typically stretch only 1% to 4% before rupturing (Lipowsky and Sackmann, 1995); hence, membrane surface areas observed are conserved in the sense that for any reduction in the surface area of the vesicle there must be a corresponding increase in surface area of tubule. As better imaging techniques such as real-time three-dimensional video microscopy become more common, it will be possible to measure surface areas more directly and account for all the membrane being trafficked.

CONSERVATION OF SURFACE AREA

In many systems it is desirable to be able to quantify how membrane is trafficked between locations. Here a geometric model of a vesicle/tubule system is constructed under the assumptions that membrane is conserved, the vesicle is a sphere, and a tubule is a cylinder. The aim is to attempt to quantify how membrane, and hence receptors, are trafficked during tubulation of a vesicle.

In Figure 4.16.3, at time 0 there is a spherical vesicle of radius r_{V0}. At time t a tubule of length $L(t)$ and radius r_T has grown causing the vesicle to decrease in radius to $r_V(t)$. The surface area of the vesicle is initially $4\pi {r_{V0}}^2$ and is $4\pi r_V(t)^2$ at time t. The loss in the surface area of the vesicle is given by $4\pi[{r_{V0}}^2 - r_V(t)^2]$. The curved surface of the tubule at time t has area $2\pi r_T L(t)$. If surface area is conserved it must then be that the loss in surface area of the vesicle equals the gain in that of the tubule, i.e., $4\pi[{r_{V0}}^2 - r_V(t)^2] = 2\pi r_T L(t)$.

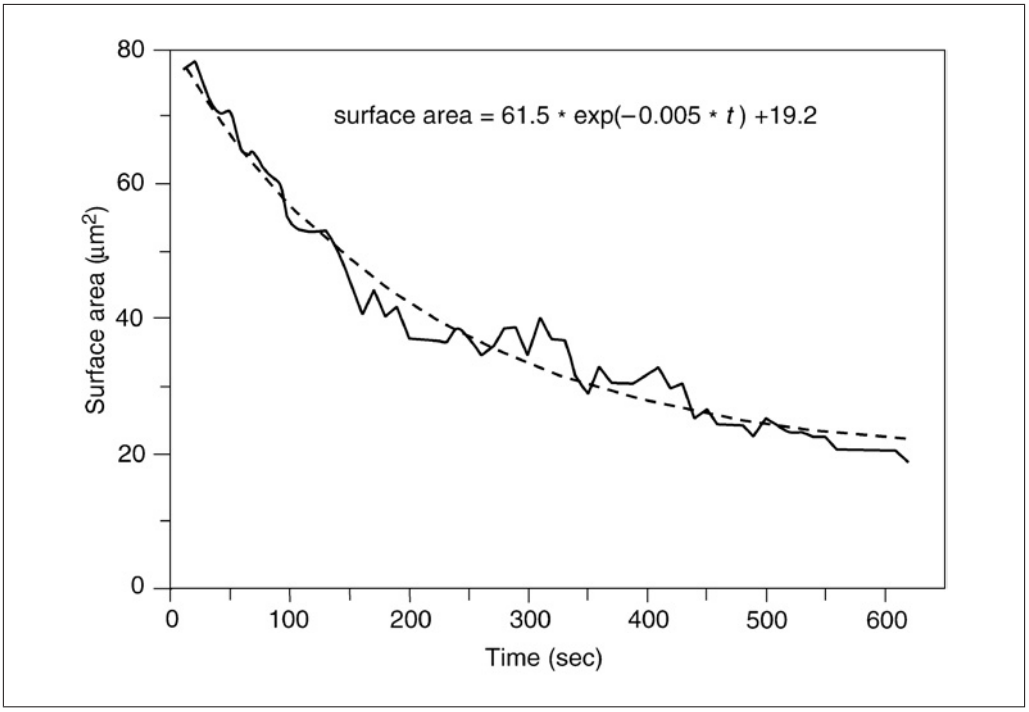

Figure 4.16.2 The rate of decrease of surface area of the vesicle in The Movie (frames 22 to 83), with an exponential best fit curve (dotted). Surface area is given as four times the area of an ellipse fitted to the vesicle membrane surface.

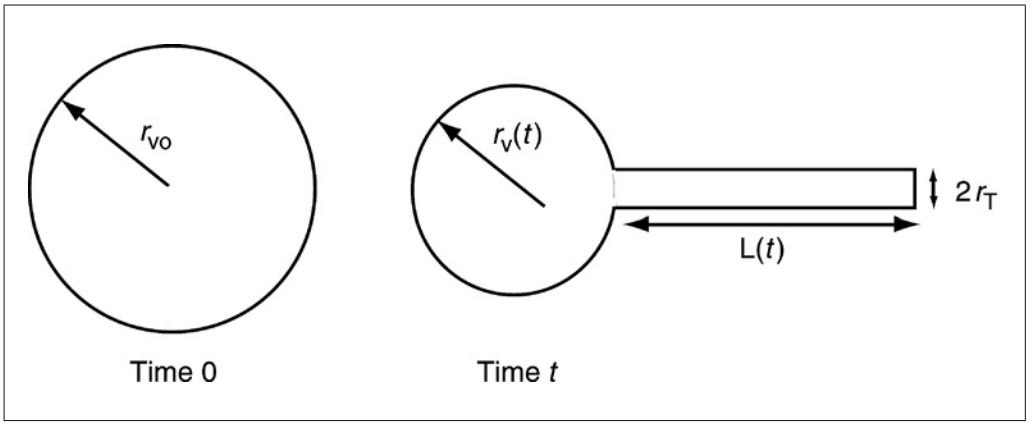

Figure 4.16.3 Change in a vesicles' surface area and volume as a tubule grows. At time 0 the spherical vesicle has radius r_{V0}. At time t, a cylindrical tubule of length $L(t)$ and radius r_T has grown, decreasing the radius of the vesicle to $r_V(t)$. If surface area is conserved, then the decrease in surface area of the vesicle will equal the increase in surface area of the tubule, i.e., $4\pi[r^2_{V0} - r^2_V(t)] = 2\pi r_T L(t)$. The volume contained in the vesicle is initially $4/3\pi r^3_{V0}$. The total volume contained with the vesicle and tubule at time t is $4/3\pi r^3_V(t) + \pi r^2_T L(t)$.

Rearranging terms gives the expression:

$$r_V(t) = \left(r_{V0}^2 - \frac{r_T L(t)}{2} \right)^{1/2}$$

Equation 4.16.1

Alternatively, the terms can be rearranged to express the amount of tubule formed for a given radius change:

$$L(t) = \frac{2\left[r_{V0}^2 - r_V^2(t) \right]}{r_T}$$

Equation 4.16.2

A typical value for the rate of growth of a tubule is 0.5 μm/sec (measurements obtained from separate movies to The Movie; data not shown), and so setting $L(t) = 0.5t$ in Equation 4.16.1 gives a complete description of how the radius of a vesicle would be expected to change as a tubule grows, under the assumption of observed surface area conservation. Further, Equation 4.16.2 can be used to estimate the total length of tubule that formed for a given observed vesicular radius decrease. For instance, in The Movie the radius changes from ~2.5 μm to 1.25 μm. Setting $r_{V0} = 2.5$ μm, $r_V(t) = 1.25$ μm, and a value of 18.4 nm for r_T, Equation 4.16.2 estimates the total length of tubule formed over the period of observation to be 510 μm. Also, while decreasing in radius from 2.5 μm to 1.25 μm, one-quarter of the membrane of the vesicle is retained by the vesicle while the remainder is transferred into the tubules.

This section has shown how a simple geometric model can be used to estimate the length of tubule and amount of membrane being trafficked. Now attention is turned to the volume contained within the systems.

MEASUREMENT OF VOLUME

Because liquids are essentially incompressible, principles of volume conservation may be applied to the movies of cellular processes and used to estimate how solutes are trafficked. Again, the approach is to assume surface area is conserved and model the membrane structures as geometric objects.

But there is a problem: a sphere is the unique surface that contains maximum volume for a given surface area. When tubules form, the total surface area of the vesicle together with the tubules remains the same, but less volume may be contained within the system. The amount of volume lost is readily calculated for a given change in radius as follows. If, as in the previous section, the initial radius of the vesicle when no tubulation has occurred is r_{V0}, and after time t the radius has decreased to $r_V(t)$ (see Fig. 4.16.3), with a total length $L(t)$ of tubule formed, then the total volume of the vesicle-tubule system at time t is

$$\frac{4}{3}\pi r_V^3(t) + \pi r_T^2 L(t)$$

Equation 4.16.3

Using the expression for $L(t)$ given in Equation 4.16.2, the difference of the initial volume, $4/3\pi r_{V0}{}^3$, and the final volume of the

vesicle-tubule system is calculated to be

$$\Delta V = \frac{4}{3}\pi\left[r_{V0}^3 - r_V^3(t)\right] - 2\pi r_T\left[r_{V0}^2 - r_V^2(t)\right]$$

Equation 4.16.4

Note this *is not* volume that is contained in the tubules; it is bulk volume that must be moving from the interior to the exterior of the vesicle by passing through the vesicle membrane. In the case of The Movie, taking $r_{V0} = 2.5$ μm, $r_V(t) = 1.25$ μm, and $r_T = 0.0184$ μm, the volume no longer contained within the vesicle-tubule system is $\Delta V = 56.73$ μm^3. This compares to an initial volume contained in the vesicle of 65.45 μm^3, a final volume in the vesicle of 8.72 μm^3, and a volume of 0.54 μm^3 that has gone into tubules. Hence approximately seven-eighths of the volume is lost. Even if nontubular (unobserved) membrane, e.g., budding vesicles, were being transported out of the system, similar volume loss problems would still occur. What happens to the lost volume is considered in the next section. It is likely that water is being transported out of the vesicle system via aquaporin channels (Murata et al., 2000). If this is indeed the case, and the solute is retained within the vesicle/tubules system, then the majority of solute remains within the vesicle, and the volume of solute transported from the vesicle via tubules is trivial (0.54 μm^3) in comparison.

FLUX ACROSS A MEMBRANE, SOLUTE CONCENTRATION, AND pH CHANGE

Whenever the volume of an enclosed system such as a vesicle is not conserved, it follows that there must be a flux into or out of the system. Depending on what is being transported, this may have consequences for concentration of solutes and pH. In this section it is shown how geometry may be used to estimate flux, concentration, and pH change.

Suppose, as in Figure 4.16.4, that initially a vesicle has radius $r + \delta r$, and at a time δt later the radius has decreased by an amount δr. For small δr, the volume contained "between" these vesicles is the surface area of the "inner" vesicle multiplied by the thickness δr, and so is given by $4\pi r^2\delta r$. The *volume flow*, i.e., the volume crossing the membrane per unit time, is then given (as δt approaches 0) by

$$4\pi r^2\frac{\delta r}{\delta t} \rightarrow -4\pi r^2\frac{dr}{dt}$$

Equation 4.16.5

The minus sign occurs because the radius is decreasing. The *volume flux*, defined to be the volume flow *per unit area* of the vesicle surface, is then just dr/dt. (Flux is sometimes defined as the number of molecules transported per unit area per unit time, rather than the volume of molecules per unit area per unit

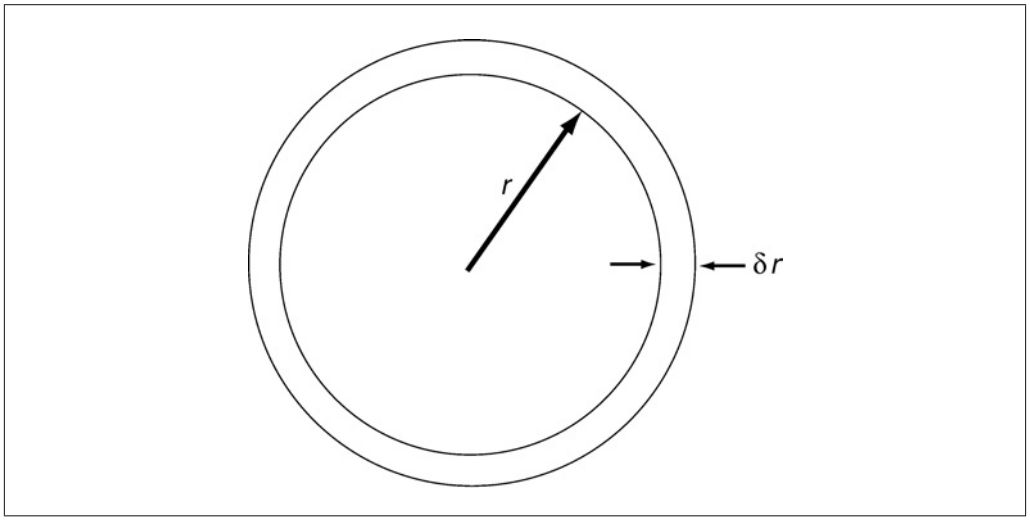

Figure 4.16.4 Flux across the membrane. Initially the spherical vesicle has radius $r + \delta r$. At a time δt later, the radius has decreased by δr. The volume "between" the vesicle is then $4\pi r^2\delta r$, and the volume crossing the membrane per unit time is $4\pi r^2\delta r/\delta t$, which becomes $-4\pi r^2 dr/dt$ as $\delta t \rightarrow 0$. Hence the volume flux, the volume flow per unit surface area of the vesicle, is $-dr/dt$.

time). But for homogenous liquids, volume and amount are essentially interchangeable given sufficient numbers of molecules. Hence to calculate the flux across the membrane only the rate of decrease of the radius of the vesicle over time needs to be known.

In Figure 4.16.2, measurements of the surface area of the vesicle over time in The Movie are shown. The radius at any time is readily calculated as $r = [A(t)/4\pi]^{1/2}$, where $A(t)$ is the surface area at that time, and plotting the radius against time for the first 200 sec gives a graph with slope of approximately -0.0041 μm/sec. Hence in The Movie there is a flux of ~ 0.0041 $\mu m^3/\mu m^2$/sec across the membrane. It may be that some volume is being lost by being transported through the membrane of the tubules. However, at any instant in time the surface area of the tubules is much smaller than that of the vesicle, and given the relatively small diameter of a tubule, the effect is likely to be trivial. Another possibility is that the vesicle ruptures allowing the content of the lumen to escape. However, separate experiments marking the contents of the vesicle have enabled the concentration of the contents of a vesicle to be observed directly. Dextran was fluorescently marked and introduced into the intercellular environment, entering the interior of each vesicle as it forms. As tubulation occurred and the area of the vesicle decreased from 7.3 μm^2 to 5.3 μm^2, a marked increase in average intensity by a factor of 1.66 was observed in the central region of the vesicle. If the vesicle membranes were ruptured the intensity would be expected to remain constant or decrease.

It seems likely that the flux across the membrane is mostly in the form of water being transported through aquaporin channels (de Baey and Lanzavecchia, 2000). A flux of 0.0041 $\mu m^3/\mu m^2$/sec is orders of magnitude slower than water fluxes across lipid bilayers that have been observed previously (see Borgnia et al., 1999 and references included there) and so is biologically feasible. In the next section it will be shown how pressure and tension considerations may be used to explain the flux.

If indeed it is water that is being transported across the vesicle membrane, then the solute in the vesicle is being significantly concentrated by the tubule formation and associated vesicle reduction. As seen above, the volume entering the tubules over the lifetime of the vesicle is small compared to the volume contained in the vesicle. Hence, in The Movie, where the radius decreases by a factor of two, the final volume of the vesicle is eight times smaller than that of the initial vesicle, and so an 8-fold increase in solute concentration is predicted. It may be that such an increase in concentration is biologically significant and that the formation of tubules is not only to enable efficient recycling of receptors, as is commonly thought, but also to increase solute concentration.

Another point of interest is that if it is indeed water that is being selectively removed, then there may be an associated pH change in the vesicle. Under the hypothesis that water and not hydrogen ions are selectively crossing the membrane, an 8-fold reduction in vesicle size could lead to an 8-fold concentration in hydrogen ions and so to a change in pH of ~ 0.9 ($\log_{10} 8$). Aquaporin channels are known to facilitate the transport of water at the expense of ions such as protons (Murata et al., 2000), and so they provide a mechanism by which such a pH change could occur. It is also known that pH facilitates ligand-receptor disassociation (Johnson et al., 1993; Presley et al., 1997), one pathway to acidification being via proton-translocating ATPases (Forgac, 1989); it may be that vesicle reduction is another pathway that affects the outcomes for trafficking of the ligand (Lindermann and Lauffenburger, 1986). Further, in Johnson et al. (1993), it was found that receptor return to the plasma membrane is slowed when the endosome is not properly acidified.

PRESSURE, TENSION, AND MORPHOLOGY

Large changes in membrane morphology are sometimes observed in real-time cellular movies, and these can often be understood in terms of pressure, tension, and flux. Whenever there is a flux though a membrane there is a pressure difference across the membrane. The difference may be osmotic in nature due to a difference in the solute concentrations in the interior and exterior (Zhu et al., 2002), or it may be hydrostatic due to some force being applied. In the hydrostatic case the flux across the membrane is proportional to the pressure difference (Zhu et al., 2002), and so the flux through the membrane over time provides a measure of the relative value of the pressure difference over time. The hydrostatic pressure difference is also proportional to the tension in the membrane (Lipowsky and Sackmann, 1995). Such a tension will often alter the shape of a membrane to a more regular shape such as a sphere. Another point of interest is that virtually all cell membranes contain ion

channels that may be opened or closed by mechanical transduction (Sachs, 1991); so it may be that different molecules are being transported across the membrane when it is under differing tensions. This section shows how proportionality principles between pressure, tension, and flux may be applied to understand how the morphology of the vesicle changes over time and to calculate relative values of pressure and tension in the vesicle membrane.

In The Movie, the vesicles is observed to be initially irregular in shape, but within a few tens of seconds of tubulation being initiated it appears circular. In the previous section it was seen that there is a flux across the vesicle membrane. The associated pressure difference might be due to differing solute concentrations between the interior and exterior of the vesicle. However, the more likely explanation is that as tubules form, the membrane of the vesicle tightens, and the tension in the surface induces a hydrostatic pressure difference. In this case, the flux across the membrane is proportional to the pressure difference, and so the value of the volume flux (or, indeed, the rate of change of radius as shown above) over time provides a measure of the relative value of the pressure difference over time. Further, because the hydrostatic pressure difference is also proportional to the tension in the membrane, the rate of change of radius over time also gives a measure of the relative tension in the membrane.

Using the fitted curve to The Movie data given in Figure 4.16.2 (the fitted curve is discussed in more detail later), an expression for the rate of change of radius can be obtained. For a given surface area $S(t)$ at time t, the radius $r(t) = [S(t)/4\pi]^{1/2}$, and taking the derivative of this with respect to time gives

$$\frac{dr}{dt} = \frac{-0.01084e^{-0.005t}}{61.5e^{-0.005t} + 19.2}$$

Equation 4.16.6

This equation has value -0.000134 at $t = 0$ and changes to -0.0000242 at $t = 600$, and so the ratio of $-0.000134/-0.0000242 = 5.5$ gives the estimate that the pressure difference and tension in the vesicle membrane were around five times larger initially than they were 600 sec later. Whether solutes are being trafficked across the membrane at all or at different rates as the tension in vesicle membrane changes, is an open question.

VESICLE FUSION

Another area open to geometric analysis is vesicle fusion. In these events, two vesicles join together to form a single vesicle. If the vesicles are spherical, then the conservation or otherwise of surface area and volume may be examined.

Suppose two vesicles of radius r_1 and r_2 fuse to form a single vesicle of radius r_3 (see Fig. 4.16.5). If surface area is conserved, the equality $4\pi {r_1}^2 + 4\pi {r_2}^2 = 4\pi {r_3}^2$ holds, i.e.,

$$r_1^2 + r_2^2 = r_3^2$$

Equation 4.16.7

As was noted previously, conservation of surface area is in conflict with conservation of volume. If the vesicles have volumes V_1, V_2 and V_3, respectively, the fractional increase in volume of the vesicle system is also readily

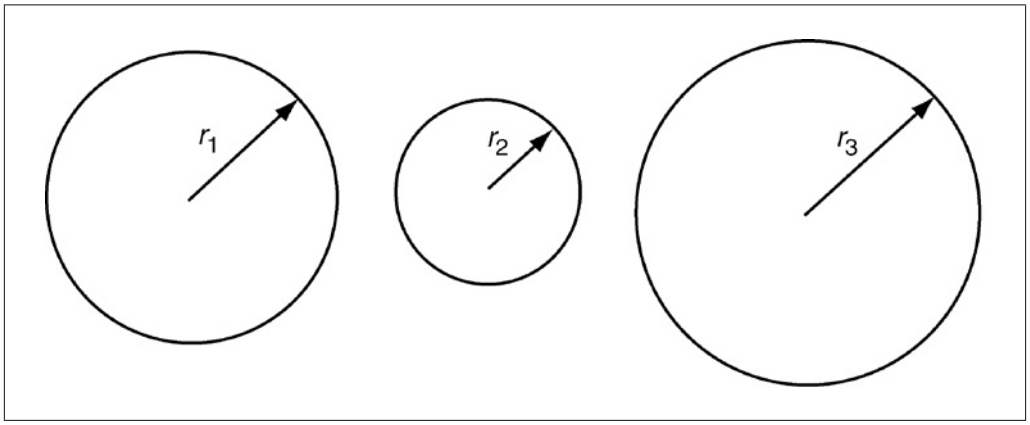

Figure 4.16.5 Fusion of vesicles. Two spherical vesicles of radius r_1 and r_2 merge to form a single vesicle of radius r_3. If surface area is conserved then the relation $4/3\pi {r_1}^2 + 4/3\pi {r_2}^2 \neq 4/3\pi {r_3}^2$ holds. However, if surface area is conserved volume can not be, i.e., $4/3\pi {r_1}^3 + 4/3\pi {r_2}^3 \neq 4/3\pi {r_3}^3$.

calculated as

$$\frac{V_3-(V_1+V_2)}{V_1+V_2}=\frac{\frac{4}{3}\pi\left[r_3^3-(r_1^3+r_2^3)\right]}{\frac{4}{3}\pi(r_1^3+r_2^3)}$$

Equation 4.16.8

In the particular case that the initial vesicles have the same radius (i.e., $r_1 = r_2$), Equation 4.16.7 shows that if surface area is conserved one would expect to observe the radius of the postfusion vesicle to be $\sqrt{2}$ times that of the prefusion vesicles. In this case, Equation 4.16.8 shows that, under the assumptions that the vesicles are all spheres and surface area is conserved, the fused vesicle will have 41.4% greater volume than the prefusion vesicles. In general, for vesicles of any radii fusing, if surface area is conserved and the vesicles are all spheres, then because a sphere is the unique shape that maximizes volume for a given surface area, there will be an increase in volume contained in the postfusion vesicle.

In Roberts et al. (1999), several high-quality real-time movies of vesicle fusion are presented, in particular figure 4 in that paper provides a sequence amenable to measurement where the vesicles are apparently circular. Taking measurements of area in units of pixels (1 μm is ∼120 pixels in the movie); in frame 29 the vesicles have areas of 2032 and 2166, while in frame 52 the fused vesicle has an area of 4181. The corresponding radii are then 50.9, 51.9, and 73.0 pixels. Under the assumption that the three vesicles are spherical, the surface area of each vesicle is then four times the area observed, giving areas of 8128, 8464, and 16724, respectively. Hence surface area appears to be approximately conserved since $8128 + 8464 = 16529 \approx 16724$. Also notice that the postfusion radius is almost exactly $\sqrt{2}$ times that of the prefusion vesicles, giving some confidence that the conservations of membrane and sphericality hypotheses are true. In contrast, the volumes of the vesicles are respectively 551238, 585770, and 1626950, giving the result that the fused vesicle appears to contain 43% more volume than the two vesicles before fusion and that a substantial volume is entering the system during fusion.

Another movie where two large vesicles fuse has been obtained by Richard et al. (2004). Taking measurements from the first and final frames in units of pixels, the prefused vesicles and the fused vesicle have measured areas of 18996, 16509 and 34106, respectively. These correspond to radii of 77.8, 72.5, and 104.5 pixels; surface areas of 75984, 66036, and 136424; and volumes of 1969505, 1595677, and 4738164. Again, the radius of the fused vesicle is $\sim\sqrt{2}$ times that of the prefusion vesicles. The surface area appears to be approximately conserved, with the fused vesicle having surface area only 4% smaller than the sum of the surface areas of the prefusion vesicles. But the volume of the fused vesicle is 33% larger than volume contained within the prefusion vesicles. It appears that as vesicles fuse there is a rapid uptake of volume, though the mechanism is not clear.

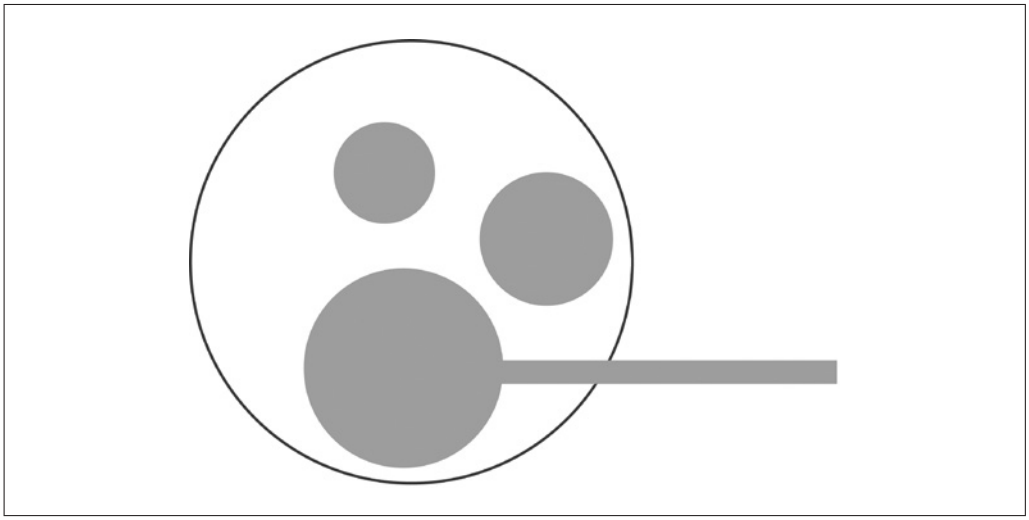

Figure 4.16.6 Vesicle membrane subdomains or patches. The vesicle membrane contains subdomains (shown in grey) on which tubulation is initiated. As the tubule grows the subdomain membrane is drawn into the tubule and the subdomain decreases in size.

PROPORTIONALITY AND SURFACE AREA

Proportionality is a common principle when describing changes in physical and biological systems: the rate at which a collection of radioactive particles decays is proportional to the number of particles, or in a self-inhibiting chemical reaction the rate of change of product may be proportional to the amount of product. The *rate equation* for some changing quantity $N(t)$ of such a process will be

$$\frac{dN(t)}{dt} = -kN(t)$$

Equation 4.16.9

where k is a constant that governs the speed with which $N(t)$ changes. It states that at time t, the rate at which $N(t)$ changes is proportional to $N(t)$ itself.

The solution to this rate equation is

$$N(t) = N_0 e^{-kt}$$

Equation 4.16.10

where N_0 is the initial quantity $N(0)$. Depending on the sign of k, $N(t)$ will either exponentially increase or decrease. Here it is shown how proportionality may be applied to describe the reduction in surface area measured in the vesicular systems.

The vesicle membrane surface is not homogeneous and contains subdomains or patches of membrane on which tubulation is initiated (Mukherjee and Maxfield, 2000; Baumgart et al., 2003; Kerr et al., 2006). When a tubule is initiated, the membrane from a patch is drawn into the tubule as it extends, and the patch reduces in size (see Fig. 4.16.6). If there were large areas of patches on the vesicle surface, it seems likely that there would be a higher probability that in a given time interval a tubule will begin to form on one of the patches than if there were only a few small patches. Hence a reasonable hypothesis is that the larger the total surface area of the patches on the vesicle surface, the more tubules that will form in a given time interval, and so the total surface area of the vesicle given over to patches will decrease at a greater rate. In other words the rate of decrease of the total patch area on the vesicle surface will be proportional to the patch area at that time. This can be formalized as a rate equation for the total patch area $S_p(t)$ of the vesicle at time t as

$$\frac{dS_p(t)}{dt} = -kS_p(t)$$

Equation 4.16.11

where k is a rate constant.

The solution to this equation is

$$S_p(t) = S_{p0} e^{-kt}$$

Equation 4.16.12

and describes how one would expect the total patch area to change over time. The constant S_{p0} then is the total area of patches at time 0.

Because the non-patch membrane area of the vesicle is not expected to decrease, the *total* surface area of the vesicle would be expected to be of the form

$$S(t) = S_{p0} e^{-kt} + S_{np}$$

Equation 4.16.13

where S_{np} is the surface area of the vesicle not able to be incorporated into tubules. Fitting a curve of the above form to The Movie data in Figure 4.16.2 gives the equation

$$S(t) = 61.5e^{-0.005t} + 19.2$$

Equation 4.16.14

A plot of Equation 4.16.14 is shown as a dotted line in Figure 4.16.2, and it appears to fit the data very well. Note that since the decrease in patch area is an exponential, the total patch area is being halved every $\ln(2)/0.005 \approx 141$ seconds. The area of the initial vesicle that was in patches at time zero is predicted as 61.6 μm^2, with the remaining surface area of the vesicle being 19.2 μm^2.

While the predicted proportion of surface area given over to patches in The Movie is no surprise since the lack of tubule activity later in the movie already suggested that the majority of the patches had tubulated, what has been gained by the proportionality model is the ability to predict given only partial data. If, instead of 600 sec of data shown in Figure 4.16.2, only the first 300 sec had been obtained, it would still be possible to create the above model and predict the final size of the vesicle even if these were not observed experimentally.

It would be appealing to be able to relate the surface area decrease measured and modeled above directly to the individual patches on which tubulation is initiated. However, detailed observations of the areas of all of the patches on a given vesicle have yet to be made, although qualitative insight can still be gained by considering the proportionality hypothesis for patch area decrease and what it would imply.

It would be expected that a larger patch will begin to tubulate more quickly than a smaller one because there is more area for tubulation to be initiated; so a likely scenario is that the

probability of a patch forming a tubule in a given time interval is proportional to the area of the patch. Hence, a patch that is twice the size of another will be twice as likely to begin tubulation in a given time interval and so will have a mean lifetime half that of the smaller one. If this is correct, then one would expect the mean lifetimes of the larger patches to be much shorter than that of the smaller ones. Indeed, in The Movie and other movies of tubulation, an explosion of growth of long tubules (large patches) is observed early on, while later only a few short tubules are seen.

Another feature that might be expected is for multiple tubules to begin growth on a single patch. If a patch is large and a tubule begins to form, it may last for several tens of seconds before the surface area is completely drawn out into the tubule. Thus, there is a probability that a second tubule will begin to form on the patch in this time. The points at which the two tubules initiated on a single patch are attached to the vesicle will become closer as the patch is depleted, until they merge and branching occurs: a single tubule is attached to the vesicle, and that tubule then splits into two branches. Again, almost all of the tubules at the beginning of The Movie are long and have multiple branches, while later the tubules are short and exhibit no branching, as predicted.

CONCLUSIONS

The authors have outlined how simple geometric and conservation principles can be applied to the analysis of real-time movies of cellular processes to make predictions and generate ideas for further experiments. The main principles are:

Surface Area. Membrane area should be conserved; if not, membrane is entering or leaving the system, the amount of which may be quantifiable.

Volume. Volume should be conserved, and if not, volume is entering or leaving the system; this may have consequences such as pH change or solute concentration.

Pressure. Flux across a membrane is associated with a pressure difference and tension in the membrane; this can lead to changes in morphology.

Proportionality. Many processes occur at rates proportional to the area available for them to occur on.

Using these principles, it has been possible to get a better qualitative understanding of the systems observed in The Movie and related experiments: why there is very rapid tubulation initially, why tubules later in the movies are of shorter length, why tubules often exhibit branching early in the movies but not later on, why vesicles are initially morphologically irregular but rapidly become regular, and what may govern the rate of decrease in vesicle size. On the quantitative side, under the hypothesis of observed surface area conservation, measurement and models allowed prediction of the surface area of a vesicle available to form tubules, the lifetime of an average patch, the total length of tubule formed, relative changes in pressure and tension across and in the vesicle membrane, volume flux across the vesicle membrane, pH change, and solute/disassociated ligand concentration. The latter is particularly interesting because it may be that one of the goals of tubulation is not just to efficiently recycle receptors but also to concentrate the solute.

It should be emphasized that the aim of the endocytosis example presented has not necessarily been to develop a complete mathematical model of the system in the mode of, for instance, the famous Hodgkin-Huxley squid axon equations. There may be membrane transport events that are not being observed in the live cell video microscopy experiments, though the experiments using nocodazole suggest that few, if any, such events are occurring, and real vesicles and tubules certainly deviate to some degree from spheres and cylinders. However, by making reasonable assumptions, attempting to capture mathematically the essence of what is being observed, and doing "back of the envelope calculations" allow refinement in thinking about the systems, investigation of whether the conclusions reached are biologically reasonable, and generation of experimentally testable hypotheses. The approach is towards an experimental mathematics in which as much as is known about a system is geometrically modeled in order to ascertain the consequences and further experiments that the model suggests.

ACKNOWLEDGEMENTS

Scanning Electron Microscopy of Cell Surface Morphology

Samantha Passey,[1] Stéphanie Pellegrin,[1] and Harry Mellor[1]

[1]Mammalian Cell Biology Laboratory, Department of Biochemistry, School of Medical Sciences, University of Bristol, United Kingdom

ABSTRACT

The surface of metazoan cells is a landscape not clearly visualized by light microscopy. Many cells elaborate protrusive structures such as microvilli, filopodia, lamellipodia, and surface ruffles that play important roles in the interaction between the cell and its environment. The high resolution of scanning electron microscopy makes it an ideal technique for studies of the cell surface; however, preservation of fine surface structure can be problematic. Here we highlight the critical factors in sample preparation to ensure optimal high-resolution imaging of the surface of mammalian cells and tissues. *Curr. Protoc. Cell Biol.* 37:4.17.1-4.17.13. © 2007 by John Wiley & Sons, Inc.

Keywords: filopodia • microvilli • lamellepodia • SEM • actin

INTRODUCTION

Many cells make protrusive surface structures including lamellipodia, filopodia, and microvilli, and the fine detail of such structures is often beyond the limits of resolution of conventional light microscopy. The higher resolution afforded by scanning electron microscopy (SEM) allows detailed examination of the three-dimensional morphology of such structures. Indeed, depending on the instrument, the scanning electron microscope has a magnification range from 15× to 200,000× with a resolution between 1 and 20 nm.

In order to be visualized by SEM, biological specimens have to be prepared carefully (i.e., dried) to withstand the vacuum inside the microscope. They also have to be made conductive, usually by being coated with a very thin layer of gold. The image is generated by an electron beam which is focused and scanned over the specimen. As the electron beam hits the sample, secondary electrons are knocked loose from its surface. These secondary electrons are detected and the final image is built up from the number of electrons emitted from each spot on the sample. The brightness of the signal depends on the number of secondary electrons reaching the detector.

This unit describes the preparation of cells for scanning electron microscopy examination. The Basic Protocol describes the preparation of nonadherent lymphocytes for SEM, with the Alternate Protocols 2 and 3 being suitable for the preparation of adherent cells.

PREPARATION OF LYMPHOCYTES FOR SCANNING ELECTRON MICROSCOPY

BASIC PROTOCOL

This protocol assumes the cells of interest are already available either as continuously growing cell lines or as recently isolated primary peripheral blood mononuclear cells (PBMC), isolated by density gradient centrifugation using a suitable reagent such as Histopaque 1077 (Sigma-Aldrich). Specific leukocyte and lymphocyte subsets can be purified from PBMC using commercially available separation technologies such as the magnetic MACS separation reagents (Miltenyi Biotec).

CAUTION: Nitric acid, glutaraldehyde, hexamethyldisilazane, and osmium tetroxide are hazardous chemicals; ensure appropriate safety, handling, storage, and disposal procedures are followed.

NOTE: Cells should be maintained at 37°C in a humidified 5% (v/v) CO_2 atmosphere unless otherwise specified. We would recommend allowing an overnight incubation of primary lymphocytes immediately following isolation to allow cells to recover their normal morphology following the isolation and purification procedures.

NOTE: All chemicals that come into contact with live cells must be sterile and aseptic technique used to prevent contamination. SEM is a good way to discover poor sterile technique.

Materials

5 M nitric acid
Methanol
Poly-L-lysine (0.1% w/v, Sigma-Aldrich)
Phosphate-buffered saline (*APPENDIX 2A*)
Cells of interest (this procedure has been used for SEM examination of primary human lymphocytes and also mouse and human lymphocyte cell lines)
RPMI 1640 medium (Sigma-Aldrich)
2.5% glutaraldehyde (see recipe)
Sodium phosphate buffer, pH 7.4 (see recipe)
Sodium phosphate buffer, pH 6.0 (see recipe)
0.5% osmium tetroxide (see recipe)
25%, 50%, 75%, 90%, and 100% ethanol
Liquid CO_2
High-purity argon

13-mm round glass coverslips
Glass petri dish
80°C oven
12-well tissue culture plates
1.5-ml microcentrifuge tube
Parafilm
Shaking incubator with variable speed
Benchtop microcentrifuge
Critical point drying apparatus (e.g., Tousimis Samdri; *http://www.tousimis.com*)
Aluminum sample stubs (12-mm, Agar Scientific)
Adhesive sample mounting pads (Adhesive Carbon Tabs, 12-mm, Agar Scientific)
Gold sputter coater
Vacuum
Dehumidified environment (e.g., sealed plastic container in the presence of silica gel)

Additional reagents and equipment for counting cells using a hemacytometer (*UNIT 1.1*)

Prepare poly-L-lysine coated coverslips

1. Immerse 13-mm round glass coverslips in 5 M nitric acid for 15 min at room temperature in a fume hood.

   Nitric acid removes traces of oil, dust, etc. from the coverslip surface and allows an even coating of poly-L-lysine.

2. Carefully decant the nitric acid in the fume hood and wash the coverslips ~10 times with copious amounts of double-distilled water. Decant all remaining water after final wash.

   Take care when adding water to any residual acid.

3. Wash the coverslips twice in methanol.
4. Spread the coverslips in a glass petri dish and dry in a hot oven at 80°C for at least 4 hr until the coverslips are completely dry.

   The acid-washed coverslips are treated as being sterile, but for more stringent sterilization they could be autoclaved.

   The acid-washed coverslips can be stored in the glass petri dish at room temperature indefinitely, but the dish should be opened only under sterile conditions to prevent contamination.
5. Transfer the required number of coverslips to wells of a 12-well plate, one per well for each sample to be prepared.
6. Immerse each coverslip in 0.5 to 1 ml poly-L-lysine and incubate for 30 min at room temperature.
7. Aspirate the poly-L-lysine and wash coverslips three times, each time with 1 ml PBS. Allow to dry (~30 min to 1 hr).

   Poly-L-lysine coated coverslips can be stored up to 1 month at 4°C, allow to warm to room temperature before use.

Fix cells with glutaraldehyde

8. Count cells (*UNIT 1.1*). Suspend cells at 4×10^7 cells/ml in prewarmed RPMI 1640 medium.

   Prewarming the medium to 37°C reduces the temperature shock when resuspending cells and helps to minimize morphological changes associated with changes in temperature. Centrifugation steps should be performed at room temperature or warmer.
9. Add 150 µl cell suspension to 1.35 ml of 2.5% glutaraldehyde at 37°C, in a 1.5-ml microcentrifuge tube. Mix gently by inversion.

   It is preferable that suspension cells be fixed in suspension prior to attachment to glass coverslips as morphological changes occur during the attachment of unfixed cells to surfaces. Fresh EM-grade glutaraldehyde must be used as older or less-pure grades may contain contaminants and breakdown products that will lead to fixation artifacts.
10. Seal tubes with Parafilm and incubate for 2 hr at 37°C, with gentle shaking (50 to 100 rpm).

    Shaking the cells minimizes cell clumping that can occur due to cross-linking of cell-surface components by the glutaraldehyde fixative. The cells should not be agitated too vigorously (100 rpm maximum) as vigorous agitation may damage fine surface structures.
11. Pellet cells by centrifuging 5 min at $300 \times g$, room temperature (or warmer) using a microcentrifuge. Remove the supernatant carefully with a pipet and resuspend the cell pellet very carefully in 1 ml sodium phosphate buffer, pH 7.4, to wash the cell. Repeat once.

    Care should be taken when resuspending cells; we recommend using a 1-ml pipet tip with the end cut to widen the tip and reduce shear forces that could result in cell damage.
12. After the second wash, remove the supernatant and carefully resuspend the cells in 20 µl sodium phosphate buffer, pH 6.0.

    The washing steps are very important to remove all traces of glutaraldehyde, which would otherwise cause reduced adhesion of fixed cells to poly-L-lysine. The lower-pH phosphate buffer ensures that the poly-L-lysine side chains are fully protonated-aiding adhesion of cells to the coverslip.

Fix the cells with osmium tetroxide

13. Spot the 20 µl of cell suspension (~6×10^6 cells) onto the corresponding poly-L-lysine-coated coverslip in the well of the 12-well plate. Repeat for each cell sample/coverslip to be prepared. Incubate the coverslips in the plate 30 min at room temperature.

    The spot may not cover the whole coverslip and will settle as a thick drop due to the high surface tension of the drop in contact with the poly-L-lysine on the coverslip surface.

14. Add 0.75 ml of 2.5% glutaraldehyde to each coverslip and incubate 30 min at room temperature.

15. Wash coverslips twice in sodium phosphate buffer, pH 7.4.

    Care should be taken when performing washes not to detach cells from the coverslip surface. Keep the pipet tip away from the coverslip and when adding fresh liquid take care to avoid directing the liquid at the coverslip surface, drip it down the side of the well to gently fill the well and prevent unwanted cell loss from the coverslips.

16. Immerse each coverslip in 0.5 ml 0.5% osmium tetroxide in sodium phosphate buffer, pH 7.4, for 1 hr at room temperature.

    Osmium tetroxide fixation is not essential for SEM but helps to preserve membrane appearance by reducing the elution of membrane lipids during the later dehydration steps (Newell, 1980). The plastic will darken. Osmium tetroxide is toxic and highly volatile—use in the fume hood at all times. Make up osmium solutions in a glass bottle as they will react with plastic.

17. Wash coverslips three times in sodium phosphate buffer, pH 7.4.

Dry fixed samples

We dry samples by critical point drying after dehydration in ethanol (Boyde and Wood, 1969). This gives the most reproducible drying without artifacts. A procedure is given for the Tousimis Samdri 780 dryer, which illustrates the main points. An alternative solvent replacement protocol is given for those without a critical point dryer.

18. Dehydrate the samples through a series of graded ethanol washes (25%, 50%, 75%, 90%, 100%), incubating for 20 min at room temperature in each ethanol grade.

    Samples can be left in the 90% wash overnight if necessary, but must then be taken through the 100% wash immediately before drying. Samples left in 100% ethanol will absorb water from the air and so become partially hydrated.

19. Place the coverslips in the chamber of the critical point dryer.

    It is essential that the samples remain submerged in ethanol—any drying before critical point drying will destroy ultrastructure.

20. Cool the chamber to ~0°C and then open the inlet vent to allow liquid CO_2 to enter the chamber for ~15 min.

    Our critical point dryer has a jacketed chamber and flushing this outer jacket with liquid CO_2 cools the sample. Other models may use refrigeration or Peltier cooling to achieve this. The aim is to replace the ethanol in the sample with a liquid transition fluid—in this case CO_2. Nitrous oxide can also be used. You should be able to see the two liquids mixing in the chamber and then becoming uniform when all of the ethanol is removed. At this point, you should also no longer be able to smell ethanol in the gas emerging from the waste vent. It is important that ALL traces of ethanol be removed before proceeding to the next step.

21. Close the chamber and heat the chamber to just over 31°C. Open the vent to allow the CO_2 to escape slowly—over ~15 min.

    The critical point of liquid CO_2 is 31.1°C at a pressure of 780 kPa. At this temperature (or above) the meniscus between the liquid and gas phase will disappear, avoiding distortion of fine surface structures by reducing surface tension forces. The pressure in the chamber will be ~8 MPa during venting.

22. Remove the dry samples and mount the coverslips on aluminum sample stubs using the adhesive pads.

Coat dried samples

The dried samples need to be given a thin coating of a conductive element before SEM to increase the surface conductance of the sample and so avoid surface charging of the sample under the beam. We use sputter coating with gold. Because of the high density of gold atoms, this treatment also decreases the penetration of the beam into the sample and so improves the resolution of surface edges. Instructions will vary between models of coater—a brief technique is given below.

23. Place samples in a sputter coater and apply a vacuum of ~1.33 Pa (10^{-2} Torr). Flush the system with high-purity argon to a pressure of ~13.3 Pa (10^{-1} Torr).

    The chamber must be clean to ensure good coating—free from residues of vacuum pump oil. Similarly, the argon should be free of contaminants.

24. Apply the current for between 1 to 5 min. The argon will glow purple.

    Under glow discharge, ions bombarding the gold cathode cause discharge of gold ions—plasma sputtering. The sample is attached to the anode and so becomes coated in a thin layer of gold. Coating is from many directions and so is relatively even over complicated three-dimensional surfaces. A metal coating of 5 to 15 nm is optimal for good image quality whilst avoiding electrical charging (Brunk et al., 1981). Thicker coats may be required if osmium fixation has not been used.

    Gold-palladium can be used to coat samples and is reported to give a less granular coating than gold alone (Brunk et al., 1981); however, at the resolution for imaging microvilli and other surface structures we see no texture to the surface coat when using gold alone. The alternative coating method to sputter coating is thermal evaporation—although this can give a less even coat over intricate three-dimensional surfaces.

25. Store samples in a dehumidified environment (i.e., in a sealed plastic container in the presence of silica gel).

    Samples can be stored for extended periods of time provided the low-humidity environment is maintained.

ALTERNATIVE DRYING PROTOCOL—HMDS REPLACEMENT

ALTERNATE PROTOCOL 1

With HMDS replacement, ethanol is replaced with the volatile solvent hexamethyldisilazane, which is then removed by evaporation (Braet et al., 1997). The technique is simpler than critical point drying, and requires no specialized equipment. HMDS has a low surface tension and also helps preserve surface structure by cross-linking proteins. In our experience the results are far more variable than critical point drying and often delicate surface structures are lost—the technique is great when it works, but it does not work reliably.

Additional Materials *(also see Basic Protocol)*

Hexamethyldisilazane (HMDS, Sigma)
Filter paper
Desiccator

1. Perform steps 1 to 18 of the Basic Protocol to prepare the sample.
2. In the fume hood, immerse samples in 100% HMDS for 3 min.
3. Blot excess HMDS with filter paper and dry samples in a desiccator for 30 min.

   Drying in an anhydrous environment is important to avoid possible contamination of the samples with water.

4. Continue with steps 22 to 25 of the Basic Protocol.

ALTERNATE PROTOCOL 2

PREPARATION OF INTESTINAL EPITHELIAL CELLS FOR SEM

The Caco-2 cell line, derived from a human colon adenocarcinoma, can assemble a microvilli-rich brush border upon reaching confluence and has been used extensively as an in vitro model for human intestinal enterocytes (Pinto et al., 1983; Grasset et al., 1984; Peterson and Mooseker, 1992; Dean and Kenny, 2004). In this protocol, Caco-2 cells are cultured for 14 days on permeable supports to allow the cells to feed basolaterally and to differentiate fully (see Fig. 4.17.1). Prior to fixation, transepithelial electrical resistance (TER) is measured with a voltohmmeter to assess monolayer differentiation and integrity. The cells are then fixed and processed according to the method described in the Basic Protocol, with only a few alterations indicated below. The permeable membranes on which the cells are grown can easily curl up when removed from their plastic support so the membranes are cut only just before gold coating (see Fig. 4.17.2).

Additional Materials *(see also Basic Protocol)*

Caco-2 cell line from ECACC or ATCC
Cell culture medium (see recipe)
1% osmium tetroxide (see recipe)

Transwell polycarbonate membrane inserts (1.1-cm^2 surface area; 0.4-μm pore; Corning, no. 3401) placed in a 12-well tissue culture dish
Humidified 37°C, 5% CO_2 incubator
Voltohmmeter
Sharp blade

Additional reagents and equipment for trypsinization of cells (*UNIT 1.1*)

Prepare cells

1. After trypsinization (*UNIT 1.1*), resuspend the Caco-2 cells in cell culture medium at a concentration of 10^6 cells/ml.

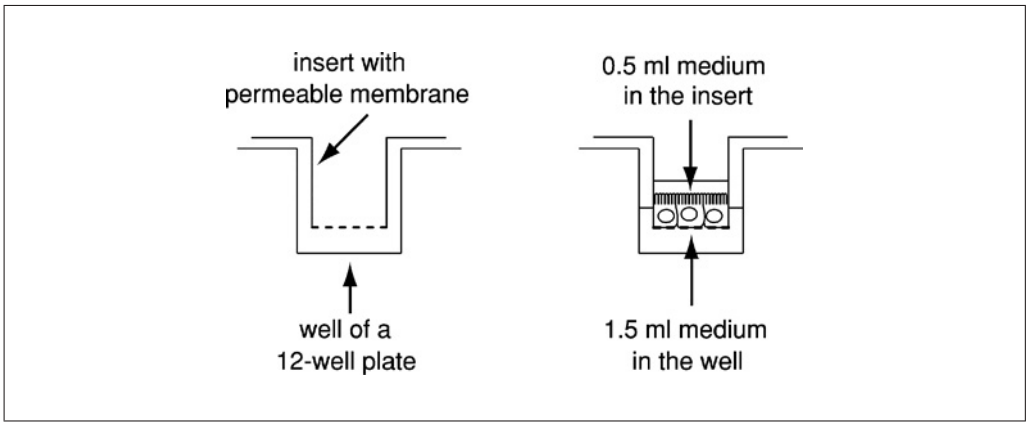

Figure 4.17.1 Culturing Caco-2 cells on permeable inserts.

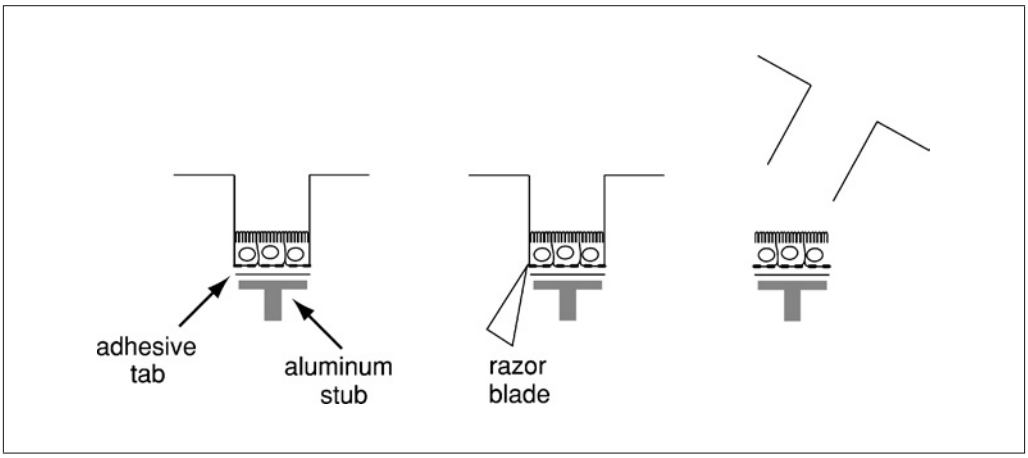

Figure 4.17.2 Cutting the insert membrane before gold coating.

2. Seed 5×10^5 Caco-2 cells (i.e., 0.5 ml) onto each 1.1-cm^2 Transwell polycarbonate membrane insert placed in a 12-well tissue culture dish. Carefully dispense 1.5 ml culture medium in the well (i.e., outside the Transwell).

   Figure 4.17.1 illustrates how the cells are cultured on permeable inserts.

3. Incubate the cells at 37°C in a humidified atmosphere of 5% CO_2 for 14 days. Give fresh culture medium daily by gently replacing both the 0.5 ml medium above the cells (i.e., inside the insert) and the 1.5 ml in the well (i.e., outside the insert).

Fix the cells

4. Before fixing the cells, measure the TER of the Caco-2 cells monolayer. Also measure the TER of a blank insert placed in tissue culture medium.

   The TER of the Caco-2 monolayer should be at least 250 Ω cm^2 above that of a blank filter. If the TER is not at the desired level, the cells are probably not confluent and not polarized, and would not have assembled a microvilli-rich brush border. The cultures with low TER can be grown for longer, to give the cells a chance to divide and become confluent. If they have been grown for 20 days or so they might never become fully confluent and polarized; in this case, they can be discarded.

   It can be very difficult to see the cells cultured on permeable filters. Measuring TER is important as it gives an idea of monolayer integrity.

5. Replace the culture medium with prewarmed 2.5% glutaraldehyde in sodium phosphate buffer, pH 7.4, at 37°C (described in the Basic Protocol). Place the fixative both above the cells (0.5 ml) and around the Transwell (1.5 ml).

6. Seal the plate with Parafilm and incubate for 2 hr at 37°C.

7. Wash three times in fresh sodium phosphate buffer, pH 7.4. Carry out all the washes in the 12-well plate by carefully removing the solutions from above and below the cells and gently adding fresh buffer to both the insert and the well.

8. In the fume hood, add 1% (w/v) osmium tetroxide in sodium phosphate buffer, pH 7.4, for 1hr.

   Osmium tetroxide is very toxic and highly volatile—use in the fume hood at all times. Make up solutions in a glass bottle as they react with plastic.

9. Wash three times in sodium phosphate buffer, pH 7.4.

   If necessary, following secondary fixation, samples can be stored at 4°C for indefinite length of time. The sodium phosphate buffer should be changed several times during the first few days to remove any unreacted osmium and the samples should not be allowed to dry. Samples should be warmed to room temperature before the ethanol dehydration procedure.

Dry the samples

10. Dehydrate the fixed samples through a series of graded ethanol washes (see Basic Protocol, step 18).
11. Dry the samples by placing the whole insert in the chamber of the critical point dryer (see Basic Protocol, steps 19 to 22).
12. Mount the whole insert onto an aluminum sample stub using a carbon adhesive pad (see Fig. 4.17.2). Be careful not to stretch the membrane.
13. Using a sharp blade, cut the membrane around the stub to remove the plastic support (see Fig. 4.17.2).

Coat the samples

14. Coat the samples with gold as described in the Basic Protocol, steps 23 to 25.

ALTERNATE PROTOCOL 3

PREPARATION OF OTHER ADHERENT CELL TYPES FOR SEM

Clearly, a modified version of the Caco-2 method (Alternate Protocol 2) can be used for any adherent cell line grown on glass coverslips. Place the coverslips in a 6- or 12-well tissue culture dish, fix the cells as described in step 5 of Alternate Protocol 2 and proceed through the remaining steps of Alternate Protocol 2

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cell culture medium

Dulbecco's modified Eagles medium (DMEM) supplemented with:
10% (v/v) heat-inactivated fetal bovine serum
2 mM L-glutamine
1% (v/v) non-essential amino acids
100 μg/ml streptomycin and 100 U/ml penicillin
Store up to manufacturer's recommended shelf life at 4°C

Glutaraldehyde, 2.5%

For 20 ml of buffer combine:
2 ml 25% (v/v) EM-grade glutaraldehyde
2 ml 1 M sodium phosphate buffer, pH 7.4 (see recipe)
16 ml ultrapure water (resistivity > 18 MΩcm^{-1}; e.g., Milli-Q grade)
Prepare fresh

CAUTION: *Glutaraldehyde is toxic and waste should be kept to a minimum.*

This recipe can be scaled up or down depending on the number of coverslips to be processed.

Different working strengths of glutaraldehyde fixative can be prepared by varying the amount of 25% stock glutaraldehyde. Concentrations below 2% are not recommended as fixation in low concentrations of glutaraldehyde can allow changes in morphology after fixation (Brunk et al., 1981).

Isoosmotic sodium phosphate buffers

The sodium phosphate buffer used is a mixture of Na_2HPO_4 and NaH_2PO_4 and the ratio of the two forms determines the final pH (Sambrook et al., 1989). Prepare the following stock solutions in ultrapure water:

1 M Na_2HPO_4
1 M NaH_2PO_4

The critical factor with the choice of buffer is that it is of the same osmotic strength as the tissue. Hypotonic or hypertonic buffers will lead to swelling or shrinking of fine surface structures, respectively. The two different buffer components will dissociate in solution as follows (the dissociation of hydrogen ions is slight):

$Na_2HPO_4 \rightarrow 2Na^+ + {}^-HPO_4$ (3 ions)
$NaH_2PO_4 \rightarrow Na^+ + {}^-H_2PO_4$ (2 ions)

For 100 ml of 1 M sodium phosphate buffer, see Table 4.17.1.
Make any necessary minor adjustments to pH using NaOH or HCl as appropriate.

The final concentration of the pH 7.4 buffer will be 100 mM sodium phosphate, and 130 mM for the pH 6.0 buffer—both will have an osmotic strength of ~280 mOsm.

Table 4.17.1 Phosphate Buffer Recipes and Osmolarity

	pH 7.4 phosphate buffer			pH 6.0 phosphate buffer		
	vol (ml)	moles/liter	Osm	vol (ml)	moles/liter	Osm
1 M Na_2HPO_4	77.4	0.774	2.32	12	0.12	0.36
1 M NaH_2PO_4	22.6	0.226	0.45	88	0.88	1.76
Total	100	1	2.77	100	1	2.12

Osmium tetroxide, 0.5%

For 8 ml of buffer combine:
1 ml 4% (w/v) osmium tetroxide solution (Sigma)
0.8 ml 1 M sodium phosphate buffer, pH 7.4 (see recipe)
6.2 ml ultrapure water (resistivity > 18 $M\Omega cm^{-1}$; e.g., Milli-Q grade)
Prepare fresh

CAUTION: *Osmium tetroxide is toxic and waste should be kept to a minimum.*

This recipe can be scaled up or down depending on the number of coverslips to be processed.

Osmium tetroxide, 1%

For 8 ml of buffer combine:
2 ml 4% (w/v) osmium tetroxide solution (Sigma)
0.8 ml 1 M sodium phosphate buffer, pH 7.4 (see recipe)
5.2 ml ultrapure water (resistivity > 18 $M\Omega cm^{-1}$; e.g., Milli-Q grade
Prepare fresh

CAUTION: *Osmium tetroxide is toxic and waste should be kept to a minimum.*

This recipe can be scaled up or down depending on the number of coverslips to be processed.

COMMENTARY

Background Information

Cells have numerous processes on their surfaces that play various roles in specialized cell functions. For example, lymphocytes circulating in the blood circulation possess thin microvilli that are important for the interaction between these cells and the endothelial cells lining the blood vessel walls, allowing the lymphocytes to exit the blood stream and migrate to lymph nodes or nonlymphoid sites in order to perform their varied roles in the immune response (Abitorabi et al., 1997). Lymphocyte microvilli are highly dynamic, extending in response to stimulation with certain cytokines, such as IL-4, or bacterial proteins including LPS (Davey et al., 1998), and being lost in response to other stimuli such as the chemokine SDF-1α (Brown et al., 2003). The ability to

regulate the lengths of their surface protrusions and the arrangement of their cytoskeleton is essential for many lymphocyte functions including rolling and tethering to allow them to exit the bloodstream and in migration within tissues in response to chemokine stimulation.

Adherent cells such as polarized epithelial cells also possess microvilli although they appear to be much more stable and long-lived structures in contrast to the dynamic microvilli seen on lymphocyte surfaces. The apical microvilli observed on intestinal epithelial cells form the brush border and are involved in increasing the surface area of the apical surface for increased absorption.

Such fine protrusive structures are very sensitive to changes in osmolarity, mechanical damage, and other conditions that affect cell behavior in living cells such as temperature and pH. The successful preservation of such delicate structures is a challenge for the preparation of cells for examination by SEM, particularly nonadherent cells such as lymphocytes that constantly collide with other cells during processing. When preparing such cells for SEM, the conditions both prior to and during the preparation process must be carefully considered to maximize the preservation of cell morphology and reduce the likelihood of introducing processing artifacts including cracking, shrinkage, and swelling of fine surface structures.

Although at first daunting, SEM provides unparalleled resolution for the examination of surface morphology in a range of cell types. When combined with light microscopy studies in fixed or live cells, SEM can greatly enhance our understanding of events that happen at an ultrastructural level that is beyond the scope of light microscopy alone.

Critical Parameters and Troubleshooting

The main problem associated with fixation of cells for SEM is the generation of fixation and processing artifacts including cracking, shrinkage, or osmotic swelling. Fine structures such as lymphocyte microvilli and membrane protrusions are particularly susceptible and various steps can be taken to minimize the introduction of artifacts during processing. Examples of such processing artifacts are shown in Figures 4.17.3, 4.17.4, and 4.17.5.

Osmolarity. Glutaraldehyde does not destroy membrane semi-permeability and cells fixed in glutaraldehyde are sensitive to changes in osmolarity during processing until they have undergone secondary fixation in OsO_4 (Brunk et al., 1981). Therefore it is important to fix and process cells using a buffer of comparable osmolarity to the cell culture medium, typically between 280 to 300 mOsm. When considering the osmolarity of the fixation buffer it has been reported that glutaraldehyde does not contribute to the effective osmotic pressure of the fixative, and it is the osmolarity of the fixative vehicle that must be equal to the osmolarity of the cell culture medium (Brunk et al., 1981). Previous workers have distinguished between the absolute osmolarity of fixative solutions, and the effective osmolarity—what the solution does to your sample. Ultimately, the ideal osmotic support can sometimes only be derived empirically, and if you see evidence of osmotic damage, you will need to adjust the osmolarity of your fixative to optimize it to your particular sample. This protocol describes the use of sodium phosphate as the fixative vehicle, other vehicles including 0.1 M Na-Cacodylate supplemented with 0.1 M sucrose have also been used successfully for fixation of cells and preservation of

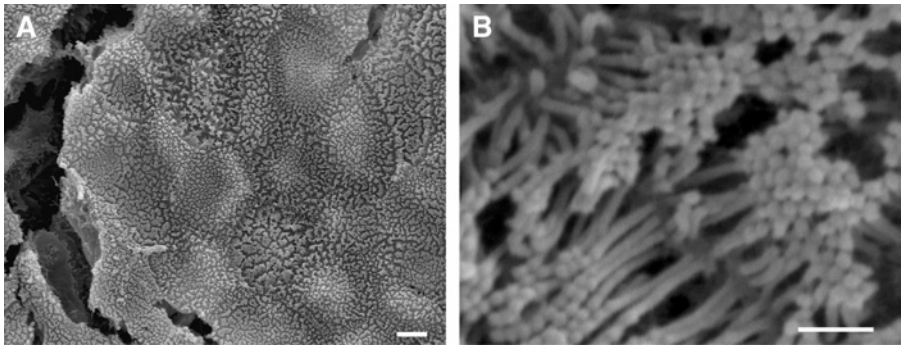

Figure 4.17.3 Artifactual cracking (**A**) and swelling of microvilli tips (**B**) in Caco-2 cells grown on permeable filters. Scale bars: 5 μm (A) and 500 nm (B).

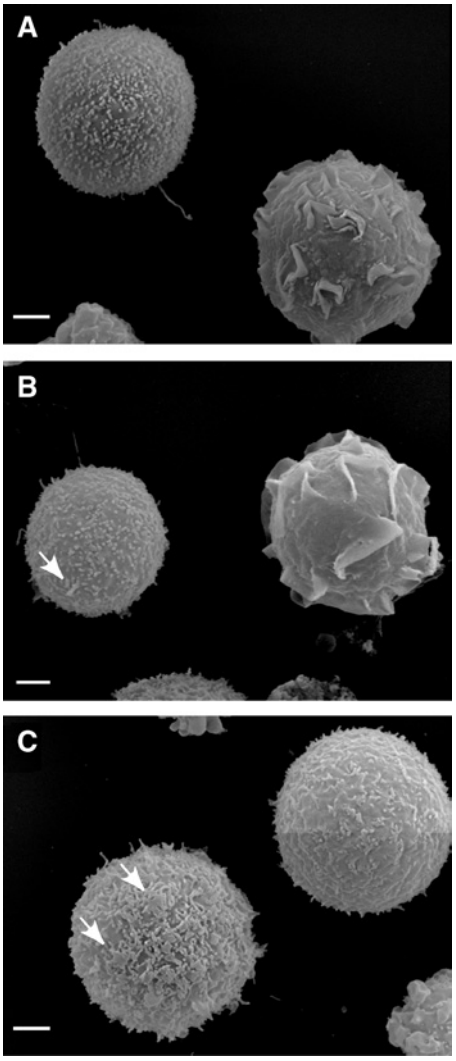

Figure 4.17.4 Varying the glutaraldehyde fixative concentration affected lymphocyte microvilli morphology. Mouse pre-B cells 300.19 were fixed in sodium phosphate buffer containing (**A**) 2.5%, (**B**) 3.5%, or (**C**) 4.5% glutaraldehyde and processed for SEM. Merging or aggregation of surface protrusions can be observed at 3.5% and 4.5% glutaraldehyde concentrations (arrows). Scale bar = 2 μm.

fine surface structures for SEM (Brunk et al., 1981).

Glutaraldehyde concentration. While glutaraldehyde concentrations of up to 6% have been reported to not affect the preservation of surface structures, we have noticed an apparent merging or aggregation of cell surface microvilli at concentrations exceeding 3%, as shown in Figure 4.17.4. We interpret this observation as being an artifact of high glutaraldehyde concentrations, potentially due to cross-linking of cell surface factors by the fixative. Ideally, optimal glutaraldehyde concentration would be determined empirically for the cells being studied.

Temperature. Temperature is an essential factor to consider when minimizing potential processing artifacts, as changes in temperature in living cells can result in altered morphology and the loss of motile surface structures (Newell, 1980; Brunk et al., 1981). All steps up to and including the primary fixation in glutaraldehyde should be performed at 37°C, and the fixative should be warmed to 37°C before use.

Dehydration. Artifacts are inevitably introduced during the dehydration process, whether dehydration is carried out by freeze-drying or by a series of graded ethanol washes followed by critical point drying or HMDS solvent

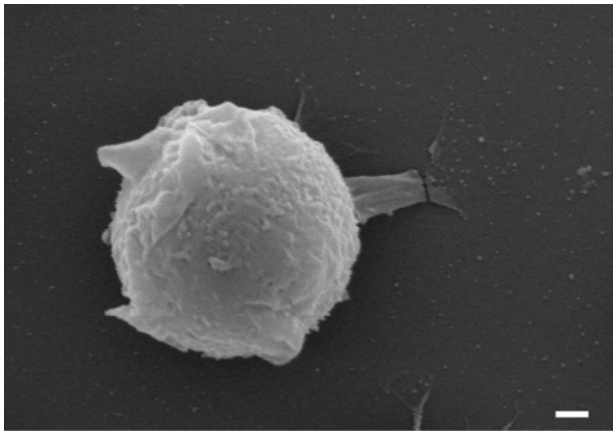

Figure 4.17.5 Artifactual cracking of attached cell protrusions and loss of surface structures in fixed lymphocytes. Mouse 300.19 pre-B cells were fixed in 2.5% glutaraldehyde and processed for SEM. Scale bar = 1 μm.

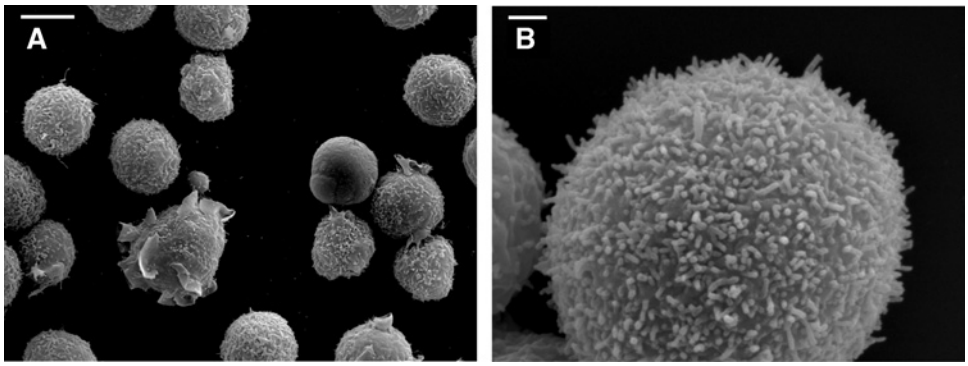

Figure 4.17.6 Surface morphology of lymphocytes. Mouse 300.19 pre-B cells were processed for SEM using the described protocol. Surface morphology has been preserved with the absence of apparent cracks and osmotic swelling, particularly in thin microvilli structures. Panel (**A**) shows lower magnification (scale bar: 5 μm); panel (**B**) shows higher magnification (scale bar: 1 μm).

dehydration as described here. Critical point drying gives rise to significantly fewer dehydration artifacts than other methods. Shrinkage often occurs during dehydration and may be apparent as large cracks in cell monolayers and as breaks in adherent protrusive structures such as retraction fibers (Brunk et al., 1981). Examples of dehydration artifacts are given in Figures 4.17.3 and 4.17.5.

Anticipated Results

Cells prepared using this protocol should possess well-preserved surface structures, as shown in Figure 4.17.6, with no evidence of swelling or distortion or artifacts including cracking of cell processes.

Time Considerations

From start to finish the preparation procedure takes ~8 hr. If necessary the fixed and dehydrated coverslips can be stored overnight in 90% ethanol prior to the critical point drying step; in this case we would recommend an additional 20 min wash in 100% ethanol before proceeding to critical point drying to ensure any residual moisture is removed. Coating takes ~5 min, but this may vary from machine to machine.

ABSTRACT

This unit describes fluorescence-based techniques for noninvasive imaging of development in living *Drosophila* embryos, discussing considerations for fluorescent imaging within living embryos and providing protocols for generation of flies expressing fluorescently tagged proteins and for preparation of embryos for fluorescent imaging. The unit details time-lapse confocal imaging of live embryos and discusses optimizing image acquisition and performing three-dimensional imaging. Finally, the unit provides a variety of specific methods for optical highlighting of specific subsets of fluorescently tagged proteins and organelles in the embryo, including fluorescence recovery after photobleaching (FRAP), fluorescence loss in photobleaching (FLIP), and photoactivation techniques, permitting analysis of specific movements of fluorescently tagged proteins within cells. These protocols, together with the relative ease of generating transgenic animals and the ability to express tagged proteins in specific tissues or at specific developmental times, provide powerful means for examining in vivo behavior of any tagged protein in embryos in myriad mutant backgrounds. *Curr. INTRODUCTION

The *Drosophila* embryo has served as a powerful model for defining the pathways and organizational principles that guide embryogenesis in a wide array of animals. Key to this success has been the development of molecular genetics tools that facilitate the rapid molecular, as well as functional, characterization of genes that act to build the embryo. But only recently, due to advances in live-cell imaging of fluorescently tagged fusion proteins, has it become possible to investigate how proteins responsible for embryonic development are dynamically expressed and distributed in living embryos. In *Drosophila*, live-cell imaging studies are greatly facilitated by the relative ease of generating transgenic animals that express fluorescently tagged proteins, as well as the ability to express tagged proteins in a specific tissue or at specific developmental times. Finally, the wealth of genetic resources available in *Drosophila* provides the unique opportunity to examine the in vivo behavior of a tagged protein in the embryo in myriad mutant backgrounds.

This unit describes several fluorescence-based techniques for noninvasive imaging of *Drosophila* development in the living embryo. It begins with a discussion of the challenges and considerations in fluorescent imaging within an embryo, which produces

Current Protocols in Cell Biology 4.18.1-4.18.43, June 2008

DOI: 10.1002/0471143030.cb0418s39

poor images under conventional wide-field fluorescence microscopy because of its thickness and the resulting autofluorescence and out-of-focus fluorescence. The unit then proceeds to Basic Protocol 1 for generating fluorescently tagged proteins within the fly. The method of choice—the Gal4/UAS system—permits expression of fluorescently tagged proteins-of-interest in a spatially and temporally controlled manner. Next, Basic Protocol 2 discusses how to prepare embryos for fluorescent imaging, including dechorionation and mounting on a coverslip in a way that allows the embryo to continue to develop normally to the first instar larval stage. Basic Protocols 3 and 4 then focus on how to perform noninvasive time-lapse confocal imaging of live fly embryos using confocal laser scanning microscopy (CLSM) and two-photon laser scanning microscopy (2PLSM), respectively. Among the issues discussed are optimizing image acquisition and performing three-dimensional (3D) imaging. The unit goes on to describe a variety of specific techniques that permit optical highlighting of specific subsets of fluorescently tagged proteins and organelles in the embryo, including fluorescence recovery after photobleaching (FRAP, Basic Protocol 5), fluorescence loss in photobleaching (FLIP, Basic Protocol 6), and photoactivation techniques (Basic Protocol 7). These techniques allow the specific movements of fluorescently tagged proteins within cells to be monitored and analyzed. Specific examples of the techniques are illustrated and discussed.

STRATEGIC PLANNING

Working Knowledge of *Drosophila* Embryonic Development

High-resolution fluorescence microscopy of living *Drosophila* embryos presents a challenge because of the optical characteristics of the embryo, as well as the rapid, dramatic changes in tissue morphology that take place during the development of the fertilized egg into a multicellular animal (first instar larva). A working knowledge of embryonic development is required for proper understanding of the optical properties of the tissue to be imaged, as well as other elements important for imaging applications (e.g., effect of temperature on development or rapid tissue movements). Morphogenesis during *Drosophila* embryogenesis has been studied in great detail, and an atlas of *Drosophila* embryo development depicting the different morphogenetic phenomena, as well as their timing, can be found on the Web site *http://www.sdbonline.org/fly/atlas/00atlas.htm*. The Interactive Fly Web site (*http://www.sdbonline.org/fly/aimain/1aahome.htm*) and the FlyMove Web site (*http://flymove.uni-muenster.de*) further provide images, movies, and detailed descriptions of tissue and organ development during embryogenesis.

Briefly, during *Drosophila* fertilization, sperm penetrate through the micropyle at the egg's anterior tip while the egg is still in the uterus. Females can retain fertilized eggs in the uterus for variable periods of time before deposition. The *Drosophila* embryo is, for the first 2 hr, a syncytium, i.e., the nuclei divide and migrate in a common cytoplasm. During the first hour after fertilization, nuclei lie and divide in the interior of the embryo (preblastoderm stage). Most nuclei then migrate synchronously to the periphery of the embryo and undergo four more divisions in a common cytoplasm (syncytial blastoderm stage). After the fourth division, ~2 hr after fertilization, membranes synchronously invaginate to encase individual nuclei and produce a layer of epithelial cells at the embryo periphery within ~1 hr. This cellularization event occurs at a time in development referred to as midblastula transition, whereby nuclear division slows down and RNA transcription from the nuclei is greatly enhanced. Foe and Alberts (1983) and Foe et al. (1993) provide excellent, in-depth descriptions of the events taking place from fertilization of the egg to cellularization in the embryo.

Cellularization is immediately followed by gastrulation (~3 hr after fertilization), a stage where dramatic cell rearrangements generate the germ layers (endoderm, mesoderm, and ectoderm), the specific regions of the embryo that will give rise to the different organ

systems. Costa et al. (1993) describe in detail the morphogenetic phenomena during this stage. During the hours that follow gastrulation, a complex series of morphogenetic processes occur, with cells in each of the germ layers differentiating to form the organs (e.g., midgut, tracheae, salivary glands). Segmentation of the embryo also occurs during this period and serves to generate the body plan of *Drosophila*, with distinct head and tail ends, as well as segments that will form the thorax and abdomen. During segmentation, the segregation of the imaginal disks (sacs of cells that will give rise to adult structures during pupal metamorphosis) also takes place. First instar larvae hatch at ~21 to 22 hr after fertilization at 25°C. For a review of embryonic development of insects, see Anderson (1972).

Practical Considerations for Fluorescence Microscopy of Living *Drosophila* Embryos

The physical properties of the *Drosophila* embryo (size, thickness, opacity, autofluorescence), properties of the developing tissues (geometry, movements), as well as imaging temperature have to be carefully considered before attempting any high-resolution imaging application. Considerations relating to these properties are discussed in the rest of this section.

Size of embryos

Wild-type *Drosophila* embryos are 511±21 μm in length and 184±5 μm in width (n = 100 Canton S embryos). If high spatial resolution is not required, a low magnification (16× or 20×), low-numerical-aperture (NA) objective can be used to look at whole embryos (e.g., a Zeiss Achroplan 20×/0.45 NA or an Olympus UPlanApo 20×/0.70 NA lens). This is particularly useful for scoring embryos expressing a specific fluorescently tagged protein or identifying fluorescent embryos at a specific stage in development. However, high-resolution imaging applications necessitate the use of higher-magnification, high-NA objectives (discussed below).

The volume of an embryo can be calculated by considering the volume of an ellipsoid of minor axes $2a = 2b$ and major axis $2c$ (Fig. 4.18.1A):

$$V = 4/3\ \pi\ \times a \times b \times c = 9.0 \pm 0.6 \text{ nl } (n = 100 \text{ Canton S embryos})$$

This information can be useful when calculating dilution factors for microinjecting drugs or fluorescent molecules into the embryo with automatic microinjectors.

Thickness of embryos

The *Drosophila* embryo is a thick specimen for optical fluorescence microscopy. One major problem encountered in imaging thick specimens is high background and emitted fluorescence from out-of-focus regions, which result in low-contrast images when using conventional (wide-field) fluorescence microscopy. Confocal laser scanning microscopy (CLSM, reviewed in *UNIT 4.5*), which we discuss in this unit, addresses this problem with the use of a pinhole to reject out-of-focus light and a point-scanning light source (laser), resulting in high-contrast images; it is the method of choice for high-resolution four-dimensional (4D; 3D over time) imaging of living *Drosophila* embryos. Multiphoton excitation microscopy (reviewed in *UNIT 4.11*) has been successfully used for deep-tissue imaging in thick living specimens. We discuss the potential of two-photon excitation for imaging living *Drosophila* embryos below (Light scattering and out-of-focus absorption) and in Basic Protocol 4.

Several powerful approaches, which are based on illumination through multiple objectives or use spatially structured illumination, have been developed to extend resolution (reviewed in Gustafsson, 1999), but they are not yet compatible with the image acquisition

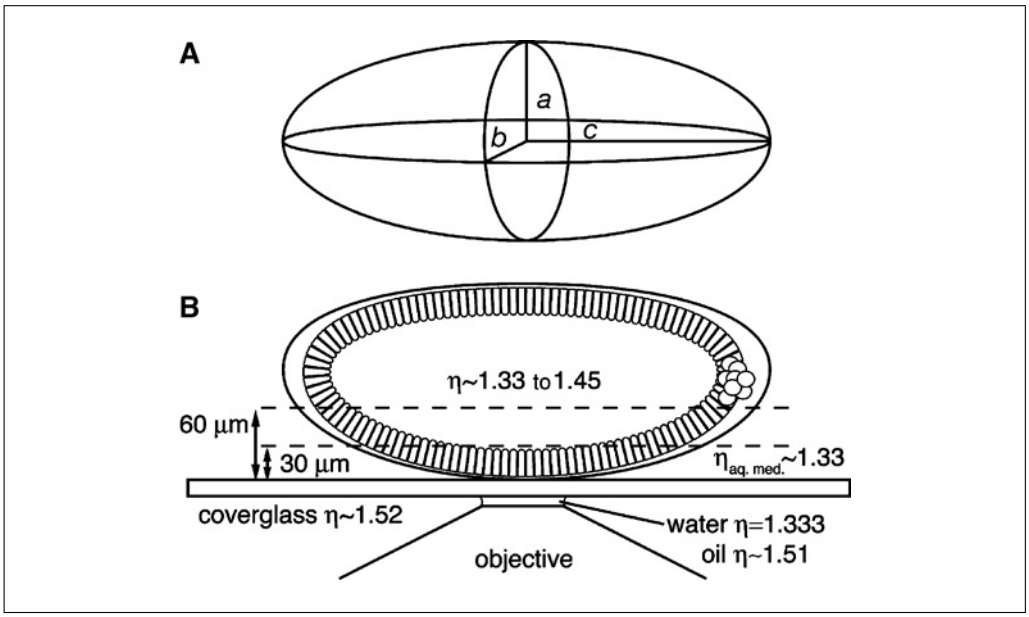

Figure 4.18.1 Size and thickness of the *Drosophila* embryo. (**A**) Schematic representation of the *Drosophila* embryo as an ellipsoid of minor axes $2a = 2b$ and major axis $2c$. (**B**) Schematic representation of a cellularizing embryo showing that imaging of the invaginating plasma membrane requires focal planes >30 μm deep in the embryo. The differences in the refractive indices of the tissue (η_{tissue} ~1.33 to 1.45), the aqueous medium (aq. med.) in which the embryo is mounted (η ~1.33), the coverglass ($\eta_{coverglass}$ ~1.52), and the immersion medium result in a distortion of the light path and severe spherical aberrations in focal planes deep in the embryo when oil is used (η_{oil} ~1.51). The use of water lenses ($\eta_{water} = 1.33$) significantly reduces these aberrations.

speed required for live imaging, and they require sophisticated equipment and alignment procedures. Of particular interest is selective plane illumination microscopy (SPIM; Huisken et al., 2004), a recently developed technique that uses a thin sheet of light to illuminate (from the side) only the focal plane of the detection lens. SPIM provides optical sectioning and large penetration depth, induces less photodamage, and further, achieves isotropic spatial resolution when images are acquired along multiple orientations of the sample. SPIM has been used for imaging deep in living *Drosophila* embryos (Huisken et al., 2004) and is particularly suited for low-NA systems (NA < 0.8), achieving a substantially increased axial resolution compared to CLSM (Engelbrecht and Stelzer, 2006).

The major considerations related to the thickness of living *Drosophila* tissue are the following:

1. *Light scattering and out-of-focus absorption*. When the excitation (illumination) or imaging (emitted fluorescence) path intersects regions with differing refractive indices (e.g., organelles, lipid droplets, yolk particles, or tissue in the embryo interior), their curved surfaces act as microlenses to scatter light in all directions. Some of the excitation light will be scattered enroute to the focal plane. Excitation photons are further absorbed by any fluorophores along the excitation light path, so overall fewer photons reach the focal plane, thus decreasing excitation intensity with increasing depth in the specimen. At the same time, scattered excitation light will be absorbed and will generate fluorescence at sites outside the imaging plane, thereby increasing the background that needs to be removed by the pinhole. Photobleaching and phototoxicity will also be induced in regions of the sample that are not contributing to the image. Emitted light from the focal spot will also be scattered, preventing it from passing through the pinhole, even though it arose from the correct focal plane. Inevitably, some of the light arising from regions outside the

imaging plane, which should be blocked at the pinhole, will be scattered so that it passes through and contributes noise. Overall, light scattering and out-of-focus absorption limit the maximum imaging depth in CLSM to <40 μm deep in the *Drosophila* embryo. The signal decreases dramatically with increasing depth (see Fig. 4.18.2), compromising resolution and quantitative measurements. Regions closest to the surface do not suffer as much from scattering and out-of-focus absorption, and they can be readily imaged up to 60 μm away from the coverglass in sagittal sections (Fig. 4.18.2, arrows).

The limited penetration depth due to scattering and out-of-focus absorption can be most efficiently addressed in two-photon laser scanning microscopy (*UNIT 4.11*). Two-photon excitation occurs only in the focal plane, so there is no absorption of excitation light (and consequently no photobleaching or photodamage) in out-of-focus regions between the objective lens and the focal plane. Furthermore, longer wavelengths used in two-photon excitation are scattered less than shorter wavelengths. Thus, much more of the two-photon excitation light penetrates through the sample to reach the focal plane, increasing the depth of penetration into the tissue to >100 μm (see Fig. 4.18.2). Finally, a pinhole is not required in two-photon excitation, and multiply-scattered photons arising from the focal plane can be collected in a nondescanned (see Basic Protocol 4, step 4 annotation) detection geometry. The net result is that the signal-to-noise ratio decreases less rapidly with imaging depth.

2. *Spherical aberrations*. The highest-NA oil-immersion objectives commonly used for high-resolution fluorescence microscopy are designed for observing specimens directly in touch with or within a few micrometers of the coverglass, which is in contact with the lens through immersion oil. The *Drosophila* embryo is mounted on a coverglass in an aqueous solution (Fig. 4.18.1B; Basic Protocol 2). Due to the thickness and ellipsoid geometry of the embryo, imaging subcellular processes during development often requires focal planes deep into the specimen. For example, imaging cytoplasmic organelles or invaginating plasma membrane during cellularization typically requires focal planes at ~40 to 60 μm away from the coverglass (Fig. 4.18.1B). As the focal plane is set deeper into the specimen (already 10 μm away from the coverglass), differences in the refractive indices of the aqueous medium in which the embryo is mounted ($\eta_{\text{aq. med.}} \sim 1.33$), interior of the embryo (cellular material has a refractive index $\eta_{\text{cell.}} \sim 1.33$ to 1.45; Beuthan et al., 1996; Johnsen and Widder, 1999; Dirckx et al., 2005), coverglass ($\eta_{\text{coverglass}} \sim 1.52$), and immersion oil ($\eta_{\text{oil}} \sim 1.51$; Fig. 4.18.1B) result in distortion of the imaging light path.

This causes severe spherical aberrations, observed as blurring, loss of contrast, and a reduced axial resolution, leading to misinterpretation of morphology and geometry of structures residing deep in the embryo. This problem is greatly ameliorated by the use of water-immersion objectives. When water immersion is used ($\eta_{\text{water}} = 1.333$), spherical aberrations are significantly reduced and images can theoretically be collected as deeply as the working distance of the lens permits. In practice, scattering and out-of-focus absorption limit the achieved penetration depth. For example, the Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens (working distance of 280 μm at a 0.17-mm coverglass thickness) enables imaging up to ~40 μm into the embryo with one-photon excitation (CLSM), ~60 μm with two-photon excitation and descanned detection, and ~100 μm with two-photon excitation and a nondescanned detection geometry (see Fig. 4.18.2). Since the correction for spherical aberration depends on the length of the optical path through the coverglass, it is critically important to adjust the correction collar on the water-immersion objective to the thickness of the coverglass used. Failure to adjust the collar to the coverglass thickness will result in severe spherical aberrations and will greatly reduce axial resolution.

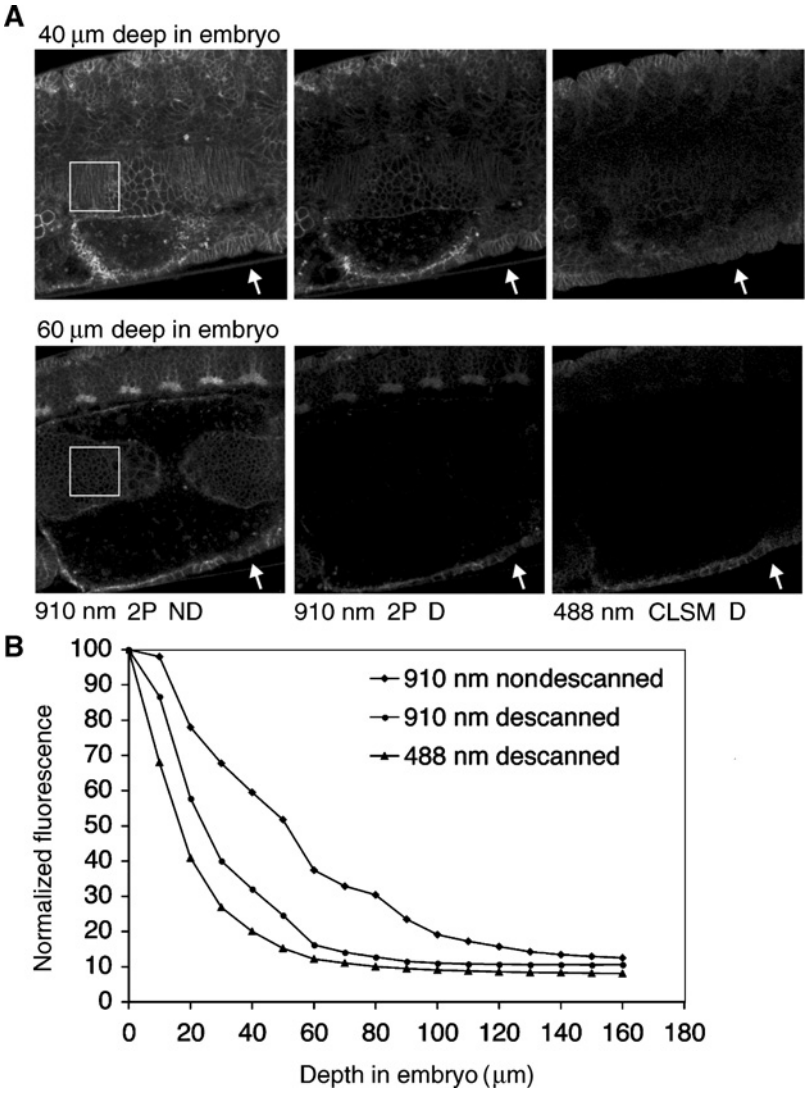

Figure 4.18.2 Fluorescence decreases dramatically with focal planes deep in the embryo in confocal laser scanning microscopy (CLSM) but less so in two-photon (2P) excitation. (**A**) Optical sections of living fluorescent embryos during late gastrulation, in focal planes 40 and 60 μm deep in the embryo. Images were acquired with two-photon excitation at 910 nm and a nondescanned (ND) detection light path (left panels), two-photon excitation at 910 nm and descanned (D) detection (middle panels), or 488 nm in CLSM (right panels). (**B**) Plot of fluorescence intensity in a region of interest (white outlined square in panel A) as a function of depth in the embryo. Fluorescence is normalized to 100% at the embryo surface. In focal planes 40 μm deep in the embryo, the signal decreased to 20% with 488-nm excitation, 30% with two-photon excitation at 910 nm, but only 60% when using two-photon excitation with a nondescanned detection light path. In focal planes 60 μm deep in the embryo, no structure is discernible with 488-nm excitation in the embryo interior. The outline of cells is visible with two-photon excitation at 910 nm and descanned detection, but much more pronounced when a nondescanned light path is used (signal decreases to 40% as opposed to <20% with descanned detection). Note that the signal decreases much less with depth in regions closest to the surface (arrows) because the light path does not intersect deep tissue that causes scattering and out-of-focus absorption.

3. *Chromatic aberrations*. Chromatic aberrations are common in multicolor confocal microscopy. These aberrations result in different excitation wavelengths being focused at different points and different emitted wavelengths being collected from different points in the tissue. Horizontal displacements in the image plane (lateral chromatic aberrations), resulting in different magnification of different colors, can be minimized by moving the region of interest (ROI) to the center of the microscope field. However, vertical color displacements along the focal axis (axial chromatic aberration) are present throughout the microscope field, and this is a serious problem when performing colocalization studies or live multifluorophore imaging (see Basic Protocol 3).

Microscope objectives for high-resolution fluorescence microscopy of living embryos must be corrected for chromatic aberrations. Commercially available lenses that are corrected to the highest degree for chromatic aberrations are named *Apochromat* or *Apo*. However, the optics design in the corrected lenses is specific for a particular arrangement of refractive indices for different wavelengths. The heterogeneity of refractive indices in the embryo interior will most likely not match the design specifications and will lead to chromatic aberrations of varying magnitudes. Chromatic aberrations are not dependent on imaging depth. However, failure to correct for spherical aberrations (e.g., by misadjusting the correction collar) will result in complicated artifactual color shifts in focal planes deep into the sample. Thus, interpretation of slight differences in localization demands careful control experiments to rule out chromatic aberrations.

4. *Choice of objective*. Long-working-distance, high-NA, water-immersion objectives corrected for coverglass thickness, field curvature and chromatic aberrations (e.g., the Zeiss C-Apochromat 40×/1.20 W Corr UV-VIS-IR water lens or the Olympus UPLAPO 60×/1.2 NA water lens) are the best choices for high-resolution live 4D imaging of thick *Drosophila* embryos with CLSM. Magnification, NA, and transmittance of the lens to specific wavelengths need to be carefully chosen based on the application (see Basic Protocols 3 to 7).

Opacity of embryos

The outermost shell of the embryo, the chorion, is a specialized layer secreted by follicle cells during oogenesis. It has two dorsal appendages that facilitate gas exchange in the developing embryo (Fig. 4.18.3B, arrow). The presence of the chorion renders the embryo opaque for transillumination and epifluorescence. However, it is easily removed (dechorionation) by immersing the embryos in a sodium hypochlorite solution (bleach; see Basic Protocol 2 and Fig. 4.18.3C), making the embryos transparent for imaging purposes. Dechorionated embryos mounted in water or phosphate-buffered saline solution develop normally to first-instar larvae.

Autofluorescence of embryos

The major sources of autofluorescence in a dechorionated *Drosophila* embryo are yolk granules and the vitelline membrane. The autofluorescence emission spectra for yolk and vitelline membrane (VM) at excitation wavelengths routinely used for common fluorophores are depicted in Figure 4.18.4. The emission spectra of ECFP, EGFP, EYFP, and mRFP1 and the respective emission detection windows for common bandpass emission filters used for these fluorescent protein (FP) variants are superimposed on the autofluorescence spectra for reference. It is evident that both yolk and VM are highly autofluorescent at violet (820 nm, two-photon) and blue (458 nm, 488 nm) wavelengths, and their emission maxima interfere with the emission detection for ECFP and EGFP. Yolk and VM autofluorescence are much less pronounced at yellow (514 nm) and minimal at red and far-red (543 nm, 633 nm) wavelengths. The problem of autofluorescence is illustrated in Figure 4.18.5A, where confocal images of wild-type (Canton S) embryos

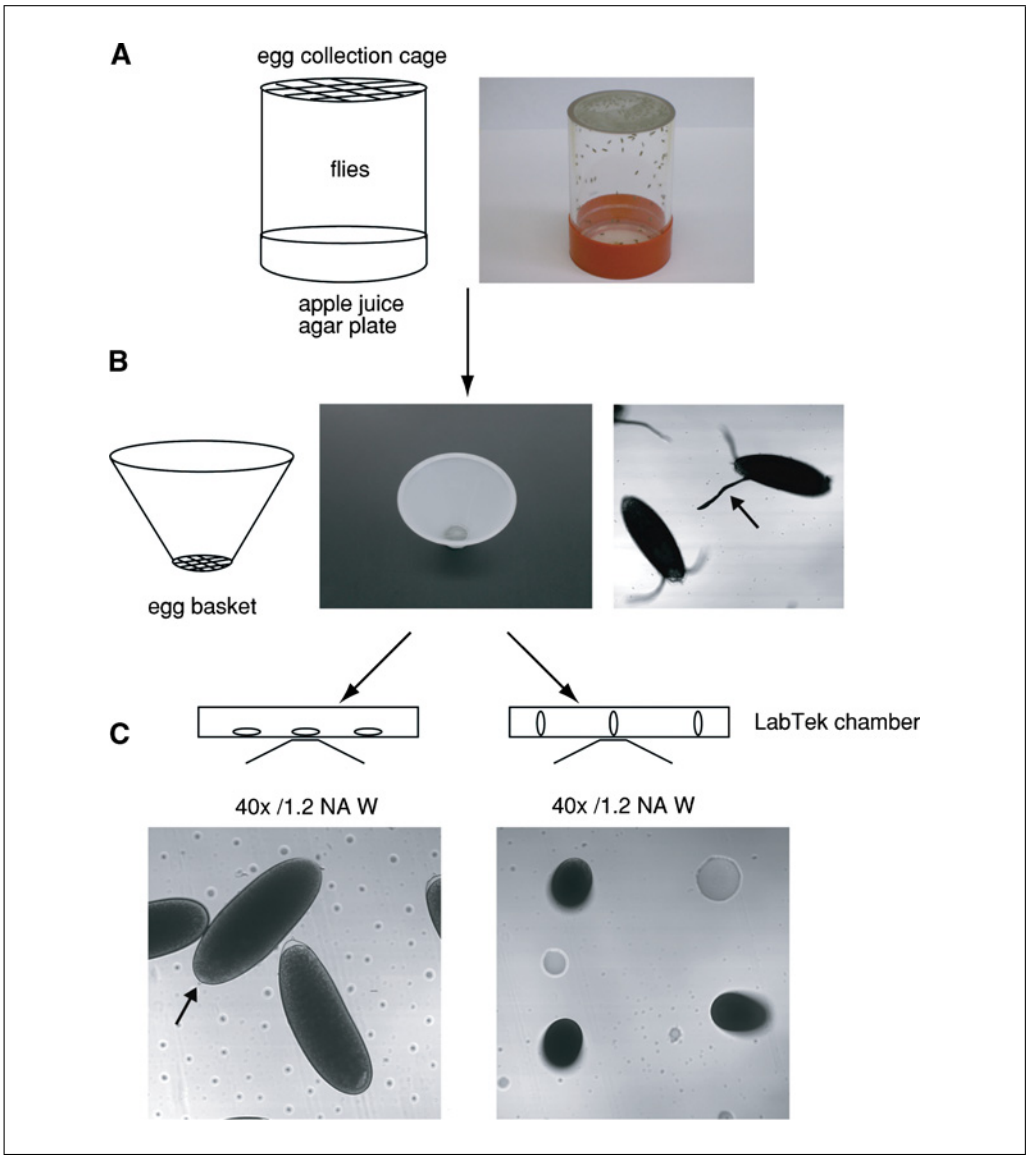

Figure 4.18.3 Preparation of *Drosophila* embryos for fluorescence microscopy. (**A**) The fly embryo collection cage with an apple juice agar plate. The left image is a schematic of the fly cage. The right image shows a cage from Genesee Scientific (which fits 60-mm petri dishes) containing adult flies over a yeasted apple juice agar plate. (**B**) The modified funnel with a 100-μm stainless steel mesh for embryo collection and dechorionation. The left image shows a schematic and the middle image is a photograph of a funnel with a mesh. The right image shows chorionated *Drosophila* embryos imaged with DIC optics on a confocal microscope. Note that the chorionated embryos appear opaque and are not suitable for imaging. The arrows point to the dorsal appendages of the embryo chorion. (**C**) Mounting of embryos in LabTek chambers for imaging. The embryos are dechorionated by treatment with diluted bleach for 1 min (see Basic Protocol 2) and then mounted on either the dorsolateral/ventrolateral side (left schematic) or on their posterior (right schematic). The left image shows dechorionated *Drosophila* embryos with DIC optics mounted on their dorsolateral/ventrolateral side. The arrow points to the micropyle on the anterior of the embryo. The right image shows dechorionated *Drosophila* embryos mounted on their posterior.

are shown, acquired with excitation/emission settings routinely used for live imaging of common fluorophores.

Although autofluorescence can be greatly reduced by imaging at longer wavelengths, live multifluorophore imaging (e.g., Cerulean/Venus, mGFP/mRFP1; see Basic Protocol 3) typically requires at least one fluorescent variant in the blue region. Because autofluorescence is not diffuse but confined to specific structures (yolk, VM), the optical

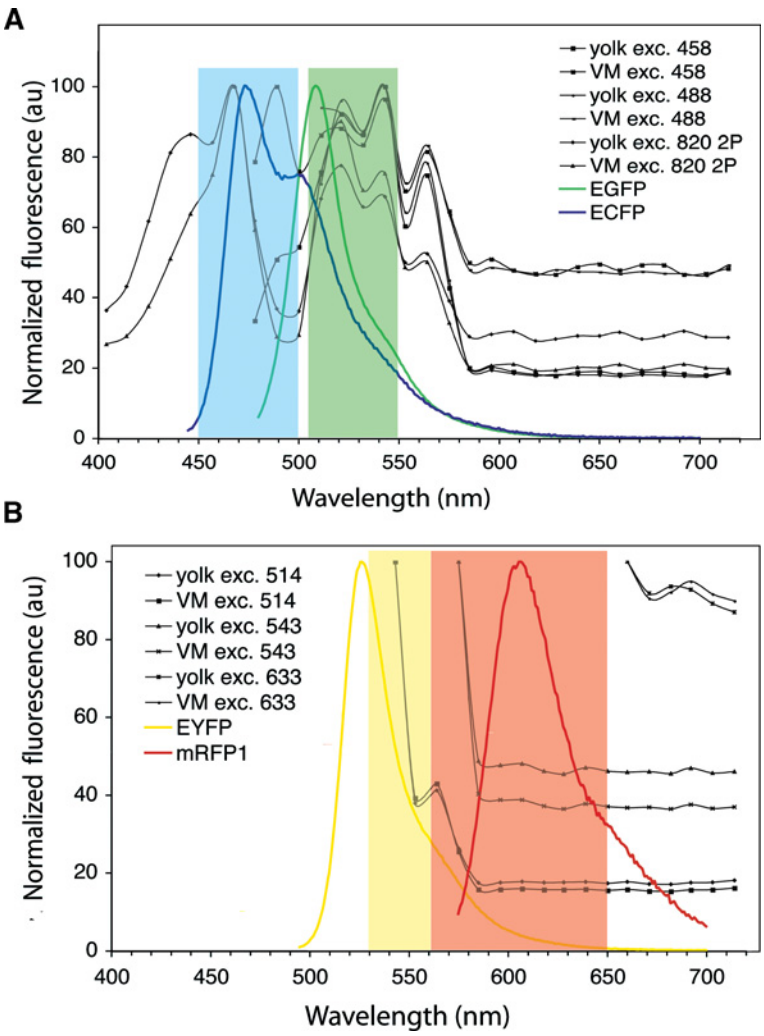

Figure 4.18.4 Yolk and vitelline membrane (VM) autofluorescence interferes with the fluorescence of common fluorophores at violet and blue visible wavelengths. The autofluorescence emission spectra for yolk and VM are shown at excitation wavelengths (exc.) routinely used to excite common fluorophores. The emission spectra of ECFP, EGFP, EYFP and mRFP1 are superimposed on the autofluorescence spectra, as are the emission detection windows commonly used for the above variants. (**A**) Yolk and VM are highly autofluorescent (two-photon excitation at 820 nm) in violet and blue (458 and 488 nm), but less pronounced (**B**) in red (543 nm) and far-red (633 nm): Abbreviation: au, arbitrary units; 2P, two-photon. For the color version of this figure go to *http://www.currentprotocols.com*.

sectioning capability of the CLSM helps to greatly reduce, if not to eliminate, this problem. This, in turn, depends on the depth of the focal plane used, as well as the stage of development of the embryo, because yolk distribution changes during embryogenesis. In focal planes closer to the embryo surface, using a narrow pinhole will eliminate VM autofluorescence. Interference from yolk will depend on the stage of the embryo. For example, in early embryos yolk is enriched in the cortical cytoplasm and interferes with ECFP/EGFP fluorescence (Fig. 4.18.5C, arrows), whereas in cellularizing embryos yolk is displaced below the nuclei and is not a problem (Fig. 4.18.5B, star). In contrast, sagittal views always suffer from VM autofluorescence when plasma membrane fluorescence directly beneath the VM is imaged (Fig. 4.18.5B, left panel). One way to distinguish

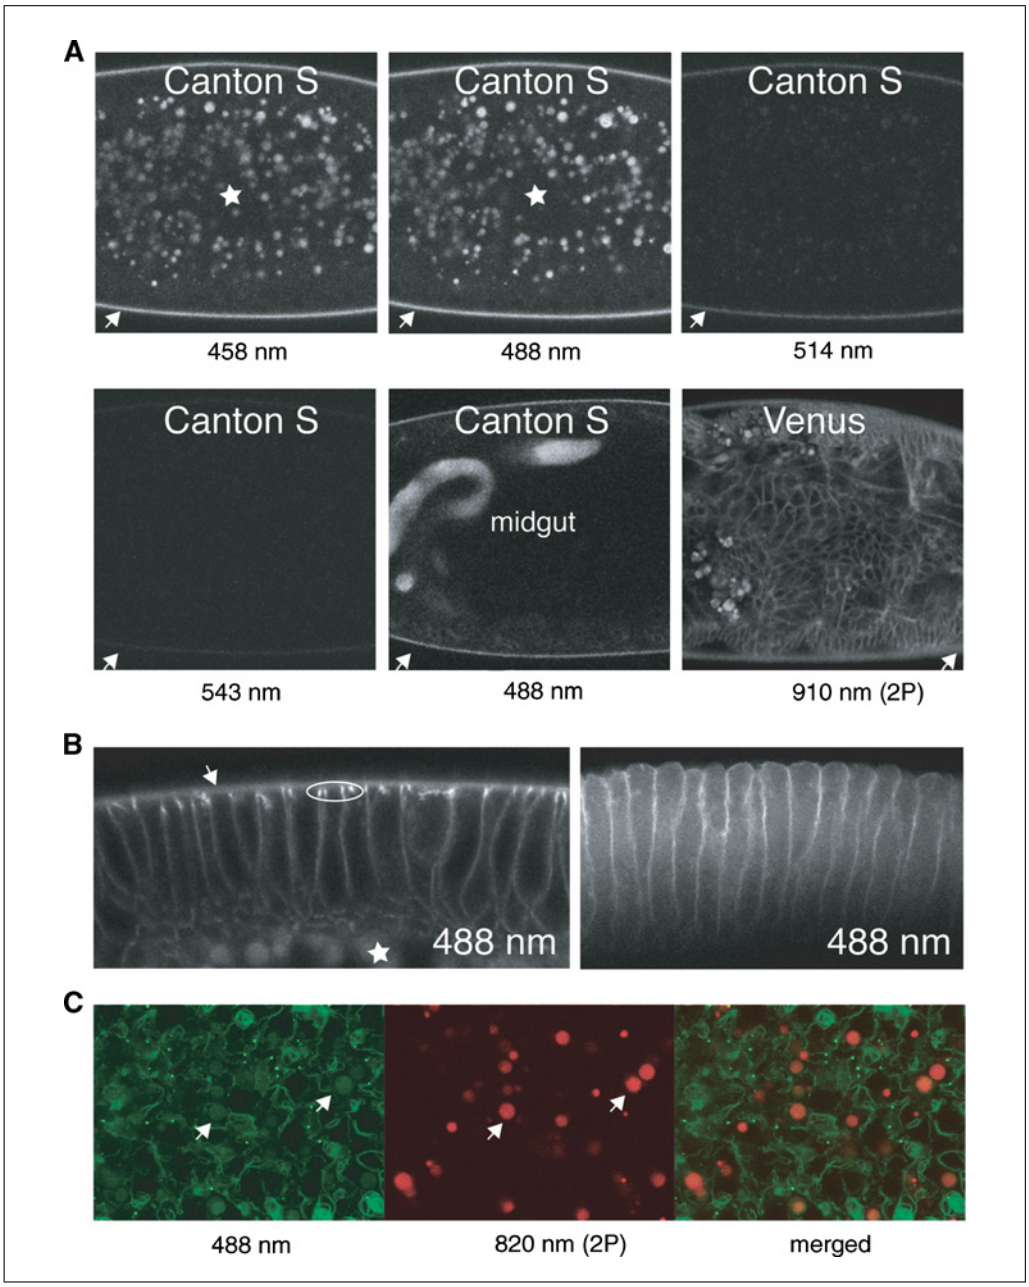

Figure 4.18.5 Interference from yolk and vitelline membrane (VM) autofluorescence depends on the depth of the focal plane, the brightness of the fluorophores, and the stage of development. (**A**) Confocal images of sagittal sections in wild-type (Canton S) embryos and a Venus-expressing embryo at wavelengths routinely used to excite common fluorophores. VM autofluorescence (arrows) is pronounced in all sagittal sections, whereas yolk autofluorescence (star) is confined to yolk granules in early embryos and the midgut in late embryos (458 and 488 nm). (**B**, left panel) Confocal image of an embryo expressing E-cadherin-GFP during early gastrulation. VM autofluorescence (arrow) interferes with green fluorescence (white outlined region) adjacent to the plasma membrane. Yolk autofluorescence does not interfere since yolk (star) is displaced below cells at this stage. (**B**, right panel) Confocal image of an embryo expressing a brighter plasma membrane fluorescent protein during the same stage. Because of the stronger signal, lower excitation levels are used, and VM and yolk autofluorescence are not observed. (**C**) Confocal image of an embryo expressing a GFP-tagged ER lumenal protein. Excitation at 488 nm (green) excites both GFP and yolk autofluorescence (green, arrows). Yolk autofluorescence (red, arrows) can be distinguished from green fluorescence by two-photon (2P) excitation at 820 nm (also see Fig. 4.18.4). For the color version of this figure go to *http://www.currentprotocols.com*.

yolk and VM autofluorescence from fluorescence is to use two-photon excitation at 820 nm. As shown in Figure 4.18.5C, a detection window of 430 to 470 nm will detect only autofluorescence (Fig. 4.18.4A and Fig. 4.18.5C, 820 nm). This is an easy way to distinguish autofluorescence from true signal, but it cannot be used to quantitatively subtract autofluorescence because the intensities of yolk/VM excited with one- versus two-photon excitation are not comparable. Alternatively, 488 nm can be used to excite both yolk autofluorescence and green fluorescence, and a linear unmixing procedure can be applied to separate the signals, based on the different emission spectra of yolk and EGFP at 488 nm (Fig. 4.18.4A).

Yolk and VM autofluorescence are particularly useful in photoactivation experiments, when the photoactivatable protein is the only protein expressed in the embryo and when it does not fluoresce at the scanning wavelength (e.g., in PA-GFP expressing embryos; see Basic Protocol 7). In these embryos, autofluorescence can be used as a guide for locating the focal plane of interest for photoactivation, since yolk and VM will be the only visible structures prior to photoactivation (see Basic Protocol 7).

Geometry

Optical sectioning in CLSM is either perpendicular (*xy*) or parallel (*xz* or *yz*) to the optical axis (*z*). Mammalian tissue culture cells grown in standard medium form thin, flat monolayers (~5 to 10 μm thick, with epithelial cells up to ~20 μm thick), and the architecture of a cell region can easily be deduced from acquired optical sections. Optical sectioning in the *Drosophila* embryo or any other living multicellular tissue presents a challenge for correlating the acquired images with the precise architecture of the corresponding region.

This complication is illustrated in Figure 4.18.6, in *xy* optical sections taken in a cellularizing embryo. Cells are organized in a predominantly hexagonal pattern, as is the case in most epithelia in the multicellular embryo (Gibson et al., 2006). Surface cross-sections (Fig. 4.18.6A) reveal the characteristic honeycomb pattern of this organization, with *xy* (the imaging focal plane) parallel to the plasma membrane closest to the coverglass, and *z* (the optical axis) parallel to the invaginating plasma membrane during cellularization. This hexagonal pattern is much less obvious as one focuses deeper, in parasagittal cross-sections (Fig. 4.18.6B). Even though cells appear to be adjacent to one another, their precise spacing and organization in the focal plane depends on the orientation of the hexagonal pattern (Fig. 4.18.6B, left versus right panel), exact position of the focal plane (Fig. 4.18.6B, focal plane α versus β, γ, δ), distribution of polygonal cell types (a mixture of pentagons, hexagons, heptagons, etc.; Gibson et al., 2006), and stage of development (e.g., cell intercalation during germband elongation in gastrulating embryos gives rise to a highly heterogeneous organization at a given time point).

Understanding the geometry of the ROI is extremely important for appropriately selecting and optimizing the image acquisition parameters (e.g., pinhole opening and interval for *z*-sectioning; see Basic Protocols 3 to 6), as well as for quantitative measurements. The use of image processing software packages with the capability of reconstructing and rendering from 3D and 4D datasets is extremely useful, both for better visualization and understanding of the biological processes observed and for quantitation. Examples of image analysis and processing software packages routinely used are ImageJ (free from the National Institutes of Health; download at *http://rsb.info.nih.gov/ij*), Volocity (Improvision), Imaris (Bitplane), and MetaMorph (Molecular Devices).

When mounted embryos are not strictly parallel or perpendicular to the coverglass, optical sections can be more complicated to interpret. Therefore, take care to mount embryos as parallel or as perpendicular as possible to the surface of the coverglass (see Basic Protocol 2).

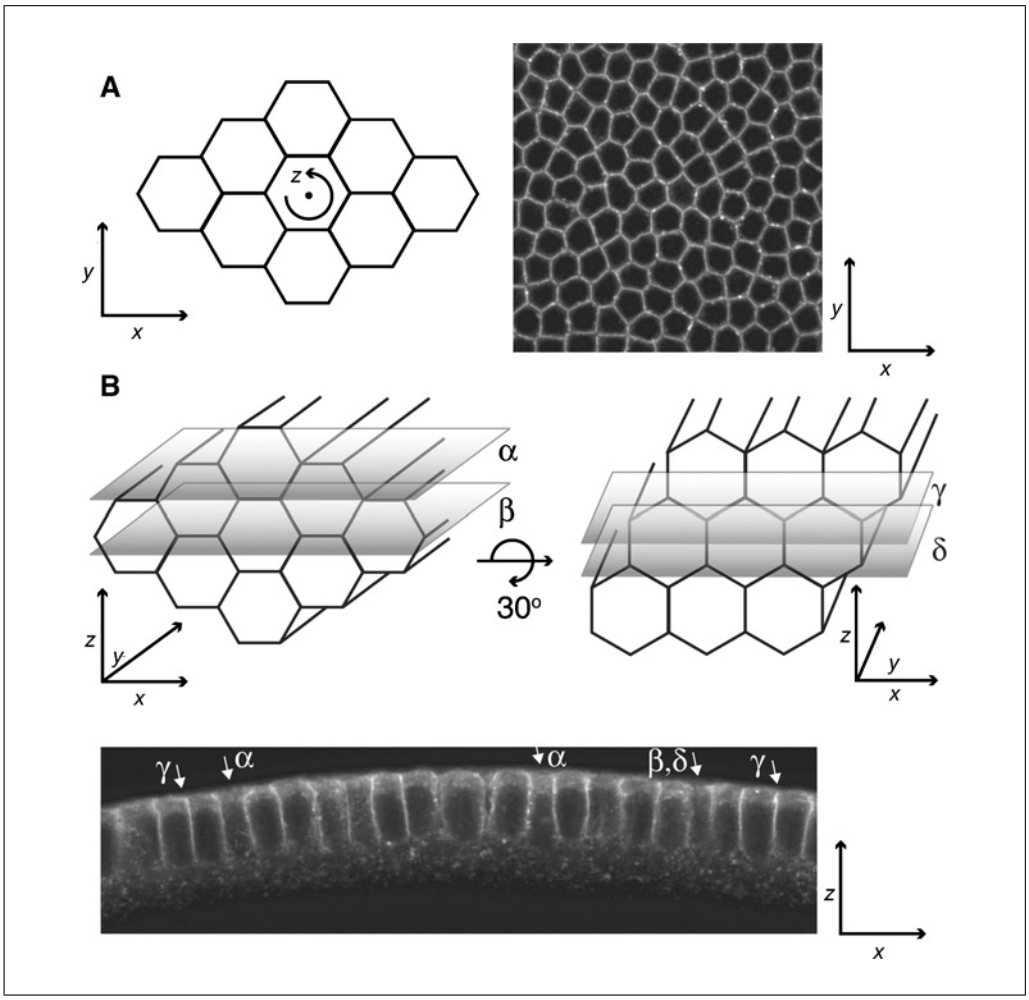

Figure 4.18.6 Tissue geometry and image acquisition. (**A**) Surface optical sections in a cellularizing embryo reveal the characteristic honeycomb pattern of the forming epithelial cells. The imaging focal plane (*xy*) is parallel to the PM closest to the coverglass, and the optical axis (*z*) is parallel to the invaginating plasma membrane. (**B**) The hexagonal pattern of the forming cells is less obvious in focal planes deeper in the embryo. Even though cells appear to be adjacent to one another, their precise architecture in the focal plane depends on the orientation of the hexagonal pattern (left versus right panel) and the exact position of the focal plane (focal plane α versus β, γ, δ), as well as the distribution of polygonal cell types (see mixture of pentagons and hexagons in A, right panel).

Movement

Large-scale movement within the developing embryo is a major problem in time-lapse imaging and photobleaching experiments. Periodic yolk contractions and mitotic waves in the early embryo or migration and rearrangement of whole epithelia in a gastrulating embryo are examples of processes that contribute to movement. These movements often result in a vertical or lateral shift of the ROI altogether. This poses a problem not only in general image acquisition; it is particularly significant in quantitative photobleaching experiments. Movement of the tissue during a FRAP protocol or movement of the bleach ROI in a FLIP protocol will compromise quantitation, and the acquired datasets will be unusable. Being aware of the speed and duration of such movements (see *http://flymove.uni-muenster.de*) will help the user to decide a good time frame for the designed experiment with minimal interference from movements. The speed of image acquisition is ultimately the limiting factor for temporal resolution and should be chosen and optimized depending on the application and question of interest.

Lowering the temperature to 18°C can be very useful to slow down overall development (see below). If temperature-sensitive measurements are made (e.g., diffusion coefficients)

Table 4.18.1 The Effect of Temperature on *Drosophila* Embryo Cellularization

Temperature (°C)	Time to complete cellularization (min)
18	67 ± 6
24	53 ± 7
28	39 ±2
32	40 ± 4

or temperature-sensitive processes are observed, control experiments at physiological temperature should be performed.

Temperature
